

Clinical Gynecologic Endocrinology and Infertility 6th ed: Leon Speroff, Robert H. Glass, Nathan G. Kase, 1999 Lippincott Williams & Wilkins

By OkDoKeY

Clinical Gynecologic Endocrinology and Infertility

Contents

	Author
	Preface
Part I: Reproductive Physiology	Chapter 1: Molecular Biology for Clinicians A basic guide to the language of molecular medicine.
	Chapter 2: Hormone Biosynthesis, Metabolism, and Mechanism of Action How hormones are formed and metabolized, and how hormones work.
	Chapter 3: The Ovary — Embryology and Development The ovary from conception to adult function; correlation of morphology with reproductive and steroidogenic function.
	Chapter 4: The Uterus Embryology, histology, and endocrinology of the uterus and menstruation. Anatomical abnormalities and leiomyomata.
	Chapter 5: Neuroendocrinology How reproductive events are perceived, integrated, and acted upon by the central nervous system.
	Chapter 6: Regulation of the Menstrual Cycle The cyclic changes of ovarian and pituitary hormones and growth factors, and what governs those changes.
	Chapter 7: Sperm and Egg Transport, Fertilization, and Implantation Mechanisms of the days just before and after conception.
	Chapter 8: The Endocrinology of Pregnancy The steroid and protein hormones of pregnancy.
Part II: Clinical Endocrinology	Chapter 9 Normal and Abnormal Sexual Development Normal and abnormal sexual differentiation, and the differential diagnosis of ambiguous genitalia.
	Chapter 10: Abnormal Puberty and Growth Problems The physiology of puberty, and abnormalities that produce accelerated or retarded sexual maturation and growth problems in adolescents.
	Chapter 11: Amenorrhea Differential diagnosis of amenorrhea of all types utilizing procedures available to all clinicians. The problems of galactorrhea and pituitary adenomas, exercise and amenorrhea.
	Chapter 12: Anovulation and the Polycystic Ovary How loss of ovulation can occur and the clinical expressions of anovulation. The polycystic ovary and hyperinsulinemia.
	Chapter 13: Hirsutism The biology of hair growth; the evaluation and management of hirsutism.
	Chapter 14: Menstrual Disorders Medical problems linked to menstruation: the premenstrual syndrome, dysmenorrhea, menstrual headache, catamenial seizures, premenstrual asthma, and catamenial pneumothorax.
	Chapter 15: Dysfunctional Uterine Bleeding A physiologic basis for medical management without primary surgical intervention.
	Chapter 16: The Breast The factors involved in physiologic lactation, and the differential diagnosis of galactorrhea. The endocrinology of breast cancer.
	Chapter 17: Menopause and the Perimenopausal Transition Physiology of the menopause; long-term effects of hormone therapy on cognition, cardiovascular disease, and osteoporosis.
	Chapter 18: Postmenopausal Hormone Therapy A clinical guide for postmenopausal hormone therapy and patient management.
	Chapter 19: Obesity The physiology of adipose tissue, and the problem of obesity.
	Chapter 20: Reproduction and the Thyroid Normal and abnormal thyroid function, including a consideration of the thyroid gland in pregnancy.
Part III: Contraception	Chapter 21: Family Planning, Sterilization, and Abortion The modern efficacy and use of contraception; the clinical methods and problems with sterilization and abortion.
	Chapter 22: Oral Contraception A survey of the risks and benefits of oral contraception. Methods for patient management.
	Chapter 23: Long-Acting Methods of Contraception The advantages and disadvantages of specific long-acting contraceptive methods.
	Chapter 24: The Intrauterine Device (IUD) The characteristics of the IUD, an excellent method of contraception.
	Chapter 25: Barrier Methods of Contraception Important information for the use of the diaphragm, the cervical cap, the sponge, spermicides, and condoms.
Part IV: Infertility	Chapter 26: Female Infertility An approach to the problem of infertility. The proper diagnostic tests and their correct interpretation.
	Chapter 27: Recurrent Early Pregnancy Losses The evaluation and management of recurring spontaneous losses in early pregnancy.
	Chapter 28: Endometriosis Diagnosis and suitable treatment for the individual patient.
	Chapter 29: Male Infertility Principles of male infertility, including analysis of semen, treatment, and therapeutic insemination.
	Chapter 30: Induction of Ovulation Programs, results, and complications for clomiphene, bromocriptine, gonadotropins, and GnRH administration; a reconsideration of the ovarian wedge resection.
	Chapter 31: Assisted Reproduction An overview of the assisted reproduction technologies.
	Chapter 32: Ectopic Pregnancy The diagnosis and treatment, both medical and surgical, of ectopic pregnancy.
	Appendix Selected laboratory values and the International System of Units (SI Units)

Preface

A quarter of a century later, the millennium and our 6th edition! The impact of our book has been one of the most gratifying experiences in our careers. We know it has helped many readers to successfully overcome examinations, but, most rewarding of all, is the recognition of the effect on patient care derived from the clinical usefulness of our text. An appreciation for this impact carries with it a profound sense of obligation. We have always understood the importance of “getting it right” and “causing no harm.” For that reason, every edition is the culmination of a tremendous effort, an effort increasingly difficult with the amazing growth of knowledge and communications. In 1972, it was a Royal portable typewriter. At the millennium, we are armed with a personal computer and a modem, Word 97 for the text, EndNote for references, and MEDLINE for searches,

The book grows progressively thicker, reflecting the explosion of knowledge in reproductive biology and medicine. Nevertheless, we believe we have stayed true to our objective: to provide both factual knowledge and systematic approaches to clinical problems. Our text continues to be an expression and formulation of our collective professional activities as teachers, investigators, and most importantly, as clinicians in the field of reproductive endocrinology and infertility. We have tried to retain the style and clinical relevance of our first edition, but at the same time to provide all the new information. This basic knowledge is the foundation for the physiologic principles that in turn are the foundation for our methods of clinical management.

As always, our book is dedicated to the improvement of patient care, and we hope that it will aid all readers in accomplishing that goal. We are grateful to those who have taught us, and most of all, we thank our patients, who are our best teachers.

Leon Speroff, M.D.
Portland, Oregon

Robert H. Glass, M.D.
San Francisco, California

Nathan G. Kase, M.D.
New York, New York

P.S. The cover color of the 6th edition is a nostalgic return to Yale blue. The symbol on the cover is the Macedonian Star, from the days of Philip of Macedon and Alexander the Great.

The above DNA sequence is obviously a mutant. But the fact that we can recognize this cryptogram as a nucleotide sequence and diagnose a mutant change illustrates the incredible progress made in the understanding of human biology. Molecular biology is the subspecialty of science devoted to understanding the structure and function of the genome, the full complement of DNA (deoxyribonucleic acid), the macromolecule which contains all the hereditary information.

The Austrian monk, Gregor Mendel, studied his garden of peas for much of his life at his monastery and was the first to express the principles of heredity in the 1860s. He described dominant and recessive traits and the “laws” of transmission governing the homozygous and heterozygous inheritance of these traits. Mendel's theories remained unknown until 1900, when they were discovered. Unfortunately, Mendel died 16 years before recognition of his work.

The pairing and splitting of chromosomes at cell division was proposed in 1903, but it was not until 1946 that Edward Tatum and Joshua Lederberg at Yale University demonstrated in bacteria that DNA carried hereditary information. James Watson and Francis Crick, working at the Cavendish Laboratories in Cambridge, proposed in 1953, the structure of DNA by creating a model based on the parameters provided by Maurice Wilkins and Rosalind Franklin obtained with x-ray crystallography. Crick, Watson, and Wilkins received the Nobel Prize in 1962; Franklin died in 1958, and Nobel prizes are not awarded posthumously.

DNA replication involves many enzyme systems. DNA polymerase was isolated in 1958, and RNA polymerase in 1960. In 1978, Werner Arber, Hamilton Smith, and Daniel Nathans received the Nobel prize for their discovery, in the 1960s, of the enzymes for joining or cutting DNA. The use of ligase and restriction endonuclease enzymes permitted the production of recombinant DNA molecules, first accomplished by Paul Berg at Stanford University in 1972.

E.M. Southern of Edinburgh University developed in 1975 the technique to transfer (to blot) DNA from agarose gels onto nitrocellulose filters, enabling DNA fragments to be joined with radiolabeled RNA probes and thus isolated. The cloning of genes or DNA fragments followed the breakthrough discovery that plasmids carrying foreign DNA molecules could be inserted into bacteria, leading to the replication of the foreign DNA.

We have entered the age of molecular biology. It won't be long before endocrine problems will be explained, diagnosed, and treated at the molecular level. Soon the traditional hormone assays will be a medical practice of the past. The power of molecular biology will touch us all, and the many contributions of molecular biology will be perceived throughout this book. But unfortunately, molecular biology has its own language, a language that is almost unintelligible to the uninitiated. We offer this chapter as a guide for the new molecular medicine.

To begin a clinical book with a chapter on molecular biology and a chapter on biochemistry only serves to emphasize that competent clinical judgment is founded on a groundwork of basic knowledge. On the other hand, clinical practice does not require a technical and sophisticated proficiency in a basic science. The purpose of these first two chapters, therefore, is not to present an intensive course in a basic science, but rather to review the most important principles and information necessary for the development of the physiological and clinical concepts to follow. It is further intended that certain details, which we all have difficulty remembering, will be available in these chapters for reference.

The Chromosomes

We are **eukaryotes**, organisms with cells having a true nucleus bounded by a nuclear membrane, with multiplication by mitosis. Bacteria are **prokaryotes**, organisms without a true nucleus, with reproduction by cell division. With the exception of DNA within mitochondria, all of our DNA is packaged in a nucleus surrounded by a nuclear membrane. Mitochondria are believed to be descendants of primitive bacteria engulfed by our ancestors, and they still contain some important genes.

Chromosomes are packages of genetic material, consisting of a DNA molecule (which contains many genes) to which are attached large numbers of proteins that maintain chromosome structure and play a role in gene expression. Human somatic cells contain 46 chromosomes, 22 pairs of autosomes, and 1 pair of sex chromosomes. All somatic cells are diploid—23 pairs of chromosomes. Only gametes are haploid with 22 autosome chromosomes and 1 sex chromosome. The chromosomes vary in size, and all contain a pinched portion called a centromere, which divides the chromosome into two arms, the shorter p arm and the longer q arm. The two members of any pair of autosomes are homologous, one homologue derived from each parent. The number of chromosomes does not indicate the level of evolutionary sophistication and complexity; the dog has 78 chromosomes and the carp has 104!

A single gene is a unit of DNA within a chromosome that can be activated to transcribe a specific RNA. The location of a gene on a particular chromosome is designated its locus. Because there are 22 pairs of autosomes, most genes exist in pairs. The pairs are homozygous when similar and heterozygous when dissimilar.

The usual human karyotype is an arrangement of the chromosomes into pairs, usually after proteolytic treatment and Giemsa staining to produce characteristic banding patterns allowing a blueprint useful for location. The staining characteristics divide each arm into regions, and each region into bands that are numbered from the centromere outward. A given point on a chromosome is designated by the following order: chromosome number, arm symbol (p for short arm, q for long arm), region number, and band number. For example, 7q31.1 is the location for the cystic fibrosis gene.

Mitosis

All eukaryotes, from yeasts to humans, undergo similar cell division and multiplication. The process of nuclear division in all somatic cells is called mitosis, during which each chromosome divides into two. For normal growth and development, the entire genomic information must be faithfully reproduced in every cell.

Mitosis consists of the following stages.

Interphase

During this phase, all normal cell activity occurs except active division. It is during this stage that the inactive X chromosome (the Barr body or the sex chromatin) can be seen in female cells.

Prophase

As division begins, the chromosomes condense, and the two chromatids become visible. The nuclear membrane disappears. The centriole is an organelle outside the nucleus that forms the spindles for cell division; the centriole duplicates itself, and the two centrioles migrate to opposite poles of the cell.

Metaphase

The chromosomes migrate to the center of the cell, forming a line designated the equatorial plate. The chromosomes are now maximally condensed. The spindle, microtubules of protein that radiate from the centrioles and attach to the centromeres, is formed.

Anaphase

Division occurs in the longitudinal plane of the centromeres. The two new chromatids move to opposite sides of the cell drawn by contraction of the spindles.

Telophase

Division of the cytoplasm begins in the equatorial plane, ending with the formation of two complete cell membranes. The two groups of chromosomes are surrounded by nuclear membranes forming new nuclei. Each strand of DNA serves as a template, and the DNA content of the cell doubles.

Meiosis

Meiosis is the cell division that forms the gametes, each with a haploid number of chromosomes. Meiosis has two purposes: **reduction** of the chromosome number and **recombination** to transmit genetic information. In meiosis I, homologous chromosomes pair and split apart. Meiosis II is similar to mitosis as the already divided chromosomes split and segregate into new cells.

The First Meiotic Division (Meiosis I)

Prophase:

Leptotene: Condensation of the chromosomes.

Zygotene: Pairing of homologous chromosomes (synapsis).

Pachytene: Each pair of chromosomes thickens to form four strands. This is the stage in which **crossing over** or **recombination** can occur (DNA exchange of homologous segments between two of the four strands). Chiasmata are the places of contact where cross-overs occur (and can be visualized). This movement of blocks of DNA is a method for creating genetic diversity. On the other hand, genetic diseases can result from the insertion of sequences during gametogenesis. Transpositional recombination, utilizing enzymes that recognize specific nucleic acid sequences, allows the insertion of a genetic element into any region of a chromosome. This is a method used by viruses (such as the human immunodeficiency virus) to transform host cells.

Diplotene: Longitudinal separation of each chromosome.

Metaphase, Anaphase, and Telophase of Meiosis I

The nuclear membrane disappears, and the chromosomes move to the center of the cell. One member of each pair goes to each pole, and the cells divide. Meiosis I is often referred to as reduction division because each new product now has the haploid chromosome number. It is during the first meiotic division that Mendelian inheritance occurs. Cross-overs, that occur prior to metaphase, result in new combinations of genetic material, both favorable and unfavorable.

The Second Meiotic Division (Meiosis II)

The second division follows the first without DNA replication. In the oocyte, meiosis II occurs after fertilization. The end result is the production of 4 haploid cells.

The Structure and Function of DNA

DNA is the material of the gene responsible for coding the genetic message as transmitted through specific proteins. Thus, it is the most important molecule of life and the fundamental mechanism for evolution. Genes are segments of DNA that code for specific proteins, together with flanking and intervening sequences that serve controlling and regulating functions. Each molecule of DNA has a deoxyribose backbone, identical repeating groups of deoxyribose sugar linked through phosphodiester bonds. Each deoxyribose is attached in order (giving individuality and specificity) to one of 4 nucleic acids, the nuclear bases:

A purine — adenine or guanine.

A pyrimidine — thymine or cytosine.

A nucleotide is the basic building block of DNA. It consists of 3 major components: the deoxyribose sugar, a phosphate group, and a nucleic acid base. The phosphate-sugar linkages are asymmetric; the phosphorous is linked to the 5-carbon of one sugar and to the 3-carbon of the following sugar. Thus, one end is the 5' (5 prime) end and the other the 3' (3 prime) end. By convention, DNA and its nuclear acid sequences are written from left to right, from the 5' end to the 3' end, the direction of the transcription process. The 5' end leads to the formation of the amino end of the protein; the 3' end forms the carboxy end of the protein.

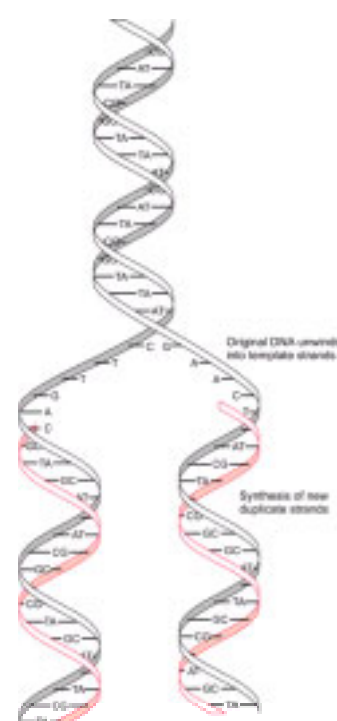

DNA consists of two deoxyribose strands twisted around each other clockwise in a double helix, with the nucleic acids on the inside and the nuclear bases paired by hydrogen bonding, adenine with thymine and cytosine with guanine. RNA differs from DNA in that it is single stranded, its sugar moiety is ribose, and it substitutes uracil for thymine.

How can a cell's DNA, which stretched out measures nearly 2 meters long, fit into a cell? Watson and Crick figured this out when they proposed a tightly coiled two-stranded helix, the double helix. Like the centimeter is a measure of length, the base pair (bp) is the unit of measure for DNA. The base pair is either adenine-guanine or cytosine-thymine, the nucleic acid of one chain paired with the facing nucleic acid of the other chain. A fragment of DNA is, therefore, measured by the number of base pairs, e.g., a 4800-bp fragment (a 4.8 kb fragment). It is estimated that we have 3 billion bp of DNA, only a small portion of which actually codes out for proteins.

DNA does not exist within the cell as a naked molecule. The nucleotide chains wind about a core of proteins (histones) to form a nucleosome. The nucleosomes become condensed into many bands, the bands that are recognized in karyotype preparations. This condensation is another important mechanism for packing the long DNA structure into a cell. Many other proteins are associated with DNA, important for both structure and function.

The process of DNA replication begins with a separation of the double-stranded DNA helix, initiated at multiple steps by enzyme action. As the original DNA unwinds into template strands, DNA polymerase catalyzes the synthesis of new duplicate strands, which reform a double helix with each of the original strands (this is called replication). Each daughter molecule, therefore, contains one of the parental strands. It is estimated that the original DNA molecule present in the fertilized zygote must be copied approximately 10^{15} times during the course of a human lifetime. Rapidity and accuracy are essential. By combining precision with error correction systems, errors that affect the function of the gene's protein are surprisingly rare.

The **homeobox** is a DNA sequence, highly conserved throughout evolution, that encodes a series of 60 amino acids, called a homeodomain. Homeodomain protein products function as transcription factors by binding to DNA. The homeobox influences specific tissue functions that are critical for growth and development of the embryo.

The Human Genome

The genome for each species consists of the complete set of DNA sequences on all the chromosomes. There are 3 billion base pairs in each haploid human genome; in the double stranded helix DNA, there are 6 billion nucleotides, and there are an estimated 60,000 to 150,000 genes, the smallest functional unit of inherited information. Genes account for only about 3% of human DNA. Although enormously complex at first glance, the entire genetic language is written with only four letters: A, C, G, and T (U in RNA). Furthermore, the language is limited to only 3 letter words, codons. Finally, the entire genetic message is fragmented into the 23 pairs of chromosomes. With four nucleotides, reading groups of three, there are 64 possible combinations. Essentially all living organisms use this code. The genome

changes only by new combinations derived from parents or by mutation.

The 20 Amino Acids in Proteins

Amino Acid	Three-Letter Abbreviation	Single-Letter Code
Glycine	Gly	G
Alanine	Ala	A
Valine	Val	V
Isoleucine	Ile	I
Leucine	Leu	L
Serine	Ser	S
Threonine	Thr	T
Proline	Pro	P
Aspartic acid	Asp	D
Glutamic acid	Glu	E
Lysine	Lys	K
Arginine	Arg	R
Asparagine	Asn	N
Glutamine	Gln	Q
Cysteine	Cys	C
Methionine	Met	M
Tryptophan	Trp	W
Phenylalanine	Phe	F
Tyrosine	Tyr	Y
Histidine	His	H

The mRNA Genetic Code

First Position (5' end)	Second Position			Third Position
	U	C	A	G (3' end)
U	Phe	Ser	Tyr	Cys U
	Phe	Ser	Tyr	Cys C
	Leu	Ser	Stop	Stop A
	Leu	Ser	Stop	Trp G
C	Leu	Pro	His	Arg U
	Leu	Pro	His	Arg C
	Leu	Pro	Gln	Arg A
	Leu	Pro	Gln	Arg G
A	Ile	Thr	Asn	Ser U
	Ile	Thr	Asn	Ser C
	Ile	Thr	Lys	Arg A
	Met	Thr	Lys	Arg G
G	Val	Ala	Asp	Gly U
	Val	Ala	Asp	Gly C
	Val	Ala	Glu	Gly A
	Val	Ala	Glu	Gly G

Reading across the first row of the table, the codon UUU specifies Phenylalanine, the codon UCU specifies Serine, the codon UAU specifies Tyrosine, and the codon UGU specifies Cysteine. UAA, UAG, and UGA are stop codons.

Gene Structure and Function

The linear arrangement of many genes forms a chromosome. A gene is composed of a segment of DNA containing exons separated by introns, the coding and noncoding codons of nucleotides, respectively. Intron–exon patterns tend to be conserved during evolution. The alpha- and beta-globin genes are believed to have arisen 500 million years ago, with the introns in the same location as they are today.

Exon

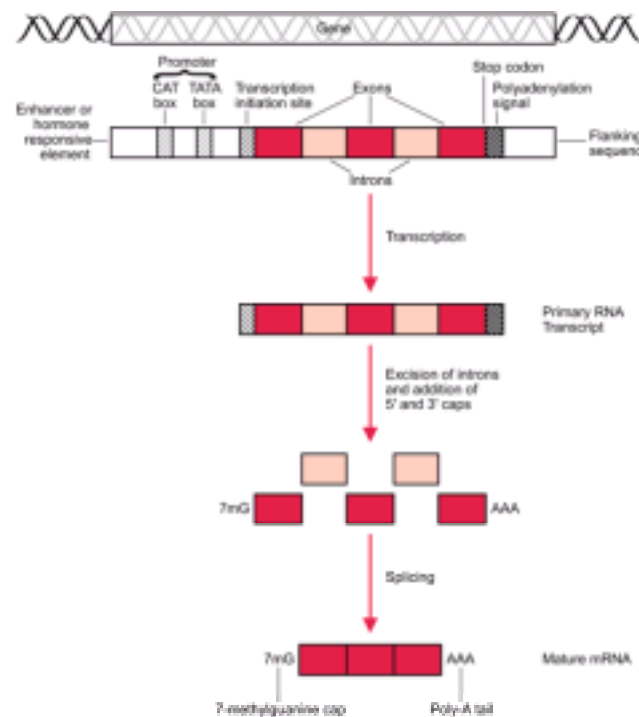

The segment of a gene that yields a messenger RNA product that codes for a specific protein.

Intron

The segment of a gene not represented in mature RNA and, therefore, noncoding for protein.

Codon

A sequence of 3 bases in RNA or DNA that codes for a specific amino acid; the triplet codon.

With some exceptions, essentially one gene yields one protein. As noted above, the introns are not translated into protein products. Only the DNA sequences in the exons (the part that “exits” the nucleus) are transcribed into messenger RNA and then translated into proteins. Genes also include flanking sequences important for gene transcription. The area that will initiate DNA action (e.g., DNA binding to the hormone-receptor complex) is called an **enhancer** region. The actual area where transcription begins is the **promoter** region. Only a few relatively short nucleotide sequences are promoters, such as the T-A-T-A-A sequence, or TATA box, and the C-C-A-A-T sequence, or CAT box. The promoter sites (the binding sites for RNA polymerase and numerous cofactors) are usually near the start of the coding region of the gene. Enhancer sites are larger than promoter sites and can be located anywhere, even far from the gene, but usually are in the 5′ flanking end. At the 3′ end, a coding sequence is usually present for the polyadenine tail common for most messenger RNA molecules.

The enhancer sites bind proteins (regulatory proteins) that serve as signals to regulate gene expression by either increasing or repressing the binding of RNA polymerase in the promoter region. This is one method of creating unique cellular functions. For example, a hormone target tissue can respond to the hormone because it contains a specific receptor protein that, on binding to the hormone, will bind to a DNA enhancer site. Specific proteins (called transcription factors) bind to enhancer sites and activate transcription. The regulation of gene transcription usually involves DNA sequences in the 5′ flanking upstream region of a gene.

Three codons (UAG, UAA, UGA) are called **stop codons**, because they specify a stop to translation of RNA into protein (like a period at the end of a sentence). By contrast, an **open reading frame** is a long series of base pairs between two stop codons; therefore, an open reading frame encodes the amino acid sequence of the protein product. Finding and identifying an open reading frame is an important step in analyzing DNA sequences because such a long sequence is usually encountered only in an active gene.

Gene expression is composed of the following steps: transcription of DNA to RNA, RNA processing to produce functional messenger RNA by splicing out introns, translation of messenger RNA on a ribosome to a peptide chain, and protein structural processing to the functional form.

Transcription

Transcription is the synthesis of single-stranded messenger RNA from a gene (double-stranded DNA). The amino acid sequence of the protein is coded in the DNA by codons; a single amino acid is coded by each codon, a triplet of 3 nucleic acid bases. RNA polymerase constructs the messenger RNA by reading the DNA strand (the “antisense” strand) that is complementary to the RNA; thus, the RNA is an exact copy of the other DNA strand (the “sense” strand), which is also called the complementary strand of the DNA molecule (remember, important differences are that thymine in DNA is replaced by uracil and ribose replaces deoxyribose in RNA).

Molecular complementarity is both a difficult and a simple concept to grasp. The simple aspect is the concept of one thing being like another. The difficult part is the necessity to understand and visualize that the complementary molecule is not identical to its template, but more like the place where the template goes in, the complementary molecule goes out. Thus, the strands of the double helix are not identical. Each DNA strand has a complementary structure, in a sense, one positive template and one negative template, each specifying the other. Each strand, therefore, serves as a template for its complementary DNA (in the process of replication) or complementary RNA (in the process of transcription). Thus, messenger RNA is synthesized from the negative template, the “antisense” strand, so that it will have the same structure as the positive template, the “sense” strand. Molecular biologists have to think in three dimensions!

Transcription is initiated at the upstream start site, the 5′ untranslated flanking region where the two strands of the double helix come apart. The process continues downstream, copying one of the strands until a specific codon is reached, which provides a stop message. RNA synthesis continues with the addition of a long chain of adenines, the poly-A tail; this is the 3′ untranslated region that is believed to stabilize RNA by preventing degradation. After transcription from a gene, the RNA moves into the cytoplasm where the intron regions are excised, and the exons are joined together (**RNA splicing**) to produce a complete, mature RNA molecule. The start and end of each exon and intron have sequences that when copied onto the RNA, signal an enzyme to remove the intervening parts. Almost all introns begin

with GU and end with AG (GT and AG in the DNA intron). Introns are of varying lengths; a single intron can be longer than the final RNA product. The mature RNA molecule has an addition at one end ("capping," by the addition of a modified nucleotide, 7-methyl guanosine) to protect against RNAases and at the other end, a polyadenine tail (the poly A tail) is added (in addition to a stabilizing factor, perhaps a signal to direct exit from the nucleus). Both ends are untranslated in the ribosomes.

Transcription Factors. Transcription factors are proteins that bind to regulatory elements in DNA (enhancers and promoters) and thus influence gene expression. The steroid hormone receptors are transcription factors. Gene transcription and the formation of messenger RNA can be either stimulated or inhibited through direct interactions with DNA. Transcription factors can further interact with other factors (coactivators and corepressors, also called adapter proteins) to produce cooperative effects. The activity of these proteins can also be affected by phosphorylation triggered by signals from cell-surface receptors (often growth factors). An important concept is to view the final result of hormonal activity and gene expression as a reflection of **cellular context**, the nature and activity of transcription factors as influenced by specific intracellular adapter proteins. This explains how similar agents (and similar transcription factors, e.g., the estrogen receptor) can have different actions in different tissues.

Translation

The messenger RNA travels from the chromosome on which it was synthesized to a ribosome in the cytoplasm, where it directs the assembly of amino acids into proteins (translation). Amino acids are brought into the process by specific transfer RNA molecules. The specific sequence of 3 bases at one end of the transfer RNA is complementary to the codon coding for the specific amino acid. Binding of this area to the messenger RNA codon places the specific amino acid at the other end into the proper sequence for the protein. The amino acids are placed one at a time as the transfer RNA molecules read the RNA template, beginning at the amino acid end (the 5' end) and finishing at the carboxy end (the 3' end). The process begins at the first AUG triplet and continues until a stop codon (UAA, UAG, or UGA) is reached, whereupon the messenger RNA falls off the ribosome and degenerates. The specific linear sequence of amino acids is specified by the genetic coding; in turn, this sequence determines the 3-dimensional form of the protein, the folded structure necessary for function.

The final expression of a gene may not end with the translation process. Further (posttranslational) processing of proteins occurs, such as glycosylation (the gonadotropins) or proteolytic cleavage (conversion of proopiomelanocortin to ACTH).

The mechanisms that produce proteins from genes are similar throughout the biologic world. This means that important knowledge regarding human function can be gained by studying simple organisms, and microbes can be engineered to produce human proteins.

Mutations

Any change in DNA sequence constitutes a mutation. Substitution refers to a change in a single nucleic acid base. A substitution in a codon can result in the incorporation of the wrong amino acid into a protein, leading to a change or loss in function. Insertion or deletion of amino acids into the final protein product can result from improper RNA splicing. Because of great redundancy in the genetic code (many triplet codons code out for the same amino acid, and there are only 20 amino acids), not all substitutions produce an effect. A clinical example of a single base substitution (point mutation) is the sickle mutation, in which thymine is substituted for adenine in the beta-globin gene. If homologous regions of DNA are misaligned, unequal crossover can occur, resulting in deletions and insertions (additions). Deletions and insertions can involve single bases, up to entire exons, or genes or several genes. Recombination or exchange of genetic material usually occurs in meiosis. Even a change at the junction of a coding and noncoding region can lead to abnormal messenger RNA.

Chromosomal Abnormalities

Numerical Abnormalities

Numerical abnormalities usually are due to nondisjunction, a failure of separation at anaphase, either during mitotic division or during meiosis. **Aneuploidy** is a chromosome number that is not an exact multiple of the haploid number, e.g., monosomy (45,X Turner syndrome) or trisomy (trisomy 13 Patau syndrome, trisomy 18 Edward syndrome, trisomy 21 Down syndrome, 47,XXY Klinefelter syndrome). **Mosaicism** indicates one or more cell lines with a different karyotype, usually arising from nondisjunction during early mitosis (failure of two paired chromosomes to separate). **Polyplody**, multiples of the haploid number of chromosomes, is a significant cause of spontaneous miscarriage.

Structural Abnormalities

Structural abnormalities are usually due to chromosomal breaks induced by radiation, drugs, or viruses. The resulting abnormality depends on the rearrangement of the broken pieces. Thus, in a **translocation** there is interchange of material between two or more nonhomologous chromosomes. A balanced translocation is associated with neither gain nor loss of genetic material, and such an individual is a translocation carrier.

Single-Gene Defects

Single-gene defects are due to mutations in specific genes. These mutations are transmitted according to mendelian inheritance: autosomal dominant, autosomal recessive, X-linked recessive, and rarely X-linked dominant.

Autosomal Dominance. Transmission is not linked to the sex of an individual, and homozygous and heterozygous children are affected (only one allele needs to be abnormal). With two heterozygous parents, each child has a 75% risk of being affected. With one heterozygous parent, each child has a 50% risk of being affected. The effect is subject to variable expression. Examples of autosomal dominant conditions include Huntington disease, neurofibromatosis, and Marfan syndrome.

Autosomal Recessive. These conditions are phenotypically expressed only in homozygotes (both alleles must be abnormal). With heterozygote parents, each child has a 25% risk of being affected and a 50% chance of being a carrier. Examples of autosomal recessive conditions are cystic fibrosis, sickle cell disease, and adrenal hyperplasia due to a deficiency in 21-hydroxylase.

X-Linked Recessive Inheritance. An affected father can transmit the condition only to daughters. Only homozygous females are affected when the condition is recessive. Red-green color blindness and hemophilia A are examples.

Genomic Imprinting

Genomic imprinting indicates persisting influences on genome function by the male and female parental contributions. For example, placental development is controlled mostly by paternally derived genes. Thus, a hydatidiform mole has a normal karyotype, but all of its chromosomes are derived from the father. Experiments in nature and animal experiments indicate that the maternal contribution to the genome is more important for embryonic development. In certain autosomal recessive conditions, the expression, severity, and age of onset will be influenced by the gender of the parent providing the mutant gene or chromosome.

Techniques of Molecular Biology

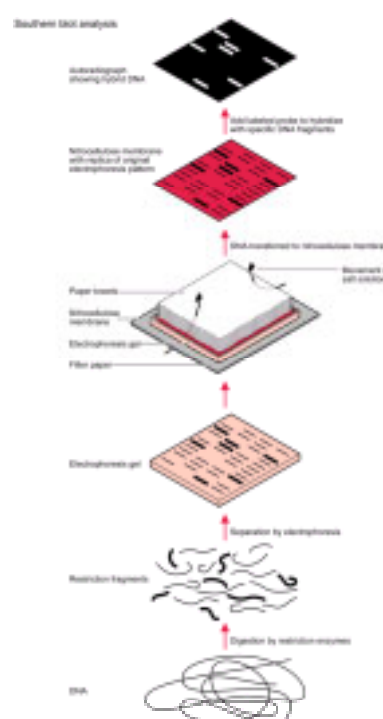

An enzyme that breaks the phosphodiester bonds and cuts the DNA molecule into fragments is an endonuclease; a **restriction enzyme** (restriction endonuclease) will cut only at sites with specific nucleic acid sequences. Restriction enzymes were discovered in bacteria in which they form a defense mechanism to cut (and thus inactivate) any foreign DNA (from invading viruses) introduced into the bacterial cell. As part of this protection mechanism, bacteria also contain methylases that methylate recognition sites in native DNA, directing the action of the restriction enzyme to the nonmethylated foreign DNA. Different bacteria have different restriction enzymes with specific action sites. Restriction enzymes are available that cut DNA into pieces (restriction fragments), ranging from many small fragments to a few large pieces, depending on the number of nucleotides in the recognition sequence. They are named for the organism and strain from which they are derived. The combination of restriction fragments, the merger of two cut pieces of DNA, yields **recombinant DNA**.

DNA polymerase is an enzyme that brings single nucleotides into a DNA molecule. A DNA polymerase can form DNA only in the presence of a DNA template; the synthesized DNA will be complementary to the template. RNA polymerase can make RNA also only in the presence of a DNA template.

A **DNAase** can remove nucleotides. By combining DNAase treatment with DNA polymerase action, radiolabeled nucleotides can be introduced into a DNA molecule, producing a **DNA probe**. A DNA probe can be compared with the antibody used in immunoassays. The antibody is specific and recognizes the hormone against which it is formed. The DNA probe specifically detects a sequence of DNA.

Reverse transcriptase is DNA polymerase that is RNA dependent. It is called reverse transcriptase because the flow of information is from RNA to DNA, the reverse of the usual direction of flow. This enzyme permits the copying of essentially any RNA molecule into single-stranded DNA; such DNA is called **complementary DNA** because it is a mirror image of the messenger RNA. Complementary DNA probes are limited by their reading only the exons (remember that introns are excised from RNA), and thus these probes read only large areas.

DNA and RNA are charged molecules and, therefore, will migrate in an electrical field. Fragments can be analyzed by gel (agarose or polyacrylamide) electrophoresis, the largest fragments migrating the slowest. By convention, the gels are read from top to bottom, with the smallest fragments at the bottom.

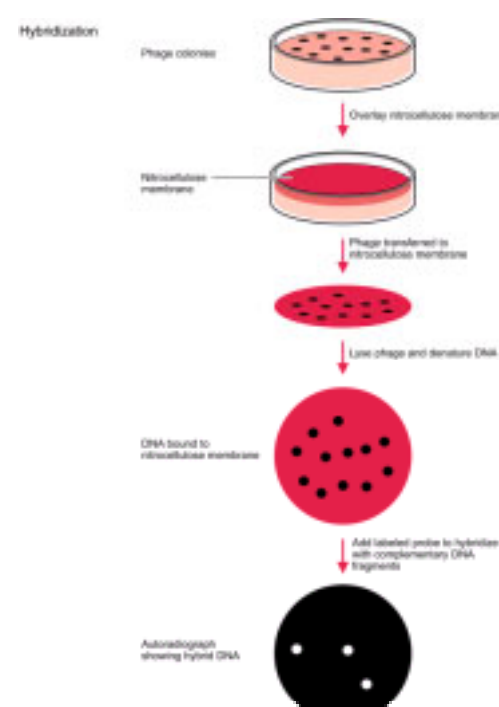

Southern Blot Analysis

DNA is first denatured to separate the two strands, then digested by restriction enzymes to produce smaller fragments. The Southern blot method, named after E.M. Southern, determines the fragment sizes. The fragments are separated by electrophoresis. The electrophoresis gel is placed over a thick piece of filter paper with its ends dipped in a high-salt solution. A special membrane (nitrocellulose) is placed over the gel, and over this is placed a stack of paper towels compressed by a weight. The salt solution rises by wick action into the filter paper; it moves by capillary action through the gel carrying the DNA with it. The DNA is carried to the nitrocellulose membrane to which it binds. The salt solution keeps moving and is absorbed by the paper towels. The nitrocellulose membrane thus creates a replica of the original electrophoresis pattern. The DNA is fixed to the membrane either by high-temperature baking or by ultraviolet light. Specific labeled probes then can be introduced for hybridization. **Hybridization** means that a specific probe anneals to its complementary sequence. The fragments with this sequence are then identified by autoradiography.

Northern blotting refers to RNA processing, Northern because RNA is the opposite image of DNA. Extracted RNA is separated by electrophoresis and transferred to a cellulose membrane as in Southern blotting for hybridization with probes (complementary DNA). Northern blotting would be used, for example, to determine whether hormone stimulation of a specific protein in a tissue is mediated by messenger RNA, i.e., gene expression.

Electrophoresis to separate proteins is called **Western blotting**, and antibodies are used for the hybridization identification process. Like Northern blotting, Western blotting tests gene expression, not just the presence of a gene. Northern and Western represent intentional witticisms (a rare event in science) in response to Southern blotting. Hybridization without electrophoresis by placing a drop of the cell extract directly on filter paper is called **dot or slot blotting**.

Hybridization

When two complementary strands of DNA reassociate, the process is called hybridization. Hybridization allows a specific area of the DNA to be studied using a radiolabeled DNA probe that is specific (a complementary sequence). The nitrocellulose membrane produced after Southern blotting is first treated to block nonspecific binding sites. The membrane is then treated (hybridized) with the labeled probe. The location of bound probe is then identified by autoradiography (for radiolabeled probes) or by colorimetric methods. The sequence of the probe, therefore, determines the sequence at the site of binding. Whenever two products are complementary, hybridization occurs. Thus, complementary DNA can be hybridized to its template messenger RNA.

In situ hybridization is the technique in which labeled DNA or RNA probes are placed directly on a slide of tissue or cells. A piece of cloned DNA labeled with a fluorescent marker can be utilized; the method is referred to as **FISH**, fluorescence in situ hybridization. The region corresponding to the cloned DNA lights up under fluorescent illumination unless the region has been deleted from one of the chromosomes. Several microdeletion syndromes have been discovered with the FISH technique, e.g., the Prader-Willi syndrome.

Polymerase Chain Reaction (PCR)

The polymerase chain reaction (PCR) is a technique to amplify (relatively quickly) small fragments or areas of DNA into quantities large enough to be analyzed with electrophoresis and blotting methods. This technique produces enormous numbers of copies of a specific DNA sequence without resorting to cloning. The sequence to be amplified must be known. Specific markers (synthesized short sequences of DNA corresponding to each end of the sequence to be studied) are selected that will delineate the region of DNA to be amplified. These flanking sequences are called primers. The DNA sample, the primers, and an excess of free single nucleotides are incubated with a DNA polymerase.

The first step involves separating DNA into its single strands by denaturation with heat (92°C), then the temperature is lowered (40°C), causing the primers to stick (anneal) to their complementary regions on the DNA. The temperature is raised to 62°C, and DNA polymerase then synthesizes a new strand beginning and ending at the primers, forming a new double-stranded DNA. Repeating the cycle many times (by alternating the reaction temperature) amplifies the amount of DNA available for study (more than 1 million-fold); the increase occurs exponentially. Thus, DNA can be analyzed from a single cell, and genes can be visualized by blotting without labeled probes.

Because the process requires alternate heating and cooling, a DNA polymerase resistant to heat is an advantage in that periodic replenishment is not necessary. This problem was solved with the discovery of DNA polymerase (Taq polymerase) in a microorganism (*Thermus aquaticus*) that is a thermophile (a hot water microbe) and was found in an out-of-the-way Yellowstone National Park hot spring called Mushroom Pool. This high-temperature polymerase allows automation of the process.

The technique of polymerase chain reaction has made possible the study of incredibly small amounts of DNA. Most impressive is the amplification of small amounts of degraded DNA from extinct and rare species preserved in museums. DNA from fossils has been amplified and sequenced (e.g., from an 18-million-year-old magnolia plant).

Cloning DNA

Cloning means isolating a gene and making copies of it. A DNA library is a collection of DNA molecules derived from cloning methods. A complementary DNA library is the DNA counterpart of all of the messenger RNA isolated from a particular cell or tissue. By starting with messenger RNA, the search for the gene of interest can be focused (instead of searching the entire genome). Such a library is made using reverse transcriptase. The DNA molecules then can be inserted into an appropriate vector (described below) and replicate molecules can be produced. Using probes, the complementary DNA can be selected that matches the gene of interest (keeping in mind that complementary DNA only includes the exons of a gene). Cloning the DNA simply means the production of many identical copies of a specified fragment of DNA. Cloning can also be performed using the polymerase chain reaction. As indicated above, complementary DNA cloning focuses on the DNA counterpart of messenger RNA; genomic DNA cloning, using a restriction endonuclease, copies the DNA in genes. Cloning also can be used to make multiple copies of probes or unknown DNA fragments.

If the amino acid sequence is unknown, one can work backward. Knowing the specific protein product, antibodies can be produced against the protein. When complementary DNA is inserted into certain vectors, production of the protein can be identified with the antibodies; thus, the DNA fragment will be isolated.

A vector is an entity in which foreign DNA can be inserted. The vector plus the foreign DNA are inserted into a host cell; the host cell produces both the vector and the foreign DNA. The first vectors were bacterial plasmids, circular DNA molecules (minichromosomes) that coexist in the cytoplasm with the bacterial chromosomal DNA. Most noteworthy, they carry genes that code for antibiotic resistance. This enables the bacterial cells that contain the plasmid to be selected by appropriate antibiotic treatment. Plasmid vectors have also been developed that allow selection by color. A variety of bacterial strains have been developed, each for a specific use.

Disruption of the plasmid DNA with restriction enzymes, followed by incorporation of foreign DNA with DNA ligase, produces plasmid DNA molecules (recombinant DNA containing the foreign DNA) that can be replicated. Plasmid vectors can incorporate foreign DNA fragments up to 10 kb in size. Digestion of recovered plasmids with restriction enzymes releases the desired DNA fragment, which can then be recovered by electrophoresis.

Other vectors exist. Bacteriophages (or phages) are viruses that infect and replicate within bacteria. Phage vectors can incorporate larger DNA inserts, up to 20 kb. Cloning DNA with phage vectors follows the same basic design as with plasmids. Larger fragments of foreign DNA are cloned with cosmid vectors, artificially produced combinations of phage and plasmid vectors. Very large fragments, up to 1000 kb, can be cloned using yeast artificial chromosomes. This method can work with whole genes.

Basic Steps for Cloning

1. Choose a DNA source: either genomic DNA or complementary DNA.
2. Fragment the DNA by restriction endonucleases.
3. Insert the fragments into vectors.
4. Introduce the vectors into bacteria.
5. Collect the cloned DNA propagated in the bacteria to form a library.

- Screen the library for the desired sequence. Possible methods include the use of complementary nucleotide probes for fragments that hybridize or the detection of a specific protein produced with antibodies to the protein or by assaying the function of the protein.

Knockout Animal Models

Animal models for the function of a gene employ the method of “knocking out” a specific gene. In a straightforward, but important demonstration, it can be determined whether a specific gene and its protein are essential for life, or for a function (such as pregnancy).

The Identification of Genes

To clone an entire gene whose protein product is known, a complementary DNA library is produced. The specific DNA fragment is identified by linking it to the protein. Once identified, the total gene can be screened using the identified complementary DNA, indicating the introns and exons. Another strategy is to synthesize an oligonucleotide probe, basing the sequence on the known amino acid sequence in the protein product (from the peptide sequence, the DNA sequence that codes for that protein can be predicted). This method can be used with just a relatively small piece of the peptide. As more and more genes are cloned, the codon frequency for particular amino acids is being established. Complementary DNA can be cloned without producing a library by using the polymerase chain reaction to amplify complementary DNA made from messenger RNA by reverse transcriptase. Overlapping sequences of the genome can be cloned, using a piece of DNA from each succeeding product, to work across a chromosome in a systematic manner to search for a gene; this is called **chromosome walking**.

The entire sequencing process can be performed by a computer, even searching for open reading frames. Once the sequence of a DNA fragment has been identified, the computer can utilize DNA and protein data bases to predict sequence, recognition site, protein translation, and homology with known sequences. The scientist can then select restriction fragment sizes for cloning. Once a gene has been analyzed, it has to be compared with the gene in the disease state. If a mutation is of large size, this can be detected by Southern blotting. Minor alterations require comparisons in DNA sequences, which is possible by using polymerase chain amplification to produce specific gene sequences in amounts readily studied.

A gene can be localized to a specific chromosome when its protein product is unknown by studies involving chromosome rearrangements and linkage analysis. Specific diseases are associated with karyotypic changes. Thus, the specific chromosome can be targeted for gene localization. Linkage analysis utilizes restriction fragment length polymorphisms.

DNA Polymorphism

Southern blotting reveals specific patterns of bands that reflect the varying lengths of the DNA fragments produced by restriction enzyme action. A specific site can exhibit a mutation by having a different pattern (a different length of the DNA fragment on Southern blotting due to sequence difference). These differences in DNA sequences are called restriction fragment length polymorphisms, or simply polymorphisms, usually a benign variation. A polymorphism will be governed by the mendelian regulations of inheritance, and if by chance, a polymorphism is identified in a patient with a specific disease, the transmission of the disease can be studied. The polymorphism, which is linked to the disease by chance, can be used to study the inheritance of a disease when the genes are unknown. The polymorphism is like a flag that marks specific areas of chromosomes. This method of study requires DNA from at least one affected individual and a sufficient number of family members to trace the polymorphism, either by Southern blotting (for long sequences) or with the polymerase chain reaction (best for short sequences).

Minisatellites are a form of polymorphisms. Minisatellites are noncoding areas of DNA that repeat in variable numbers, so-called variable number **tandem repeat sequences**, distributed throughout the length of every human chromosome. These areas can be followed by DNA probes, providing a “fingerprint” for specific individuals. This uniqueness is applied in forensic medicine. Microsatellites, as the name implies, are smaller than minisatellites. Usually, microsatellites consist of repetitions of only two nucleotides.

DNA polymorphisms now number in the thousands and allow genetic mapping with great precision. A polymorphism can serve as a genetic marker for a medically important gene.

The Human Genome Project

All of the human genes are collectively known as the genome. Begun in 1990, the goal of the international human genome project is to sequence the 3 billion base pairs of the human genome, enough information to occupy 10,000 conventional floppy disks. Using the standard thin-layer vertical gel electrophoresis followed by autoradiographs of gel blots, it would require tens of millions of gels to accomplish this project. Shared data and computer analysis are necessary, and high speed automated sequencing technology must be utilized. Each laboratory will determine its small part of the sequence and then have to figure out where it fits in the big picture. When the computer finds an open reading frame, the probable amino acid sequence and the function can be predicted for the gene's protein. A genetic linkage map can serve as a foundation for locating disease sites and for integrating the genetic sequencing with biologic functions. Remember that there are anywhere from 60,000 to 150,000 genes. By the end of 1997, more than 60 million (of the total 3 billion) base pairs had been analyzed, and an electronic version is available on the World Wide Web at <http://www.ncbi.nlm.nih.gov/>. This represents about 50,000 genes. The complete genomic sequences had been determined for 141 viruses, 51 organelles, 2 eubacteria, and one eukaryote. A complete map of the human genome is predicted to be available by 2005. Soon, we will be able to have in our possession a personal CD that contains our individual complete genetic blueprint.

The U.S. Department of Energy maintains a Web site that provides basic information and useful links to other sites regarding the human genome project:

http://www.ornl.gov/techresources/human_genome/publicat/publications.html

Genetic Maps. By 1997, about 6000 polymorphic markers had been identified to localize genes that predispose to disease. Using this method, a gene can be targeted for more specific localization.

Physical Maps. Genes of interest are localized by comparing overlapping DNA fragments. This isolates chromosomal segments for sequencing.

Sequence Maps. The challenge of the Human Genome Project can be appreciated by considering that technology is capable of reading about 36,000 DNA letters per day, and there are about 130 million DNA letters in the average human chromosome. Although the genetic and physical maps are nearing completion, complete

sequence maps will take many more years.

The chromosomal locations of genes responsible for hormone production are rapidly being mapped. From the cloned DNA sequences, the amino acid sequences can be predicted. Every protein product of a gene represents a potential diagnostic or therapeutic target. And of course, inherited disorders will be subject to characterization and, eventually, gene therapy. However, even after a gene has been identified and genetically mapped, its full characterization remains a difficult and time-consuming task. Full understanding of disorders that involve the interactions of multiple genes will be even more complicated.

But molecular progress is inexorable. The future will see preventive medicine by prediction. By knowing an individual's genetic constitution, appropriate and intensive screening can be directed to predisposed conditions. This kind of knowledge will also require social and political considerations. It is not far-fetched to envision marriages and children avoided because of a bad match of genetic predispositions. Society will have to develop guidelines regarding the use of this information: by individuals, by employers, by health organizations, and by the government. Scientific progress must be matched by public and professional education to appropriately manage this knowledge.

Clinical Applications

The molecular diagnosis of genetic disorders requires only a small sample of DNA, obtainable from any cells that are nucleated, such as white blood cells or epithelial cells. Polymerase chain reaction carried out by automatic machinery allows speedy DNA diagnosis with material amplified from a single cell. This is an important advantage in prenatal genetic analysis and in preimplantation sexing and diagnosis. PCR makes it possible to perform DNA diagnosis from a single cell removed from embryos fertilized in vitro.

Molecular diagnosis is limited by the prevalence of heterogeneous genetic changes. In other words, many disorders involve different mutations in different people. In contrast, some (like sickle cell disease) always involve the same change. With cystic fibrosis, 70% of patients (of northern European ancestry) have the same 3-base deletion, whereas the remaining 30% have an extremely heterogeneous collection of mutations. Molecular diagnosis is further challenged by the need to not only find a subtle change in a gene but to distinguish important changes from benign variations (polymorphisms). Ingenious PCR-based methods have been developed for rapid screening and detection of mutations. The significance of detected mutations requires segregation of the mutation with an identified disease in a family.

At least one type of growth hormone deficiency is inherited in an autosomal recessive pattern. The cloning of growth hormone DNA complementary to its messenger RNA permitted localization of the growth hormone gene. The growth hormone gene is in a cluster that also includes the gene for human placental lactogen. This cluster of genes contains multiple units of DNA that are homologous and prone to recombination, which leads to deletion on one chromosome and duplication on another. Similar mechanisms operate for other protein products governed by genes in clusters, such as the globins.

The commercial production of proteins from cloned genes inserted into bacteria is rapidly increasing. The production of insulin (the first) and growth hormone are good examples. Glycosylation does not occur in bacterial systems, and therefore the commercial production of recombinant glycoproteins requires a mammalian cell line for the process. This has been accomplished, and recombinant gonadotropins are now available. The gene for gonadotropin-releasing hormone on the short arm of chromosome 8 has been isolated and cloned. Molecular technology was important in the characterization of inhibin, the ovarian follicular hormone that inhibits follicle-stimulating hormone (FSH) secretion. The inhibin gene has been sequenced and found to be homologous to the gene for antimüllerian hormone. The alpha-subunit common to gonadotropins, thyroid-stimulating hormone, and human chorionic gonadotropin (HCG) has been traced to a gene that has been isolated, sequenced, and localized on chromosome 6.

The Y chromosome carries a genetic locus responsible for differentiation of the testes, called the testes-determining factor. The theory that this is a male-specific histocompatibility antigen (the H-Y antigen) has been abandoned. Using material from intersex patients, maps of the Y chromosome have placed the testes determining factor on the short arm, and it is now believed that this activity resides specifically with the SRY gene. Certain intersex disorders, therefore, result from an exchange of X and Y DNA when the short arms of the X and Y chromosomes pair and crossover during meiosis. The exact locus (or loci) of the ovarian determinants on the X chromosomes has not yet been identified.

Because of the importance of X-linked disease, the X chromosome is one of the most studied of all human chromosomes. By 1993, about 40% of the 160 million base pairs of the X chromosome DNA had been cloned; in addition, 26 inherited disease genes had been cloned, and more than 50 other genes had been localized by linkage analysis.

Insertion of a foreign gene into an embryo results in a transgenic animal. The inserted foreign gene will be present in many tissues, and if the animal is fertile, it will be inherited. There are many applications for transgenic animals. Transgenic animals provide animal models for inherited diseases and malignant tumors and provide a means to carry out experiments in gene therapy. The transfer of new or altered genes is an important method to study gene function. Transgenic plants can even be developed to produce new pharmaceuticals, and the introduction of genes conferring resistance to insects may solve the problem of insecticide contamination.

The human genome contains many genes with the potential to cause cancer. Other genes have the ability to block malignant growth. Cancer is a genetic disease in that tumors can be said to be clonal; all the cells are genetically related. **Oncogenes**, discovered in tumor viruses, are genes that transform cells from normal to abnormal growth by encoding proteins that are involved in signal transduction, specifically the transmission of growth-regulatory messages. There are many oncogenes and many different pathways of action, all of which result in a proliferative state. The mutations that activate these genes either lead to protein activity independent of incoming signals or to activity at the wrong place at the wrong time. The bottom line is the turning on (by an altered oncogene) of persistent growth.

There are also antioncogenes in normal cells, growth-suppressing genes that must be inactivated before tumors can grow. Inherited susceptibility for cancer can also result from a mutation in tumor suppresser genes. Although activation of an oncogene is a dominant effect, tumor suppresser mutations are recessive and can be carried and transmitted, but are not active as long as pairing occurs with a normal antioncogene.

Cancer, therefore, is a genetic disease, but regulation of normal growth involves a complex system that takes a long time to overcome. During this time period, the technology of recombinant DNA may be able to achieve diagnosis sufficiently early to yield cures. Knowing the specific oncogene involved in a given tumor also offers therapeutic possibilities. For example, an antimetabolite can be attached to antibody for an oncogene, targeting the cancer cells.

Molecular biology is changing both diagnosis and therapy. Viral and bacterial DNA can be identified. The automated PCR process can produce electrophoretic patterns that can be read automatically. With this technique, a single human papillomavirus DNA molecule can be detected among 10,000 or more human cells.

Faulty endogenous protein production can be corrected by replacing the problematic mechanism. There are two strategies: foreign cells that produce the missing protein could be introduced, or the faulty gene could be replaced (or more accurately, adding a complementary-corrected DNA). Thus, recessive single-gene disorders are potentially amenable to gene therapy, as are acquired diseases such as cancer and infections. Gene therapy is broadly defined as the enlistment of the patient's own cellular machinery to produce a therapeutic agent. A gene delivered to a cell can either replace a defective or missing gene or produce a protein with a desired effect. However, this is a field in its infancy.

Specific guidelines for gene therapy have been developed requiring several levels of review. One class of human therapy is the use of retroviral vectors to transfer marker genes into cultured human cells that are returned to patients of origin. For example, this allows tracking of tumor-infiltrating lymphocytes, donor hepatocytes, or killer T cells that are specific for the human immunodeficiency virus. These transferred genes can also be crafted to provide a function in patients with single-gene inherited disorders. Another class of therapy involves the transfer of genes that encode for factors that destroy tumor cells, such as tumor necrosis factor or interleukin. Retroviral vectors are viruses that have been altered so that no viral proteins can be made by cells infected by the vectors. Thus, viral replication and spread are prevented, but gene transfer into replicating cells can take place. Other transfer methods being developed include the use of adenovirus vectors and specifically targeted plasmid DNA.

The classical definition of a hormone is a substance that is produced in a special tissue, where it is released into the bloodstream, and travels to distant responsive cells in which the hormone exerts its characteristic effects. What was once thought of as a simple voyage is now appreciated as an odyssey that becomes more complex as new facets of the journey are unraveled in research laboratories throughout the world. Indeed, the notion that hormones are products only of special tissues has been challenged.

Complex hormones and hormone receptors have been discovered in primitive, unicellular organisms, suggesting that endocrine glands are a late development of evolution. The widespread capability of cells to make hormones explains the puzzling discoveries of hormones in strange places, such as gastrointestinal hormones in the brain, reproductive hormones in intestinal secretions, and the ability of cancers to unexpectedly make hormones. Hormones and neurotransmitters were and are a means of communication. Only when animals evolved into complex organisms did special glands develop to produce hormones that could be used in a more sophisticated fashion. Furthermore, hormones must have appeared even before plants and animals diverged because there are many plant substances similar to hormones and hormone receptors. Therefore, it is not surprising that, because every cell contains the genes necessary for hormonal expression, cancer cells, because of their dedifferentiation, can uncover gene expression and, in inappropriate locations and at inappropriate times, make hormones.

Hormones, therefore, are substances that provide a means of communication and should now be viewed broadly as chemical regulatory and signaling agents. The classic endocrine hormones travel through the bloodstream to distant sites, but cellular communication is also necessary at local sites. Words that are now encountered frequently are paracrine, autocrine, and intracrine, depicting a more immediate form of communication.

Paracrine Communication

Intercellular communication involving the local diffusion of regulating substances from a cell to nearby (contiguous) cells.

Autocrine Communication

Intracellular communication whereby a single cell produces regulating substances that in turn act upon receptors on or within the same cell.

Intracrine Communication

This form of intracellular communication occurs when unsecreted substances bind to intracellular receptors.

Let us follow an estradiol molecule throughout its career and in so doing gain an overview of how hormones are formed, how hormones work, and how hormones are metabolized. Estradiol begins its lifespan with its synthesis in a cell specially suited for this task. For this biosynthesis to take place, the proper enzyme capability must be present along with the proper precursors. In the adult human female the principal sources of estradiol are the granulosa cells of the developing follicle and the corpus luteum. These cells possess the ability to turn on steroidogenesis in response to specific stimuli. The stimulating agents are the gonadotropins, follicle-stimulating hormone (FSH) and luteinizing hormone (LH). The initial step in the process that will give rise to estradiol is the transmission of the message from the stimulating agents to the steroid-producing mechanisms within the cells.

Messages that stimulate steroidogenesis must be transmitted through the cell membrane. This is necessary because gonadotropins, being large glycopeptides, do not ordinarily enter cells but must communicate with the cell by joining with specific receptors on the cell membrane. In so doing they activate a sequence of communication. A considerable amount of investigation has been devoted to determining the methods by which this communication takes place. E. M. Sutherland received the Nobel Prize in 1971 for proposing the concept of a second messenger.

Gonadotropin, the first messenger, activates an enzyme in the cell membrane called adenylate cyclase. This enzyme transmits the message by catalyzing the production of a second messenger within the cell, cyclic adenosine 3',5'-monophosphate (cyclic AMP). The message passes from gonadotropin to cyclic AMP, much like a baton in a relay race.

Cyclic AMP, the second messenger, initiates the process of steroidogenesis, leading to the synthesis and secretion of the hormone estradiol. This notion of message transmission has grown more and more complex with the appreciation of new physiologic concepts, such as the heterogeneity of peptide hormones, the up- and

down-regulation of cell membrane receptors, the regulation of adenylate cyclase activity, and the important roles for autocrine and paracrine regulating factors.

Secretion of estradiol into the bloodstream directly follows its synthesis. Once in the bloodstream, estradiol exists in two forms, bound and free. A majority of the hormone is bound to protein carriers, albumin and sex steroid hormone-binding globulin. The purpose of this binding is not totally clear. The biologic activity of a hormone may be limited by binding in the blood, thereby avoiding extreme or sudden reactions. In addition, binding may prevent unduly rapid metabolism, allowing the hormone to exist for the length of time necessary to ensure a biologic effect. This reservoir-like mechanism avoids peaks and valleys in hormone levels and allows a more steady state of hormone action.

The biologic and metabolic effects of a hormone are determined by a cell's ability to receive and retain the hormone. The estradiol that is not bound to a protein, but floats freely in the bloodstream, readily enters cells by rapid diffusion. For estradiol to produce its effect, however, it must be grasped by a receptor within the cell. The job of the receptor is to aid in the transmission of the hormone's message to nuclear gene transcription. The result is production of messenger RNA leading to protein synthesis and a cellular response characteristic of the hormone.

Once estradiol has accomplished its mission, it is eventually released back into the bloodstream. It is possible that estradiol can perform its duty several times before being cleared from the circulation by metabolism. On the other hand, many molecules will be metabolized without ever having the chance to produce an effect. Unlike estradiol, other hormones, such as testosterone, are metabolized and altered within the cell in which an effect is produced. In the latter case, a steroid is released into the bloodstream as an inactive compound. Clearance of steroids from the blood varies according to the structure of the molecules.

Cells that are capable of clearing estradiol from the circulation accomplish this by biochemical means (conversion to estrone and estriol, moderately effective and very weak estrogens, respectively) and conjugation to products that are water soluble and excreted in the urine and bile (sulfo and glucuro conjugates).

Thus, a steroid hormone has a varied career packed into a short lifetime. We are now ready to review the important segments of this lifespan in greater detail.

Nomenclature

All steroid hormones are of basically similar structure with relatively minor chemical differences leading to striking alterations in biochemical activity. The basic structure is the perhydrocyclopentanephenthrane molecule. It is composed of three 6-carbon rings and one 5-carbon ring. One ring is benzene, two rings naphthalene, and three rings phenanthrene; add a cyclopentane (5-carbon ring), and you have the perhydrocyclopentanephenthrane structure of the steroid nucleus.

The sex steroids are divided into 3 main groups according to the number of carbon atoms they possess. The 21-carbon series includes the corticoids and the progestins, and the basic structure is the **pregnane** nucleus. The 19-carbon series includes all the androgens and is based on the **androstane** nucleus, whereas the estrogens are 18-carbon steroids based on the **estrane** nucleus.

There are 6 centers of asymmetry on the basic ring structure, and there are 64 possible isomers. Almost all naturally occurring and active steroids are nearly flat, and substituents below and above the plane of the ring are designated alpha (α) (dotted line) and beta (β) (solid line), respectively. Changes in the position of only one substituent can lead to inactive isomers. For example, 17-epitestosterone is considerably weaker than testosterone; the only difference being a hydroxyl group in the α position at C-17 rather than in the β position.

The convention of naming steroids uses the number of carbon atoms to designate the basic name (e.g., pregnane, androstane, or estrane). The basic name is preceded by numbers that indicate the position of double bonds, and the name is altered as follows to indicate 1, 2, or 3 double bonds: -ene, -diene, and -triene. Following the basic name, hydroxyl groups are indicated by the number of the carbon attachment, and 1, 2, or 3 hydroxyl groups are designated -ol, -diol, or -triol. Ketone groups are listed last with numbers of carbon attachments, and 1, 2, or 3 groups designated -one, -dione, or -trione. Special designations include: dehydro, elimination of 2 hydrogens; deoxy, elimination of oxygen; nor, elimination of carbon; delta or D, location of double bond.

Lipoproteins and Cholesterol

Cholesterol is the basic building block in steroidogenesis. All steroid-producing organs except the placenta can synthesize cholesterol from acetate. Progestins, androgens, and estrogens, therefore, can be synthesized in situ in the various ovarian tissue compartments from the 2-carbon acetate molecule via cholesterol as the common steroid precursor. However, in situ synthesis cannot meet the demand, and, therefore, the major resource is blood cholesterol that enters the ovarian cells and can be inserted into the biosynthetic pathway or stored in esterified form for later use. The cellular entry of cholesterol is mediated via a cell membrane receptor for low-density lipoprotein (LDL), the bloodstream carrier for cholesterol.

Lipoproteins are large molecules that facilitate the transport of nonpolar fats in a polar solvent, the blood plasma. There are 5 major categories of lipoproteins according to their charge and density (flotation during ultracentrifugation). They are derived from each other in the following cascade of decreasing size and increasing density.

Chylomicrons

Large, cholesterol (10%)- and triglyceride (90%)-carrying particles formed in the intestine after a fatty meal.

Very Low-Density Lipoproteins (VLDL)

Also carry cholesterol, but mostly triglyceride; more dense than chylomicrons.

Intermediate-Density Lipoproteins (IDL)

Formed (for a transient existence) with the removal of some of the triglyceride from the interior of VLDL particles.

Low-Density Lipoproteins (LDL)

The end products of VLDL catabolism, formed after further removal of triglyceride leaving approximately 50% cholesterol; the major carriers (2/3) of cholesterol in the plasma and thus a strong relationship exists between elevated LDL levels and cardiovascular disease.

High-Density Lipoproteins (HDL)

The smallest and most dense of the lipoproteins with the highest protein and phospholipid content; HDL levels are inversely associated with atherosclerosis (high levels are protective). HDL can be further separated into a lighter fraction (HDL₂) and a denser fraction (HDL₃). HDL₂ is strongly associated with cardiovascular disease.

The lipoproteins contain 4 ingredients: 1) cholesterol in two forms: free cholesterol on the surface of the spherical lipoprotein molecule and esterified cholesterol in the molecule's interior; 2) triglycerides in the interior of the sphere; 3) phospholipid, and 4) protein: electrically charged substances on the surface of the sphere and responsible for miscibility with plasma and water. The surface proteins, called **apoproteins**, constitute the sites that bind to the lipoprotein receptor molecules on the cell surfaces. The principal surface protein of LDL is apoprotein B, and apoprotein A-1 is the principal apoprotein of HDL.

Lipids for peripheral tissues are provided by the secretion of VLDL by the liver. Triglycerides are liberated from VLDL by lipoprotein lipase located in the capillary endothelial cells as well as a lipase enzyme located on the endothelial cells in liver sinusoids. In this process, the surface components (free cholesterol, phospholipids, and apoproteins) are transferred to HDL. Finally, the VLDL is converted to LDL, which plays the important role of transporting cholesterol to cells throughout the body. The hepatic lipase enzyme is sensitive to sex steroid changes: suppression by estrogen and stimulation by androgens.

LDL is removed from the blood by cellular receptors that recognize one of the surface apoproteins. The lipoprotein bound to the cell membrane receptor is internalized and degraded. Intracellular levels of cholesterol are partly regulated by the up- and down-regulation of cell membrane LDL receptors. When these LDL receptors are saturated or deficient, LDL is taken up by "scavenger" cells (most likely derived from macrophages) in other tissues, notably the arterial intima. Thus, these cells can become the nidus for atherosclerotic plaques.

HDL is secreted by the liver and intestine or is a product of the degradation of VLDL. Cholesteryl ester molecules move to form a core in a small spherical particle, the HDL₃ particle. These particles accept additional free cholesterol, perhaps mediated by receptors that recognize apoprotein A-1. With uptake of cholesterol, the

particle size increases to form HDL₂, the fraction that reflects changes in diet and hormones. HDL₃ levels remain relatively stable.

The protein moieties of the lipoprotein particles are strongly related to the risk of cardiovascular disease, and genetic abnormalities in their synthesis or structure can result in atherogenic conditions. The lipoproteins are a major reason for the disparity in atherosclerosis risk between men and women. Throughout adulthood, the blood HDL-cholesterol level is about 10 mg/dL higher in women, and this difference continues through the postmenopausal years. Total and LDL-cholesterol levels are lower in premenopausal women than in men, but after menopause they rise rapidly.

The protective nature of HDL is due to its ability to pick up free cholesterol from cells or other circulating lipoproteins. This lipid-rich HDL is known as HDL₃, which is then converted to the larger, less dense particle, HDL₂. Thus, HDL converts lipid-rich scavenger cells (macrophages residing in arterial walls) back to their low-lipid state and carries the excess cholesterol to sites (mainly liver) where it can be metabolized. Another method by which HDL removes cholesterol from the body focuses on the uptake of free cholesterol from cell membranes. The free cholesterol is esterified and moves to the core of the HDL particle. Thus, HDL can remove cholesterol by delivering cholesterol to sites for utilization (steroid-producing cells) or metabolism and excretion (liver).

Understanding the role of the cell surface receptors for the homeostasis of cholesterol (discussed later in this chapter), the work of the 1985 Nobel Laureates, Michael S. Brown and Joseph L. Goldstein, revolutionized our concepts of cholesterol, lipoprotein metabolism, and hormone action at the cell membrane. ¹ In their Nobel lecture, Brown and Goldstein paid tribute to cholesterol as the most highly decorated small molecule in biology.

For good cardiovascular health, the blood concentration of cholesterol must be kept low, and its escape from the bloodstream must be prevented. The problem of cholesterol transport is solved by esterifying the cholesterol and packaging the ester within the cores of plasma lipoproteins. The delivery of cholesterol to cells is in turn solved by lipoprotein receptors. After binding the lipoprotein with its package of esterified cholesterol, the complex is delivered into the cell by receptor-mediated endocytosis (discussed later in this chapter), in which the lysosomes liberate cholesterol for use by the cell.

Major protection against atherosclerosis depends on the high affinity of the receptor for LDL and the ability of the receptor to recycle multiple times, thus allowing large amounts of cholesterol to be delivered while maintaining a healthy low blood level of LDL. Cells can control their uptake of cholesterol by increasing or decreasing the number of LDL receptors according to the intracellular cholesterol levels. Thus, a high cholesterol diet influences the liver to reduce the number of LDL receptors on its cells, causing an elevated blood level of LDL. Brown and Goldstein postulate that the LDL receptor evolved under dietary conditions of a lower fat intake, and that the high-fat, high-cholesterol modern diet suppresses the production of LDL receptors, thereby allowing cholesterol to rise to levels associated with cardiovascular disease.

Steroidogenesis

The overall steroid biosynthesis pathway shown in the figure is based primarily on the pioneering work of Kenneth J. Ryan and his coworkers. ^{2,3} These pathways follow a fundamental pattern displayed by all steroid-producing endocrine organs. As a result, it should be no surprise that the normal human ovary produces all 3 classes of sex steroids: estrogens, progestins, and androgens. The importance of ovarian androgens is appreciated, not only as obligate precursors to estrogens, but also as clinically important secretory products. The ovary differs from the testis in its fundamental complement of critical enzymes and, hence, its distribution of secretory products. The ovary is distinguished from the adrenal gland in that it is deficient in 21-hydroxylase and 11 β -hydroxylase reactions. Glucocorticoids and mineralocorticoids, therefore, are not produced in normal ovarian tissue.

During steroidogenesis, the number of carbon atoms in cholesterol or any other steroid molecule can be reduced but never increased. The following reactions can take place.

1. Cleavage of a side chain (desmolase reaction).
2. Conversion of hydroxyl groups into ketones or ketones into hydroxyl groups (dehydrogenase reactions).
3. Addition of OH group (hydroxylation reaction).
4. Creation of double bonds (removal of hydrogen).
5. Addition of hydrogen to reduce double bonds (saturation).

The traditional view of steroidogenesis was that each step was mediated by many enzymes, with differences from tissue to tissue. A fundamental simplicity to the system emerged when the responsible complementary DNAs and genes were cloned. ^{4,5}

Steroidogenic enzymes are either dehydrogenases or members of the cytochrome P450 group of oxidases. Cytochrome P450 is a generic term for a family of oxidative enzymes, termed 450 because of a pigment (450) absorbance shift when reduced. P450 enzymes can metabolize many substrates; e.g., in the liver, P450 enzymes metabolize toxins and environmental pollutants. The following distinct P450 enzymes are identified with steroidogenesis: P450scc is the cholesterol side chain cleavage enzyme; P450c11 mediates 11-hydroxylase, 18-hydroxylase, and 19-methyloxidase; P450c17 mediates 17-hydroxylase and 17,20-lyase; P450c21 mediates the 21-hydroxylase; and P450arom mediates aromatization of androgens to estrogens. Marked differences in the exon—intron organization of the P450 genes are compatible with an ancient origin; thus, the superfamily of P450 genes diverged more than 1.5 billion years ago.

Enzyme	Cellular Location	Reactions
P450scc	Mitochondria	Cholesterol side chain cleavage
P450c11	Mitochondria	11-hydroxylase 18-hydroxylase 19-methyloxidase
P450c17	Endoplasmic reticulum	17-hydroxylase, 17,20-lyase
P450c21	Endoplasmic reticulum	21-hydroxylase
P450arom	Endoplasmic reticulum	Aromatase

The structural knowledge of the P450 enzymes that has been derived from amino acid and nucleotide sequencing studies demonstrated that all the steps between cholesterol and pregnenolone were mediated by a single protein, P450scc, bound to the inner mitochondrial membrane. Cloning data indicate the presence of a

single, unique P450scc gene on chromosome 15. These experiments indicated that multiple steps did not require multiple enzymes. Differing activity may reflect posttranslational modifications. These genes contain tissue-specific promoter sequences which is at least one reason that regulatory mechanisms can differ in different tissues (e.g., placenta and ovary).

Conversion of cholesterol to pregnenolone involves hydroxylation at the carbon 20 and 22 positions, with subsequent cleavage of the side chain. Conversion of cholesterol to pregnenolone by P450scc takes place within the mitochondria. It is one of the principal effects of tropic hormone stimulation, which also causes the uptake of the cholesterol substrate for this step. The tropic hormones from the anterior pituitary bind to the cell surface receptor of the G protein system, activate adenylate cyclase, and increase intracellular cyclic AMP. Cyclic AMP activity leads to gene transcription that encodes the steroidogenic enzymes and accessory proteins. More acutely, cyclic AMP stimulates the hydrolysis of cholesteryl esters and the transport of free cholesterol to the mitochondria.

Most of the cholesterol used for steroid synthesis is derived from the mobilization and transport of intracellular stores.^{6,7} Indeed, the rate-limiting step in steroidogenesis is the transfer of cholesterol from the outer mitochondrial membrane to the inner mitochondrial membrane where fully active P450scc waits for substrate. The rate-limiting transfer of hydrophobic cholesterol through the aqueous space between the outer and inner mitochondrial membranes is mediated by protein activation stimulated by the tropic hormone. Long-term, chronic steroidogenesis requires gene transcription and protein synthesis, but short-term, acute responses occur independently of new RNA synthesis, although protein synthesis is still necessary, specifically the proteins that regulate cholesterol transfer across the mitochondrial membrane.

Several proteins have been characterized and proposed as regulators of acute intracellular cholesterol transfer. Sterol carrier protein 2 (SCP2) is able to bind and transfer cholesterol between compartments within a cell. Another candidate is a small molecule, steroidogenesis activator polypeptide (SAP), and still another is peripheral benzodiazepine receptor (PBR), which affects cholesterol flux through a pore structure. But the most studied and favored protein as a regulator of acute cholesterol transfer is **steroidogenic acute regulator (StAR) protein**.^{8,9} StAR messenger RNA and protein are induced concomitantly with acute steroidogenesis in response to cyclic AMP stimulation; StAR increases steroid production; and StAR is imported and localized in the mitochondria. But most impressively, congenital lipoid adrenal hyperplasia (an autosomal recessive disorder) has been demonstrated to be a failure in adrenal and gonadal steroidogenesis due to a mutation in the StAR gene, which results in premature stop codons.^{10,11} With this mutation, a low level of steroidogenesis is possible, even permitting feminization at puberty, but continuing tropic hormonal stimulation results in an accumulation of intracellular lipid deposits that destroy steroidogenic capability.¹²

StAR mediates the transport of cholesterol into mitochondria in adrenal and gonadal steroidogenesis, but not in the placenta and brain. It is synthesized in a precursor form as a 285-amino acid protein that has a 25-residue sequence cleaved from the NH₂-terminal after transport into mitochondria.¹³ The mutant forms of StAR undergo premature truncation that prevents this proteolytic cleavage. Mutations of the StAR gene, located on chromosome 8p11.2, are the only inherited disorder of steroidogenesis not caused by a defect in one of the steroidogenic enzymes. The absence of StAR expression in placenta and brain indicates the presence of different mechanisms for cholesterol transport in those tissues.

It is important to note that once pregnenolone is formed further steroid synthesis in the ovary can proceed by one of 2 pathways, either via D⁵-3 β -hydroxysteroids or via the D⁴-3-ketone pathway. The first (the D⁵ pathway) proceeds by way of pregnenolone and dehydroepiandrosterone (DHA) and the second (the D⁴ pathway) via progesterone and 17 α -hydroxyprogesterone.

The conversion of pregnenolone to progesterone involves two steps: the 3 β -hydroxysteroid dehydrogenase and D⁴ and D⁵ isomerase reactions that convert the 3-hydroxyl group to a ketone and transfer the double bond from the 5–6 position to the 4–5 position. The 3 β -hydroxysteroid dehydrogenase enzyme catalyzes both the dehydrogenation and isomerization reactions, and exists in 2 forms (type I and type II), encoded by two separate genes on chromosome 1 (the type II gene is expressed in the gonads and the adrenal glands). Once the D⁴ and D⁵ ketone is formed, progesterone is hydroxylated at the 17 position to form 17 α -hydroxyprogesterone. 17 α -Hydroxyprogesterone is the immediate precursor of the C-19 (19 carbons) series of androgens in this pathway. By peroxide formation at C-20, followed by epoxidation of the C-17, C-20 carbons, the side chain is split off, forming androstenedione. The 17-ketone may be reduced to a 17 β -hydroxyl to form testosterone by the 17 β -hydroxysteroid dehydrogenase reaction. Both C-19 steroids (androstenedione and testosterone) are rapidly converted to corresponding C-18 phenolic steroid estrogens (estrone and estradiol) by microsomal reactions in a process referred to as aromatization. This process includes hydroxylation of the angular 19-methyl group, followed by oxidation, loss of the 19-carbon as formaldehyde, and ring A aromatization (dehydrogenation).

As an alternative, pregnenolone can be directly converted to the D⁵-3 β -hydroxy C-19 steroid, DHA, by 17 α -hydroxylation followed by cleavage of the side chain. With formation of the D⁴-3-ketone, DHA is converted into androstenedione. It is thought that conversion of each of the D⁵ compounds to their corresponding D⁴ compounds can occur at any step; however, the principal pathways are via progesterone and DHA. Regardless of the precursor source, C-19 D⁴-3-ketone substrates proceed to estrogens as noted above.

The four reactions involved in converting pregnenolone and progesterone to their 17-hydroxylated products are mediated by a single enzyme, P450c17, bound to smooth endoplasmic reticulum, regulated by a gene on chromosome 10. 17-Hydroxylase and 17,20 lyase were traditionally regarded as separate enzymes. These two different functions of a single enzyme, P450c17, are not genetic or structural but represent the effect of local influencing factors.

Characterization of the P450c21 protein and gene cloning indicate that there is only one 21-hydroxylase enzyme, the P450c21 in the smooth endoplasmic reticulum. Two human P450c21 genes (the A and B genes) have been cloned (on chromosome 6p), and the evidence indicates that only one (the B gene) is active. The molecular genetics of 21-hydroxylase deficiency indicate that the syndrome can be due to gene conversions of material in the active B gene to resemble material in the inactive A gene, as well as deletions in the P450c21 B gene. A conversion is similar to a cross-over in genetic effect. However, rather than appearing as a deletion or addition, the gene changes, but the number of gene copies does not change.

Aromatization is mediated by P450arom found in the endoplasmic reticulum.¹⁴ The human genome has one P450arom gene, located on chromosome 15q21.1, and designated as the CYP19 gene, denoting oxidation of the C-19 methyl group. Aromatization in different tissues with different substrates is the result of the single P450arom enzyme encoded by the single gene. Aromatase transcription is regulated by several promoter sites that respond to cytokines, cyclic nucleotides, gonadotropins, glucocorticoids, and growth factors. Tissue-specific expression is regulated by tissue-specific promoters. Thus, this gene has alternative promoters that allow the extremes of highly regulated expression in the ovary and nonregulated expression in the placenta and adipose. Very specific inhibitors of P450arom have been developed which allow intense blockage of estrogen production, with clinical applications that include the treatment of breast cancer (e.g., anastrozole) and dysfunctional uterine bleeding. The aromatase complex also includes NADPH-cytochrome P450 reductase, a ubiquitous flavoprotein for transferring reducing equivalents.

The 17 β -hydroxysteroid dehydrogenase and 5 α -reductase reactions are due to non-P450 enzymes. The 17 β -hydroxysteroid dehydrogenase is bound to the endoplasmic reticulum and the 5 α -reductase to the nuclear membrane. The 17 β -hydroxysteroid dehydrogenase enzymes convert estrone to estradiol, androstenedione to testosterone, and DHA to androstenediol, and vice versa. Four different isozymes have been identified, types I–IV.¹⁵ The type I enzyme is active in the placenta, converting estrone to estradiol. The type II and type IV enzymes form androstenedione and estrone from testosterone and estradiol, respectively, and the type III enzyme in the testis reduces androstenedione to testosterone.

The Two-Cell System

The two-cell system is a logical explanation of the events involved in ovarian follicular steroidogenesis.¹⁶ This explanation, first proposed by Falck in 1959,¹⁷ brings together information on the site of specific steroid production, along with the appearance and importance of hormone receptors. The following facts are important:

1. FSH receptors are present on the granulosa cells.
2. FSH receptors are induced by FSH itself.
3. LH receptors are present on the theca cells and initially absent on the granulosa cells, but, as the follicle grows, FSH induces the appearance of LH receptors on the granulosa cells.
4. FSH induces aromatase enzyme activity in granulosa cells.
5. The above actions are modulated by autocrine and paracrine factors secreted by the theca and granulosa cells.

These facts combine into the two-cell system to explain the sequence of events in ovarian follicular growth and steroidogenesis. The initial change from a primordial follicle to a preantral follicle is independent of hormones, and the stimulus governing this initial step in growth is unknown. Continued growth, however, depends on FSH stimulation. As the granulosa responds to FSH, proliferation and growth are associated with an increase in FSH receptors, a specific effect of FSH itself, but an action that is enhanced very significantly by the autocrine and paracrine peptides. The theca cells are characterized by steroidogenic activity in response to LH, specifically resulting in androgen production, by transcription of the P450_{scc}, P450_{c17}, and 3 β -hydroxysteroid dehydrogenase genes. Aromatization of androgens to estrogens is a distinct activity within the granulosa layer induced by FSH by activation of the P450_{arom} gene. Androgens produced in the theca layer, therefore, must diffuse into the granulosa layer. In the granulosa layer they are converted to estrogens, and the increasing level of estradiol in the peripheral circulation reflects release of the estrogen back toward the theca layer and into blood vessels.

The theca and granulosa cells secrete peptides that operate as both autocrine and paracrine factors.¹⁸ Insulin-like growth factor (IGF) is secreted by the theca and enhances the LH stimulation of androgen production in the theca cells as well as FSH-mediated aromatization in the granulosa. Evidence indicates that the endogenous insulin-like growth factor in the human ovarian follicle is IGF-II in both the granulosa and the thecal cells.¹⁹ Studies indicating activity of IGF-I with human ovarian tissue can be explained by the fact that both IGF-I and IGF-II activities can be mediated by the type I IGF receptor which is structurally similar to the insulin receptor. Theca production of transforming growth factor can promote the growth of granulosa cells and FSH induction of LH receptors on the granulosa. The regulation of FSH receptors on granulosa cells is relatively complex. Although FSH increases the activity of its own receptor gene in a cyclic AMP-mediated mechanism, this action is influenced by inhibitory agents, such as epidermal growth factor, fibroblast growth factor, and even a gonadotropin-releasing hormone (GnRH)-like protein. Inhibin and activin are produced in the granulosa in response to FSH, and activin has the important autocrine role of enhancing FSH actions, especially the production of FSH receptors. Inhibin enhances LH stimulation of androgen synthesis in the theca to serve as substrate for aromatization to estrogen in the granulosa, whereas activin suppresses androgen synthesis. This important paracrine regulation of androgen production in theca cells by inhibin and activin is exerted primarily through modification of the expression of steroidogenic enzymes, especially P450_{c17}.²⁰

After ovulation, the dominance of the luteinized granulosa layer is dependent on preovulatory induction of an adequate number of LH receptors, and, therefore, dependent on adequate FSH action. Prior to ovulation the granulosa layer is characterized by aromatization activity and conversion of the theca androgens to estrogens, an FSH-mediated activity. After ovulation the granulosa layer secretes progesterone and estrogens directly into the bloodstream, an LH-mediated activity.

Granulosa and theca cells each have an androgen aromatase system that can be demonstrated in vitro. However, in vivo, the activity of the granulosa layer in the follicular phase is several hundred times greater than the activity of the theca layer, and, therefore, the granulosa is the main biosynthetic source of estrogen in the growing follicle.²¹ Because granulosa cells lack P450_{c17}, the rate of aromatization in the granulosa layer is directly related to and dependent on the androgen substrate made available by the theca cells. Hence, estrogen secretion by the follicle prior to ovulation is the result of combined LH and FSH stimulation of the two-cell types, the theca and the granulosa. After ovulation, it is believed the two-cell types continue to function as a two-cell system; luteal cells derived from theca produce androgens for aromatization into estrogens by luteal cells derived from granulosa.

Blood Transport of Steroids

While circulating in the blood, a majority of the principal sex steroids, estradiol and testosterone, is bound to a protein carrier, known as sex hormone-binding globulin (SHBG) produced in the liver. Another 10–30% is loosely bound to albumin, leaving only about 1% unbound and free. A very small percentage also binds to corticosteroid-binding globulin. Hyperthyroidism, pregnancy, and estrogen administration all increase SHBG levels, whereas corticoids, androgens, progestins, growth hormone, insulin, and IGF-I decrease SHBG.

	Free (Unbound)	Albumin-Bound	SHBG-Bound
Estrogen	1%	30%	69%
Testosterone	1%	30%	69%
DHA	4%	88%	8%
Androstenedione	7%	85%	8%
Dihydrotestosterone	1%	71%	28%

From Mendel²²

The circulating level of SHBG is inversely related to weight, and, thus, significant weight gain can decrease SHBG and produce important changes in the unbound levels of the sex steroids. Another important mechanism for a reduction in circulating SHBG levels is insulin resistance and hyperinsulinemia (independent of age and weight).²³ Thus, increased insulin levels in the circulation lower SHBG levels, and this may be the major mechanism that mediates the impact of increased body weight on SHBG. This relationship between the levels of insulin and SHBG is so strong that SHBG concentrations are a marker for hyperinsulinemic insulin resistance, and a low level of SHBG is a predictor for the development of type II diabetes mellitus.²⁴

The distribution of body fat has a strong influence on SHBG levels. Android or central fat is located in the abdominal wall and visceral-mesenteric locations. This fat distribution is associated with hyperinsulinemia, hyperandrogenism, and decreased levels of SHBG.²⁵ The common mechanism for these changes is probably the hyperinsulinemia.

SHBG is a glycoprotein that contains a single binding site for androgens and estrogens, even though it is a homodimer composed of two monomers. Its gene has been localized to the short arm (p12–13) of chromosome 17.²⁶ Genetic studies have revealed that the SHBG gene also encodes the androgen-binding protein present in the seminiferous tubules, synthesized by the Sertoli cells.^{27, 28} Dimerization is believed to be necessary to form the single steroid-binding site. Specific chromosomal abnormalities with decreased or abnormal SHBG have not been reported. However, SHBG gene expression has now been identified in other tissues (brain, placenta, and endometrium), although a biologic significance has not been determined.

Transcortin, also called corticosteroid-binding globulin, is a plasma glycoprotein that binds cortisol, progesterone, deoxycorticosterone, corticosterone, and some of the other minor corticoid compounds. Normally about 75% of circulating cortisol is bound to transcortin, 15% is loosely bound to albumin, and 10% is unbound or free. Progesterone circulates in the following percentages: 2% unbound, 80% bound to albumin, 18% bound to transcortin, and less than 1% bound to SHBG. Binding in the circulation follows the law of mass action: the amount of the free, unbound hormone is in equilibrium with the bound hormone. Thus, the total binding capacity of

SHBG will influence the amount that is free and unbound.

The biologic effects of the major sex steroids are largely determined by the unbound portion, known as the free hormone. In other words, the active hormone is unbound and free, whereas the bound hormone is relatively inactive. This concept is not without controversy. The hormone-protein complex may be involved in an active uptake process at the target cell plasma membrane.²⁹ The albumin-bound fraction of steroids may also be available for cellular action because this binding has low affinity. Because the concentration of albumin in plasma is many-fold greater than that of SHBG, the contribution of the albumin-bound fraction is significant. Routine assays determine the total hormone concentration, bound plus free, and special steps are required to measure the active free level of testosterone, estradiol, and cortisol.

Estrogen Metabolism

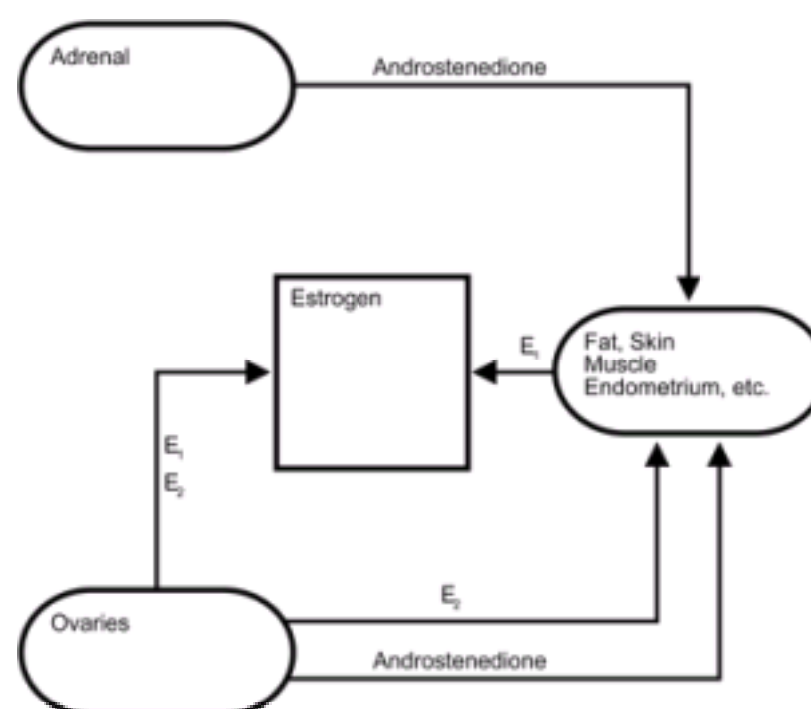

Androgens are the common precursors of estrogens. 17 β -Hydroxysteroid dehydrogenase activity converts androstenedione to testosterone, which is not a major secretory product of the normal ovary. It is rapidly demethylated at the C-19 position and aromatized to estradiol, the major estrogen secreted by the human ovary. Estradiol also arises to a major degree from androstenedione via estrone, and estrone itself is secreted in significant daily amounts. Estriol is the peripheral metabolite of estrone and estradiol and not a secretory product of the ovary. The formation of estriol is typical of general metabolic “detoxification,” conversion of biologically active material to less active forms.

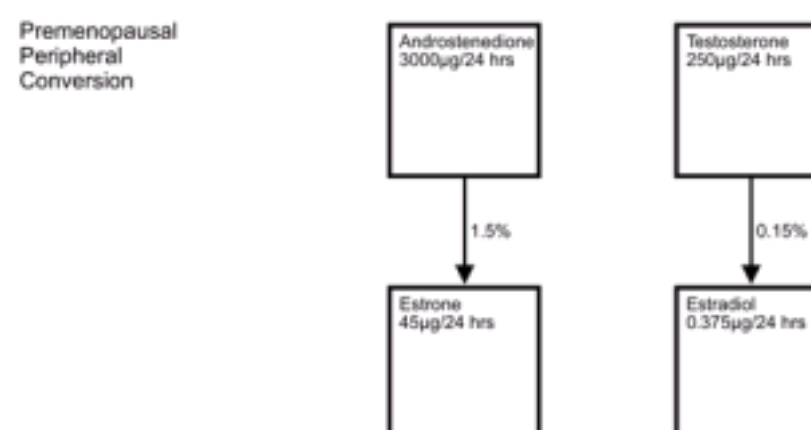

The conversion of steroids in peripheral tissues is not always a form of inactivation. Free androgens are peripherally converted to free estrogens, for example, in skin and adipose cells. The location of the adipose cells influences their activity. Women with central obesity (the abdominal area) produce more androgens.³⁰ The work of Siiteri and MacDonald³¹ demonstrated that enough estrogen can be derived from circulating androgens to produce bleeding in the postmenopausal woman. In the female the adrenal gland remains the major source of circulating androgens, in particular androstenedione. In the male, almost all of the circulating estrogens are derived from peripheral conversion of androgens.

It can be seen, therefore, that the pattern of circulating steroids in the female is influenced by the activity of various processes outside the ovary. Because of the peripheral contribution to steroid levels, the term **secretion rate** is reserved for direct organ secretion, whereas **production rate** includes organ secretion plus peripheral contribution via conversion of precursors. The **metabolic clearance rate (MCR)** equals the volume of blood that is cleared of the hormone per unit of time. The **blood production rate (PR)** then equals the metabolic clearance rate multiplied by the concentration of the hormone in the blood.

$MCR = \text{Liters/Day}$
 $PR = MCR \times \text{Concentration}$
 $PR = \text{Liters/Day} \times \text{Amount/Liter} = \text{Amount/Day}$

In the normal nonpregnant female, estradiol is produced at the rate of 100–300 $\mu\text{g/day}$. The production of androstenedione is about 3 mg/day, and the peripheral conversion (about 1%) of androstenedione to estrone accounts for about 20–30% of the estrone produced per day. Because androstenedione is secreted in milligram amounts, even a small percent conversion to estrogen results in a significant contribution to estrogens, which exist and function in microgram amounts. Thus, the circulating estrogens in the female are the sum of direct ovarian secretion of estradiol and estrone, plus peripheral conversion of C-19 precursors.

Progesterone Metabolism

Peripheral conversion of steroids to progesterone is not seen in the nonpregnant female; rather, the progesterone production rate is a combination of secretion from the adrenal and the ovaries. Including the small contribution from the adrenal, the blood production rate of progesterone in the preovulatory phase is less than 1 mg/day. During the luteal phase, production increases to 20–30 mg/day. The metabolic fate of progesterone, as expressed by its many excretion products, is more

complex than estrogen. About 10–20% of progesterone is excreted as pregnanediol.

Pregnanediol glucuronide is present in the urine in concentrations less than 1 mg/day until ovulation. Postovulation pregnanediol excretion reaches a peak of 3–6 mg/day, which is maintained until 2 days prior to menses. The assay of pregnanediol in the urine now has little use, except in home test kits that allow women to self-test for ovulation.

In the preovulatory phase in adult females, in all prepubertal females, and in the normal male, the blood levels of progesterone are at the lower limits of immunoassay sensitivity: less than 100 ng/dL. After ovulation, i.e., during the luteal phase, progesterone ranges from 500 to 2000 ng/dL. In congenital adrenal hyperplasia, progesterone blood levels can be as high as 50 times above normal.

Pregnanetriol is the chief urinary metabolite of 17 α -hydroxyprogesterone and has clinical significance in the adrenogenital syndrome, in which an enzyme defect results in accumulation of 17 α -hydroxyprogesterone and increased excretion of pregnanetriol. The plasma or serum assay of 17 α -hydroxyprogesterone is a more sensitive and accurate index of this enzyme deficiency than measurement of pregnanetriol. Normally, the blood level of 17 α -hydroxyprogesterone is less than 100 ng/dL, although after ovulation and during the luteal phase of a normal menstrual cycle, a peak of 200 ng/dL can be reached. In syndromes of adrenal hyperplasia, values can be 10–400 times normal.

Androgen Metabolism

The major androgen products of the ovary are dehydroepiandrosterone (DHA) and androstenedione (and only a little testosterone), which are secreted mainly by stromal tissue derived from theca cells. With excessive accumulation of stromal tissue or in the presence of an androgen-producing tumor, testosterone becomes a significant secretory product. Occasionally, a nonfunctioning tumor can induce stromal proliferation and increased androgen production. The normal accumulation of stromal tissue at midcycle results in a rise in circulating levels of androstenedione and testosterone at the time of ovulation.

The adrenal cortex produces 3 groups of steroid hormones, the glucocorticoids, the mineralocorticoids, and the sex steroids. The adrenal sex steroids represent intermediate byproducts in the synthesis of glucocorticoids and mineralocorticoids, and excessive secretion of the sex steroids occurs only with neoplastic cells or in association with enzyme deficiencies. Under normal circumstances, adrenal gland production of the sex steroids is less significant than gonadal production of androgens and estrogens. About one-half of the daily production of DHA and androstenedione comes from the adrenal gland; the other half of androstenedione is secreted by the ovary, but the other half of DHA is split almost equally between the ovary and peripheral tissues. The production rate of testosterone in the normal female is 0.2–0.3 mg/day, and approximately 50% arises from peripheral conversion of androstenedione (and a small amount from DHA) to testosterone, whereas 25% is secreted by the ovary and 25% by the adrenal. The major androgens are excreted in the urine as 17-ketosteroids.

There is no circadian cycle of the major sex steroids in the female. However, short-term variations in the blood levels due to episodic secretion require multiple sampling for absolutely accurate assessment. **Although frequent sampling is necessary for a high degree of accuracy, a random sample is sufficient for clinical purposes to determine whether a level is within a normal range.**

The testosterone-binding capacity is decreased by androgens; hence, the binding capacity in men is lower than that in normal women. The binding globulin level in women with increased androgen production is also depressed. Androgenic effects are dependent on the unbound fraction that can move freely from the vascular compartment into the target cells. Routine assays determine the total hormone concentration, bound plus free. Thus, a total testosterone concentration can be in the normal range in a woman who is hirsute or even virilized, but because the binding globulin level is depressed by the androgen effects, the percent free and active testosterone is elevated. The need for a specific assay for the free portion of testosterone can be questioned because the very presence of hirsutism or virilism indicates increased androgen effects. In the face of hirsutism, one can reliably interpret a normal testosterone level as compatible with decreased binding capacity and increased active free testosterone.

Both total and unbound testosterone are normal in only a few women with hirsutism. In these cases, the hirsutism, heretofore regarded as idiopathic, most likely results from excessive intracellular androgen effects (specifically increased intracellular conversion of testosterone to dihydrotestosterone).

Reduction of the D⁴ unsaturation (an irreversible pathway) in testosterone is very significant, producing derivatives very different in their spatial configuration and activity. The 5 β -derivatives are not androgenic, and this is not an important pathway; however, the 5 α -derivative (a very active pathway) is extremely potent. Indeed, dihydrotestosterone (DHT), the 5 α -derivative, is the principal androgenic hormone in a variety of target tissues and is formed within the target tissue itself.

In men, the majority of circulating DHT is derived from testosterone that enters a target cell and is converted by means of 5 α -reductase to DHT. In women, because the production rate of androstenedione is greater than testosterone, blood DHT is primarily derived from androstenedione and partly from dehydroepiandrosterone.³² Thus, in women, the skin production of DHT may be predominantly influenced by androstenedione. DHT is by definition an intracrine hormone, formed and acting within target tissues.³³ The 5 α -reductase enzyme exists in two forms, type I and II, each encoded by a separate gene, with the type I enzyme found in skin and the type II reductase predominantly expressed in reproductive tissues.³⁴

DHT is largely metabolized intracellularly; hence, the blood DHT is only about one-tenth the level of circulating testosterone, and it is clear that testosterone is the major circulating androgen. In tissues sensitive to DHT (which includes hair follicles), only DHT enters the nucleus to provide the androgen message. DHT also can perform androgenic actions within cells that do not possess the ability to convert testosterone to DHT. DHT is further reduced by a 3α-keto-reductase to androstane-2,3-diol, which is relatively inactive. The metabolite of androstane-2,3-diol, 3α-androstane-2,3-diol glucuronide, is the major metabolite of DHT and can be measured in the plasma, indicating the level of activity of target tissue conversion of testosterone to DHT.

Not all androgen-sensitive tissues require the prior conversion of testosterone to DHT. In the process of masculine differentiation, the development of the wolffian duct structures (epididymis, the vas deferens, and the seminal vesicle) is dependent on testosterone as the intracellular mediator, whereas development of the urogenital sinus and urogenital tubercle into the male external genitalia, urethra, and prostate requires the conversion of testosterone to DHT. ³⁵ Muscle development is under the direct control of testosterone. Testosterone is also aromatized to a significant extent in the brain, liver, and breast; and in some circumstances (e.g., in the brain) androgenic messages can be transmitted via estrogen.

Excretion of Steroids

Active steroids and metabolites are excreted as sulfo and glucuro conjugates. Conjugation of a steroid converts a hydrophobic compound into a hydrophilic one and generally reduces or eliminates the activity of a steroid. This is not completely true, however, because hydrolysis of the ester linkage can occur in target tissues and restore the active form. Furthermore, estrogen conjugates can have biologic activity, and it is known that sulfated conjugates are actively secreted and may serve as precursors, present in the circulation in relatively high concentrations because of binding to serum proteins. Ordinarily, however, conjugation by liver and intestinal mucosa is a step in deactivation preliminary to, and essential for, excretion into urine and bile.

Cellular Mechanism of Action

Hormones circulate in extremely low concentrations and, in order to respond with specific and effective actions, target cells require the presence of special mechanisms. There are 2 major types of hormone action at target tissues. One mediates the action of tropic hormones (peptide and glycoprotein hormones) with receptors at the cell membrane level. In contrast, the smaller steroid hormones enter cells readily, and the basic mechanism of action involves specific receptor molecules within the cells. It is the affinity, specificity, and activity of the receptors, together with the large concentration of receptors in cells, that allow a small amount of hormone to produce a biologic response. The many different types of receptors can be organized into the following basic categories.

Intracellular Receptors

Receptors in the nucleus lead to transcription activation. Examples include the receptors for estrogen and thyroid hormones.

G Protein Receptors

These receptors are composed of a single polypeptide chain that spans the cell membrane. Binding to a specific hormone leads to interaction with G proteins that, in turn, activate second messengers. Examples include receptors for tropic hormones, prostaglandins, light, and odors. The second messengers include the adenylate cyclase enzyme, the phospholipase system, and calcium ion changes.

Ion Gate Channels

These cell surface receptors are composed of multiple units, that after binding, open ion channels. The influx of ions changes the electrical activity of the cells. The best example of this type is the acetylcholine receptor.

Receptors With Intrinsic Enzyme Activity

These transmembrane receptors have an intracellular component with tyrosine or serine kinase activity. Binding leads to receptor autophosphorylation and activity. Examples include the receptors for insulin and growth factors (tyrosine kinase) and the receptors for activin and inhibin (serine kinase).

Other Receptors

Receptors that do not fit the above categories include the receptors for LDL, prolactin, growth hormone, and some of the growth factors.

Mechanism of Action for Steroid Hormones

The specificity of the reaction of tissues to sex steroid hormones is due to the presence of intracellular receptor proteins. Different types of tissues, such as liver, kidney, and uterus, respond in a similar manner. The mechanism includes: 1) steroid hormone diffusion across the cell membrane, 2) steroid hormone binding to receptor protein, 3) interaction of a hormone-receptor complex with nuclear DNA, 4) synthesis of messenger RNA (mRNA), 5) transport of the mRNA to the ribosomes, and finally, 6) protein synthesis in the cytoplasm that results in specific cellular activity.³⁶ The steroid hormone receptors primarily affect gene transcription, but also regulate post transcriptional events and nongenomic events. **Steroid receptors regulate gene transcription through multiple mechanisms, not all of which require direct interactions with DNA.**

Each of the major classes of the sex steroid hormones, including estrogens, progestins, and androgens, has been demonstrated to act according to this general mechanism. Glucocorticoid, mineralocorticoid, and probably androgen receptors, when in the unbound state, reside in the cytoplasm and move into the nucleus after hormone-receptor binding. Estrogens and progestins are transferred across the nuclear membrane and bind to their receptors within the nucleus.

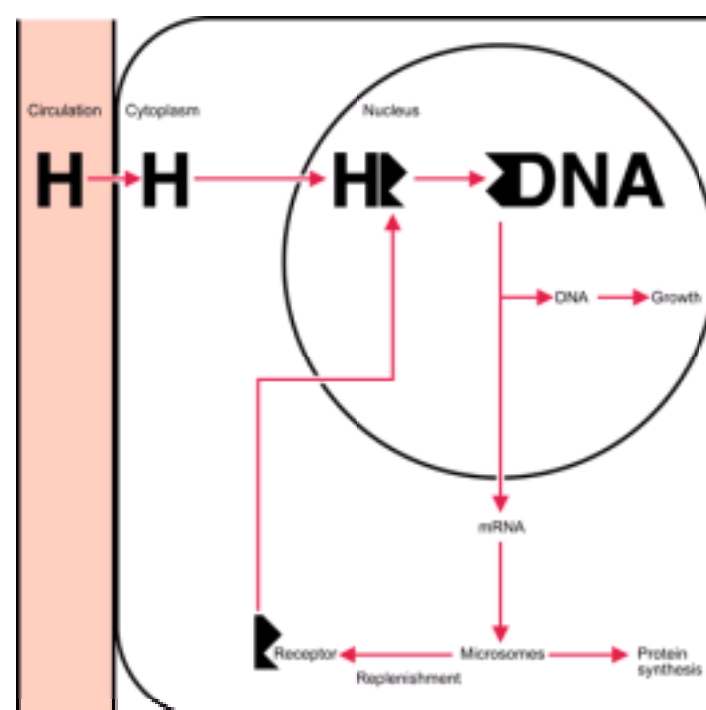

Steroid hormones are rapidly transported across the cell membrane by simple diffusion. The factors responsible for this transfer are unknown, but the concentration of free (unbound) hormone in the bloodstream seems to be an important and influential determinant of cellular function. Once in the cell, the sex steroid hormones bind to their individual receptors.^{37, 38 and 39} During this process, **transformation or activation** of the receptor occurs. Transformation refers to a conformational change of the hormone-receptor complex revealing or producing a binding site that is necessary in order for the complex to bind to the chromatin. In the unbound state, the receptor is associated with heat shock proteins that stabilize and protect the receptor and maintain the DNA binding region in an inactive state. Activation of the receptor is driven by hormone binding that causes a dissociation of the receptor-heat shock protein complex.

The hormone-receptor complex binds to specific DNA sites (**hormone-responsive elements**) that are located upstream of the gene. The specific binding of the hormone-receptor complex with DNA results in RNA polymerase initiation of transcription. Transcription leads to translation, mRNA-mediated protein synthesis on the ribosomes. The principal action of steroid hormones is the regulation of intracellular protein synthesis by means of the receptor mechanism.

Biologic activity is maintained only while the nuclear site is occupied with the hormone-receptor complex. The dissociation rate of the hormone and its receptor as well as the half-life of the nuclear chromatin-bound complex are factors in the biologic response because the hormone response elements are abundant and, under normal conditions, are occupied only to a small extent.⁴⁰ Thus, an important clinical principle is the following: **duration of exposure to a hormone is as important as dose.** One reason only small amounts of estrogen need be present in the circulation is the long half-life of the estrogen hormone-receptor complex. Indeed, a major factor in the potency differences among the various estrogens (estradiol, estrone, estriol) is the length of time the estrogen-receptor complex occupies the nucleus. The higher rate of dissociation with the weak estrogen (estriol) can be compensated for by continuous application to allow prolonged nuclear binding and activity. Cortisol and progesterone must circulate in large concentrations because their receptor complexes have short half-lives in the nucleus.

An important action of estrogen is the modification of its own and other steroid hormone activity by affecting receptor concentrations. Estrogen increases target tissue responsiveness to itself and to progestins and androgens by increasing the concentration of its own receptor and that of the intracellular progestin and androgen receptors. This process is called **replenishment**. Progesterone and clomiphene, on the other hand, limit tissue response to estrogen by blocking the replenishment mechanism, thus decreasing over time the concentration of estrogen receptors. Replenishment is very responsive to the available amount of steroid and receptors. Small amounts of receptor depletion and small amounts of steroid in the blood activate the mechanism.

Replenishment, the synthesis of the sex steroid receptors, obviously takes place in the cytoplasm, but with estrogen and progestin receptors, synthesis must be quickly followed by transportation into the nucleus. There is an incredible nuclear traffic.⁴¹ The nuclear membrane contains 3000 to 4000 pores. A cell synthesizing DNA imports about one million histone molecules from the cytoplasm every 3 minutes. If the cell is growing rapidly, about 3 newly assembled ribosomes will be transported every minute in the other direction. The typical cell can synthesize 10,000 to 20,000 different proteins. How do they know where to go? The answer is that these proteins have localization signals. In the case of steroid hormone receptor proteins, the signal sequences are in the hinge region.

Estrogen and progestin receptors exit continuously from the nucleus to the cytoplasm and are actively transported back to the nucleus. This is a constant shuttle; constant diffusion into the cytoplasm is balanced by the active transport into the nucleus. This raises the possibility that some diseases are due to poor traffic control. This can be true of some acquired diseases as well; e.g., Reye's syndrome, an acquired disorder of mitochondrial enzyme function.

The fate of the hormone-receptor complex after gene activation is referred to as hormone-receptor **processing**. In the case of estrogen receptors, processing involves the conversion of high-affinity estrogen receptor sites to a rapidly dissociating form followed by loss of binding capacity, which is completed in about 6 hours. The rapid turnover of estrogen receptors has clinical significance. The continuous presence of estrogen is an important factor for continuing response.

The best example of the importance of these factors is the difference between estradiol and estriol. Estriol has only 20–30% affinity for the estrogen receptor compared with estradiol; therefore, it is rapidly cleared from a cell. But if the effective concentration is kept equivalent to that of estradiol, it can produce a similar biologic response.⁴² In pregnancy, where the concentration of estriol is very great, it can be an important hormone, not just a metabolite.

The depletion of estrogen receptors in target tissues by progestational agents is the fundamental reason for adding progestins to estrogen treatment programs. The progestins accelerate the turnover of pre-existing receptors, and this is followed by inhibition of estrogen-induced receptor synthesis. Using monoclonal antibody immunocytochemistry, this action has been pinpointed to the interruption of transcription in estrogen-regulated genes. The mechanism is different for androgen antiestrogen effects. Androgens do not involve depletion of estrogen receptors but in some way decrease estrogen-induced RNA activity in the cytoplasm.⁴³

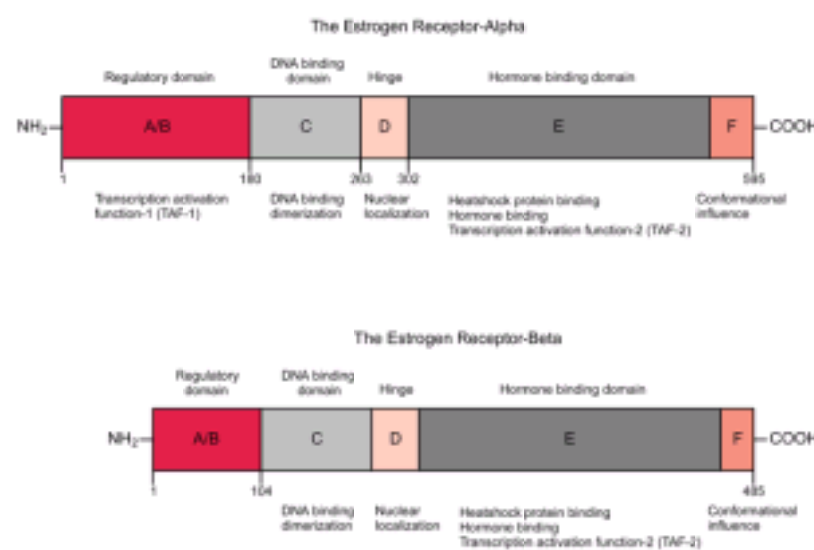

The Receptor Superfamily

Recombinant DNA techniques have permitted the study of the gene sequences that code for the synthesis of nuclear receptors. Steroid hormone receptors share a common structure with the receptors for thyroid hormone, 1,25-dihydroxy vitamin D₃, and retinoic acid; thus, these receptors are called a superfamily.⁴⁴ Each receptor contains characteristic domains that are similar and interchangeable. Therefore, it is not surprising that the specific hormones can interact with more than one receptor in this family. Analysis of these receptors suggests a complex evolutionary history during which gene duplication and swapping between domains of different origins occurred.⁴⁵ This family now includes about 150 proteins, present in practically all species, from worms to insects to humans. Many are called **orphan receptors** because specific ligands for these proteins have not been identified.

The Estrogen Receptors

Two estrogen receptors have been identified, designated as estrogen receptor-alpha (ER-a) and estrogen receptor-beta (ER-b).^{46, 47} The estrogen receptor-alpha was discovered about 1960, and the amino acid sequence was reported in 1986.^{48, 49 and 50} The estrogen receptor-alpha is translated from a 6.8-kilobase mRNA that contains 8 exons derived from a gene on the long arm of chromosome 6.⁵¹ It has a molecular weight of approximately 66,000 with 595 amino acids. The receptor alpha half-life is approximately 4–7 hours, thus the estrogen receptor-alpha is a protein with a rapid turn over. The more recently discovered estrogen receptor-beta is encoded by a gene localized to chromosome 14,q22-q24, in close proximity to genes related to Alzheimer's disease.⁵²

The estrogen receptors are divided into 6 regions in 5 domains, labeled A to F. The ER-b is 97% homologous in amino acid sequence with the alpha estrogen receptor in the DNA binding domain and 59% homologous in the hormone-binding domain.⁴⁷ The full comparison is as follows:⁵² Estrogen receptor-alpha Estrogen receptor-beta

ER-a and ER-b Homology	
The regulatory domain	17.5%
The DNA-binding domain	97%
The hinge	30%
The hormone-binding domain	59.1%
The F region	17.9%

The following discussion represents information derived from studies of the ER-a. The hormone binding characteristics of the ER-a and the ER-b are similar, indicating that they respond in a comparable manner to the same hormones.⁵³ There are differences, however; for example, phytoestrogens have a greater affinity for ER-b than for ER-a. Different genetic messages can result not only because of differences in binding affinity, but through variations in the mechanisms to be discussed, notably differences in conformational shape and cellular contexts. In addition, because the regulatory domains differ in the two receptors, ER-b may not be capable of activating gene transcription by means of TAF-1 (discussed below).

A/B Region, The Regulatory Domain

The amino acid terminal is the most variable in the superfamily of receptors, ranging in size from 20 amino acids in the Vitamin D receptor, to 600 amino acids in the mineralocorticoid receptor. In the ER-a, it contains several phosphorylation sites and the **transcription activation function called TAF-1**. TAF-1 can stimulate transcription in the absence of hormone binding. The regulatory domain is considerably different in the two estrogen receptors, and in ER-b, TAF-1 is either

significantly modified or absent.

C Region, The DNA-Binding Domain

The middle domain binds to DNA and consists of 100 amino acids with 9 cysteines in fixed positions, the two **zinc fingers**. This domain is essential for activation of transcription. Hormone binding induces a conformational change that allows binding to the hormone-responsive elements in the target gene. This domain is very similar for each member of the steroid and thyroid receptor superfamily; however, the genetic message is specific for the hormone that binds to the hormone-binding domain. The DNA-binding domain controls which gene will be regulated by the receptor and is responsible for target gene specificity and high-affinity DNA binding. The specificity of receptor binding to its hormone responsive element is determined by the zinc finger region, especially the first finger. The specific message can be changed by changing the amino acids in the base of the fingers. Substitutions of amino acids in the fingertips lead to loss of function. Functional specificity is localized to the second zinc finger in an area designated the d (distal) box. Different responses are due to the different genetic expression of each target cell (the unique activity of each cell's genetic constitution allows individual behavior).

D Region, The Hinge

The region between the DNA-binding domain and the hormone-binding domain contains a signal area that is important for the movement of the receptor to the nucleus following synthesis in the cytoplasm. This nuclear localization signal must be present for the estrogen receptor to remain within the nucleus in the absence of hormone. This region is also a site of rotation (hence the hinge designation) in achieving conformational change.

E Region, The Hormone-Binding Domain

The carboxy end of the estrogen receptor- α is the hormone-binding domain (for both estrogens and antiestrogens), consisting of 251 amino acids (residues 302–553). In addition to hormone binding, this region is responsible for **dimerization** and contains the **transcription activation function called TAF-2**. This is also the site for binding by heat shock proteins (specifically hsp 90), and it is this binding to the heat shock proteins that prevents dimerization and DNA binding. In contrast to TAF-1 activity, TAF-2 depends on hormone binding for full activity. The hormone-binding domain of the steroid receptors contains a characteristic structure, containing helices that form a pocket (also referred to as a sandwich fold).⁵⁴ After binding with a hormone, this pocket undergoes a conformational change that creates new surfaces with the potential to interact with co-activator and co-repressor proteins.

F Region

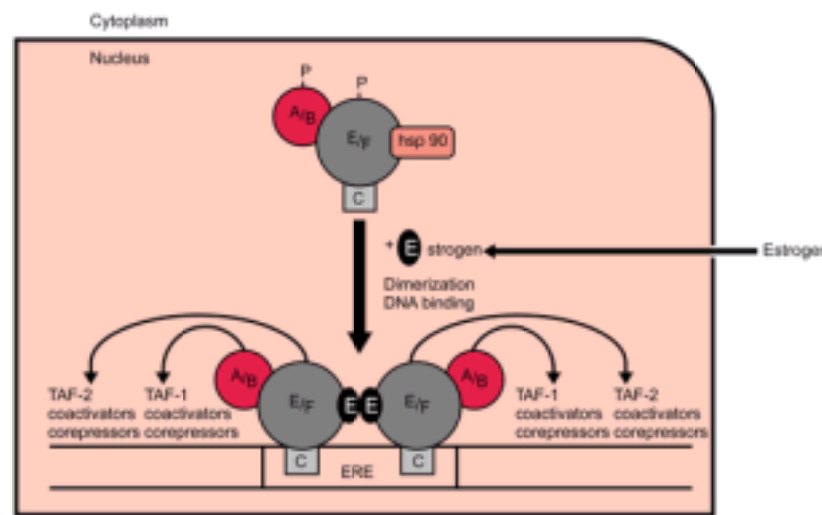

The F region of ER- α is a 42 amino acid C-terminal segment. This region modulates gene transcription by estrogen and antiestrogens, having a role that influences antiestrogen efficacy in suppressing estrogen-stimulated transcription.⁵⁵ The conformation of the receptor-ligand complex is different with estrogen and antiestrogens, and this conformation is different with and without the F region. The F region is not required for transcriptional response to estrogen; however, it affects the magnitude of ligand-bound receptor activity. It is speculated that this region affects conformation in such a way that protein interactions are influenced. Thus, it is appropriate that the effects of the F domain vary according to cell type and protein context. The F region affects the activities of both TAF-1 and TAF-2, which is what one would expect if the effect is on conformation.⁵⁶

Mechanism of Action

The steroid family receptors are predominantly in the nucleus even when not bound to a ligand, except for the androgen, mineralocorticoid, and glucocorticoid receptors where nuclear uptake depends on hormone binding. But the estrogen receptor does undergo what is called **nucleocytoplasmic shuttling**. The estrogen receptor constantly diffuses out of the nucleus and is rapidly transported back in. When this shuttling is impaired, receptors are more rapidly degraded in the cytoplasm. Agents that inhibit dimerization (e.g., the pure estrogen antagonists) inhibit nuclear translocation and thus increase cytoplasmic degradation.

Prior to binding, the estrogen receptor is an inactive complex that includes a variety of proteins, including the heat shock proteins. Heat shock protein 90 appears to be a critical protein, and many of the others are associated with it. This heat shock protein is not only important for maintaining an inactive state, but also for causing proper folding for transport across membranes. "Activation" or "transformation" is the dissociation of heat shock protein 90.⁵⁷

Imagine the unoccupied steroid receptor as a loosely packed, mobile protein complexed with heat shock proteins. The steroid family of receptors exists in this complex and cannot bind to DNA until union with a steroid hormone liberates the heat shock proteins and allows dimerization. The conformational change induced by hormone binding involves a dissociating process to form a tighter packing of the receptor. The hormone-binding domain contains helices that form a pocket (also referred to as a sandwich fold).⁵⁴ After binding with a hormone, this pocket undergoes a conformational change that creates new surfaces with the potential to interact with co-activator and co-repressor proteins. **Conformational shape is an important factor in determining the exact message transmitted to the gene.** Conformational shape is slightly but significantly different with each ligand; estradiol, tamoxifen, and raloxifene each induce a distinct conformation that contributes to the ultimate message of agonism or antagonism.^{58, 59} The weak estrogen activity of estriol is because of its altered conformation shape when combined with the estrogen receptor in comparison with estradiol.⁶⁰

The hormone-binding domain of the estrogen receptors contains a cavity surrounded by a wedge-shaped structure, and it is the fit into this cavity that is so influential in influencing the genetic message. The size of this cavity on the estrogen receptor is relatively large, larger than the volume of an estradiol molecule, explaining the acceptance of a large variety of ligands. Thus, estradiol, tamoxifen, and raloxifene each bind at the same site within the hormone binding domain, but the conformational shape with each is not identical.

Conformational shape is a major factor in determining the ability of a ligand and its receptor to interact with coactivators and corepressors. Conformational shapes are not simply either “on” or “off,” but intermediate conformations are possible providing a spectrum of agonist/antagonistic activity.

Members of the thyroid and retinoic acid receptor subfamily do not exist in inactive complexes with heat shock proteins. They can form dimers and bind to response elements in DNA, but without ligand, they act as repressors of transcription.

Estrogen receptor mutants can be created that are unable to bind estradiol. These mutants can form dimers with natural estrogen receptor (wild type), and then bind to the estrogen response element, but they cannot activate transcription.⁶¹ This indicates that transcription is dependent on the result after estradiol binding to the estrogen receptor, an estrogen-dependent structural change. Dimerization by itself is not sufficient to lead to transcription; neither is binding of the dimer to DNA sufficient.

Molecular modeling and physical energy calculations indicate that binding of estrogen with its receptor is not a simple key and lock mechanism. It involves conversion of the estrogen-receptor complex to a preferred geometry dictated to a major degree by the specific binding site of the receptor. The estrogenic response depends on the final bound conformation and the electronic properties of functional groups that contribute energy. The final transactivation function is dependent on these variables.⁶²

Estrogen, progesterone, androgen, and glucocorticoid receptors bind to their response elements as dimers, one molecule of hormone to each of the two units in the dimer. The estrogen receptor-alpha can form dimers with other alpha receptors (homodimers) or with an estrogen receptor-beta (heterodimer). Similarly, the estrogen receptor-beta can form homodimers or heterodimers with the alpha receptor. This creates the potential for many pathways for estrogen signaling, alternatives that are further increased by the possibility of utilizing various response elements in target genes. Cells that express only one of the estrogen receptors would respond to the homodimers; cells that express both could express to a homodimer and a heterodimer.

The similar amino acid sequence of the DNA-binding domains in this family of receptors indicates evolutionary conservation of homologous segments. An important part of the conformational pattern consists of multiple cysteine-repeating units found in two structures, each held in a finger like shape by a zinc ion, the so-called zinc fingers Zinc fingers.⁶³ The zinc fingers on the various hormone receptors are not identical. These fingers of amino acids are thought to interact with similar complementary patterns in the DNA. Directed changes (experimental mutations) indicate that conservation of the cysteine residues is necessary for binding activity, as is the utilization of zinc.

The DNA binding domain is specific for an enhancer site (called the hormone responsive element) in the gene promoter, located in the 5' flanking region. The activity of the hormone-responsive element requires the presence of the hormone-receptor complex. Thus, this region is the part of the gene to which the DNA-binding domain of the receptor binds. There are at least four different hormone-responsive elements, one for glucocorticoids/progesterone/androgen, one for estrogen, one for vitamin D₃, and one for thyroid/retinoic acid.⁶⁴ These sites significantly differ only in the number of intervening nucleotides.

Binding of the hormone-receptor complex to its hormone-responsive element leads to many changes, only one of which is a conformational alteration in the DNA. Although the hormone-responsive elements for glucocorticoids, progesterone, and androgens mediate all of these hormonal responses, there are subtle differences in the binding sites, and there are additional sequences outside of the DNA-binding sites that influence activation by the three different hormones. The cloning of complementary DNAs for steroid receptors has revealed a large number of similar structures of unknown function. It is believed that the protein products of these sequences are involved in the regulation of transcription initiation that occurs at the TATA box.

There are 3 different RNA polymerases (designated as I, II, and III), each dedicated to the transcription of a different set of genes with specific promoters (the site of polymerase initiation of transcription). **Transcription factors are polypeptides, complexed with the polymerase enzyme, that modulate transcription either at the promoter site or at a sequence further upstream on the DNA.**³⁶ The steroid hormone receptors, therefore, are transcription factors. The polymerase transcription factor complex can be developed in sequential fashion with recruitment of individual polypeptides, or transcription can result from interaction with a preformed complete complex. The effect can be either positive or negative, activation or repression.

In most cases, therefore, the steroid hormone receptor activates transcription in partnership with several groups of polypeptides.³⁶

1. Other transcription factors — peptides that interact with the polymerase enzyme and DNA.
2. Coactivators and corepressors — peptides that interact with the TAF areas of the receptor, also called adaptor proteins.
3. Chromatin factors — structural organizational changes that allow an architecture appropriate for transcription response.

The steroid-receptor complex regulates the amount of mRNA transcripts emanating from target genes. The estrogen-occupied receptor binds to estrogen response elements in the 5' flanking regions of estrogen-regulated genes, allowing efficient induction of RNA transcription. This can occur by direct binding to DNA and interaction with the estrogen response element or by protein interactions with **coactivators** between the estrogen receptor and DNA sites. **Coactivators and corepressors are intracellular proteins (called adaptor proteins) that activate or suppress the TAF areas, either by acting on the receptors or on DNA.**^{65, 66} and⁶⁷ Most of the genes regulated by estrogens respond within 1–2 hours after estrogen administration. Only a few respond within minutes. This time requirement may reflect the necessity to synthesize regulating proteins.⁶⁸

One of the aspects of activation, for example with the estrogen receptor, is an increase in affinity for estrogen. This is an action of estrogen, and it is greatest with estradiol and least with estriol. This action of estradiol, the ability of binding at one site to affect another site, is called **cooperativity**. An increase in affinity is called positive cooperativity. The biologic advantage of positive cooperativity is that this increases the receptor's ability to respond to small changes in the concentration of the hormone. One of the antiestrogen actions of clomiphene is its property of negative cooperativity, the inhibition of the transition from a low-affinity to a high-affinity

state. The relatively long duration of action exhibited by estradiol is due to the high-affinity state achieved by the receptor.

TAF (transcriptional activation function) is the part of the receptor that activates gene transcription after binding to DNA. Ligand binding produces a conformation that allows TAFs to accomplish its tasks. TAF-1 can stimulate transcription in the absence of hormone when it is fused to DNA; however, it also promotes DNA binding in the intact receptor. TAF-2 is affected by the bound ligand, and the estrogen receptor depends on estrogen binding for full activity. TAF-2 consists of a number of dispersed elements that are brought together after estrogen binding. The activities of TAF-1 and TAF-2 vary according to the promoters in target cells. These areas can act independently or with one another.

Thus the differential activities of the TAFs account for different activities in different cells. In addition to the binding of the dimerized steroid receptor to the DNA response element, steroid hormone activity is modulated by other pathways (other protein transcription factors and coactivators/corepressors) that influence transcription activation.⁶⁹ This is an important concept: the concept of cellular context. The same hormone can produce different responses in different cells according to the cellular context of protein regulators.

The concentration of coactivators/corepressors can affect the cellular response, and this is another explanation for strong responses from small amounts of hormone. A small amount of receptor but a large amount of coactivator/corepressor and the cell can be very responsive to a weak signal.

Phosphorylation of specific receptor sites is an important method of regulation, as well as phosphorylation of other peptides that influence gene transcription. Phosphorylation can be regulated by cell membrane receptors and ligand binding, thus establishing a method for cell membrane-bound ligands to communicate with steroid receptor genes.

Cyclic AMP and protein kinase A pathways increase transcriptional activity of the estrogen receptor by phosphorylation. In some cases phosphorylation modulates the activity of the receptor; in other cases, the phosphorylation regulates the activity of a specific peptide or coactivator/corepressor that, in turn, modulates the receptor. The steroid receptor superfamily members are phosphoproteins. Phosphorylation follows steroid binding and occurs in both the cytoplasm and nucleus. This phosphorylation is believed to enhance activity of the steroid receptor complex.

Phosphorylation of the receptor increases the potency of the molecule to regulate transcription. Growth factors can stimulate protein kinase phosphorylation that can produce synergistic activation of genes or even ligand-independent activity. Epidermal growth factor (EGF), IGF-I, and TGF- α can activate the estrogen receptor in the absence of estrogen. This response to growth factors can be blocked by pure antiestrogens (suggesting that a strong antagonist locks the receptor in a conformation that resists ligand-independent pathways). The exact mechanism of growth factor activation is not known, but it is known that a steroid receptor can be activated by means of a chemical signal (a phosphorylation cascade) originating at the plasma membrane. **The recruitment of kinase activity is specific for specific ligands; thus not all ligands stimulate phosphorylation.**

Another explanation for strong responses from small amounts of steroids is a positive feedback relationship. Estrogen activates its receptor, gene expression stimulates growth factors (EGF, IGF-I, TGF- α , FGF), and the growth factors in an autocrine fashion further activate the estrogen receptor.⁷⁰

Summary — Steps in the Steroid Hormone—Receptor Mechanism

1. Binding of the hormone to the hormone-binding domain that has been kept in an inactive state by various heat shock proteins.
2. Activation of the hormone-receptor complex, by **conformational change**, follows the dissociation of the heat shock proteins.
3. Dimerization of the complex.
4. Binding of the dimer to the hormone-responsive element on DNA by the zinc finger area of the DNA-binding domain.
5. Stimulation of transcription, mediated by transcription activation functions (TAFs), and influenced by the protein (other transcription factors and coactivators/corepressors) **context of the cell**, and by **phosphorylation**.

Summary — Factors that Determine Biologic Activity

1. Affinity of the hormone for the hormone-binding domain of the receptor.
2. Target tissue differential expression of the receptor subtypes (e.g., ER- α and ER- β).
3. Conformational shape of the ligand-receptor complex, with effects on two important activities: dimerization and modulation of adapter proteins.
4. Differential expression of target tissue adaptor proteins and phosphorylation.

Different Roles for ER- α and ER- β

Male and female mice have been developed that are homozygous for disruption of the alpha estrogen receptor gene, “estrogen receptor-alpha knockout mice.”⁷¹ Both sexes with this knockout are infertile. Spermatogenesis in the male is reduced and the testes undergo progressive atrophy, a result of a testicular role for estrogen, because gonadotropin levels and testicular steroidogenesis remain normal. Sexual mounting behavior is not altered, but intromission, ejaculation, and aggressive behaviors are reduced. Female mice with the alpha estrogen receptor gene disrupted do not ovulate, and the ovaries do not respond to gonadotropin stimulation. These female animals have high levels of estradiol, testosterone, and LH. FSH b-subunit synthesis is increased, but FSH secretion is at normal levels, indicating different sites of action for estrogen and inhibin. Uterine development is normal (due to a lack of testosterone in early life), but growth is impaired. Mammary gland ductal and alveolar development is absent. Female mice with absent alpha estrogen receptor activity do not display sexual receptive behaviors. This genetically engineered line of mice demonstrates essential activities for the alpha estrogen receptor. Relatively normal fetal and early development suggests that the beta estrogen receptor plays a primary role in these functions. For example, the fetal adrenal gland expresses high levels of ER- β and low levels of ER- α .⁷² However, nongenomic actions of estrogen are also possible and can explain some of the estrogenic responses in a knockout model.

Differential expression of the alpha and beta receptors is likely in various tissues (e.g., ER- β is the prevalent estrogen receptor in certain areas of the brain and the cardiovascular system) resulting in different and selective responses to specific estrogens. Human granulosa cells from the ovarian follicle contain *only* ER- β mRNA; the human breast expresses both ER- α and ER- β .⁵² Some parts of the rat brain contain only ER- β , others only ER- α , and some areas contain both receptors.⁷³

The estrogen story is further complicated by the fact that the same estrogen binding to the alpha and beta receptors can produce opposite effects. For example, estradiol can stimulate gene transcription with ER- α and a given site of the estrogen response element, whereas estradiol inhibits gene transcription with ER- β in this same system.⁷⁴ Different and unique messages, therefore, can be determined by the specific combination of (1) a particular estrogen, (2) the alpha or beta receptor, and (3) the targeted response element. To some degree, differences with ER- α and ER- β are influenced by activation of TAF-1 and TAF-2; agents that are capable of mixed estrogen agonism and antagonism produce agonistic messages via TAF-1 with ER- α , but because ER- β lacks a similar TAF-1, such agents can be pure antagonists in cells that respond only to ER- β . ER- α and ER- β affect the peptide context of a cell, especially coactivators and corepressors, differently.

The Progesterone Receptor

The progesterone receptor is induced by estrogens at the transcriptional level and decreased by progestins at both the transcriptional and translational levels (probably through receptor phosphorylation).⁷⁵ The progesterone receptor (in a fashion similar to the estrogen receptor) has two major forms, designated the A and B receptors.⁷⁶ The two forms are expressed by a single gene; the two forms are a consequence of transcription from distinctly different promoters, in a complex system of transcription regulation.⁷⁷ Each form is associated with additional proteins, which are important for folding of the polypeptide into a structure that allows hormone binding and receptor activity.⁷⁸ The molecular weight of A is 94,000 and B, 114,000, with 933 amino acids, 164 more than A. The B receptor has a unique upstream segment (164 amino acids) referred to as the B-upstream segment (BUS).

On the progesterone receptor, TAF-1 is located in a 91-amino acid segment just upstream of the DNA-binding domain. TAF-2 is located in the hormone-binding domain. A fragment missing the hormone-binding domain activates transcription to levels comparable to full-length hormone-activated B receptors, and higher than that with the A receptor, thus beyond that of TAF-1 alone. In appropriate cells, therefore, BUS contains a third activation domain, TAF-3, and can autonomously activate transcription or it can synergize with the other TAFs.⁷⁹ In the absence of hormone binding, the C-terminal region of the progesterone receptor exerts an inhibitory effect on transcription.⁸⁰ Progesterone agonists induce a conformational change that overcomes the inherent inhibitory function within the carboxy tail of the receptor. Binding with a progesterone antagonist produces a structural change that allows the inhibitory actions to be maintained.

Progestational agents can elicit a variety of responses determined by target tissue production and activity of the two receptor forms with dimerization as AA and BB (homodimers) or AB (heterodimer). The progesterone receptors function in the mechanism shared by this superfamily of receptors: an unbound complex with heat shock proteins, hormone binding, dimerization, DNA binding to a progesterone response element, and modulation of transcription by phosphorylation and various proteins.^{58, 81}

A and B are expressed in approximately equal amounts in breast cancer and endometrial cancer cell lines. Studies indicate that the two receptors can be regulated independently; e.g., the relative levels differ in endometrium during the menstrual cycle.⁸² Tissue specificity with the progesterone receptor is influenced by which receptor and which dimer is active, and in addition, the transcriptional activities of A and B depend on target cell differences, especially in promoter context. However, in most cells, B is the positive regulator of progesterone-responsive genes, and A inhibits B activity. Mutations within the carboxy terminus of B affect the transcriptional activity of B. But mutations in A have no effect on its transcriptional inhibitory activity. This indicates two separate pathways for transcription activation and repression by the progesterone receptor. Thus, repression of human estrogen receptor transcriptional activity (as well as glucocorticoid, mineralocorticoid, and androgen transcription) is dependent on the expression of A.^{83, 84}

The broad activity of A in regards to all steroids suggests that A regulates steroid hormone action wherever it is expressed. A does not form a heterodimer with the estrogen receptor. A does not prevent the estrogen receptor from binding with DNA. A does not change the structure of the estrogen receptor. Therefore, A either competes with the estrogen receptor for a critical protein; in this case A would inhibit the estrogen receptor only in cells that contain the critical factor. Or the target is a critical protein, again an essential transcription activator.^{78, 82}

The Androgen Receptor

The cellular mechanism is more complex for androgens. Androgens can work in any one of three ways.

1. By intracellular conversion of testosterone to dihydrotestosterone (DHT), intracrine activity.
2. By testosterone itself, endocrine activity.
3. By intracellular conversion of testosterone to estradiol (aromatization), intracrine activity.

Tissues that exclusively operate via the testosterone pathway are the derivatives of the wolffian duct, whereas hair follicles and derivatives of the urogenital sinus and urogenital tubercle require the conversion of testosterone to DHT. The hypothalamus actively converts androgens to estrogens; hence, aromatization may be necessary for certain androgen feedback messages in the brain.

In those cells that respond only to DHT, only DHT will be found within the nucleus activating messenger RNA production. Because testosterone and DHT bind to the same high-affinity androgen receptor, why is it necessary to have the DHT mechanism? One explanation is that this is a mechanism for amplifying androgen action, because the androgen receptor preferentially will bind DHT (greater affinity). The antiandrogens, including cyproterone acetate and spironolactone, bind to the androgen receptor with about 20% of the affinity of testosterone.⁸⁵ This weak affinity is characteristic of binding without activation of the biologic response.

The androgen receptor, like the progesterone receptor, exists as the full-length B form and a shorter A form.⁸⁶ It is likely that the A and B forms of the androgen receptor have functional differences; however, this remains to be characterized. The amino acid sequence of the androgen receptor in the DNA-binding domain resembles that of the receptors for progesterone, mineralocorticoids, and glucocorticoids but most closely that of the progesterone receptor.⁸⁷ Androgens and progestins can cross react for their receptors but do so only when present in pharmacologic concentrations. Progestins not only compete for androgen receptors but also compete for the metabolic utilization of the 5 α -reductase enzyme. The dihydroprogesterone that is produced, in turn, also competes with testosterone and DHT for the androgen receptor. A progestin, therefore, can act both as an antiandrogen and as an antiestrogen. Androgen-responsive gene expression can also be modified by estrogen; it has been known for years that androgens and estrogens can counteract each other's biologic responses. These responses of target tissues are determined by gene interactions with the hormone-receptor complexes, androgen with its receptor and estrogen with its receptor. The ultimate biologic response reflects the balance of actions of the different hormones with their respective receptors, modified by various transcription regulators.

The syndrome of testicular feminization (androgen insensitivity) represents a congenital abnormality in the androgen intracellular receptor (about 200 unique mutations have been identified).⁸⁸ The androgen receptor gene is localized on the human X chromosome at Xq11–12, the only steroid hormone receptor to be located on the X chromosome.⁸⁹ Thus, testicular feminization is an X-linked disorder. Molecular studies of patients with testicular feminization have indicated a deletion of amino acids from the steroid-binding domain due to nucleotide alterations in the gene that encodes the androgen receptor.⁹⁰ What was once a confusing picture is now easily understood as a progressive increase in androgen receptor action. At one end, there is a complete absence of androgen binding—complete testicular feminization. In the middle is a spectrum of clinical presentations representing varying degrees of abnormal receptors and binding. While at the other end, it has been suggested that about 25% of infertile men with normal genitalia and normal family histories have azoospermia due to a receptor disorder.⁹¹ The androgen receptor also plays a role in motor neuron physiology, because a specific mutation in the androgen receptor is responsible for Kennedy's disease (X-linked spinobulbar muscular atrophy), a condition associated with motor neuron degeneration.⁹²

Nongenomic Actions of Steroid Hormones

The genomic effects of steroid hormones are characterized by a relatively slow response time of 1 hour or longer. However, some steroid hormone effects are immediate, within a few seconds, and nongenomic mechanisms must be operative in order to achieve such rapid responses.⁹³ These rapid responses are also unaffected by inhibitors of gene transcription or protein synthesis. Rapid actions have been reported for all steroid hormones and include calcium and sodium transport across membranes, neural effects, and certain oocyte and sperm reactions. The messenger and effector systems utilized vary from cell to cell and from steroid to steroid. Specific cell membrane receptors have been identified for various steroids; however, it has been difficult to demonstrate physiologic roles for these binding sites. Nevertheless, investigation thus far indicates that steroid hormones can bind to membrane receptors and trigger rapid changes in electrolyte transport systems.⁹⁴ Estrogen-induced vasodilatation in the coronary arteries is believed to be mediated, at least in part, through a nongenomic calcium flux mechanism.⁹⁵

Agonists and Antagonists

An agonist is a substance that stimulates a response. An antagonist completely inhibits the actions of an agonist. Agonistic activity follows receptor binding which leads to stimulation of the message associated with that receptor. Antagonistic activity follows receptor binding and is characterized by blockage of the receptor message or nontransmission of the message. Most compounds used in this fashion that bind to hormone nuclear receptors have a mix of agonist and antagonist responses, depending on the tissue and hormonal milieu. Examples of antagonists include tamoxifen, RU486, and the histamine receptor antagonists.

Short-Acting Antagonists

Short-acting antagonists, such as estriol, are actually a mixed combination of agonism and antagonism depending on time. Short-term estrogen responses can be elicited because estriol binds to the nuclear receptor, but long-term responses do not occur because this binding is short-lived. Antagonism results when estriol competes with estradiol for receptors. However, if a constant presence of the weak hormone, estriol, can be maintained, then long-term occupation is possible, and a potent estrogen response can be produced.

Long-Acting Antagonists

Clomiphene and tamoxifen are mixed estrogen agonists and antagonists. The endometrium is very sensitive to the agonistic response, whereas the breast is more sensitive to the antagonistic behavior. The antagonistic action is the result of nuclear receptor binding with an alteration in the normal receptor-DNA processing and a failure to replenish hormone receptors, resulting in eventual depletion.

Alteration of the GnRH molecule has produced both agonists and antagonists. GnRH is a decapeptide; antagonists have substitutions at multiple positions, while agonists have substitutions at the 6 or 10 positions. The GnRH agonist molecules first stimulate the pituitary gland to secrete gonadotropins, then because of the constant stimulation, down-regulation and desensitization of the cell membrane receptors occur, and gonadotropin secretion is literally turned off. The antagonist molecules bind to the cell membrane receptor and fail to transmit a message and thus are competitive inhibitors. Various GnRH agonists are used to treat endometriosis, uterine leiomyomas, precocious puberty, cancer of the prostate gland, ovarian hyperandrogenism, and the premenstrual syndrome.

Physiologic Antagonists

Strictly speaking, a progestin is not an estrogen antagonist. It modifies estrogen action by causing a depletion of estrogen receptors. There is also evidence that a progestin can inhibit transcription activation by the estrogen receptor.⁹⁶ In addition, progestins induce enzyme activity that converts the potent estradiol to the impotent estrone sulfate, which is then secreted from the cell.⁹⁷ Androgens do block the actions of estrogen, but the mechanism is not entirely clear. Rather than a direct impact on estrogen receptor levels, the action is directed to gene activity subsequent to estrogen-receptor binding.⁴³ High levels of androgen can produce estrogen and progestational effects by binding to the estrogen and progesterone receptors.

Antiestrogens

Currently, there are two groups of antiestrogens: pure antiestrogens and compounds with both agonistic and antagonistic activities. The mixed agonist—antagonist compounds include both the triphenylethylene derivatives (the nonsteroidal estrogen relatives such as clomiphene and tamoxifen) and the nonsteroidal sulfur-containing agents (the benzothiophenes, such as raloxifene). The pure antiestrogens have a bulky side chain that, with only a little imagination, can be pictured as an obstruction to appropriate conformational changes. An ideal antiestrogen would have the following properties:

1. A compound that would be a pure antagonist on proliferating breast carcinoma cells
2. Development of resistance would be rare or require long exposure.
3. High affinity for the estrogen receptor so that therapeutic doses could be easily achieved.
4. No interference with the beneficial actions of estrogens.
5. No toxic or carcinogenic effects.

The Antiestrogen Tamoxifen

Tamoxifen is very similar to clomiphene (in structure and actions), both being nonsteroidal compounds structurally related to diethylstilbestrol. Tamoxifen, in binding to the estrogen receptor, competitively inhibits estrogen binding. In vitro, the estrogen binding affinity for its receptor is 100–1000 times greater than that of tamoxifen. Thus, tamoxifen must be present in a concentration 100–1000 times greater than estrogen to maintain inhibition of breast cancer cells. In vitro studies demonstrate that this action is not cytotoxic, but, rather, cytostatic (and thus its use must be long-term). The tamoxifen-estrogen receptor complex binds to DNA, but whether an agonistic, estrogenic message or an antagonistic, antiestrogenic message predominates is determined by what promoter elements are present in specific cell types.

There have been many clinical trials with adjuvant treatment of breast cancer with tamoxifen, and many are still on going.⁹⁸ Overall, the impact of tamoxifen treatment on breast cancer can be summarized as follows: disease-free survival is prolonged. There is an increased survival at 5 years of approximately 20%, most evident in women over age 50. Response rates in advanced breast cancer are 30–35%, most marked in patients with tumors that are positive for estrogen receptors, reaching 75% in tumors highly positive for estrogen receptors.

Serum protein changes reflect the estrogenic (agonistic) action of tamoxifen. This includes decreases in antithrombin III, cholesterol, and LDL-cholesterol, while HDL-cholesterol and sex hormone-binding globulin (SHBG) levels increase (as do other binding globulins). The estrogenic activity of tamoxifen, 20 mg daily, is nearly as potent as 2 mg estradiol in lowering FSH levels in postmenopausal women, 26% versus 34% with estradiol.⁹⁹ The estrogenic actions of tamoxifen include the stimulation of progesterone receptor synthesis, an estrogen like maintenance of bone, and estrogenic effects on the vaginal mucosa and the endometrium. Tamoxifen increases the frequency of hepatic carcinoma in rats at very large doses. This is consistent with its estrogenic, agonistic action, but this effect is unlikely to be a clinical problem (and it has not been observed) at doses currently used.⁹⁸ Tamoxifen causes a decrease in antithrombin III, and there has been a small increase in the incidence of thrombo-embolism observed in tamoxifen-treated patients compared with controls.^{100, 101} However, in the world overview of randomized trials, no significant cardiac or vascular increase in mortality was noted in tamoxifen-treated women.⁹⁸

All too often, the antagonistic, antiestrogenic action of tamoxifen is featured, and the estrogenic, agonistic action is ignored. In the 1980s, it was reported that human endometrial cancer transplanted into mice would grow more rapidly during tamoxifen therapy, although the growth of breast cancer cells would be inhibited. This growth in response to tamoxifen can be duplicated in laboratory culture preparations of endometrial cancer cells.

There now have been many reports of endometrial hyperplasia, endometrial polyps, and endometrial cancer occurring in women receiving tamoxifen treatment.^{102, 103} In addition, tamoxifen has been associated with major flare-ups in endometriosis. Tamoxifen, therefore, has a variety of side effects that indicate both estrogenic activity and antiestrogenic activity. How can tamoxifen be both an estrogen agonist and an estrogen antagonist?

Tamoxifen Mechanism of Action

TAF-1 and TAF-2 areas can both activate transcription, but TAF-2 activates transcription only when it is bound by estrogen. The individual transactivating abilities of TAF-1 and TAF-2 depend on the promoter and cell context. Tamoxifen's agonistic ability is due to activation of TAF-1; its antagonistic activity is due to competitive inhibition of the estrogen-dependent activation of TAF-2.

An estrogen-associated protein binds to the right hand side of TAF-2. Estrogen binding induces binding of this protein, which then activates transcription. This protein recognizes only an activated conformation of the estrogen receptor, the result of estrogen binding. Tamoxifen binding to the TAF-2 area does not activate this domain because, in at least one explanation, the conformational change does not allow binding of the estrogen-associated protein, the activating factor.^{65, 104}

The activity of TAF-2 is negligible in the presence of tamoxifen. In cells where TAF-1 and TAF-2 function independently of each other, tamoxifen would be chiefly an antagonist in cells where TAF-2 predominates, and an agonist where TAF-1 predominates, and in some cells a mixed activity is possible.¹⁰⁵

The contact sites of estrogens and antiestrogens with the estrogen receptor are not identical.¹⁰⁶ When an antiestrogen binds to the estrogen receptor, the conformational changes that are induced alter the ability of the estrogen receptor-antiestrogen complex to modulate transcriptional activity. The relative agonist—antagonist activity is determined by the specific conformation achieved by the specific antiestrogen.

Even though tamoxifen can block estrogen-stimulated transcription of many genes, its degree of antagonistic activity varies among different animals, different cell types, and with different promoters within single cells. These differences are due to differences in the relative activities of the TAFs. Thus, the extent to which an antiestrogen inhibits an estrogen-mediated response depends on the degree to which that response is mediated by TAF-2 activity as opposed to TAF-1 activity, or mixed activity.¹⁰⁷ In some cell lines TAF-1 is dominant, in others, both are necessary. No cells have yet been identified where TAF-2 is dominant.

In most cell types, TAF-1 is too weak to activate transcription by itself, but, of course, there are now well-known exceptions: endometrium, bone, and liver. In these tissues, the promoter context is right. Tamoxifen is a significant activator of estrogen receptor-mediated induction of promoters that are regulated by the TAF-1 site. Antiestrogens have no effects on TAF-1 dependent transcription in breast cells.¹⁰⁸

This explanation may not be the same for other mixed agonists and antagonists. Raloxifene may activate an estrogen-responsive gene through a response element

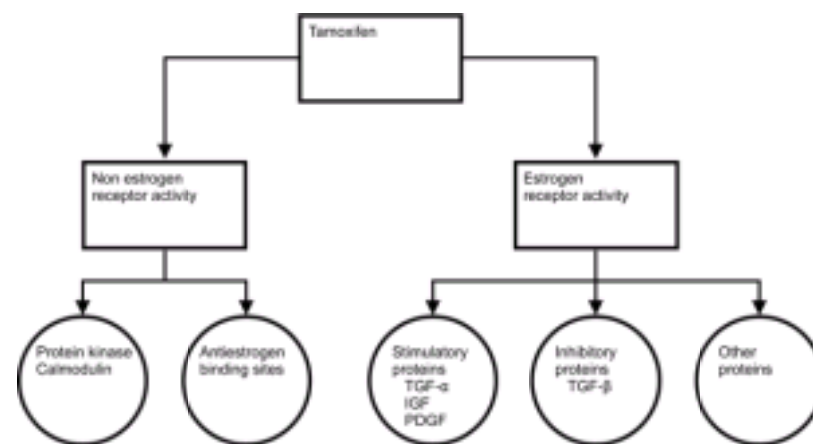

separate from the estrogen response element, an action that requires specific activating peptides.¹⁰⁹ Estrogen metabolites also can interact with response elements other than the classical estrogen response element. The bottom line is that there are multiple pathways to gene activation. The estrogen receptor, depending on the ligand, can regulate more than one response element. Thus, estrogen and antiestrogen actions in various tissues can reflect the presence of different response elements.

Summary — The Response of Cells to Estrogens and Antiestrogens Depends on:

1. The nature of the estrogen receptor.
2. The estrogen response elements and nearby promoters.
3. The cell context of protein coactivators and corepressors.
4. The properties of the ligand.
5. Modulation by growth factors and agents that affect protein kinases and phosphorylation.

Tamoxifen Treatment of Breast Cancer

Tamoxifen treatment achieves its greatest effect (50% reduction in recurrent disease) in estrogen receptor-positive tumors, but it is also effective in estrogen receptor-negative tumors. Most importantly, it is now recognized that acquired resistance eventually develops. Therefore, there are two important questions. *Why is tamoxifen treatment effective with estrogen receptor-negative tumors? How does tamoxifen resistance develop?*

Efficacy of Tamoxifen With Estrogen Receptor-Negative Tumors. Besides binding to the estrogen receptor and providing competitive inhibition, tamoxifen has the following actions:

1. Tamoxifen and clomiphene inhibit protein kinase C activity (phosphorylation).
2. Tamoxifen inhibits calmodulin-dependent cyclic AMP phosphodiesterase, by binding to calmodulin.
3. Tamoxifen and estrogen have opposing effects on growth factors:^{110, 111} Tamoxifen stimulates secretion of TGF- β in breast cancer cells as well as in fibroblasts and stromal cells, and TGF- β inhibits growth of breast cancer cells, whereas estrogen and insulin decrease the secretion of TGF- β in cancer cells. Tamoxifen decreases and estrogen increases IGF-I and IGF-II production in stromal fibroblasts.

Some of these actions (especially inhibition of protein kinase activity and stimulation of TGF- β production) occur independently of tamoxifen binding to the estrogen receptor, and thus, estrogen receptor-negative tumors can be affected by these actions.

Mechanisms for Tamoxifen Resistance. The results of randomized clinical trials have indicated that there is little reason to extend tamoxifen treatment of breast cancer patients beyond 5 years.^{101, 112} Indeed, the data suggested that survival and recurrence rates worsened with longer therapy, probably due to the emergence of tamoxifen-resistant tumors. There are several possible explanations for resistance, and whichever of these are operative, it is believed that a subpopulation resistant to tamoxifen is present from the beginning, and over time grows to be clinically apparent.¹¹³

1. Loss of estrogen receptors

Generally it is believed that estrogen receptor expression is not a permanent phenotype of breast cancer cells; thus, tumors can change from receptor-positive to receptor-negative. But more than 50% of resistant tumors retain estrogen receptors.¹¹⁴ The conventional wisdom has been that progression is associated with loss of cellular control and loss of estrogen receptor expression. However, the correlation between metastatic disease and estrogen receptor-negative state is not strong. Indeed, metastatic disease with estrogen receptor-positive cells despite an estrogen receptor-negative primary lesion has been reported. In addition, the rate of estrogen receptor expression is about the same in *in situ* disease and invasive disease. Most normal breast cells are estrogen receptor-negative, and *in vitro*, cell lines maintain their receptor status. Thus, there is little reason to believe that tamoxifen-resistant tumors lose receptor expression. *The importance of this is that resistance is not a wild, potentially uncontrollable dedifferentiation.*¹¹⁵

2. Variant and mutant estrogen receptors

Mutations in resistant breast tumors are infrequent and are unlikely to account for resistance.¹¹⁶ Studies of breast tumors from tamoxifen-resistant patients indicate that most express wild type normal estrogen receptor; very few mutated estrogen receptors have been described.

3. Changes in coactivators

If a breast cancer cell were to begin expressing these factors in a fashion similar to endometrium or bone, then agonistic actions would occur.

4. Cross talk between signaling pathways

Because of the synergism between the estrogen receptor and protein kinase pathways, stimulation of protein kinase pathways can change an antagonist message to agonism.¹¹⁷ This mechanism operates through the phosphorylation of the estrogen receptor or proteins involved in estrogen receptor-mediated transcription. Stimulation of this protein kinase phosphorylation activates the agonist activity of tamoxifen-like antiestrogens. Furthermore, the lack of response of pure antiestrogens to this phosphorylation may be part of the reason for the response of resistant tumors to pure antiestrogens.

5. Binding to other proteins

A remote possibility is the prevention of action by binding to other proteins, such as antiestrogen binding sites, microsomal proteins that bind to tamoxifen with high affinity but do not bind estrogen.¹¹⁸

6. Differential cellular transport

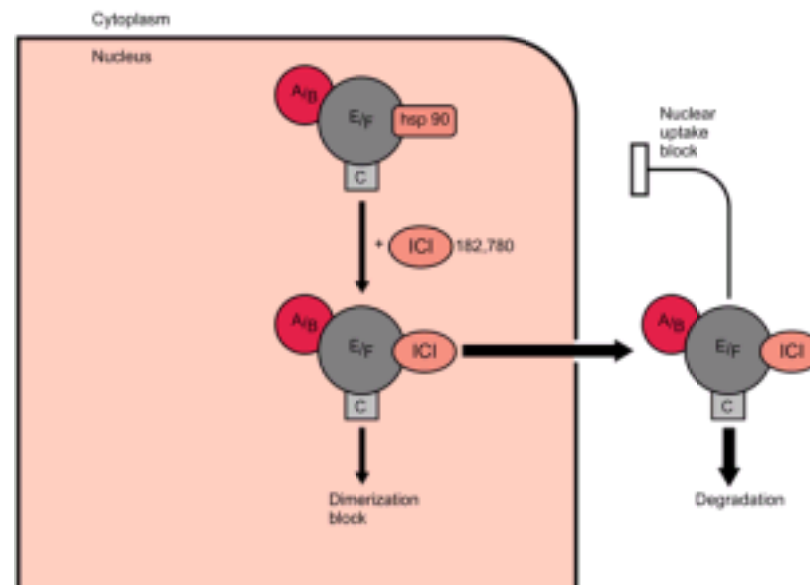

Overexpression of the transmembrane efflux pump that excretes compounds from cells could diminish the intracellular amount of tamoxifen present.

7. Differential metabolism

Changes in pharmacology and metabolism of tamoxifen might occur so that cells acquire the ability to metabolize the antagonist to greater agonist activity. Some breast cancer patients develop tumors that regress when tamoxifen is withdrawn. However, estrogenic metabolites of tamoxifen have been reported in only one study of patients with resistant tumors.¹¹⁹

The Pure Antiestrogens

The pure antiestrogens are derivatives of estradiol with long hydrophobic side chains at the 7 position. Binding with the pure antiestrogens prevents DNA binding. Because the site responsible for dimerization overlaps with the hormone-binding site, it is believed that pure antiestrogens sterically interfere with dimerization, and thus inhibit DNA binding. In addition, these compounds increase the cellular turnover of estrogen receptor, and this action contributes to its antiestrogen effectiveness. Estrogen and progesterone receptors exit the nucleus but are rapidly transported back. When this shuttling is impaired, receptors are more rapidly degraded in the cytoplasm. Agents that inhibit dimerization inhibit nuclear translocation and thus increase cytoplasmic degradation. The half-life of the estrogen receptor when occupied with estradiol is about 5 hours, when occupied with a pure antiestrogen, it is less than 1 hour. This mechanism may be due to interference with nuclear localization exerted by the hinge region. Thus, newly synthesized receptors cannot be efficiently transported into the nucleus and those in the nucleus will leak back into the cytoplasm.

Another possible mechanism for pure antiestrogens involves a binding protein for the insulin-like growth factors. In a breast cancer cell line, ICI 182,780 inhibited growth and increased transcription of the IGFBP-3 gene. Estradiol did the opposite. In the uterus, tamoxifen and estrogen suppress IGFBP-3 production, while the ICI antagonist markedly increases IGFBP and causes uterine involution.¹²⁰

Because these agents function in a different manner than tamoxifen, it is not surprising that tamoxifen-resistant tumors respond to these agents.¹²¹

Selective Estrogen Agonists/Antagonists (Selective Estrogen Receptor Modulators)

Agents such as raloxifene and droloxifene have antiestrogenic activity in the uterus as well as in the breast, and at the same time exert agonistic effects in certain target tissues.^{122, 123 and 124} Raloxifene inhibits bone resorption and improves lipids (although there is no effect on HDL-cholesterol). By virtue of variations in conformational changes in the drug-receptor complex and the cellular context of specific tissues, drugs such as these can be developed to produce beneficial effects in certain target systems (such as bone) and to avoid unwanted actions (such as endometrial stimulation).

The Antiprogestin RU486

Both progesterone and the antiprogestins, RU486 (mifepristone) and ZK98299 (onapristone), form hormone-responsive element-receptor complexes that are similar, but the antiprogestin complex has a slightly different conformational change (in the hormone-binding domain) that prevents full gene activation.¹²⁵ RU486 has some agonistic activity due to its ability to activate certain, but not all, of the transcription activation functions on the progesterone receptor. New antiprogestins are in development that bind to the progesterone receptor and prevent the subsequent binding of the receptor to gene response elements.

The search for inhibitors of progesterone binding began many years ago, in the late 1960s, but it wasn't until the early 1980s that RU486, the first successful antiprogestin was produced by scientists at Roussel Uclaf, a pharmaceutical company in Paris. RU486 is a 19-nortestosterone derivative. The dimethyl (dimethylaminophenyl) side chain at carbon 11 is the principal factor in its antiprogestone action. There are three major characteristics of its action which are important: a long half-life, high affinity for the progesterone receptor, and active metabolites.

The affinity of RU486 for the progesterone receptor is 5 times greater than that of the natural hormone. In the absence of progesterone, it can produce an agonistic (progesterone) effect. It does not bind to the estrogen receptor, but it can act as a weak antiandrogen because of its low-affinity binding to the androgen receptor. RU486 also binds to the glucocorticoid receptor, but higher doses are required to produce effects. The binding affinity of RU486 and its metabolites for the glucocorticoid receptor is very, very high. The reason why it takes such a high dose to produce an effect is because the circulating level of cortisol is so high, 1000-fold higher than progesterone. This allows titration of clinical effects by adjustments of dose.

Both progesterone and RU486 induce conformational changes with the progesterone receptor, especially in the hormone-binding domain.^{126, 127} Thus, the antiprogestin not only competes with progesterone for the progesterone receptor, but after binding to the hormone-binding domain, the receptor structure is altered in such a way that the transcription activity of the B progesterone receptor is inhibited. In cells where the A progesterone receptor is expressed, antiprogestin binding stimulates A receptor-induced inhibition of transcription activity for all steroid hormone receptors (this would explain the antiestrogen activity of RU486).

RU486 is most noted for its abortifacient activity and the political controversy surrounding it. However, the combination of its agonistic and antagonistic actions can be exploited for many uses, including contraception, therapy of endometriosis, induction of labor, treatment of Cushing's syndrome, and, potentially, treatment of various cancers. Hopefully, new antiprogestins will be free of political and emotional constraints, and the many potential applications will be pursued.

Androgen Antagonists

The two most commonly used androgen antagonists are cyproterone acetate and spironolactone. Cyproterone and spironolactone bind to the androgen receptor and exert mixed agonism—antagonism. In the presence of significant levels of androgens, the antagonism predominates, and these agents are effective for the treatment of hirsutism. Flutamide is a nonsteroidal pure antiandrogen, effectively blocking androgenic action at target sites by competitive inhibition.

Mechanism of Action for Tropic Hormones

Tropic hormones include the releasing hormones originating in the hypothalamus and a variety of peptides and glycoproteins released by the anterior pituitary gland and placenta. The specificity of the tropic hormone depends on the presence of a receptor in the cell membrane of the target tissue. Tropic hormones do not enter the cell to stimulate physiologic events but unite with a receptor on the surface of the cell.

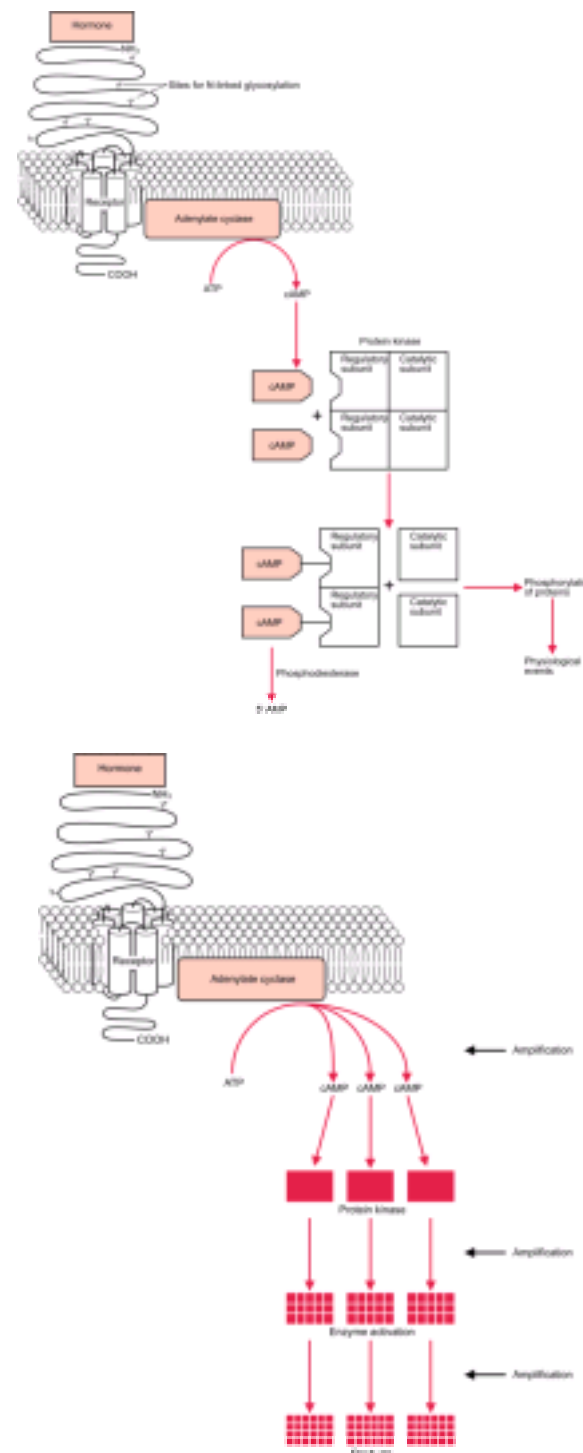

The receptor protein in the cell membrane can either act as the active agent and, after binding, operate as an ion channel or function as an enzyme. Alternatively, the receptor protein is coupled to an active agent, an intracellular messenger. The major intracellular messenger molecules are cyclic AMP, inositol 1,4,5-triphosphate (IP₃), 1,2-diaclyglycerol (1,2-DG), calcium ion, and cyclic GMP.

Receptors from this membrane family are also found in the membranes of lysosomes, endoplasmic reticulum, Golgi complex, and in nuclei. The regulation of these intracellular organelle receptors differs from those of the cell surface membranes.

The Cyclic AMP Mechanism

Cyclic AMP is the intracellular messenger for FSH, LH, human chorionic gonadotropin (HCG), thyroid-stimulating hormone (TSH), and ACTH. Union of a tropic hormone with its cell membrane receptor activates the adenylate cyclase enzyme within the membrane wall leading to the conversion of adenosine 5'-triphosphate (ATP) within the cell to cyclic AMP. Specificity of action and/or intensity of stimulation can be altered by changes in the structure or concentration of the receptor at the cell wall binding site. In addition to changes in biologic activity due to target cell alterations, changes in the molecular structure of the tropic hormone can interfere with cellular binding and physiologic activity.

The cell's mechanism for sensing the low concentrations of circulating tropic hormone is to have an extremely large number of receptors but to require only a very small percentage (as little as 1%) to be occupied by the tropic hormone. The cyclic AMP released is specifically bound to a cytoplasm receptor protein, and this cyclic AMP-receptor protein complex activates a protein kinase. The protein kinase is present in an inactive form as a tetramer containing 2 regulatory subunits and 2 catalytic subunits. Binding of cyclic AMP to the regulatory units releases the catalytic units, with the regulatory units remaining as a dimer. The catalytic units catalyze the phosphorylation of serine and threonine residues of cellular proteins such as enzymes and mitochondrial, microsomal, and chromatin proteins. The physiologic event follows this cyclic AMP-mediated energy-producing event. Cyclic AMP is then degraded by the enzyme phosphodiesterase into the inactive compound, 5'-AMP.

Most noteworthy, DNA contains responsive elements that bind proteins phosphorylated by the catalytic units, thus leading to activation of gene transcription. The **cyclic AMP responsive element (CRE)** functions as an enhancer element upstream from the start of transcription.¹²⁸ A large family of transcription factors interact with the CRE, creating an important regulatory unit for gene transcription. Cyclic AMP activates a specific transcription factor, cyclic AMP regulatory element-binding protein (CREB); the binding of CREB to CRE activates many genes. This system can also involve DNA sequences upstream from the CRE site.

Because LH can stimulate steroidogenesis without apparent changes in cyclic AMP (at low hormone concentrations), it is possible that an independent pathway exists; i.e., a mechanism independent of cyclic AMP. Mechanisms independent of cyclic AMP could include ion flow, calcium distribution, and changes in phospholipid metabolism.

The cyclic AMP system can be regarded as an example of evolutionary conservation. Rather than developing new regulatory systems, certain critical regulators have been preserved from bacteria to mammals. How is it that a single intracellular mediator can regulate different events? This is accomplished by turning on different biochemical events governed by the different gene expression in individual cells. In addition, the adenylate cyclase enzyme exists in several isoforms, which respond either with stimulation or inhibition to various systems and agents.¹²⁹

The cyclic AMP system provides a method for amplification of the faint hormonal signal swimming in the sea of the bloodstream. Each cyclase molecule produces a lot of cyclic AMP; the protein kinases activate a large number of molecules that in turn lead to an even greater number of products. This is an important part of the sensitivity of the endocrine system. This is a major reason why only a small percentage of the cell membrane receptors need be occupied in order to generate a response.

Prostaglandins stimulate adenylate cyclase activity and cyclic AMP accumulation. Despite the effect on adenylate cyclase, prostaglandins appear to be synthesized after the action of cyclic AMP. This implies that tropic hormone stimulation of cyclic AMP occurs first; cyclic AMP then activates prostaglandin synthesis and, finally, intracellular prostaglandin moves to the cell wall to facilitate the response to the tropic hormone. In addition to actions mediated by cyclic AMP, prostaglandins can also operate through changes in intracellular concentrations of calcium.

Prostaglandins and cyclic GMP (cyclic guanosine 3'-5'-monophosphate) may participate in an intracellular negative feedback mechanism governing the degree of, or direction of, cellular activity (e.g., the extent of steroidogenesis or shutting off of steroidogenesis after a peak of activity is reached). In other words, the level of cellular function may be determined by the interaction among prostaglandins, cyclic AMP, and cyclic GMP.

There are differences among the tropic hormones. Oxytocin, insulin, growth hormone, prolactin, and human placental lactogen (HPL) do not utilize the adenylate cyclase mechanism. Receptors for prolactin, growth hormone, and a number of cytokines (including erythropoietin and interleukins) belong to a single transmembrane domain receptor family.¹³⁰ Studies of this receptor family indicate that prolactin operates through various signal transduction mechanisms, including ion channels and nuclear kinase activation.

Gonadotropin releasing hormone (GnRH) is calcium dependent in its mechanism of action and utilizes IP_3 and 1,2-DG as second messengers to stimulate protein kinase activity.¹³¹ These responses require a G protein and are associated with cyclical release of calcium ions from intracellular stores and the opening of cell membrane channels to allow entry of extracellular calcium.

The Calcium Messenger System

The intracellular calcium concentration is a regulator of both cyclic AMP and cyclic GMP levels. ¹³² Activation of the surface receptor either opens a channel in the cell membrane that lets calcium ions into the cell, or calcium is released from internal stores (the latter is especially the case in muscle). This calcium flux is an important intracellular mediator of response to hormones, functioning itself as a second messenger in the nervous system and in muscle.

The calcium messenger system is linked to hormone-receptor function by means of a specific enzyme, phospholipase C, that catalyzes the hydrolysis of polyphosphatidylinositols, specific phospholipids in the cell membrane. Activation of this enzyme by hormone binding to its receptor leads to the generation of 2 intracellular messengers, inositol triphosphate (IP_3) and diacyl glycerol (DAG), which initiate the function of the 2 parts of the calcium system. The first part is a calcium activated protein kinase responsible for sustained cellular responses, and the second part involves a regulator called calmodulin responsible for acute responses. These responses are secondary to alterations in enzyme activity and in transcription factors.

Calmodulin has been identified in all animal and plant cells that have been examined. Therefore, it is a very ancient protein. It is a single polypeptide chain of 148 amino acid residues whose sequence and structural and functional properties are similar to those of troponin C, the substance that binds calcium during muscle contractions, facilitating the interaction between actin and myosin. The calmodulin molecule has 4 calcium-binding sites, and binding with calcium gives a helical conformation which is necessary for biologic activity. A typical animal cell contains more than 10 million molecules of calmodulin, constituting about 1% of the total cell protein. As a calcium regulatory protein, it serves as an intracellular calcium receptor and modifies calcium transport, enzyme activity, the calcium regulation of cyclic nucleotide and glycogen metabolism, and such processes as secretion and cell motility. Thus, calmodulin serves a role analogous to that of troponin C, mediating calcium's actions in noncontractile tissues, and cyclic AMP works together with calcium and calmodulin in the regulation of intracellular metabolic activity.

Kinase Receptors

The cell membrane receptors of insulin, insulin-like growth factor, epidermal growth factor, platelet-derived growth factor, and fibroblast growth factor are tyrosine kinases. All tyrosine kinase receptors have a similar structure: an extracellular domain for ligand binding, a single transmembrane domain, and a cytoplasmic domain. The unique amino acid sequences determine a 3-dimensional conformation that provides ligand specificity. The transmembrane domains are not highly conserved (thus differing in make up). The cytoplasmic domains respond to ligand binding by undergoing conformational changes and autophosphorylation. The structure of the receptors for insulin and insulin-like growth factor is more complicated, with two alpha- and two beta-subunits, forming two transmembrane domains connected extracellularly by disulfide bridges. The receptors for the important autocrine and paracrine factors, activin and inhibin, function as serine-specific protein kinases.

Kinase activation requires distinctive sequences; thus there is considerable homology among the kinase receptors in the cytoplasmic domain. Many of the substrates for these kinases are the enzymes and proteins in other messenger systems; e.g., the calcium messenger system. Thus, the kinase receptors can cross talk with other receptor regulated systems that involve the G proteins.

Regulation of Tropic Hormones

Modulation of the peptide hormone mechanism is an important biologic system for enhancing or reducing target tissue response. The regulation of tropic hormone action can be divided into 4 major components.

1. Autocrine and paracrine regulation factors.
2. Heterogeneity of the hormone.
3. Up- and down-regulation of receptors.
4. Regulation of adenylate cyclase.

Autocrine and Paracrine Regulation Factors

Growth factors are polypeptides that modulate activity either in the cells in which they are produced or in nearby cells; hence, they are autocrine and paracrine regulators. Regulation factors of this type (yet another biologic family) are produced by local gene expression and protein translation, and they operate by binding to cell membrane receptors. The receptors usually contain an intracellular component with tyrosine kinase activity that is energized by a binding-induced conformational change that induces autophosphorylation. However, some factors work through the other second messenger systems, such as cyclic AMP or IP_3 . Growth factors are involved in a variety of tissue functions, including mitogenesis, tissue and cellular differentiation, chemotactic actions, and angiogenesis. The growth factors involved

in reproductive physiology include activin, inhibin, insulin-like growth factor-I (IGF-I), insulin-like growth factor-II (IGF-II), transforming growth factor-b (TGF-b), fibroblast growth factor (FGF), and epidermal growth factor (EGF).

In addition to the growth factors, various immune factors, especially cytokines, modulate ovarian steroidogenesis. These factors, including interleukin-1, tumor necrosis factor, and interferon, are found in human follicular fluid and, in general, inhibit gonadotropin stimulation of steroidogenesis.

For mitogenesis to occur, cells may require exposure to a sequence of growth factors, with important limitations in duration and concentrations. Growth factors are important for the direction of embryonic and fetal growth and development. In cellular differentiation, growth factors can operate in a cooperative, competitive, or synergistic fashion with other hormones. For example, IGF-I plus FSH, but not IGF-I alone, increases the number of LH receptors, progesterone synthesis, and aromatase activity in granulosa cells.¹³³

Activin and inhibin are disulfide-linked dimers composed of peptide subunits (one alpha subunit and two beta subunits) as follows:¹³⁴

The 3 Forms of Activin:

Activin A:

Beta_A-Beta_A

Activin AB:

Beta_A-Beta_B

Activin B:

Beta_B-Beta_B

The 2 Forms of Inhibin:

Inhibin A:

Alpha-Beta_A

Inhibin B:

Alpha-Beta_B

Each of the subunits is encoded by separate genes that produce precursor proteins that are cleaved to form the subunits. In addition, the free subunits and related monomeric products can be secreted. Despite the structural similarity between activin and inhibin, they function as antagonists in some systems (e.g., activin stimulates and inhibin inhibits FSH secretion). Activins, inhibins, and TGF-b come from the same gene family, which also includes antimüllerian hormone, and proteins active during insect and frog embryogenesis. The activity of activin is regulated by protein binding, specifically to follistatin. Follistatin is a single-chain glycosylated peptide, structurally unrelated to inhibin and activin, that regulates the activin-inhibin system. Signaling by this family of peptides is accomplished by several receptor isoforms that are transmembrane serine kinases.

TGF-b can either stimulate or inhibit growth and differentiation, depending on the target cell and the presence or absence of other growth factors. In the ovary, TGF-b promotes granulosa cell differentiation by enhancing the actions of FSH (especially in expression of FSH and LH receptors) and antagonizing the down-regulation of FSH receptors. TGF-b and the insulin-like growth factors are required for the maintenance of normal bone mass. EGF is a structural analog of TGF-a and is involved in mitogenesis. In the ovary, EGF, secreted by theca cells, is important for granulosa cell proliferation, an action opposed by TGF-b that is also secreted by the theca cells. The most potent mitogens are the two forms of FGF. Additional roles for FGF, secreted by the granulosa, include modulation of enzyme activity involved in the physical act of ovulation and angiogenic function during the development of the corpus luteum.

The Insulin-Like Growth Factors

The insulin-like growth factors (also called somatomedins) are single-chain polypeptides that resemble insulin in structure and function.¹³³ These factors are widespread and are involved in growth and differentiation in response to growth hormone, and as local regulators of cell metabolism. IGF-II is more prominent during embryogenesis, while IGF-I is more active postnatally. Only the liver produces more IGF-I than the ovary. According to animal studies, both IGF-I and IGF-II are secreted by granulosa cells. IGF-I amplifies the action of gonadotropins and coordinates the functions of theca and granulosa cells. IGF-I receptors on the granulosa are increased by FSH and LH and augmented by estrogen. In the theca, IGF-I increases steroidogenesis. In the granulosa, IGF-I is important for the formation and increase in numbers of FSH and LH receptors, steroidogenesis, the secretion of inhibin, and oocyte maturation. It should be noted that the endogenous insulin-like growth factor in the human ovarian follicle is IGF-II in both the granulosa and the thecal cells.¹⁹ Studies indicating activity of IGF-I with human ovarian tissue can be explained by the fact that both IGF-I and IGF-II activities can be mediated by the type I IGF receptor that is structurally similar to the insulin receptor.

Granulosa cells also contain receptors for insulin, and insulin can bind to the IGF-I receptor. The IGF-I receptor is a heterotetramer with two alpha- and two beta-subunits in a structure similar to that of the insulin receptor. Insulin can bind to the alpha-subunit ligand-binding domain and activate the beta-subunit, which is a protein kinase. Thus, insulin can modulate ovarian cellular functions either through its own receptor or through the IGF-I receptor.

The biologic potency and availability of the insulin-like growth factors are further modulated by a collection of IGF-binding proteins that bind circulating insulin-like growth factors and also alter cellular responsiveness. Six insulin-like growth factor binding proteins (IGFBP-1 through IGFBP-6) have been detected in serum and various tissues.¹³⁵ IGF-I and IGF-II circulate in the blood in a concentration 1000 times greater than insulin; however, largely all of the circulating IGFs are bound to IGFBPs. The multiple IGFBPs and their proteases provide a mechanism for tissue-specific activities of IGFs. The various IGFBPs differ in their actions and individual expression, depending upon the specific cell type and tissue. The principal IGFBP that regulates IGF biologic availability can vary according to metabolic changes. There are many possible permutations because the IGFBPs are not simply transport proteins; there are inhibitory and stimulatory IGFBPs that inhibit or potentiate IGF actions. Tissue-specific regulation of IGFBP protease activity can change the bioavailability of IGFs at specific sites. In addition, the IGFBPs have been demonstrated to have direct effects of their own, independent of IGF. Therefore, this is a complex regulatory system that provides both endocrine signals and autocrine and paracrine functions.

Orphan Receptors Involved in Steroidogenesis

Steroidogenic factor-1 (SF-1) and DAX-1 (a name that represents: Dosage-sensitive sex reversal-Adrenal hypoplasia congenita critical region on the X chromosome) are nuclear receptors for which specific ligands have not been identified ("orphan receptors"). SF-1 influences the expression of genes that encode steroidogenic enzymes, and when genetic expression of SF-1 is disrupted in mice, gonads and adrenal glands fail to develop.^{136, 137} In addition, SF-1 regulates transcription of the StAR gene.¹³⁸ Mutations in the DAX-1 gene result in adrenal hypoplasia, and DAX-1 is believed to work with SF-1 in regulating development and function of steroid-producing tissues.¹³⁹ SF-1 also regulates genes that encode the gonadotropin subunits, as well as the GnRH receptor.¹³⁷ Thus, SF-1 is involved at all levels: the hypothalamus, the pituitary, and in the steroid-producing organs. These proteins function as transcription factors (as are the traditional nuclear hormone receptors such as the estrogen receptor) in the complex mechanisms being unraveled by molecular biologists.

Heterogeneity

The glycoproteins, such as FSH and LH, are not single proteins but should be viewed as a family of heterogeneous forms of varying immunologic and biologic activity.¹⁴⁰ The various forms (isoforms) arise in various ways, including different DNA promoter actions, alterations in RNA splicing, point mutations, and post-translational carbohydrate changes.¹⁴¹ The impact of the variations is to alter structure and metabolic clearance, thus affecting binding and activity. The isoforms have different molecular weights, circulating half-lives, and biologic activities. Throughout the menstrual cycle, the amazing number of at least 20–30 isoforms of both FSH and LH are present in the bloodstream.¹⁴² **The overall activity of a glycoprotein, therefore, is due to the effects of the mixture of forms that reach and bind to the target tissue.**

The nonglycosylated subunit precursors of glycoprotein hormones are synthesized in the endoplasmic reticulum, followed by glycosylation. The glycosylated subunits combine and then are transported to the Golgi apparatus for further processing of the carbohydrate component. The units combine to form a compact heterodimer. The protein moiety binds to specific target tissue receptors, while the carbohydrate moiety plays a critical role in coupling the hormone-receptor complex to adenylate cyclase (perhaps by determining the necessary conformational structure).

The preciseness of the chemical make up of the tropic hormones is an essential element in determining the ability of the hormone to mate with its receptor. The glycopeptides (FSH, LH, TSH, and HCG) are dimers composed of two glycosylated polypeptide subunits, the a- and b-subunits. The a- and b-subunits are tightly bound in a noncovalent association. The three-dimensional structure and the active conformation of the subunits are maintained by internal disulfide bonds.¹⁴³ All of the glycopeptides of the human species (FSH, LH, TSH, and HCG) share a common a-chain, an identical structure containing 92 amino acids. The b-chains (or the

b-subunits) differ in both amino acid and carbohydrate content, conferring the specificity inherent in the relationship between hormones and their receptors. Therefore, the specific biologic activity of a glycopeptide hormone is determined by the b-subunit; hypogonadism has been reported due to single amino acid substitution in the LH b-subunit.¹⁴⁴

b-HCG is the largest b-subunit, containing a larger carbohydrate moiety and 145 amino acid residues, including a unique carboxyl-terminal tail piece of 24 amino acid groups. It is this unique part of the HCG structure that allows the production of highly specific antibodies and the utilization of highly specific immunologic assays. The extended sequence in the carboxy-terminal region of b-HCG contains 4 sites for glycosylation, the reason why HCG is glycosylated to a greater extent than LH, a difference that is responsible for the longer circulating half-life for HCG.

These differences in structure are associated with a different promoter and transcriptional site that is located upstream in the HCG b-subunit gene compared with the site in the LH b-subunit gene. The HCG b-subunit site does not contain a hormone response element, allowing HCG secretion to escape feedback regulation by the sex steroids, in contrast to FSH and LH.

The rate-limiting step in the synthesis of gonadotropins and TSH is the availability of b-subunits, because excess a-units can be found in blood and in tissue. Furthermore, the three dimensional structure of the b-subunit, accomplished by folding the subunit by the formation of the disulfide bonds, is an important conformational step that is essential for assembly with the a-subunit.¹⁴⁵ This conformational change is not completed until the subunits are fully united to produce the final whole hormone.

The half-life of a-HCG is 6–8 minutes, that of whole HCG from the placenta about 24 hours. All human tissues appear to make HCG as a whole molecule, but the placenta is different in having the ability to glycosylate the protein, thus reducing its rate of metabolism and giving it biologic activity through a long half-life. The carbohydrate components of the glycoproteins are composed of fructose, galactose, mannose, galactosamine, glucosamine, and sialic acid. Although the other sugars are necessary for hormonal function, sialic acid is the critical determinant of biologic half-life. Removal of sialic acid residues in HCG, FSH, and LH leads to very rapid elimination from the circulation.

FSH consists of the a-subunit of 92 amino acids and a b-subunit of 118 amino acids. It has four carbohydrate side chains, two on each subunit. The b-subunit of LH consists of 121 amino acids. LH has 3 carbohydrate side chains with a single glycosylation site (with less than half of the sialic acid in FSH). The initial half-life of LH is approximately 20 minutes, compared with the initial half-life of FSH of 3–4 hours.

Genes for tropic hormones contain promoter and enhancer or inhibitor regions located in the 5'-flanking regions upstream from the transcription site. These sites respond to second messengers (cyclic AMP) as well as steroids and other yet unknown regulators. The protein cores of the two glycoprotein subunits are the products of distinct genes.¹⁴⁶ Using recombinant DNA technology, it has been demonstrated that there is a single human gene for the expression of the a-subunit. The gene for the a-subunit shared by FSH, LH, HCG, and TSH is located on chromosome 6p21.1–23. A single promoter site subject to multiple signals and hormones regulates transcription of the a-gene in both placenta and pituitary. The a-subunit gene is expressed in several different cell types, but the b-subunit genes are restricted in cell type. The TSH b-gene is expressed only in thyrotropes regulated by thyroid hormone; the FSH b-gene is expressed in gonadotropes regulated by GnRH, activin, inhibin and gonadal steroids; the LH b-gene, also expressed in gonadotropes, is regulated by GnRH and unaffected by activin and inhibin.¹⁴⁷

The a-subunit gene requires the activation of distinct regulatory elements in thyrotrope and gonadotrope cells, as well as in the placenta. It is the activation of these cell-specific elements that produces tissue specificity for a-gene expression. In gonadotropes, the GnRH signaling pathway for a-gene transcription utilizes phosphorylation of diacyl glycerol (DAG) and inositol triphosphate (IP₃) that leads to a release of intracellular calcium stores. GnRH also stimulates the influx of calcium at the cell membrane. DAG, IP₃, and calcium work together to stimulate protein kinase C activity. Protein kinase regulation of the a promoter is a principal part of the overall mechanism. This pituitary process is influenced by multiple factors, including growth factors and gonadal steroids. In the placenta, the mechanism also utilizes specific regulatory elements, but the primary signal is mediated by the cyclic AMP-protein kinase A pathway.

The gene for the FSH b-subunit is on chromosome 11p13, and in the pituitary, it is markedly influenced by activin.¹⁴⁸ Although FSH and LH both require GnRH stimulation, the FSH b-gene is unique in that response to GnRH is dependent on activin.¹⁴⁹ With increasing GnRH stimulation, the role of activin is increasingly repressed by its binding protein, follistatin, the secretion of which is also stimulated by GnRH and activin. Activin is further antagonized by inhibin, the first of these factors recognized to suppress FSH secretion.¹⁵⁰

The genes that encode for the b-subunits of LH, HCG, and TSH are located in a cluster on chromosome 19q13.3. There are 6 genes for the b-subunit of HCG, and only one for b-LH.¹⁵¹ Transcription for the 6 HCG genes, each with different promoter activity, varies, and it is not certain why HCG requires multigenic expression (perhaps this is necessary to reach the extremely high level of production in early pregnancy). It is thought that b-HCG evolved relatively recently from b-LH, and the unique amino acid terminal extension of b-HCG arose by a read through mutation of the translation stop codon in the b-LH gene; the DNA sequences of the b-HCG genes and the b-LH gene are 96% identical.¹⁵¹ Only primates and horses have been demonstrated to have genes for the b-subunit of chorionic gonadotropin. In contrast to human chorionic gonadotropin, equine chorionic gonadotropin exerts both LH and FSH activities in many mammalian species because it contains peptide sequences in its b-subunit that are homologous to those in the pituitary gonadotropins of other species. The equine b-chorionic gonadotropin gene is identical to the equine b-LH gene, and although the primate b-HCG gene evolved from the same ancestral b-LH gene, the horse chorionic gonadotropin gene evolved in a different way. The b-LH gene is not expressed in the placenta.

A specific immunological LH variant is relatively common. This variant is due to two point mutations in the LH b-subunit gene and is more common in people of northern European descent, reaching a carrier frequency of 41.9% in Lapps of northern Finland.¹⁵² The clinical significance of this mutation is not known; however, routine immunoassays can provide falsely low readings because this variant is not detected.

The placenta-specific expression of b-HCG is due to several differences in DNA sequences between the b-HCG and b-LH genes.¹⁴⁷ The cyclic AMP-mediated enhancement of the b-HCG promoter is influenced by several regulatory proteins. The study of the b-subunit genes has been hampered by difficulties in maintaining glycoprotein-producing cell lines. The availability of choriocarcinoma cell lines, however, has allowed greater investigation of the b-HCG genes.

Although the b-subunit specifies the biologic activity of an individual glycoprotein, the combination of the a- and b-subunits is necessary for full hormonal expression. Furthermore, the a-subunit also plays an important role in accomplishing normal receptor binding and activation.^{153, 154} Neither subunit alone can effectively bind to the receptor with high affinity or exert biologic effect. In other words, binding and activation occur only when the hormone is in the combined a-b form.

Variations in Carbohydrate

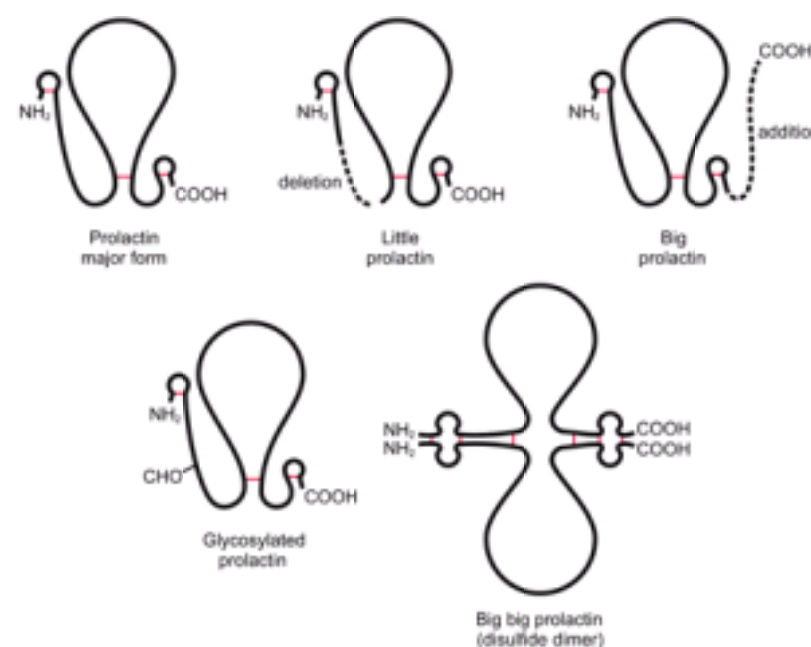

The glycopeptide hormones can be found in the pituitary existing in a variety of forms, differing in their carbohydrate (oligosaccharides) make up. The isoform mixture of gonadotropins is influenced both quantitatively and qualitatively by GnRH and the feedback of the steroid hormones, producing post translational carbohydrate modifications.^{155, 156} This heterogeneity in structure (which is also associated with heterogeneity in charge) represents a mechanism under endocrine control that modulates half-lives and bioactivity.

Certain clinical conditions may be associated with alterations in the usual chemical structure of the glycopeptides, resulting in an interference with the ability to bind to receptors and stimulate biological activity. In addition to deglycosylation and the formation of antihormones, gonadotropins can be produced with an increased carbohydrate content. A low-estrogen environment in the pituitary gland, for example, favors the production of so-called big gonadotropins, gonadotropins with an increased carbohydrate component and, as a result, decreased biological activity.¹⁵⁷ Immunoassay in these situations may not reveal the biologic situation; an immunoassay sees only a certain set of molecules but not all. Therefore, immunologic results do not always indicate the biologic situation.

Bioactive levels of FSH and LH are very low in women receiving oral contraceptives and during the luteal and late follicular phases. The highest values are during the midcycle surge and in postmenopausal women (including women with premature ovarian failure).¹⁵⁸ The levels of bioactive FSH parallel those of immunoactive FSH with a constant ratio throughout the cycle. The greater bioactivity of FSH at midcycle is associated with less sialylated, shorter-lived isoforms. These changes are effects of both GnRH and estrogen.

The carbohydrate component, therefore, affects target tissue response in two ways: 1) metabolic clearance and half-life and 2) biologic activity. The latter action focuses on two functions for the hormone-receptor complex: binding and activation. One structural domain is important for binding and another for triggering the biologic response. Carbohydrate residues, especially the sialic acid residues, are less important in binding. Indeed, experimental data indicate that the carbohydrate chains have no role in the binding of gonadotropins to their receptors.¹⁵⁹ Nevertheless, removal of the carbohydrate moiety of either subunit diminishes gonadotropic activity. Therefore, the carbohydrate component affects the biologic activity of the hormone-receptor complex after binding. Specific studies indicate that the carbohydrate component plays a critical role in activation (coupling) of the adenylate cyclase system.¹⁶⁰

The circulating half-life of a gonadotropin is mainly proportional to the amount of sialic acid present.¹⁶¹ The higher content of sialic acid in FSH compared with LH accounts for the more rapid clearance of LH from the circulation (FSH half-life is several hours; LH half-life is about 20 minutes). HCG is highly sialylated, and accordingly, has a half-life of many hours. However, clearance of gonadotropins as measured by half-lives is not explained totally by carbohydrate differences. Differences in amino acid sequences also contribute, and most importantly, the stability of the complete hormone (resisting dissociation into the rapidly cleared subunits) is a major factor.

Heterogeneity of Prolactin

In most mammalian species, prolactin is a single-chain polypeptide of 199 amino acids, 40% similar in structure to growth hormone and placental lactogen.¹⁶² All three hormones are believed to have originated in a common ancestral protein about 400 million years ago. Many hormones, growth factors, and neurotransmitters affect the prolactin gene.

Simultaneous measurements of prolactin by both bioassay and immunoassay reveal discrepancies. At first, differences in prolactin were observed based on size, leading to the use of terms such as little, big, and the wonderfully sophisticated term, big big prolactin. Further chemical studies have revealed structural modifications that include glycosylation, phosphorylation, and variations in binding and charge. This heterogeneity is the result of many influences at many levels: transcription, translation, and peripheral metabolism.^{163, 164}

Prolactin is encoded by a single gene on chromosome 6, producing a molecule that in its major form is maintained in 3 loops by disulfide bonds.¹⁶² Most, if not all, variants of prolactin are the result of posttranslational modifications. Little prolactin probably represents a splicing variant resulting from the proteolytic deletion of amino acids. Big prolactin can result from the failure to remove introns; it has little biologic activity and does not cross-react with antibodies to the major form of prolactin. The so-called big big variants of prolactin are due to separate molecules of prolactin binding to each other, either noncovalently or by interchain disulfide bonding. Some of the apparently larger forms of prolactin are prolactin molecules complexed to binding proteins.

Other variations exist. Enzymatic cleavage of the prolactin molecule yields fragments that may be capable of biologic activity. Prolactin that has been glycosylated continues to exert activity; differences in the carbohydrate moieties can produce differences in biologic activity and immunoreactivity. However, the nonglycosylated form of prolactin is the predominant form of prolactin secreted into the circulation.¹⁶⁵ Modification of prolactin also includes phosphorylation, deamidation, and sulfation.

The prolactin receptor is encoded by a gene on chromosome 5 that is near the gene for the growth hormone receptor. However, there is evidence for more than one receptor, depending upon the site of action (e.g., decidua and placenta).¹⁶⁶ The prolactin receptor belongs to the receptor family that includes many cytokines and some growth factors, supporting a dual role for prolactin as a classic hormone and as a cytokine. The prolactin signal is mediated through a cytoplasmic tyrosine kinase pathway.

At any one point of time, the bioactivity (e.g., galactorrhea) and the immunoactivity (circulating level by immunoassay) of prolactin represent the cumulative effect of the family of structural variants. Remember, immunoassays do not always reflect the biologic situation (e.g., a normal prolactin level in a woman with galactorrhea).

Up- and Down-Regulation

Positive or negative modulation of receptors by homologous hormones is known as up- and down-regulation. Little is known regarding the mechanism of up-regulation; however, hormones such as prolactin and GnRH can increase the cell membrane concentrations of their own receptors.

Theoretically, deactivation of the hormone-receptor complex could be accomplished by dissociation of the complex or loss of receptors from the cell, either by shedding (externally) or by internalization of the receptors into the cell. It is the process of **internalization** which is the major biologic mechanism by which polypeptide hormones down-regulate their own receptors and thus limit hormonal activity. As a general rule, an excess concentration of a tropic hormone, such as LH or GnRH, will stimulate the process of internalization, leading to a loss of receptors in the cell membrane and a decrease in biological response. We now understand

that the principal reason for the episodic (pulsatile) secretion of hormones is to avoid down-regulation and to maintain, if not up-regulate, its receptors. The pulse frequency is a key factor, therefore, in regulating receptor number; however, further effects on target tissue response also occur at sites distal to receptors. ¹⁶⁷

It is believed that receptors are randomly inserted into the cell membrane after intracellular synthesis. The receptor may be viewed as having 3 important segments, an external binding site that is specific for a polypeptide hormone, the transmembrane region, and an internal site that plays a role in the process of internalization. When the receptor is bound to a polypeptide hormone and when high concentrations of the hormone are present in the circulation, the hormone-receptor complex moves through the cell membrane in a process called lateral migration. Lateral migration carries the complex to a specialized region of the cell membrane, **the coated pit**. Each cell in target tissues contains from 500 to 1500 coated pits. Lateral migration, thus, concentrates hormone-receptor complexes in the coated pit (**clustering**), allowing increased internalization of the complex via the special mechanism of receptor-mediated endocytosis. ¹⁶⁸ The time course for this process (minutes rather than seconds) is too slow to explain the immediate hormone-induced responses, but other cellular events may be mediated by this mechanism that circumvents the intracellular messenger, cyclic AMP.

The coated pit is a lipid vesicle hanging on a basket of specific proteins, called **clathrins** (from the Latin "clathra" meaning "lattice"). The unit is a network of hexagons and pentagons, thus looking like a soccer ball. The internal margin of the pit has a brush border, hence the name coated pit. The clathrin protein network serves to localize the hormone-receptor complexes by binding to the internal binding site on the receptor.

When fully occupied, the coated pit invaginates, pinches off, and enters the cell as a coated vesicle also called a receptosome. The coated vesicle is delivered to the lysosomes in which the structure then undergoes degradation, releasing the substance (e.g., a polypeptide hormone) and the receptor. The receptor may be recycled; i.e., it may be reinserted into the cell membrane and used again. On the other hand, the receptor and the hormone may be metabolized, thus decreasing that hormone's biologic activity. The internalized hormones may also mediate biologic response by influencing cellular organelles such as the Golgi apparatus, the endoplasmic reticulum, and even the nucleus. For example, nuclear membranes from human ovaries bind HCG and LH and there follows an enzyme response that is involved in the transfer of mRNA from nucleus to the cytoplasm. ¹⁶⁹

A similar process, called **potocytosis**, utilizes cholesterol-rich membrane invaginations called **caveolae** (far fewer in number and smaller in structure than the clathrin coated pits) for the internalization of small molecules and ions. ¹⁷⁰ This is another method of intracellular signaling in response to hormones, and many proteins involved in cell signaling have been detected in caveolae; e.g., G proteins, kinases, and growth factor receptors. Caveolin is the major protein structural component of caveolae. Nitric oxide, the important mediator of vascular events, resides in caveolae and is regulated by tyrosine phosphorylation and interaction with caveolin. ^{171, 172} Caveolae also facilitate endocytosis and exocytosis of substances, by the recycling of caveolin between the cell surface and the Golgi network. ¹⁷³

Besides down-regulation of polypeptide hormone receptors, the process of internalization can be utilized for other cellular metabolic events, including the transfer into the cell of vital substances such as iron or vitamins.

Cell membrane receptors can be randomly distributed in the cell membrane and transmit information to modify cell behavior. ¹⁷⁴ For these receptors, internalization is a method for down-regulation by degradation in lysosomes. Because of this degradation, recycling is usually not a feature of this class of receptors. Hormones that utilize this category of receptors include FSH, LH, HCG, GnRH, TSH, TRH, and insulin. For these hormones, the coated pit can be viewed as a trap to immobilize hormone-receptor complexes. The fate of the hormone, however, can vary from tissue to tissue. In some target tissues, HCG is internalized and the HCG-receptor complex is transferred intact from the coated vesicle into the lysosomes for dissociation and degradation. In other tissues, especially the placenta, it is thought that the HCG-receptor complex is recycled back to the cell surface as a means of transporting HCG across the placenta into both maternal and fetal circulations. ¹⁷⁵

Cell membrane receptors, located in the coated pits, when bound to ligands lead to internalization, thus providing the cell with required factors, the removal of noxious agents from the biologic fluid bathing the cell, or the transfer of substances through the cell (transendocytosis). These receptors are spared from degradation and can be recycled. Examples of this category include low-density lipoproteins (LDL), which supply cholesterol to steroid-producing cells, cobalamin and transferrin, which supply vitamin B₁₂ and iron, respectively, and the transfer of immunoglobulins across the placenta to provide fetal immunity.

A closer look at LDL and its receptor is informative. The low-density lipoprotein particle is a sphere. It contains in its center about 1500 molecules of cholesterol which are attached as esters to fatty acids. This core is contained by a bilayer lipid membrane. Protein-binding proteins (the apoproteins) project on the surface of this membrane, and it is these proteins that the receptor must recognize.

Remember, this is an important story, because all cells that produce steroids must use cholesterol as the basic building block. Such cells cannot synthesize enough cholesterol and, therefore, must bring cholesterol into the cell from the bloodstream. LDL is the principal messenger delivering the cholesterol. Experimental evidence, however, indicates that HDL-cholesterol as well as LDL can provide cholesterol to steroid-producing cells. ¹⁷⁶ Indeed, human ovarian granulosa cells use HDL-cholesterol in a system that differs from the LDL-cholesterol pathway: the lipoproteins are not internalized, but rather, the cholesteryl esters are extracted from the lipoproteins at the cell surface and then transferred into the cell. ¹⁷⁷

Different cell surface receptors and proteins contain similar structural parts. ¹⁷⁸ For example, the receptor for LDL contains a region that is homologous to the precursor of epidermal growth factor and another region that is homologous to a component of complement. The LDL receptor is a “mosaic protein.” There are regions of proteins derived from the exons of different gene families. This is an example of a protein that evolved as a new combination of pre-existing functional units of other proteins.

The LDL receptor is synthesized as a precursor of 860 amino acids. The precursor includes 21 amino acids that constitute a hydrophobic signal sequence that is cleaved prior to its insertion into the cell surface. This signal sequence presumably directs the protein where to go in the cell. This leaves an 839 amino acid protein that has 5 recognizable domains.

1. NH₂-terminal of 292 amino acids, composed of a sequence of 40 amino acids repeated with some variation 7 times. This domain is the binding site for LDL and is located on the external surface of the cell membrane.
2. Approximately 400 amino acids 35% homologous to epidermal growth factor precursor.
3. The sugar-linked site.
4. 22 Hydrophobic amino acids that cross the cell membrane. Deletion of the transmembrane signal sequence (found in a naturally occurring mutation) results in an LDL receptor that is secreted from the cell instead of being inserted into the membrane.
5. Cytoplasmic tail of 50 amino acids that is located internally and serves to cluster LDL receptors in coated pits.

When the coated pit is fully occupied with LDL, a coated vesicle is delivered into the cell in the process called endocytosis. The vesicle moves to the Golgi system and then is routed by an unknown mechanism (although a similar coated pit system in the Golgi appears to be involved) to the lysosomes in which the structure undergoes degradation, releasing cholesterol esters and the receptor. The receptor may be recycled or degraded. The intracellular level of free cholesterol influences the following important activities: the rate-limiting enzyme for cholesterol synthesis, the reesterification of excess cholesterol for storage as lipid droplets, and the synthesis of LDL receptors. The cholesterol derived from the LDL transport process can have any one of the following fates: utilization in the mitochondria for steroidogenesis, reesterification for storage, use in membrane structures, or excretion. ¹⁷⁹ Excretion (release of free cholesterol into the circulation by means of the HDL mechanism) involves the cell surface caveolae. ^{170, 173} Thus, entry is via coated pits (endocytosis) and efflux from endoplasmic reticulum to the cell membrane is via caveolae (exocytosis).

Synthesis and insertion of new LDL receptors are a function of LH in the gonads and ACTH in the adrenal. This process is relatively fast. It has been calculated that the coated pit system turns over an amount of cell surface equivalent to the total amount of plasma membrane every 30–90 minutes. ¹⁷⁹ The LDL receptor makes one round trip every 10 minutes during its 20-hour lifespan for a total of several hundred trips. ¹ Genetic defects in receptors for LDL lead to a failure in internalization and hyperlipidemia.

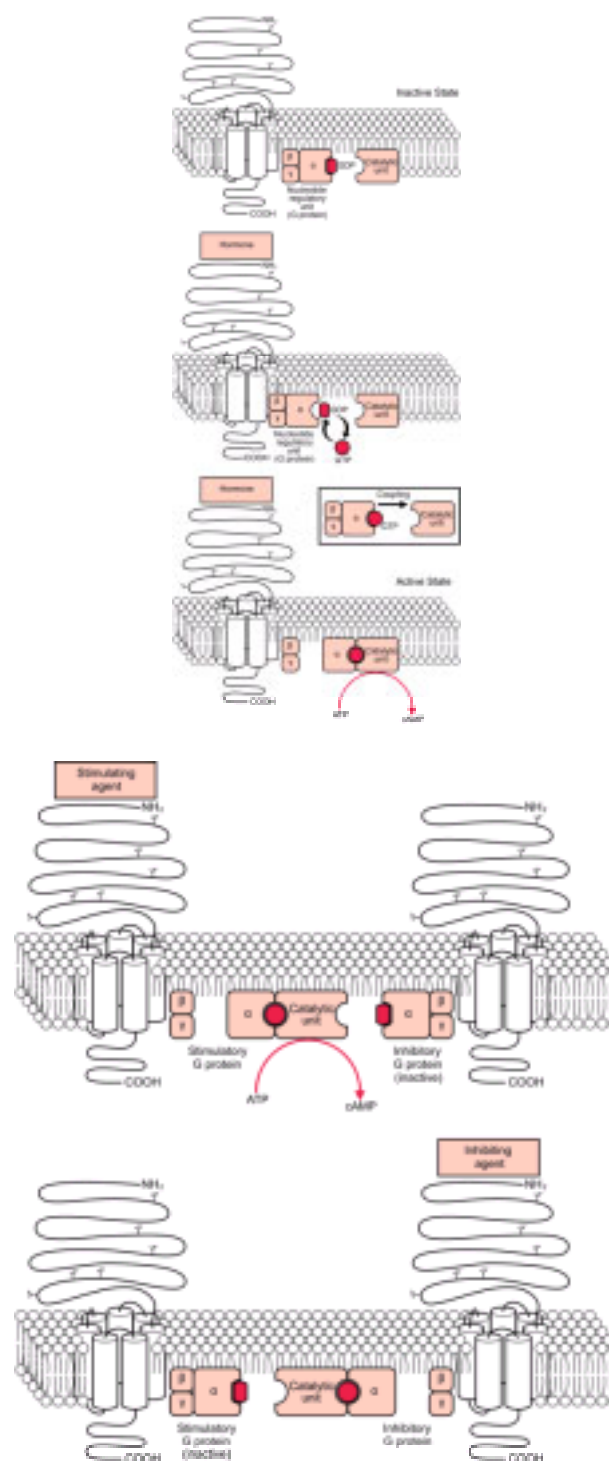

Regulation of Adenylate Cyclase

The biologic activity of polypeptide or glycoprotein hormones (such as FSH or LH) can be altered by autocrine and paracrine regulators, the heterogeneity of the molecules, up- and down-regulation of the receptors, and, finally, by modulation of the activity of the enzyme, adenylate cyclase.

The G Protein System

The 1994 Nobel Prize in Medicine and Physiology was awarded to Alfred G. Gilman and Martin Rodbell for the discovery and description of G proteins. Adenylate cyclase is composed of 3 protein units: the receptor, a guanyl nucleotide regulatory unit, and a catalytic unit. ¹⁸⁰ The regulatory unit is a coupling protein, regulated by guanine nucleotides (specifically GTP), and therefore it is called GTP binding protein or G protein for short. ^{181, 182} The catalytic unit is the enzyme itself which converts ATP to cyclic AMP. The receptor and the nucleotide regulatory unit are structurally linked, but inactive until the hormone binds to the receptor. Upon binding, the complex of hormone, receptor, and nucleotide regulatory unit is activated leading to an uptake of guanosine 5 ϵ -triphosphate (GTP) by the regulatory unit. The activation and uptake of GTP result in an active enzyme that can convert ATP to cyclic AMP. This result can be viewed as the outcome of the regulatory unit **coupling** with the catalytic unit, forming an intact complete enzyme. Enzyme activity is then terminated by hydrolysis of the GTP to guanosine 5 ϵ -diphosphate (GDP) returning the enzyme to its inactive state. Quick action and acute control of adenylate cyclase are assured because the G protein is a GTPase that self-activates upon binding of GTP.

The G protein has been purified. From the amino acid sequence, complementary DNA clones have been produced. These studies have indicated that a family of G proteins exists that couples receptors to active proteins, playing roles in signal transduction, intracellular transport, and exocytosis. The ability of the hormone-receptor complex to work through a common messenger (cyclic AMP) and produce contrasting actions (stimulation and inhibition) is thought to be due to the presence of both stimulatory nucleotide regulatory G proteins and inhibitory nucleotide regulatory G proteins. ^{183, 184} However, the G protein system is not limited to the cyclic AMP signal, but can activate other messenger-generating enzymes, as well as ion channels.

The G proteins are composed of α -, β -, and γ -subunits, each the product of many distinct genes.¹⁸⁵ The β - and γ -subunits are not all alike, and they exhibit selectivity for specific receptors. Each G protein has a unique α -subunit, and there are 16 mammalian α -subunit genes. Based on amino acid similarities, they are grouped into 4 subfamilies: $G_{\alpha s}$, $G_{\alpha q}$, $G_{\alpha i}$, $G_{\alpha 12}$. $G_{\alpha s}$ and $G_{\alpha q}$ proteins mediate stimulatory events such as hormone secretion, whereas $G_{\alpha i}$ proteins exert inhibition. The role of the $G_{\alpha 12}$ group is not yet certain. These multiple subunits allow great variability in function to be expressed by many different combinations.

In the inactive state GDP is bound to the α -subunit. Hormone-receptor interaction and binding change the α -subunit conformation. GTP replaces GDP on the α -subunit, freeing the β - and γ -subunits, which allows the GTP- α -subunit to bind to the catalytic unit of adenylate cyclase, forming the active enzyme. The GTP- α -subunit can also activate other messengers, such as ion channels. Intrinsic GTPase activity quickly hydrolyzes the GTP- α to GDP- α , which leads to reassociation with the β - and γ -subunits, reforming the G protein complex for further activation. The functional specificity is due to the α -subunit which differs for each G protein, and therefore there are many different α -subunits encoded by different genes.

The G protein Receptors

The more than 200 receptors linked to G proteins are derived from a supergene family, presumably originating from a common ancestral gene. The gonadotropin receptor contains a transmembrane region that has the structural features of a receptor that couples with G protein and a large extracellular domain.¹⁸⁶ Receptors that utilize the G proteins are inserted in membranes and consist of a long polypeptide chain that folds into 7 helices, the amino acid loops that connect the helices extend either into the cytoplasm or into the extracellular space. The amino end extends outside the cell, and the carboxyl end extends into the cell. The large extracellular segment is the site for specific gonadotropin recognition and binding. Binding changes the conformation (which is associated with phosphorylation), leading to interaction with the G proteins, which in turn activate second messengers, either enzymes or ion channels. These are ancient proteins; e.g., they are used by yeast to detect mating pheromones (perhaps this is why this protein is the basic structure for sight and smell in higher organisms; rhodopsin is a G protein located in the light-sensitive rod of the retina). Thus, the G receptors can be activated by hormones, neurotransmitters, growth factors, odorants, and photons of light.

LH and HCG bind to a common receptor, encoded by a gene on chromosome 2. The LH/HCG receptor is highly conserved in mammals; the human receptor is very similar to that of rat and bovine receptors.¹⁸⁷ It is likely that expression of the LH/HCG receptor is regulated by many factors, including endocrine, paracrine, and autocrine mechanisms, but the primary requirement is FSH. In addition to the G protein pathway, activation of the LH/HCG receptor stimulates the calcium messenger system. Actually, two LH/HCG receptor genes have been isolated (Gene I and Gene II), Gene I from a lymphocyte library and Gene II from a human placental library.^{188, 189} Gene II appears to be the major form expressed in the ovary.

The receptor for FSH is very similar to the LH/HCG receptor, but it is structurally distinct.^{190, 191} Appropriately (for specificity), the extracellular segment contains the major sequence divergence. The FSH receptor gene is located on chromosome 2p21, near the LH/HCG receptor gene. The FSH receptor is also regulated by its hormone environment, especially by FSH and estradiol. Other members of this family include receptors for TSH, catecholamines, vasopressin, angiotensin II, and dopamine.

Mutations in the G protein System

Mutations that alter the structure and activity of G proteins can result in disease.^{182, 192} Loss of function mutations of a G protein or a given receptor will result in hormone deficiency syndromes; e.g., the TSH receptor and hypothyroidism, the LH receptor and male pseudohermaphroditism, and pseudohypoparathyroidism due to a $G_{\alpha s}$ mutation. The McCune-Albright syndrome (sexual precocity, polyostotic fibrous dysplasia, café-au-lait skin pigmentation, and autonomous functioning of various endocrine glands) is due to unregulated activity (gain in function) of the adenylate cyclase system because of a mutation in the $G_{\alpha s}$ gene. $G_{\alpha s}$ protein mutations have also been found in adrenal and ovarian tumors, growth hormone-secreting pituitary adenomas, and thyroid adenomas. It is possible that alterations in the G protein system may ultimately explain abnormalities in endocrine-metabolic functions, as well as oncogenic mutations.^{183, 184, 193}

Some Genetic Diseases Due to Specific G Protein System Mutations

Mutation	Disorder
Activating LH receptor	Precocious puberty in boys
Inactivating LH receptor	Male pseudohermaphroditism
Inactivating FSH receptor	Premature ovarian failure
$G_{\alpha s}$ (stimulatory)	McCune-Albright syndrome
$G_{\alpha i}$ (inhibitory)	Hypothyroidism

Rhodopsin	Retinitis pigmentosa
Vasopressin	Diabetes insipidus

Coupling and Uncoupling, Desensitization

Another way to explain stimulating and inhibiting actions at the adenylate cyclase level focuses on the mechanism of coupling. LH stimulates steroidogenesis in the corpus luteum and works through the coupling of stimulatory regulatory units to the catalytic units of adenylate cyclase. Prostaglandin F_{2a} is directly luteolytic, inhibiting luteal steroidogenesis through a mechanism that follows binding to specific receptors. This luteolytic action may be exerted via an inhibitory regulatory unit that leads to uncoupling with the catalytic unit, thus interfering with gonadotropin action.

Increasing concentrations of tropic hormones, such as gonadotropins, are directly associated with desensitization of adenylate cyclase independent of the internalization of receptors. Desensitization is a rapid, acute change without loss of receptors in contrast to the slower process of internalization and true receptor loss. The desensitization process after prolonged agonist exposure involves receptor phosphorylation (which uncouples the receptor from the G protein). The LH/HCG receptor, a member of the G protein family, undergoes desensitization/uncoupling in response to LH or HCG in a process that involves phosphorylation of the C-terminal cytoplasmic tail of the receptor.¹⁹⁴ Decreased gonadotropin secretion in the presence of prolonged continuous GnRH stimulation is a desensitization response that can occur followed by recovery within the time frame of a normal endogenous GnRH secretory pulse.¹⁹⁵

Summary of Down-Regulation

Down-regulation is a decrease in response in the presence of continuous stimulation. It involves the following 3 mechanisms:

1. **Desensitization by autophosphorylation of the cytoplasmic segment of the receptor.**
2. **Loss of receptors by internalization, a relatively slow mechanism.**
3. **Uncoupling of the regulatory and catalytic subunits of the adenylate cyclase enzyme.**

The great names of early Western medicine were Hippocrates, Soranus, and Galen. Although Aristotle (384–322 BC) referred to castration as a common agricultural practice, it was Soranus who provided the first anatomical description of the ovaries. Soranus of Ephesus (a city founded by Greeks on the coast of what is now Turkey) lived from 98 to 138 AD and has often been referred to as the greatest gynecologist of antiquity. ¹ He studied in Alexandria and practiced in Rome. His great text was lost for centuries and was not published until 1838.

Galen was born in 130 AD in Pergamum, a Greek city in eastern Turkey, studied in Alexandria and became a famous practitioner and teacher of medicine in Rome. He lived 70 years and wrote about 400 treatises, 83 of which are still in existence. Galen preserved in his own writings (in Greek) Aristotle's descriptions of reproduction. He was a true scholar and was regarded as the ultimate authority on anatomy and physiology until the sixteenth century. ² It was Galen who established bleeding as the appropriate treatment for almost every disorder. Although in retrospect Galen's conclusions and teachings contained many errors, how many other individuals have been able to satisfy the needs of scholars and physicians for hundreds of years?

After Galen, no further thoughts or advances were recorded for well over 1000 years as the dark weight of the medieval ages descended on western civilization. During the medieval years, it was safe to copy Galen's works but literally dangerous to contribute anything original. Medieval scholars believed it was impossible to progress in knowledge beyond Galen. The doctrine according to Galen was not challenged until the introduction of printing made Galen's works available to scholars.

Although Leonardo da Vinci (1452–1519) drew accurately the anatomy of the uterus and the ovaries, the major advances in anatomical knowledge can be traced to the University of Padua, the famed Italian university where a succession of anatomists made important contributions. ³ It was Andreas Vesalius (1514–1564), who while still in his 20s, because of his own human dissections, realized that Galen described only animals. Appointed Professor of Surgery and Anatomy at the University of Padua at the age of 23, he published *De Humani corporis Fabrica*, his authoritative, illustrated book on human anatomy, in 1543, at the age of 29. Vesalius was harshly attacked by the medical establishment, and one year after the publication of his book, he left Padua to become the court physician in Spain.

Vesalius was the first to describe ovarian follicles and probably the corpus luteum. Fallopius (1534–1562), remembered for his description of the fallopian tubes, was a pupil of Vesalius, and then a successful and popular teacher of anatomy at Padua. Fabricius (Girolamo Fabrici d'Acquapendente, 1533–1619), a pupil of Fallopius, succeeded Fallopius as chair of anatomy at Padua and made major contributions to embryology. Studying the organ in the bird that contained eggs, Fabricius called it the “vary.” During this period of time, the ovaries came to be recognized as structures, but their function remained a mystery.

William Harvey published the first original English book on reproductive anatomy and physiology in 1651, at the age of 69, 35 years after his discovery of the circulation of blood. He obtained his medical education at the University of Padua where he learned to describe accurately his own observations, a practice he was to continue and that culminated in his writings. Unfortunately, Harvey promoted and maintained the Aristotelian belief that the egg was a product of conception, a result of an interaction between semen and menstrual blood. This view was corrected by Bishop Niels Stensen of Denmark in 1667, and in 1672, at the age of 31, the Dutch physician Regnier de Graaf published his great work on the female reproductive organs, *De Mulierum Organis Generationi Inservientibus Tractatus Novus* (A New Treatise on the Female Reproductive Organs), that established the ovary as the source of the ovum.

Ovarian follicles had been described by Vesalius and Fallopius, but the impact of his publication earned de Graaf eternal recognition as the ovarian follicle became known as the Graafian follicle, even though de Graaf believed that the whole follicle was the egg. de Graaf was the first to accurately describe the corpus luteum, although Malpighi, whose works were published posthumously in 1697, invented the name “corpus luteum.”

With the discovery of mammalian spermatozoa by van Leeuwenhoek in 1677, it became possible to speculate that fertilization resulted from the combination of a spermatozoon and the Graafian follicle. It would be another 150 years before it was appreciated that the oocyte resides within the follicle (described in 1827 by Carl Ernst von Baer), and that there is a relationship between the ovaries and menstruation. The process of fertilization was described by Newport in 1853–54, bringing to a close the era of descriptive anatomy of the ovary and marking the beginning of scientific explorations into physiology and endocrinology.

The Human Ovary

The physiologic responsibilities of the ovary are the periodic release of gametes (eggs) (oocytes) and the production of the steroid hormones, estradiol and progesterone. Both activities are integrated in the continuous repetitive process of follicle maturation, ovulation, and corpus luteum formation and regression. The ovary, therefore, cannot be viewed as a relatively static endocrine organ whose size and function expand and contract, depending on the vigor of stimulating tropic hormones. Rather, the female gonad is a heterogeneous ever-changing tissue whose cyclicity is measured in weeks, rather than hours.

The ovary consists of three major portions, the outer cortex, the central medulla, and the rete ovarii (the hilum). The hilum is the point of attachment of the ovary to the mesovarium. It contains nerves, blood vessels, and hilus cells, which have the potential to become active in steroidogenesis or to form tumors. These cells are very similar to the testosterone-producing Leydig cells of the testes. The outermost portion of the cortex is called the tunica albuginea, topped on its surface by a single layer of cuboidal epithelium, the germinal epithelium. The oocytes, enclosed in complexes called follicles, are in the inner part of the cortex, embedded in stromal tissue. The stromal tissue is composed of connective tissue and interstitial cells which are derived from mesenchymal cells, and have the ability to respond to luteinizing hormone (LH) or human chorionic gonadotropin (HCG) with androgen production. The central medullary area of the ovary is derived largely from mesonephric cells.

The Fetal Ovary

During fetal life, the development of the human ovary can be traced through four stages. ⁴ These are 1) the indifferent gonad stage, 2) the stage of differentiation, 3) the period of oogonial multiplication and oocyte formation, and finally 4) the stage of follicle formation.

The Indifferent Gonad Stage

At approximately 5 weeks of gestation, the paired gonads are structurally consolidated coelomic prominences overlying the mesonephros, forming the gonadal ridges. At this point, the gonad is morphologically indistinguishable as a primordial testis or ovary. The gonad is composed of primitive germ cells intermingled with coelomic surface epithelial cells and an inner core of medullary mesenchymal tissue. Just below this ridge lies the mesonephric duct. This indifferent stage lasts about 7–10

days. Together, the mesonephros and the genital ridge are called the urogenital ridge, indicating the close association of the urinary and reproductive systems.

The origin of the gonadal somatic cells is still not certain. The earliest recognizable gonad contains, besides the germ cells, somatic cells derived from at least 3 different tissues: coelomic epithelium, mesenchyme, and mesonephric tissue. In one model, the gonad is formed by the invasion of the "germinal epithelium" into the underlying mesenchyme. The germinal epithelium is simply that part of the coelomic epithelium that gives rise to gonadal tissue. The invading cells form the primary sex cords that contain the germ cells surrounded by somatic cells (the cells destined to form the tissue that holds the germ cells). In a newer model, the somatic cells of the gonad are believed to arise from the mesonephros and not the coelomic epithelium.⁵ Ultrastructural studies have even suggested that both coelomic epithelial and underlying mesonephric cells provide the somatic cells that are destined to become follicular cells.⁶

The primordial germ cells originate within the primitive ectoderm, but the specific cells of origin cannot be distinguished. The germ cells are first identified at the end of the 3rd week after fertilization in the primitive endoderm at the caudal end and in the dorsal wall of the adjacent yolk sac, and, soon, they also appear in the splanchnic mesoderm of the hindgut.⁷ The gonadal ridge is the one and only site where the germ cells can survive. By displacement because of growth of the embryo and also by active amoeboid movement along the dorsal mesentery of the genital ridges, the germ cells "migrate" from the yolk sac through the hindgut to their gonadal sites between weeks 4 and 6 of gestation. The factors that initiate and guide the migration of the germ cells are not known, although chemotactic and adhesive peptides are involved. In rodents, germ cell migration involves stem cell factor and the expression of its receptor (kit) encoded by the C-kit proto-oncogene. In gonads obtained from individuals with intersex disorders that have a high risk of testicular tumors, the expression of kit protein was detected at a later gestational age than in normal controls, consistent with both later germ cell migration and a change in the oncogene expression.⁸

The germ cells begin their proliferation during their migration.⁶ The germ cells are the direct precursors of sperm and ova, and by the 6th gestational week, on completion of the indifferent state, these primordial germ cells have multiplied by mitosis to a total of 10,000. By the 6th week of gestation, the indifferent gonads contain the germ cells and supporting cells derived from the coelomic epithelium and the mesenchyme of the gonadal ridge.

The Stage of Differentiation

If the indifferent gonad is destined to become a testis, differentiation along this line will take place at 6–9 gestational weeks. The absence of testicular evolution (formation of medullary primary sex cords, primitive tubules, and incorporation of germ cells) gives implicit evidence of the existence of a primitive, albeit momentarily quiescent, ovary. In contrast to the male, female internal and external genitalia differentiation precedes gonadal maturation. These events are related to the genetic constitution and the territorial receptivity of the mesenchyme. If either factor is deficient or defective, improper development occurs. As has been noted, primitive germ cells are unable to survive in locations other than the gonadal ridge. If partial or imperfect gonadal tissue is formed, the resulting abnormal nonsteroidal and steroidal events have wide ranging morphologic, reproductive, and behavioral effects.

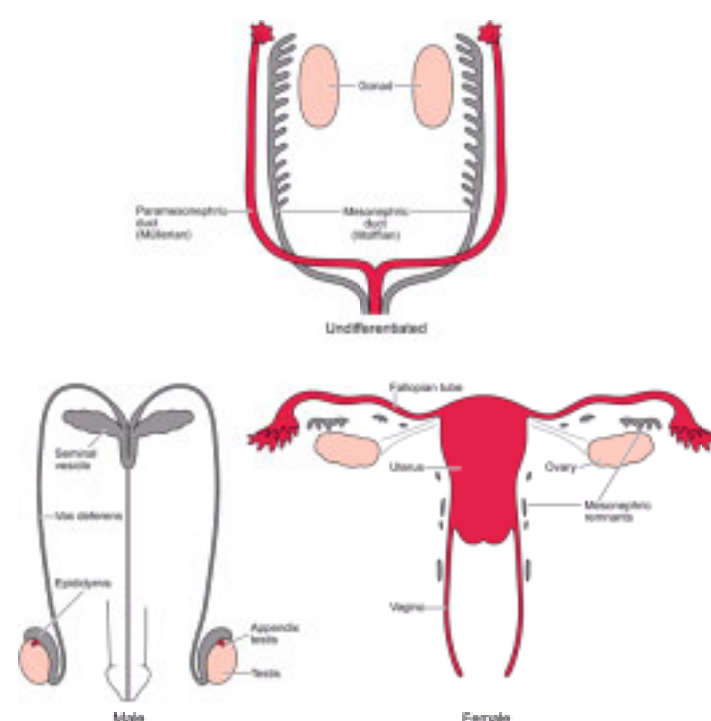

The Testes

The factor that determines whether the indifferent gonad will become a testis is called, appropriately, the testes-determining factor (TDF), a product of a gene located on the Y chromosome.⁹ Currently, the best candidate for the testicular determining factor gene is located within a region named SRY, the sex-determining region on the Y chromosome.¹⁰ The protein product of the SRY gene contains a DNA-binding domain to activate gene transcription.¹¹ Normal testis development requires not only the presence of the SRY gene but its interaction with other genes.¹² Genes similar to SRY have been named SOX genes (the similarity is with the SRY box region that contains the DNA-binding sequence).¹¹ The expression of the SRY gene is confined to the genital ridge during fetal life, but the gene is also active in the germ cells of the adult, perhaps playing a role in spermatogenesis.⁹ The traditional view assigns active gene control and expression for testicular differentiation and a more passive, "default" mode of development for the ovary. However, any process of differentiation requires gene expression, and therefore ovarian development, too, must involve genes and gene products.

When the Y chromosome containing the testes-determining region is present, the gonads develop into testes. The male phenotype is dependent on the products (anti-müllerian hormone and testosterone) of the fetal testes, while the female phenotype is the result of an absence of these fetal gonadal products.¹³ Anti-müllerian hormone (AMH), which inhibits the formation of the müllerian ducts, is secreted at the time of Sertoli cell differentiation, beginning at 7 weeks. AMH expression is altered only by mutations in the AMH gene.¹⁴ Regression of the müllerian ducts is dependent on the presence of an adequate number of Sertoli cells, and probably the regulation of AMH receptor.¹⁵ After involution of the müllerian system, AMH continues to be secreted, but there is no known function. However, evidence in the mouse suggests a role in early germ cell transformation during spermatogenesis.¹⁶ In the ovary, very small amounts of AMH mRNA are present early in life, and although there may be no role in female development, its production later in life by the granulosa cells raises the possibility of autocrine and paracrine actions in oocyte maturation and follicular development.¹⁷

The testis begins its differentiation in week 6–7 of gestation by the appearance of Sertoli cells that aggregate to form the testicular cords. The primordial germ cells are embedded in the testicular cords that will form the Sertoli cells and spermatogonia. The mature Sertoli cells are the site of production of ABP (androgen binding protein, important in maintaining the high local androgen environment necessary for spermatogenesis) and inhibin.

The Leydig cells differentiate (beginning week 8) from mesenchymal cells of the interstitial component surrounding the testicular cords. Thus, secretion of AMH precedes steroidogenesis in Leydig cells. Shortly after the appearance of the Leydig cells, secretion of testosterone begins. Androgen secretion increases in conjunction with increasing Leydig cell numbers until a peak is reached at 15–18 weeks. At this time, Leydig cell regression begins, and at birth, only a few Leydig cells are present.

The cycle of fetal Leydig cells follows the rise and decline of fetal human chorionic gonadotropin (HCG) levels during pregnancy. This relationship and the presence of HCG receptors in the fetal testes indicate a regulatory role for HCG.⁴ The pattern of HCG in the fetus parallels that of the mother, peaking at about 10 weeks and declining to a nadir at 20 weeks of gestation, but the concentrations are only 5% of maternal concentrations.

Testosterone synthesis in human fetal testes begins at the 8th week of gestation, reaches a peak between 15–18 weeks, and then declines. Testicular function in the fetus can be correlated with the fetal hormonal patterns. Although the initial testosterone production and sexual differentiation are in response to the fetal levels of HCG, further testosterone production and masculine differentiation are maintained by the fetal pituitary gonadotropins. Decreased testosterone levels in late gestation probably reflect the decrease in gonadotropin levels. The fetal Leydig cells, by an unknown mechanism, avoid down-regulation and respond to high levels of HCG and LH by increased steroidogenesis and cell multiplication. This generation of cells is replaced by the adult generation of Leydig cells that becomes functional at puberty.

and responds to high levels of HCG and LH with down-regulation and decreased steroidogenesis.

Leydig cells, therefore, are composed of two distinct populations, one active during fetal life and one active during adult life. The regression of fetal Leydig cells and the appearance of morphologically distinct adult cells during the peripubertal period raise many questions: what is the relationship between these two types, what is the mechanism for the regression and for the new appearance, and what is the origin of the adult cells?

The fetal spermatogonia, derived from the primordial germ cells, are in the testicular cords, surrounded by the Sertoli cells. In contrast to the female, male germ cells do not start meiotic division before puberty.

The differentiation of the wolffian system begins with the increase in testicular testosterone production. The classic experiments by Jost indicate that this effect of testosterone is due to local action, probably explaining why male internal genitalia in true hermaphrodites are only on the side of the testis.¹³ Not all androgen-sensitive tissues require the prior conversion of testosterone to dihydrotestosterone (DHT). In the process of masculine differentiation, the development of the wolffian duct structures (epidymis, the vas deferens, and the seminal vesicle) is dependent on testosterone as the intracellular mediator, whereas development of the urogenital sinus and urogenital tubercle into the male external genitalia, urethra, and prostate requires the conversion of testosterone to DHT.¹⁸ In the female, the loss of the wolffian system is due to the lack of locally produced testosterone.

The Stage of Oogonal Multiplication and Oocyte Formation

At 6–8 weeks, the first signs of ovarian differentiation are reflected in the rapid mitotic multiplication of germ cells, reaching 6–7 million oogonia by 16–20 weeks.^{7, 19} This represents the maximal oogonal content of the gonad. From this point in time, germ cell content will irretrievably decrease until, some 50 years later, the store of oocytes will be finally exhausted.

By mitosis, the germ cells give rise to the oogonia. The oogonia are transformed to oocytes as they enter the first meiotic division and arrest in prophase. This process begins at 11–12 weeks, perhaps in response to a factor or factors produced by the rete ovarii.²⁰ Progression of meiosis to the diplotene stage is accomplished throughout the rest of pregnancy and completed by birth. Arrest of meiosis at the end of the first stage is probably maintained by inhibiting substances produced by granulosa cells. A single ovum is formed from the two meiotic divisions of the oocyte, one just before ovulation and the second (forming the haploid ovum) at the time of sperm penetration. The excess genetic material is extruded as one polar body at each meiotic division. Gonadotropins and various growth factors (but not sex steroids) can induce resumption of meiosis in vitro, but only in oocytes enclosed by cumulus-granulosa cells. A family of sterols is present in follicular fluid, presumably secreted by the cumulus cells, that activates oocyte meiosis.²¹

Loss of germ cells takes place throughout all of these events: during mitosis of germ cells, during the various stages of meiosis, and finally, after follicle formation. The massive loss of oocytes during the second half of pregnancy is the consequence of several mechanisms. Besides follicular growth and atresia, substantial numbers of oocytes regress during meiosis, and those oogonia that fail to be enveloped by granulosa cells undergo degeneration. This process is influenced by genes that actively repress germ cell death.²² In addition, germ cells (in the cortical area) migrate to the surface of the gonad and become incorporated into the surface epithelium or are eliminated into the peritoneal cavity.^{23, 24} In contrast, once all oocytes are encased in follicles (shortly after birth), the loss of oocytes will be only through the process of follicular growth and atresia.

Chromosomal anomalies can accelerate germ cell loss. Individuals with Turner syndrome (45,X) experience normal migration and mitosis of germ cells, but the oogonia do not undergo meiosis, and rapid loss of oocytes leaves the gonad without follicles by birth, and it appears as a fibrous streak.

The Stage of Follicle Formation

At 18–20 weeks, the highly cellular cortex is gradually perforated by vascular channels originating in the deeper medullary areas, and this marks the beginning of follicle formation.²⁵ As the finger-like vascular projections enter the cortex, it takes on the appearance of secondary sex cords. As blood vessels invade and penetrate, they divide the previously solid cortical cell mass into smaller and smaller segments. Drawn in with the blood vessels are perivascular cells that are either mesenchymal or epithelial in origin. These cells surround the oocytes that have completed the first stage of meiosis. The resulting unit is the **primordial follicle — an oocyte arrested in prophase of meiosis, enveloped by a single layer of spindle-shaped pregranulosa cells, surrounded by a basement membrane.** Eventually all oocytes are covered in this fashion. Residual mesenchyme not utilized in primordial follicle formation is noted in the interstices between follicles, forming the primitive ovarian stroma. The granulosa cells differentiate from coelomic epithelial or mesenchymal precursors (their specific origin is still disputed). This process of primordial follicular development continues until all oocytes in the diplotene stage can be found in follicles, some time shortly after birth.

As soon as the oocyte is surrounded by the rosette of pregranulosa cells, the entire follicle can undergo variable degrees of maturation before arresting and becoming atretic. The formation of a **primary follicle** is marked by a change of the pregranulosa layer to a cuboidal layer of granulosa cells. Further differentiation into a **preantral follicle** is expressed as more complete granulosa proliferation. Call-Exner body formation (coalescence to form an antrum) and occasionally a minor thecal layer system that differentiates from surrounding mesenchymal cells can be seen. Preantral follicles can be found in the 6th month of gestation, and **antral follicles** (the Graafian follicle, characterized by a fluid-filled space) are present by the end of pregnancy, but not in large numbers. It is only during the last third of gestation that theca cells can be found surrounding follicles.¹⁹

Even in fetal life the cycle of follicle formation, variable ripening, and atresia occurs. Although these steps are precisely those typical of adult reproductive life, full maturity, as expressed in ovulation, does not occur. Estrogen production does not occur until late in pregnancy when follicular development takes place, and even then steroidogenesis is not significant. Unlike the male, gonadal steroid production is not required for development of a normal phenotype. The development of the

müllerian duct into the fallopian tubes, the uterus, and the upper third of the vagina is totally independent of the ovary.

The ovary at birth and in the first year of life can contain cystic follicles of varying size, undoubtedly stimulated by the reactive gonadotropin surge accompanying the withdrawal of the neonatal hypothalamus and pituitary from the negative feedback of fetoplacental steroids.²⁶ Ovarian cysts can also be occasionally detected in fetuses by ultrasonography.

The anterior pituitary begins development between 4 and 5 weeks of fetal life. The median eminence is apparent by week 9 of gestation, and the hypothalamic-pituitary portal circulation is functional by the 12th week. Pituitary levels of follicle-stimulating hormone (FSH) peak at 20–23 weeks, and circulating levels peak at 28 weeks. Levels are higher in female fetuses than in males until the last 6 weeks of gestation. Ovaries in anencephalic fetuses which lack gonadotropin-releasing hormone (GnRH) and gonadotropin secretion lack antral follicles and are smaller at term, but progression through meiosis and development of primordial follicles occur, apparently not dependent upon gonadotropins.⁴ The ovary develops receptors for gonadotropins only in the second half of pregnancy. Thus, the loss of oocytes during fetal life cannot be solely explained by the decline in gonadotropins. The follicular growth and development observed in the second half of pregnancy, however, is gonadotropin dependent.²⁷ Hypophysectomy of a fetal monkey is followed by an increase in oocyte loss by atresia.²⁸

The Neonatal Ovary

The total cortical content of germ cells falls to 1–2 million by birth as a result of prenatal oocyte depletion.²⁹ This huge depletion of germ cell mass (close to 4–5 million) has occurred over as short a time as 20 weeks. No similar rate of depletion will be seen again. Because of the fixed initial endowment of germ cells, the newborn female enters life, still far from reproductive potential, having lost 80% of her oocytes.

The ovary is approximately 1 cm in diameter and weighs about 250–350 mg at birth, although sizable cystic follicles can enlarge the total dimensions. Intriguingly, the gonad on the right side of the body in both males and females is larger, heavier, and greater in protein and DNA content than the gonad on the left side.³⁰ Compartmentalization of the gonad into cortex and a small residual medulla has been achieved. In the cortex, almost all the oocytes are involved in primordial follicle units. Varying degrees of maturation in some units can be seen as in the fetal state.

There is a sex difference in fetal gonadotropin levels. There are higher pituitary and circulating FSH and pituitary LH levels in female fetuses. The lower male levels are probably due to testicular testosterone and inhibin production. In infancy, the postnatal FSH rise is more marked and more sustained in females, whereas LH values are not as high. The FSH levels are greater than the levels reached during a normal adult menstrual cycle, decreasing to low levels usually by one year of age, but sometimes later.³¹ LH levels are in the range of lower adult levels. This early activity is accompanied by inhibin levels comparable to the low range observed during the follicular phase of the menstrual cycle. Follicular response to the antral stage is relatively common in the first 6 months of life in response to these elevated gonadotropin levels. The most common cause of abdominal masses in fetuses and newborns is ovarian cysts, a consequence of gonadotropin stimulation.³²

Interference with the postnatal rise in gonadotropins in monkeys is associated with disturbances in normal hypothalamic-pituitary function at puberty.³³ Indeed, in male monkeys, the administration of a GnRH analogue in the neonatal period has an adverse impact on subsequent immunologic and behavioral functions as well as normal reproduction.³³ After the postnatal rise, gonadotropin levels reach a nadir during early childhood (by about 6 months of age in males and 1–2 years in females) and then rise slightly between 4 and 10 years.

The Ovary in Childhood

The childhood period is characterized by low levels of gonadotropins in the pituitary and in the blood, little response of the pituitary to GnRH, and maximal hypothalamic suppression. The ovary, however, is not quiescent during childhood. Follicles begin to grow at all times and frequently reach the antral stage. Ultrasonography can commonly demonstrate ovarian follicular cysts during childhood, ranging in size from 2 to 15 mm.³⁴ These small unilocular ovarian cysts are not clinically significant.³⁵ The process of atresia with an increasing contribution of follicular remnants to the stromal compartment yields progressive ovarian enlargement during childhood, about a ten-fold increase in weight.³⁶ Of course, the lack of gonadotropin support prevents full follicular development and function. There is no evidence that ovarian function is necessary until puberty. However, the oocytes during this time period are active, synthesizing mRNAs and protein. Furthermore, ovariectomy in prepubertal monkeys indicates that the prepubertal suppression of GnRH and gonadotropins is partially dependent on the presence of ovaries, suggesting some functional activity of the ovary in childhood.³⁷

The Adult Ovary

At the onset of puberty, the germ cell mass has been reduced to 300,000 to 500,000 units.^{7,38} During the next 35–40 years of reproductive life, 400 to 500 will be selected to ovulate, and the primary follicles will eventually be depleted to a point at menopause when only a few hundred remain.³⁹ In the last 10–15 years before menopause, there is an acceleration of follicular loss.^{40,41} This loss correlates with a subtle but real increase in FSH and decrease in inhibin B as well as insulin-like growth factor-I (IGF-I).^{42,43,44,45 and 46} The accelerated loss is probably secondary to the increase in FSH stimulation. Fewer follicles grow per cycle as a woman ages, and cycles are at first shorter due to more rapid follicular growth prior to ovulation (because of the elevated FSH levels) and then longer as anovulation becomes more common.^{47,48 and 49} These changes, including the increase in FSH (which is probably due to the decrease in inhibin B), all reflect the reduced quality and capability of aging follicles. However, the rise in FSH due to a decrease in inhibin B may be the consequence of a decreasing number of follicles in each cohort of active follicles.⁵⁰

The loss of oocytes (and follicles) through atresia is a response to changes in many factors. Certainly gonadotropin stimulation and withdrawal are important, but ovarian steroids and autocrine and paracrine factors are also involved. The consequence of these unfavorable changes, atresia, is a process called **apoptosis**, programmed cell death. This process is heralded by alterations in mRNAs required for cell proteins that maintain follicle integrity.⁵¹ Indeed, the process is a consequence of an orderly expression of key gene products that either promote or repress the apoptotic events.

Unlike nonprimate species, human ovaries and nonhuman primate ovaries are innervated by sympathetic and sensory neurons.⁵² This neuronal network innervates the ovarian vasculature, interstitial tissue, and developing follicles. These neuronal cells produce catecholamines and nerve growth factor. The precise function for this unique primate ovarian nervous system is not known. However, nerve fibers (not in an organized network) are present in nonprimate ovaries. Vasoactive intestinal peptide derived from these nerve fibers suppresses follicular atresia (apoptosis) in a mechanism that also involves IGF-I.⁵³

During the reproductive years, the typical cycle of follicle maturation, including ovulation and corpus luteum formation, will be realized. This results from the complex

but well defined sequence of hypothalamic-pituitary-gonadal interactions in which follicle and corpus luteum steroid hormones, pituitary gonadotropins, and autocrine and paracrine factors are integrated to yield ovulation. These important events are described in detail in [Chapter 5](#) and [Chapter 6](#). For the moment, our attention will be exclusively directed to a description of the events as the gonad is driven inexorably to final and complete exhaustion of its germ cell supply. The major feature of this reproductive period in the ovary's existence is the full maturational expression of some follicle units in ovulation and corpus luteum formation and the accompaniment of varying steroid output of estradiol and progesterone. For every follicle that ovulates, close to 1000 will pursue abortive growth periods of variable length.

Follicular Growth

In the adult ovary, the stages of follicle development observed even in the prenatal period are repeated but to a more complete degree. Initially, the oocyte enlarges and the granulosa cells proliferate markedly. A solid sphere of cells encasing the oocyte is formed. At this point, the theca interna is noted in initial stages of formation. The zona pellucida begins to form.

It is now believed that the time that elapses in progressing from a primary follicle to ovulation is approximately 85 days. ^{54, 55} The majority of this time passes in development that is independent of gonadotropins, achieving a state of readiness that will yield further growth in response to FSH stimulation. If gonadotropin increments are available, as can be seen early in a menstrual cycle, a further FSH-dependent stage of follicle maturation is seen. The number of follicles that mature is dependent on the amount of FSH available to the gonad and the sensitivity of the follicles to the gonadotropins. FSH receptor expression is greatest in granulosa cells, but significant expression can be detected in ovarian surface epithelium and fallopian tube epithelium, where the function is uncertain, but a role in epithelium-derived tumors is possible. ⁵⁶

The antrum first appears as a coalescence of numerous intragranulosa cavities called Call-Exner bodies, that were described by Emma Call and Siegmund Exner in Vienna, in 1875. Emma Call was one of the first woman physicians in the United States. ⁵⁷ After receiving her medical degree from the University of Michigan, in 1873, she went to Vienna as Exner's postgraduate student. She returned to Boston and practiced as an obstetrician for more than 40 years. Emma Call was the first woman elected to the Massachusetts Medical Society (in 1884). Her description of the Call-Exner bodies was her only publication.

Whether Call-Exner bodies represent liquefaction or granulosa cell secretion is uncertain. At first, the cavity is filled with a coagulum of cellular debris. Soon a liquor accumulates, which is essentially a transudation of blood filtered through the avascular granulosa from the thecal vessels. With antral formation, the theca interna develops more fully, expressed by increased cell mass, increased vascularity, and the formation of lipid-rich cytoplasmic vacuoles within the theca cells. As the follicle expands, the surrounding stroma is compressed and is called the theca externa.

The granulosa cells that surround the oocyte are avascular and separated from the surrounding stroma by a basement membrane. Deprived of a vascular supply until after ovulation, the granulosa cells depend on specialized gap junctions that connect cells and communicate with the oocyte for the purpose of metabolic exchange and the transport of signaling molecules. It is this structure that allows repression and stimulation for the correct timing of meiosis. The granulosa cells differ in function and activity; e.g., LH receptor concentrations are highest in those cells closest to the basement membrane and lowest in those that surround the oocyte. ⁵⁸

At any point in this development, individual follicles become arrested and eventually regress in the apoptotic process known as atresia. At first the granulosa component begins to disrupt. The antral cavity constituents are resorbed, and the cavity collapses and obliterates. The oocyte degenerates in situ. Finally, a ribbon-like scarred streak surrounded by theca is seen. Eventually this theca mass loses its lipid and becomes indistinguishable from the growing mass of stroma. Thus, the process of apoptosis is extensive in the granulosa, and the thecal layer is largely spared to be incorporated into the interstitial tissue. Prior to regression, cystic follicles can be retained in the cortex for variable periods of time.

Ovulation

If gonadotropin stimulation is adequate, one of the several follicle units propelled to varying degrees of maturity will advance to ovulation. Morphologically, these events include distension of the antrum by increments of antral fluid and compression of the granulosa against the limiting membrane separating the avascular granulosa and the luteinized, vascularized theca interna. In addition, the antral fluid increment gradually pinches off the cumulus oophorus, the mound of granulosa enveloping the oocyte. The mechanisms of the thinning of the theca over the surface of the now protruding, distended follicle, the creation of an avascular area weakening the ovarian capsule, and the final acute distension of the antrum with rupture and extrusion of the oocyte in its cumulus, are multiple and complex (discussed in [Chapter 6](#)). Repeated evaluation of intrafollicular pressures has failed to indict an explosive factor in this crucial event.

As demonstrated in a variety of animal experiments, the physical expulsion of the oocyte is dependent on a preovulatory surge in prostaglandin synthesis within the follicle. Inhibition of this prostaglandin synthesis produces a corpus luteum with an entrapped oocyte. Both prostaglandins and the midcycle surge of gonadotropins are thought to increase the concentration and activity of local proteases, such as plasminogen conversion to plasmin. As a result of generalized tissue weakening (loss of intercellular gap junction integrity and disruption of elastic fibers), there is swift accumulation of antral fluid followed by rupture of the weakened tissue envelope surrounding the follicle.

Corpus Luteum

Shortly after ovulation, profound alterations in cellular organization occur in the ruptured follicle that go well beyond simple repair. After tissue integrity and continuity are retrieved, the granulosa cells hypertrophy markedly, gradually filling in the cystic, sometimes hemorrhagic, cavity of the early corpus luteum. In addition, for the first time, the granulosa becomes markedly luteinized by incorporation of lipid-rich vacuoles within its cytoplasm. Both these properties had been the exclusive features of the theca prior to ovulation. For its part, the theca of the corpus luteum becomes less prominent, vestiges being noted eventually only in the interstices of the typical scalloping of the mature corpus luteum. As a result, a new yellow body is formed, now dominated by the enlarged, lipid-rich, fully vascularized granulosa. In the 14 days of its life, dependent on the low but important quantities of LH available in the luteal phase, this unit produces estradiol and progesterone. Failing a new enlarging source of LH-like human chorionic gonadotropin (HCG) from a successful implantation, the corpus luteum rapidly ages. Its vascularity and lipid content wane, and the sequence of scarification (albicans) ensues.

Modulators of Function

The complex events that yield an ovum for fertilization and ovarian structures that provide hormonal support are the products of essentially every regulating mechanism in human biology. This includes classic endocrine signals, autocrine and paracrine/intracrine regulation, neuronal input, and immune system contributions. Representatives of the white blood cell series constitute a major component of the ovarian stromal (interstitial) compartment. Macrophages present in permanent, noncyclic numbers may influence ovarian function through the secretion of regulatory cytokines. ⁵⁹ During the adult ovarian cycle, there is an infiltration of

white blood cells in a pattern characterized by increasing numbers of mast cells culminating in degranulation and release of histamine that is associated with hyperemia at ovulation.⁶⁰ The corpus luteum attracts eosinophils and T lymphocytes, that signal and activate monocytes and macrophages involved in luteolysis. However, this immune mechanism should not be viewed just as a healing and resolving response, but also as an important regulatory system (involving the secretion of cytokines and growth factors) for ovarian function.⁵⁹

Anatomical knowledge of the uterus was slow to accumulate.^{1,2} Papyrus writings from 2500 BC indicate that the ancient Egyptians made a distinction between the vagina and uterus. Because the dead had to be embalmed, dissection was precluded, but prolapse was recognized because it was important to return the uterus into its proper place prior to mummification. Next to the Egyptian papyri in antiquity were Hindu writings in which descriptions of the uterus, tubes, and vagina indicate knowledge gained from dissections. This was probably the earliest description of the fallopian tubes.

There is little information in Greek writings about female anatomy; however, Herophilus (4th century BC), the great anatomist in Alexandria and the originator of scholarly dissection, recorded the different positions of the uterus. Soranus of Ephesus (98–138 AD) accurately described the uterus (probably the first to do so), obviously from multiple dissections of cadavers. He recognized that the uterus is not essential for life, acknowledged the presence of leiomyomata, and treated prolapse with pessaries.

Herophilus and Soranus were uncertain about the function of the fallopian tubes, but Galen, Rufus, and Aetius guessed correctly their function. Galen promoted the practice of bleeding for the treatment of almost every disorder. In his argument that nature prevented disease by discharging excess blood, Galen maintained that women were healthier because their superfluous blood was eliminated by menstruation.³ The writings of Galen (130–200 AD) represented the knowledge of medicine for over 1000 years until the end of the medieval dark ages. Galen's description of the uterus and tubes indicates that he had only seen the horned uteri of animals.

In the 16th century, Berengarius, Vesalius, Eustachius, and Fallopius made significant contributions to the anatomical study of the female genitalia. Berengarius (Giacomo Berengario da Carpi) was the first anatomist to work with an artist. His anatomical text, published in 1514, depicted dissected subjects as if they were still alive.

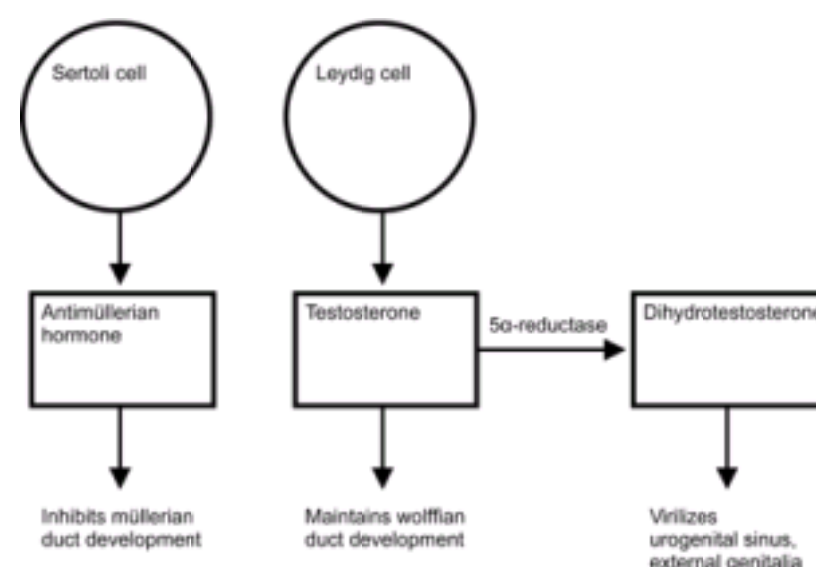

Gabriele Fallopio (or Fallopius) published his work, *Observationes Anatomicae*, in Venice in 1561, one year before his death from pleurisy at age 40. He provided the first descriptions of the clitoris and the hymen, and the first exact descriptions of the ovaries and the tubes. He named the vagina and the placenta and called the tubes the uteri tuba (the trumpet of the uterus), but soon they were known universally as the fallopian tubes. It was his professor and mentor at the University of Padua, however, Andreas Vesalius, who was the first to accurately reveal the presence of the endometrial cavity.

Development of the Müllerian System

The wolffian (mesonephric) and müllerian (paramesonephric) ducts are discrete primordia that temporarily coexist in all embryos during the ambisexual period of development (up to 8 weeks). Thereafter, one type of duct system persists normally and gives rise to special ducts and glands, whereas the other disappears during the 3rd fetal month, except for nonfunctional vestiges.

Hormonal control of mammalian somatic sex differentiation was established by the classic experiments of Alfred Jost.⁴ In Jost's landmark studies, the active role of male determining factors, as opposed to the constitutive nature of female differentiation, was defined as the directing feature of sex differentiation. This principle applies not only to the internal ducts but to the gonad, external genitalia, and perhaps even the brain. The critical factors in determining which of the duct structures stabilize or regress are the secretions from the testes: AMH (anti-müllerian hormone, also known as müllerian inhibiting substance or müllerian inhibiting factor) and testosterone.

AMH is a member of the transforming growth factor- β family of glycoprotein differentiation factors that include inhibin and activin. The gene for AMH has been mapped to chromosome 19. AMH is synthesized by Sertoli cells soon after testicular differentiation and is responsible for the ipsilateral regression of the müllerian ducts by 8 weeks. Despite its presence in serum up to puberty, lack of regression of the uterus and tubes is the only consistent expression of AMH gene mutations. In the absence of AMH, the fetus will develop fallopian tubes, uterus, and upper vagina from the paramesonephric ducts (the müllerian ducts). This development requires the prior appearance of the mesonephric ducts, and for this reason, abnormalities in development of the tubes, uterus, and upper vagina are associated with abnormalities in the renal system.

The internal genitalia possess the intrinsic tendency to feminize. In the absence of a Y chromosome and a functional testis, the lack of AMH allows retention of the müllerian system and development of fallopian tubes, uterus, and upper vagina. In the absence of testosterone, the wolffian system regresses. In the presence of a

normal ovary or the absence of any gonad, müllerian duct development takes place.

The paramesonephric ducts come into contact in the midline to form a Y-shaped structure, the primordium for the uterus, tubes, and the upper one-third of the vagina.⁵ The fallopian tubes, uterus, and the upper portion of the vagina are created by the fusion of the müllerian ducts by the 10th week of gestation. Canalization to create the uterine cavity, the cervical canal, and the vagina is complete by the 22nd week of gestation. Under the epithelium lies mesenchymal tissue that will be the origin of the uterine stroma and smooth muscle cells. By the 20th week of pregnancy, the uterine mucosa is fully differentiated into the endometrium.

The endometrium, derived from the mucosal lining of the fused müllerian ducts, is essential for reproduction and may be one of the most complex tissues in the human body. It is always changing, responding to the cyclic patterns of estrogen and progesterone of the ovarian menstrual cycle, and to a complex interplay among its own autocrine and paracrine factors.⁶

The Histologic Changes in Endometrium During an Ovulatory Cycle

The sequence of endometrial changes associated with an ovulatory cycle has been carefully studied by Noyes in the human and Bartlemez and Markee in the subhuman primate.^{7, 8, 9, 10 and 11} From these data a description of menstrual physiology has developed based upon specific anatomic and functional changes within glandular, vascular, and stromal components of the endometrium.¹² These changes will be discussed in five phases: 1) the menstrual endometrium, 2) the proliferative phase, 3) the secretory phase, 4) preparation for implantation, and finally 5) the phase of endometrial breakdown. Although these distinctions are not entirely arbitrary, it must be recalled that the entire process is an integrated evolutionary cycle of endometrial growth and regression, which is repeated some 400 times during the adult life of the human female.

The endometrium can be divided morphologically into an upper two-thirds “functionalis” layer and a lower one-third “basalis” layer. The purpose of the functionalis layer is to prepare for the implantation of the blastocyst and, therefore, it is the site of proliferation, secretion, and degeneration. The purpose of the basalis layer is to provide the regenerative endometrium following menstrual loss of the functionalis.

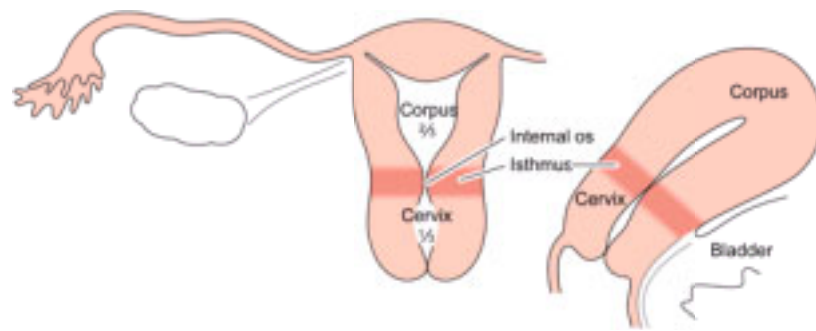

The Uterine Vasculature

The two uterine arteries that supply the uterus are branches of the internal iliac arteries. At the lower part of the uterus, the uterine artery separates into the vaginal artery and an ascending branch that divides into the arcuate arteries. The arcuate arteries run parallel to the uterine cavity and anastomose with each other, forming a vascular ring around the cavity. Small centrifugal branches (the radial arteries) leave the arcuate vessels, perpendicular to the endometrial cavity, to supply the myometrium. When these arteries enter the endometrium, small branches (the basal arteries) extend laterally to supply the basalis layer. These basal arteries do not demonstrate a response to hormonal changes. The radial arteries continue in the direction of the endometrial surface, now assuming a corkscrew appearance (and now called the spiral arteries), to supply the functionalis layer of the endometrium. It is the spiral artery (an end artery) segment that is very sensitive to hormonal changes. One reason the functionalis layer is more vulnerable to vascular permutations is that there are no anastomoses among the spiral arteries. The endometrial glands and the stromal tissue are supplied by capillaries that emerge from the spiral arteries at all levels of the endometrium. The capillaries drain into a venous plexus and eventually into the myometrial arcuate veins and into the uterine veins. This unique vascular architecture is important in allowing a repeated sequence of endometrial growth and desquamation.

The Menstrual Endometrium

The menstrual endometrium is a relatively thin but dense tissue. It is composed of the stable, nonfunctioning basalis component and a variable, but small, amount of residual stratum spongiosum. At menstruation, this latter tissue displays a variety of functional states including disarray and breakage of glands, fragmentation of vessels and stroma with persisting evidence of necrosis, white cell infiltration, and red cell interstitial diapedesis. Even as the remnants of menstrual shedding dominate the overall appearance of this tissue, evidence of repair in all tissue components can be detected. The menstrual endometrium is a transitional state bridging the more dramatic proliferative and exfoliative phases of the cycle. Its density implies that the shortness of height is not entirely due to desquamation. Collapse of the supporting matrix also contributes significantly to the shallowness. Reticular stains in rhesus endometrium confirm this “deflated” state. Nevertheless, as much as two-thirds of the functioning endometrium is lost during menstruation. The more rapid the tissue loss, the shorter the duration of flow. Delayed or incomplete shedding is associated with heavier flow and greater blood loss.

DNA synthesis is occurring in those areas of the basalis that have been completely denuded by day 2–3 of the menstrual cycle (the endometrium in the isthmic area, the narrow area between the cervix and the corpus, and the endometrium in the cornual recesses at the ostia of the tubes remain intact). The new surface epithelium emanates from the flanks of stumps of glands in the basalis layer left standing after menstrual desquamation.¹³ Rapid reepithelialization follows the proliferation of the cells in the basalis layer and the surface epithelium in the isthmic and tubal ostial endometrium. This epithelial repair is supported by underlying fibroblasts. The stromal fibroblast layer forms a compact mass over which the resurfacing epithelium can “migrate.” In addition, it is likely that the stromal layer contributes important autocrine and paracrine factors for growth and migration. Because hormone levels are at their nadir during this repair phase, the response may be due to injury rather than hormone mediated. However, the basalis layer is rich in its content of estrogen receptors. This “repair” is fast; by day 4 of the cycle, more than two-thirds of the cavity is covered with new epithelium.¹³ By day 5–6, the entire cavity is reepithelialized, and stromal growth begins.

The Proliferative Phase

The proliferative phase is associated with ovarian follicle growth and increased estrogen secretion. Undoubtedly as a result of this steroidal action, reconstruction and growth of the endometrium are achieved. The glands are most notable in this response. At first they are narrow and tubular, lined by low columnar epithelium cells. Mitoses become prominent and pseudostratification is observed. As a result, the glandular epithelium extends peripherally and links one gland segment with its immediate neighbor. A continuous epithelial lining facing the endometrial cavity is formed. The stromal component evolves from its dense cellular menstrual condition through a brief period of edema to a final loose syncytial-like status. Coursing through the stroma, spiral vessels extend (unbranched and uncoiled in the early proliferative phase) to a point immediately below the epithelial binding membrane. Here they form a loose capillary network. All of the tissue components (glands, stromal cells, and endothelial cells) demonstrate proliferation, which peaks on days 8–10 of the cycle, corresponding to peak estradiol levels in the circulation and maximal estrogen receptor concentration in the endometrium.¹⁴ This proliferation is marked by increased mitotic activity and increased nuclear DNA and cytoplasmic RNA synthesis, that is most intense in the functionalis layer in the upper two-thirds of the uterus, the usual site of blastocyst implantation.

During proliferation, the endometrium grows from approximately 0.5 mm to 3.5–5.0 mm in height. This proliferation is mainly in the functionalis layer. Restoration of tissue constituents has been achieved by estrogen-induced new growth as well as incorporation of ions, water, and amino acids. The stromal ground substance has reexpanded from its menstrual collapse. Although true tissue growth has occurred, a major element in achievement of endometrial height is “re-inflation” of the stroma.

An important feature of this estrogen dominant phase of endometrial growth is the increase in ciliated and microvillous cells. Ciliogenesis begins on days 7–8 of the cycle.¹³ This response to estrogen is exaggerated in hyperplastic endometrium that is the result of hyperestrogenism. The concentration of these ciliated cells around gland openings and the ciliary beat pattern influence the mobilization and distribution of endometrial secretions during the secretory phase. Cell surface microvilli, also a response to estradiol, are cytoplasmic extensions and serve to increase the active surface of cells.

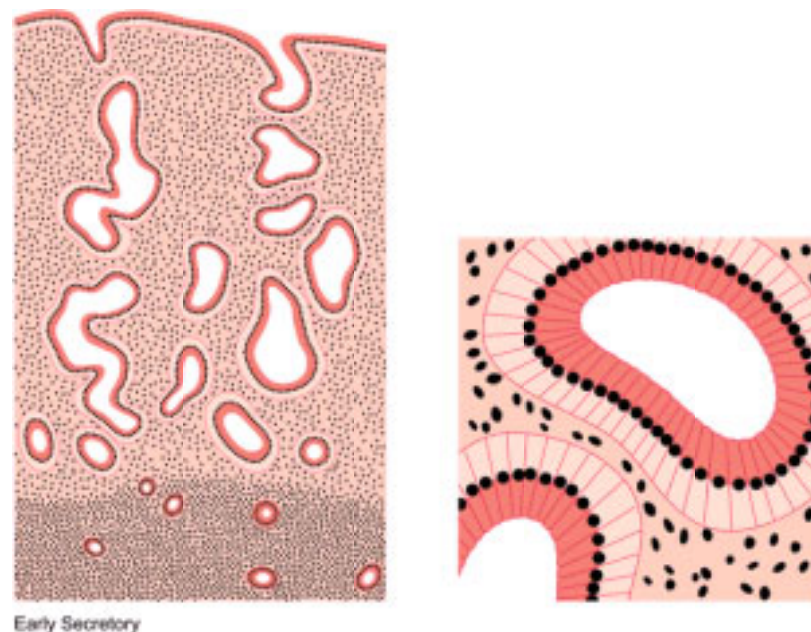

Ciliated Cells

At all times, a large number of cells derived from bone marrow are present in the endometrium. These include lymphocytes and macrophages, diffusely distributed in

the stroma.

The Secretory Phase

After ovulation, the endometrium now demonstrates a combined reaction to estrogen and progesterone activity. Most impressive is that total endometrial height is fixed at roughly its preovulatory extent (5–6 mm) despite continued availability of estrogen. Epithelial proliferation ceases 3 days after ovulation.¹⁵ This restraint or inhibition is believed to be induced by progesterone. This limitation of growth is associated with a decline in mitosis and DNA synthesis, significantly due to progesterone interference with estrogen receptor expression and progesterone stimulation of 17 β -hydroxysteroid dehydrogenase and sulfotransferase, which convert estradiol to estrone sulfate (which is rapidly excreted from the cell).^{16, 17} In addition, estrogen stimulates many oncogenes that probably mediate estrogen-induced growth. Progesterone antagonizes this action by suppressing the estrogen-mediated transcription of oncogene mRNA.¹⁸

Individual components of the tissue continue to display growth, but confinement in a fixed structure leads to progressive tortuosity of glands and intensified coiling of the spiral vessels. The secretory events within the glandular cells, with progression of vacuoles from intracellular to intraluminal appearance, are well known and take place over a 7-day postovulatory interval. At the conclusion of these events, the glands appear exhausted, the tortuous lumina variably distended, and individual cell surfaces fragmented in a sawtooth appearance. Stroma is increasingly edematous, and spiral vessels are prominent and densely coiled.

The first histologic sign that ovulation has occurred is the appearance of subnuclear intracytoplasmic glycogen vacuoles in the glandular epithelium on cycle days 17–18. Giant mitochondria and the “nucleolar channel system” appear in the gland cells. The nucleolar channel system has a unique appearance due to progesterone, an infolding of the nuclear membranes. Individual components of the tissue continue to display growth, but confinement in a fixed structure leads to progressive tortuosity of glands and intensified coiling of the spiral vessels. These structural alterations are soon followed by active secretion of glycoproteins and peptides into the endometrial cavity. Transudation of plasma also contributes to the endometrial secretions. Important immunoglobulins are obtained from the circulation and delivered to the endometrial cavity by binding proteins produced by the epithelial cells. The peak secretory level is reached 7 days after the midcycle gonadotropin surge, coinciding with the time of blastocyst implantation.

The Implantation Phase

Significant changes occur within the endometrium from the 7th to the 13th day postovulation (days 21–27 of the cycle). At the onset of this period, the distended tortuous secretory glands have been most prominent with little intervening stroma. By 13 days postovulation, the endometrium has differentiated into three distinct zones. Something less than one-fourth of the tissue is the unchanged basalis fed by its straight vessels and surrounded by indifferent spindle-shaped stroma. The midportion of the endometrium (approximately 50% of the total) is the lace like **stratum spongiosum**, composed of loose edematous stroma with tightly coiled but ubiquitous spiral vessels and exhausted dilated glandular ribbons. Overlying the spongiosum is the superficial layer of the endometrium (about 25% of the height) called the **stratum compactum**. Here the prominent histologic feature is the stromal cell, which has become large and polyhedral. In its cytoplasmic expansion one cell abuts the other, forming a compact, structurally sturdy layer. The necks of the glands traversing this segment are compressed and less prominent. The subepithelial capillaries and spiral vessels are engorged.

At the time of implantation, on days 21–22 of the cycle, the predominant morphologic feature is edema of the endometrial stroma. This change may be secondary to the estrogen- and progesterone-mediated increase in prostaglandin production by the endometrium. An increase in capillary permeability is a consequence of this local increase in prostaglandins. Receptors for the sex steroids are present in the muscular walls of the endometrial blood vessels, and the enzyme system for prostaglandin synthesis is present in both the muscular walls and the endothelium of the endometrial arterioles. Mitoses are first seen in endothelial cells on cycle day 22. Vascular proliferation leads to the coiling of the spiral vessels, a response to the sex steroids, the prostaglandins, and to autocrine and paracrine factors produced in response to estrogen and progesterone.

During the secretory phase, so-called K (Körnchenzellen) cells appear, reaching a peak concentration in the first trimester of pregnancy. These are granulocytes that have an immunoprotective role in implantation and placentation. They are located perivascularly and are believed to be derived from the blood. By day 26–27, the endometrial stroma is infiltrated by extravasated polymorphonuclear leukocytes.

The stromal cells of the endometrium respond to hormonal signals, synthesize prostaglandins, and, when transformed into decidual cells, produce an impressive array of substances, some of which are prolactin, relaxin, renin, insulin-like growth factors (IGFs), and insulin-like growth factor binding proteins (IGFBPs). The endometrial stromal cells, the progenitors of decidual cells, were originally believed to be derived from the bone marrow (from cells invading the endometrium), but they are now considered to emanate from the primitive uterine mesenchymal stem cells.⁶

The decidualization process begins in the luteal phase under the influence of progesterone and mediated by autocrine and paracrine factors. On cycle days 22–23, predecidual cells can be identified, initially surrounding blood vessels, characterized by cytonuclear enlargement, increased mitotic activity, and the formation of a basement membrane. The decidua, derived from stromal cells, becomes an important structural and biochemical tissue of pregnancy. Decidual cells control the invasive nature of the trophoblast, and the products of the decidua play important autocrine and paracrine roles in fetal and maternal tissues.

Lockwood assigns a key role to decidual cells in both the process of endometrial bleeding (menstruation) and the process of endometrial hemostasis (implantation and placentation).¹⁹ Implantation requires endometrial hemostasis and the maternal uterus requires resistance to invasion. Inhibition of endometrial hemorrhage can

be attributed, to a significant degree, to appropriate changes in critical factors as a consequence of decidualization; e.g., lower plasminogen activator levels, reduced expression of the enzymes that degrade the stromal extracellular matrix (such as the metalloproteinases), and increased levels of plasminogen activator inhibitor-1. Withdrawal of estrogen and progesterone support, however, leads to changes in the opposite directions, consistent with endometrial breakdown.

The Phase of Endometrial Breakdown

Predecidual transformation has formed the “compacta” layer in the upper part of the functionalis layer by day 25 (3 days before menstruation). In the absence of fertilization, implantation, and the consequent lack of sustaining quantities of human chorionic gonadotropin from the trophoblast, the otherwise fixed life span of the corpus luteum is completed, and estrogen and progesterone levels wane.

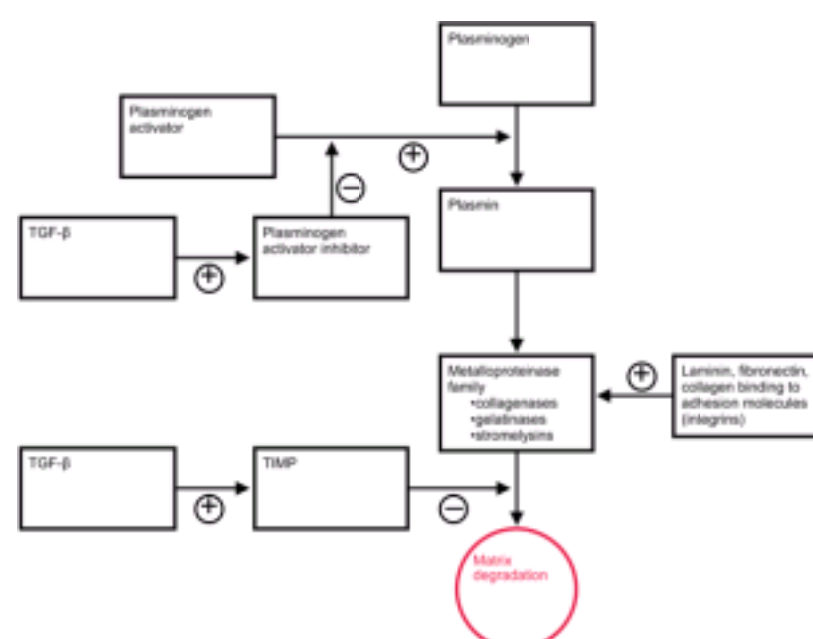

The withdrawal of estrogen and progesterone initiates important endometrial events: vasomotor reactions, the process of apoptosis, tissue loss, and finally, menstruation. The most prominent immediate effect of this hormone withdrawal is a modest shrinking of the tissue height and remarkable spiral arteriole vasomotor responses. The following vascular sequence has been constructed from direct observations of rhesus endometrium.^{7,8} With shrinkage of height, blood flow within the spiral vessels diminishes, venous drainage is decreased, and vasodilatation ensues. Thereafter, the spiral arterioles undergo rhythmic vasoconstriction and relaxation. Each successive spasm is more prolonged and profound, leading eventually to endometrial blanching.

Within the 24 hours immediately preceding menstruation, these reactions lead to endometrial ischemia and stasis. White cells migrate through capillary walls, at first remaining adjacent to vessels, but then extending throughout the stroma. During arteriolar vasomotor changes, red blood cells escape into the interstitial space. Thrombin-platelet plugs also appear in superficial vessels. The prostaglandin content (PGF_{2a} and PGE₂) in the secretory endometrium reaches its highest levels at the time of menstruation. The vasoconstriction and myometrial contractions associated with the menstrual events are believed to be significantly mediated by PGF_{2a} from glandular cells and the potent vasoconstrictor, endothelin-1, derived from stromal decidual cells.

In the first half of the secretory phase, acid phosphatase and potent lytic enzymes are confined to lysosomes. Their release is inhibited by progesterone stabilization of the lysosomal membranes. With the waning of estrogen and progesterone levels, the lysosomal membranes are not maintained, and the enzymes are released into the cytoplasm of epithelial, stromal, and endothelial cells, and eventually into the intercellular space. These active enzymes will digest their cellular constraints, leading to the release of prostaglandins, extravasation of red blood cells, tissue necrosis, and vascular thrombosis. This process is one of **apoptosis**, (programmed cell death, characterized by a specific morphologic pattern that involves cell shrinkage and chromatin condensation culminating in cell fragmentation) mediated by cytokines.²⁰ An important step in this breakdown is the dissolution of cell to cell adhesion by key proteins. Binding of endometrial epithelial cells utilizes transmembrane proteins, **cadherins**, that link intercellularly with each other and intracellularly with catenins that are bound to actin filaments.²¹

Endometrial tissue breakdown also involves a family of enzymes, matrix metalloproteinases, that degrade components (including collagens, gelatins, fibronectin, and laminin) of the extracellular matrix and basement membrane.²² The metalloproteinases include collagenases that degrade interstitial and basement membrane collagens, gelatinases that further degrade collagens, and stromelysins that degrade fibronectin, laminin, and glycoproteins. The expression of metalloproteinases in human endometrium follows a pattern correlated with the menstrual cycle, indicating a sex steroid response as part of the growth and remodeling of the endometrium, with a marked increase in late secretory and early menstrual endometrium.²³ Progesterone withdrawal from endometrial cells induces matrix metalloproteinase secretion, which is followed by the breakdown of cellular membranes and the dissolution of extracellular matrix.²⁴

Appropriately, this enzyme expression increases in the decidualized endometrium of the late secretory phase, during the time of declining progesterone levels. With the continuing progesterone secretion of early pregnancy, the decidua is maintained and metalloproteinase expression is suppressed, in a mechanism mediated by TGF-β.²⁵ In a nonpregnant cycle, metalloproteinase expression is suppressed after menses, presumably by increasing estrogen levels. Metalloproteinase activity is restrained by specific tissue inhibitors designated as TIMP. Thus, progesterone withdrawal can lead to endometrial breakdown through a mechanism that is independent of vascular events (specifically ischemia), a mechanism that involves cytokines.²⁰ During bleeding, both normal and abnormal, there is evidence indicating that specific genes are activated in the endometrium; one such gene has the structural features of the TGF-β family.²⁶

There is considerable evidence to support a major role for a cytokine, tumor necrosis factor-α (TNF-α) in menstruation.²⁰ TNF-α is a transmembrane protein whose receptor belongs to the nerve growth factor/TNF family for inducing apoptotic signals. The key change is an increase in secretion because TNF-α secretion by endometrial cells reaches a peak at menstruation, but there is no cycle change in receptor content. TNF-α inhibits endometrial proliferation and induces apoptosis; this cytokine causes a loss of adhesion proteins (the cadherin-catenin-actin complex) and induces cell-to-cell dissolution. In addition to endometrial cells, TNF-α also causes damage to vascular endothelium.

Eventually, considerable leakage occurs as a result of diapedesis, and finally, interstitial hemorrhage occurs due to breaks in superficial arterioles and capillaries. As ischemia and weakening progress, the continuous binding membrane is fragmented, and intercellular blood is extruded into the endometrial cavity. New thrombin-platelet plugs form intravascularly upstream at the shedding surface, limiting blood loss. Increased blood loss is a consequence of reduced platelet numbers and inadequate hemostatic plug formation. Menstrual bleeding is influenced by activation of clotting and fibrinolysis. Fibrinolysis is principally the consequence of the potent enzyme, plasmin, formed from its inactive precursor, plasminogen. Endometrial stromal cell tissue factor (TF) and plasminogen activators and inhibitors are involved in achieving a balance in this process. TF stimulates coagulation, initially binding to factor VII. TF and plasminogen activator inhibitor-1 (PAI-1) expression accompanies decidualization, and the levels of these factors may govern the amount of bleeding.²⁷ PAI-1, in particular, exerts an important restraining action on fibrinolysis and proteolytic activity.²⁸

With further tissue disorganization, the endometrium shrinks even more and coiled arterioles are buckled. Additional ischemic breakdown ensues with necrosis of cells and defects in vessels adding to the menstrual effluvia. A natural cleavage point exists between basalis and spongiosum, and, once breached, the loose,

vascular, edematous stroma of the spongiosum desquamates and collapses. The process is initiated in the fundus and inexorably extends throughout the uterus. In the end, the typical deflated, shallow, dense, menstrual endometrium results. Within 13 hours, the endometrial height shrinks from 4 mm to 1.25 mm.¹² Menstrual flow stops as a result of the combined effects of prolonged vasoconstriction, tissue collapse, vascular stasis, and estrogen-induced “healing.” In contrast to postpartum bleeding, myometrial contractions are not important for control of menstrual bleeding. Thrombin generation in the basal endometrium in response to extravasation of blood is essential for hemostasis. Thrombin promotes the generation of fibrin, the activation of platelets and clotting cofactors, and angiogenesis.

The basalis endometrium remains during menses, and repair takes place from this layer. This endometrium is protected from the lytic enzymes in the menstrual fluid by a mucinous layer of carbohydrate products that are discharged from the glandular and stromal cells.²⁹

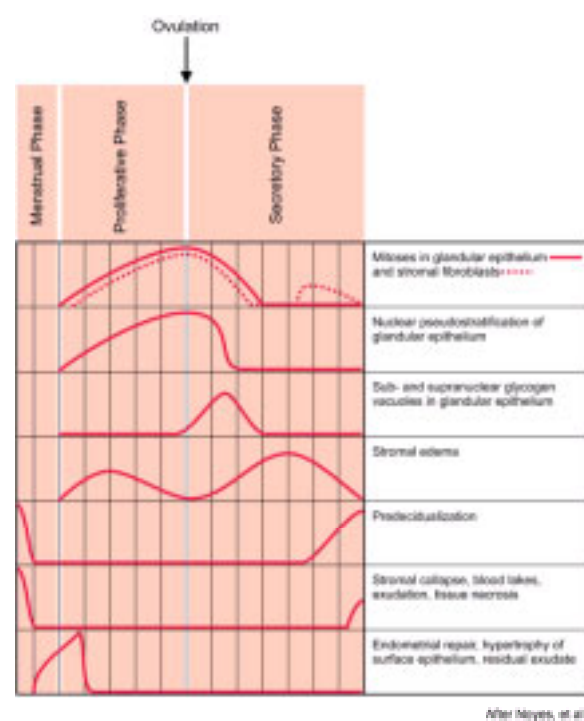

Normal Menses

Approximately 50% of the menstrual detritus is expelled in the first 24 hours of menstrual flow. The menstrual fluid is composed of the autolysed functionalis, inflammatory exudate, red blood cells, and proteolytic enzymes (at least one of which, plasmin, lyses fibrin clots as they form). The high fibrinolytic activity advances emptying of the uterus by liquefaction of tissue and fibrin. If the rate of flow is great, clotting can and does occur.

Most women (90%) have menstrual cycles with an interval of 24 to 35 days (Chapter 6).^{30, 31} Menarche is followed by approximately 5–7 years of increasing regularity as cycles shorten to reach the usual reproductive age pattern. In the 40s, cycles begin to lengthen again. The usual duration of flow is 4–6 days, but many women flow as little as 2 days and as much as 8 days. The normal volume of menstrual blood loss is 30 mL; greater than 80 mL is abnormal (Chapter 15).

Dating the Endometrium

The postovulatory endometrium can be dated according to the histologic changes throughout a hypothetical 28-day menstrual cycle. These changes were described by Noyes, Hertig, and Rock in the lead article of the first volume of *Fertility and Sterility* in 1950.⁹ Dating of the endometrium is most accurately accomplished with biopsy specimens obtained 2–3 days before the onset of menses. This method continues to be the most accepted way to diagnose an inadequate luteal phase (endometrium inadequate to sustain a pregnancy because of deficient progesterone secretion by the corpus luteum).

A Teleologic Theory of Endometrial-Menstrual Events

Menstruation is a very recent phenomenon in the evolutionary time line. It occurs in very few species, even among viviparous animals. An unabashedly teleologic view of menstrual events was offered by Rock et al.³² The basic premise of this thesis is that every endometrial cycle has, as its only goal, nourishing support of an early embryo. Failure to accomplish this objective is followed by orderly elimination of unutilized tissue and prompt renewal to achieve a more successful cycle.

The ovum must be fertilized within 12–24 hours of ovulation. Over the next 2 days, it remains unattached within the tubal lumen utilizing tubal fluids and residual cumulus cells to sustain nutrition and energy for early cellular cleavage. After this stay, the solid ball of cells (morula) which is the embryo leaves the tube and enters the uterine cavity. Here the embryo undergoes another 2–3 days of unattached but active existence. Fortunately, by this time endometrial gland secretions have filled the cavity and they bathe the embryo in nutrients. This is the first of many neatly synchronized events that mark the conceptus-endometrial relationship. By 6 days after ovulation, the embryo (now a blastocyst) is ready to attach and implant. At this time, it finds an endometrial lining of sufficient depth, vascularity, and nutritional richness to sustain the important events of early placentation to follow. Just below the epithelial lining, a rich capillary plexus has been formed and is available for creation of the trophoblast-maternal blood interface. Later, the surrounding zona compactum, occupying more and more of the endometrium, will provide a sturdy splint to retain endometrial architecture despite the invasive inroads of the burgeoning trophoblast.

Failure of the appearance of human chorionic gonadotropin, despite otherwise appropriate tissue reactions, leads to the vasomotor changes associated with estrogen-progesterone withdrawal and menstrual desquamation. However, not all the tissue is lost, and, in any event, a residual basalis is always available, making resumption of growth with estrogen a relatively rapid process. Indeed, even as menses persists, early regeneration can be seen. As soon as follicle maturation occurs (in as short a time as 10 days), the endometrium is ready once again to perform its reproductive function.

The Uterus Is an Endocrine Organ

The uterus is dynamic. It not only responds and changes in a sensitive fashion to classic hormonal signals (the endocrine events of the menstrual cycle), but it is also composed of complex tissues, with important autocrine and paracrine functions that serve not only the uterus but the contiguous tissues of the fetoplacental unit during pregnancy. The most dynamic component of the uterus is the endometrium.

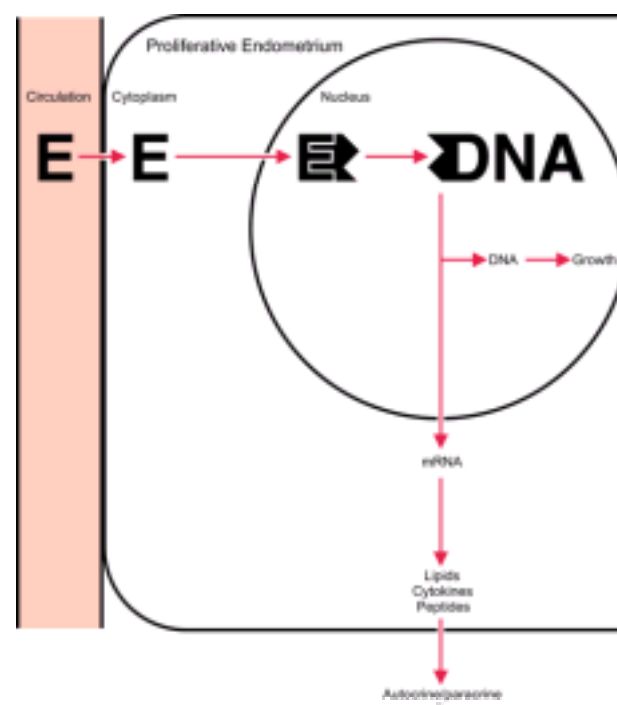

Endometrial Products

The endometrium secretes many substances, the functions of which (and their interrelationships) represent a major investigative challenge.³³ In addition to producing a nourishing, supportive environment for the early embryo, the endometrium plays an important role in suppressing the immune response within the pregnant uterus. The mechanisms controlling the immune response in decidual cells are not understood, but hormonal influence is undoubtedly important.

Lipids	Cytokines	Peptides
Prostaglandins	Interleukin-1a	Prolactin
Thromboxanes	Interleukin-1b	Relaxin
Leukotrienes	Interleukin-6	Prorenin and renin
	Interferon-g	Endorphin
	Colony-stimulating factor-1	Endothelin-1
	Tumor necrosis factor-a	Corticotropin-releasing hormone
	Leukemia-inhibiting factor	Fibronectin

Uteroglobin
Lipocortin-1
Parathyroid hormone-like protein
Integrins
Epidermal growth factor family
EGF
Heparin-binding EGF
TGF-a
Insulin-like growth factor family
IGF-I
IGF-II
IGFBPs 1–6
Platelet-derived growth factor
Transforming growth factor-b
Fibroblast growth factor
Vascular endothelial growth factor

The presence of the cytokine family, involved in inflammation and immune responses, is not surprising in a tissue that undergoes cyclic degeneration. The interleukins stimulate prostaglandin production as well as other cytokines.³⁴ Colony-stimulating factor-1 is a cytokine that influences cellular proliferation and the presence of macrophages. Interferon-g is produced by activated T-lymphocytes and inhibits endometrial epithelial proliferation. Leukemia-inhibiting factor (LIF) is expressed in response to a variety of other cytokines and growth factors. Like the interleukins, LIF is most abundant during the progesterone-dominated secretory phase and early decidua, and may have a role in embryo implantation.^{35, 36} Tumor necrosis factor-a (TNF-a) gene expression is present in endometrium, and its activity is increased during the proliferative phase, decreased early in the secretory phase, and increased again in the midsecretory phase.³⁷ TNF-a exerts multiple influences on cellular growth.

Growth factors are peptides that bind to specific cell membrane receptors and initiate intracellular signaling pathways. Because the growth factors are potent mitogens, it is also not surprising that the follicular phase of the cycle, associated with proliferative activity of the endometrium, is marked by dramatic alterations in growth factors. Estrogen stimulates gene expression for epidermal growth factor (EGF) (and its receptor) and insulin-like growth factor (IGF) production. In turn, EGF elicits estrogen-like actions by interacting with the estrogen receptor mechanism.³⁸ EGF, a potent mitogen, is present in endometrial stromal and epithelial cells during the follicular phase of the cycle and in the stromal cells during the luteal phase.³⁹ Transforming growth factor-a (TGF-a) and EGF work through the same receptor and are important mediators of estrogen-induced growth of the endometrium. TGF-a levels peak at midcycle, in contrast to EGF levels, which are relatively stable and noncyclic.^{40, 41} and ⁴² Platelet-derived growth factor is a potent mitogen localized to stromal cells.

The insulin-like growth factors promote cellular mitosis and differentiation. They are expressed in a pattern controlled by estrogen and progesterone. IGF-I is predominant in proliferative and early secretory endometrium, while IGF-II appears in the mid to late secretory phase and persists in early pregnancy decidua.⁴³ Endometrial IGF-I expression is correlated with the circulating estrogen levels during the menstrual cycle.⁴⁴ This suggests that IGF-I synthesis is regulated by estrogen and mediates estrogen-induced growth of the endometrium, and IGF-II is involved in differentiation in response to progesterone. Evidence in the monkey indicates that IGF-I is the primary regulator of myometrial growth in response to estrogen as well as to estrogen plus progesterone.⁴⁵

As elsewhere in the body, the myometrial IGF activity is modulated by the IGF binding proteins, which respond to the sex steroids in a differential manner; IGFBP-2 parallels IGF-I response, whereas IGFBP-3 is decreased in muscle but increased in vascular endothelium by estrogen.⁴⁶ IGFBP-4 and IGFBP-5 respond to estrogen but are unaffected by the addition of progesterone. IGFBP-1, as discussed later, is a major product of decidualized endometrium.

Human myometrial smooth muscle and endometrial stromal cells express mRNA for parathyroid hormone-like protein, the function of which is unknown.⁴⁷ Transforming growth factor-b (TGF-b) stimulates the production of the parathyroid hormone-like protein. TGF-b production is greatest in the secretory phase and may inhibit cellular proliferation by increasing IGFBP-3 synthesis.

Prostaglandins are produced by both epithelial and stromal cells, and the prostaglandin content in the endometrium reaches a peak level in late secretory endometrium. The predominant prostaglandin produced by endometrium is prostaglandin F_{2a}, a potent stimulus for myometrial contractions.⁴⁸ Endometrial prostaglandin production decreases dramatically after implantation, suggesting the presence of an active mechanism for suppression.⁴⁹ The production of prostaglandins requires estrogen support, but the increased production by secretory endometrium suggests progesterone enhancement, and acute withdrawal of progesterone promotes a further increase.⁴⁸ Endometrial stromal cells produce prostacyclin and thromboxane in response to estrogen, a response that can be blocked by progestins.⁵⁰ The myometrium principally produces prostacyclin, utilizing precursors derived from the endometrium. However, receptors for all members of the prostaglandin family are present on human myometrial cells, and contraction of the myometrium is a major consequence of prostaglandin F_{2a}.⁵¹

Thromboxane is synthesized by uterine tissues. Gene expression for the thromboxane synthase and for the thromboxane receptor can be identified in endometrial glands, stromal cells, myometrial smooth muscle, and uterine blood vessels.⁵² Thromboxane A₂ is a potent vasoconstrictor and stimulator of smooth muscle cells. Because of its rapid metabolism, it is limited to autocrine and paracrine activity.

Women with excessive menstrual bleeding have alterations in the normal rates of prostaglandin production. For this reason, effective reductions in menstrual blood loss can be achieved with treatment utilizing one of the nonsteroidal anti-inflammatory agents that inhibit prostaglandin synthesis. These agents are also effective

treatment for prostaglandin-mediated dysmenorrhea.

Fibronectin and laminin are extracellular matrix substances that are secreted by stromal cells of the endometrium in response to progesterone.⁵³ These proteins are important adhesion molecules during implantation. Integrins are a family of glycoproteins that function as receptors for proteins such as collagen, fibronectin, and laminin. The integrins are highly expressed in endometrium and are important for cell-to-cell and cell-to-matrix interactions.⁵⁴ The expression of integrins appears to be regulated by cytokines and growth factors, not estrogen and progesterone.⁵⁵

Uteroglobin is a small protein expressed in endometrial epithelial cells.⁵⁶ The physiologic function of uteroglobin is uncertain. Uteroglobin, with high affinity, binds progesterone and may play a role in immunosuppression. Uteroglobin gene expression is stimulated by estrogen, and this response is enhanced by progesterone. Human endometrium can secrete b-endorphin, yet another candidate for involvement in endometrial immunologic events, and its release is inhibited by both estrogens and glucocorticoids.⁵⁷

Endothelins are potent vasoconstrictors produced in the vascular endothelial cells. The vasoconstrictor activity of endothelin-1, present in the endometrium, is balanced by the fact that it promotes the synthesis of the vasodilators, nitric oxide and prostacyclin. Endothelin-1 is synthesized in endometrial stromal cells and the glandular epithelium, stimulated by both TGF- β and interleukin-1 α .⁵⁸ Endothelin-1 is at least one agent responsible for the vasoconstriction that shuts off menstrual bleeding. It is also a potent stimulator of myometrial contractions and can contribute to dysmenorrhea. Finally, endothelin-1 is a mitogen and can promote the healing and reepithelialization of the endometrium. Human decidual cells also synthesize and secrete endothelin-1, from where it may be transported into the amniotic fluid.⁵⁹

Angiogenesis, the formation of new blood vessels, is an essential process in tissue growth and development. Angiogenesis is necessary for tumor growth, and in normal tissues, it is usually kept in check by regulating factors. The female reproductive tissues (specifically ovarian follicles, the trophoblast, and the endometrium), however, must experience periodic and rapid growth and regression. In these tissues, angiogenesis is part of normal events. The endometrium is a major source for angiogenic factors during the menstrual cycle and during pregnancy.⁶⁰ Vascular endothelial growth factor, a specific mitogen for endothelial cells, is abundantly expressed in human endometrium, reaching a peak that correlates with the maximal angiogenesis reached during the secretory phase.⁶¹ Angiogenesis is also influenced by many of the growth factors, and other substances such as fibronectin and prostaglandins. Fibroblast growth factor, in particular, is highly mitogenic for endothelial cells as well as endometrial stromal cells.

In all types of endometrial and myometrial cells, estrogen receptor expression reaches a maximum in the late follicular phase.^{62, 63} The concentration is greatest in the glandular epithelium. During the early luteal phase, estrogen receptor expression declines, followed by an increase in the mid and late luteal phases. These changes reflect the cyclic changes in estradiol (which increases estrogen receptor expression) and progesterone (which decreases estrogen receptor expression).

Progesterone receptor expression in endometrial glandular epithelium reaches a maximum in the late follicular and early luteal phases (reflecting induction of progesterone receptor by estrogen), and then declines to nearly undetectable levels by the midpoint of the secretory phase. Stromal cells in the endometrium show only minor fluctuations in progesterone receptors during the menstrual cycle. Decidualizing stromal cells exhibit strong progesterone receptor expression, although progesterone receptors are absent from decidual epithelial cells. Smooth muscle cells of the uterus demonstrate strong progesterone receptor expression throughout the menstrual cycle. Many of the events in uterine growth and function are regulated by the interplay between estrogen and progesterone. In general, progesterone antagonizes estrogen stimulation of proliferation and metabolism. This antagonism can be explained by the effects of progestins on the estrogen receptor (a decrease in levels) and on the enzymes that lead to excretion of estrogen from cells and by progesterone suppression of estrogen-mediated transcription of oncogenes.

Androgen receptor is present in endometrium at all stages of the menstrual cycle, in postmenopausal endometrium, and in the decidua of pregnancy.⁶⁴ Surprisingly, the androgen receptor concentration is constant throughout the cycle.

The Decidua

The decidua is the specialized endometrium of pregnancy. The biochemical dialogue between the fetoplacental unit and the mother must pass back and forth through the decidua. The classic view of the decidua conformed to its designation as a thin line in anatomical diagrams, a minor, inactive structural component. We now know that the decidua is a vigorous, active tissue.

The glycoprotein α -subunit, common to follicle-stimulating hormone (FSH), luteinizing hormone (LH), thyroid-stimulating hormone (TSH), and HCG, is secreted into the circulation by the pituitary and placenta. A specific role for the α -subunit has not been apparent; however, gonadotropin receptors are present in the endometrium and in vitro, α -subunit acts synergistically with progesterone to induce decidualization of endometrial cells.⁶⁵ In addition, the α -subunit stimulates decidual prolactin secretion.⁶⁶

Decidual cells are derived from the stroma cells of the endometrium, under the stimulation of progesterone. Thus, they appear during the luteal phase and continue to proliferate during early pregnancy, eventually lining the entire uterus, including the implantation site. The decidual cell is characterized by the accumulation of glycogen and lipid droplets and the new expression of a host of substances, including prolactin, relaxin, renin, insulin-like growth factors (IGFs), and insulin-like growth factor binding proteins (IGFBPs). There is no evidence that these proteins are secreted into the circulation, therefore they serve as autocrine and paracrine agents.^{67, 68}

Riddick was the first to detect prolactin in the decidualizing endometrium of the late luteal phase.⁶⁹ The amino acid sequence and the chemical and biological properties of decidual prolactin are identical to those of pituitary prolactin. Decidual prolactin synthesis and release are controlled by the placenta, fetal membranes, and decidual factors. Dopamine, bromocriptine, and thyroid-releasing hormone (TRH), in contrast to their action in the pituitary, have no effect on decidual synthesis and release of prolactin. A protein named decidual prolactin-releasing factor has been purified from the placenta, and an inhibiting protein, which blocks the stimulatory activity of the releasing factor, has been purified from decidua.⁶⁸ IGF-1, relaxin, and insulin all stimulate decidual prolactin synthesis and release, each through its own receptor. The same decidual cells produce both prolactin and relaxin.

Lipocortin-1 is a calcium and phospholipid binding protein, present in the placenta and decidua, that inhibits phospholipase A₂ and responds to glucocorticoids. Lipocortin-1 inhibits decidual prolactin release but in a mechanism independent of phospholipase action and independent of glucocorticoids. The prostaglandin system is not involved in decidual prolactin production, and corticoid steroids do not affect decidual prolactin release.⁷⁰

There is good reason to believe that the amniotic fluid prolactin is derived from the decidua. In vitro experiments indicate that the passage of prolactin across the fetal

membranes is in the direction of the amniotic cavity. The amniotic fluid concentration correlates with the decidual content, not maternal circulating levels. Amniotic fluid prolactin reaches peak levels in the first half of gestation (about 4000 ng/mL) when maternal plasma levels are approximately 50 ng/mL and fetal levels about 10 ng/mL. Maternal circulating prolactin reaches maximal levels near term. Finally, amniotic fluid prolactin is unaffected by bromocriptine treatment (which reduces both fetal and maternal circulating levels to baseline levels).

It is believed that decidual prolactin regulates amniotic fluid volume and electrolyte concentrations. It can be demonstrated that prolactin regulates water and ion transport in lower animals, and prolactin binds to amniotic membranes. Disorders in human pregnancy associated with abnormal amniotic fluid volumes may be explained by this mechanism, especially idiopathic polyhydramnios (which is associated with a decrease in the number of prolactin receptors in the membranes). Prolactin may be involved in the regulation of surfactant synthesis in the fetus, and prolactin may inhibit uterine muscle contractility. Prolactin suppresses the immune response and contributes to the prevention of immunologic rejection of the conceptus. Prolactin can also function as an autocrine and paracrine growth factor in the uterus.⁷¹

Fibroblast growth factor, derived from decidua, stimulates blood vessel growth in early pregnancy. Another factor, endothelial-cell-stimulating angiogenesis factor (a nonprotein mitogen), is also derived from decidua and contributes to the vascularization of the decidua during the first trimester of pregnancy.⁷² The expression of corticotropin-releasing hormone (CRH) has been demonstrated in human decidua, and many actions for decidual CRH are possible: activation of prostaglandins, stimulation of myometrial contractions, and a contribution to both maternal and fetal stress responses during pregnancy and labor.⁷³

Prorenin (the inactive precursor of renin) is produced in decidua in response to IGF-1, insulin, endothelin, and relaxin.^{74,75} A uterine role for renin has not been determined. The insulin-like growth factor binding proteins, IGFBP-1, -2, -3, and -4, are produced by endometrial stromal cells.⁷⁶ Large amounts of IGFBP-1 are present in amniotic fluid. The IGFBPs appear to be regulated by insulin, the IGFs, and relaxin.⁷⁷ Relaxin is related structurally to insulin and the IGFs. However, in contrast to insulin and IGF, it stimulates IGFBP-1 production in endometrial stromal cells.⁷⁸

IGFBP-1 begins to appear in midluteal phase endometrium and reaches a level of major production in decidua by late in the first trimester of pregnancy. IGFBP-1, when first identified, was known as placental protein 12 and then as pregnancy-associated a-globulin. By the second trimester of pregnancy, high levels of IGFBP-1 are present in the amniotic fluid and the circulation, which then fall significantly during the third trimester. The decidual production of IGFBP-1 is correlated with the morphologic and histologic changes induced by progesterone and regulated by progesterone, relaxin, insulin, IGF-I, and IGF-II. Binding of the insulin-like growth factors to the IGFBPs would limit further mitogenic activity in the endometrium in the secretory phase and during pregnancy. In addition, decidual IGFBP-1 may contribute to the limitation of trophoblast invasion.

The continuous stimulation of IGFBP-1 production by human endometrium can be maintained in women as long as they retain an intrauterine device that releases a progestin into the endometrial cavity.⁷⁹ In endometrial samples from these women, areas of endometrial atrophy correlate with intense staining for IGFBP-1. This makes a strong argument for the importance of insulin-like growth factors for endometrial growth and the potential for prevention of endometrial growth by providing IGFBP-1.

The chorion laeve, villous trophoblast, and decidua are all sites of TGF- β production.⁸⁰ TGF- β can signal its own production; thus, TGF- β can be a messenger from fetal tissues to decidua. TGF- β is also believed to play a role in limiting trophoblastic invasion.⁸¹ This may be accomplished by stimulating the production of plasminogen activator inhibitor and the factor that causes tissue inhibition of metalloproteinases.⁸²

Summary: The Uterus Is an Endocrine Organ

One cannot dispute the fact that the uterus is an endocrine organ, but the vast array of active substances can be bewildering and overwhelming. It is helpful to keep in mind a fundamental and relatively simple description: the endometrium is necessary for reproduction, and the synchronous, complex cycle of events is dependent on the endocrine guidance of estradiol and progesterone, modulated and mediated by the plethora of locally produced biochemical agents. Each and every signaling substance utilizes one of the pathways discussed in Chapter 2, and makes a contribution to the dynamic sequence of morphological and biochemical events repeatedly dedicated to nourishing and supporting an early embryo.

Anatomical Abnormalities of the Uterus

Congenital abnormalities of the müllerian ducts are relatively common and contribute to the problems of infertility, recurrent pregnancy loss, and poor outcome in pregnancy (encountered in approximately 25% of women with uterine anomalies).^{83, 84, 85 and 86} The problems encountered in pregnancy include preterm labor, breech presentations, and complications that lead to interventions and greater perinatal mortality. Cervical cerclage is often indicated for prevention of preterm labor due to these anomalies. In addition, these abnormalities can produce the symptoms of dysmenorrhea and dyspareunia, and even amenorrhea. Because the embryologic origin of the ovaries is separate and distinct from that of the müllerian structures, patients with müllerian anomalies have normal ovaries and ovarian function.

Incidence of Müllerian Defects⁸⁷

Overall	5%
Fertile women	2–3%
Infertile women	3%
Women with recurrent miscarriages	5–10%
Women with late miscarriages and preterm deliveries	>25%

Anomalies can originate in the failure of the müllerian ducts to fuse in the midline, to connect with the urogenital sinus, or to create the appropriate lumen in the upper vagina and uterus by resorption of the central vaginal cells and the septum between the fused müllerian ducts. Because fusion begins in the midline and extends caudally and cephalad, abnormal results can exist at either end. Formation of the uterine cavity begins at the lower pole and extends cephalad with dissolution of midline tissue; hence, incomplete resorption of tissue commonly yields persistence of the midline uterine wall intruding into the cavity. The molecular pathophysiology of these abnormalities has been insufficiently studied; however, the association with other somatic anomalies and occasional reports of familial transmission suggest genetic linkages.

Vaginal outflow tract obstruction can be minimal with a transverse septum or complete due to agenesis. A septum is the result of a defect in the connection of the fused müllerian ducts to the urogenital sinus or a failure of canalization of the vagina. The location of the septum varies, although it is usually in the upper or middle third of the vagina. Vaginal agenesis is the result of a complete failure in canalization; these patients present with amenorrhea or pain due to accumulated menstrual effluvium. Surgical correction is frequently necessary to relieve the relative constriction (and obstruction) of the vaginal canal. An absent vagina is usually accompanied by an absent uterus and tubes, the classic müllerian agenesis of the Mayer-Rokitansky-Kuster-Hauser syndrome (discussed in Chapter 11).

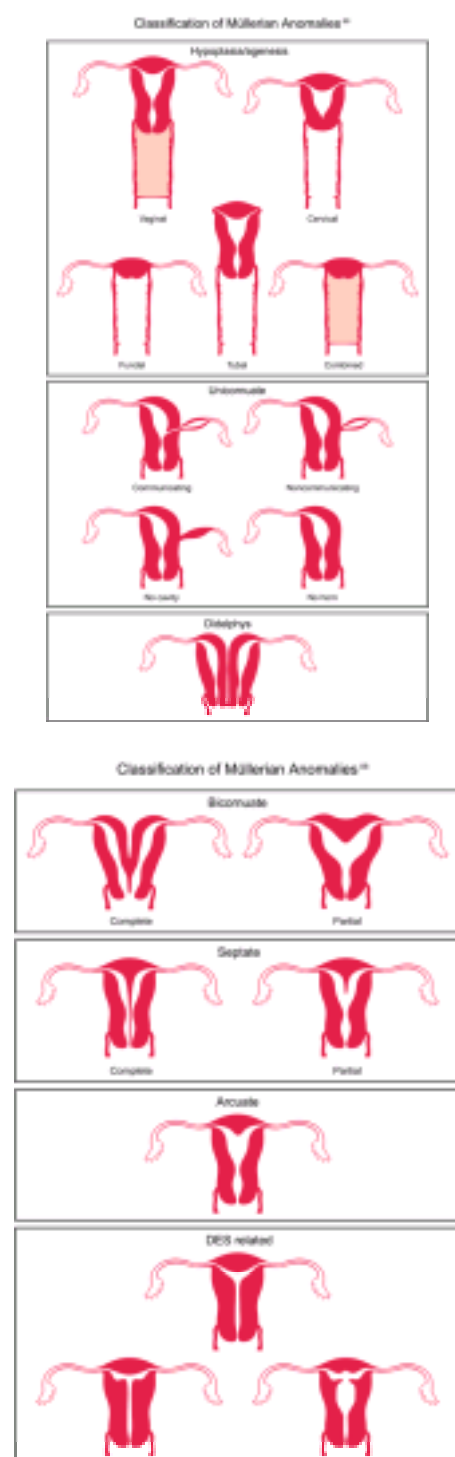

Distribution of Specific Anomalies⁸⁷

Bicornuate uterus	37%
Arcuate uterus	15%
Incomplete septum	13%
Uterus didelphys	11%
Complete septum	9%
Unicornuate uterus	4.4%

Uterine anomalies can be organized into the following categories.⁸⁸ Each of these can be associated with obstructions that present during adolescence with amenorrhea and cyclic pain.⁸⁹

Unicornuate Uterus

An abnormality that is unilateral obviously is due to a failure of development in one müllerian duct (probably a failure of one duct to migrate to the proper location). The altered uterine configuration is associated with an increase in obstetrical complications (early spontaneous miscarriage, ectopic pregnancy, abnormal presentations, intrauterine growth retardation, and

premature labor).^{90, 91 and 92} There may be a rudimentary horn present, and implantation in this horn is followed by a very high rate of pregnancy wastage or tubal pregnancies. A rudimentary horn can also be a cause of chronic pain, and surgical excision may be worthwhile. However, most rudimentary horns are asymptomatic because they are non-communicating, and the endometrium is not functional. Because of the potential for problems, prophylactic removal of the rudimentary horn is recommended when it is encountered during a surgical procedure. Approximately 40% of patients with a unicornuate uterus will have a urinary tract anomaly (usually of the kidney).⁹³

Uterus Didelphus (Double Uterus)

Lack of fusion of the two müllerian ducts results in duplication of corpus and cervix. These patients usually have no difficulties with menstruation and coitus. Occasionally, one side is obstructed and symptomatic. In addition, a double uterus is occasionally associated with an obstructed hemivagina (often with ipsilateral renal agenesis); early diagnosis and excision of the obstructing vaginal septum will preserve fertility. Pregnancy is associated with an increased risk of malpresentations and premature labor, although many patients will have no reproductive difficulties.⁹²

The Bicornuate Uterus

Partial lack of fusion of the two müllerian ducts produces a single cervix with a varying degree of separation in the two uterine horns. This anomaly is relatively common, and pregnancy outcome has usually been reported to be near normal. Some, however, find a high rate of early miscarriage, preterm labor, and breech presentations.^{86, 92}

The Septate Uterus

Partial lack of resorption of the midline septum between the two müllerian ducts results in defects that range from a slight midline septum (the arcuate, heart-shaped cavity) to a significant midline division of the endometrial cavity. A total failure in resorption can leave a longitudinal vaginal septum (a double vagina). This defect is not a cause of infertility, but once pregnant, the greater the septum the greater the risk of recurrent spontaneous miscarriage. The complete septate uterus is associated with a high risk of preterm labor and breech presentation.⁸⁶ Outcomes are excellent with treatment by hysteroscopy.^{94, 95} Posttreatment miscarriage rates are approximately 10% in contrast to the 90% pretreatment rates. A longitudinal vaginal septum usually does not have to be excised (unless dyspareunia is a problem). In some reports, the arcuate uterus had no adverse impact on reproductive outcome.⁹²

Very Rare Anomalies

Isolated agenesis of the cervix or the endometrium is incredibly rare. Absence of the cervix can lead to so much pain and obstruction that hysterectomy is the best solution. Attempts to preserve fertility by creating a fistulous communication between uterus and vagina have achieved little success, and repeat surgery due to reappearance of obstruction is common.⁹⁶ In asymptomatic patients, consideration should be given to preservation of structures for the possibility of pregnancy that can be achieved by means of one of the techniques of assisted reproduction. ([Chapter 31](#))

The Diethylstilbestrol-Associated Anomaly

We are still encountering women whose mothers were treated with high doses of estrogen during their pregnancies. Exposure to these high levels of estrogen during müllerian development caused a variety of anomalies, ranging from the hypoplastic "T" shaped uterus to irregular cavities with adhesions.⁹⁷ Women with uterine abnormalities usually also have cervical defects. In these individuals, the chance of term pregnancy is decreased because of higher risks of ectopic pregnancy, spontaneous miscarriage, and premature labor. An incompetent cervix is common. Poor outcome is correlated with an abnormal uterus on hysterosalpingography. No treatment is available beyond cervical cerclage.

Accurate Diagnosis of Anomalies

In the past, full diagnosis has required surgical intervention, first laparotomy and then, more recently, laparoscopy. Today, vaginal ultrasonography and magnetic resonance imaging are highly accurate, and surgical intervention is usually not necessary.⁹⁸ Hysterosalpingography is relatively inaccurate, and decisions should not be based upon hysterosalpingography alone. Congenital anomalies of the müllerian ducts are frequently accompanied by abnormalities in the urinary tract. Renal agenesis is often present on the same side as a müllerian defect.

Leiomyomata (Uterine Fibroids)

Uterine leiomyomas are benign neoplasms that arise from uterine smooth muscle. It is hypothesized that leiomyomas originate from somatic mutations in myometrial cells, resulting in progressive loss of growth regulation.^{99, 100} The tumor grows as genetically abnormal clones of cells derived from a single progenitor cell (in which the original mutation took place). Studies indicate that leiomyomas are monoclonal. Different rates of growth can reflect the different cytogenetic abnormalities present in individual tumors. Multiple myomas within the same uterus are not clonally related; each myoma arises independently. The presence of multiple myomas (which have a higher recurrence rate than single myomas) argues in favor of a genetic predisposition for myoma formation; however, the familial inheritance of uterine myomas has not been well studied. It is not certain whether leiomyosarcomas arise independently or from leiomyomas. However, the incidence of leiomyosarcomas in patients with leiomyomata is very low (less than 1%).¹⁰¹

If surgical specimens are serially sectioned, about 77% of women who come to hysterectomy will have myomas, many of which are occult.¹⁰² Overall, about 17% of hysterectomies are performed for myomas in the U.S. (44% in women 45–54 years old).¹⁰³ The peak incidence for myomas requiring surgery occurs around age 45, approximately 8 cases per 1000 women each year. In the U.S., approximately 10–15% of women require hysterectomy for myomas. For unknown reasons, uterine leiomyomas are 2–3 times more prevalent in black women compared with white, Hispanic, and Asian women.¹⁰⁴ The major symptoms associated with myomas are menorrhagia and the physical effects produced by large myomas.

Myomas will be encountered in about 1% of pregnant women. The risk of myoma is decreased with increasing parity and with increasing age at last term birth.¹⁰⁵ Women with at least two full term pregnancies have half the risk for myomas. Smoking decreases the risk (presumably by decreasing estrogen levels), and obesity increases the risk (presumably by increasing estrogen levels). Although a lower risk for myomas is associated with factors that decrease estrogen levels, including leanness, smoking, and exercise, the use of oral contraceptives is not associated with an increased risk of uterine myomas, although the Nurses' Health Study reported a slightly increased risk when oral contraceptives were first used in early teenage years.^{105, 106 and 107}

The hormone sensitivity of leiomyomas is indicated by the following clinical observations. Leiomyomas develop during the reproductive (hormonally active) years and regress after menopause. Occasionally, leiomyomas grow during pregnancy, and the hypogonadal state induced by treatment with gonadotropin-releasing hormone (GnRH) agonists often causes shrinkage of myomas.

The environment within the leiomyoma is hyperestrogenic. The estradiol concentration is increased, and leiomyomas contain more estrogen and progesterone receptors.^{108, 109 and 110} Aromatase gene and enzyme expression are present in significant levels in leiomyomata.¹¹¹ Indeed, leiomyoma tissue is hypersensitive to estrogen and appears to have lost a regulatory influence that limits estrogen response.¹¹² Endometrial hyperplasia is frequently observed at the margins of submucous myomas.¹¹³ In the myometrium and in leiomyomas, peak mitotic activity occurs during the luteal phase, and mitotic activity is increased by the administration of high doses of progestational agents.^{114, 115} These facts indicate that progesterone stimulates mitotic activity in leiomyomas, but animal studies indicate both stimulation and inhibition of myometrial growth. Similarly, clinicians have reported both regression and growth with progestational treatment. Nevertheless, most of the evidence supports a growth-promoting role for progestins (the association with estrogen can be explained by the estrogen enhancement of progesterone receptor expression).^{116, 117} Treatment with RU486, the progesterone antagonist, is associated with a reduction in leiomyomata size.¹¹⁸

The *bcl-2* protooncogene, presumably a cell survival gene, produces a protein that prevents apoptosis and promotes cell replication. Bcl-2 protein expression is increased in leiomyoma cells, and markedly increases in response to progesterone.¹¹⁹ In contrast, normal myometrial cells do not respond to estradiol or progesterone with Bcl-2 protein expression, and there is no cyclic change throughout the menstrual cycle. This further supports a key role for progestins in leiomyoma growth.

As in the normal uterus, the effects of estrogen and progestins on leiomyomata are mediated by growth factors.¹²⁰ EGF is overexpressed in myomas, EGF receptors are present in leiomyomata, and GnRH agonist treatment (and hypogonadism) decreases EGF concentration in myomas (but not in normal myometrium).^{121, 122} IGF-I and IGF-II and their receptors are abundant in myometrium, and actively overexpressed in leiomyomas.^{123, 124} Leiomyomas express more IGF-II and less IGF-BP-3 than myometrium, a situation that would enhance growth factor availability and activity in the tumor.¹²⁵ Leiomyomata cells express more parathyroid hormone-related protein (another growth factor) than normal myometrium.¹²⁶ Like the endometrium and myometrium, leiomyomas secrete prolactin, and prolactin functions in the uterus as a growth factor.⁷¹ Even hematopoiesis is possible in a leiomyoma.¹²⁷

One of the consequences of altered growth factor expression in myomas is an abnormal vasculature, characterized by a dilated venous plexus.¹²⁸ This morphologic feature may be the result of specific vascular regulators of angiogenesis, such as basic fibroblast growth factor and vascular endothelial growth factor. These changes probably contribute to the heavy menstrual bleeding associated with submucosal myomas.

Reproductive Function and Leiomyomata

Leiomyomas are an infrequent cause of infertility, either by mechanical obstruction or distortion (and interference with implantation).¹²⁹ When a mechanical obstruction of fallopian tubes, cervical canal, or endometrial cavity is present and no other cause of infertility or recurrent miscarriage can be identified, myomectomy is usually followed by a prompt achievement of pregnancy in a high percentage of patients (usually within the first year).¹³⁰ Submucous myomas are best treated by hysteroscopic resection. Preoperative visualization is important, and mapping of myomas by magnetic resonance imaging (MRI) is superior to ultrasonography (which is relatively inaccurate).¹³¹ It is difficult to distinguish between submucous myomas and endometrial polyps with ultrasonography.¹³² Very large myomas (greater than 4–5 cm) and myomas that do not have greater than 50% protrusion into the cavity are not good candidates for hysteroscopic removal.

The short-term recurrence rate after myomectomy (either abdominal myomectomy or hysteroscopic resection) is about 15%, with subsequent hysterectomy necessary in 1–5% of patients.¹³³ In a series with long-term follow-up, the recurrence rate over 10 years reached 27%.¹³⁴ Women who gave birth after myomectomy had a

recurrence rate (over 10 years) of 16%, compared to a rate of 28% in those who did not give birth. In an Italian study of recurrence, the rate at 5 years reached 55% in those who did give birth after surgery and 42% in those with no childbirth.¹³⁵ These differences may reflect the diligence and sensitivity of the ultrasonographic assessments.

An increased incidence of spontaneous miscarriage because of myomas has not been definitively documented in the literature. Myomectomy for infertility or recurrent miscarriage requires a deliberate and careful decision after all factors have been considered. Intracavitary myomas, however, usually require surgery. Because of the rapid regrowth of myomas following cessation of GnRH agonist therapy, medical therapy for infertility is not recommended.

Myomas are present (diagnosed by ultrasonography) in about 1–2% of pregnancies.¹³⁶ Most myomas do not grow during pregnancy.¹³⁷ When they do, most of the growth is in the first trimester, and most myomas regress in size after the pregnancy. The size of a myoma will not predict its course; large myomas will not necessarily grow more than small ones. Most pregnancies, in the presence of myomas, will, therefore, be uncomplicated (although a higher incidence of cesarean section has been observed).¹³⁶ So-called red degeneration of myomas is occasionally observed during late pregnancy, a condition due to central hemorrhagic infarction of the myoma. Pain is the hallmark of this condition, occasionally associated with rebound tenderness, mild fever, leukocytosis, nausea, and vomiting. Usually pain is the only symptom and resolution follows rest and analgesic treatment.¹³⁸ Surgery should be a last resort. The larger the myoma, the greater the risk of premature labor.¹³⁹

Medical Therapy of Leiomyomata

The goals of medical therapy for leiomyomas are to **temporarily** reduce symptoms and to reduce myoma size, and the therapy of choice is treatment with a GnRH agonist.¹⁴⁰

The short half-life of GnRH is due to rapid cleavage of the bonds between amino acids 5–6, 6–7, and 9–10. By altering amino acids at these positions, analogues of GnRH can be synthesized with different properties. Substitution of amino acids at the 6 position or replacement of the C-terminal glycine-amide (inhibiting degradation) produces agonists. An initial agonistic action (the so-called flare effect) is associated with an increase in the circulating levels of follicle-stimulating hormone (FSH) and luteinizing hormone (LH). This response is greatest in the early follicular phase when GnRH and estradiol have combined to create a large reserve pool of gonadotropins. After 1–3 weeks, desensitization and down-regulation of the pituitary produce a hypogonadotropic, hypogonadal state. The initial response is due to desensitization, the uncoupling of the receptor from its effector system, whereas the sustained response is due to a loss of receptors by down-regulation and internalization. Furthermore, postreceptor mechanisms lead to secretion of biologically inactive gonadotropins, which, however, can still be detected by immunoassay.

The GnRH analogues cannot escape destruction if administered orally. Higher doses administered subcutaneously can achieve nearly equal effects as observed with intravenous treatment; however, the smaller blood peaks are slower to develop and take longer to return to baseline. Other forms of administration include nasal spray, sustained release implants, and intramuscular injections of biodegradable microspheres.

Treatment With GnRH Agonists

Summarizing the experience with GnRH agonist treatment of leiomyomata, the mean uterine size decreases 30–64% after 3–6 months of treatment.¹⁴⁰ Maximal response is usually achieved by 3 months. The reduction in size correlates with the estradiol level and with body weight. Menorrhagia, anemia, pelvic pressure, and urinary frequency all respond favorably to GnRH agonist treatment. A decrease in operative blood loss can be achieved when the pretreatment uterus is as large or larger as a 16-week pregnancy. Why is there a variation in response? When one considers the many factors involved in myoma growth (estrogen, progesterone, growth factors, and receptors), it makes sense that not every myoma is the same. After cessation of GnRH agonist therapy, menses return in 4–10 weeks, and myoma and uterine size return to pretreatment levels in 3–4 months. The rapid regrowth is consistent with the fact that reduction in size is not due to a cytotoxic effect.

Preoperative GnRH agonist therapy offers several advantages for hysteroscopic removal of submucous tumors. In addition to a decrease in myoma size, endometrial atrophy will improve visualization, and decreased vascularity will reduce blood loss.

Leiomyomatosis Peritonealis Disseminata is a condition in which multiple small nodules of benign smooth muscle are found throughout the abdominal cavity, and occasionally in the pulmonary cavity. This condition appears to be sensitive to estrogen because it has been aggravated by postmenopausal estrogen treatment, and regression has been achieved with GnRH agonist treatment.¹⁴¹

Adenomyosis is the ectopic presence of endometrial glands within the myometrium. This diagnosis can be made by magnetic resonance imaging, and successful treatment with a GnRH agonist has been reported.^{142, 143}

Side Effects With GnRH Agonists

Hot flushes are experienced by more than 75% of patients, usually in 3–4 weeks after beginning treatment. Approximately 5–15% of patients will complain of headache, vaginal dryness, joint and muscle stiffness, and depression. About 30% of patients will continue to have irregular (although light) vaginal bleeding. It is useful to measure the circulating estradiol level. If the level is greater than 30 pg/mL, suppression is inadequate. On the other hand, Friedman and colleagues have suggested that maintaining the estradiol level in the early follicular phase range (30–50 pg/mL) can protect against osteoporosis and reduce hot flushes, but not allow the growth of myomas.¹⁴⁴ The efficacy of this titration of response requires validation by clinical studies.

A small number (10%) of patients will experience a localized allergic reaction at the site of injection of depot forms of GnRH analogues. More serious reaction is rare, but immediate and delayed anaphylaxis can occur, requiring intense support and management.¹⁴⁵

Bone loss occurs with GnRH therapy, but not in everyone, and it is reversible (although it is not certain if it is totally reversible in all patients). A significant vaginal hemorrhage 5–10 weeks after beginning treatment is encountered in about 2% of treated women, due to degeneration and necrosis of submucous myomas.¹⁴⁶ A disadvantage of agonist treatment is a delay in diagnosis of a leiomyosarcoma. Keep in mind that almost all leiomyosarcomas present as the largest or only uterine mass. Close monitoring is necessary and surgery has been the usual recommendation when either enlargement or no shrinkage of myomas occurs during GnRH agonist treatment.¹⁴⁷ The use of Doppler ultrasonography or magnetic resonance imaging offers greater accuracy of evaluation. However, the incidence of leiomyosarcoma, even in patients with “rapidly growing leiomyomata,” is very low (less than 0.5%) and almost unheard of in premenopausal women.¹⁰¹ In premenopausal women, a conservative approach is warranted.

Escape of suppression can result in an unexpected pregnancy. No adverse effects of fetal exposure to GnRH agonists have been reported, even when exposure has persisted throughout the early weeks of pregnancy.¹⁴⁸

GnRH Agonists and Steroid Add-Back

Treatment with a GnRH agonist with steroid add-back has been explored to permit long-term therapy without bone loss.¹⁴⁰ Two strategies have been employed: simultaneous agonist and steroid add-back treatment or a sequential regimen in which the agonist is used alone for 3 months, followed by the combination of the agonist and steroid add-back. This long-term treatment is attractive for women who are perimenopausal, perhaps avoiding surgery. In addition, long-term treatment would be useful for women with coagulopathies, and in women with medical problems who need to postpone surgery.

Simultaneous treatment with agonist and medroxyprogesterone acetate (20 mg daily) or norethindrone (10 mg daily) effectively reduced hot flushing, but was less effective (consistent with a major supportive role for progestins in myomas) in reducing uterine volume.^{140, 149} A sequential program, adding a traditional postmenopausal hormone regimen (0.625 mg conjugated estrogens on days 1–25 and 10 mg medroxyprogesterone acetate on days 16–25) effectively reduced uterine volume and maintained the reduced volume for 2 years (and avoided any loss in bone density).¹⁴⁰ A daily 2.5 mg dose of tibolone also prevents bone loss and inhibits vasomotor symptoms without reducing the therapeutic efficacy of GnRH agonist treatment.¹⁵⁰

We recommend 1 month of GnRH agonist treatment followed by agonist treatment combined with a daily, continuous add-back of estrogen and progestin using one of the available postmenopausal daily regimens. In view of the sensitivity of leiomyomata tissue to progestational agents, it makes sense to keep the dose of progestin

relatively low.

Summary of Clinical Advantages With GnRH Agonist Treatment

- Reduction in menstrual blood loss.
- Improvement in anemia prior to surgery.
- Time for autologous blood donation.
- Less operative blood loss.
- Hysterectomy less likely.
- More likely to allow laparoscopic technique.
- Possible conversion from abdominal to vaginal hysterectomy.

Treatment with a GnRH Antagonist

GnRH antagonist treatment can suppress pituitary-gonadal function without the initial stimulatory (flare) response observed with GnRH agonists. Results with depot Cetrorelix preoperative treatment of uterine fibroids are similar to those with GnRH agonist treatment; however, the response is faster (a maximal reduction in size within 14 days), probably because there is no initial flare response. ¹⁵¹

There are two major sites of action within the brain which are important in the regulation of reproductive function, the hypothalamus and the pituitary gland. In the past, the pituitary gland was viewed as the master gland. Then a new concept emerged in which the pituitary was relegated to a subordinate role as part of an orchestra, with the hypothalamus as the conductor, responding to both peripheral and central nervous system messages and exerting its influence by means of neurotransmitters transported to the pituitary by a portal vessel network. Regardless of which site was dominant, the conventional thesis was that the central nervous system-pituitary complex determined and directed the chronology of developmental events within a responsive ovary. However, developments over the past two decades indicate that the complex sequence of events known as the menstrual cycle is controlled by the sex steroids and peptides produced within the very follicle destined to ovulate. The hypothalamus and its direction, and the pituitary, are essential for the operation of the entire mechanism, but the endocrine function that leads to ovulation is brought about by endocrine feedback on the anterior pituitary.

A full understanding of this feature of reproductive biology will benefit the clinician who faces problems in gynecologic endocrinology. With this understanding, the clinician can comprehend the hitherto mysterious, but significant, effects of stress, diet, exercise, and other diverse influences on the pituitary-gonadal axis. Furthermore, we will be prepared to make advantageous use of the numerous neuropharmacologic agents that are the dividends of neuroendocrine research. To these ends, this chapter offers a clinically oriented review of the current status of reproductive neuroendocrinology.

Hypothalamic-Hypophyseal Portal Circulation

The hypothalamus is at the base of the brain just above the junction of the optic nerves. In order to influence the anterior pituitary gland, the brain requires a means of transmission or connection. A direct nervous connection does not exist. The blood supply of the anterior pituitary, however, originates in the capillaries that richly lace the median eminence area of the hypothalamus. The superior hypophyseal arteries form a dense network of capillaries within the median eminence, which then drain into the portal vessels that descend along the pituitary stalk to the anterior pituitary. The direction of the blood flow in this hypophyseal portal circulation is from the brain to the pituitary. Section of the neural stalk which interrupts this portal circulation leads to inactivity and atrophy of the gonads, along with a decrease in adrenal and thyroid activity to basal levels. With regeneration of the portal vessels, anterior pituitary function is restored. Thus, the anterior pituitary gland is under the influence of the hypothalamus by means of neurohormones released into this portal circulation. There also exists retrograde flow so that pituitary hormones can be delivered directly to the hypothalamus, creating the opportunity for pituitary feedback on the hypothalamus. An additional blood supply is provided by short vessels which originate in the posterior pituitary that in turn receives its arterial supply from the inferior hypophyseal arteries.

The Neurohormone Concept

A considerable body of evidence indicates that influence of the pituitary by the hypothalamus is achieved by materials secreted in the cells of the hypothalamus and transported to the pituitary by the portal vessel system. Indeed, pituitary cell proliferation and gene expression are controlled by hypothalamic peptides and their receptors. In addition to the stalk section experiments cited above, transplantation of the pituitary to ectopic sites (e.g., under the kidney capsule) results in failure of gonadal function. With retransplantation to an anatomic site under the median eminence, followed by regeneration of the portal system, normal pituitary function is regained. This retrieval of gonadotropic function is not accomplished if the pituitary is transplanted to other sites in the brain. Hence, there is something very special about the blood draining the basal hypothalamus. An exception to this overall pattern of positive influence is the control of prolactin secretion. Stalk secretion and transplantation cause release of prolactin from the anterior pituitary, implying a negative hypothalamic control. Furthermore, cultures of anterior pituitary tissue release prolactin in the absence of hypothalamic tissue or extracts.

Neuroendocrine agents originating in the hypothalamus have positive stimulatory effects on growth hormone, thyroid-stimulating hormone (TSH), adrenocorticotropin hormone (ACTH), as well as the gonadotropins, and represent the individual neurohormones of the hypothalamus. The neurohormone that controls gonadotropins is called gonadotropin-releasing hormone (GnRH). The neurohormone that controls prolactin is called prolactin-inhibiting hormone and is dopamine. Human corticotropin-releasing hormone (CRH) is a 41 amino acid peptide that besides being the principal regulator of ACTH secretion, also activates the sympathetic nervous system. As we shall see, CRH can suppress gonadotropin secretion, an action partly mediated by endorphin inhibition of GnRH.

In addition to their effects on the pituitary, behavioral effects within the brain have been demonstrated for several of the releasing hormones. Thyrotropin-releasing hormone (TRH) antagonizes the sedative action of a number of drugs and also has a direct antidepressant effect in humans. GnRH evokes mating behavior in male and female animals.¹

Initially, it was believed that there were two separate releasing hormones, one for follicle-stimulating hormone (FSH) and another for luteinizing hormone (LH). It is now apparent that there is a single neurohormone (GnRH) for both gonadotropins. GnRH is a small peptide with 10 amino acids with some variation in the amino acid

sequence among various mammals. Purified or synthesized GnRH stimulates both FSH and LH secretion. The divergent patterns of FSH and LH in response to a single GnRH are due to the modulating influences of the endocrine environment, specifically the feedback effects of steroids on the anterior pituitary gland.

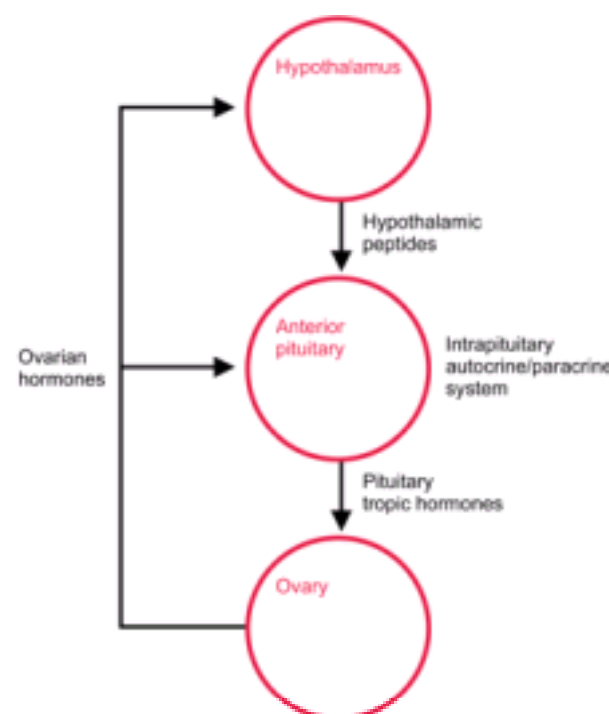

The classic neurotransmitters are secreted at the nerve terminal. Brain peptides require gene transcription, translation, and posttranslational processing, all within the neuronal cell body, the final product being transported down the axon to the terminal for secretion. Small neuroendocrine peptides share common large precursor polypeptides, called polyproteins or polyfunctional peptides. These proteins can serve as precursors for more than one biologically active peptide.

The gene that encodes for the 92 amino acid precursor protein for GnRH is located on the short arm of chromosome 8.² The precursor protein for GnRH contains (in the following order) a 23 amino acid signal sequence, the GnRH decapeptide, a 3 amino acid proteolytic processing site, and a 56 amino acid sequence called GAP (GnRH-associated peptide).³ GAP is a potent inhibitor of prolactin secretion as well as a stimulator of gonadotropins; however, a physiologic role for GAP has not been established. Its primary role may be to provide appropriate conformational support for GnRH.

It is now apparent that GnRH has autocrine/paracrine functions throughout the body. It is present in both neural and nonneural tissues, and receptors are present in many extrapituitary tissues (such as the ovarian follicle and the placenta). Although GnRH is identical in all mammals, other nonmammalian forms exist, indicating that the GnRH molecule has existed for at least 500 million years.^{4,5} The central sequence, Tyr-Gly-Leu-Arg, is the nonconserved segment of GnRH, the segment with the most variability in other species. Accordingly, substitutions in this segment are well tolerated.

A second form of GnRH, known as GnRH-II, has been known to exist in many other species. GnRH-II consists of the following sequence: pGln-His-Trp-Ser-His-Gly-Trp-Tyr-Pro-Gly. Prompted by its existence in other species, a search for its presence in humans was ultimately successful. A gene encoding GnRH-II is located on the human chromosome 20p13, obviously distinct from the GnRH-I gene on 8p21-p11.2.⁶ Both genes produce a peptide with a signal sequence, a GnRH decapeptide, a proteolytic site, and a GAP. Human GnRH-II expression is highest outside the brain. An analysis of the evolution of GnRH indicates 3 major forms: GnRH localized to the hypothalamus (GnRH-I), forms in midbrain nuclei and outside the brain (GnRH-II), and forms in several fish species (GnRH-III); thus indicating appearance of the various forms before the emergence of vertebrates.⁶

Perhaps the notion that the pituitary is a master gland should not be discarded. Although it is highly regulated by input from other sites, its function is essential for sustaining life. Pituitary development and activity are under the control of the hypothalamus (with input from other central nervous system sites), and pituitary response is finely tuned by hormonal messages from tissues that are the targets of the pituitary trophic hormones. In addition, the pituitary has its own autocrine/paracrine system for enhancement and suppression of growth and function. But the pituitary gland is the focus for all of this activity, and this central, coordinating role is critical for normal life.

Prolactin Secretion

Prolactin gene expression occurs in the lactotrophs of the anterior pituitary gland, in decidualized endometrium, and the myometrium. The prolactin secreted in these various sites is identical, but there are differences in mRNA indicating differences in prolactin gene regulation.

Transcription of the prolactin gene is regulated by a transcription factor (a protein named Pit-1) that binds to the 5' promoter region and that is also necessary for growth hormone and TSH.⁷ In addition, prolactin gene transcription is regulated by the interaction of estrogen and glucocorticoid receptors with 5' flanking sequences. Mutations in the sequences of these flanking regions or in the gene for the Pit-1 protein can result in the failure to secrete prolactin. The Pit-1 gene is also involved in differentiation and growth of anterior pituitary cells, and therefore mutations in this gene can lead not only to absent secretion of growth hormone, prolactin, and TSH, but also an absence of their trophic cells in the pituitary; the result is significant hypopituitarism.⁸ Molecular studies indicate that Pit-1 participates in mediating both stimulatory and inhibitory hormone signals for prolactin gene transcription. However, alterations in Pit-1 gene expression are not involved in pituitary tumor formation.⁹

The main function of prolactin in mammals is lactogenesis, while in fish prolactin is important for osmoregulation. The prolactin gene from the Chinook salmon contains coding sequences that are similar to those in mammals, and it is regulated similarly in the pituitary.¹⁰ Pit-1, the pituitary specific transcription factor, therefore, appears to be highly conserved among species.

Prolactin gene expression is further regulated by other species-specific factors. Prolactin gene transcription is stimulated by estrogen and mediated by estrogen receptor binding to estrogen responsive elements. This activation by estrogen requires interaction with Pit-1, in a manner not yet determined. Proximal promoter sequences are also activated by peptide hormones binding to cell surface receptors; e.g., TRH and growth factors. In addition, various agents that control cyclic AMP and calcium channels can stimulate or inhibit prolactin promoter activity.

Pituitary secretion of prolactin is chiefly under the inhibitory control of hypothalamic dopamine released into the portal circulation. The action of dopamine in the pituitary is mediated by receptors that are coupled to the inhibition of adenylate cyclase activity. There are 5 forms of the dopamine receptor, divided into 2 functional groups, D₁ and D₂.¹¹ The D₂ type is the predominant receptor in the anterior pituitary gland. The structure and function of the dopamine receptors are of the G protein system as described in [Chapter 2](#). Binding of dopamine to the receptor leads to suppression of adenylate cyclase and cyclic AMP maintenance of prolactin gene transcription and prolactin secretion. Other mechanisms are also activated, including suppression of intracellular calcium levels. Pit-1 binding sites are involved in this dopamine response. In addition to direct inhibition of prolactin gene expression, dopamine binding to the D₂ receptor also inhibits lactotroph development and growth. These multiple effects of dopamine explain the ability of dopamine agonists to suppress prolactin secretion and the growth of prolactin-secreting pituitary adenomas. No activating or inactivating mutations of the dopamine receptors have been reported.

The secretion of prolactin is inhibited and stimulated by the association and dissociation of dopamine from its receptors.¹² Several factors exert a stimulatory effect on prolactin secretion (prolactin-releasing factors), especially TRH, vasoactive intestinal peptide (VIP), epidermal growth factor, and perhaps GnRH. These factors interact with each other, affecting the overall lactotroph responsiveness.

The Hypothalamus and GnRH Secretion

The hypothalamus is the part of the diencephalon at the base of the brain that forms the floor of the third ventricle and part of its lateral walls. Within the hypothalamus are peptidergic neural cells that secrete the releasing and inhibiting hormones. These cells share the characteristics of both neurons and endocrine gland cells. They respond to signals in the bloodstream, as well as to neurotransmitters within the brain, in a process known as neurosecretion. In neurosecretion, a

neurohormone or neurotransmitter is synthesized on the ribosomes in the cytoplasm of the neuron, packaged into a granule in the Golgi apparatus, and then transported by active axonal flow to the neuronal terminal for secretion into a blood vessel or across a synapse.

The cells that produce GnRH originate from the olfactory area. By migration during embryogenesis, the cells move along cranial nerves connecting the nose and the forebrain to their primary location, where eventually 1000–3000 GnRH-producing cells can be found in the arcuate nucleus of the hypothalamus.¹³ The GnRH neurons appear in the medial olfactory placode (a thickened plate of ectoderm from which a sense organ develops) and enter the brain with the nervus terminalis, a cranial nerve that projects from the nose to the septal-preoptic nuclei in the brain.¹⁴ This amazing journey accounts for Kallmann's syndrome, an association between an absence of GnRH and a defect in smell (a failure of both olfactory axonal and GnRH neuronal migration from the olfactory placode). Three modes of transmission have been documented: X-linked, autosomal dominant, and autosomal recessive.¹⁵ The 5–7-fold increased frequency in males indicates that X-linked transmission is the most common. The mutations responsible for this syndrome result in the failure to produce a protein (homologous to members of the fibronectin family) responsible for cell adhesion and protease inhibition, functions necessary for neuronal migration.^{16, 17} Like olfactory epithelial cells in the nasal cavity, GnRH neurons have cilia.¹⁸ The olfactory origin and the structural similarity of GnRH neurons and nasal epithelial cells suggest an evolution from reproduction controlled by pheromones.

Pheromones are airborne chemicals released by one individual that can affect other members of the same species. Odorless compounds obtained from the axillae of women in the late follicular phase of their cycles accelerated the LH surge and shortened the cycles of recipient women, and compounds from the luteal phase had the opposite effects.¹⁹ This may be one mechanism by which women who are together much of the time often exhibit a synchrony in menstrual cycle timing.^{20, 21}

In primates, the primary network of GnRH cell bodies is located within the medial basal hypothalamus.²² and²⁴ Most of these cell bodies can be seen within the arcuate nucleus where GnRH is synthesized in GnRH neurons. The GnRH neurons exist in a complex network and are connected to each other and to many other neurons. This physical arrangement allows multiple interactions with neurotransmitters, hormones, and growth factors to modulate GnRH release. The delivery of GnRH to the portal circulation is via an axonal pathway, the GnRH tuberoinfundibular tract.

Fibers, identified with immunocytochemical techniques using antibodies to GnRH, can also be visualized in the posterior hypothalamus, descending into the posterior pituitary, and in the anterior hypothalamic area projecting to sites within the limbic system.²² Using hybridization techniques, messenger RNA for GnRH has been localized to the same sites previously identified by immunoreactivity. However, lesions that interrupt GnRH neurons projecting to regions other than the median eminence do not affect gonadotropin release. Only lesions of the arcuate nucleus in the monkey lead to gonadal atrophy and amenorrhea.²⁵ Therefore, the arcuate nucleus can be viewed with the median eminence as a unit, the key locus within the hypothalamus for GnRH secretion into the portal circulation. The other GnRH neurons may be important for a variety of behavioral responses.

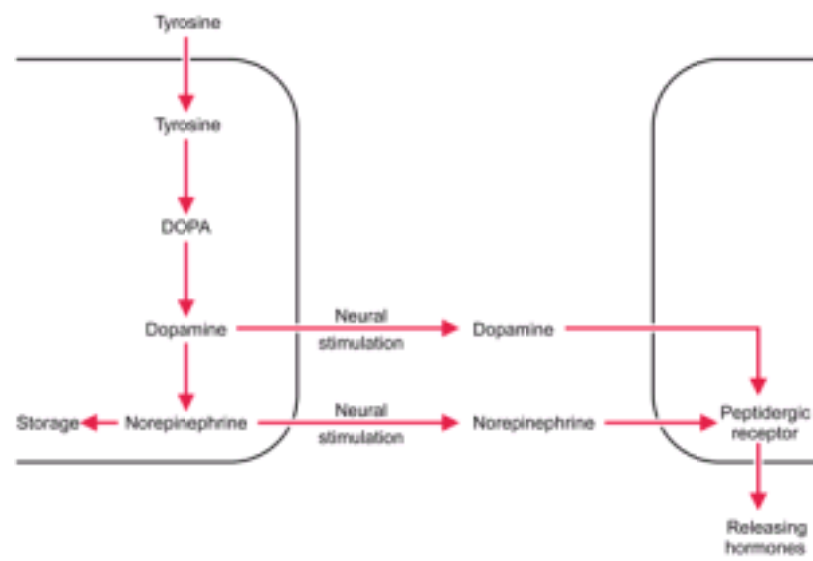

GnRH Secretion

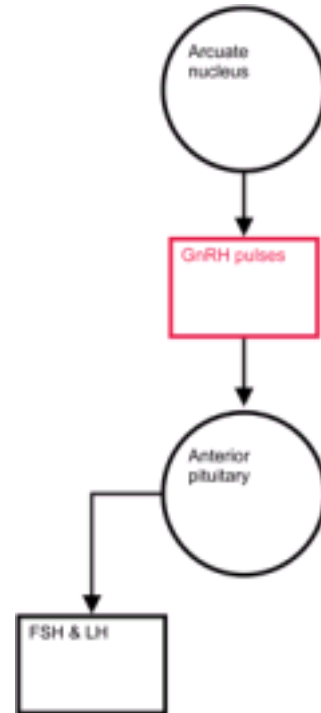

The half-life of GnRH is only 2–4 minutes. Because of this rapid degradation, combined with the enormous dilution upon entry into the peripheral circulation, biologically effective amounts of GnRH do not escape the portal system. Therefore, control of the reproductive cycle depends on constant release of GnRH. This function, in turn, depends upon the complex and coordinated interrelationships among this releasing hormone, other neurohormones, the pituitary gonadotropins, and the gonadal steroids. The interplay among these substances is governed by feedback effects, both positive stimulatory and negative inhibitory. **The long feedback loop** refers to the feedback effects of circulating levels of target gland hormones, and this occurs both in the hypothalamus and the pituitary. **The short feedback loop** indicates a negative feedback of pituitary hormones on their own secretion, presumably via inhibitory effects on releasing hormones in the hypothalamus. **Ultrashort feedback** refers to inhibition by the releasing hormone on its own synthesis. These signals as well as signals from higher centers in the central nervous system may modify GnRH secretion through an array of neurotransmitters, primarily dopamine, norepinephrine, and endorphin but also serotonin and melatonin. GnRH neurons lack estradiol receptors; therefore, steroid hormone regulation is believed to be mediated through this collection of neurotransmitters.

Dopamine and norepinephrine are synthesized in the nerve terminals by decarboxylation of dihydroxyphenylalanine (DOPA), which in turn is synthesized by hydroxylation of tyrosine. Dopamine is the immediate precursor of norepinephrine, but dopamine itself functions as a key neurotransmitter in the hypothalamus and the pituitary.

A most useful concept is to view the arcuate nucleus as the central site of action, releasing GnRH into the portal circulation in pulsatile fashion. In a classic series of experiments, it was demonstrated that normal gonadotropin secretion requires pulsatile GnRH discharge within a critical range in frequency and amplitude.²⁶ Even pituitary hormone gene transcription is sensitive to the pulsatile nature of GnRH release.²⁷

Experimental manipulations have indicated that the critical range of GnRH pulsatile secretion is rather narrow. The administration (to monkeys) of 1 mg GnRH per minute for 6 minutes every hour (1 pulse per hour) produces a portal blood concentration about equal to the peak concentration of GnRH in human portal blood, about 2 ng/mL. Increasing the frequency to 2 and 5 pulses per hour extinguishes gonadotropin secretion. A similar decline in gonadotropin secretion is obtained by increasing the dose of GnRH. Decreasing the pulse frequency decreases LH secretion but increases FSH secretion.

Like GnRH, gonadotropins are also secreted in pulsatile fashion, and indeed, the pulsatile pattern of gonadotropin release reflects the pulsatile GnRH pattern. ^{28, 29} GnRH and gonadotropin secretion are always pulsatile in nature, but an augmentation of the pulsatile pattern of gonadotropin secretion occurs just before puberty with nighttime increases in LH. After puberty, enhanced pulsatile secretion is maintained throughout the 24-hour period, but it varies in both amplitude and frequency. In puberty, arcuate activity begins with a low frequency of GnRH release and proceeds through a cycle of acceleration of frequency, characterized by passage from relative inactivity, to nocturnal activation, to the full adult pattern. The progressive changes in FSH and LH reflect this activation of GnRH pulsatile secretion. Ovarian steroid release is also pulsatile, coordinated with LH pulses, the major stimulator of ovarian steroidogenesis. ³⁰

Timing of GnRH Pulses

The measurement of LH pulses is utilized as an indication of GnRH pulsatile secretion (the long half-life of FSH precludes its use for this purpose). ³¹ The characteristics of LH pulses (and presumably of GnRH pulses) during the menstrual cycle are as follows: ³²

LH pulse mean amplitude:

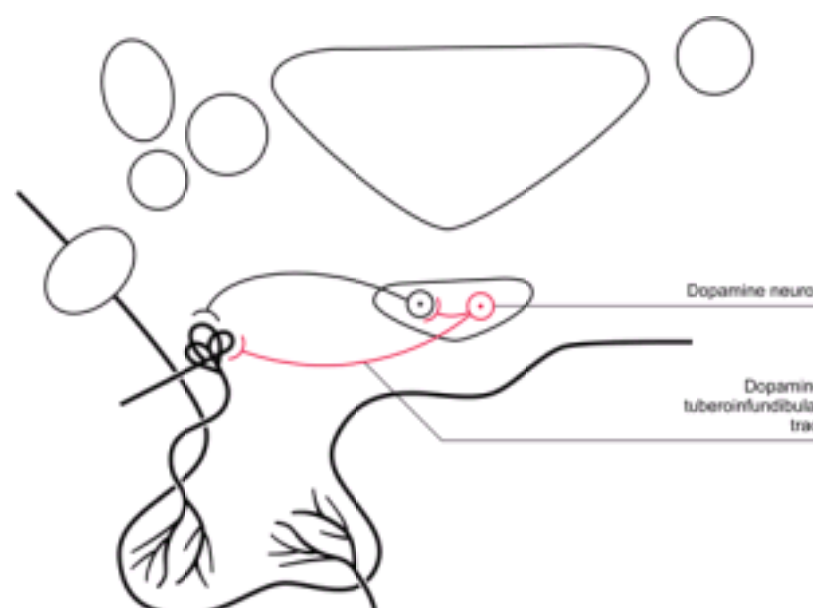

Early follicular phase	6.5 IU/L.
Midfollicular phase	5.0 IU/L.
Late follicular phase	7.2 IU/L.
Early luteal phase	15.0 IU/L.
Midluteal phase	15.0 IU/L.
Late luteal phase	8.0 IU/L.

LH pulse mean frequency:

Early follicular phase	90 minutes.
Late follicular phase	60–70 minutes.
Early luteal phase	100 minutes.
Late luteal phase	200 minutes

Pulsatile secretion is more frequent but lower in amplitude during the follicular phase compared to the luteal phase. It should be emphasized that these numbers are not inviolate. There is considerable variability between and within individuals and a wide normal range exists. ³³ Despite the handicap of the long half-life, it has been ascertained that FSH secretion is correlated with LH secretion.

The anterior pituitary gland also appears to have a pulsatile pattern of its own. Although pulses of significant amplitude are linked to GnRH, small amplitude pulses of high frequency represent spontaneous secretion (at least as demonstrated in isolated pituitary glands in vitro). ³⁴ It is not known whether this has any importance physiologically, and at the present time, the pituitary secretory pattern is thought to reflect GnRH.

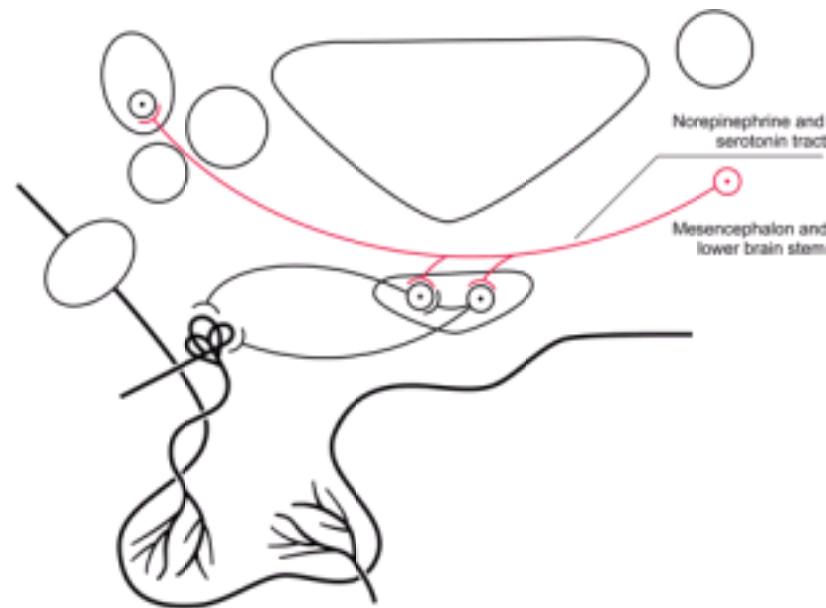

Control of GnRH Pulses

Normal menstrual cycles require the maintenance of the pulsatile release of GnRH within a critical range of frequency and amplitude. Pulsatile, rhythmic activity is an intrinsic property of GnRH neurons, and the effect of various hormones and neurotransmitters must be viewed as modulating actions.³⁵

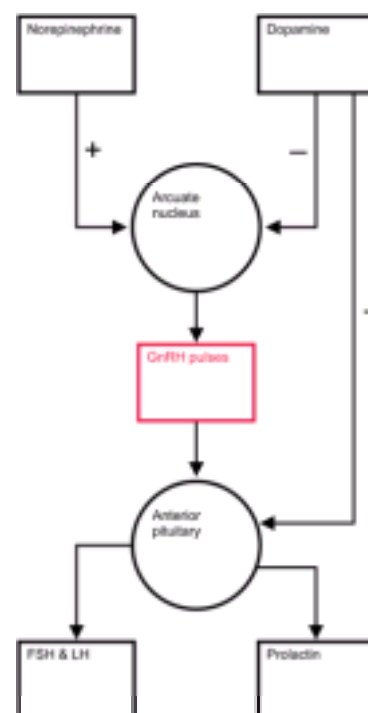

The Dopamine Tract. Cell bodies for dopamine synthesis can be found in the arcuate and periventricular nuclei. The dopamine tuberoinfundibular tract arises within the medial basal hypothalamus and projects to the median eminence.

The administration of dopamine by intravenous infusion to men and women is associated with a suppression of circulating prolactin and gonadotropin levels.³⁶ Dopamine does not exert a direct effect on gonadotropin secretion by the anterior pituitary; thus, this effect is mediated through GnRH release in the hypothalamus. Dopamine is directly secreted into the portal blood, thus behaving like a neurohormone. Therefore, dopamine may directly suppress arcuate GnRH activity, and also be transported via the portal system to directly and specifically suppress pituitary prolactin secretion. The hypothalamic tuberoinfundibular dopamine pathway is not the only dopamine pathway in the CNS, and it is only one of two major dopamine pathways in the hypothalamus. But it is this pathway that directly participates in the regulation of prolactin secretion.

The Norepinephrine Tract. Most of the cell bodies that synthesize norepinephrine are located in the mesencephalon and lower brainstem. These cells also synthesize serotonin. Axons for amine transport ascend into the medial forebrain bundle to terminate in various brain structures including the hypothalamus.

Neuropeptide Y. The secretion and gene expression of neuropeptide Y in hypothalamic neurons is regulated by gonadal steroids.³⁸ Neuropeptide Y stimulates pulsatile release of GnRH and in the pituitary potentiates gonadotropin response to GnRH.³⁹ It thus may facilitate pulsatile secretion of GnRH and gonadotropins. In the absence of estrogen, neuropeptide Y inhibits gonadotropin secretion. Because undernutrition is associated with an increase in neuropeptide Y (see [Chapter 19](#)) and increased amounts have been measured in cerebrospinal fluid of women with anorexia and bulimia nervosa, it has been proposed that neuropeptide Y is at least one link between nutrition and reproductive function.^{40, 41}

The current concept is that the biogenic catecholamines modulate GnRH pulsatile release.³⁷ Norepinephrine is thought to exert stimulatory effects on GnRH, while dopamine and serotonin exert inhibitory effects. For an understanding of clinical problems, it is best to view dopamine as an inhibitor of both GnRH and prolactin. Little is known, however, about the role of serotonin. The probable mode of action of catecholamines is to influence the frequency (and perhaps the amplitude) of GnRH discharge. Thus, pharmacologic or psychologic factors that affect pituitary function probably do so by altering catecholamine synthesis or metabolism, and thus the pulsatile release of GnRH.

Pituitary Gonadotropin Secretion

The gene for the α subunit of the gonadotropins is expressed in both the pituitary and placenta. The β -subunit for human chorionic gonadotropin (HCG) is expressed in the placenta but only minimally (and with alterations in structure) in the pituitary, while the LH β -subunit, as expected, is expressed in the pituitary but not significantly in the placenta.^{42, 43} Studies of gonadotropin gene expression confirm the relationships established by earlier studies. The sex steroids decrease and castration increases the rate of gonadotropin gene transcription as reflected by the levels of specific messenger RNAs. In addition, the sex steroids can act at the membrane level, affecting the interaction of GnRH with its receptor.⁴⁴

Both LH and FSH are secreted by the same cell, the gonadotrope, localized primarily in the lateral portions of the pituitary gland and responsive to the pulsatile stimulation by GnRH. GnRH is calcium dependent in its mechanism of action and utilizes inositol 1,4,5-triphosphate (IP_3) and 1,2-diacylglycerol (1,2-DG) as second messengers to stimulate protein kinase activity ([Chapter 2](#)).⁴⁵ These responses require a G protein receptor, and are associated with cyclical release of calcium ions from intracellular stores and the opening of cell membrane channels to allow entry of extracellular calcium. Thus, both protein kinase and calmodulin are mediators of GnRH action. The GnRH receptor, a member of the G protein family, is encoded by a gene on chromosome 4q13.—14q21.1.⁴⁶ GnRH receptors are regulated by many agents, including GnRH itself, inhibin, activin, and the sex steroids.⁴⁷ A decreased gonadotropin response to continued excessive GnRH stimulation is not due to a loss of GnRH receptors alone but includes desensitization and uncoupling of the receptors (discussed in [Chapter 2](#)).

Synthesis of gonadotropins takes place on the rough endoplasmic reticulum. The hormones are packaged into secretory granules by the Golgi cisternae of the Golgi apparatus and then stored as secretory granules. Secretion requires migration (activation) of the mature secretory granules to the cell membrane where an alteration in membrane permeability results in extrusion of the secretory granules in response to GnRH. The rate-limiting step in gonadotropin synthesis is the GnRH-dependent availability of the beta-subunits.

Binding of GnRH to its receptor in the pituitary activates multiple messengers and responses. The immediate event is a secretory release of gonadotropins, while

delayed responses prepare for the next secretory release. One of these delayed responses is the self-priming action of GnRH that leads to even greater responses to subsequent GnRH pulses due to a complex series of biochemical and biophysical intracellular events. This self-priming action is important to achieve the large surge in secretion at midcycle; it requires estrogen exposure, and it can be augmented by progesterone. This important action of progesterone depends upon estrogen exposure (for an increase in progesterone receptors) and activation of the progesterone receptor by GnRH stimulated phosphorylation. This latter action is an example of cross-talk between peptide and steroid hormone receptors.

Five different types of secretory cells coexist within the anterior pituitary gland: gonadotropes, lactotropes, thyrotropes, somatotropes, and corticotropes. Autocrine and paracrine interactions combine to make anterior pituitary secretion subject to more complicated control than simply reaction to hypothalamic releasing factors and modulation by feedback signals. Substantial experimental evidence exists to indicate stimulatory and inhibitory influences of various substances on the pituitary secretory cells.

The Intrapituitary Autocrine/Paracrine System

Intrapituitary cytokines and growth factors provide an autocrine/paracrine system for regulating pituitary cell development and replication as well as pituitary hormone synthesis and secretion. The pituitary contains the familiar cast of substances encountered in organs throughout the body, including the interleukins, epidermal growth factor, fibroblast growth factors, the insulin-like growth factors, nerve growth factor, activin, inhibin, and many others.⁴⁸ As in most tissues, the interaction among these substances is a complex story, but the activin/inhibin mechanism deserves emphasis.

Activin, Inhibin, and Follistatin

Activin and inhibin are peptide members of the transforming growth factor- β family.⁴⁶ Inhibin consists of two dissimilar peptides (known as alpha- and beta-subunits) linked by disulfide bonds. Two forms of inhibin (inhibin A and inhibin B) have been purified, each containing an identical alpha-subunit and distinct but related beta-subunits. Thus, there are three subunits for inhibins: alpha, beta-A, and beta-B. Each subunit is a product of different messenger RNA; therefore, each is derived from its own large precursor molecule.

Inhibin is secreted by granulosa cells, but messenger RNA for the alpha and beta chains has also been found in pituitary gonadotropes.⁵⁰ Inhibin selectively inhibits FSH, but not LH, secretion. Indeed, while suppressing FSH synthesis, inhibin may enhance LH activity.⁵¹ Cells actively synthesizing LH respond to inhibin by increasing GnRH receptor number; FSH dominant cells are suppressed by inhibin.⁵¹ Inhibin has little or no effect on growth hormone, ACTH, and prolactin production.

Activin, also derived from granulosa cells, but present as well in the pituitary gonadotropes, contains two subunits that are identical to the beta-subunits of inhibins A and B. Activin augments the secretion of FSH and inhibits prolactin, ACTH, and growth hormone responses.^{52, 53 and 54} Activin increases pituitary response to GnRH, probably by enhancing GnRH receptor formation.⁴⁷ The effects of activin are blocked by inhibin and follistatin.⁵⁵ The roles for inhibin and activin in regulating the events of the menstrual cycle are discussed in [Chapter 6](#).

The Two Forms of Inhibin

Inhibin-A:	Alpha-Beta _A
Inhibin-B:	Alpha-Beta _B

The Three Forms of Activin

Activin-A:	Beta _A -Beta _A
Activin-AB:	Beta _A -Beta _B
Activin-B:	Beta _B -Beta _B

Follistatin is a peptide secreted by a variety of pituitary cells, including the gonadotropes.⁵⁶ This peptide has also been called FSH-suppressing protein because of its main action: inhibition of FSH synthesis and secretion and the FSH response to GnRH, probably by binding to activin and in that fashion decreasing the activity of activin.^{57, 58} Activin stimulates follistatin production, and inhibin prevents this response.

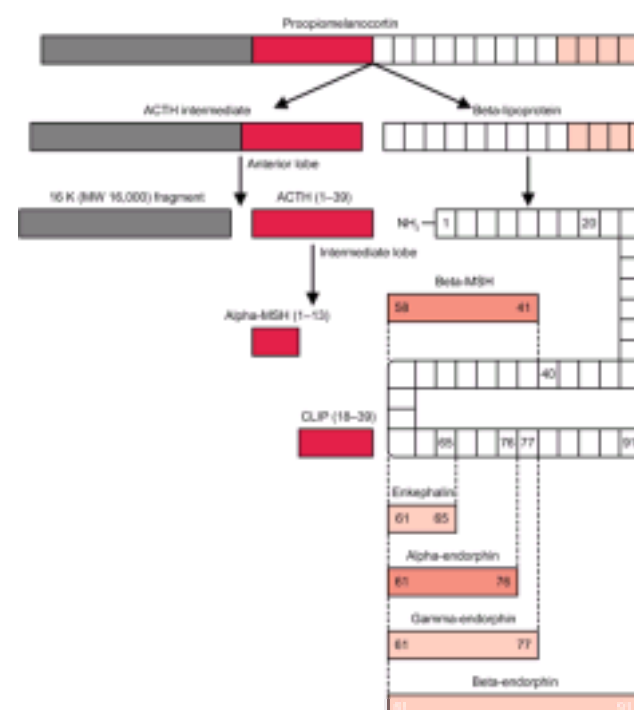

In summary, GnRH stimulates gonadotropin synthesis and secretion, as well as activin, inhibin, and follistatin. Activin enhances and follistatin suppresses GnRH activity. Evidence in vivo and in vitro indicates that gonadotropin response to GnRH requires activin activity.⁵⁹ This relationship may contribute to the down-regulation of pituitary gonadotropin secretion by prolonged GnRH stimulation. Increasing GnRH pulsatile frequency first increases FSH production, and then with high frequency or continuous GnRH stimulation, follistatin production is increased.⁵⁹

The Endogenous Opiates

The most fascinating peptide group is the endogenous opioid peptide family.⁶⁰ β -Lipotropin is a 91 amino acid molecule which was first isolated from the pituitary in 1964. Its function remained a mystery for more than 10 years until receptors for opioid compounds were identified, and by virtue of their existence, it was postulated that endogenous opioid compounds must exist and serve important physiological roles. Endorphin was a word coined to denote morphine-like action and endogenous origin in the brain.

Opiate production is regulated by gene transcription and the synthesis of precursor peptides and at a posttranslational level where the precursors are processed into the various bioactive smaller peptides.⁶¹ All opiates derive from one of 3 precursor peptides.

- Proopiomelanocortin (POMC)** — the source of endorphins.
- Proenkephalin A and B** — the source of several enkephalins.
- Prodynorphin** — yields dynorphins.

POMC was the first precursor peptide to be identified. It is made in the anterior and intermediate lobes of the pituitary, in the hypothalamus and other areas of the brain, in the sympathetic nervous system, and in other tissues including the gonads, the placenta, the gastrointestinal tract, and the lungs. The highest concentration

is in the pituitary gland.

Proopiomelanocortin is split into 2 fragments, an ACTH intermediate fragment and b-lipotropin. b-Lipotropin has no opioid activity but is broken down in a series of steps to b-melanocyte-stimulating hormone (b-MSH), enkephalin, and a-, g-, and b-endorphins. Melanocytestimulating hormone acts in lower animals to stimulate melanin granules within cells, causing darkening of the skin. In humans, there is no known function.

Enkephalin and the a- and g-endorphins are as active as morphine on a molar basis, while b-endorphin is 5–10 times more potent. In the adult pituitary gland, the major products are ACTH and b-lipotropin, with only small amounts of endorphin. Thus, ACTH and b-lipotropin blood levels show similar courses, and they are major secretion products of the anterior pituitary in response to stress. In the intermediate lobe of the pituitary (which is prominent only during fetal life), ACTH is cleaved to CLIP (corticotropin-like intermediate lobe peptide) and b-MSH. In the placenta and adrenal medulla, POMC processing yields a-MSH-like and b-endorphin peptides. b-Endorphin has also been detected in the ovaries and in the testes.

In the brain, the major products are the opiates, with little ACTH. In the hypothalamus the major products are b-endorphin and a-MSH in the region of the arcuate nucleus and the ventromedial nucleus. The pituitary system is a system for secretion into the circulation while the hypothalamic system allows for distribution via axons to regulate other brain regions and the pituitary gland.

b-Endorphin is appropriately considered a neurotransmitter, a neurohormone, and a neuromodulator. b-Endorphin influences a variety of hypothalamic functions, including regulation of reproduction, temperature, cardiovascular and respiratory function, as well as extrahypothalamic functions such as pain perception and mood. POMC gene expression in the anterior pituitary is controlled mainly by corticotropin-releasing hormone and influenced by the feedback effects of glucocorticoids. In the hypothalamus, regulation of POMC gene expression is via the sex steroids.⁶² In the absence of sex steroids, little, if any, secretion occurs.

Proenkephalin A is produced in the adrenal medulla, the brain, the posterior pituitary, the spinal cord, and the gastrointestinal tract. It yields several enkephalins: methionine-enkephalin, leucine-enkephalin, and other variants. The enkephalins are the most widely distributed endogenous opioid peptides in the brain and are probably mainly involved as inhibitory neurotransmitters in the modulation of the autonomic nervous system. Prodynorphin, found in the brain (concentrated in the hypothalamus) and the gastrointestinal tract, yields dynorphin, an opioid peptide with high analgesic potency and behavioral effects, as well as a-neoendorphin, b-neoendorphin, and leuromorphin. The last 13 amino acids of leuromorphin constitute another opioid peptide, rimorphin. The prodynorphin products probably function in a fashion similar to endorphin.

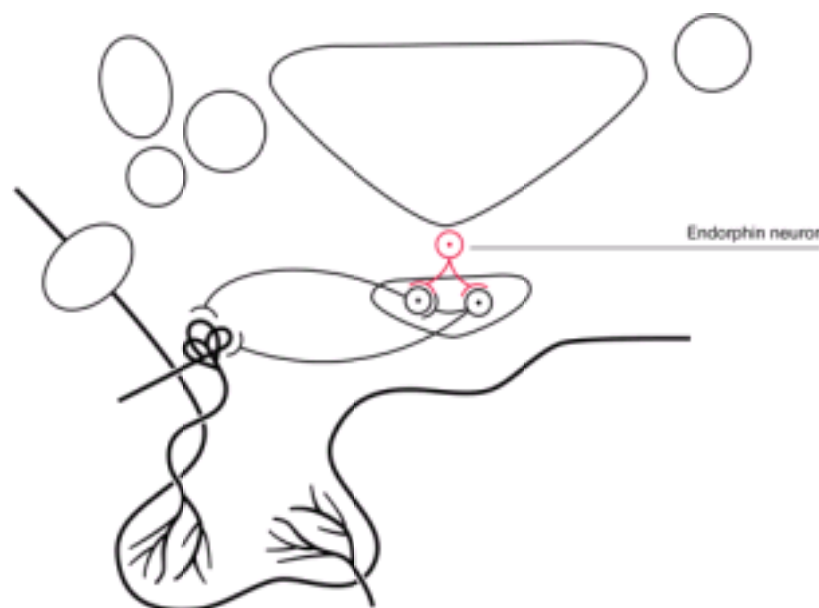

It is simpler to say that there are 3 classes of opiates: enkephalins, endorphin, and dynorphin.

Opioid peptides are able to act through different receptors, although specific opiates bind predominantly to one of the various receptor types. Naloxone, used in most human studies, does not bind exclusively to any one receptor type, and thus results with this antagonist are not totally specific. Localization of opioid receptors explains many of the pharmacological actions of the opiates. Opioid receptors are found in the nerve endings of sensory neurons, in the limbic system (site of euphoric emotions), in brainstem centers for reflexes such as respiration, and widely distributed in the brain and the spinal cord.

Opioid Peptides and the Menstrual Cycle

The opioid tone is an important part of menstrual function and cyclicity.⁶³ Although estradiol alone increases endorphin secretion, the highest levels of endorphin occur with sequential therapy of both estradiol and progesterone (in ovariectomized monkeys). Endogenous endorphin levels, therefore, increase throughout the cycle from nadir levels during menses to highest levels during the luteal phase. Normal cyclicity thus requires sequential periods of high (luteal phase) and low (during menses) hypothalamic opioid activity.

A reduction in LH pulse frequency is linked to increased endorphin release.⁶⁴ Naloxone increases both the frequency and the amplitude of LH pulses. ***Thus, the endogenous opiates inhibit gonadotropin secretion by suppressing the hypothalamic release of GnRH.*** Opiates have no effect on the pituitary response to GnRH. The gonadal steroids modify endogenous opioid activity, and the negative feedback of steroids on gonadotropins appears to be mediated by endogenous opiates. Because the fluctuating levels of endogenous opiates in the menstrual cycle are related to the changing levels of estradiol and progesterone, it is attractive to speculate that the sex steroids directly stimulate endogenous opioid receptor activity. There is an absence of opioid effect on postmenopausal and oophorectomized levels of gonadotropins, and the response to opiates is restored with the administration of estrogen, progesterone, or both.⁶⁵ Both estrogen and progesterone alone increase endogenous opiates, but estrogen enhances the action of progesterone, which could explain the maximal suppression of GnRH and gonadotropin pulse frequency during the luteal phase.^{66, 67} In pubertal boys and girls, however, naloxone could not prevent the suppression of LH by estradiol administration, indicating that in this circumstance estradiol may directly inhibit GnRH secretion.^{68, 69} Nevertheless, the evidence overall indicates that endogenous opiates exert an inhibiting influence over GnRH secretion.⁷⁰

The inhibiting tone of endogenous opiates is reduced at the time of the ovulatory surge, allowing a release from suppression.⁷¹ This is probably a response to estrogen, specifically an estrogen-induced decrease in opioid receptor binding and opioid release.^{72, 73}

Experiments with naloxone administration suggest that the suppression of gonadotropins during pregnancy and the recovery during the postpartum period reflect steroid-induced opioid inhibition, followed by a release from central opioid suppression.

The principal endogenous opiates affecting GnRH release are b-endorphin and dynorphin, and it is probable that the major effect is modulation of the catecholamine pathway, principally norepinephrine. The action does not involve dopamine receptors, acetylcholine receptors, or alpha-adrenergic receptors. On the other hand, endorphin may affect GnRH release directly, without the involvement of any intermediary neuroamine.

Because a-MSH counteracts the effects of b-endorphin, posttranslational processing of POMC can affect hypothalamic-pituitary function by altering the amounts of a-MSH and b-endorphin.⁷⁴ This introduces another potential site for neuroendocrine regulation of reproductive function. Gonadal hormones likely have multiple sites for feedback signals.

Clinical Implications

A change in opioid inhibitory tone is not important in the changes of puberty because the responsiveness to naloxone does not develop until after puberty. A change in opioid tone does seem to mediate the hypogonadotropic state seen with elevated prolactin levels, exercise, and other conditions of hypothalamic amenorrhea, while endogenous opioid inhibition does not seem to play a causal role in delayed puberty or hereditary problems such as Kallmann's syndrome.^{75, 76} Treatment of patients with hypothalamic amenorrhea (suppressed GnRH pulsatile secretion) with a drug (naltrexone) which blocks opioid receptors restores normal function

(ovulation and pregnancy).⁷⁷ Thus, the reduced GnRH secretion associated with hypothalamic amenorrhea is mediated by an increase in endogenous opioid inhibitory tone.

Experimental evidence indicates that corticotropin-releasing hormone (CRH) directly inhibits hypothalamic GnRH secretion, both directly and by augmenting endogenous opioid secretion. Women with hypothalamic amenorrhea demonstrate hypercortisolism, suggesting that this could be the pathway by which stress interrupts reproductive function.⁷⁸ Mathematical analysis of the associations among FSH, LH, b-endorphin and cortisol pulses support the existence of significant functional coupling between the neuroregulatory systems that control the gonadal and adrenal axes.⁷⁹ The CRH gene contains two segments that are similar to estrogen response elements, allowing estrogen enhancement of CRH activity, perhaps explaining the greater vulnerability of the reproductive axis to stress in females.⁸⁰

Cumming concludes that most studies indicate an exercise-induced increase in endogenous opiates, but a significant impact on mood remains to be substantiated.⁸¹ He notes that *runners' high* is more common in California than in Canada (euphoria is hard to come by when running in below freezing temperatures!).

Administration of morphine, enkephalin analogs, and b-endorphin causes release of prolactin. The effect is mediated by inhibition of dopamine secretion in the tuberoinfundibular neurons in the median eminence. Most studies have reported no effect of naloxone on basal, stress-induced, or pregnant levels of prolactin nor on secretion by prolactinomas. Thus a physiological role for endogenous opioid regulation of prolactin does not appear to exist in men and women. However, suppression of GnRH secretion associated with hyperprolactinemia does appear to be mediated by endogenous opiates.⁸²

Every pituitary hormone appears to be modulated by opiates. Physiologic effects are important with ACTH, gonadotropins, and possibly vasopressin. Opioid compounds have no direct action on the pituitary, nor do they alter the action of releasing hormones on the pituitary.

POMC-like mRNA is present in the ovary and the placenta.⁸³ Expression is regulated by gonadotropins in the ovary but not in the placenta. Reasons for endorphin presence in these tissues are not yet apparent. High concentrations of all of the members of the POMC family are found in human ovarian follicular fluid, but only b-endorphin shows significant changes during the menstrual cycle, reaching highest levels just before ovulation.⁸⁴

Catecholestrogens

The enzyme that converts estrogens to catecholestrogens (2-hydroxylase) is richly concentrated in the hypothalamus; hence there are higher concentrations of catecholestrogens than estrone and estradiol in the hypothalamus and pituitary gland. Catecholestrogens have two faces, a catechol side and an estrogen side. Because catecholestrogens have two faces, they have the potential for interacting with both catecholamine and estrogen-mediated systems.⁸⁵ To be specific, catecholestrogens can inhibit tyrosine hydroxylase (which would decrease catecholamines) and compete for catechol-*o*-methyltransferase (which would increase catecholamines). Since GnRH, estrogens, and catecholestrogens are located in similar sites, it is possible that catecholestrogens may serve to interact between catecholamines and GnRH secretion. However, these functions remain speculative because a definite role for catecholsteroids has not been established.

Summary: Control of GnRH Pulses

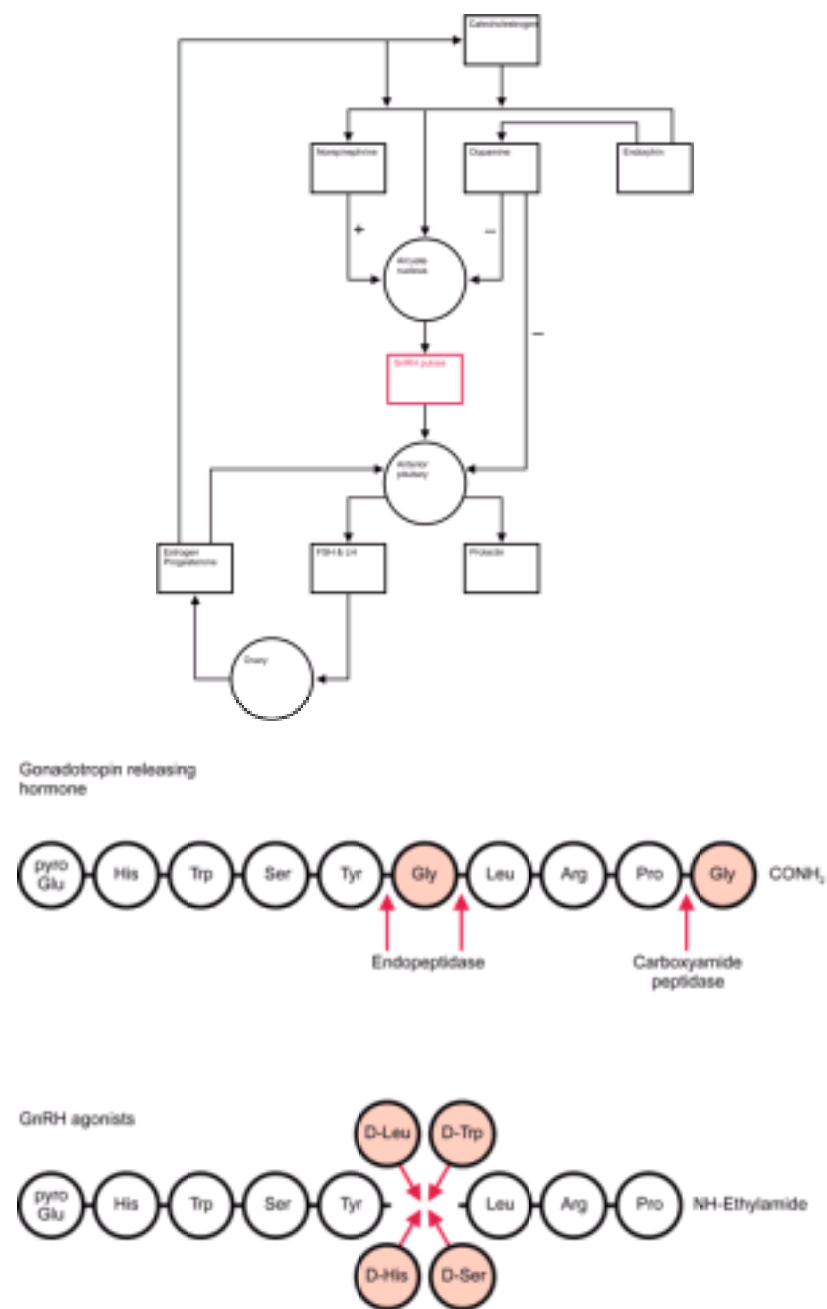

The key concept is that normal menstrual function requires GnRH pulsatile secretion in a critical range of frequency and amplitude.^{29, 31, 86} The normal physiology and pathophysiology of the menstrual cycle, at least in terms of central control, can be explained by mechanisms which affect the pulsatile secretion of GnRH. The pulses of GnRH appear to be directly under the influence of a dual catecholaminergic system: norepinephrine facilitatory and dopamine inhibitory. In turn, the catecholamine system can be influenced by endogenous opioid activity. The feedback effects of steroids may be mediated through this system via catecholsteroid messengers or directly by influencing the various neurotransmitters.

GnRH Agonists and Antagonists

The short half-life of GnRH is due to rapid cleavage of the bonds between amino acids 5–6, 6–7, and 9–10. By altering amino acids at these positions, analogues of GnRH can be synthesized with different properties. Thousands of GnRH analogues have been produced. Substitution of amino acids at the 6 position or replacement of the C-terminal glycine-amide (inhibiting degradation) produces agonists. The GnRH agonists are administered either intramuscularly or subcutaneously or by intranasal absorption. An initial agonistic action (the so-called flare effect) is associated with an increase in the circulating levels of FSH and LH. This response is greatest in the early follicular phase when GnRH and estradiol have combined to create a large reserve pool of gonadotropins. After 1–3 weeks, desensitization and down-regulation of the pituitary produce a hypogonadotropic, hypogonad state. The initial response is due to desensitization, while the sustained response is due to loss of receptors and the uncoupling of the receptor from its effector system. Furthermore, postreceptor mechanisms lead to secretion of biologically inactive gonadotropins, which, however, can still be detected by immunoassay.

Suppression of pituitary secretion of gonadotropins by a GnRH agonist can be utilized for the treatment of endometriosis, uterine leiomyomas, precocious puberty, or the prevention of menstrual bleeding in special clinical situations (e.g., in thrombocytopenic patients). Various tumors contain receptors for GnRH, such as breast, pancreatic, and ovarian, and therefore, there exists a potential for treatment.

GnRH antagonists are synthesized by multiple amino acid substitutions. GnRH antagonists bind to the GnRH receptor and provide competitive inhibition of the naturally occurring GnRH. Thus GnRH antagonists produce an immediate decline in gonadotropin levels with an immediate therapeutic effect. The early products either lacked potency or were associated with undesirable side effects due to histamine release. New analogues continue to be developed and tested, aimed toward the control of fertility.⁶⁴ The combination of a GnRH antagonist and testosterone holds promise as a male contraceptive agent.

The GnRH analogues cannot escape destruction if administered orally. Higher doses administered subcutaneously can achieve nearly equal effects as observed with intravenous treatment; however, the smaller blood peaks are slower to develop and take longer to return to baseline. Other forms of administration include nasal spray, sustained release implants, and injections of biodegradable microspheres. With the nasal route, absorption enhancers have to be added to increase bioavailability; these agents produce considerable nasal irritation. Goserelin consists of a small biodegradable cylinder which is inserted subcutaneously and monthly using a prepackaged syringe. The depot formulations of GnRH agonists are administered intramuscularly and monthly.

GnRH Agonists in Clinical Use

Position	1	2	3	4	5	6	7	8	9	10
Native GnRH	pGlu	His	Trp	Ser	Tyr	Gly	Leu	Arg	Pro	Gly-NH ₂
Leuprolide						D-Leu				NH-Ethylamide
Buserelin						D-Ser (tertiary butanol)				NH-Ethylamide
Nafarelin						D-Naphthylalanine (2)				
Histrelin						D-His (tertiary benzyl)				NH-Ethylamide
Goserelin						D-Ser (tertiary butanol)				Aza-Gly
Deslorelin						D-Trp				NH-Ethylamide
Tryptorelin						D-Trp				

Tanycytes

A significant pathway for hypothalamic influence may be via the cerebrospinal fluid (CSF). Tanycytes are specialized ependymal cells whose ciliated cell bodies line the third ventricle over the median eminence. The cells terminate on portal vessels, and they can transport materials from ventricular CSF to the portal system, e.g., substances from the pineal gland, or vasopressin, or oxytocin. Tanycytes change morphologically in response to steroids and exhibit morphological changes during the ovarian cycle.

The Posterior Pituitary Pathway

The posterior pituitary is a direct prolongation of the hypothalamus via the pituitary stalk, whereas the anterior pituitary arises from pharyngeal epithelium that migrates into position with the posterior pituitary. Separate neurosecretory cells in both the supraoptic and paraventricular nuclei make vasopressin and oxytocin as parts of large precursor molecules that also contain the transport peptide, neurophysin.⁸⁷ Both oxytocin and vasopressin consist of 9 amino acid residues, two of which are half cystines forming a bridge between positions 1 and 6. In the human, vasopressin contains arginine, unlike animals that have lysine vasopressin. The neurophysins are polypeptides with a molecular weight of about 10,000. There are two distinct neurophysins, estrogen-stimulated neurophysin known as neurophysin I, and nicotine-stimulated neurophysin, known as neurophysin II.

The genes for oxytocin and vasopressin are closely linked on chromosome 20, derived from a common ancestor about 400 million years ago.⁸⁸ The transcriptional activity of these genes is regulated by endocrine factors, such as the sex steroids and thyroid hormone, through hormone-response elements located upstream. The neurons secrete two large protein molecules, a precursor called pro-pressophysin, which contains vasopressin and its neurophysin, and a precursor called

pro-oxyphysin, which contains oxytocin and its neurophysin.⁸⁷ Neurophysin I is specifically related to oxytocin, and neurophysin II accompanies vasopressin. Because of this unique packaging, the hormones and their neurophysins are stored together and released at the same time into the circulation. The neurophysins are cleaved from their associated neurohormones during axonal transport from the neuronal cell bodies in the supraoptic and paraventricular nuclei to the posterior pituitary. The only known function for the neurophysins is axonal transport for oxytocin and vasopressin.

The posterior pathway is complex and not limited to the transmission of vasopressin and oxytocin to the posterior pituitary. The transportation of vasopressin and oxytocin to the posterior pituitary occurs via nerve tracts which emanate from the supraoptic and paraventricular nuclei and descend through the median eminence to terminate in the posterior pituitary. However, these hormones are also secreted into the cerebrospinal fluid and directly into the portal system. Therefore, vasopressin and oxytocin can reach the anterior pituitary and influence, in the case of vasopressin, ACTH secretion, and in the case of oxytocin, gonadotropin secretion. Vasopressin cooperates with corticotropin-releasing hormone to cause an increased yield of ACTH. Vasopressin and oxytocin-like materials are also found in the ovary, the oviduct, the testis, and the adrenal gland, suggesting that these neurohypophyseal peptides have roles as paracrine or autocrine hormones.⁸⁸ The concentrations of these substances in the cerebrospinal fluid exhibit a circadian rhythm (with peak levels occurring during the day), suggesting a different mechanism for CSF secretion compared to posterior pituitary release.⁹⁰

Neurophysin II is called nicotine neurophysin because the administration of nicotine or hemorrhage increases the circulating levels. Neurophysin I is called estrogen neurophysin because estrogen administration increases the levels in the peripheral blood, and peak levels of both neurophysin I and oxytocin are found at the time of the LH surge.⁹¹ Oxytocin neurons and vasopressin neurons have been demonstrated in the rat to contain the estrogen receptor-beta.⁹² The rise in estrogen neurophysin begins 10 hours after the rise in estrogen and precedes that of the LH surge, and the elevation of neurophysin lasts longer than the LH surge. Because GnRH and oxytocin are competing substrates for hypothalamic degradation enzymes, it has been hypothesized that oxytocin in the portal blood at the midcycle may inhibit the metabolism of GnRH, thus increasing the amount of GnRH available. Furthermore, oxytocin may have direct actions on the pituitary, ovary, uterus, and fallopian tube during ovulation.

Neurophysin-containing pathways have been traced from the hypothalamic nuclei to various centers in the brainstem and the spinal cord. In addition, behavioral studies suggest a role for vasopressin in learning and memory. Administration of vasopressin has been associated with improvement in memory in brain-damaged human subjects, and enhanced cognitive responses (learning and memory) in both young, normal individuals and depressed patients.

Both oxytocin and vasopressin circulate as the free peptides with a rapid half-life (initial component less than 1 minute, second component of 2–3 minutes). Three major stimuli for vasopressin secretion are changes in osmolality of the blood, alterations in blood volume, and psychogenic stimuli such as pain and fear. The osmoreceptors are located in the hypothalamus; the volume receptors are in the left atrium, aortic arch, and carotid sinus. Angiotensin II also produces a release of vasopressin, suggesting another mechanism for the link between fluid balance and vasopressin. Cortisol may modify the osmotic threshold for the release of vasopressin.

The major functions of vasopressin involve the regulation of osmolality and blood volume. Vasopressin is a powerful vasoconstrictor and antidiuretic hormone. Vasopressin release increases when plasma osmolality rises and is inhibited by water loading (resulting in diuresis). Diabetes insipidus is a condition marked by loss of water because of a lack of vasopressin action in the tubules of the kidney, secondary to a defect in synthesis or secretion of vasopressin. The opposite condition is the continuous and autonomous secretion of vasopressin, the syndrome of inappropriate ADH (antidiuretic hormone) secretion. This syndrome, with its resultant retention of water, is associated with a variety of brain disorders as well as the production of vasopressin and its precursor by malignant tumors.

Oxytocin stimulates muscular contractions in the uterus and myoepithelial contractions in the breast. Thus it is involved in parturition and the letdown of milk. The release of oxytocin is so episodic that it is described as spurts. Ordinarily, there are about 3 spurts every 10 minutes. Oxytocin is released during coitus, probably by the Ferguson reflex (vaginal and cervical stimulation) but also by olfactory, visual, and auditory pathways. Perhaps oxytocin has some role in muscle contractions during orgasm.⁹³ In the male, release of oxytocin during coitus may contribute to sperm transport during ejaculation.

Using sensitive assays, an increase in maternal levels of oxytocin can be detected prior to parturition, occurring at first only at night.^{94, 95} Once labor has begun, oxytocin levels rise significantly, especially during the second stage. Thus, oxytocin may be important for developing the more intense uterine contractions. Extremely high concentrations of oxytocin can be measured in the cord blood at delivery, and release of oxytocin from the fetal pituitary may also be involved in labor. However, this is controversial, and studies in monkeys fail to indicate a role for fetal oxytocin in parturition.⁹⁵ Part of the contribution of oxytocin to parturition is the stimulation of prostaglandin synthesis in decidua and myometrium.⁹⁶ Cervical dilatation appears to be dependent on oxytocin stimulation of prostaglandin production, probably in the decidua. The greater frequency of labor and delivery at night may be due to greater nocturnal oxytocin secretion.⁹⁴ In addition, oxytocin is synthesized in the amnion, chorion, and significantly, in the decidua.⁹⁴ This locally produced oxytocin may be a significant stimulus for myometrial and membrane production of prostaglandins.

It is likely that oxytocin action during the initial stages of labor may depend on myometrial sensitivity to oxytocin in addition to the levels of oxytocin in the blood. The concentration of oxytocin receptors in the myometrium is low in the nonpregnant state and increases steadily throughout gestation (an 80-fold increase), and during labor, the concentration doubles. This receptor concentration correlates with the uterine sensitivity to oxytocin.⁹⁷ The mechanism for the increase is unknown, but it likely is due to a change in the prostaglandin and hormonal milieu of the uterus. The local production and effects of oxytocin, estrogen, and progesterone combine in a complicated process of autocrine, paracrine, and endocrine actions to result in parturition.

Oxytocin is released in response to suckling, mediated through impulses generated at the nipple and transmitted via the 3rd, 4th, and 5th thoracic nerves to the spinal cord to the hypothalamus. In addition to causing milk ejection, the reflex is responsible for the uterine contractions associated with breastfeeding. Opioid peptides inhibit oxytocin release, and this may be the means by which stress, fear, and anger inhibit milk output in lactating women. Oxytocin is also expressed in many tissues where it exerts autocrine/paracrine actions.

The Brain and Ovulation

Classic studies in a variety of rodents indicated the presence of feedback centers in the hypothalamus that responded to steroids with the release of GnRH. The release of GnRH was the result of the complex, but coordinated, relationships among the neurohormones, the pituitary gonadotropins, and the gonadal steroids designated by the time-honored terms positive and negative feedback.

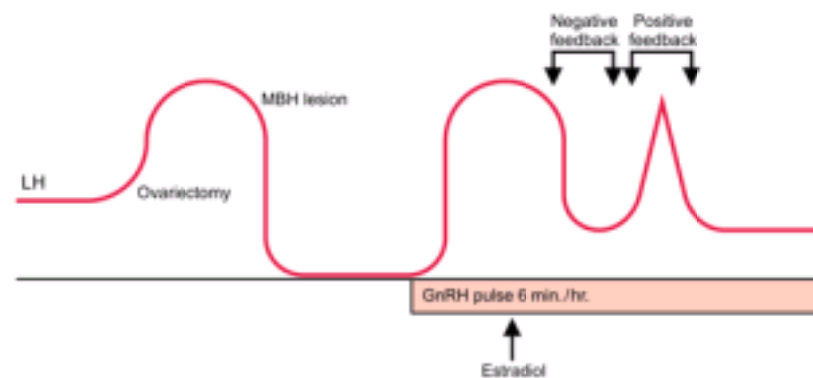

FSH levels were thought to be largely regulated by a negative inhibitory feedback relationship with estradiol. In the case of LH, there existed both a negative inhibitory feedback relationship with estradiol and a positive stimulatory feedback with high levels of estradiol. The feedback centers were located in the hypothalamus, and they were called the tonic and cyclic centers. The tonic center controlled the day-to-day basal level of gonadotropins and was responsive to the negative feedback effects of steroids. The cyclic center in the female brain was responsible for the midcycle surge of gonadotropins, a response mediated by the positive feedback of estrogen. Specifically, the midcycle surge of gonadotropins was thought to be due to an outpouring of GnRH in response to the positive feedback action of estradiol

on the cyclic center of the hypothalamus.

This classic concept was not inaccurate. The problem was that the concept accurately described events in the rodent, but the mechanism is different in the primate.

In the primate, the “center” for the midcycle surge of gonadotropins has moved from the hypothalamus to the pituitary. Experiments in the monkey have demonstrated that GnRH, originating in the hypothalamus, plays a permissive and supportive role. Its pulsatile secretion is an important prerequisite for normal pituitary function, ⁸⁶ but the feedback responses regulating gonadotropin levels are controlled by ovarian steroid feedback on the anterior pituitary cells.

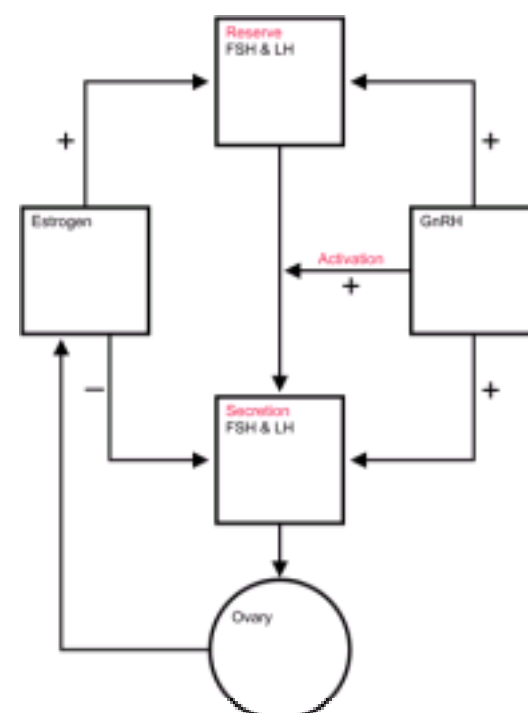

The present concept is derived from experiments in which the medial basal hypothalamus (MBH) is either destroyed ²⁶ or the hypothalamus is surgically separated from the pituitary. ⁹⁶ In a typical (and now classic) experiment, lesion of the MBH by radiofrequency waves was followed by loss of LH levels as the source of GnRH was eliminated. ²⁵ Administration of GnRH in a pulsatile fashion by an intravenous pump restored LH secretion. The administration of estradiol was then able to produce both negative and positive feedback responses, clearly actions that must be directly on the anterior pituitary because the hypothalamus was absent and GnRH was being administered in a steady and unchanging frequency and dose.

Administration of GnRH intravenously as a bolus produces an increase in blood levels of LH and FSH within 5 minutes, reaching a peak in about 20–25 minutes for LH and 45 minutes for FSH. Levels return to pretreatment values after several hours. When administered by constant infusion at submaximal doses, there is first a rapid rise with a peak at 30 minutes, followed by a plateau or fall between 45 and 90 minutes, then a second and sustained increase at 225–240 minutes. This biphasic response suggests the presence of two functional pools of pituitary gonadotropins. ⁹⁹ The readily releasable pool (secretion) produces the initial response, and the later response is dependent upon a second, reserve pool of stored gonadotropins.

There are three principal positive actions of GnRH on gonadotropin elaboration.

1. Synthesis and storage (the reserve pool) of gonadotropins.
2. Activation, movement of gonadotropins from the reserve pool to a pool ready for direct secretion, a self-priming action.
3. Immediate release (direct secretion) of gonadotropins.

Secretion, synthesis, and storage change during the cycle. At the beginning of the cycle, when estrogen levels are low, both secretion and storage levels are low. With increasing levels of estradiol, a greater increase occurs in storage, with little change in secretion. Thus, in the early follicular phase, estrogen has a positive effect on the synthesis and storage response, building up a supply of gonadotropins in order to meet the requirements of the midcycle surge. Premature release of gonadotropins is prevented by a negative (inhibitory) action of estradiol on the pituitary secretory response to GnRH.

As the midcycle approaches, subsequent responses to GnRH are greater than initial responses, indicating that each response not only induces release of gonadotropins but also activates the storage pool for the next response. This sensitizing or priming action of GnRH also involves an increase in the number of its own receptors and requires the presence of estrogen. ^{100, 101} Estrogen itself is capable of increasing the number of GnRH receptors. ^{51, 102} The rise in estrogen at midcycle prepares the gonadotrope to further respond to GnRH.

Because the midcycle surge of LH can be produced in the experimental monkey in the absence of a hypothalamus, and in the face of unchanging GnRH, the ovulatory surge of LH is now believed to be a response to positive feedback action of estradiol on the anterior pituitary. When the estradiol level in the circulation reaches a critical concentration and this concentration is maintained for a critical time period, the inhibitory action on LH secretion changes to a stimulatory action. The mechanism of this steroid action is not known with certainty, but experimental evidence suggests that the positive feedback action involves many mechanisms, including an increase in GnRH receptor concentration, and an increase in pituitary sensitivity to GnRH. The negative feedback of estrogen operates through an uncertain, but different, system. ^{103, 104 and 105}

What a logical mechanism! The midcycle surge must occur at the right time of the cycle to ovulate a ready and waiting mature follicle. What better way to achieve this extreme degree of coordination and timing than by the follicle itself, through the feedback effects of the sex steroids originating in the follicle destined to ovulate.

GnRH is increased in the peripheral blood of women and the portal blood of monkeys at midcycle. While this increase may not be absolutely necessary (as demonstrated in the monkey experiments), studies do indicate that activity is occurring in both the hypothalamus and the pituitary. ^{104, 106, 107} Therefore, although the system can operate with only an unwavering, permissive action of GnRH, fine tuning probably takes place by means of simultaneous effects on GnRH pulsatile secretion and pituitary response to GnRH. This is supported by gonadotropin gene expression studies, indicating steroid effects at both the hypothalamus and the pituitary. The upstream region of the LH b-subunit gene (in the rat) binds the estrogen receptor, providing a means for direct steroid hormone modulation in the pituitary. ¹⁰⁸ The human GnRH gene contains a hormone responsive element that binds estrogen and its receptor. ¹⁰⁹ However, studies have failed to detect the presence of estrogen receptors in GnRH neurons, ^{110, 111 and 112} and this hormone responsive element may be regulated by other substances, or other estrogen responsive neurons may synapse with GnRH cell bodies. ¹¹³ Another possibility is that GnRH neurons contain estrogen receptor-beta, and the previous immunoreactive studies have been directed to estrogen receptor-alpha. Nevertheless, in vivo studies in the sheep have demonstrated that estradiol has both negative and positive feedback effects on hypothalamic GnRH secretion, and that a GnRH surge is involved in the preovulatory LH surge. ^{114, 115 and 116} Certainly, the presence of GnRH is essential; the administration of a GnRH antagonist to women at midcycle prevents the LH surge. ¹¹⁷

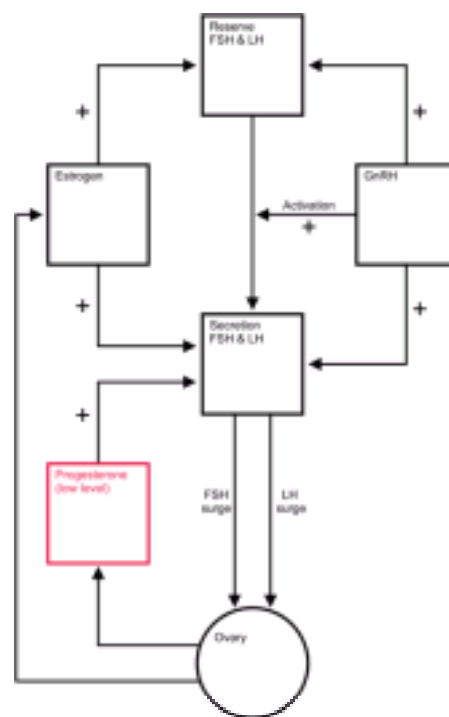

Influencing the hypothalamic frequency of GnRH secretion can in turn influence pituitary response to GnRH. Faster or slower frequencies of GnRH pulses result in lower GnRH receptor numbers in the pituitary.¹¹⁸ Thus, a critical peak frequency is necessary for peak numbers of GnRH receptors and the peak midcycle response. Here is a method for the fine tuning at both the hypothalamus (pulse frequency) and the pituitary (receptor number). Indeed, turning off the surge may involve down-regulation because of excessive GnRH. Studies in sheep indicate that a surge of GnRH at the time of the LH surge is associated with a switch from episodic secretion to continuous secretion into the portal circulation, producing the high exposure known to result in down-regulation.¹¹⁹

Another aspect of gonadotropin secretion is clinically important. A disparity exists between the quantity of LH measured during the midcycle surge as determined by immunoassay and bioassay. More LH is secreted at midcycle in a molecular form with greater biological activity.¹²⁰ There is a well-established relationship between the activity and half-life of glycoprotein hormones and molecular composition (see Chapter 2, under “[Heterogeneity](#)” of tropic hormones). The estrogen influence on gonadotropin synthesis is an additional method for maximizing the biologic effects of the midcycle surge. The bioactivity is also very dependent upon pulsatile stimulation by GnRH.

The midcycle surge of FSH has an important clinical purpose. A normal corpus luteum requires the induction of an adequate number of LH receptors on granulosa cells, a specific action of FSH. In addition, FSH accomplishes important intrafollicular changes necessary for the physical expulsion of the ovum. The midcycle surge of FSH, therefore, plays a critical role in ensuring ovulation and a normal corpus luteum. Emerging progesterone secretion, just prior to ovulation, is the key.

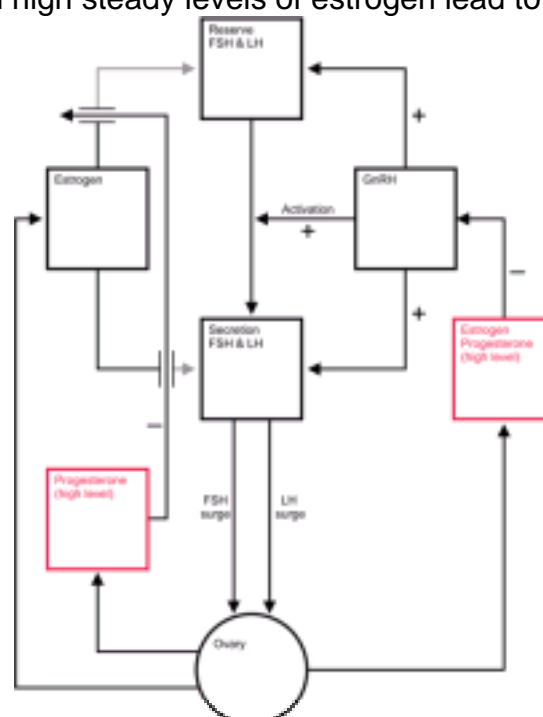

Progesterone, at low levels and in the presence of estrogen, augments the pituitary secretion of LH and is responsible for the FSH surge in response to GnRH.^{121, 122, 123 and 124} As the rising levels of LH produce the morphologic change of luteinization in the ovulating follicle, the granulosa layer begins to secrete progesterone directly into the bloodstream. The process of luteinization is inhibited by the presence of the oocyte, and therefore progesterone secretion is relatively suppressed, ensuring that only low levels of progesterone reach the brain.

After ovulation, rapid and full luteinization is accompanied by a marked increase in progesterone levels, which, in the presence of estrogen, exercise a profound negative feedback action to suppress gonadotropin secretion. This action of progesterone takes place in two locations.^{125, 126 and 127} First, there definitely is a central action to decrease GnRH.¹²⁸ Progesterone fails to block estradiol-induced gonadotropin discharges in monkeys with hypothalamic lesions if pulsatile GnRH replacement is provided. Therefore, high levels of progesterone inhibit ovulation at the hypothalamic level. In addition, progesterone can also block estrogen-induced responses to GnRH at the pituitary level. In contrast, the facilitatory action of low levels of progesterone is exerted only at the pituitary on the response to GnRH.

Summary: Key Points

1. Pulsatile GnRH secretion must be within a critical range for frequency and concentration (amplitude). This is absolutely necessary for normal reproductive function.
2. GnRH has only positive actions on the anterior pituitary: synthesis and storage, activation, and secretion of gonadotropins. The gonadotropins are secreted in a pulsatile fashion in response to the similar pulsatile release of GnRH.
3. Low levels of estrogen enhance FSH and LH synthesis and storage, have little effect on LH secretion, and inhibit FSH secretion.
4. High levels of estrogen induce the LH surge at midcycle, and high steady levels of estrogen lead to sustained elevated LH secretion.

5. Low levels of progesterone acting at the level of the pituitary gland enhance the LH response to GnRH and are responsible for the FSH surge at midcycle.
6. High levels of progesterone inhibit pituitary secretion of gonadotropins by inhibiting GnRH pulses at the level of the hypothalamus. In addition, high levels of progesterone antagonize pituitary response to GnRH by interfering with estrogen action.

The Pineal Gland

Although no physiologic role has been firmly established in the human, the reproductive functions of the hypothalamus may also be under inhibitory control of the brain via the pineal gland. The pineal arises as an outgrowth of the roof of the third ventricle, but soon after birth it loses all afferent and efferent neural connections with the brain. Instead the parenchymal cells receive a new and unusual sympathetic innervation which allows the pineal gland to be an active neuroendocrine organ that responds to photic and hormonal stimuli and exhibits circadian rhythms.^{129, 130 and 131}

The neural pathway begins in the retina and passes through the suprachiasmatic and paraventricular nuclei in the hypothalamus to the inferior accessory optic tracts and the medial forebrain bundle to the upper spinal cord. Preganglionic fibers terminate at the superior cervical ganglion, and postganglionic sympathetic nerves terminate directly on pineal cells. Interruption of this pathway gives the same effect as darkness, which is an increase in pineal biosynthetic activity.

Hydroxyindole-*c*-methyltransferase (HIOMT), an enzyme essential for melatonin synthesis, is found mainly in pineal parenchymal cells, and its products are

essentially unique to the pineal. Norepinephrine stimulates tryptophan entry into the pineal cell and also adenylate cyclase activity in the membrane. The resulting increase in cyclic AMP leads to Λ -acetyltransferase activity, the rate-limiting step in melatonin synthesis. Tryptophan is converted by the combined action of *N*-acetyltransferase and HIOMT into melatonin. Thus, melatonin synthesis is controlled by norepinephrine stimulation of adenylate cyclase, and the norepinephrine is liberated by sympathetic stimulation due to the absence of light. HIOMT is also found in the retina where melatonin may serve to regulate the pigment in retinal cells, and in the intestine. However, pinealectomy completely eliminates detectable levels of melatonin in the circulation. Calcification of the pineal gland is common. It is frequently present in young children, and almost all elderly people have pineal calcification.

The association of hyperplastic pineal tumors with decreased gonadal function, and destructive tumors with precocious puberty, suggested that the pineal is the source of gonadal inhibiting substances. However, pineal mechanisms cannot be absolutely essential for gonadal function. Normal reproductive function returns to the pinealectomized rat several weeks after pinealectomy; blind women have normal fertility, and pinealectomy in a primate did not affect pubertal development. ¹³²

DARKNESS \longrightarrow INCREASED MELATONIN \longrightarrow DECREASED GnRH

A rat in constant light develops a small pineal with decreased HIOMT and melatonin, while the ovarian weight increases. A rat in constant dark has the opposite result, increased pineal size, HIOMT, and melatonin, with decreased ovarian weight and pituitary function. A rhythm is established in pineal HIOMT activity by the presence or absence of light. Short days and long nights result in gonadal atrophy, and this is the major mechanism governing seasonal breeding. ¹³³ In humans, melatonin secretion increases after darkness and peaks in the middle of the night, and then decreases. This rhythm is endogenous, originating in the suprachiasmatic nucleus. Light does not cause the rhythm, but influences its timing.

Possible roles in humans may be to give circadian rhythmicity to other functions such as temperature and sleep. In all vertebrates tested so far, there is a daily and seasonal rhythm in melatonin secretion: high values during the dark and low during light, greater secretion in the winter compared to the summer. Desynchronization with travel across time zones may contribute to the symptom complex known as jet lag. Melatonin ingestion improves both the duration and quality of sleep, but the optimal timing of administration is unknown. ¹³¹

The pineal, therefore, serves as an interface between the environment and hypothalamic-pituitary function. In order to correctly interpret day length, animals require a daily rhythm in melatonin secretion. This coordination of temporal, environmental information is especially important in seasonal breeders. This pineal rhythm appears to require the suprachiasmatic nucleus, perhaps the site at which pineal function and light changes are coordinated.

Melatonin is synthesized and secreted by the pineal gland and circulates in the blood like a classical hormone. It affects distant target organs, especially the neuroendocrine centers of the central nervous system. Whether melatonin is secreted primarily into the CSF or blood is still debated, but most evidence favors blood. Melatonin may reach the hypothalamus from the CSF by way of tanycyte transport.

The gonadal changes associated with melatonin are mediated via the hypothalamus and suggest a general suppressive effect on GnRH pulsatile secretion and reproductive function. ¹³⁴ In humans, melatonin blood levels are highest in the first year of life (with highest levels at night), then decrease with age, eventually releasing, some claim, the suppression of GnRH prior to puberty. ¹³³ This hypothesis is challenged by the association of blindness in human females with an age of menarche that is earlier than normal. ¹³⁵ Furthermore, pinealectomy in monkeys does not affect puberty. ¹³²

Pineal activity can be viewed as the net balance between hormone and neuron mediated influences. The pineal contains receptors for the active sex hormones, estradiol, testosterone, dihydrotestosterone, progesterone, and prolactin. Furthermore, the pineal converts testosterone and progesterone to the active 5 α -reduced metabolites, and androgens are aromatized to estrogens. The pineal also appears to be unique in that a catecholamine neurotransmitter (norepinephrine), interacting with cell membrane receptors, stimulates cellular synthesis of estrogen and androgen receptors. In general, however, the sympathetic activity producing the circadian rhythm takes precedence over hormonal effects.

Despite a variety of suggestive leads, there is no definitive evidence for a role of the pineal in humans. Nevertheless the important relationship between light exposure and circadian rhythms continues to focus attention on the pineal gland as a coordinator. ¹³⁶ There is a seasonal distribution in human conception in northern countries with a decrease in ovarian activity and conception rates during the dark winter months. ^{137, 138} In addition, the pineal can disrupt normal gonadal function. A male with delayed puberty due to hypogonadotropism has been described, who had an enlarged, hyperfunctional pineal gland. ¹³⁹ Over time, his melatonin levels spontaneously decreased, and normal pituitary-gonadal function developed. Elevated nocturnal levels of melatonin have been reported in patients with hypothalamic amenorrhea and women with anorexia nervosa. ¹³⁴

A possible influence of the pineal gland may be the synchronization of menstrual cycles noted among women who spend time together. A significant increase in synchronization of cycles among roommates and among closest friends occurred in the first 4 months of residency in a dormitory of a women's college. ²⁰ A similar increase in synchrony has been observed in women coworkers in occupations characterized by levels of interdependency that were equal to or greater than the levels of encountered job stress. ²¹ However, efforts to replicate these results have not always been successful. ¹⁴⁰

Melatonin is available in 1 and 5 mg doses that produce blood levels that are 10 to 100 times higher than normal nighttime peaks. ¹³¹ The effects include increased sleepiness and decreased alertness. No data are available regarding long-term consequences on reproductive function.

A number of other indoles (also derivatives of tryptophan) have been identified in the pineal gland. Biologic roles for these indoles remain elusive, but one in particular has been extensively investigated. Arginine vasotocin differs from oxytocin by a single amino acid in position 8 and from vasopressin by a single amino acid in position 3. In general, arginine vasotocin has an inhibitory action on the gonads and pituitary secretion of prolactin and LH. Nevertheless a precise role continues to be elusive.

Gonadotropin Secretion Through Fetal Life, Childhood, and Puberty

We have often considered the endocrine events during puberty as an awakening, a beginning. However, endocrinologically, puberty is not a beginning, but just another stage in a development that began at conception. The development of the anterior pituitary in the human starts between the 4th and 5th weeks of fetal life, and by the 12th week of gestation the vascular connection between the hypothalamus and the pituitary is functional. Gonadotropin production has been documented throughout fetal life, during childhood, and into adult life. ¹⁴¹ Remarkable levels of FSH and LH, similar to postmenopausal levels, can be measured in the fetus. GnRH is detectable in the hypothalamus by 10 weeks of gestation, and by 10–13 weeks when the vascular connection is complete, FSH and LH are being produced in the pituitary. The peak pituitary concentrations of FSH and LH occur at about 20–23 weeks of intrauterine life, and peak circulating levels occur at 28 weeks.

The increasing production rate of gonadotropins until midgestation reflects the growing ability of the hypothalamic-pituitary axis to perform at full capacity. Beginning at midgestation, there is an increasing sensitivity to inhibition by steroids and a resultant decrease in gonadotropin secretion. Full sensitivity to steroids is not reached until late in infancy. The rise in gonadotropins after birth reflects loss of the high levels of placental steroids. Thus, in the first year of life there is considerable follicular activity in the ovaries in contrast to later in childhood when gonadotropin secretion is suppressed. Furthermore, the postnatal rise in gonadotropins is even greater in infants born prematurely.

Testicular function in the fetus can be correlated with the fetal hormone patterns. Initial testosterone production and sexual differentiation are in response to the fetal levels of HCG, whereas further testosterone production and masculine differentiation appear to be maintained by the fetal pituitary gonadotropins. Decreased testosterone levels in late gestation probably reflect the decrease in gonadotropin levels. The fetal generation of Leydig cells somehow avoids down-regulation and responds to high levels of HCG and LH by increased steroidogenesis and cell multiplication. This generation of cells is replaced by the adult generation which becomes functional at puberty and responds to high levels of HCG and LH with down-regulation and decreased steroidogenesis.

There is a sex difference in fetal gonadotropin levels. There are higher pituitary and circulating FSH and pituitary LH levels in female fetuses. The lower male levels are probably due to testicular testosterone and inhibin production. In infancy, the postnatal FSH rise is more marked and more sustained in females, while LH values are not as high. This early activity is accompanied by inhibin levels comparable to the low range observed during the follicular phase of the menstrual cycle. ¹⁴² After the postnatal rise, gonadotropin levels reach a nadir during early childhood (by about 6 months of age in males and 1–2 years in females) and then rise slightly between 4 and 10 years. This childhood period is characterized by low levels of gonadotropins in the pituitary and in the blood, little response of the pituitary to

GnRH, and maximal hypothalamic suppression.

The precise signal that initiates the events of puberty is unknown.¹⁴³ In girls, the first steroids to rise in the blood are dehydroepiandrosterone (DHA) and its sulfate (DHAS) beginning at 6–8 years of age, shortly before FSH begins to increase. Estrogen levels, as well as LH, do not begin to rise until 10–12 years of age. If the onset of puberty is triggered by the first hormone to increase in the circulation, then a role for adrenal steroids must be considered. However, there is no evidence to suggest that the adrenal steroids are necessary for the proper timing of puberty, and adrenarche appears to be independent, not controlled by the same mechanism that turns on the gonads.¹⁴⁴ Neither is there a definite relationship demonstrated between melatonin secretion and puberty. Because the studies have focused on the amount of melatonin secreted rather than the rhythm of secretion, this question remains open.

Prior to puberty, gonadotropin levels are low but still associated with pulses (although quite irregular).¹⁴⁵ The clinical onset of puberty is preceded by an increase in pulse frequency, amplitude, and regularity, especially during the night.^{145, 146, 147, 148 and 149} At the time of appearance of secondary sex characteristics, the mean LH levels are 2 to 4 times higher during sleep than during wakefulness. This pattern is not present before or after puberty and is an early sign of changes taking place in the hypothalamus, where there is increasing coordination of GnRH neurons with increasing GnRH pulsatile secretion. This pattern can be detected in individuals who develop increasing and decreasing degrees of hypothalamic suppression (such as in individuals with worsening and improving anorexia nervosa). FSH levels plateau by midpuberty, while LH and estradiol levels continue to rise until late puberty. Biologically active LH has been found to rise proportionately more than immunoreactive LH with the onset of puberty.

The rise of gonadotropins at puberty appears to be independent of the gonads in that the same response can be observed in patients with gonadal dysgenesis (who lack functional steroid-producing gonadal tissue). Adolescent girls with Turner syndrome (45,X) also demonstrate augmented gonadotropin secretion during sleep.¹⁵⁰ Thus, maturation at puberty must involve changes in the hypothalamus that are independent of ovarian steroids.

The maturational change in the hypothalamus is followed by an orderly and predictable sequence of events. Increased GnRH secretion leads to increased pituitary responsiveness to GnRH (a combination of steroid influence on the pituitary and a frequency effect of GnRH pulses on GnRH receptor numbers), leading to increasing production and secretion of gonadotropins. Increased gonadotropins are responsible for follicular growth and development in the ovary and increased sex steroid levels. The rising estrogen contributes to achieving an adult pattern of pulsatile GnRH secretion, finally leading to cyclic menstrual patterns.

The trend toward lowering of the menarcheal age and the period of acceleration of growth has halted. In a 10-year prospective study of middle class contemporary American girls, the mean age of menarche was 12.83 with a range of 9.14–17.70 years.¹⁵¹ The age of onset of puberty is variable and influenced by genetic factors, socioeconomic conditions, and general health. The earlier menarche today compared to the past is undoubtedly due to improved nutrition and better health. It has been suggested that initiation of growth and menarche occur at a particular body weight (48 kg) and percent of body fat (17%).¹⁵² It is thought that this relationship reflects a required stage of metabolism. Although this hypothesis of a critical weight is a helpful concept, the extreme variability in onset of menarche indicates that there is no particular age or size at which an individual girl should be expected to experience menarche.

In the female, the typical sequence of events is growth initiation, thelarche, pubarche, and finally menarche. This generally begins sometime between 8 and 14 years of age. The length of time involved in this evolution is usually 2–4 years. During this time span, puberty is said to occur. Individual variation in the order of appearance of this sequence is great. For example, growth of pubic hair and breast development are not always correlated.

Puberty is due to the reactivation of the hypothalamic-pituitary axis, once fully active during fetal life but suppressed during childhood. If the systems are potentially responsive, what holds function in check until puberty? The hypothalamic-pituitary-gonadal system is operative prior to puberty but is extremely sensitive to steroids and therefore suppressed. The changes at puberty are due to a gradually increasing gonadotropin secretion that takes place because of a decrease in the sensitivity of the hypothalamic centers to the negative-inhibitory action of gonadal steroids. This can be pictured as a slowly rising set point of decreased sensitivity, resulting in increasing GnRH pulsatile secretion, leading to increasing gonadotropin production and ovarian stimulation, and finally to increasing estrogen levels. The reason that FSH is the first gonadotropin to rise at puberty is that arcuate activity begins with a low frequency of GnRH pulses. This is associated with a rise in FSH and little change in LH. With acceleration of frequency, FSH and LH reach adult levels. In addition, there is a qualitative change as a greater increase occurs in the bioactive forms of the gonadotropins.

Negative feedback of steroids, however, cannot be the sole explanation for the low gonadotropin levels in children. Agonadal children show the same decline in gonadotropins from age 2 to 6 as do normal children.¹⁵³ This indicates an intrinsic CNS inhibitory mechanism independent of gonadal steroids. Therefore, the restraint of puberty can be viewed as the result of two forces:

1. A CNS inhibitory force, a mechanism suppressing GnRH pulsatile secretion.
2. A very sensitive negative feedback of gonadal steroids (6–15 times more sensitive before puberty).

Because agonadal children show a rise in gonadotropins at pubertal age following suppression to a nadir during childhood, the dominant mechanism must be a CNS inhibitory force. The initial maturational change in the hypothalamus would then be a decrease in this inhibitory influence. A search for this mechanism continues. Some have argued that, rather than a chronic state of inhibition prior to puberty, the GnRH neurons exist in an unrestrained but uncoordinated pattern of activity that prevents adequate secretion.

The development of the positive feedback response to estrogen occurs later. This explains the well-known finding of anovulation in the first months (as long as 18 months) of menstruation. There are frequent exceptions, however, and ovulation can occur even at the time of menarche.

Don't think of puberty as being turned on by a controlling center in the brain but rather as a functional confluence of all factors. This is more a concept than an actual locus of action.

The overall result of this change in the hypothalamus is the development of secondary sex characteristics, attainment of adult set point levels, and the ability to reproduce. Neoplastic and vascular disorders that alter hypothalamic sensitivity can reverse the prepubertal threshold restraint and lead to precocious puberty.

[The Normal Menstrual Cycle](#)
[Chapter References](#)

Many superstitious beliefs have surrounded menstruation throughout recorded history. Indeed, attitudes and ideas about this aspect of female physiology have changed slowly. Hopefully, the scientific progress of the last few decades, which has revealed the dynamic relationships between the pituitary and gonadal hormones and the cyclic nature of the normal reproductive process, will yield a new understanding. The hormone changes, correlated with the morphologic and autocrine/paracrine events in the ovary, make the coordination of this system one of the most remarkable events in biology.

The diagnosis and management of abnormal menstrual function must be based on an understanding of the physiologic mechanisms involved in the regulation of the normal cycle. To understand the normal menstrual cycle, it is helpful to divide the cycle into 3 phases: the follicular phase, ovulation, and the luteal phase. We will examine each of these phases, concentrating on the changes in ovarian and pituitary hormones, what governs the pattern of hormone changes, and the effects of these hormones on the ovary, pituitary, and hypothalamus in regulating the menstrual cycle.

The Follicular Phase

During the follicular phase an orderly sequence of events takes place that ensures the proper number of follicles is ready for ovulation. In the human ovary the end result of this follicular development is (usually) one surviving mature follicle. This process, which occurs over the space of 10–14 days, features a series of sequential actions of hormones and autocrine/paracrine peptides on the follicle, leading the follicle destined to ovulate through a period of initial growth from a primordial follicle through the stages of the preantral, antral, and preovulatory follicle.

The Primordial Follicle

The primordial germ cells originate in the endoderm of the yolk sac, allantois, and hindgut of the embryo, and by 5–6 weeks of gestation, they have migrated to the genital ridge. A rapid mitotic multiplication of germ cells begins at 6–8 weeks of pregnancy, and by 16–20 weeks, the maximum number of oocytes is reached: a total of 6–7 million in both ovaries.¹ The primordial follicle is nongrowing and consists of an oocyte, arrested in the diplotene stage of meiotic prophase, surrounded by a single layer of spindle-shaped granulosa cells.

Until their numbers are exhausted, follicles begin to grow and undergo atresia under all physiologic circumstances. Growth and atresia are not interrupted by pregnancy, ovulation, or periods of anovulation. This dynamic process continues at all ages, including infancy and around the menopause. From the maximum number at 16–20 weeks of pregnancy, the number of oocytes will irretrievably decrease. The rate of decrease is proportional to the total number present; thus, the most rapid decrease occurs before birth, resulting in a decline from 6–7 million to 2 million at birth and to 300,000 at puberty. From this large reservoir, about 400 follicles will ovulate during a woman's reproductive years.

The mechanism for determining which follicles and how many will start growing during any one cycle is unknown. The number of follicles that starts growing each cycle appears to be dependent upon the size of the residual pool of inactive primordial follicles.^{2,3} Reducing the size of the pool (e.g., unilateral oophorectomy) causes the remaining follicles to redistribute their availability over time. It is possible that the follicle which is singled out to play the leading role in a particular cycle is the beneficiary of a timely match of follicle “readiness” (perhaps prepared by autocrine/paracrine actions in its microenvironment) and appropriate tropic hormone stimulation. The first follicle able to respond to stimulation may achieve an early lead that it never relinquishes. Nevertheless, each cohort of follicles that begins growth is engaged in a serious competition that ends with only one follicle succeeding.

Rescue From Atresia (Apoptosis)

The follicle destined to ovulate is recruited in the first few days of the cycle.⁴ The early growth of follicles occurs over the timespan of several menstrual cycles, but the ovulatory follicle is one of a cohort recruited at the time of the luteal-follicular transition.^{5,6} The total duration of time to achieve preovulatory status is approximately 85 days. The majority of this time (until a late stage) involves responses that are independent of hormonal regulation.⁷ Eventually, this cohort of follicles reaches a stage where, unless recruited (rescued) by follicle-stimulating hormone (FSH), the next step is atresia. Thus, follicles are continuously available (2–5 mm in size) for a response to FSH. An increase in FSH is the critical feature in rescuing a cohort of follicles from atresia, the usual fate of most follicles, eventually allowing a dominant follicle to emerge and pursue a path to ovulation. In addition, maintenance of this increase in FSH for a critical duration of time is essential.⁸ Without the appearance and persistence of an increase in the circulating FSH level, the cohort is doomed to the process of apoptosis, programmed physiologic cell death to eliminate superfluous cells.⁹ “Apoptosis” is derived from Greek and means falling off, like leaves from a tree.

The first visible signs of follicular development are an increase in the size of the oocyte and the granulosa cells becoming cuboidal rather than squamous in shape. These changes may be better viewed as a process of maturation rather than growth. At this same time, small gap junctions develop between the granulosa cells and the oocyte. Gap junctions are channels that when open permit the exchange of nutrients, ions, and regulatory molecules. Thus, the gap junctions serve as the pathway for nutritional, metabolite, and signal interchange between the granulosa cells and the oocyte. The process of follicular growth is influenced by factors derived from the oocyte. Mice that are genetically deficient in growth differentiation factor-9 (GDF-9), a peptide synthesized only in the oocyte after the primordial follicle becomes a preantral follicle, are infertile because follicular development cannot proceed beyond the primordial follicle stage.¹⁰

With multiplication of the cuboidal granulosa cells (to approximately 15 cells), the primordial follicle becomes a primary follicle. The granulosa layer is separated from the stromal cells by a basement membrane called the basal lamina. The surrounding stromal cells differentiate into concentric layers designated the theca interna (closest to the basal lamina) and the theca externa (the outer portion). The theca layers appear when granulosa proliferation produces 3–6 layers of granulosa cells. ⁶

The belief that the initiation of follicular growth is independent of gonadotropin stimulation is supported by the persistence of this initial growth in gonadotropin-deficient mutant mice and in anencephalic fetuses. ^{11, 12} In the vast majority of instances this growth is limited and rapidly followed by atresia. In studies of human ovarian follicles, expression of the gene for the FSH receptor could not be detected until after primordial follicles began to grow. ¹³

The general pattern of limited growth and quick atresia is interrupted at the beginning of the menstrual cycle when a group of follicles (after approximately 60 days of development) responds to a hormonal change and is propelled to grow. In young women, this cohort numbers 3–11 per ovary. ¹⁴ The decline in luteal phase steroidogenesis and inhibin A secretion allows a rise in FSH, beginning a few days before menses. ^{15, 16} The timing of this important event was based on data derived from the immunoassay of FSH. Using a sensitive measurement of FSH bioactivity, it has been suggested that increasing bioactivity of FSH begins in the mid- to late luteal phase. ¹⁷

Follicular Growth and Development Based on Nonprimate and Primate Data. *The following discussion of events, which mark the growth and development of the ovarian follicle from the preantral stage to ovulation, is based on a formulation that assigns a key role to estradiol functioning as a classic hormone to transmit messages to the brain and as a local regulator within the follicle. This description has been challenged. The belief that the follicular estrogen concentration plays a paramount role within the follicle is based upon evidence (estrogens augment FSH action) derived from rodent experiments. There is no similar evidence derived from primate studies. We will first describe the traditional conventional view regarding ovarian follicular growth and development derived from 10–15 years of scientific pursuit; and then we will consider the differences in primates. Local autocrine/paracrine peptides probably have replaced steroid hormones as the principal regulators within primate ovarian follicles.*

The Preantral Follicle

Once growth is accelerated, the follicle progresses to the preantral stage as the oocyte enlarges and is surrounded by a membrane, the zona pellucida. The granulosa cells undergo a multilayer proliferation as the thecal layer continues to organize from the surrounding stroma. This growth is dependent upon gonadotropins and is correlated with increasing production of estrogen. Molecular studies indicate that all of the granulosa cells in mature follicles are derived from as few as 3 precursor cells. ¹⁸

The granulosa cells of the preantral follicle have the ability to synthesize all 3 classes of steroids; however, significantly more estrogens than either androgens or progestins are produced. An aromatase enzyme system acts to convert androgens to estrogens and is a factor limiting ovarian estrogen production. Aromatization is induced or activated through the action of FSH. The binding of FSH to its receptor and activation of the adenylate cyclase mediated signal is followed by expression of multiple mRNAs which encode proteins responsible for cell proliferation, differentiation, and function. Thus, FSH both initiates steroidogenesis (estrogen production) in granulosa cells and stimulates granulosa cell growth. ¹⁹

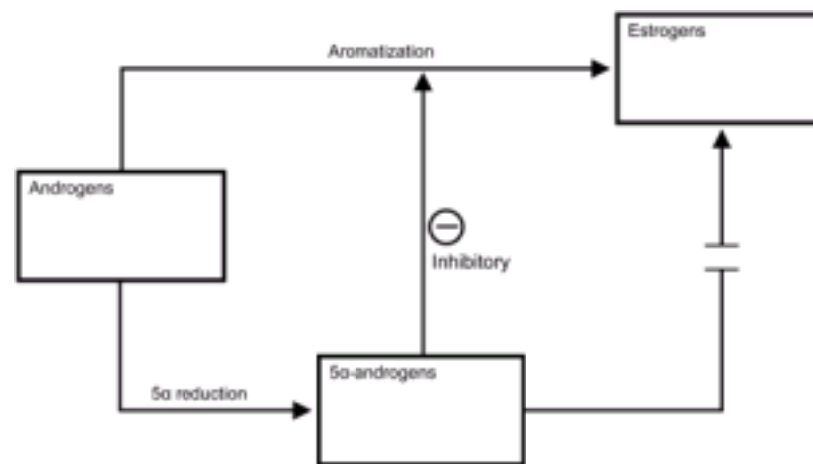

Specific receptors for FSH are not detected on granulosa cells until the preantral stage, ¹³ and the preantral follicle requires the presence of FSH in order to aromatize androgens and generate its own estrogenic microenvironment. ²⁰ Estrogen production is, therefore, limited by FSH receptor content. The administration of FSH will raise and lower the concentration of its own receptor on granulosa cells (up- and down-regulation) both in vivo and in vitro. ²¹ This action of FSH is modulated by growth factors. ²² FSH receptors quickly reach a concentration of approximately 1500 receptors per granulosa cell. ²³

FSH operates through the G protein, adenylate cyclase system (described in [Chapter 2](#)), which is subject to down-regulation and modulation by many factors, including a calcium-calmodulin intermediary. Although steroidogenesis in the ovarian follicle is mainly regulated by the gonadotropins, multiple signaling pathways are involved that respond to many factors besides the gonadotropins. Besides the adenylate cyclase enzyme system, these pathways include ion gate channels, tyrosine kinase receptors, and the phospholipase system of second messengers. These pathways are regulated by a multitude of factors, including growth factors, nitric oxide, prostaglandins, and peptides such as gonadotropin-releasing hormone (GnRH), angiotensin II, tissue necrosis factor- α , and vasoactive intestinal peptide. The binding of luteinizing hormone (LH) to its receptor in the ovary is also followed by activation of the adenylate cyclase-cyclic AMP pathway via the G protein mechanism.

FSH combines synergistically with estrogen to exert (at least in the nonprimate) a mitogenic action on granulosa cells to stimulate their proliferation. Together, FSH and estrogen promote a rapid accumulation of FSH receptors, reflecting in part the increase in the number of granulosa cells. The early appearance of estrogen within the follicle allows the follicle to respond to relatively low concentrations of FSH, an autocrine function for estrogen within the follicle. As growth proceeds, the granulosa cells differentiate into several subgroups of different cell populations. This appears to be determined by the position of the cells relative to the oocyte.

There is a system of communication that exists within follicles. Not every cell has to contain receptors for the gonadotropins. Cells with receptors can transfer a signal (by gap junctions), which causes protein kinase activation in cells that lack receptors. ²⁴ Thus, hormone-initiated action can be transmitted throughout the follicle despite the fact that only a subpopulation of cells binds the hormone. This system of communication promotes a coordinated and synchronous performance throughout the follicle, a system that continues to operate in the corpus luteum.

The role of androgens in early follicular development is complex. Specific androgen receptors are present in the granulosa cells. ²⁵ The androgens serve not only as substrate for FSH-induced aromatization but, in low concentrations, can further enhance aromatase activity. When exposed to an androgen-rich environment, preantral granulosa cells favor the conversion of androgens to more potent 5 α -reduced androgens rather than to estrogens. ²⁶ These androgens cannot be converted to estrogen and, in fact, inhibit aromatase activity. ²⁷ They also inhibit FSH induction of LH receptor formation, another essential step in follicular development. ²⁸

The fate of the preantral follicle is in delicate balance. At low concentrations, androgens enhance their own aromatization and contribute to estrogen production. At higher levels, the limited capacity of aromatization is overwhelmed, and the follicle becomes androgenic and ultimately atretic.²⁹ Follicles will progress in development only if emerging when FSH is elevated and LH is low. Those follicles arising at the end of the luteal phase or early in the subsequent cycle would be favored by an environment in which aromatization in the granulosa cell can prevail. **The success of a follicle depends upon its ability to convert an androgen-dominated microenvironment to an estrogen-dominated microenvironment.**³⁰

Summary of Events in the Preantral Follicle

1. Initial follicular development occurs independently of hormone influence.
2. FSH stimulation propels follicles to the preantral stage.
3. FSH-induced aromatization of androgen in the granulosa results in the production of estrogen.
4. Together, FSH and estrogen increase the FSH receptor content of the follicle.

The Antral Follicle

Under the synergistic influence of estrogen and FSH there is an increase in the production of follicular fluid that accumulates in the intercellular spaces of the granulosa, eventually coalescing to form a cavity, as the follicle makes its gradual transition to the antral stage. The accumulation of follicular fluid provides a means whereby the oocyte and surrounding granulosa cells can be nurtured in a specific endocrine environment. The granulosa cells surrounding the oocyte are now designated the cumulus oophorus. The differentiation of the cumulus cells is believed to be a response to signals originating in the oocyte.³¹

In the presence of FSH, estrogen becomes the dominant substance in the follicular fluid. Conversely, in the absence of FSH, androgens predominate.^{32,33} LH is not normally present in follicular fluid until the midcycle. If LH is prematurely elevated in plasma and antral fluid, mitotic activity in the granulosa decreases, degenerative changes ensue, and intrafollicular androgen levels rise. Therefore, the dominance of estrogen and FSH is essential for sustained accumulation of granulosa cells and continued follicular growth. Antral follicles with the greatest rates of granulosa proliferation contain the highest estrogen concentrations and the lowest androgen:estrogen ratios, and are the most likely to house a healthy oocyte.³⁴ An androgenic milieu antagonizes estrogen-induced granulosa proliferation and, if sustained, promotes degenerative changes in the oocyte.

The steroids present in follicular fluid can be found in concentrations several orders of magnitude higher than those in plasma and reflect the functional capacity of the surrounding granulosa and theca cells. The synthesis of steroid hormones is functionally compartmentalized within the follicle—the two-cell system.^{23,29,33,35,36}

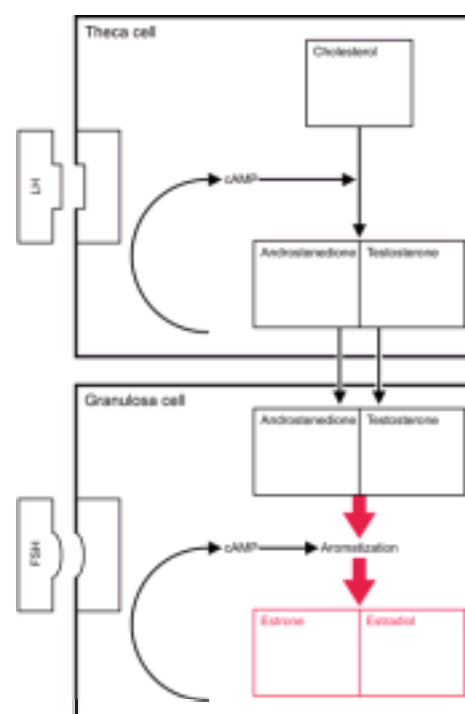

The Two-Cell, Two-Gonadotropin System

The aromatase activity of the granulosa far exceeds that observed in the theca. In human preantral and antral follicles, LH receptors are present only on the theca cells and FSH receptors only on the granulosa cells.^{37,38} Thecal interstitial cells, located in the theca interna, have approximately 20,000 LH receptors in their cell membranes. In response to LH, thecal tissue is stimulated to produce androgens that can then be converted, through FSH-induced aromatization, to estrogens in the granulosa cells.

The interaction between the granulosa and theca compartments, with resulting accelerated estrogen production, is not fully functional until later in antral development. Like preantral granulosa cells, the granulosa of small antral follicles exhibits an *in vitro* tendency to convert significant amounts of androgen to the more potent 5 α -reduced form. In contrast, granulosa cells isolated from large antral follicles readily and preferentially metabolize androgens to estrogens. The conversion from an androgen microenvironment to an estrogen microenvironment (a conversion essential for further growth and development) is dependent upon a growing sensitivity to FSH brought about by the action of FSH and the enhancing influence of estrogen.

As the follicle develops, theca cells begin to express the genes for LH receptors, P450_{scc}, and 3 β -hydroxysteroid dehydrogenase.³⁹ The separately regulated (by LH) entry of cholesterol into mitochondria, utilizing internalization of LDL-cholesterol, is essential for steroidogenesis. **Therefore, ovarian steroidogenesis is LH-dependent to a significant degree.** Human ovarian granulosa cells, after luteinization and vascularization that occur following ovulation, can use HDL-cholesterol in a system that differs from the LDL-cholesterol pathway. The lipoproteins are not internalized, but rather, the cholesteryl esters are extracted from the lipoproteins at the cell surface and then transferred into the cell.⁴⁰

As the follicle emerges, the theca cells are characterized by their expression of P450_{c17}, the enzyme step which is rate-limiting for the conversion of 21-carbon substrate to androgens.⁴¹ Granulosa cells do not express this enzyme and thus are dependent upon androgens from the theca in order to make estrogen. Increasing expression of the aromatization system (P450_{arom}) is a marker of increasing maturity of granulosa cells. The presence of P450_{c17} only in thecal cells and P450_{arom} only in granulosa cells is impressive evidence confirming the two-cell, two-gonadotropin explanation for estrogen production.⁴²

The importance of the two-cell, two-gonadotropin system in the primate is supported by the response of women with a deficiency in gonadotropins to treatment with recombinant (pure) FSH.^{43,44} and⁴⁵ Follicles developed (confirming the essential role of FSH, and the lesser role for LH, in recruitment and initial growth), but estradiol production was limited. Some aromatization occurred, perhaps using androgens originating in the adrenal glands, producing early follicular phase estradiol levels, but

the usual robust steroidogenesis was impossible without the presence of LH to provide thecal production of androgen substrate. This same response has been observed in experiments that use a GnRH antagonist to produce LH-deficient monkeys and then the administration of recombinant, pure human FSH.^{46, 47} These results indicate that only FSH is required for folliculogenesis, and that in the primate, autocrine/paracrine peptides have replaced estrogen in the important intraovarian role of modulating gonadotropin response.

Selection of the Dominant Follicle

The successful conversion to an estrogen dominant follicle marks the “selection” of a follicle destined to ovulate, the process whereby, with rare exception, only a single follicle succeeds.⁴⁸ This selection process is to a significant degree the result of two estrogen actions: 1) a local interaction between estrogen and FSH within the follicle (in the nonprimate model), and 2) the effect of estrogen on pituitary secretion of FSH. While estrogen exerts a positive influence on FSH action within the maturing follicle, its negative feedback relationship with FSH at the hypothalamic-pituitary level serves to withdraw gonadotropin support from the other less developed follicles. The fall in FSH leads to a decline in FSH-dependent aromatase activity, limiting estrogen production in the less mature follicles. Even if a lesser follicle succeeds in achieving an estrogen microenvironment, decreasing FSH support would interrupt granulosa proliferation and function, promote a conversion to an androgenic microenvironment, and thereby induce irreversible atretic change. Indeed, the first event in the process of atresia is a reduction in FSH receptors in the granulosa layer.

The loss of oocytes (and follicles) through atresia is a response to changes in many factors. Certainly gonadotropin stimulation and withdrawal are important, but ovarian steroids and autocrine/paracrine factors are also involved. The consequence of these unfavorable changes, atresia, is a process called **apoptosis**, programmed cell death. This process is heralded by alterations in mRNAs required for cell proteins which maintain follicle integrity.⁴⁹ This type of “natural death” is a physiologic process, in contrast to the pathologic cell death of necrosis.

Once cells have entered the process of apoptosis, their response to FSH is modulated by local growth factors. Tumor necrosis factor (TNF), produced in the granulosa cells, inhibits FSH stimulation of estradiol secretion, except in the dominant follicle.⁵⁰ An inverse relationship exists between TNF expression and gonadotropin stimulation of granulosa cells. Thus, as the successful follicle increases its response to gonadotropins, its TNF production decreases. Those follicles with a failing response to gonadotropins increase their TNF production, hastening their demise.

An asymmetry in ovarian estrogen production, an expression of the emerging dominant follicle, can be detected in ovarian venous effluent on day 5 of the cycle, corresponding with the gradual fall of FSH levels observed at the midfollicular phase and preceding the increase in diameter that marks the physical emergence of the dominant follicle.⁵¹ This is a crucial time in the cycle. Exogenous estrogen, administered even after selection of the dominant follicle, disrupts preovulatory development and induces atresia by reducing FSH levels below the sustaining level. Because the lesser follicles have entered the process of atresia, loss of the dominant follicle during this period of time requires beginning over, with recruitment of another set of preantral follicles.⁵²

The negative feedback of estrogen on FSH serves to inhibit the development of all but the dominant follicle. The selected follicle remains dependent upon FSH and must complete its preovulatory development in the face of declining plasma levels of FSH. The dominant follicle, therefore, must escape the consequences of FSH suppression induced by its own accelerating estrogen production. The dominant follicle has two significant advantages, a greater content of FSH receptors acquired because of a rate of granulosa proliferation that surpasses that of its cohorts and enhancement of FSH action because of its high intrafollicular estrogen concentration (the nonprimate model) or because of local autocrine/paracrine peptides (as will be described below in the primate model). Thus, the dominant follicle is more sensitive to FSH, and as long as a critical duration of FSH exposure was initially present, the dominant follicle continues to develop.⁵³ As a result, the stimulus for aromatization, FSH, can be maintained, while at the same time it is being withdrawn from among the less developed follicles. A wave of atresia among the lesser follicles, therefore, is seen to parallel the rise in estrogen.

The accumulation of a greater mass of granulosa cells is accompanied by advanced development of the thecal vasculature. By day 9, thecal vascularity in the dominant follicle is twice that of other antral follicles.⁵³ This allows a preferential delivery of gonadotropins to the follicle, permitting the dominant follicle to retain FSH responsiveness and sustain continued development and function despite waning gonadotropin levels. The monkey ovary expresses a potent growth factor (vascular endothelial growth factor) that induces angiogenesis, and this expression is observed at the two development points when proliferation of capillaries is important: the emerging dominant follicle and the early corpus luteum.^{54, 55}

In order to respond to the ovulatory surge and to become a successful corpus luteum, the granulosa cells must acquire LH receptors. FSH induces LH receptor development on the granulosa cells of the large antral follicles. Here again either estrogen (the nonprimate), or local autocrine/paracrine peptides (primate), serves as the chief coordinator.

In the nonprimate model, with increasing concentrations of estrogen within the follicle, FSH changes its focus of action, from up-regulating its own receptor to generation of the LH receptors.⁵⁶ The combination of a capacity for continued response despite declining levels of FSH and a high local estrogen environment in the dominant follicle provides optimal conditions for LH receptor development. LH can induce the formation of its own receptor in FSH-primed granulosa cells, but the primary mechanism utilizes FSH stimulation and estrogen enhancement.^{57, 58} The role for estrogen goes beyond synergism and enhancement; it is obligatory. Inhibition of estrogen synthesis prevents FSH-stimulated increases in LH receptors.⁵⁹

Although prolactin is always present in follicular fluid, there is no evidence to suggest that prolactin is important during normal ovulatory cycles in the primate.

The Feedback System

Through its own estrogen and peptide production, the dominant follicle assumes control of its own destiny. By altering gonadotropin secretion through feedback mechanisms it optimizes its own environment to the detriment of the lesser follicles.

As reviewed in [Chapter 5](#), gonadotropin-releasing hormone (GnRH) plays an obligatory role in the control of gonadotropin secretion, but the pattern of gonadotropin secretion observed in the menstrual cycle is the result of feedback modulation of steroids and peptides originating in the dominant follicle, acting directly on the hypothalamus and anterior pituitary.⁴ In addition, an increase in GnRH accompanies the LH surge, indicating that estrogen positive feedback operates at both pituitary and hypothalamic sites.⁶⁰ Estrogen exerts its inhibitory effects in both the hypothalamus and the anterior pituitary, decreasing both GnRH pulsatile secretion and GnRH pituitary response.⁶¹ Progesterone also operates in two sites. Its inhibitory action is at the hypothalamic level, and, like estrogen, its positive action is directly

on the pituitary.⁶²

The secretion of FSH is very sensitive to the negative inhibitory effects of estrogen even at low levels. At higher levels, estrogen combines with inhibin for a suppression of FSH that is profound and sustained. In contrast, the influence of estrogen on LH release varies with concentration and duration of exposure. At low levels, estrogen imposes a negative feedback relationship with LH. At higher levels, however, estrogen is capable of exerting a positive stimulatory feedback effect on LH release.

The transition from suppression to stimulation of LH release occurs as estradiol rises during the midfollicular phase. There are two critical features in this mechanism: 1) the concentration of estradiol and 2) the length of time during which the estradiol elevation is sustained. In women, the estradiol concentration necessary to achieve a positive feedback is more than 200 pg/mL, and this concentration must be sustained for approximately 50 hours.⁶³ This level of estrogen essentially never occurs until the dominant follicle has reached a diameter of 15 mm.⁶⁴ The estrogen stimulus must be sustained beyond the initiation of the LH surge until after the surge actually begins. Otherwise, the LH surge is abbreviated or fails to occur at all.

Within the well-established monthly pattern, the gonadotropins are secreted in a pulsatile fashion with a frequency and magnitude that vary with the phase of the cycle. The pulsatile pattern is directly due to a similar pulsatile secretion of GnRH, but amplitude and frequency modulation (mean values below) is probably the consequence of steroid feedback on both hypothalamus and anterior pituitary.^{65, 66 and 67} **Pulsatile secretion is more frequent but smaller in amplitude during the follicular phase compared to the luteal phase, with a slight increase in frequency observed as the follicular phase progresses to ovulation.**

LH Pulse Frequency:

Early follicular phase	—90 minutes.
Late follicular phase	—60–70 minutes.
Early luteal phase	—100 minutes.
Late luteal phase	—200 minutes.

LH Pulse Amplitude:

Early follicular phase	—6.5 IU/L.
Midfollicular phase	—5.0 IU/L.
Late follicular phase	—7.2 IU/L.
Early luteal phase	—15.0 IU/L.
Midluteal phase	—12.2 IU/L.
Late luteal phase	—8.0 IU/L.

The pulsatile pattern of FSH is not easily discerned because of its relatively longer half-life compared to LH, but the experimental data indicate that FSH and LH are secreted simultaneously and that GnRH stimulates the secretion of both gonadotropins. Even as late as only 36–48 hours before menses, gonadotropin secretion is still characterized by infrequent LH pulses and low FSH levels typical of the late luteal phase.⁶⁶ During the transition from the previous luteal phase to the next follicular phase, GnRH and the gonadotropins are released from the inhibitory effects of estradiol, progesterone, and inhibin. A progressive and fairly rapid increase in GnRH pulse secretion is associated with a preferential secretion of FSH compared to LH. The frequency of GnRH and LH pulses increases 4.5-fold during this period of time, accompanied by a 3.5-fold increase in the circulating levels of FSH, and a lesser 2-fold increase in LH levels.⁶⁸

The GnRH pulse frequency changes in the luteal phase correlate with duration of exposure to progesterone, while pulse amplitude changes appear to be influenced by changes in progesterone levels.⁶⁵ Both estradiol and progesterone are required to achieve the low, suppressed secretory pattern of GnRH during the luteal phase.⁶⁹ The studies suggest that steroids influence the hypothalamic release of GnRH for frequency changes and the pituitary for action on amplitude of the gonadotropin pulses. The inhibitory action of luteal phase steroids appears to be mediated by an increase in hypothalamic endogenous opioid peptides. Both estrogen and progesterone can increase endogenous opiates, and administration of clomiphene (an estrogen antagonist) during the luteal phase increases the LH pulse frequency with no effect on amplitude.⁷⁰ Thus, estrogen appears to enhance the stimulatory action of progesterone in the luteal phase on endogenous opioid peptides, creating relatively high levels of endogenous opiates during the luteal phase.

Plasma endorphin begins to rise in the 2 days before the LH peak, coinciding with the midcycle gonadotropin surge.⁷¹ The maximal level is reached just after the LH peak, coinciding with ovulation. Levels then gradually decline until the nadir is reached during menses and the early follicular phase. Monkeys have their highest beta-endorphin levels in the hypophyseal portal blood at midcycle.⁷² Normal cyclicity requires sequential periods of high (midcycle and luteal phase) and low (during menses) hypothalamic opioid activity.

There is another important action of estrogen. A disparity exists between the patterns of FSH and LH secretion as determined by immunoassay and bioassay, indicating that more biologically active gonadotropins are secreted at midcycle than at other times in the cycle.^{73, 74} This quality, bioactivity vs immunoreactivity, is determined by the molecular structure of the gonadotropin molecule, a concept referred to in [Chapter 2](#) as heterogeneity of the tropic hormones. There is a well-established relationship between the activity and half-life of glycoprotein hormones and their sialic acid content. The feedback effects of estrogen include modulation of sialylation and the size and activity of the gonadotropins subsequently released, as well as an augmentation of GnRH-stimulated secretory release of biologically active gonadotropin. It certainly makes sense to intensify the gonadotropin effect at midcycle. The positive feedback action of estrogen, therefore, both increase the quantity and the quality (the bioactivity) of FSH and LH.

There is a diurnal rhythm in FSH and LH secretion.⁷⁵ In contrast to the nocturnal rise seen with ACTH, thyroid-stimulating hormone (TSH), growth hormone, and prolactin, FSH and LH exhibit nocturnal decline, probably mediated by endogenous opiates. This diurnal rhythm for LH is present only in the early follicular phase, while FSH maintains a circadian rhythm throughout the menstrual cycle (and thus it is not influenced by steroid hormone feedback) and even in the postmenopausal period of life.

Inhibin, Activin, Follistatin

This family of peptides is synthesized by granulosa cells in response to FSH and secreted into the follicular fluid and ovarian venous effluent.^{76, 77, 78 and 79} The expression of these peptides is not limited to the ovary; they are present in many tissues throughout the body serving as autocrine/paracrine regulators. Inhibin is an important inhibitor of FSH secretion. Activin stimulates FSH release in the pituitary and augments FSH action in the ovary. Follistatin suppresses FSH activity, probably by binding activin.

Inhibin consists of two dissimilar peptides (known as alpha- and beta-subunits) linked by disulfide bonds. Two forms of inhibin (inhibin A and inhibin B) have been purified, each containing an identical alpha-subunit and distinct but related beta-subunits. Thus, there are three subunits for inhibins: alpha, beta-A, and beta-B. Each subunit is a product of different messenger RNA, each derived from its own precursor molecule. Initial efforts to understand the role of inhibin in physiology were hampered by imprecise assays and the fact that multiple forms are present in the circulation, including free subunits.

The 2 Forms of Inhibin:

Inhibin A:	Alpha-Beta_A
Inhibin B:	Alpha-Beta_B

FSH stimulates the secretion of inhibin from granulosa cells and, in turn, is suppressed by inhibin — a reciprocal relationship.^{80, 81} Refinements in assay techniques have revealed that inhibin B is the form of inhibin predominantly secreted by granulosa cells in the follicular phase of the cycle.^{82, 83} The secretion of inhibin is further regulated by local autocrine/paracrine control. GnRH and epidermal growth factor diminish FSH stimulation of inhibin secretion, whereas insulin-like growth factor-I enhances inhibin production. The inhibitory effects of GnRH and epidermal growth factor are consistent with their known ability to decrease FSH-stimulated estrogen production and LH receptor formation. The action of GnRH lends some support for an endogenous ovarian GnRH-like substance (which is found in follicular fluid) and which is involved in inhibin production.

The secretion of inhibin B into the circulation further amplifies the withdrawal of FSH from other follicles, another mechanism by which an emerging follicle secures dominance. Inhibin B rises slowly but steadily, in a pulsatile fashion (60–70 min periodicity) reaching peak levels in the early and midfollicular phases, and then decreasing in the late follicular phase before ovulation to reach a nadir in the midluteal phase. ^{16, 82, 84, 85} An inhibin B peak the day after ovulation is probably the result of release from the ruptured follicle. This relationship of inhibin B and FSH is supported by the demonstration that Inhibin B levels are lower and FSH levels are higher in the follicular phase in women 45–49 years old compared to younger women. ^{84, 86}

With the appearance of LH receptors on the granulosa cells of the dominant follicle and the subsequent development of the follicle into a corpus luteum, inhibin expression comes under the control of LH, and expression changes from inhibin B to inhibin A. ⁸⁷ The circulating levels of inhibin A rise in the late follicular phase to reach a peak level at the midluteal phase. ^{16, 88} Inhibin A, therefore, contributes to the suppression of FSH to nadir levels during the luteal phase, and to the changes at the luteal-follicular transition.

Inhibin has multiple, diverse inhibitory effects on gonadotropin secretion. Inhibin can block the synthesis and secretion of FSH, prevent the up-regulation of GnRH receptors by GnRH, reduce the number of GnRH receptors present, and, at high concentrations, promote the intracellular degradation of gonadotropins.

Activin is a peptide that is related to inhibin but has an opposite action (the stimulation of FSH release and GnRH receptor number). ^{83, 89, 90} This peptide contains two subunits that are identical to the beta-subunits of inhibins A and B. Thus, when each of the beta-subunits of the inhibins is combined with an alpha-subunit, the resulting molecule, inhibin A or B, inhibits the release of FSH. If the beta-subunits are paired together, the molecule stimulates the release of FSH. Each activin subunit is encoded by a distinct gene. The structure of the activin genes is homologous to that of transforming growth factor- β , indicating that these products all come from the same gene family. ⁹¹ Another important member of this family is the antimüllerian hormone, as well as a protein active during insect embryogenesis, and a protein active in frog embryos.

The 3 Forms of Activin:

Activin A:

Activin AB:

Activin B:

Beta_A-Beta_A

Beta_A-Beta_B

Beta_B-Beta_B

Activin is present in many cell types, regulating growth and differentiation. In the ovarian follicle, activin increases FSH binding in granulosa cells (by regulating receptor numbers) and augments FSH stimulation of aromatization and inhibin production. ⁷⁸ Considerable evidence derived from human cells exists to indicate that inhibin and activin act directly on thecal cells to regulate androgen synthesis. ^{92, 93 and 94} Inhibin enhances the stimulatory action of LH and/or IGF-I, while activin suppresses this action. Inhibin in increasing doses can overcome the inhibitory action of activin. Prior to ovulation, activin suppresses granulosa progesterone production, perhaps preventing premature luteinization. There is a repertoire of cell transmembrane kinase receptors for activin, with differing binding affinities and domain structures. ⁹⁵ This receptor heterogeneity allows the many different responses elicited by a single peptide. Both activin A and inhibin A have been demonstrated to be very potent in stimulating in vitro maturation of oocytes that subsequently yield a high rate of fertilization. ⁹⁶

In the male, activin inhibits and inhibin facilitates LH stimulation of androgen biosynthesis in Leydig cells. In addition, activin stimulates and inhibin decreases spermatogonial proliferation; inhibin is produced in the Sertoli cell, the locus that has the principal role in modulating spermatogenesis. Thus, activin and inhibin play similar autocrine/paracrine roles in both the male and female gonads.

The anterior pituitary expresses the inhibin/activin subunits, and locally produced activin B augments FSH secretion. Activin A has been demonstrated to directly stimulate the synthesis of GnRH receptors in pituitary cells. ⁹⁰ Follistatin is a peptide secreted by a variety of pituitary cells, including the gonadotropes. ⁹⁷ This peptide has also been called FSH-suppressing protein because of its main action: inhibition of FSH synthesis and secretion and the FSH response to GnRH, probably by binding to activin and in that fashion decreasing the activity of activin. ^{98, 99} Activin stimulates follistatin production, and inhibin prevents this response. Follistatin is also expressed by granulosa cells in response to FSH, and, therefore, follistatin, like inhibin and activin, functions locally in the follicle and in the pituitary. ¹⁰⁰ Circulating levels of activin increase in the late luteal phase to peak at menses; however, activin A is highly bound in the circulation, and it is not certain it has an endocrine role. ¹⁰¹ Nevertheless, the timing is right for activin to contribute to the rise in FSH during the luteal-follicular transition.

In summary, the pituitary secretion of FSH can be significantly regulated by the balance of activin and inhibin, with follistatin playing a role by inhibiting activin and enhancing inhibin activity. Within the ovarian follicle, activin and inhibin influence growth and development by modulating thecal and granulosa responses to the gonadotropins.

The inhibin-activin family of peptides (also including antimüllerian hormone and transforming growth factor- β) inhibits cell growth and can be considered as a class of tumor-suppressor proteins. Mice have been generated that are deficient in the inhibin alpha-subunit gene. ⁷⁹ The mice that are homozygous and lack inhibin are susceptible to the development of gonadal stromal tumors which appear after normal sexual differentiation and development. Thus, the alpha-inhibin gene is a specific tumor-suppressor gene for the gonads. A contributing factor to this tumor development could be the high FSH levels associated with the deficiency in inhibin.

Growth Factors

Growth factors are polypeptides that modulate cell proliferation and differentiation, operating through binding to specific cell membrane receptors. They are not classic endocrine substances; they act locally and function in paracrine and autocrine modes. There are multiple growth factors, and most cells contain multiple receptors for the various growth factors.

Insulin-Like Growth Factors. The insulin-like growth factors (also called somatomedins) are peptides that have structural and functional similarity to insulin and mediate growth hormone action. ¹⁰² Insulin-like growth factor-I (IGF-I) and insulin-like growth factor-II (IGF-II) are single chain polypeptides containing 3 disulfide bonds. IGF-I is encoded on the long arm of chromosome 12 and IGF-II on the short arm of chromosome 11 (which also contains the insulin gene). The genes are subject to a variety of promoters, and thus differential regulation can govern ultimate actions.

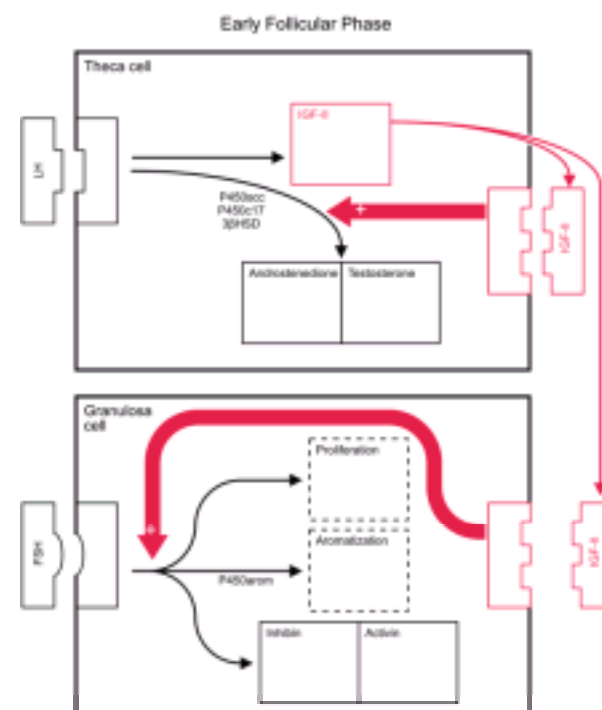

IGF-I mediates the growth promoting actions of growth hormone. The majority of circulating IGF-I is derived from growth hormone dependent synthesis in the liver. However, IGF-I is synthesized in many tissues where production can be regulated in conjunction with growth hormone or **independently** by other factors.

IGF-II has little growth hormone dependence. It is believed to be important in fetal growth and development. Both IGFs induce the expression of cellular genes

responsible for cellular proliferation and differentiation.

Insulin-like Growth Factor Binding Proteins. There are 6 known nonglycosylated peptides that function as IGF binding proteins, IGFBP-1 to IGFBP-6. ¹⁰³ These binding proteins serve to carry the IGFs in serum, prolong half-lives, and regulate tissue effects of the IGFs. The regulating action appears to be due to binding and sequestering of the IGFs, preventing their access to the cell membrane surface receptors, and, thus, not permitting the synergistic actions that result when gonadotropins and growth factors are combined. The IGFBPs may also exert direct actions on cellular functions, independently of growth factor functions. IGFBP-1 is the principal BP in amniotic fluid; IGFBP-3 is the main BP in serum and its synthesis, primarily in the liver, is dependent on growth hormone. Circulating levels of IGFBP-3 reflect the total IGF concentration (IGF-I plus IGF-II) and carry at least 90% of the circulating IGFs. These BPs do not bind insulin. The BPs change with age (decreasing levels of IGFBP-3) and during pregnancy (decreasing IGFBP-3 due to a circulating protease unique to pregnancy).

The IGF Receptors. The Type I receptor preferentially binds IGF-1 and can be called the IGF-I receptor. The Type II receptor in a similar fashion can be called the IGF-II receptor. IGF-I also binds to the insulin receptor but with low affinity. Insulin binds to the IGF-I receptor with moderate affinity. The IGF-I receptor and the insulin receptor are similar in structure: tetramers composed of two α -subunits and two β -subunits linked by disulfide bonds. The intracellular component of the β -subunit is a tyrosine kinase that is activated by autophosphorylation. The IGF-II receptor does not bind insulin. It is a single chain glycoprotein, with 90% of its structure extending extracellularly. This receptor functions as a receptor coupled to a G protein. The physiologic effects of IGF-I are mediated by its own receptor, but IGF-II can exert its actions via both receptors. Indeed, the IGF-I receptor binds IGF-I and IGF-II with equal affinity. In human cells, the IGF-I receptor and IGF-II receptor are present in theca and granulosa cells and in luteinized granulosa cells. Ovarian stromal tissue contains IGF-I receptors.

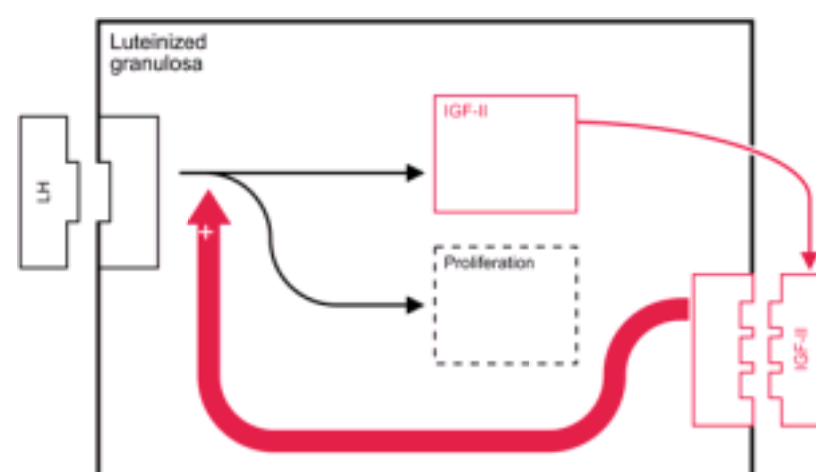

The Ovarian Actions of IGFs. IGF-I has been demonstrated to stimulate the following events in ovarian theca and granulosa cells: DNA synthesis, steroidogenesis, aromatase activity, LH receptor synthesis, and inhibin secretion. IGF-II stimulates granulosa mitosis. In human ovarian cells, IGF-I, in synergy with FSH, stimulates protein synthesis and steroidogenesis. After LH receptors appear, IGF-I enhances LH-induced progesterone synthesis and stimulates proliferation of granulosa-luteal cells. IGF-I, in synergy with FSH, is very active in stimulating aromatase activity in preovulatory follicles. Thus, IGF-I can be involved in both estradiol and progesterone synthesis.

In animal experiments, the synthesis of IGF-I by granulosa cells is dependent upon FSH but enhanced by estradiol. Growth hormone also acts synergistically with FSH and estradiol to increase IGF synthesis. The story becomes confused when various growth factors and regulators are studied, because of their various stimulating and inhibiting effects. In the rat, the granulosa cell is the major site for IGF-I gene expression, which is active only prior to ovulation. It is not detected in atretic follicles or in corpora lutea. Again in the rat, IGF-II gene expression appears to be limited to the theca and interstitial cells. However, the site of IGF expression is different in primates.

In studies with human ovarian tissue, IGF-II is highly expressed in both thecal cells and granulosa cells; however, the level is highest in the granulosa and increases with growth of the follicle. ^{104, 105} IGF-II is also synthesized by luteinized granulosa and appears to function locally in an autocrine fashion. ¹⁰⁶ These findings indicate that IGF-II is the primary IGF in the human ovary. Nevertheless, IGF-I is still a significant product of human thecal cells. ¹⁰⁷

Human thecal cells express mRNA transcripts which encode receptors for both IGF-I and insulin. ¹⁰⁸ Because insulin and IGF-II can both activate the receptor for IGF-I, this pathway provides a method for the exertion of a paracrine influence on granulosa cells and autocrine activity in the theca (augmenting LH stimulation of androgen production). In vitro studies confirm that IGF-II is capable of stimulating steroidogenesis and proliferation in human theca and granulosa cells. ^{109, 110 and 111}

These actions are augmented by growth hormone, which increases IGF production and, thus, indirectly enhances gonadotropin stimulation of ovarian follicles. ¹¹²

This primate scenario is supported by finding higher levels of IGF-II, but not IGF-I, in the follicular fluid of developing follicles, with the highest levels present in dominant follicles. ¹¹³ The IGF levels in follicular fluid correlate with estradiol levels and undergo a further short increase after the LH surge. There are no menstrual cycle changes in the circulating levels of IGF-I, IGF-II, IGFBP-1, or IGFBP-3; high levels in the dominant follicle are not associated with an increase in circulating levels. ¹¹⁴

The 6 IGF binding proteins are synthesized in different amounts in various follicular tissues in response to gonadotropins, insulin, and IGF-I. In the rat, IGFBP-3 is made in the theca, stimulated by growth hormone, and inhibited by FSH and estradiol. ¹¹⁵ In the rat, low concentrations of FSH stimulate the expression of IGFBPs, while FSH at high concentrations inhibits IGFBP synthesis. It is proposed that this biphasic response allows an increase in IGF-I facilitation of mitosis during FSH-induced follicular growth, while IGF-I availability is limited during periods of low FSH when follicular steroidogenesis is the major effort. ¹¹⁶

In studies with human tissue, IGFBP-1 inhibits IGF-1 mediated steroidogenesis and proliferation of luteinized granulosa cells. The synthesis of IGFBPs by human granulosa is inhibited by FSH, IGF-I, and IGF-II. ^{117, 118} These findings fit with the overall idea that the BPs counteract the synergistic results of gonadotropins and growth factors. In general, IGFBP-1 expression is found in granulosa cells of growing follicles; IGFBP-3 in theca cells and the granulosa of the dominant follicle; IGFBP-2, -4, and -5 in thecal and granulosa of antral and atretic follicles; and IGFBP-6 has not been found in the ovary. ¹⁰⁴ The predominant binding protein in preovulatory follicles is IGFBP-2 in the granulosa and IGFBP-3 in the theca, that increase progressively in the follicle that emerges as the dominant follicle, and then decrease in the late follicular phase. ^{105, 119, 120} This suggests that -1, -2, and -3 play a role in growing follicles, -2, -4, and -5 in atretic and failing follicles. IGFBP expression in polycystic ovaries is similar to that seen in atretic follicles. The decrease in IGFBP-3 that occurs in dominant follicles should allow an increase in IGF levels and activity. The increase in IGFBP-2 in failing follicles probably correlates with sequestering of IGF, depriving the follicle of an important force in gonadotropin augmentation.

Circulating levels of IGFBP-1 decrease in response to insulin, and thus circulating levels are decreased in women with anovulation and polycystic ovaries who have elevated levels of insulin. ¹²¹ These patients also have increased circulating levels of IGF-I, probably a consequence of LH-stimulated synthesis and secretion in theca cells. The level of IGFBP-1 in follicular fluid from polycystic ovaries is decreased; thus this BP is not playing a role inhibiting the action of IGF-I in polycystic ovaries. The levels of IGFBPs -2 and -4 in the follicular fluid from follicles in anovulatory patients are increased (as in atretic follicles). ^{104, 122} Even though these changes may play a role in anovulatory pathophysiology, they are consistent with failure in development and thus may not be etiologic factors.

IGF activity may also be modulated by the proteases that regulate the activity of the IGF binding proteins. ¹²³ Estrogen-dominant follicular fluid contains very low levels of IGFBP-4, in contrast to the high levels present in androgen-dominant follicular fluid. The low level of IGFBP-4 in estrogen-dominant follicular fluid is associated with the presence of an IGFBP-4 specific protease. This protease would decrease IGFBP activity and enhance IGF activity, another mechanism for ensuring the success of the dominant follicle.

In addition to ovarian activities, IGF-I and its receptor and binding proteins operate in the pituitary gland. In the rat, the hyperplasia of various pituitary cell types appears to be mediated by estrogen regulation of the IGF-I system. ¹²⁴ This mechanism is of special interest when considering the development of pituitary tumors, such as the prolactin secreting pituitary adenoma.

The insulin-like growth factor story is at once complex, fascinating, and compelling. However, its contribution may be facilitatory and not essential. Laron-type dwarfism is characterized by a deficiency in IGF-I due to an abnormality in the growth hormone receptor. Despite low levels of IGF-I and high levels of IGFBP, a woman with Laron-type dwarfism responded to exogenous gonadotropin stimulation with the production of multiple, mature follicles with good estrogen production and fertilizable oocytes. ¹²⁵ Another explanation for this observation is that IGF-II, rather than IGF-I, is the important factor in the human dominant follicle. This possibility is supported by evidence indicating that IGF-II is the most abundant IGF in human ovarian follicles. ^{104, 105} Another possibility is that the Laron-type dwarf is deficient only in growth hormone-dependent IGF-I, and ovarian IGFs are not totally dependent on growth hormone.

Summary of Insulin-Like Growth Factor Action in the Ovary

1. IGF-II stimulates granulosa cell proliferation, aromatase activity, and progesterone synthesis.
2. IGF-II is produced in thecal cells, granulosa cells, and luteinized granulosa cells. In the pig and rat, the primary IGF is IGF-I.
3. Gonadotropins stimulate IGF production, and in animal experiments, this stimulation is enhanced by estradiol and growth hormone.
4. IGF-I receptors are present in theca and granulosa cells, and only IGF-II receptors are present in luteinized granulosa. IGF-II activates both IGF-I and IGF-II receptors.
5. The most abundant IGF in human follicles is IGF-II.
6. FSH inhibits binding protein synthesis, and thus maximizes growth factor availability.

Epidermal Growth Factor. Epidermal growth factor is a mitogen for a variety of cells, and its action is potentiated by other growth factors. Granulosa cells, in particular, respond to this growth factor in a variety of ways related to gonadotropin stimulation, including proliferation. Epidermal growth factor suppresses the up-regulation of FSH on its own receptor. ²²

Transforming Growth Factor. TGF- α is a structural analog of epidermal growth factor and can bind to the epidermal growth factor receptor. TGF- β utilizes a receptor distinct from the epidermal growth factor receptor. These factors are thought to be autocrine growth regulators. Inhibin and activin are derived from the same gene family. TGF- β , secreted by theca cells, enhances FSH induction of LH receptors on granulosa cells, an action which is opposite that of epidermal growth factor. ¹²⁶ While this action can be viewed as a positive impact on granulosa cells, in the theca, TGF- β has a negative action, inhibiting androgen production. ¹²⁷

Fibroblast Growth Factor. This factor is a mitogen for a variety of cells and is present in all steroid-producing tissues. Important roles in the ovarian follicle include stimulation of mitosis in granulosa cells, stimulation of angiogenesis, stimulation of plasminogen activator, inhibition of FSH up-regulation of its own receptor, and inhibition of FSH-induced LH receptor expression and estrogen production. ^{22, 128} These actions are opposite of those of transforming growth factor- β .

Platelet-Derived Growth Factor. This growth factor modifies cyclic AMP pathways responding to FSH, especially those involved in granulosa cell differentiation. Both platelet-derived growth factor and epidermal growth factor may also modify prostaglandin production within the follicle.

Angiogenic Growth Factors. Vascularization of the follicle is influenced by peptides into the follicular fluid, especially vascular endothelial growth factor (VEGF), a cytokine produced in granulosa cells in response to LH. ^{129, 130} Luteal cells respond to HCG with greater VEGF output, a probable mechanism contributing to the increased vascular permeability associated with ovarian hyperstimulation that can occur with exogenous gonadotropin administration ([Chapter 30](#)). ¹³¹

The Interleukin-1 System. Leukocytes are a prominent component of the ovarian follicle and a major source of interleukins. Interleukin-1 is a member of the cytokine family of immunomediators. The human ovary contains the complete interleukin-1 system (ligand and receptor). In the rat, interleukin-1 stimulates ovarian prostaglandin synthesis and perhaps plays a role in ovulation. ¹³²

Tumor Necrosis Factor- α (TNF- α). TNF- α is also a product of leukocytes (macrophages). It very likely is a key player in the process of apoptosis, a feature of follicular atresia as well as luteolysis of the corpus luteum.

Other Peptides. The follicular fluid is a veritable protein soup! It is composed of exudates from plasma and secretions from follicular cells. A variety of hormones can be found in the follicular fluid, as well as enzymes and peptides, which play important roles in follicular growth and development, ovulation, and modulation of hormonal responses.

Follicular fluid contains **prorenin**, the inactive precursor of renin, in a concentration that is about 12 times higher than plasma levels. ¹³³ It appears that LH stimulates its synthesis in the follicle, and there is a midcycle peak in prorenin plasma levels. The circulating levels of prorenin also increase (10-fold) during the early stages of pregnancy, the result of ovarian stimulation by the rise in human chorionic gonadotropin (HCG). These increases in prorenin from the ovary are not responsible for any significant changes in the plasma levels of the active form, renin. Possible roles for this ovarian prorenin-renin-angiotensin system include stimulation of

steroidogenesis to provide androgen substrate for estrogen production, regulation of calcium and prostaglandin metabolism, and stimulation of angiogenesis. This system may affect vascular and tissue functions both within and outside the ovary.

Members of the proopiomelanocortin family are found in human follicular fluid.¹³⁴ Follicular levels of **ACTH** and **b-lipotropin** remain constant throughout the cycle, but **b-endorphin** levels peak just before ovulation. In addition, enkephalin is present in relatively unchanging concentrations. The corticotropin-releasing hormone (CRH) system is present in thecal cells, but not in granulosa cells, complete with CRH, the CRH receptor, and CRH-binding protein.¹³⁵ CRH inhibits LH-stimulated androgen production in thecal cells, apparently by suppressing P450c17 gene expression.¹³⁶

Antimüllerian hormone is produced by granulosa cells and may play a role in oocyte maturation (it inhibits oocyte meiosis) and follicular development.^{137, 138} Antimüllerian hormone directly inhibits proliferation of granulosa and luteal cells, as well as epidermal growth factor-stimulated proliferation.

Follicular fluid prevents resumption of meiosis until the preovulatory LH surge either overcomes or removes this inhibition. This action is attributed to **oocyte maturation inhibitor (OMI)**. **Pregnancy-associated plasma protein A**, found in the placenta, is also present in follicular fluid. It may inhibit proteolytic activity within the follicle before ovulation. **Endothelin-1** is a peptide, produced in vascular endothelial cells, which may be the substance previously known as luteinization inhibitor; endothelin gene expression is induced by the hypoxia associated with the avascular granulosa, and it inhibits LH-induced progesterone production.¹³⁹ It is uncertain whether **GnRH-like peptides** have a follicular role or represent sequestered GnRH. **Oxytocin** is found in preovulatory follicles and the corpus luteum. Growth hormone-binding protein is present in follicular fluid and similar in characteristics to the same binding protein in serum.

Summary of Events in the Antral Follicle

1. Follicular phase estrogen production is explained by the two-cell, two-gonadotropin mechanism.
2. Selection of the dominant follicle is established during days 5–7, and consequently, peripheral levels of estradiol begin to rise significantly by cycle day 7.
3. Estradiol levels, derived from the dominant follicle, increase steadily and, through negative feedback effects, exert a progressively greater suppressive influence on FSH release.
4. While directing a decline in FSH levels, the midfollicular rise in estradiol exerts a positive feedback influence on LH secretion.
5. The positive action of estrogen also includes modification of the gonadotropin molecule, increasing the quality (the bioactivity) as well as the quantity of FSH and LH at midcycle.
6. LH levels rise steadily during the late follicular phase, stimulating androgen production in the theca.
7. A unique responsiveness to FSH allows the dominant follicle to utilize the androgen as substrate and further accelerate estrogen production.
8. FSH induces the appearance of LH receptors on granulosa cells.
9. Follicular response to the gonadotropins is modulated by a variety of growth factors and autocrine/paracrine peptides.
10. Inhibin B, secreted by the granulosa cells in response to FSH, directly suppresses pituitary FSH secretion.
11. Activin, originating in both pituitary and granulosa, augments FSH secretion and action.

Follicular Growth and Development in the Primate Ovary

Concern that the story for ovarian follicular growth and development might be different in the primate originated with the failure to find estrogen receptors in any of the significant ovarian compartments in the monkey: follicles, stromal tissue, interstitial tissue, or corpora lutea.¹⁴⁰ The importance of this finding in the monkey has been challenged by the discovery that human granulosa cells contain only mRNA for estrogen receptor-beta.¹⁴¹ However, in further monkey experiments, no reduction in total number or size of follicles resulted when estradiol production was effectively suppressed by treatment with an inhibitor of the aromatase enzyme system or with an inhibitor of

3 β -hydroxysteroid dehydrogenase.^{142, 143} Oocyte development was not altered, although the subsequent fertilization rate was reduced by this treatment. Another argument against a major role for estrogen in follicular growth and development is the successful stimulation with gonadotropins of normal follicular growth and development in women with 17 α -hydroxylase deficiency (an inherited disorder that prevents the production of androgens and estrogens).^{144, 145}

A reduced role for estrogen is further supported by the response of women with a deficiency in gonadotropins to treatment with recombinant (pure) FSH.^{45, 46 and 47} Some aromatization occurred, perhaps using androgens originating in the adrenal glands, producing early follicular phase estradiol levels, but the usual robust steroidogenesis was impossible without the presence of LH to provide thecal production of androgen substrate. Nevertheless, oocytes were retrieved, and with in vitro fertilization, pregnancy was achieved. This same response was observed in experiments that used a GnRH antagonist to produce LH-deficient monkeys and then the administration of recombinant, pure human FSH.^{46, 47}

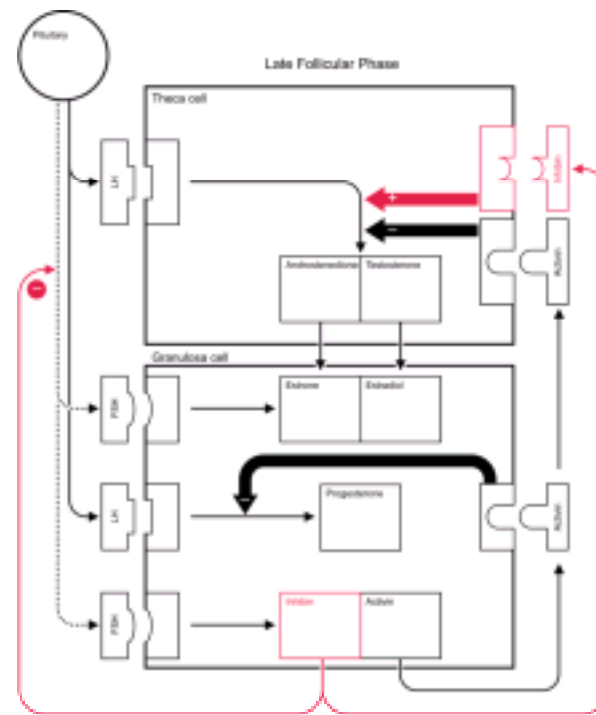

These results indicate that only FSH is required for folliculogenesis, and that in the primate, autocrine/paracrine peptides have replaced estrogen in the important role of modulating gonadotropin response. Consider the following actions that have been documented in primate ovaries:

1. Inhibin and activin regulate androgen synthesis in human theca cells. Inhibin enhances and activin suppresses the stimulatory action of LH and/or IGF-I, and inhibin can overcome the inhibitory action of activin on theca cells.^{92, 93 and 94}
2. In immature granulosa cells, activin augments all FSH activities, especially aromatase activity (estrogen production).^{78, 146}
3. In luteinizing granulosa cells, activin has direct mitogenic activity and suppresses steroidogenesis in response to LH, while inhibin has no effect on LH-dependent aromatase in mature granulosa cells.^{146, 147}
4. In the follicular phase, granulosa production of inhibin is under the control of FSH, but during the late follicular phase a change occurs, culminating in LH control of luteal synthesis of inhibin.^{148, 149}
5. As the follicle grows, activin production decreases and inhibin production increases.^{150, 151} In addition, follistatin levels increase in follicular fluid with increasing growth of the follicle, a mechanism for decreasing activin activity.¹⁵²

These actions may come together as follows. In the early follicular phase, activin produced by granulosa in immature follicles enhances the action of FSH on aromatase activity and FSH and LH receptor formation, while simultaneously suppressing thecal androgen synthesis. In the late follicular phase, increased production of inhibin by the granulosa (and decreased activin) promotes androgen synthesis in the theca in response to LH and IGF-II to provide substrate for even greater estrogen production in the granulosa. In the mature granulosa of the dominant preovulatory follicle, activin serves to prevent premature luteinization and progesterone production.

The successful follicle is the one that acquires the highest level of aromatase activity and LH receptors in response to FSH. The successful follicle is characterized by the highest estrogen (for central feedback action) and the greatest inhibin production (for both local and central actions).

This accomplishment occurs in synchrony with the appropriate activin expression. The highest level of gene activity encoding activin B is found in immature antral follicles and the lowest level in preovulatory follicles. Thus the activin proteins (which enhance FSH activity) are produced in greatest amounts early in follicular development to enhance follicle receptivity to FSH. It is not certain which form of inhibin plays a key role, but as with circulating levels of inhibin, inhibin B is the predominant inhibin in the follicular fluid of growing follicles.¹⁵³

The right concentration of androgens in granulosa cells promotes aromatase activity and inhibin production and, in turn, inhibin promotes LH stimulation of thecal androgen synthesis. With development of the follicle, inhibin expression comes under control of LH. A key to successful ovulation and luteal function is conversion of the inhibin production to LH responsiveness to maintain FSH suppression centrally and enhancement of LH action locally.

A lesser role is assigned to the insulin-like growth factors in view of the successful production of multiple, estrogen-producing follicles which yielded fertilizable oocytes in a woman with IGF-I deficiency treated with gonadotropins.¹²⁵ The growth factors assume an important, but perhaps not essential, role as facilitating agents. However, the successful pregnancy in a woman with IGF-I deficiency may indicate the greater importance of IGF-II. In addition, the IGFs in the ovary may not be growth hormone-dependent, and therefore IGF-I and/or IGF-II may also be important in primate ovarian follicles.

Summary of Events in the Primate Ovarian Follicle

1. FSH stimulates inhibin and activin production by granulosa cells.
2. Activin augments FSH activities: FSH receptor expression, aromatization, inhibin/activin production, and LH receptor expression.
3. Inhibin enhances LH stimulation of androgen synthesis in the theca to provide substrate for aromatization to estrogen in the granulosa.
4. Inhibin B is secreted by the granulosa cells into the circulation, where it acts in a classic endocrine fashion to suppress FSH secretion by the pituitary gland.
5. With the appearance of LH receptors, inhibin production is maintained as it comes under control of LH.
6. All functions are modulated by a host of growth factors, and IGF-II may be especially important.

The Preovulatory Follicle

Granulosa cells in the preovulatory follicle enlarge and acquire lipid inclusions while the theca becomes vacuolated and richly vascular, giving the preovulatory follicle a hyperemic appearance. The oocyte proceeds in meiosis, approaching completion of its reduction division.

Approaching maturity, the preovulatory follicle produces increasing amounts of estrogen. During the late follicular phase, estrogens rise slowly at first, then rapidly, reaching a peak approximately 24–36 hours prior to ovulation.¹⁵⁴ The onset of the LH surge occurs when the peak levels of estradiol are achieved.¹⁵⁵ In providing the ovulatory stimulus to the selected follicle, the LH surge seals the fate of the remaining follicles, with their lower estrogen and FSH content, by further increasing androgen superiority.

Acting through its own receptors, LH promotes luteinization of the granulosa in the dominant follicle, resulting in the production of progesterone. The LH receptor, once expressed, inhibits further cell growth and focuses the cell's energy on steroidogenesis (actions enhanced by IGF).¹⁵⁶ An increase in progesterone can be detected in the venous effluent of the ovary bearing the preovulatory follicle as early as day 10 of the cycle.⁵¹ This small but significant increase in the production of progesterone in the preovulatory period has immense physiologic importance. Prior to the emergence of this follicular progesterone, the circulating level of progesterone was derived from the adrenal gland.¹⁵⁷

Progesterone receptors begin to appear in the granulosa cells of the dominant follicle in the periovulatory period.¹⁴⁰ The traditional view has been that progesterone receptors are expressed in response to estrogen through an estrogen-receptor mediated mechanism. This is not the case with the primate ovarian follicle. Experimental data in the monkey provide excellent evidence that LH stimulates progesterone receptor expression in granulosa cells.¹⁵⁸ In vitro data with human cells suggest that the preovulatory progesterone and progesterone receptor expression directly inhibit granulosa cell mitosis, probably explaining the limitation of granulosa cell proliferation as these cells gain LH receptors.¹⁵⁹

Progesterone affects the positive feedback response to estrogen in both a time and dose dependent manner. When introduced after adequate estrogen priming, progesterone facilitates the positive feedback response, in a direct action on the pituitary, and in the presence of subthreshold levels of estradiol can induce a characteristic LH surge.^{160, 161} Hence, the surprising onset of ovulation occasionally observed in an anovulatory, amenorrheic woman administered a progestin challenge. When administered before the estrogen stimulus, or in high doses (achieving a blood level greater than 2 ng/mL), progesterone blocks the midcycle LH

surge. Appropriately low levels of progesterone derived from the maturing follicle contribute to the precise synchronization of the midcycle surge.

In addition to its facilitatory action on LH, progesterone at midcycle is significantly responsible for the FSH surge.¹⁶¹ This action of progesterone can be viewed as a further step in ensuring completion of FSH action on the follicle, especially making sure that a full complement of LH receptors is in place in the granulosa layer. In certain experimental situations, incremental estradiol alone can elicit simultaneous surges of LH and FSH, suggesting that progesterone certainly enhances the effect of estradiol but may not be obligatory.¹⁶² Nevertheless, blockade of midcycle progesterone synthesis or activity in the monkey impaired the ovulatory process and luteinization.¹⁶³ These actions of estrogen and progesterone require the presence and continuous action of GnRH.

The preovulatory period is associated with a rise in plasma levels of 17 α -hydroxyprogesterone. This steroid does not appear to have a role in cycle regulation, and its appearance in the blood simply represents the secretion of an intermediate product. As such, however, it signals the LH stimulation of P450_{scc} and P450_{c17}, important enzyme activity for the production of theca androgens, the substrate for granulosa estrogen. After ovulation, some theca cells become luteinized as part of the corpus luteum and lose the ability to express P450_{c17}. Other luteinized theca cells retain P450_{c17} activity and are believed to continue to produce androgens for aromatization to estrogens.

When the lesser follicles fail to achieve full maturity and undergo atresia, the theca cells return to their origin as a component of stromal tissue, retaining, however, an ability to respond to LH with P450 activity and steroid production. Because the products of thecal tissue are androgens, the increase in stromal tissue in the late follicular phase is associated with a rise in androgen levels in the peripheral plasma at midcycle. There is a 15% increase in androstenedione and a 20% increase in testosterone.¹⁶⁴ This response is enhanced by the rise in inhibin, known to augment LH stimulation of androgen production in thecal cells.

Androgen production at this stage in the cycle may serve two purposes: 1) a local role within the ovary to enhance the process of atresia, and 2) a systemic effect to stimulate libido.

Intraovarian androgens accelerate granulosa cell death and follicular atresia. The specific mechanism for this action is unclear, although it is attractive to suspect an interference with estrogen and the autocrine/paracrine factors in enhancing FSH activity. Therefore, androgens may play a regulatory role in ensuring that only a dominant follicle reaches the point of ovulation.

It is well known that libido can be stimulated by androgens. If the midcycle rise in androgens affects libido, then an increase in sexual activity should coincide with this rise. Early studies failed to demonstrate a consistent pattern in coital frequency in women because of the effect of male partner initiation. If only sexual behavior initiated by women is studied, a peak in female-initiated sexual activity is seen during the ovulatory phase of the cycle.¹⁶⁵ The coital frequency of married couples has also been noted to increase at the time of ovulation.¹⁶⁶ Therefore, the midcycle rise in androgens may serve to increase sexual activity at the time most likely to achieve pregnancy.

Summary of Events in the Preovulatory Follicle

1. Estrogen production becomes sufficient to achieve and maintain peripheral threshold concentrations of estradiol that are required in order to induce the LH surge.
2. Acting through its receptors, LH initiates luteinization and progesterone production in the granulosa layer.
3. The preovulatory rise in progesterone facilitates the positive feedback action of estrogen and may be required to induce the midcycle FSH peak.
4. A midcycle increase in local and peripheral androgens occurs, derived from the thecal tissue of lesser, unsuccessful follicles.

Ovulation

The preovulatory follicle, through the elaboration of estradiol, provides its own ovulatory stimulus. Considerable variation in timing exists from cycle to cycle, even in the same woman. A reasonable and accurate estimate places ovulation approximately 10–12 hours after the LH peak and 24–36 hours after peak estradiol levels are attained.^{154, 167} The onset of the LH surge appears to be the most reliable indicator of impending ovulation, occurring 34–36 hours prior to follicle rupture.¹⁶⁸ A threshold of LH concentration must be maintained for 14–27 hours in order for full maturation of the oocyte to occur.¹⁶⁹ Usually the LH surge lasts 48–50 hours.¹⁶⁸

Because of the careful timing involved in in vitro fertilization programs, we have available some interesting data.¹⁷⁰ The LH surge tends to occur at approximately 3 A.M., beginning between midnight and 8:00 A.M. in over two-thirds of women.⁶⁴ Ovulation occurs primarily in the morning during Spring, and primarily in the evening during Autumn and Winter. From July to February in the Northern Hemisphere, about 90% of women ovulate between 4 and 7 P.M.; during Spring, 50% of women ovulate between midnight and 11 A.M.

The gonadotropin surge stimulates a large collection of events that ultimately leads to ovulation, the physical release of the oocyte and its cumulus mass of granulosa cells.¹⁷¹ This is not an explosive event; therefore, a complex series of changes must occur which cause the final maturation of the oocyte and the decomposition of the collagenous layer of the follicular wall.¹⁷²

The LH surge initiates the continuation of meiosis in the oocyte (meiosis is not completed until after the sperm has entered and the second polar body is released), luteinization of granulosa cells, expansion of the cumulus, and the synthesis of prostaglandins and other eicosanoids essential for follicle rupture. Premature oocyte maturation and luteinization are prevented by local factors. LH-induced cyclic AMP activity overcomes the local inhibitory action of oocyte maturation inhibitor (OMI) and luteinization inhibitor (LI). LI may be endothelin-1, a product of vascular endothelial cells.¹³⁹ OMI originates from the granulosa cells, and its activity depends upon an intact cumulus oophorus. Activin also suppresses progesterone production by luteal cells, providing yet another means of preventing premature luteinization.^{173, 174}

There is abundant evidence that the oocyte exerts control over granulosa functions.³¹ The cumulus oophorus differs from other granulosa cells, lacking in LH receptors and progesterone production; FSH-induced LH receptor expression is suppressed in the contiguous granulosa cells by the oocyte. The oocyte enables cumulus cells to respond to the gonadotropin-induced physical and biochemical changes just before ovulation. The local factors that prevent premature oocyte maturation and luteinization are probably under control of the oocyte.

With the LH surge, levels of progesterone in the follicle continue to rise up to the time of ovulation. The progressive rise in progesterone may act to terminate the LH surge as a negative feedback effect is exerted at higher concentrations. In addition to its central effects, progesterone increases the distensibility of the follicle wall. A

change in the elastic properties of the follicular wall is necessary to explain the rapid increase in follicular fluid volume, which occurs just prior to ovulation, unaccompanied by any significant change in intrafollicular pressure. The escape of the ovum is associated with degenerative changes of the collagen in the follicular wall so that just prior to ovulation the follicular wall becomes thin and stretched. FSH, LH, and progesterone stimulate the activity of proteolytic enzymes, resulting in digestion of collagen in the follicular wall and increasing its distensibility. The gonadotropin surge also releases histamine, and histamine alone can induce ovulation in some experimental models.

The proteolytic enzymes are activated in an orderly sequence.¹⁷⁵ The granulosa and theca cells produce plasminogen activator in response to the gonadotropin surge. Plasminogen is activated by either of two plasminogen activators: tissue-type plasminogen activator and urokinase-type plasminogen activator. These activators are encoded by separate genes and are also regulated by inhibitors.

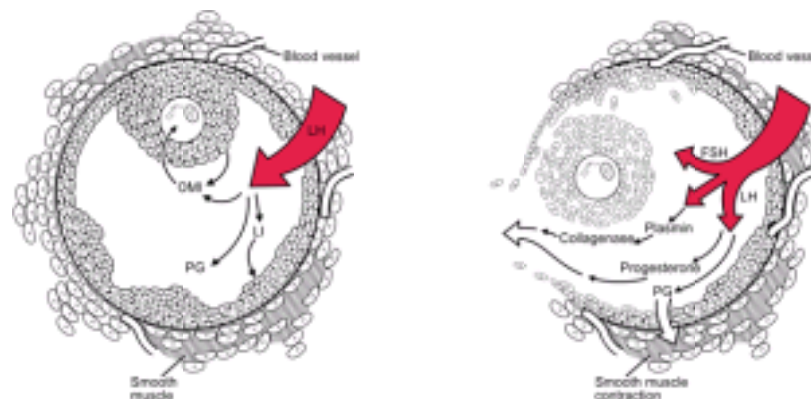

Plasminogen activators produced by granulosa cells activate plasminogen in the follicular fluid to produce plasmin. Plasmin, in turn, generates active collagenase to disrupt the follicular wall. In rat models, plasminogen activator synthesis is triggered by LH stimulation (as well as growth factors and FSH), while plasminogen inhibitor synthesis is decreased.¹⁷⁶ Thus, before and after ovulation, the inhibitor activity is high, while just at ovulation, activator activity is high and the inhibitors are at a nadir. The molecular regulation of these factors is necessary for the coordination that leads to ovulation. Plasminogen activator synthesis in granulosa cells is expressed only at the right preovulatory stage in response to LH. The inhibitor system, which is very active in the thecal and interstitial cells, prevents inappropriate activation of plasminogen and disruption of growing follicles. The inhibitor system has been demonstrated to be present in human granulosa cells and preovulatory follicular fluid and to be responsive to paracrine substances, epidermal growth factor and interleukin-1b.^{177, 178 and 179} Movement of the follicle destined to ovulate to the surface of the ovary is important in that the exposed surface of the follicle is now prone to rupture because it is separated from cells rich in the plasminogen inhibitor system. Ovulation is the result of proteolytic digestion of the follicular apex, a site called the stigma.

In the rat, the gene that encodes for plasminogen activator contains a promoter region which has several sequences for known transcription factors, such as the cyclic AMP-responsive element (CRE). The activation of this CRE (which involves the CRE binding protein) requires FSH stimulation. Thus, both gonadotropins appear to be involved in this process.

Prostaglandins of the E and F series and other eicosanoids (especially HETEs, hydroxyeicosatetraenoic acid methyl esters) increase markedly in the preovulatory follicular fluid, reaching a peak concentration at ovulation.^{180, 181} Prostaglandin synthesis is stimulated by interleukin-1b, implicating this cytokine in ovulation.¹⁸² Inhibition of the synthesis of these products from arachidonic acid blocks follicle rupture without affecting the other LH-induced processes of luteinization and oocyte maturation.^{183, 184} Prostaglandins may act to free proteolytic enzymes within the follicular wall, and the HETEs may promote angiogenesis and hyperemia (an inflammatory-like response).^{181, 185} Prostaglandins may also contract smooth muscle cells that have been identified in the ovary, thereby aiding the extrusion of the oocyte-cumulus cell mass. ***This role of prostaglandins is so well demonstrated that infertility patients should be advised to avoid the use of drugs that inhibit prostaglandin synthesis.***^{186, 187}

A large number of leukocytes enter the follicle prior to ovulation. Neutrophils are a prominent feature in the theca compartment of both healthy and atretic antral follicles.¹⁸⁸ The accumulation of leukocytes is mediated by chemotactic mechanisms of the interleukin system.¹⁸⁹ These immune cells probably contribute to the cellular changes associated with ovulation, corpus luteum function, and apoptosis.

Estradiol levels plunge as LH reaches its peak. This may be a consequence of LH down-regulation of its own receptors on the follicle. Thecal tissue derived from healthy antral follicles exhibits marked suppression of steroidogenesis when exposed to high levels of LH whereas exposure over a low range stimulates steroid production. The low midcycle levels of progesterone exert an inhibitory action on further granulosa cell multiplication, and the drop in estrogen may also reflect this local follicular role for progesterone. Finally, estrogen can exert an inhibitory effect on P450c17, a direct action on the gene that is not receptor-mediated.

The granulosa cells that are attached to the basement membrane and enclose the follicle become luteal cells. The cumulus granulosa cells attach to the oocyte. In the mouse, the cumulus cells are metabolically linked to the oocyte and respond to the FSH surge by secreting hyaluronic acid that disperses the cumulus cells prior to ovulation. This hyaluronic acid response depends upon maintenance of the link with the oocyte, indicating the secretion of a supporting factor. The oocyte further secretes factors that promote granulosa cell proliferation and maintain the structural organization of the follicle.¹⁹⁰ Proliferation of the cumulus cells is suppressed by FSH, while FSH stimulates mural granulosa cell proliferation, supported by the oocyte factor or factors.

The FSH peak, partially and perhaps totally dependent on the preovulatory rise of progesterone, has several functions. Plasminogen activator production is sensitive to FSH as well as LH. Expansion and dispersion of the cumulus cells allows the oocyte-cumulus cell mass to become free-floating in the antral fluid just before follicle rupture. The process involves the deposition of a hyaluronic acid matrix, the synthesis of which is stimulated by FSH. Finally, an adequate FSH peak ensures an adequate complement of LH receptors on the granulosa layer. It should be noted that a shortened or inadequate luteal phase is observed in cycles when FSH levels are low or selectively suppressed at any point during the follicular phase.

The mechanism that shuts off the LH surge is unknown. Within hours after the rise in LH, there is a precipitous drop in the plasma estrogens. The decrease in LH may be due to a loss of the positive stimulating action of estradiol or to an increasing negative feedback of progesterone. The abrupt fall in LH levels may also reflect a depletion in pituitary LH content due to down-regulation of GnRH receptors, either by alterations in GnRH pulse frequency or by changes in steroid levels.^{191, 192} LH may further be controlled by "short" negative feedback of LH upon the hypothalamus. Direct LH suppression of hypothalamic-releasing hormone production has been demonstrated. However, in the sheep, the LH surge ends before the GnRH signal begins to decline.¹⁹³ Another possibility has been suggested, a so-called gonadotropin surge-inhibiting factor (GnSIF) originating in the ovary.^{194, 195} GnSIF is produced in granulosa cells under the control of FSH and reaches a peak level in the circulation in the midfollicular phase. Its major role is believed to be prevention of premature luteinization. It is likely that a combination of all of these influences cause the rapid decline in gonadotropin secretion.

The many contributions of progesterone to ovulation are highlighted by the results of experiments in the monkey. Suppression of steroidogenesis at midcycle prevented ovulation, but not resumption of oocyte meiosis.¹⁶³ The administration of a progestin agonist to this experimental model restored ovulation.

An adequate gonadotropin surge does not ensure ovulation. The follicle must be at the appropriate stage of maturity in order for it to respond to the ovulating stimulus. In the normal cycle, gonadotropin release and final maturation of the follicle coincide because the timing of the gonadotropin surge is controlled by the level of estradiol, which in turn is a function of follicular growth and maturation. Therefore, gonadotropin release and morphological maturity are usually coordinated and coupled in time. In the majority of human cycles, the requisite feedback relationships in this system allow only one follicle to reach the point of ovulation. Nonidentical multiple births may, in part, reflect the random statistical chance of more than one follicle fulfilling all the requirements for ovulation.

Summary of the Ovulatory Events

1. The LH surge stimulates continuation of reduction division in the oocyte, luteinization of the granulosa, and synthesis of progesterone and prostaglandins within the follicle.
2. Progesterone enhances the activity of proteolytic enzymes responsible, together with prostaglandins, for digestion and rupture of the follicular wall.
3. The progesterone-influenced midcycle rise in FSH serves to free the oocyte from follicular attachments, to convert plasminogen to the proteolytic enzyme,

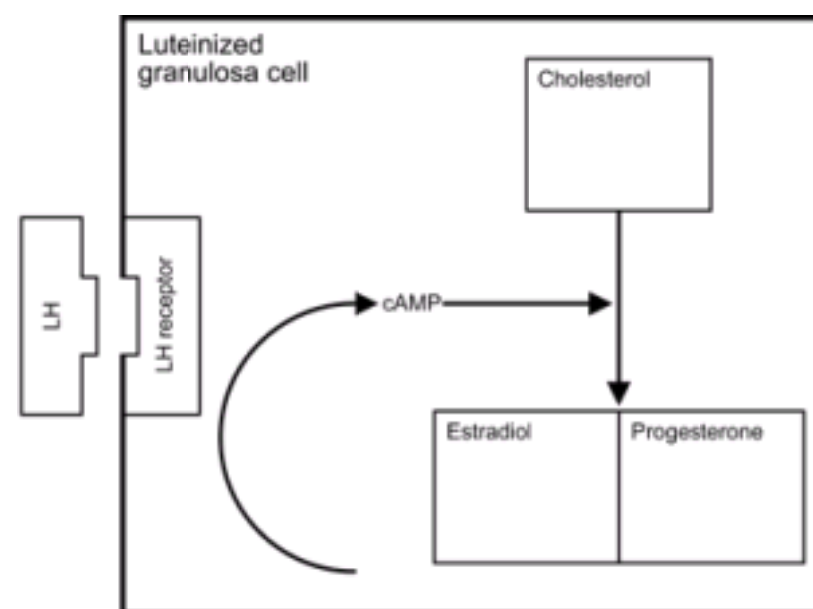

plasmin, and to ensure that sufficient LH receptors are present to allow an adequate normal luteal phase.

Luteal Phase

Before rupture of the follicle and release of the ovum, the granulosa cells begin to increase in size and assume a characteristic vacuolated appearance associated with the accumulation of a yellow pigment, lutein, which lends its name to the process of luteinization and the anatomical subunit, the corpus luteum. During the first 3 days after ovulation, the granulosa cells continue to enlarge. In addition, theca lutein cells may differentiate from the surrounding theca and stroma to become part of the corpus luteum. Dissolution of the basal lamina and rapid vascularization and luteinization make it difficult to distinguish the origin of specific cells.

Capillaries begin to penetrate into the granulosa layer after the cessation of the LH surge, reach the central cavity, and often fill it with blood. ¹⁹⁶ Angiogenesis is an important feature of the luteinization process, a response to LH mediated by growth factors produced in luteinized granulosa cells, such as vascular endothelial growth factor (VEGF).^{129, 130} By day 8 or 9 after ovulation, a peak of vascularization is reached, associated with peak levels of progesterone and estradiol in the blood. The corpus luteum has one of the highest blood flows per unit mass in the body. On occasion, this ingrowth of vessels and bleeding will result in unchecked hemorrhage and an acute surgical emergency that can present at any time during the luteal phase. Indeed, this is a significant clinical risk in women who are anticoagulated; such women should receive medication to prevent ovulation.

Normal luteal function requires optimal preovulatory follicular development. Suppression of FSH during the follicular phase is associated with lower preovulatory estradiol levels, depressed midluteal progesterone production, and a decrease in luteal cell mass. ¹⁹⁷ Experimental evidence supports the contention that the accumulation of LH receptors during the follicular phase predetermines the extent of luteinization and the subsequent functional capacity of the corpus luteum. The successful conversion of the avascular granulosa of the follicular phase to the vascularized luteal tissue is also of importance. Because steroid production is dependent upon low-density lipoprotein (LDL) transport of cholesterol, the vascularization of the granulosa layer is essential to allow LDL-cholesterol to reach the luteal cells to provide sufficient substrate for progesterone production. One of the important jobs for LH is to regulate LDL receptor binding, internalization, and postreceptor processing; the induction of LDL receptor expression occurs in granulosa cells during the early stages of luteinization in response to the midcycle LH surge.^{198, 199} This mechanism supplies cholesterol to the mitochondria for utilization as the basic building block in steroidogenesis.

The lifespan and steroidogenic capacity of the corpus luteum are dependent on continued tonic LH secretion. Studies in hypophysectomized women have demonstrated that normal corpus luteum function requires the continuous presence of small amounts of LH. ²⁰⁰ The dependence of the corpus luteum on LH is further supported by the prompt luteolysis that follows the administration of GnRH agonists or antagonists or withdrawal of GnRH when ovulation has been induced by the administration of pulsatile GnRH.^{201, 202} There is no evidence that other luteotropic hormones, such as prolactin, play a role in primates during the menstrual cycle. ²⁰³

The corpus luteum is not homogeneous. Besides the luteal cells, also present are endothelial cells, leukocytes, and fibroblasts. The nonsteroidogenic cells form the bulk (70–85%) of the total cell population. The leukocyte immune cells produce several cytokines, including interleukin-1b and tumor necrosis factor- α . ²⁰⁴ The many different leukocytes in the corpus luteum are also a rich resource for cytolytic enzymes, prostaglandins, and growth factors involved in angiogenesis, steroidogenesis, and luteolysis.

The corpus luteum is one of the best examples of communication and cross talk in biology. For example, endothelial cells contribute vasoactive compounds, and, in turn, steroidogenic cells contribute factors that influence angiogenesis. The harmonious function of this system is in inverse proportion to its complexity.

Endothelial cells constitute about 50% of the cells in a mature corpus luteum. ²⁰⁵ As elsewhere in the body, endothelial cells participate in immune reactions and endocrine functions. The endothelial cells are a source of endothelin-1, expressed in response to changes in blood flow, blood pressure, and oxygen tension. Studies have now indicated that endothelin-1 may be a mediator of luteolysis.^{206, 207}

Even the luteal cell population is not homogeneous, being composed of at least two distinct cell types, large and small cells. ²⁰⁸ Some believe that the large cells are derived from granulosa cells and the small cells from thecal cells. The small cells are the most abundant. Despite the fact that greater steroidogenesis takes place in the large cells, it is the small cells that contain LH and HCG receptors.^{209, 210} The absence of LH/HCG receptors on the large cells, presumably derived from granulosa cells that acquire LH receptors in the late follicular phase, requires explanation. Perhaps large cells are functioning at a maximal level with receptors totally occupied and functional, or because of intercellular communication through gap junctions, the large cells do not require direct gonadotropin support. Thus, the large cells can be functioning at a high level, under the control of regulating factors that originate in the small cells in response to gonadotropins. In addition, the overall function is influenced by autocrine/paracrine signals from endothelial and immune cells.

Large luteal cells produce peptides (oxytocin, relaxin, inhibin, and other growth factors) and are more active in steroidogenesis, with greater aromatase activity and more progesterone synthesis than small cells. ²¹¹ Human granulosa cells (already luteinizing when recovered from in vitro fertilization patients) contain minimal amounts of P450c17 mRNA. This is consistent with the two-cell explanation, which assigns androgen production (and P450c17) to the cells derived from thecal cells. With luteinization, expression of P450scc and 3 β -hydroxysteroid dehydrogenase markedly increases as expected, to account for the increasing production of progesterone, and the continued expression of mRNAs for these enzymes requires LH. ²¹² The aromatase system (P450arom), of course, continues to be active in luteinized granulosa cells.

Progesterone levels normally rise sharply after ovulation, reaching a peak approximately 8 days after the LH surge. Progesterone acts both locally and centrally to suppress new follicular growth. If progesterone concentrations are monitored in ovarian venous effluents following luteectomy in the monkey, ovulation in the subsequent cycle uniformly occurs on the side opposite the higher progesterone level and contralateral to the previous corpus luteum. ²¹³ If circulating progesterone levels are maintained after luteectomy, the subsequent ovulation again occurs in the ovary having a lower progesterone concentration in its venous effluent. ²¹⁴ Under normal circumstances (i.e., regular, 28-day cycles), a woman may ovulate from alternate sides.^{51, 215} However, short-term ultrasonographic studies have failed to substantiate this pattern.

Initiation of new follicular growth during the luteal phase is further inhibited by the low levels of gonadotropins due to the negative feedback actions of estrogen, progesterone, and inhibin A. With the appearance of LH receptors on the granulosa cells of the dominant follicle and the subsequent development of the follicle into a corpus luteum, inhibin expression comes under the control of LH, and expression changes from inhibin B to inhibin A. ^{87, 209, 216} The circulating levels of inhibin A rise in the late follicular phase to reach a peak level at the midluteal phase. ^{16, 88} Inhibin A, therefore, contributes to the suppression of FSH to nadir levels during the luteal phase, and to the changes at the luteal-follicular transition.

The secretion of progesterone and estradiol during the luteal phase is episodic, and the changes correlate closely with LH pulses. ^{65, 217} Because of this episodic secretion, relatively low midluteal progesterone levels, which some believe are indicative of an inadequate luteal phase, can be found in the course of totally normal

luteal phases.

In the normal cycle the time period from the LH midcycle surge to menses is consistently close to 14 days. For practical purposes, luteal phases lasting between 11 and 17 days can be considered normal.²¹⁸ The incidence of short luteal phases is about 5–6%. It is well known that significant variability in cycle length among women is due to the varying number of days required for follicular growth and maturation in the follicular phase. The luteal phase cannot be extended indefinitely even with progressively increasing LH exposure, indicating that the demise of the corpus luteum is due to an active luteolytic mechanism.

The corpus luteum rapidly declines 9–11 days after ovulation, and the mechanism of the degeneration remains unknown. In certain nonprimate mammalian species, a luteolytic factor originating in the uterus (prostaglandin F_{2a}) regulates the lifespan of the corpus luteum. No definite luteolytic factor has been identified in the primate menstrual cycle, and removal of the uterus in the primate does not affect the ovarian cycle; however, the morphological regression of luteal cells may be induced by the estradiol produced by the corpus luteum. There is evidence to support a role for estrogen in the decline of the corpus luteum.²¹⁹ The premature elevation of circulating estradiol levels in the early luteal phase results in a prompt fall in progesterone concentrations. Direct injections of estradiol into the ovary bearing the corpus luteum induce luteolysis while similar treatment of the contralateral ovary produces no effect.²²⁰

There is another possible role for the estrogen produced by the corpus luteum. In view of the known estrogen requirement for the synthesis of progesterone receptors in endometrium, luteal phase estrogen may be necessary to allow the progesterone-induced changes in the endometrium after ovulation. Inadequate progesterone receptor content due to inadequate estrogen priming of the endometrium is an additional possible mechanism for infertility or early miscarriage, another form of luteal phase deficiency.

Auletta postulated that prostaglandin F_{2a} produced within the ovary bearing the corpus luteum or within the corpus luteum serves as the luteolytic agent, and the production of the prostaglandin is initiated by the luteal estrogen.²²⁰ Experiments using inhibitors of prostaglandin synthesis have not been helpful because luteal tissue also produces members of the prostaglandin family that have stimulating effects (such as PGE and prostacyclin).²²¹

Experimental evidence indicates that the luteolytic effect of prostaglandin F_{2a} is mediated by endothelin-1.^{206, 207} Prostaglandin F_{2a} stimulates the synthesis of endothelin, and endothelin-1 inhibits luteal steroidogenesis. In addition, endothelin-1 stimulates the release of tumor necrosis factor- α , a growth factor known to induce apoptosis.²²²

A newly appreciated characteristic of the corpus luteum has emerged, the importance of cellular interactions that require cell-to-cell contact. Gap junctions are a prominent feature of luteal cells, just as they are in the follicle before ovulation. When the various cell types of the corpus luteum are studied together, the performance is different compared with studies of single cell types, greater steroidogenesis more closely approximating the total function of the corpus luteum.²²³ It is believed that communication and exchange of signals takes place through the gap junction structures, explaining how the small cells respond to LH and HCG, but the large cells are the main site of steroidogenesis. Regulation of the gap junction system is influenced by oxytocin, a paracrine role for oxytocin in the corpus luteum.²²⁴

When ovulation is induced by the administration of GnRH, normal luteal phase demise occurs despite no change in treatment, arguing against a change in LH as the luteolytic mechanism. In addition, LH receptor binding affinity does not change throughout the luteal phase; thus the decline in steroidogenesis must reflect deactivation of the system (producing a refractoriness of the corpus luteum to LH), perhaps through the uncoupling of the G protein adenylate cyclase system. This is supported by studies in the monkey in which alteration in LH pulse frequency or amplitude did not provoke luteolysis.²²⁵

The process of luteolysis involves proteolytic enzymes, especially the matrix metalloproteinases (MMPs). These enzymes are held under inhibitory control by tissue inhibitors of metalloproteinases (TIMPs) secreted by the steroidogenic luteal cells, and because TIMP levels do not change in luteal tissue, luteolysis is believed to involve a direct increase in MMP expression. An important part of the rescue mission for human chorionic gonadotropin (HCG) is to prevent this increase in MMP expression.²²⁶ Others have indicated that HCG can increase TIMP production, and this, too, would inhibit MMP activity and luteolysis.²²⁷ In addition, the human ovary contains the complete interleukin-1 system, providing another resource for cytolytic enzymes.

The survival of the corpus luteum is prolonged by the emergence of a new stimulus of rapidly increasing intensity, HCG. This new stimulus first appears at the peak of corpus luteum development (9–13 days after ovulation), just in time to prevent luteal regression.²²⁸ HCG serves to maintain the vital steroidogenesis of the corpus luteum until approximately the 9th or 10th week of gestation, by which time placental steroidogenesis is well established. In some pregnancies placental steroidogenesis will be sufficiently established by the 7th week of gestation.

Unlike the biphasic pattern demonstrated by the circulating level of progesterone (a decrease after ovulation and then a new higher peak at the midluteal phase), the mRNA levels for the two major enzymes involved in progesterone synthesis (cholesterol side-chain cleavage and 3 β -hydroxysteroid dehydrogenase) are maximal at

ovulation and decline throughout the luteal phase.²²⁹ This suggests that the lifespan of the corpus luteum is established at the time of ovulation, and luteal regression is inevitable unless the corpus luteum is rescued by the HCG of pregnancy. Therefore, primates have developed a system that requires rescue of the corpus luteum in contrast to lower animals that use a mechanism that actively causes the demise of the corpus luteum (luteolysis).

Summary of Events in the Luteal Phase

1. Normal luteal function requires optimal preovulatory follicular development (especially adequate FSH stimulation) and continued tonic LH support.
2. Progesterone acts both centrally and within the ovary to suppress new follicular growth.
3. Regression of the corpus luteum may involve the luteolytic action of its own estrogen production, mediated by an alteration in local prostaglandin and endothelin-1 concentrations.
4. In early pregnancy, HCG rescues the corpus luteum, maintaining luteal function until placental steroidogenesis is well established.

The Luteal-Follicular Transition

The interval extending from the late luteal decline of estradiol and progesterone production to the selection of the dominant follicle is a critical and decisive time, marked by the appearance of menses, but less apparent and very important are the hormone changes that initiate the next cycle. The critical factors include GnRH, FSH, LH, estradiol, progesterone, and inhibin.

Given the important role for FSH-mediated actions on the granulosa cells, it is appropriate that the recruitment of a new ovulating follicle is directed by a selective increase in FSH that begins approximately 2 days before the onset of menses.^{230, 231 and 232} Using a sensitive FSH bioassay, an increase in FSH bioactivity can be measured beginning as early as the midluteal phase.¹⁷ There are at least two influential changes that result in this important increase in FSH: a decrease in luteal steroids and inhibin and a change in GnRH pulsatile secretion.

Inhibin B, originating in the granulosa cells of the corpus luteum and now under the regulation of LH, reaches a nadir in the circulation at the midluteal period. Inhibin A reaches a peak in the luteal phase, and, thus, may help to suppress FSH secretion by the pituitary to the lowest levels reached during a menstrual cycle.¹⁶ The process of luteolysis, whatever the mechanism, with the resulting demise of the corpus luteum, affects inhibin A secretion as well as steroidogenesis. The administration of inhibin A to monkeys effectively suppresses circulating FSH.²³³ Thus, an important suppressing influence on FSH secretion is removed from the anterior pituitary during the last days of the luteal phase. The selective action of inhibin on FSH (and not LH) is partly responsible for the greater rise in FSH seen during the luteal-follicular transition, compared to the change in LH. The administration of recombinant (pure) FSH to gonadotropin-deficient women has demonstrated that the early growth of follicles requires FSH, and that LH is not essential during this period of the cycle.^{43, 44}

Inhibin B levels begin to rise shortly after the increase in FSH (a consequence of FSH stimulation of granulosa cell secretion of inhibin) and reach peak levels about 4 days after the maximal increase in FSH.^{16, 82} Thus, suppression of FSH secretion during the follicular phase is an action exerted by Inhibin B, whereas escape of FSH inhibition during the luteal-follicular transition is partly a response to decreasing inhibin A secretion by the corpus luteum.

Circulating levels of activin increase in the late luteal phase to peak at menses; however, activin A is highly bound in the circulation, and it is not certain it has an endocrine role.¹⁰¹ Nevertheless, the timing is right for activin to contribute to the rise in FSH during the luteal-follicular transition. Activin enhances and follistatin suppresses GnRH activity. Evidence in vivo and in vitro indicates that gonadotropin response to GnRH requires activin activity.²³⁴

The selective rise in FSH is also significantly influenced by a change in GnRH pulsatile secretion, previously strongly suppressed by the high estradiol and progesterone levels of the luteal phase.⁶⁵ A progressive and rapid increase in GnRH pulses (as assessed by the measurement of LH pulses) occurs during the luteal-follicular transition.⁶⁸ From the midluteal peak to menses, there is a 4.5-fold increase in LH pulse frequency (and presumably GnRH) from approximately 3 pulses/24 hours to 14 pulses/24 hours.⁶⁸ During this time period, the mean level of LH increases approximately 2-fold, from approximately a mean of 4.8 IU/L to 8 IU/L. The increase in FSH is, as noted, greater than that of LH. FSH pulse frequency increases 3.5-fold from the midluteal period to the time of menses, and FSH levels increase from a mean of approximately 4 IU/L to 15 IU/L.

An increase in GnRH pulse frequency from a low level of secretion has been associated with an initial selective increase in FSH in several experimental models, including the ovariectomized monkey with destruction of the hypothalamus. Treatment of hypogonadal women with pulsatile GnRH results first in predominance of FSH secretion (over LH). This experimental response and the changes during the luteal-follicular transition are similar to that observed during puberty, a predominance of FSH secretion as GnRH pulsatile secretion begins to increase.

The pituitary response to GnRH is also a factor. Estradiol suppresses FSH secretion by virtue of its classic negative feedback relationship at the pituitary level. The decrease in estradiol in the late luteal phase restores the capability of the pituitary to respond with an increase in FSH secretion.²³⁵

Summary of Events in the Luteal-Follicular Transition

1. The demise of the corpus luteum results in a nadir in the circulating levels of estradiol, progesterone, and inhibin.
2. The decrease in inhibin A removes a suppressing influence on FSH secretion in the pituitary.
3. The decrease in estradiol and progesterone allows a progressive and rapid increase in the frequency of GnRH pulsatile secretion and a removal of the pituitary from negative feedback suppression.
4. The removal of inhibin A and estradiol and increasing GnRH pulses combine to allow greater secretion of FSH compared with LH, with an increase in the frequency of the episodic secretion.
5. The increase in FSH is instrumental in rescuing a approximately 60-day-old group of ready follicles from atresia, allowing a dominant follicle to begin its emergence.

The Normal Menstrual Cycle

Menstrual cycle length is determined by the rate and quality of follicular growth and development, and it is normal for the cycle to vary in individual women. Our best information comes from two longitudinal studies (with very similar results): the study of Vollman of more than 30,000 cycles recorded by 650 women and the study of Treloar of more than 25,000 woman-years in a little over 2700 women.^{236, 237} The observations of Vollman and Treloar documented a normal evolution in length and variation in menstrual cycles.

Menarche is followed by approximately 5–7 years of increasing regularity as cycles shorten to reach the usual reproductive age pattern. In the 40s, cycles begin to lengthen again. The highest incidence of anovulatory cycles is under age 20 and over age 40.^{236, 238} At age 25, over 40% of cycles are between 25 and 28 days in length; from 25 to 35, over 60% are between 25 and 28 days. The perfect 28-day cycle is indeed the most common mode, but it totaled only 12.4% of Vollman's cycles. Overall, approximately 15% of reproductive age cycles are 28 days in length. Only 0.5% of women experience a cycle less than 21 days long, and only 0.9% a cycle greater than 35 days.²³⁹ Most women have cycles that last from 24 to 35 days, but at least 20% of women experience irregular cycles.

The duration of the follicular phase is the major determinant of cycle length. Sherman and Korenman predicted in 1975 that a factor other than estrogen is the key — inhibin.²⁴⁰ Cycle lengths are the shortest (with the least variability) in the late 30s, a time when subtle but real increases in FSH and decreases in inhibin are occurring.^{86, 218, 241, 242, 243 and 244} This can be pictured as accelerated follicular growth (because of the changes in FSH and inhibin B). At the same time, fewer follicles grow per cycle as a woman ages.²⁴⁵ Approximately 2–4 years (6–8 years according to Trelolar) prior to menopause, the cycles lengthen again. In the last 10–15 years before menopause, there is an acceleration of follicular loss.³ This accelerated loss begins when the total number of follicles reaches approximately 25,000, a number reached in normal women at age 37–38.²⁴⁶ Eventually menopause occurs because the supply of follicles is depleted.²⁴⁷

The changes in the later reproductive years reflect either lesser follicular competence as the better primordial follicles respond early in life, leaving the lesser follicles for later, or the fact that the total follicular pool is reduced in number (or both factors). Arguing in favor of a role for a reduced follicular pool is the observation that follicular fluid obtained from preovulatory follicles of older women contains amounts of inhibin A and B that are similar to that measured in follicular fluid from young women.²⁴⁸

Among his many accomplishments, Galileo Galilei gave to science, in 1609, two important instruments, the telescope and the microscope. ¹ Antonj van Leeuwenhoek of Delft, Holland, was fascinated by Galileo's microscope. Leeuwenhoek was a draper and had no medical or scientific training, yet he became a Fellow of the Royal Society of London to which he submitted 375 scientific papers. In 1677, Leewenhoek described (fairly accurately) the "little animals of the sperm." It was another 198 years before Wilhelm August Oscar Hertwig, in Germany, demonstrated the union of sperm and egg, fertilization, in the sea urchin.

The coming together of sperm and egg is one of the essentials of reproduction; however, the remote site of this event and the enclosed origins of the participants made fertilization a difficult subject for study. This changed with the advent of in vitro fertilization. Greater understanding of sperm and egg development and union is one of the major benefits of the clinical application of the assisted reproductive technologies. This chapter examines the mechanisms involved in sperm and egg transport, fertilization, and implantation.

Sperm Transport

The evolution of scrotal mammals and the adoption of internal fertilization are associated with sperm maturation that occurs outside of the testes. This includes epididymal maturation and capacitation in the female before fertilization. The need for capacitation (the final step required to acquire the ability to fertilize) may be an evolutionary consequence of the development of a storage system for inactive sperm in the caudal epididymis. ²

The sperm reach the caudal epididymis approximately 72 days after the initiation of spermatogenesis. At this time, the head of the sperm contains a membrane-bound nucleus capped by the acrosome, a large vesicle of proteolytic enzymes. The inner acrosomal membrane is closely apposed to the nuclear membrane, and the outer acrosomal membrane is next to the surface plasma membrane. The flagellum is a complex structure of microtubules and fibers, surrounded at the proximal end by mitochondria. Motility and the ability to fertilize are acquired gradually as the sperm pass into the epididymis.

The caudal epididymis stores sperm available for ejaculation. The ability to store functional sperm provides a capacity for repetitive fertile ejaculations. Preservation of optimal sperm function during this period of storage requires adequate testosterone levels in the circulation and maintenance of the normal scrotal temperature. ³ The importance of temperature is emphasized by the correlation of reduced numbers of sperm associated with episodes of body fever. The epididymis is limited to a storage role because sperm that have never passed through the epididymis and that have been obtained from the vasa efferentia in men with a congenital absence of the vas deferens can fertilize the human oocyte in vitro and result in pregnancy with live birth. ⁴ Indeed, the injection of one sperm directly into an oocyte (intracytoplasmic sperm injection) with sperm obtained by testicular biopsy (in men with congenital absence of epididymides) is very successful in achieving fertilization and pregnancy. ⁵ However, the use of sperm from men with sperm abnormalities, and especially the use of immature germ cells for intracytoplasmic injection should be pursued with some caution. The outcome in subsequent generations must be assessed and appropriate genetic screening must be developed to avoid the transmission of subtle but important genetic alterations.

Semen forms a gel almost immediately following ejaculation but then is liquefied in 20–30 minutes by enzymes derived from the prostate gland. The alkaline pH of semen provides protection for the sperm from the acid environment of the vagina. This protection is transient, and most sperm left in the vagina are immobilized within 2 hours. The more fortunate sperm, by their own motility, gain entrance into the tongues of cervical mucus that layer over the ectocervix. These are the sperm that enter the uterus; the seminal plasma is left behind in the vagina. This entry is rapid, and sperm have been found in mucus within 90 seconds of ejaculation. ⁶ The destruction of all sperm in the vagina 5 minutes after ejaculation does not interfere with fertilization in the rabbit, further attesting to the rapidity of transport. ⁷

Contractions of the female reproductive tract occur during coitus, and these contractions may be important for entry of sperm into the cervical mucus and further transport. Presumably successful entry is the result of combined female and male forces (the flagellar activity of the sperm). The success of therapeutic insemination, however, indicates that coitus and female orgasm are not essential for sperm transport.

The sperm swim and migrate through pores in the mucus microstructure that are smaller than the sperm head; therefore, the sperm must actively push their way through the mucus.⁸ One cause of infertility, presumably, is impaired sperm movement that prevents this transport through the mucus. This movement is probably also influenced by the interaction between the mucus and the surface properties of the sperm head; for example, sperm antibodies on the sperm head inhibit sperm movement in the mucus.⁹ Abnormal morphology of the sperm head is often associated with impaired flagellar function; however, abnormal head morphology alone can be a cause of poor mucus penetration.^{10, 11} It is generally believed that the cervical mucus has a filtering action; abnormal and less “capable” sperm have difficulty getting through.¹²

Uterine contractions and sperm motility propel the sperm upward, and in the human, sperm can be found in the tube 5 minutes after insemination.¹³ It is possible that the first sperm to enter the tube are at a disadvantage. In the rabbit these early sperm have only poor motility, and there is frequent disruption of the head membranes.¹⁴ The sperm in this vanguard are unlikely to achieve fertilization. Other sperm that have colonized the cervical mucus and the cervical crypts then make their way more slowly to the ampulla of the tube in order to meet the egg. The number of sperm in the cervical mucus is relatively constant for 24 hours after coitus, and after 48 hours there are relatively few remaining in the mucus.¹⁵ Although the isthmus region of the tube functions as a sperm reservoir in many species, this does not appear to be the case in human fallopian tubes.¹⁶

Human sperm have been found in the fallopian tube as long as 80 hours after intercourse, and these sperm can still perform normally with zona-free hamster oocytes.¹⁷ In animals, the fertilizable lifespan is usually one-half the motile lifespan.

The **attrition in sperm numbers** from vagina to tube is substantial.¹⁸ Of an average of 200 to 300 million sperm deposited in the vagina, at most only a few hundred, and often less, achieve proximity to the egg.¹⁶ Greater numbers are observed in the tubal ampulla at the time of ovulation. The major loss occurs in the vagina, with expulsion of semen from the introitus playing an important role. Other causes for loss are digestion of sperm by vaginal enzymes and phagocytosis of sperm along the reproductive tract. There are also reports of sperm burrowing into or being engulfed by endometrial cells. Sperm are not stored in the fallopian tube, and indeed, many sperm continue past the oocyte to be lost into the peritoneal cavity. However, the cervix does serve as a reservoir providing a supply of sperm for up to 72 hours.

Within the fallopian tube ampulla, sperm display a new pattern of movement that has been called **hyperactivated motility**.¹⁵ This motility may be influenced by an interaction with the tubal epithelium that results in greater speed and better direction as well as prevention of attachment and entrapment.

Structure of the Cervical Mucus

The cervical mucus is a complex structure that is not homogeneous.²⁰ The mucus is secreted in granular form, and a networked structure of the mucus is formed in the cervical canal. Thus, not all areas of the cervical mucus are equally penetrable by the sperm. It is proposed, based upon animal studies, that the outward flow of the cervical mucus establishes a linear alignment of parallel strands that direct the sperm upward. Pressurization of the mucus by contractions of the uterus further aid this alignment and may contribute to the speed of sperm transport. Responding to the midcycle estrogen peak, cervical mucus production, water content, and space between its large glycoproteins reach a maximum in the immediate preovulatory period. The process of capacitation is initiated, and perhaps completed, during the sperm's passage through the cervix.

Capacitation

The discovery, in 1951, that rabbit and rat spermatozoa must spend some hours in the female tract before acquiring the capacity to penetrate ova stimulated intensive research efforts to delineate the environmental conditions required for this change in the sperm to occur.^{21, 22} The process by which the sperm were transformed was called **capacitation, the cellular changes that ejaculated spermatozoa must undergo in order to fertilize**.²³ Attention was focused on the hormonal and time requirements and the potential for in vitro capacitation. Capacitation is characterized by 3 accomplishments:

1. The ability to undergo the acrosome reaction.
2. The ability to bind to the zona pellucida.
3. The acquisition of hypermotility.

Capacitation changes the surface characteristics of sperm, as exemplified by removal of seminal plasma factors that coat the surface of the sperm, modification of their surface charge, and restriction of receptor mobility. This is associated with modifications of sperm cell membrane sterols, lipids, and glycoproteins that cause decreased stability of the plasma membrane and the membrane lying immediately under it, the outer acrosomal membrane. The membranes undergo further, more striking, modifications when capacitated sperm reach the vicinity of an oocyte or when they are incubated in follicular fluid. There is a breakdown and merging of the plasma membrane and the outer acrosomal membrane, **the acrosome reaction**.²⁴ This allows egress of the enzyme contents of the acrosome, the caplike structure that covers the sperm nucleus. These enzymes, which include hyaluronidase, a neuraminidase-like factor, cumulus-dispersing enzyme, and a protease called acrosin, are all thought to play roles in sperm penetration of the egg investments. The changes in the sperm head membranes also prepare the sperm for fusion with the egg membrane. It is the inner acrosomal membrane that fuses with the oocyte plasma membrane. The acrosome reaction can be induced by zona pellucida proteins of the oocyte and by human follicular fluid in vitro.^{25, 26} In addition, capacitation endows the sperm with hypermotility, and the increased velocity of the sperm is a very critical factor in achieving zona penetration.¹⁹

The events that constitute the process of capacitation are regulated by the redox status of the sperm cell.^{27, 28} Redox reactions induce tyrosine phosphorylation, an absolute requirement for capacitation. These reactions are dependent on a critical increase in intracellular calcium concentrations due to an influx of extracellular calcium, believed to be induced by progesterone.

Although capacitation classically has been defined as a change sperm undergo in the female reproductive tract, it is apparent that sperm of some species, including the human, can acquire the ability to fertilize after a short incubation in defined media and without residence in the female reproductive tract. Therefore, success with assisted reproductive technologies is possible. In vitro capacitation requires a culture medium that is a balanced salt solution containing energy substrates such as lactate, pyruvate, and glucose and a protein such as albumin, or a biologic fluid such as serum or follicular fluid. Sperm-washing procedures probably remove factors that coat the surface of the sperm, one of the initial steps in capacitation. The removal of cholesterol from the sperm membrane is believed to prepare the sperm membrane for the acrosome reaction.²⁹ The loss of cholesterol regulates the expression of sperm cell membrane surface lectins that are involved in sperm surface receptors for the zona pellucida.³⁰ The time required for in vitro capacitation is approximately 2 hours.³¹

The final dash to the oocyte is aided by the increased motility due to the state of hyperactivity. This change in motility can be measured by an increase in velocity and flagellar beat amplitude. Perhaps the increase in thrust gained by this hyperactivity is necessary for avoiding attachment to tubal epithelium and achieving penetration of the cumulus and zona pellucida.

Key Steps in Sperm Transport

1. *Approximately 72 days are required to produce spermatozoa, a time period followed by storage in the epididymis prior to ejaculation.*
2. *Sperm enter the cervical mucus and then the fallopian tubes within minutes, but only a few hundred sperm or less reach the oocyte. The cervix serves as a reservoir of sperm for up to 72 hours.*
3. *Capacitation, a process initiated during the sperm's passage through the cervix or during in vitro incubation in an appropriate medium, is characterized by the acquired ability of sperm to undergo the acrosome reaction to bind to the zona pellucida and to acquire hyperactivated motility.*
4. *The acrosome reaction is due to the modification and breakdown, followed by a merger, of the sperm cell membrane and the outer acrosomal membrane, allowing the release of enzymes and changes in the inner acrosomal membrane, necessary for fusion with the oocyte cell membrane.*

Egg Transport

The oocyte, at the time of ovulation, is surrounded by granulosa cells (the **cumulus oophorus**) that attach the oocyte to the wall of the follicle. The **zona pellucida**, a noncellular porous layer of glycoproteins secreted by the oocyte, separates the oocyte from the granulosa cells. The granulosa cells communicate metabolically with the oocyte by means of **gap junctions** between the oocyte plasma membrane and the cumulus cells. In response to the midcycle surge in luteinizing hormone (LH), maturation of the oocyte proceeds with the resumption of meiosis as the oocyte completes the first meiotic division, enters into the second meiotic division, and arrests in the second metaphase. Just before ovulation, the cumulus cells retract their cellular contacts from the oocyte. The disruption of the gap junctions induces maturation and migration of the cortical granules to the outer cortex of the oocyte.³² Prior to ovulation, the oocyte and its cumulus mass of cells prepare to leave their long residence in the ovary by becoming detached from the follicular wall.

Egg transport encompasses the period of time from ovulation to the entry of the morula into the uterus. The egg can be fertilized only during the early stages of its sojourn in the fallopian tube. Within 2–3 minutes of ovulation, the cumulus and oocyte are in the ampulla of the fallopian tube.

In rats and mice the ovary and distal portion of the tube are covered by a common fluid-filled sac. Ovulated eggs are carried by fluid currents to the fimbriated end of the tube. In contrast, in primates, including humans, the ovulated eggs adhere with their cumulus mass of follicular cells to the surface of the ovary. The fimbriated end of the tube sweeps over the ovary in order to pick up the egg. Entry into the tube is facilitated by muscular movements that bring the fimbriae into contact with the surface of the ovary. Variations in this pattern surely exist, as evidenced by women who achieve pregnancy despite having only one ovary and a single tube located on the contralateral side. Furthermore, eggs deposited in the cul-de-sac by transvaginal injection are picked up by the tubes.³³

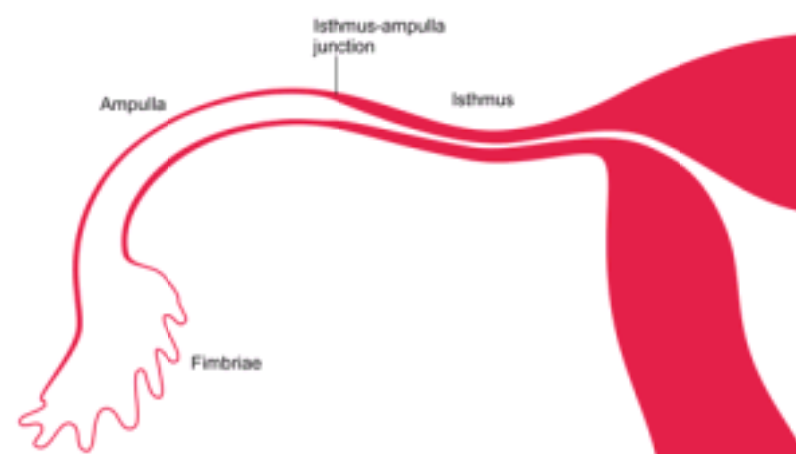

Although there can be a small negative pressure in the tube in association with muscle contractions, oocyte pickup is not dependent on a suction effect secondary to this negative pressure. Ligation of the tube just proximal to the fimbriae does not interfere with pickup.³⁴

The fallopian tubes are lined by an epithelium that undergoes cyclic changes comparable to the endometrium, in response to the hormonal changes of the menstrual cycle.³⁵ The epithelium is composed of nonciliated cells and ciliated cells. The nonciliated cells are characterized by major secretory activity during the follicular phase of the cycle, culminating in the release of cytoplasmic components during the passage of the egg, perhaps providing important metabolic factors for transport and implantation.

Some have described a menstrual cycle variation in ciliated cells in the tube, but most have not.³⁵ The apparent variation is probably due to differential changes in response to cyclic hormone levels. The cilia on the surface of the fimbriae (where they are present in greater concentrations) display adhesive sites, and these seem to have prime responsibility for the initial movement of the egg into the tube. This movement is dependent on the presence of follicular cumulus cells surrounding the egg, because removal of these cells prior to egg pickup prevents effective egg transport.

In the ampulla of the tube the many cilia beat synchronously in the direction of the uterus. In women and monkeys, this unidirectional beat is also found in the isthmus of the tube. The specific contribution of the cilia to egg transport in the ampulla and isthmus is an unresolved question. Most investigators have credited muscular contractions of the tubes as the primary force for moving the egg.³⁶ However, interference with muscle contractility in the rabbit did not block egg transport.³⁷ Reversing a segment of the ampulla of the tube so that the cilia in this segment beat toward the ovary interferes with pregnancy in the rabbit without blocking fertilization. The fertilized ova are arrested when they come in contact with the transposed area.³⁸ This suggests that ciliary beating is crucial for egg transport. There are *fertile* women who suffer from Kartagener's syndrome in which there is a congenital absence of dynein arms (a protein structure associated with motility) in all bodily cilia, and thus the cilia do not beat. However, motility of cilia in the tube may be disordered and not totally absent.³⁹

Transvaginal endoscopic observation of actual ovum and cumulus oophorus pickup in a woman revealed that the process is relatively slow (more than 15 minutes), the fimbriae on the ovulating side are distinguished by being erect (probably due to engorged blood vessels and suggesting a local ovarian influence), and the only observable active mechanism involved ciliary movement.⁴⁰

It is probable, therefore, that in normal circumstances, smooth muscle contractions and the flow of secretory fluid in response to ciliary activity work together to accomplish egg transport.

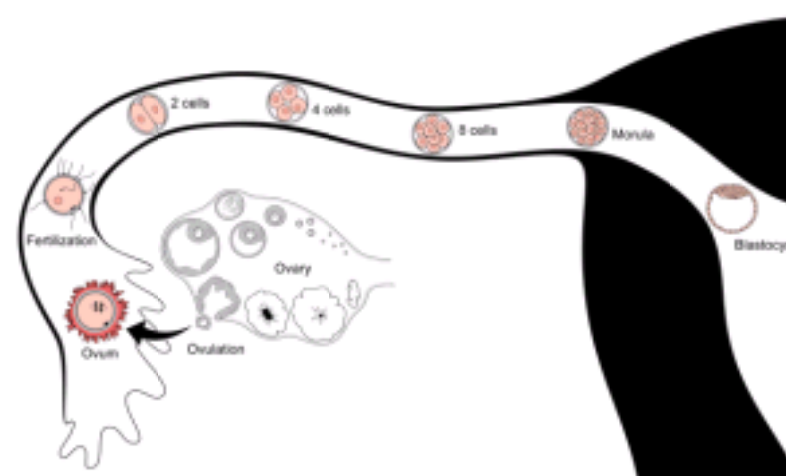

In most species, transport of the ovum (the fertilized oocyte) through the tube requires approximately 3 days.⁴¹ The time spent within the various parts of the tube varies from one species to another. Transport through the ampulla is rapid in the rabbit, whereas in women the egg spends about 80 hours in the tube, 90% of which is in the ampulla.

Attempts to modify tubal function as a method for understanding its physiology have involved three major pharmacologic approaches: 1) altering levels of steroid hormones, 2) interference with or supplementation of adrenergic stimuli, and 3) treatment with prostaglandins. Although there is abundant literature on the effects of estrogen and progesterone on tubal function, it is clouded by the use of different hormones, different doses, and different timing of injections. Because of these variations, it is difficult to obtain a coherent picture and to relate the experimental results to the *in vivo* situation. In general, pharmacologic doses of estrogen favor retention of eggs in the tube. This "tube-locking" effect of estrogen can be partially reversed by treatment with progesterone.

The isthmus of the tube has an extensive adrenergic innervation. Surgical denervation of the tube, however, does not disrupt ovum transport. Prostaglandins (PG) of the E series relax tubal muscle, whereas those of the F series stimulate muscle activity of the tube. Although PGF_{2a} stimulates human oviductal motility *in vivo*, it does not cause acceleration of ovum transport.

Is there an essential anatomical segment of the tube? Excision of the ampullary-isthmic junction in rabbits does not prevent fertility.⁴² This is equally true if small segments of the ampulla are removed, and pregnancy can occur even if the entire isthmus and uterotubal junction are excised. Although the fimbriae are thought to play a crucial role in fertility, spontaneous pregnancies have been reported following sterilization by fimbriectomy or following surgical repair of tubes whose fimbriated ends had been excised.^{43, 44} The fallopian tube appears to readily adapt to anatomical changes and restrictions.

In most species, a period of residence in the tube appears to be a prerequisite for full development. Rabbit eggs can be fertilized in the uterus, but they do not develop unless transferred to the tubes within 3 hours of fertilization.⁴⁵ This implies that there may be a component in uterine fluid during the first 48 hours following ovulation that is toxic to the egg.⁴⁵ Indirect evidence of an inhospitable environment is also provided by studies indicating that there must be synchrony between development of the endometrium and the egg for successful pregnancy to occur.^{46, 47} If the endometrium is in a reduced or advanced stage of development compared with the egg, fertility is compromised. In addition, the blastocyst must undergo cleavage and development in order to gain the capability to implant in the uterus. **Thus, it is conceptually useful to view the fallopian tube not as an active transport mechanism, but as a structure that provides an important holding action. This functional behavior is coordinated by the changing estrogen and progesterone levels after ovulation, although local embryonic signals may also be involved.**

Successful pregnancies have occurred in the human following the Estes procedure, in which the ovary is transposed to the uterine cornua.⁴⁸ Eggs are ovulated directly into the uterus, completely bypassing the tube. Moreover, when fertilized donor eggs are transferred to women who are receiving hormone supplementation, there are several days during the treatment cycle when the blastocysts will implant. This crucial difference between animal and human physiology is of more than academic importance. There has been speculation about the use of drugs that could accelerate tubal transport as a means of providing contraception by ensuring that the egg would reach the uterus when it was in an unreceptive state. Although this may work in animals, it is of doubtful value in the human because perfect synchrony is not required.

Animal and human reproduction also differ in the occurrence of ectopic pregnancy. Ectopic pregnancies are rare in animals, and in rodents, they are not induced even

if the uterotubal junction is occluded immediately following fertilization. The embryos reach the blastocyst stage and then degenerate.

Key Steps in Egg Transport

1. After ovulation, the oocyte and its surrounding cumulus are in the ampulla of the fallopian tube within 2–3 minutes.
2. Tubal transport depends on smooth muscle contractions and ciliary-induced flow of secretory fluid.
3. The fallopian tube provides an important holding action to allow time for the endometrium to become receptive and the blastocyst to become capable of implantation, a time period of approximately 80 hours, 90% of which is in the ampulla.

Oocyte Maturation

Oocyte maturation is regulated by the sex hormones, and in nonmammalian species a nongenomic action of progesterone causes an increase in intracellular calcium concentrations. In human oocytes, an influx of extracellular calcium occurs in response to estradiol, followed by secondary rises in calcium ions from intracellular stores, characterized by wavelike oscillations.⁴⁸ This is a nongenomic response to estradiol at the cell surface, and the transient increases in intracellular calcium improve the quality of the oocyte and contribute to the capability for fertilization.

Calcium oscillations are a property common to mammalian oocytes and are also an early reaction to the fertilizing spermatozoan.⁵⁰ Neither the presence of estradiol nor the calcium oscillations are required for oocytes to resume meiosis. However, improved fertilization following estradiol-induced calcium increases indicates an important role for intrafollicular estradiol in overall oocyte maturation.

Fertilization

The fertilizable life of the human oocyte is unknown, but most estimates range between 12 and 24 hours. However, immature human eggs recovered for in vitro fertilization can be fertilized even after 36 hours of incubation. Equally uncertain is knowledge of the fertilizable lifespan of human sperm. The most common estimate is 48–72 hours, although motility can be maintained after the sperm have lost the ability to fertilize. The extreme intervals that have achieved pregnancy documented after a single act of coitus are 6 days prior to and 3 days after ovulation.⁵¹ The great majority of pregnancies occur when coitus takes place within the 3-day interval just prior to ovulation.⁵²

Contact of sperm with the egg, which occurs in the ampulla of the tube, may not be random; there is some evidence for sperm-egg communication that attracts sperm to the oocyte.^{53, 54} This chemotactic responsiveness of sperm requires the changes that take place in the capacitation process.⁵⁵ Thus, this may be a system to select a sperm that is fully capable of fertilization.

The cumulus oophorus undergoes a preovulatory expansion that may have two important roles. The ampullary space of the human fallopian tube is relatively large (compared with the oocyte), and the expanded cumulus may serve to increase the chances of an encounter with one of the few spermatozoa that have reached the far section of the tube. In addition, this change may facilitate sperm passage through the cumulus. Sperm pass through the cumulus without the release of acrosomal enzymes.⁵⁶ It has been suggested, based upon *in vitro* experiments, that the cumulus is essential for full development of the fertilizing ability of sperm; however, removal of the cumulus does not prevent sperm penetration and fertilization.

Despite the evolution from external to internal fertilization over a period of about 100 million years, many of the mechanisms have remained the same.^{57, 58} The acellular zona pellucida that surrounds the egg at ovulation and remains in place until implantation has two major functions in the fertilization process:

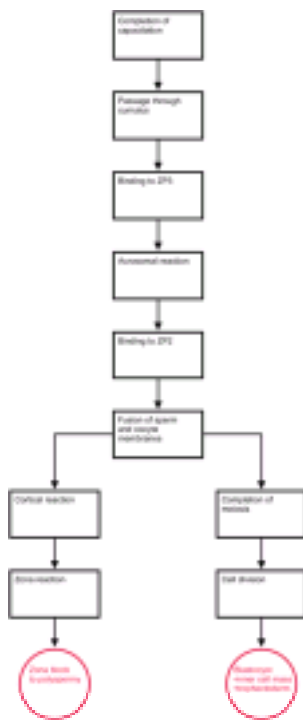

1. The zona pellucida contains ligands for sperm, which are, with some exceptions, relatively species-specific.
2. The zona pellucida undergoes the **zona reaction** in which the zona becomes impervious to other sperm once the fertilizing sperm penetrates, and thus it provides a bar to polyploidy.⁵⁹

Penetration through the zona is rapid and mediated by acrosin, a trypsinlike proteinase that is bound to the inner acrosomal membrane of the sperm.^{60, 61} The pivotal role assigned to acrosin has been disputed. For example, manipulations that increase the resistance of the zona to acrosin do not interfere with sperm penetration, and thus sperm motility may be the critical factor. The zona pellucida is a porous structure due to the many glycoproteins assembled into long, interconnecting filaments. Nevertheless, a preponderance of evidence favors tenacious binding of capacitated spermatozoa to the zona pellucida as a requirement for penetration, although it is clear that penetration requires active motility not only of the tail but of the head as well. Indeed, the sperm head undergoes rapid lateral oscillations of the head about a fulcrum at the head-tail junction, suggesting a scythelike action on the zona.²

The acrosome is a lysosomelike organelle in the anterior region of the sperm head, lying just beneath the plasma membrane like a cap over the nucleus. The lower part of the two arms is called the equatorial segment. The acrosome contains many enzymes that are exposed by **the acrosome reaction, the loss of the acrosome immediately before fertilization. This reaction is one of exocytosis, the fusion of an intracellular storage vesicle with the inner surface of the cell membrane, followed by release of the vesicle contents.** This reaction requires an influx of calcium ions, the efflux of hydrogen ion, an increase in pH, and fusion of the plasma membrane with the outer acrosomal membrane, leading to the exposure and escape of the enzymes contained on the inner acrosomal membrane. Binding to the zona pellucida is required to permit a component of the zona to induce the acrosomal reaction. This component is believed to be a glycoprotein sperm receptor, which thus serves dual functions: binding of sperm and induction of the acrosomal reaction.

The initial contact between the sperm and the oocyte is a receptor-mediated process. The zona pellucida is composed of glycoproteins secreted by the oocyte, known as ZP1, ZP2, and ZP3, with ZP3 being the most abundant.⁶² ZP3 is the primary ligand for sperm and ZP2 binding occurs after the acrosome reaction, participating in the zona reaction to prevent polyspermy. Structural alteration of these glycoproteins leads to a loss of activity; inactivation of these ligands after fertilization is probably accomplished by one or more cortical granule enzymes. The ZP3 gene is expressed only in growing oocytes. DNA sequence similarities of the ZP3 gene in various mammals indicates that this gene has been evolutionarily conserved and that the sperm-ligand interaction is a common mechanism among mammals.⁶³ Mice with a disrupted ZP3 gene produce oocytes lacking a zona pellucida and are unable to become pregnant.^{64, 65} A vaccine against zona pellucida proteins from pigs is used to control reproduction in female elephants and deer.

The initial binding of the sperm to the zona requires recognition on the part of the sperm of the carbohydrate component of the species-specific glycoprotein ligand molecule.⁶⁶ Once binding is accomplished, the acrosome reaction is triggered by the peptide chain component of the receptor glycoprotein. At least one receptor on the sperm head is a tyrosine kinase, activated by binding to the ZP3 glycoprotein and an initiator of the acrosome reaction.^{67, 68} This interaction is analogous to the general principle of behavior for hormone-receptor binding and activity. In the case of sperm and oocyte, recognition of the oocyte zona ligand involves an enzyme on the surface of the sperm that becomes exposed during capacitation. Formation of the ZP3-enzyme

complex, therefore, not only produces binding but also induces the acrosome reaction. The G protein signaling system is also present on sperm heads, and activation at this point in time opens calcium channels to increase intracellular levels of calcium ions, a requirement for the acrosome reaction.^{69, 70} Thus, the initial sperm-zona interaction depends on binding of acrosome-intact spermatozoa, followed by a process mediated by the enzymes released by the zona-induced acrosome reaction. Protein kinase C activation is an important step in the acrosomal reaction, leading to phosphorylation of sperm proteins involved in the process.⁷¹

Spermatozoa enter the perivitelline space at an angle. The oocyte is a spherical cell covered with microvilli. The sperm head is like a flat dish, and the thickness of the head is a little less than the distance between the oocyte microvilli.⁷² The region of the equatorial segment of the sperm head, the distal portion of the acrosome, makes initial contact with the vitelline membrane (the egg plasma membrane or oolemma). At first, the egg membrane engulfs the sperm head, and, subsequently, there is fusion of egg and sperm membranes. This fusion is mediated by specific proteins. Two membrane proteins from the sperm head have been sequenced; one (PH-20) is involved in binding to the zona pellucida, and the other (PH-30, also called fertilin) is involved in fusion with the oocyte.^{73, 74} PH-20, with hyaluronidase activity, is also active in dispelling the cumulus.⁷⁵ The cell membrane of the unfertilized oocyte contains integrin adhesion/fusion molecules that recognize peptides such as fibronectin, laminin, and collagen.⁷⁶ Fibronectin appears on the spermatozoa, but it is disputed whether it appears with caudal maturation or after capacitation. Vitronectin is a sperm protein that is activated after capacitation and the acrosome reaction and may be the key peptide interacting with oocyte cell membrane integrins.⁷⁷ These steps in the fusion process will occur only with sperm that have undergone the acrosome reaction.

Fusion of the sperm and oocyte membrane is followed by the cortical reaction and metabolic activation of the oocyte. An increase in intracellular free calcium in a periodic, oscillatory pattern always precedes the cortical reaction and oocyte activation at fertilization, and this is believed to be the mechanism by which the spermatozoon triggers these developmental events.^{50, 78} A soluble sperm protein, called **oscillin**, has been identified in the equatorial segment of the sperm head that may be the signaling agent for the critical calcium oscillations.^{79, 80}

The initiation of the block to penetration of the zona (and the vitellus) by other sperm is mediated by the **cortical reaction**, another example of exocytosis with the release of materials from the **cortical granules**, lysosomelike organelles that are found just below the egg surface.⁸¹ As with other lysosomelike organelles, these materials include various hydrolytic enzymes. Changes brought about by these enzymes lead to the **zona reaction, the hardening of the extracellular layer by cross-linking of structural proteins, and inactivation of ligands for sperm receptors**.⁸² Thus, the zona block to polyspermy is accomplished. The initial change in this zona block is a rapid depolarization of the oocyte membrane associated with a release of calcium ions from calmodulin. The increase in intracellular calcium acts as a signal or trigger to activate protein synthesis in the oocyte. The depolarization of the membrane initiates only a transient block to sperm entry. The permanent block is a consequence of the cortical reaction and release of enzymes, also apparently triggered by the increase in calcium.

Approximately 3 hours after insemination, meiosis is completed.⁸³ The second polar body is released and leaves the egg with a haploid complement of chromosomes. The addition of chromosomes from the sperm restores the diploid number to the now fertilized egg. The chromatin material of the sperm head decondenses, and the male pronucleus is formed. The male and the female pronuclei migrate toward each other, and as they move into close proximity the limiting membranes break down, and a spindle is formed on which the chromosomes become arranged. Thus, the stage is set for the first cell division.

Embryonic genome activity in the human begins early; DNA synthesis activity can be detected 9–10 hours after insemination.⁸⁴ Human gene expression (transcription) begins between the 4- and 8-cell stages of preimplantation cleavage, 2–3 days after fertilization.⁸⁵ Early embryonic signals may be derived from a store of maternal messenger RNAs, termed the “maternal legacy.”⁸⁶ An arrest of development in this pre-blastocyst cleavage stage is well recognized.

The clinician is interested not only in how normal fertilization takes place but also in the occurrence of abnormal events that can interfere with pregnancy. It is worthwhile, therefore, to consider the failures that occur in association with in vivo fertilization. Studies in the nonhuman primate have involved monkeys and baboons. A surgical method was used to flush the uterus of regularly cycling rhesus monkeys, and 9 preimplantation embryos and 2 unfertilized eggs were recovered from 22 flushes. Two of the 9 embryos were morphologically abnormal and probably would not have implanted.⁸⁷ Hendrickx and Kraemer used a similar technique in the baboon and recovered 23 embryos, of which 10 were morphologically abnormal.⁸⁸ This suggests that, in nonhuman primates, some ovulated eggs are not fertilized and that many early embryos are abnormal and, in all likelihood, will be aborted. Similar findings have been reported in the human in the classic study of Hertig et al.⁸⁹ They examined 34 early embryos recovered by flushing and examination of reproductive organs removed at surgery. Ten of these embryos were morphologically abnormal, including 4 of the 8 preimplantation embryos. Because the 4 preimplantation losses would not have been recognized clinically, there would have been 6 losses recorded in the remaining 30 pregnancies.

By using sensitive pregnancy tests, it has been suggested that the total rate of pregnancy loss after implantation is approximately 30%.⁹⁰ When the loss of fertilized oocytes before implantation is included, approximately 46% of all pregnancies end before the pregnancy is clinically perceived.⁹¹

In the postimplantation period, if only clinically diagnosed pregnancies are considered, the generally accepted figure for spontaneous miscarriage in the first trimester is 15%. Approximately 50–60% of these abortuses have chromosome abnormalities.⁹² This suggests that a minimum of 7.5% of all human conceptions are chromosomally abnormal. The fact that only 1 in 200 newborns has a chromosome abnormality attests to the powerful selection mechanisms operating in early human gestation. In each ovulatory cycle, only 30% of normally fertile couples can achieve a pregnancy. Once conception is achieved, only 30% survive to birth.⁵²

Key Steps in Fertilization

1. Sperm penetration of the zona pellucida depends on a combination of sperm motility, an acrosomal proteinase, and binding of sperm head receptors to zona ligands.
2. Binding of sperm head receptors and zona ligands produces an enzyme complex that induces the acrosome reaction, releasing enzymes essential for the fusion of the sperm and oocyte membranes.
3. Fusion of the sperm and oocyte membranes triggers the cortical reaction, the release of substances from the cortical granules, organelles just below the egg cell membrane.
4. The cortical reaction leads to the enzyme-induced zona reaction, the hardening of the zona and the inactivation of ligands for sperm receptors, producing an obstacle to polyspermy.
5. Cell division begins promptly after fertilization; human gene expression begins between the 4- and 8-cell stages.

Implantation and Placentation

A normal pregnancy is, of course, impossible without successful implantation and placentation. Because there are differences among the various species, we will focus on the physical and biochemical events that are relevant in human reproduction.⁹³ Shortly after the 8-cell morula enters the uterine cavity about 4 days after the gonadotropin surge and 3 days after ovulation, a blastocyst (a preimplantation embryo of varying cell number, from 30 to 200) is formed. Implantation (the embedding of the blastocyst in the endometrial stroma) begins with the loss of the zona pellucida (hatching) about 1–3 days after the morula enters the uterine cavity.

Preparation for Implantation

The change from proliferative to secretory endometrium, described in detail in [Chapter 4](#), is an essential part of achieving the receptive conditions required for implantation. The primary endocrine requirement is the presence of progesterone; in the monkey, implantation and pregnancy can be achieved in the absence of luteal phase estrogen.⁹⁴ This change is the histologic expression of many biochemical and molecular events. The endometrium is 10–14 mm thick at the time of implantation in the midluteal phase. By this time, secretory activity has reached a peak, and the endometrial cells are rich in glycogen and lipids. Understanding the dynamic endocrine behavior of the endometrium ([Chapter 4](#)) increases the appreciation for its active participation in the implantation process. The window of endometrial receptivity is restricted to days 16–22 of a 28-day normal cycle, and days 16–19 of cycles stimulated by exogenous gonadotropins.^{47, 95, 96 and 97} Endometrial receptivity is heralded by formation of **pinopodes**, surface epithelial microvilli that exhibit a cystic change, appearing and regressing during the window of receptivity.⁹⁸ The pinopodes may serve to absorb fluid from the uterine cavity forcing the blastocyst to be in contact with the endometrial epithelium.

Even before the blastocyst adheres to the surface epithelium, but after hatching from the zona pellucida, a dialogue between the mother and the early embryo has begun. Early pregnancy factor (EPF) can be detected in the maternal circulation within 1–2 days after fertilization.⁹⁹ EPF prior to implantation is apparently produced by the ovary in response to a signal from the embryo. After implantation, EPF is no longer secreted by the ovary but is derived from the embryo. EPF has immunosuppressive properties and is associated with cell proliferation and growth.

Blastocysts grown in culture produce and secrete human chorionic gonadotropin (HCG), beginning days 7–8 after fertilization.¹⁰⁰ Messenger RNA for HCG can be found in 6- to 8-cell human embryos.¹⁰¹ Because the 8- to 12-cell stage is achieved about 3 days after fertilization, it is believed that the human embryo begins to produce HCG before implantation when it can be detected in the mother (about 6–7 days after ovulation). The embryo is capable, therefore, of preimplantation signaling, and higher levels of estradiol and progesterone can be measured in the maternal circulation even before maternal HCG is detectable, presumably because of stimulation of the corpus luteum by HCG delivered directly from the uterine cavity to the ovary.¹⁰² Function of the corpus luteum is crucial during the first 7–9 weeks of pregnancy, and luteectomy early in pregnancy can precipitate abortion.¹⁰³ Similarly, early pregnancy loss in primates can be induced by injections of anti-HCG serum.¹⁰⁴ Another substance secreted very early by the preimplantation embryo is platelet-activating factor, perhaps part of the immunosuppressive activity required to induce maternal tolerance of the embryo. It is not surprising that various growth factors are produced by the early embryo.¹⁰⁵

In rodents and rabbits, implantation can be interrupted by injection of prostaglandin inhibitors.^{106, 107} Indomethacin prevents the increase in endometrial vascular permeability normally seen just prior to implantation. Additional evidence for a role by prostaglandins in the earliest stages of implantation is the finding of increased concentrations at implantation sites, similar to any inflammatory response.¹⁰⁸ The blastocysts of mice, rabbits, sheep, and cows produce prostaglandins, and prostaglandin E₂ release from human blastocysts and embryos has been demonstrated.¹⁰⁹ The secretory endometrial epithelial cells are also a source of prostaglandin E₂ (but not prostaglandin F_{2a}), and its synthesis may be stimulated by the tissue response that accompanies implantation. However, decidual synthesis of prostaglandins is significantly reduced compared with proliferative and secretory endometrium, apparently a direct effect of progesterone activity and perhaps a requirement in order to maintain the pregnancy.¹⁰⁸ Nevertheless, prostaglandin E₂ synthesis is increased at the implantation site, perhaps in response to blastocyst factors, e.g., platelet-activating factor, and correlates with an increase in vascular permeability.^{108, 110} In the rabbit, platelet-activating factor also induces the production of early pregnancy factor (discussed above).¹¹¹

As discussed in [Chapter 4](#), the many cytokines, peptides, and lipids secreted by the endometrium are interrelated through the stimulating and inhibiting actions of estrogen and progesterone, as well as the autocrine/paracrine activities of these substances on each other. The response to implantation certainly involves the many members of the growth factor and cytokine families.

Implantation

Implantation is defined as the process by which an embryo attaches to the uterine wall and penetrates first the epithelium and then the circulatory system of the mother to form the placenta. It is a process that is limited in both time and space. Implantation begins 2–3 days after the fertilized egg enters the uterus on day 18 or 19 of the cycle.⁹⁷ Thus, implantation occurs 5–7 days after fertilization. The implantation site in the human uterus is usually in the upper, posterior wall in the midsagittal plane. Implantation consists of 3 stages: apposition, adhesion, and invasion (also called migration to denote its benign nature).

Apposition and Adhesion

The human blastocyst remains in the uterine secretions for approximately 1 to 3 days and then hatches from its zona pellucida in preparation for attachment. Implantation is marked initially by apposition of the blastocyst to the uterine epithelium, usually about 2–4 days after the morula enters the uterine cavity. A prerequisite for this contact is a loss of the zona pellucida, which, *in vitro*, can be ruptured by contractions and expansions of the blastocyst. *In vivo*, this activity is less critical, because the zona can be lysed by components of the uterine fluid. Nevertheless, blastocyst movement and escape from the zona pellucida appear to involve cytoplasmic projections (this leads to penetrations of the zona by the trophectoderm prior to zona hatching).¹¹² By this time, the blastocyst has differentiated into an inner cell mass (embryo) and trophectoderm (placenta), both essential for implantation.

The endometrial production of at least 3 cytokines appears to be involved in implantation.¹¹³ These are colony-stimulating factor-1 (CSF-1), leukemia-inhibitory factor (LIF), and interleukin-1 (IL-1). CSF-1 expression and receptors for CSF-1 are found in both the human endometrium (peaking in decidua) and the preimplantation embryo. Mice with an inactivating mutation in the CSF-1 gene are infertile because of low rates of implantation and fetal viability.¹¹⁴ LIF displays the same pattern of expression as CSF-1, and mice with an LIF gene mutation have a failure of blastocyst implantation.^{115, 116} Blocking the interleukin-1 receptor in mice also prevents implantation.¹¹³ However, the role of interleukin-1 is less clear because mice that are deficient in the interleukin receptor have normal reproduction.¹¹⁷ Perhaps the first maternal change in the implantation process, increased permeability of the capillaries near the adherent blastocyst, is due to a blastocyst-directed change in heparin-binding epidermal growth factor (HB-EGF) expression in the surface epithelium.¹¹⁸ In addition, the blastocyst contains receptors for epidermal growth factor

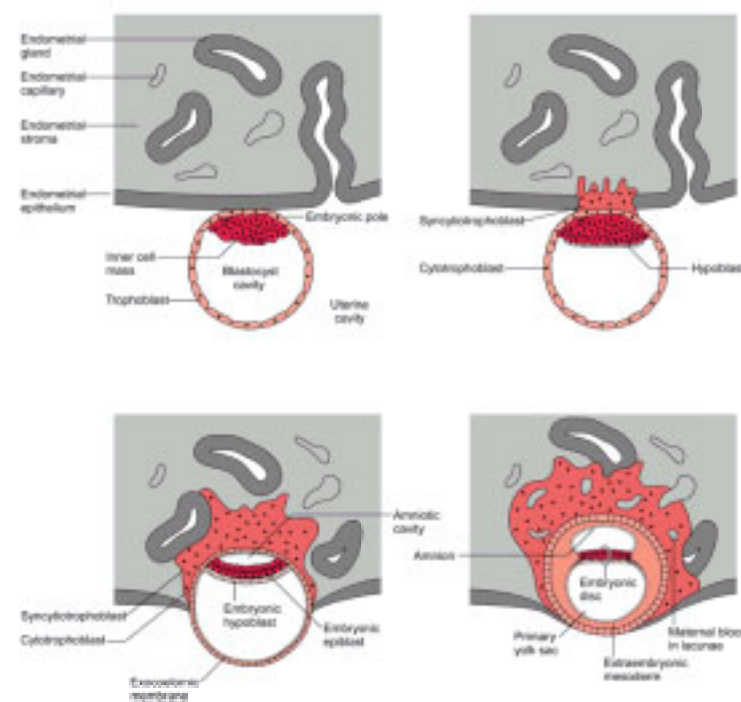

that respond to HB-EGF and promote growth and zona hatching.

The adhesion process further involves a whole collection of adhesion molecules, including integrins and selectins. The decidualized endometrium and the early embryo express extracellular matrix components, especially laminin and fibronectin, which mediate cell adhesion via the adhesion molecules.¹¹⁹ Cells are fixed and supported by the extracellular matrix utilizing components such as laminin and fibronectin with attachments to these components via cell surface receptors, especially the integrins. An increase in specific isoforms of laminin in decidua at the time of implantation suggests an important interaction with the invading trophoblast.¹²⁰ Thus implantation starts with adhesion due to binding with endometrial integrins, followed by invasion (migration) of the trophoblast by proteinase degradation of the extracellular matrix.

Integrins are members of a family of transmembrane cell surface receptors for collagen, fibronectin, and laminin. Integrins are utilized in cell-cell and cell-matrix interactions, contributing to cell migration, cell differentiation, and tissue structure. A cyclic change in integrin expression in the endometrial epithelial cells indicates peak expression at the time of implantation.¹²¹ It has been suggested that a lack of integrin expression during the implantation window can be a cause of infertility.¹²² The blastocyst also expresses integrins in a time sequence and at a site (outgrowing trophoblast cells) that are appropriate for key activity during implantation.¹²³

The process of tissue disruption is accompanied by an increase in lymphocytes, another source for cytokines and growth factors in addition to trophoblast and endometrial cells. The distinction between cytokines and growth factors is not always clear, but T lymphocytes and macrophages are significant secretors of cytokines.

In general, cytokines, growth factors, and their receptors have been identified in virtually all tissues associated with implantation. The cataloging is lengthy and often confusing.^{113, 124} It is helpful to simply view these various substances as the biochemical tools by which the physical process of trophoblast adhesion and invasion is accomplished.

Even if the hormonal milieu and protein composition of the uterine fluid are hospitable to the implantation, it may not occur if the embryo is not at the proper stage of development. It has been inferred from this information that there must be developmental maturation of the surface of the embryo before it is able to achieve attachment and implantation.

Reports on changes in the surface charge of preimplantation embryos differ in their findings, and it is unlikely that changes in surface charge are solely responsible for adherence of the blastocyst to the surface of epithelial cells. Binding of the lectin concanavalin A to the blastocyst changes during the preimplantation period, an indication that the surface glycoproteins of the blastocyst are in transition.¹²⁵ It is reasonable to assume that these changes in configuration on the surface occur in order to enhance the ability of the early embryo to adhere to the maternal surface.

As the blastocyst comes into close contact with the endometrium, the microvilli on the surface flatten and interdigitate with those on the luminal surface of the epithelial cells. A stage is reached where the cell membranes are in very close contact and junctional complexes are formed. The early embryo can no longer be dislodged from the surface of the epithelial cells by flushing the uterus with physiologic solutions.

Invasion and Placentation

In the second week after ovulation, the placenta is formed.¹¹⁹ By this time, the trophoblasts at the implantation site have formed masses of cytotrophoblasts and syncytiotrophoblasts, and invasion of maternal blood vessels has begun. The walls of the spiral arteries are destroyed, as sinusoidal sacs are formed lined with endovascular trophoblast.

Three types of interactions between the implanting trophoblast and the uterine epithelium have been described.¹²⁶ In the first, trophoblast cells intrude between uterine epithelial cells on their path to the basement membrane. In the second type of interaction, the epithelial cells lift off the basement membrane, an action that allows the trophoblast to insinuate itself underneath the epithelium. Last, fusion of trophoblast with individual uterine epithelial cells has been identified by electron microscopy in the rabbit.¹²⁷ This latter method of gaining entry into the epithelial layer raises interesting questions about the immunologic consequences of mixing embryonic and maternal cytoplasm.

Trophoblast has the ability to phagocytose a variety of cells, but, in vivo, this activity seems largely confined to removal of dead endometrial cells, or cells that have been sloughed from the uterine wall. Similarly, despite the invasive nature of the trophoblast, destruction of maternal cells by enzymes secreted by the embryo does not seem to play a major role in implantation; there is virtually no necrosis. The early embryo does secrete a variety of enzymes (e.g., collagenase and plasminogen activators), and these are important for digesting the intercellular matrix that holds the epithelial cells together. Studies in vitro have demonstrated the presence of plasminogen activator in mouse embryos and in human trophoblast, and its activity is important in the attachment and early outgrowth stages of implantation.^{128, 129} Urokinase and proteases, trophoblastic enzymes that convert plasminogen to plasmin, are inhibited by HCG, indicating regulation of this process by the embryo.¹³⁰

The trophoblast at a somewhat later stage of implantation can digest, in vitro, a complex matrix composed of glycoproteins, elastin, and collagen, all of which are components of the normal intercellular matrix.^{131, 132} Additional studies in vitro have shown that cells move away from trophoblast in a process called "contact inhibition."¹³³ Trophoblast then spreads to fill the spaces vacated by the cocultured cells. Once the intracellular matrix has been lysed, this movement of epithelial cells away from trophoblast would allow space for the implanting embryo to move through the epithelial layer. Trophoblast movement is aided by the fact that only parts of its surface are adhesive, and the major portion of the surface is nonadhesive to other cells.

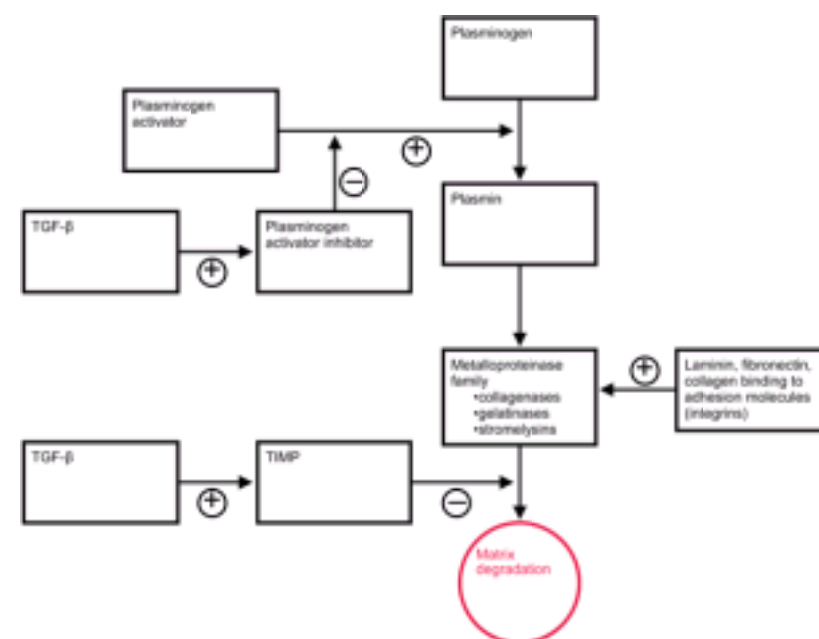

The highly proliferative phase of trophoblastic tissue during early embryogenesis is regulated by the many growth factors and cytokines produced in both fetal and maternal tissues. Invasion of the early trophoblast requires the expression of integrins, stimulated by insulin-like growth factor-II and inhibited by transforming growth factor-b.¹³⁴

Actively migrating trophoblast cells have a different integrin profile than nonmigrating cells, specifically cell surface receptors that preferentially bind laminin.^{119, 135} The controlling mechanism (not yet known) for this change in integrin expression must be a key regulator of trophoblast invasion. The specific nature of integrin expression can determine binding to matrix components, a requirement for migration.

Integrin cell surface binding for the matrix components can be also regulated by activating and inactivating the integrins. This would allow trophoblast cells to alternate between adhesive and nonadhesive states, thus achieving directional cell migration.¹³⁶ The role of integrin cell surface receptors is not simply to bind to a

structural component. Binding activates cellular signaling pathways (similar to the classic endocrine tropic hormone-cell membrane receptor pathway) that activate enzymes that ultimately produce adhesion as well as cellular gene transcription. ¹¹⁹

The uterine spiral arterioles are invaded by cytotrophoblasts, and the maternal endothelium is replaced by cytotrophoblast tissue as far as the first third of the myometrium. The maternal vascular invasion by trophoblast cells and replacement of vascular endothelium with endovascular trophoblast may utilize a different class of surface molecules, the selectin family. ¹¹⁹ The selectins have been demonstrated to be present in decidual vascular endothelial cells, but only at the site of implantation. The selectins are responsive to inflammatory mediators, including cytokines. As the trophoblast cells replace maternal endothelium, the receptor profile for adhesion peptides of the trophoblast changes to resemble endothelial cells. ¹³⁷ It has been long recognized that this invasion process is limited in pregnancies with preeclampsia. The relative failure in this process in preeclampsia is characterized by insufficient conversion to endothelial adhesion receptors. ¹³⁸

The matrix metalloproteinases, significantly involved in the process of menstruation (Chapter 4), are also key players in matrix degradation during trophoblast invasion. The metalloproteinases include collagenases, gelatinases, and the stromelysins. Integrin-mediated adhesion can activate this family of proteolytic enzymes, which then accomplish the degradation of matrix proteins that is necessary in order for trophoblast migration to take place. Production of the metalloproteinases is regulated by the combined actions of plasminogen activators, cytokines, and tissue inhibitors (TIMP).

Further penetration and survival depend on factors that are capable of suppressing the maternal immune response to paternal antigens. The endometrial tissue makes a significant contribution to growth factor activity and immune suppression by synthesizing proteins in response to the blastocyst even before implantation. ¹³⁹ ¹⁴⁰ One of the great mysteries associated with implantation is the mechanism by which the mother rejects a genetically abnormal embryo or fetus. It is possible that the abnormal embryo cannot produce a signal in early pregnancy that can be recognized by the mother.

The embryonic signals will be effective only in a proper hormone milieu. Much of the knowledge concerning the hormone requirements for implantation in animals has been gained from studies of animals with delayed implantation. In a number of species, preimplantation embryos normally lie dormant in the uterus for periods of time, which may extend for as long as 15 months before implantation is initiated. In other species, delayed implantation can be imposed by postpartum suckling or by performing ovariectomy on day 3 of pregnancy. This produces a marked decrease in synthesis of DNA and protein by the blastocyst. The embryo can be maintained at the blastocyst stage by injecting the mother with progesterone. Using this model, hormonal requirements for implantation have been determined. In mice, there is a requirement for estrogen and progesterone. In other species, including the primate, the nidatory stimulus of estrogen is not required, and progesterone alone is sufficient. ⁹⁴

Although it is known that the hormone milieu of delayed implantation renders the embryo quiescent, it is not known whether this represents a direct effect on the embryo or whether there is a metabolic inhibitor present in uterine secretions that acts upon the embryo. Removal of the embryo from the uterus to culture dishes allows rapid resumption of normal metabolism, suggesting that there has, in fact, been a release from the inhibitory effects of a uterine product.

Limitation of Invasion

Invasion of the endometrial stromal compartment, breaching of the basement membrane, and penetration of maternal blood vessels are mediated by serine proteases and metalloproteinases. The serine proteases are plasminogen activators that provide plasmin for proteolytic degradation of the extracellular matrix. Plasmin activates the metalloproteinase family. Trophoblast cells contain plasminogen activator receptors. Binding of plasminogen activator to this receptor is believed to be a method by which plasmin proteolysis is exerted in a controlled and limited site. ¹⁴¹

Many components of the inflammatory response play roles in the process of implantation. Cytokine secretion from the lymphocyte infiltrate in the endometrium activates cellular lysis of trophoblast, perhaps an important process in limiting invasion. ¹⁴² The decidua at the time of implantation contains a large number of natural killer cells (large granular lymphocytes). It has been proposed that an interaction between these cells and a human leukocyte antigen uniquely present in invading trophoblast limits invasion by producing appropriate cytokines. ¹⁴³

Invasion by the trophoblast is limited by the formation of the decidual cell layer in the uterus. Fibroblast-like cells in the stroma are transformed into glycogen and lipid-rich cells. In the human, decidual cells surround blood vessels late in the nonpregnant cycle, but extensive decidualization does not occur until pregnancy is established. Ovarian steroids govern decidualization, and in the human a combination of estrogen and progesterone is critical.

Histamine may initiate the decidual response. ¹⁴⁴ Antihistamines given systemically or directly into the uterus prevent the decidual response in rats. This was disputed when other workers found that systemic antihistamines were not effective in preventing the decidual response. However, there are two different receptors for histamines, H1 and H2. These are not blocked by the same agents, and early experiments demonstrating a lack of effect of antihistamines may have utilized only a block to one receptor. Blockage of both receptors in rats is followed by a decrease in the number of implantation sites. ¹⁴⁵ Mast cells in the uterus are a major source of histamine, but it is possible that the embryo can also synthesize histamine. ¹⁴⁶

More recently, limitation of trophoblastic invasion is attributed to the balance of promoting and restraining growth factors, cytokines, and enzymes. Plasminogen activator inhibitor-1 (PAI-1) is a major product of decidual cells, inhibiting excessive bleeding during menses and restraining trophoblast invasion in early pregnancy. ¹⁴⁷ PAI-1 binds plasminogen activator with a high affinity and is regulated by cytokines and growth factors. The metalloproteinases that degrade the extracellular matrix components, such as collagens, gelatins, fibronectin, and laminin, are restrained by tissue inhibitors of metalloproteinases (TIMP). In addition, metalloproteinase degradation can be suppressed by inhibiting trophoblast production of these enzymes and by preventing conversion from an inactive to an active form. ¹⁴⁸ Decidual TGF- β is a key growth factor involved in limitation of trophoblast invasion by inducing the expression of both TIMP and PAI-1. In addition, TGF- β can inhibit integrin expression and influence cytotrophoblasts to differentiate into non-invasive syncytiotrophoblasts. ^{134, 149} Even human chorionic gonadotropin (HCG) may exert a governing force by inhibiting protease activity. ^{130, 150}

Key Steps in Implantation

1. The early embryo enters the uterine cavity as an 8-cell morula and becomes a 30 to 200-cell blastocyst before implantation.
2. Implantation begins with hatching from the zona pellucida about 1–3 days after the morula entered the uterine cavity.
3. The endometrium is prepared for implantation by the complex activity of cytokines, growth factors, and lipids modulated by the sex hormones, especially progesterone. The endometrium is receptive for implantation for only a few days.
4. The process of implantation begins with apposition and adhesion of the blastocyst to the uterine epithelium, about 2–4 days after the morula enters the uterine cavity. This process is mediated by cytokines and involves adhesion molecules (integrins)

that interact with extracellular components, especially laminin and fibronectin.

5. **Trophoblastic invasion rapidly follows adhesion of the blastocyst, mediated by proteinase degradation of the extracellular matrix. The placenta is formed in the second week after ovulation. Limitation of trophoblastic invasion is due to a restraint imposed by proteinase inhibitors, especially plasminogen activator inhibitor and tissue inhibitors of metalloproteinases.**

Unanswered Questions

Why is gamete production so wasteful? Billions of sperm are produced, but only a few are ever successful in fertilizing an egg. Does it relate to early forms of reproduction; e.g., those in fish, where the sperm are released into the sea and large numbers are needed to ensure that a few reach the egg? Does the overpopulation of sperm allow selection processes to take place, ensuring that the more abnormal sperm are filtered out before the tube is reached? In the human female, approximately 400 ova are ovulated during a woman's life, yet the ovaries contain millions of eggs at birth.

What is the purpose of capacitation? Is it needed to overcome the protective mechanisms that have been built into the sperm, specifically those that prevent premature release of acrosomal enzymes? Penetration by sperm of the egg is desirable, but invasion of other maternal cells might trigger immunologic reactions against sperm. Capacitation does free the sperm from some inhibitors, thus allowing the hypermotility that may be needed for zona penetration.

Why are there so many abnormal embryos? Current estimates are that 50% of embryos in young women and 70% in older women do not survive to term. Why is there a high rate of embryo loss, and, specifically, why is there a high selection against abnormal embryos? Is it because of intrinsic programming defects within the embryo or an inability of the embryo to produce a signal recognized by the mother, or does the maternal organism in some way recognize abnormality and react against it?

Why has embryo transfer in the human following in vitro fertilization resulted in a low number of takes? Can the uterine environment be manipulated in such a way as to increase successful implantation of in vitro fertilization eggs?

Who is in charge of pregnancy, the mother or her fetus? From the vantage point of an outsider looking in, it seems as if the mother is in charge. But from the fetal point of view, it is overwhelmingly logical that the maternal adaptations of pregnancy are controlled by the fetus. For the fetus, one of the crucial aspects of intrauterine life is its dependency on the effective exchange of nutritive and metabolic products with the mother. It is not surprising that mechanisms exist by which a growing fetus can influence or control the exchange process and, hence, its environment. The methods by which a fetus can influence its own growth and development involve a variety of messages transmitted, in many cases, by hormones. Hormonal messengers from the conceptus can affect metabolic processes, utero-placental blood flow, and cellular differentiation. Furthermore, a fetus may signal its desire and readiness to leave the uterus by hormonal initiation of parturition. This chapter will review the mechanisms by which the fetus establishes influence over important events during pregnancy. The important process of lactation is discussed in [Chapter 16](#).

Steroid Hormones in Pregnancy

Steroidogenesis in the fetoplacental unit does not follow the conventional mechanisms of hormone production within a single organ. Rather, the final products result from critical interactions and interdependence of separate organ systems that individually do not possess the necessary enzymatic capabilities. It is helpful to view the process as consisting of a fetal compartment, a placental compartment (specifically the syncytiotrophoblast), and a maternal compartment. Separately, the fetal and placental compartments lack certain steroidogenic activities. Together, however, they are complementary and form a complete unit that utilizes the maternal compartment as a source of basic building materials and as a resource for clearance of steroids.

Progesterone

In its key location as a way station between mother and fetus, the placenta can utilize precursors from either mother or fetus to circumvent its own deficiencies in enzyme activity. The placenta converts little, if any, acetate to cholesterol or its precursors. Cholesterol, as well as pregnenolone, is obtained from the maternal bloodstream for progesterone synthesis. The fetal contribution is negligible because progesterone levels remain high after fetal demise. Thus, the massive amount of progesterone produced in pregnancy depends on placental-maternal cooperation, although some have argued that the fetal liver is an important source of cholesterol (discussed below).

Progesterone is largely produced by the corpus luteum until about 10 weeks of gestation. Indeed, until approximately the 7th week, the pregnancy is dependent upon

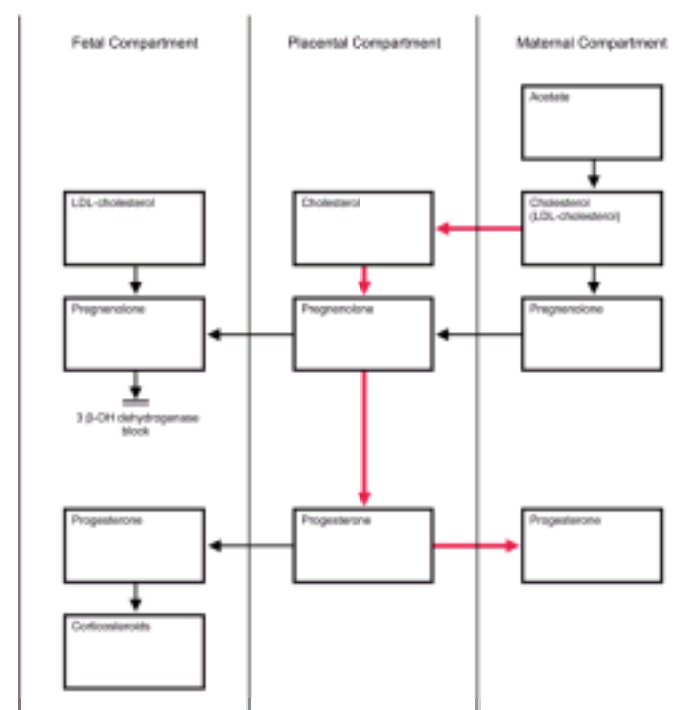

the presence of the corpus luteum.¹ Exogenous support for an early pregnancy (until 10 weeks) requires 100 mg of progesterone daily, associated with a maternal circulating level of approximately 10 ng/mL.² Despite this requirement, patients pregnant after ovarian stimulation with one of the techniques of assisted reproductive technology have concluded a successful pregnancy after experiencing extremely low progesterone levels.^{3,4} Thus, individual variation is great, and very low circulating levels of progesterone can be encountered occasionally in women who experience normal pregnancies. The predictive value, therefore, of progesterone measurements is limited.

After a transition period of shared function between the 7th week and 10th week during which there is a slight decline in circulating maternal progesterone levels, the placenta emerges as the major source of progesterone synthesis and maternal circulating levels progressively increase.^{2,5,6} At term, progesterone levels range from 100 to 200 ng/mL, and the placenta produces about 250 mg per day. Most of the progesterone produced in the placenta enters the maternal circulation.

In contrast to estrogen, progesterone production by the placenta is largely independent of the quantity of precursor available, the uteroplacental perfusion, fetal well being, or even the presence of a live fetus. This is because the fetus contributes essentially no precursor. The majority of placental progesterone is derived from maternal cholesterol that is readily available. At term a small portion (3%) is derived from maternal pregnenolone.

The cholesterol utilized for progesterone synthesis enters the trophoblast from the maternal bloodstream as low-density lipoprotein (LDL)-cholesterol, by means of the process of endocytosis (internalization, as described in [Chapter 2](#)) involving the LDL cell membrane receptors, a process enhanced in pregnancy by estrogen.^{7,8} Hydrolysis of the protein component of LDL may yield amino acids for the fetus, and essential fatty acids may be derived from hydrolysis of the cholesteryl esters. Unlike steroidogenesis elsewhere, it is not clear whether placental progesterone production requires the control of tropic hormones. Although some evidence suggests tropic hormone support is not necessary, other evidence indicates that a small amount of human chorionic gonadotropin (HCG) must be present.^{9,10}

There is evidence in the baboon that estrogen (estradiol) regulates progesterone production in the placenta.¹¹ The fetoplacental units in human and baboon pregnancies are virtually identical. Estradiol increases LDL-cholesterol uptake in baboon trophoblastic tissue by increasing LDL receptor gene transcription, and in human syncytiotrophoblast, estradiol increases progesterone production by means of an increase in LDL uptake.^{11,12} Estrogen also stimulates cholesterol production in the human fetal liver to provide circulating LDL-cholesterol substrate for steroidogenesis.¹³ In addition, estrogen increases placental P450_{scc} enzyme activity that converts cholesterol to pregnenolone, the immediate precursor for progesterone. Because estrogen production ultimately depends on the fetal adrenal gland for precursors, the influence of estrogen on progesterone production would be another example of fetal direction and control in the endocrinology of pregnancy. The proponents of this interaction and dependence of progesterone production on fetal precursors argue that the lack of impact of conditions of estrogen deficiency (e.g., anencephaly, fetal demise) on progesterone production is due to the fact that active, unbound estrogen remains within a critical, effective range, and what is lost reflects the degree of excess production in pregnancy.¹¹

The human decidua and fetal membranes also synthesize and metabolize progesterone.¹⁴ In this case, neither cholesterol nor LDL-cholesterol are significant substrates; pregnenolone sulfate may be the most important precursor. This local steroidogenesis may play a role in regulating parturition.

Amniotic fluid progesterone concentration is maximal between 10 and 20 weeks, and then decreases gradually. Myometrial levels are about 3 times higher than maternal plasma levels in early pregnancy, remain high, and are about equal to the maternal plasma concentration at term.

In early pregnancy, the levels of 17 α -hydroxyprogesterone rise, marking the activity of the corpus luteum. By the 10th week of gestation, this compound has returned to baseline levels, indicating that the placenta has little 17 α -hydroxylase activity. However, beginning about the 32nd week there is a second, more gradual rise in 17 α -hydroxyprogesterone due to placental utilization of fetal precursors.

There are two active metabolites of progesterone, that increase significantly during pregnancy. There is about a 10-fold increase of the 5 α -reduced metabolite, 5 α -pregnane-3,20-dione.¹⁵ This compound contributes to the resistance in pregnancy against the vasopressor action of angiotensin II. The circulating level, however, is the same in normal and hypertensive pregnancies. The concentration of deoxycorticosterone (DOC) at term is 1200 times the nonpregnant levels. Some of this is due to the 3–4-fold increase in cortisol-binding globulin during pregnancy, but a significant amount is due to 21-hydroxylation of circulating progesterone in the kidney.¹⁶ This activity is significant during pregnancy because the rate is proportional to the plasma concentration of progesterone. The fetal kidney is also active in 21-hydroxylation of the progesterone secreted by the placenta into the fetal circulation. At the present time, there is no known physiologic role for DOC during pregnancy.

Progesterone has a role in parturition as will be discussed later in this chapter. It has been suggested that progesterone is important in suppressing the maternal immunological response to fetal antigens, thereby preventing maternal rejection of the trophoblast. Progesterone prepares and maintains the endometrium to allow implantation. The human corpus luteum makes significant amounts of estradiol, but it is progesterone and not estrogen that is required for successful implantation.¹⁷ Because implantation normally occurs about 5–6 days after ovulation, and human chorionic gonadotropin (HCG) must appear by the 10th day after ovulation to rescue the corpus luteum, the blastocyst must successfully implant and secrete HCG within a narrow window of time. In the first 5–6 weeks of pregnancy, HCG stimulation of the corpus luteum results in the daily secretion of about 25 mg of progesterone and 0.5 mg of estradiol. Although estrogen levels begin to increase at 4–5 weeks due to placental secretion, progesterone production by the placenta does not significantly increase until about 10–11 weeks after ovulation.

Progesterone serves as the substrate for fetal adrenal gland production of glucocorticoids and mineralocorticoids; however, cortisol synthesis is also derived from low-density lipoprotein cholesterol (LDL-cholesterol) obtained from the fetal circulation and synthesized in the fetal liver.^{13,18} The fetal zone in the adrenal gland is extremely active, but produces steroids with a 3 β -hydroxy-D⁵ configuration like pregnenolone and dehydroepiandrosterone, rather than 3-keto-D⁴ products such as progesterone. The fetus, therefore, lacks significant activity of the 3 β -hydroxysteroid dehydrogenase, D⁴⁻⁵ isomerase system. Thus, the fetus must borrow progesterone from the placenta to circumvent this lack in order to synthesize the biologically important corticosteroids. In return, the fetus supplies what the placenta lacks: 19-carbon compounds to serve as precursors for estrogens.

Steroid levels have been compared in maternal blood, fetal blood, and amniotic fluid obtained at fetoscopy in women undergoing termination of pregnancy at 16–20 weeks gestation.¹⁹ Cortisol, corticosterone, and aldosterone are definitely secreted by the fetal adrenal gland independently of the mother. The fetal arterial-venous differences confirm that placental progesterone is a source for fetal adrenal cortisol and aldosterone.

Estrogens

Estrogen production in pregnancy is under the control of the fetus and is a fundamental signaling method by which the fetus directs important physiologic processes

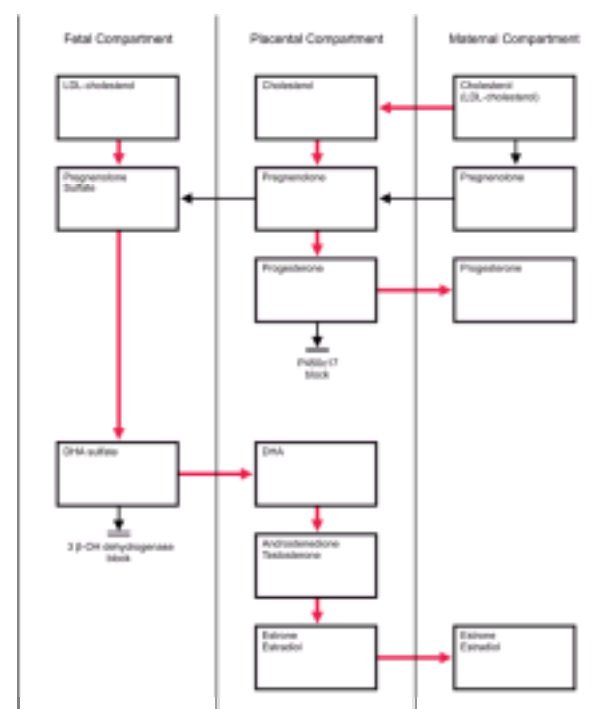

that affect fetal well-being. Estrogen influences progesterone production, uteroplacental blood flow, mammary gland development, and fetal adrenal gland function. ¹¹

The basic precursors of estrogens are 19-carbon androgens. However, there is a virtual absence of 17 α -hydroxylation and 17–20 desmolase (lyase) activity (P450c17) in the human placenta. As a result, 21-carbon products (progesterone and pregnenolone) cannot be converted to 19-carbon steroids (androstenedione and dehydroepiandrosterone). Like progesterone, estrogen produced by the placental aromatase (P450arom) enzyme system must derive precursors from outside the placenta.²⁰

The androgen compounds utilized for estrogen synthesis in human pregnancy are, in the early months of gestation, derived from the maternal bloodstream. By the 20th week of pregnancy, the vast majority of estrogen excreted in the maternal urine is derived from fetal androgens. In particular, approximately 90% of estriol excretion can be accounted for by dehydroepiandrosterone sulfate (DHAS) production by the fetal adrenal gland.^{20, 21} The high output of DHAS by the fetal zone is due to low 3 β -hydroxysteroid dehydrogenase gene expression.²² Removed into cell culture conditions, this gene becomes active in response to adrenocorticotrophic hormone (ACTH).

The fetal endocrine compartment is characterized by rapid and extensive conjugation of steroids with sulfate. This is a protective mechanism, blocking the biologic effects of potent steroids present in such great quantities. In order to utilize fetal precursors, the placenta must be extremely efficient in cleaving the sulfate conjugates brought to it via the fetal bloodstream. Indeed, the sulfatase activity in the placenta is rapid and quantitatively very significant. It is recognized that a deficiency in placental sulfatase is associated with low estrogen excretion, giving clinical importance to this metabolic step. This syndrome will be discussed in greater detail later in this chapter.

The fetal adrenal provides DHAS as precursor for placental production of estrone and estradiol. However, the placenta lacks 16 α -hydroxylation ability, and estriol with its 16 α -hydroxyl group must be derived from an immediate fetal precursor. The fetal adrenal, with the aid of 16 α -hydroxylation in the fetal liver, provides the 16 α -hydroxydehydroepiandrosterone sulfate for placental estriol formation. After birth, neonatal hepatic 16 α -hydroxylation activity rapidly disappears. The maternal contribution of DHAS to total estrogen synthesis must be negligible because, in the absence of normal fetal adrenal glands (as in an anencephalic infant), maternal estrogen levels and excretion are extremely low. The fetal adrenals secrete more than 200 mg of DHAS daily, about 10 times more than the mother.²³ Estriol is the estrogen produced in greatest quantity during pregnancy; estrone and estradiol are derived equally from fetal and maternal precursors.²¹

The profiles of the unconjugated compounds in the maternal compartment for the 3 major estrogens in pregnancy are:

1. A rise in estrone begins at 6–10 weeks, and individual values range from 2 to 30 ng/mL at term.²⁴ This wide range in normal values precludes the use of estrone measurements in clinical applications.
2. A rise in estradiol begins in weeks 6–8 when placental function becomes apparent.^{2, 25, 26} Individual estradiol values vary between 6 and 40 ng/mL at 36 weeks of gestation and then undergo an accelerated rate of increase.²⁴ At term, an equal amount of estradiol arises from maternal DHAS and fetal DHAS, and its

importance in fetal monitoring is negligible.

3. Estriol is first detectable at 9 weeks when the fetal adrenal gland secretion of precursor begins. Estriol concentrations plateau at 31–35 weeks and then increase again at 35–36 weeks.²⁷

During pregnancy, estrone and estradiol excretion is increased about 100 times over nonpregnant levels. However, the increase in maternal estriol excretion is about a thousand-fold. The traditional view that estriol is a weak estrogen metabolite is not accurate. A weak estrogen provided in high concentrations can produce a biologic response equivalent to that of estradiol.²⁶ Because of its high production rate and concentration, estriol is an important hormone in pregnancy. The maternal level of estradiol is higher than in the fetus; in contrast, the estriol level in the fetus is greater than in the mother.

The maternal cardiovascular adaptations to pregnancy that are so necessary to serve the fetus are appropriately under the influence of the fetus and significantly regulated by estrogen.²⁹ Blood volume is increased by estrogen stimulation of the maternal and trophoblastic renin-angiotensin systems, and uteroplacental blood flow, that is so critical for the fetus, is influenced by the vasodilatory effects of estrogen.

The enzyme responsible for estrogen synthesis is the cytochrome P450 aromatase enzyme (P450arom), the product of the CYP19 gene.³⁰ The CYP19 gene is regulated in various tissues by tissue-specific promoters. The placenta, with its huge capacity for estrogen synthesis, uses a powerful, unique promoter that allows specific regulation. An autosomal recessive disorder due to mutations in the P450arom gene is associated with a failure to convert androgen precursors to estrogen by placental aromatase.³¹ Consequently, a female fetus and the mother can undergo virilization. Nevertheless, growth and development of the fetus are not impaired, and this disorder raises the question: how much, if any, estrogen is essential in human pregnancy? Is this another example of backup mechanisms operating to achieve the goal?

Normally, placental aromatization is so efficient that little androgen presented to the placenta escapes.³² For this reason, fetuses are well protected against masculinization, and even in the presence of an androgen-secreting tumor, extremely large amounts of aromatizable androgens or the secretion of nonaromatizable androgens are required to produce unwanted virilization.

The estrogens presented to the maternal bloodstream are rapidly metabolized by the maternal liver prior to excretion into the maternal urine as a variety of more than 20 products. The bulk of these maternal urinary estrogens is composed of glucosiduronates conjugated at the 16-position. Significant amounts of the 3-glucosiduronate and the 3-sulfate-16-glucosiduronate are also excreted. Only approximately 8–10% of the maternal blood estriol is unconjugated.

The Fetal Adrenal Cortex

The fetal adrenal cortex is differentiated by 8–9 weeks gestational age into a thick inner fetal zone and a thin outer definitive zone, the source of cortisol and the forerunner of the adult cortex.³³ Early in pregnancy, adrenal growth and development are remarkable, and the gland achieves a size equal to or larger than that of the kidney by the end of the first trimester. After 20–24 weeks, the adrenal glands slowly decrease in size until a second spurt in growth begins at about 34–35 weeks. The gland remains proportionately larger than the adult adrenal glands. After delivery, the fetal zone (about 80% of the bulk of the gland) rapidly involutes to be replaced by simultaneous expansion of the adrenal cortex composed of the zona glomerulosa, the zona fasciculata, and the zona reticularis. Thus, the specific steroidogenic characteristics of the fetus are associated with a specific adrenal morphology that is dependent on specific factors present during intrauterine life.

Fetal dehydroepiandrosterone (DHA) and DHAS production rises steadily concomitant with the increase in the size of the fetal zone and adrenal weight.³⁴ DHA and DHAS are the major secretory products of the fetal zone because 3 β -hydroxysteroid dehydrogenase-isomerase activity and the expression of this enzyme's gene are suppressed.²² The well-known increase in maternal estrogen levels is significantly influenced by the increased availability of fetal DHAS as a precursor. Indeed, the accelerated rise in maternal estrogen levels near term can be explained, in part, by an increase in fetal DHAS. The stimulus for the substantial adrenal growth and steroid production has been a puzzle.

Early in pregnancy, the adrenal gland can grow and function without ACTH, perhaps in response to HCG.³⁵ After 15–20 weeks, fetal ACTH is required. However, during the last 12–14 weeks of pregnancy when fetal ACTH levels are declining, the adrenal quadruples in size.³⁵ Because pituitary prolactin is the only fetal pituitary hormone to increase throughout pregnancy, paralleling fetal adrenal gland size changes, it was proposed that fetal prolactin is the critical tropic substance. In experimental preparations, however, only ACTH exerts a steroidogenic effect. There is no fetal adrenal response to prolactin, HCG, growth hormone, melanocyte-stimulating hormone (MSH), or thyrotropin-releasing hormone (TRH).^{36,37} Furthermore, in patients treated with bromocriptine, fetal blood prolactin levels are suppressed, but DHAS levels are unchanged.³⁸ Nevertheless, interest in prolactin persists because both ACTH and prolactin can stimulate steroidogenesis in vivo in the fetal baboon.³⁹

There is no question that, in the second half of pregnancy, ACTH is essential for the morphologic development and the steroidogenic mechanism of the fetal adrenal gland.^{40,41} ACTH activates adenylate cyclase, leading to steroidogenesis. Soon the supply of cholesterol becomes rate limiting. Further ACTH action results in an increase in LDL receptors, leading to an increased uptake of circulating LDL-cholesterol, largely derived from the fetal liver.¹⁸ With internalization of LDL-cholesterol, hydrolysis by lysosomal enzymes of the cholesteryl ester makes cholesterol available for steroidogenesis. For this reason, fetal plasma levels of LDL are low, and after birth newborn levels of LDL rise as the fetal adrenal involutes. In the presence of low levels of LDL-cholesterol, the fetal adrenal is capable of synthesizing cholesterol de novo.⁴² Thus, near term, both de novo synthesis and utilization of LDL-cholesterol are necessary to sustain the high rates of DHAS and estrogen formation. In addition, ACTH increases adrenal response by increasing the expression of its own receptor.⁴³

The tropic support of the fetal adrenal gland by ACTH from the fetal pituitary is protected by placental estrogen. The placenta prevents maternal cortisol from reaching the fetus by converting cortisol to cortisone. This 11 β -hydroxysteroid dehydrogenase activity is stimulated by placental estrogen.⁴⁴ Regulation of this enzyme by estrogen thus influences fetal ACTH secretion. With increasing estrogen levels in late gestation, even greater 11 β -hydroxysteroid dehydrogenase activity would result in even less maternal cortisol reaching the fetal circulation. Thus, it is proposed that, in late gestation, fetal ACTH secretion increases, the fetal adrenal gland undergoes greater maturation, and fetal cortisol synthesis from endogenous cholesterol increases.⁴⁵ A relative deficiency in 11 β -hydroxysteroid dehydrogenase type 1 (the placental isoform) is correlated with low birth weight, which in turn is correlated with insulin resistance, abnormal lipids, and hypertension in adult life.^{46,47} This enzyme is abundantly expressed in syncytiotrophoblast at the interface between fetal tissue and maternal blood.⁴⁸ Expression of the second isoform, type 2 11 β -hydroxysteroid dehydrogenase, is found in the liver and the distal nephron of the kidney where enzyme activity excludes glucocorticoids from mineralocorticoid receptors. Fetal hypoxemia down-regulates fetal renal expression of the type 2 enzyme, potentially affecting glucocorticoid availability.⁴⁹

It has been suggested that rising fetal cortisol secretion competes with progesterone for the glucocorticoid receptor in the placenta, thus blocking the inhibitory action of progesterone on corticotropin-releasing hormone (CRH) synthesis, leading to an increase in CRH.⁵⁰ Placental production of CRH and the size of the fetal adrenal gland are closely correlated in several primates, both reaching a peak in humans at the time of parturition. The increase in CRH would augment fetal ACTH secretion, producing adrenal growth and even more fetal cortisol in a positive feedback relationship, as well as more DHAS to serve as precursor for the increase in estrogen that occurs prior to parturition. Another possibility is CRH direct stimulation of DHAS by the fetal adrenal gland, as has been demonstrated in vitro.⁵¹

Adrenal gland steroidogenesis involves autocrine and paracrine regulation by various growth factors.³³ Fetal adrenal cells produce inhibin, and the α -subunit (present only in inhibin) is preferentially increased by ACTH.^{52,53} In the fetal adrenal, the β -subunit is not expressed; thus, inhibin A and activin A are the principal forms. Inhibin consists of two dissimilar peptides, α - and β -subunits, linked by disulfide bonds. Inhibin A and inhibin B each contain an identical α -subunit, but distinct β -subunits. Activin contains two subunits that are identical to the β -subunits of the inhibins.

The Two Forms of Inhibin (Heterodimers)

Inhibin-A:	Alpha-Beta _A
Inhibin-B:	Alpha-Beta _B

The Three Forms of Activin (Homodimers)

Activin-A:	Beta _A -Beta _A
Activin-AB:	Beta _A -Beta _B
Activin-B:	Beta _B -Beta _A

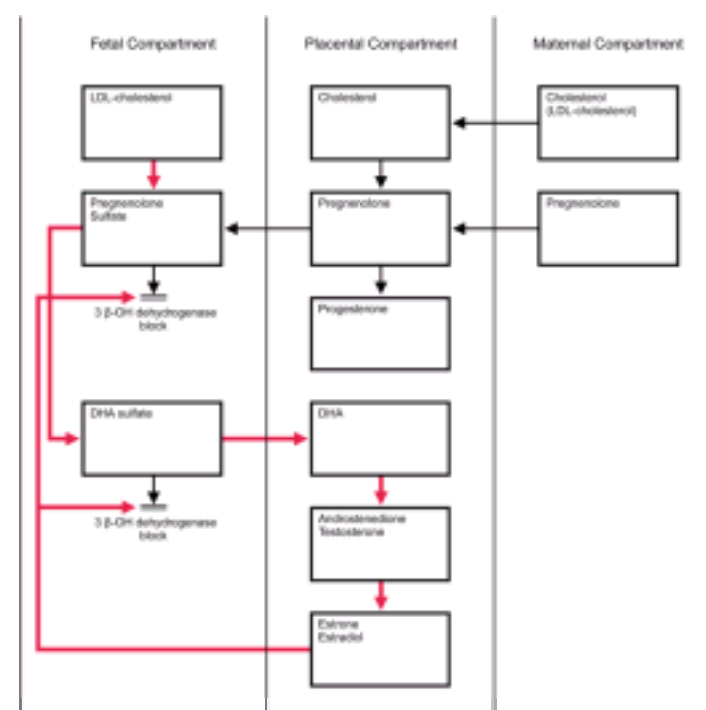

Activin enhances ACTH-stimulated steroidogenesis while inhibiting mitogenesis in human fetal zone adrenal cells.⁵² This effect on steroidogenic activity is not present in adult adrenal cells. In vitro, activin enhances a shift in fetal adrenal cells from ACTH stimulation of DHAS production to cortisol production. This shift is analogous to the shift that occurs after birth. Perhaps activin plays this role in the remodeling of the fetal zone in the newborn. A specific action for inhibin in fetal adrenal cells has not been described.

We should not expect the fetal adrenal gland to be an exception to the ubiquitous presence and actions of all growth factors.³³ Basic fibroblast growth factor has potent mitogenic activity mediating the growth response of the fetal adrenal cortex to ACTH. Evidence indicates that the epidermal growth factor receptor is activated in the fetal adrenal, but the ligand using this receptor is probably transforming growth factor- α . Like activin, transforming growth factor- β inhibits fetal zone cellular proliferation, and in addition, suppresses steroidogenesis.

The insulin-like growth factors (IGF-I and IGF-II) are important in mediating the tropic effects of ACTH, particularly increasing adrenal responsiveness to ACTH in the second half of pregnancy.⁵⁴ IGF-II production in the fetal adrenal is very significant and is stimulated by ACTH. IGF-II is believed to be important in prenatal growth.⁵⁵ The abundance of IGF-II in the fetal adrenal gland implicates this growth factor as a mediator of ACTH-induced growth.⁵⁶ Both IGF-I and IGF-II are equally mitogenic in a cell culture system of fetal adrenal cells and enhance the proliferation stimulated by basic fibroblast growth factor and epidermal growth factor.⁵⁶ However, only transcription of IGF-II is stimulated by ACTH. IGF-II augments ACTH-stimulated steroidogenesis in the fetal adrenal, specifically by increasing the expression of P450c17.⁵⁴ Thus, the growth-promoting and steroidogenic effects of ACTH are mediated by various growth factors, with a principal role played by IGF-II. In this regard, the fetal adrenal differs from the adult adrenal where IGF-I is predominant; however, IGF-II is able to modulate responsiveness to ACTH in the fetal adrenal by activating the IGF-I receptor.

Steroidogenic factor-1 (SF-1) and DAX-1 (named for the location of its gene on the X chromosome) are nuclear receptors for which specific ligands have not been identified ("orphan receptors"). SF-1 influences the expression of genes that encode steroidogenic enzymes, and when genetic expression of SF-1 is disrupted in mice, gonads and adrenal glands fail to develop.^{57, 58} Mutations in the DAX-1 gene result in adrenal hypoplasia, and DAX-1 is believed to work with SF-1 in regulating development and function of steroid producing tissues.⁵⁹

The unique features of the fetal adrenal gland can be ascribed to its high-estrogen environment. Tissue culture studies have demonstrated that hormonal peptides of pituitary or placental origin are not the factors that are responsible for the behavior of the fetal adrenal gland.^{60, 61 and 62} Estrogens at high concentration inhibit 3 β -hydroxysteroid dehydrogenase-isomerase activity in the fetal adrenal gland and, in the presence of ACTH in conjunction with IGF-II, enhance the secretion of dehydroepiandrosterone (DHA).⁶³ Estradiol concentrations of 10–100 ng/mL are required to inhibit cortisol secretion.⁶⁴ The total estrogen concentrations in the fetus are easily in this range. A study of the kinetics of 3 β -hydroxysteroid dehydrogenase activity in human adrenal microsomes reveals that all steroids are inhibitory, and most notably, estrone and estradiol at levels found in fetal life cause almost total inhibition.⁶⁵ In a study utilizing a human adrenocortical cell line, estradiol in high concentrations inhibited 3 β -hydroxysteroid dehydrogenase and the mechanism appeared to be independent of the estrogen receptor.⁶⁶ The hyperplasia of the fetal adrenal may be the result of the high ACTH levels due to the relatively low cortisol levels, a consequence of the enzyme inhibition.

The development of the adrenal gland during human fetal life and during the neonatal period is paralleled in the baboon.⁶⁷ The adrenal cortex of the fetal baboon is characterized by the same deficiency in 3 β -hydroxysteroid dehydrogenase as that seen in the human, with the same diversion of steroidogenesis into production of DHAS. Treatment of the neonatal baboon with estrogens and progesterone did not halt the regression of the fetal zone and DHAS production, arguing against the hypothesis that the fetal zone is dependent on an estrogen-induced deficiency in 3 β -hydroxysteroid dehydrogenase. Treatment of the pregnant baboon with estradiol reduced production of DHAS.⁶⁸ It continues to be uncertain, however, whether the internal microenvironment of the adrenal gland can be affected by the exogenous administration of steroids. In the monkey, epidermal growth factor can increase the 3 β -hydroxysteroid dehydrogenase content in the fetal adrenal gland, but it is not clear how this action is regulated.⁶⁹

This explanation (estrogen regulation of 3 β -hydroxysteroid dehydrogenase) is further challenged by in vitro studies of human fetal zone cells indicating that estradiol and IGF-II combine to direct steroidogenesis to DHAS in a mechanism not due to inhibition of 3 β -hydroxysteroid dehydrogenase.⁶³

Nevertheless, it is an attractive and useful hypothesis to view the principal mission of the fetal adrenal as providing DHAS as the basic precursor for placental estrogen production. Estrogen, in turn, feeds back to the adrenal to direct steroidogenesis along the D⁵ pathway to provide even more of its precursor, DHAS. Thus far, this is the only known function for DHAS. With birth and loss of exposure to estrogen, the fetal adrenal gland quickly changes to the adult type of gland.

Measurement of Estrogen in Pregnancy

Because pregnancy is characterized by a great increase in maternal estrogen levels, and estrogen production is dependent on fetal and placental steroidogenic cooperation, the amount of estrogen present in the maternal blood or urine reflects both fetal and placental enzymatic capability and, hence, well-being. Attention focused on estriol because 90% of maternal estriol is derived from fetal precursors. The end product to be assayed in the maternal blood or urine is influenced by a multitude of factors. Availability of precursor from the fetal adrenal gland is a prime requisite as well as the ability of the placenta to perform its conversion steps. Maternal metabolism of the product as well as the efficiency of maternal renal excretion of the product can modify the daily amount of estrogen in the urine. Blood flow to any of the key organs in the fetus, placenta, and mother becomes important.^{70, 71} Fetal hypoxemia due to reduced uteroplacental blood flow is associated with a marked increase in adrenal androgen production in response to an increase in fetal ACTH and, in response to the availability of androgen precursors, an increase in maternal estrogen levels.⁷² The response to acute stress is in contrast to the effect of chronic uteroplacental insufficiency which is associated with a reduction in fetal androgens and maternal estrogens. In addition, drugs or diseases can affect any level in the cascade of events leading up to the assay of estrogen.

For years, measurement of estrogen in a 24-hour urine collection was the standard hormonal method of assessing fetal well-being. This was replaced by radioimmunoassay of unconjugated estriol in the plasma.⁷³ Because of its short half-life (5–10 minutes) in the maternal circulation, unconjugated estriol has less variation than urinary or total blood estriol. However, assessment of maternal estriol levels has been superseded by various biophysical fetal monitoring techniques such as nonstress testing, stress testing, and measurement of fetal breathing and activity. Modern screening for fetal aneuploidy (discussed later in the chapter) utilizes 3 markers in the maternal circulation: alpha fetoprotein, human chorionic gonadotropin, and unconjugated estriol.

Amniotic Fluid Estrogen Measurements

Amniotic fluid estriol is correlated with the fetal estrogen pattern rather than the maternal. Most of the estriol in the amniotic fluid is present as 16-glucosiduronate or

as 3-sulfate-16-glucosiduronate. A small amount exists as 3-sulfate. Very little unconjugated estriol is present in the amniotic fluid because free estriol is rapidly transferred across the placenta and membranes. Estriol sulfate is low in concentration because the placenta and fetal membranes hydrolyze the sulfated conjugates, and the free estriol is then passed out of the fluid. Because the membranes and the placenta have no glucuronidase activity, the glucosiduronate conjugates are removed slowly from the fetus. The glucosiduronates therefore predominate in the fetal urine and the amniotic fluid. Because of the slow changes in glucosiduronates, measurements of amniotic fluid estriol have wide variations in both normal and abnormal pregnancies. An important clinical use for amniotic fluid estrogen measurements has not emerged.

Estetrol

Estetrol (15a-hydroxyestriol) is formed from a fetal precursor, and is very dependent upon 15a-hydroxylation activity in the fetal liver. The capacity for 15a-hydroxylation of estrogens increases during fetal life, reaching a maximum at term. This activity then declines during infancy and is low, absent, or undetectable in adults. There is no clinical use for maternal blood or urine estetrol measurements during pregnancy. The clinical use of maternal blood and urine estetrol measurements is of no advantage over the usual estriol assessment.

Placental Sulfatase Deficiency

There is an X-linked metabolic disease characterized by a placental sulfatase deficiency in the syncytiotrophoblast, and postnatally, ichthyosis, occurring in about 1 in 2000–3000 newborn males.⁷⁴ Patients with the placental sulfatase disorder are unable to hydrolyze DHAS or 16a-hydroxy-DHAS, and, therefore, the placenta cannot form normal amounts of estrogen. A deficiency in placental sulfatase is usually discovered when patients go beyond term and are found to have extremely low estriol levels and no evidence of fetal distress. The patients usually fail to go into labor and require delivery by cesarean section. Most striking is the failure of cervical softening and dilatation; thus, cervical dystocia occurs that is resistant to oxytocin stimulation. There are many case reports of this deficiency, almost all detected by finding low estriol levels. It has been suggested that mothers who are carriers of this disorder are at increased risk for intrauterine growth retardation and perinatal complications even if the fetus is not affected.⁷⁵ However, a careful analysis of unexplained low estriol levels concluded that this is a rare occurrence (about 3 per 10,000 pregnancies), and that perinatal complications in pregnancies at risk for placental sulfatase deficiency are not increased (other than a higher cesarean section rate).⁷⁶ All newborn children, with a few exceptions, have been male. The steroid sulfatase X-linked recessive ichthyosis locus (the steroid sulfatase gene) has been mapped to the distal short arm portion of the X chromosome. There are no known geographic or racial factors that affect the gene frequency.

The characteristic steroid findings are as follows: extremely low estriol and estetrol levels in the mother with extremely high amniotic fluid DHAS and normal amniotic fluid DHA and androstenedione. The normal DHA and androstenedione with a high DHAS rule out congenital adrenal hyperplasia. The small amount of estriol that is present in these patients probably arises from 16a-hydroxylation of DHAS in the maternal liver, thus providing 16a-hydroxylated DHA to the placenta for aromatization to estriol. Maternal estrone and estradiol are also low but not as markedly reduced because of their utilization of maternal precursors. Measurement in maternal urine of steroids derived from fetal sulfated compounds is a simple and reliable means of prenatal diagnosis. Demonstration of a high level of DHAS in the amniotic fluid is reliable. To establish the diagnosis with certainty, a decrease in sulfatase activity should be demonstrated in an in vitro incubation of placental tissue. The clinician should keep in mind that fresh tissue is needed for this procedure because freezing lowers enzyme activity. Alternatively, steroid sulfatase activity can be assayed in leukocytes.

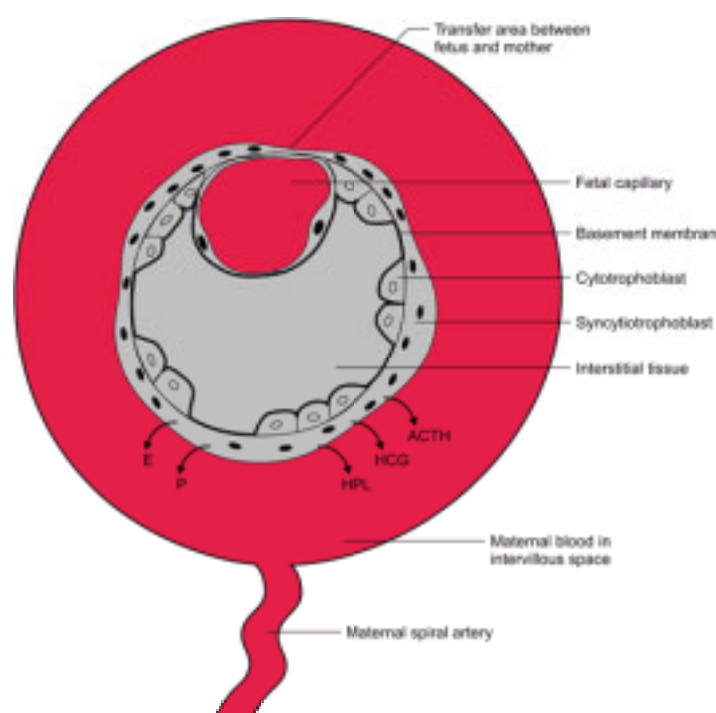

It is now recognized that steroid sulfatase deficiency is present in other tissues and can persist after birth. These children develop ichthyosis beginning between birth and 6 months of age, characterized by hyperkeratosis (producing scales on the neck, trunk, and palms) and associated with mild corneal opacities, pyloric stenosis, and cryptorchidism. The skin fibroblasts have a low activity of steroid sulfatase, and scale formation that occurs early in the first year of life is thought to be due to an alteration in the cholesterol:cholesteryl ester ratio (due to the accumulation of cholesterol sulfate). This inherited disorder, thus, represents a single entity: placental sulfatase deficiency and X-linked ichthyosis, both reflecting a deficiency of microsomal sulfatase. A family history of scaling in males (as well as repeated postdate pregnancies and cesarean sections) should prompt a consideration for prenatal diagnosis. Because the clinical use of estriol measurements has declined, there is no effective method to identify the presence of this problem in women with normal obstetrical histories. However, a low maternal level of unconjugated estriol can be encountered with multiple marker screening (discussed later in this chapter). Furthermore, consideration should be given to antenatal screening by estriol measurement in pregnancies in which a male fetus is present and there is a previous history of a growth-retarded or stillborn male. However, perinatal outcome is good even when placental sulfatase deficiency is not known to be present and only a very small number of affected boys have serious manifestations of the disorder; therefore, it is difficult to justify the need for antenatal diagnosis.⁷⁶

The Differential Diagnosis of an Extremely Low Estriol

1. Impending or present fetal demise.
2. Adrenal hypofunction.
3. Placental sulfatase deficiency.
4. Placental aromatase deficiency.
5. Drug-related effects.

Protein Hormones of Pregnancy

The placental villus is composed of trophoblast, mesenchymal cells, and fetal blood vessels. The two main trophoblastic layers consist of the cytotrophoblast, separate mononuclear cells prominent early in pregnancy and sparse late in pregnancy, and the syncytiotrophoblast, a continuous multinuclear layer on the surface of the villi. The cytotrophoblast is the basic placental stem cell from which the syncytiotrophoblasts arise by differentiation. The syncytiotrophoblast is, therefore, the functional cell of the placenta, the major site of hormone and protein production. Control of this important cellular differentiation is still not understood; however, the process is influenced by HCG and, undoubtedly, a variety of growth factors.⁷⁷ The protein hormone system is complicated because individual peptides can have multiple functions.⁷⁸ The surface of the syncytiotrophoblast is in direct contact with the maternal blood in the intervillous space. This may be a reason why placental proteins are secreted preferentially into the mother.

Hypothalamic-like Releasing Hormones

The human placenta contains many releasing and inhibiting hormones, including gonadotropin-releasing hormone (GnRH), corticotropin-releasing hormone (CRH), thyrotropin-releasing hormone (TRH) and somatostatin.⁷⁹ Because of the presence of hypothalamic-like releasing hormones in an organ that produces tropic hormones, we are motivated to construct a system of regulation analogous to the hypothalamic-pituitary axis. However, as we shall see, this proves to be very difficult.

Immunoreactive GnRH can be localized in the cytotrophoblast and syncytiotrophoblast. Evidence indicates that placental GnRH regulates placental steroidogenesis and release of prostaglandins as well as HCG.^{79, 80, 81, 82 and 83} In some studies, the highest amount of GnRH was present early in pregnancy when the number of cytotrophoblasts is greatest and HCG secretion reaches its peak; however, others report relatively constant levels throughout pregnancy.^{84, 85} The placental receptors for GnRH have a lower affinity than that of GnRH receptors in the pituitary, ovary, and testis.^{86, 87} This reflects the situation in which the binding site is in close proximity to the site of secretion for the regulatory hormone. A higher affinity is not necessary because of the large amount of GnRH available in the placenta, and the low affinity receptors avoid response to the low levels of circulating GnRH. GnRH receptors, present in both cytotrophoblasts and syncytiotrophoblasts, are produced in a pattern that parallels the curve of HCG secretion, further evidence that placental GnRH and its receptor regulate HCG secretion.⁸⁸ GnRH release is increased by estrogen, activin A, insulin, and prostaglandins, and inhibited by progesterone, endogenous opiates, inhibin, and follistatin.⁷⁸

CRH, identical in structure to hypothalamic CRH, is produced in the trophoblast, the fetal membranes, and the decidua.⁷⁸ Its production is regulated by steroids, decreased by progesterone and, in contrast to the usual negative feedback action in the hypothalamus, increased by glucocorticoids.⁸⁹ These interactions are consistent with the increase in fetal and maternal ACTH and cortisol associated with the last weeks of pregnancy and labor. Placental CRH is further regulated (as in the hypothalamus) by an array of substances such as vasopressin, norepinephrine, angiotensin-II, prostaglandins, neuropeptide Y, and oxytocin. CRH release is stimulated by activin and interleukin, and inhibited by inhibin and nitric oxide. The progressive increase in maternal CRH levels during pregnancy is due to the secretion of intrauterine CRH into the maternal circulation. The highest levels are found at labor and delivery. A binding protein for CRH exists in the human circulation, and it is produced in placenta, membranes and decidua.⁹⁰ Maternal levels of this binding protein are not different in pregnancy until a slight increase at 35 weeks, followed by a major decrease until term. Maternal CRH levels are elevated in women with pregnancies under stress; e.g., with preeclampsia and preterm labor.⁷⁸ The increase in placental CRH may be a response to the activation of fetal pituitary ACTH and adrenal cortisol secretion in the presence of hypoxemia.

Trophoblast, amnion, chorion, and decidua also produce a peptide similar to CRH, named urocortin, that binds to CRH receptors and CRH-binding protein.⁹¹ Little is yet known about this peptide.

Human Chorionic Gonadotropin (HCG)

Human chorionic gonadotropin is a glycoprotein, a peptide framework to which carbohydrate side chains are attached.⁹² Alterations in the carbohydrate component (about one-third of the molecular weight) change the biologic properties. For example, the long half-life of HCG is approximately 24 hours as compared with 2 hours for luteinizing hormone (LH), a 12-fold difference, which is due mainly to the greater sialic acid content of HCG. As with the other glycoproteins, follicle-stimulating hormone (FSH), LH, and thyroid-stimulating hormone (TSH), HCG consists of two subunits, noncovalently linked by disulfide bonds, called alpha (α) and beta (β).⁹³ The α-subunit in these glycoprotein hormones is identical, consisting of 92 amino acids. Unique biological activity as well as specificity in radioimmunoassays is attributed to the molecular and carbohydrate differences in the β-subunits (see “[Heterogeneity](#)” in Chapter 2).

β-HCG is the largest β-subunit, containing a larger carbohydrate moiety and 145 amino acid residues, including a unique carboxyl terminal tailpiece of 24 amino acid groups. It is this unique part of the HCG structure that allows the production of highly specific antibodies and the utilization of highly specific immunologic assays. The extended sequence in the carboxyl-terminal region of β-HCG contains 4 sites for glycosylation, the reason why HCG is glycosylated to a greater extent than LH, a difference that is responsible for the longer circulating half-life for HCG.

All human tissues appear to make HCG, but the placenta is different in having the ability to glycosylate the protein, thus reducing its rate of metabolism and giving it biologic activity through a long half-life. The carbohydrate components of the glycoproteins are composed of fructose, galactose, mannose, galactosamine, glucosamine, and sialic acid. Although the other sugars are necessary for hormonal function, sialic acid is the critical determinant of biologic half-life. Removal of sialic acid residues in HCG, FSH, and LH leads to very rapid elimination from the circulation.

These differences in structure are associated with a different promoter and transcriptional site that is located upstream in the HCG b-subunit gene compared with the transcriptional site in the LH b-subunit gene. The HCG b-subunit promoter does not contain steroid hormone response elements, allowing HCG secretion to escape feedback regulation by the sex steroids, in contrast to FSH and LH.

Genes for tropic hormones contain promoter and enhancer or inhibitor regions located in the 5' flanking regions upstream from the transcription site. These sites respond to second messengers (cyclic AMP) as well as steroids and other yet unknown regulators. The protein cores of the two glycoprotein subunits are the products of distinct genes.⁹⁴ Using recombinant DNA technology, it has been demonstrated that there is a single human gene for the expression of the α -subunit. The gene for the α -subunit shared by FSH, LH, HCG, and TSH is located on chromosome 6p21.1–23. A single promoter site subject to multiple signals and hormones regulates transcription of the α -gene in both placenta and pituitary. The α -subunit gene is expressed in several different cell types, but the b-subunit genes are restricted in cell type. The TSH b-gene is expressed only in thyrotrophs regulated by thyroid hormone; the FSH b-gene is expressed in gonadotrophs regulated by GnRH, activin, inhibin, and gonadal steroids; the LH b-gene, also expressed in gonadotrophs, is regulated by GnRH and is unaffected by activin and inhibin.⁹⁵

The α -subunit gene requires the activation of distinct regulatory elements in thyrotroph and gonadotroph cells, as well as in the placenta. It is the activation of these cell-specific elements that produces tissue specificity for α -gene expression. In gonadotrophs, the GnRH-signaling pathway for α -gene transcription utilizes phosphorylation of diacyl glycerol (DAG) and inositol triphosphate (IP_3) that lead to a release of intracellular calcium stores. GnRH also stimulates the influx of calcium at the cell membrane. DAG, IP_3 , and calcium work together to stimulate protein kinase C activity. Protein kinase regulation of the α -promoter is a principal part of the overall mechanism. This pituitary process is influenced by multiple factors including growth factors and gonadal steroids. In the placenta, the mechanism also utilizes specific regulatory elements, but the primary signal is mediated by the cyclic AMP-protein kinase A pathway.

The genes that encode for the b-subunits of LH, HCG, and TSH are located in a cluster on chromosome 19q13.3. There are 6 genes for the b-subunit of HCG, and only one for b-LH.⁹⁶ Transcription for the 6 HCG genes, each with different promoter activity, varies, and it is not certain why HCG requires multigenic expression (perhaps this is necessary to reach the extremely high level of production in early pregnancy). It is thought that b-HCG evolved relatively recently from b-LH, and the unique amino acid terminal extension of b-HCG arose by a read-through mutation of the translation stop codon in the b-LH gene; the DNA sequences of the b-HCG genes and the b-LH gene are 96% identical.⁹⁶ Only primates and horses have been demonstrated to have genes for the b-subunit of chorionic gonadotropin. In contrast to human chorionic gonadotropin, equine chorionic gonadotropin exerts both LH and FSH activities in many mammalian species because it contains peptide sequences in its b-subunit that are homologous to those in the pituitary gonadotropins of other species. The equine b-chorionic gonadotropin gene is identical to the equine b-LH gene, and although the primate b-HCG gene evolved from the same ancestral b-LH gene, the horse chorionic gonadotropin gene evolved in a different way. The b-LH gene is not expressed in the placenta.

The placenta-specific expression of b-HCG is due to several differences in DNA sequences between the b-HCG and b-LH genes.⁹⁵ The cyclic AMP-mediated enhancement of the b-HCG promoter is influenced by several regulatory proteins. The study of the b-subunit genes has been hampered by difficulties in maintaining glycoprotein-producing cell lines. The availability of choriocarcinoma cell lines, however, has allowed greater investigation of the b-HCG genes.

The genetic complexity for the transcription of b-HCG raises the possibility for mutations of these genes as causes of reproductive problems. A search for b-HCG gene deletions in women with recurrent miscarriage or unexplained infertility and for duplications in women with gestational trophoblastic neoplasia found only normal gene structures.⁹⁷

HCG production and secretion are the result of complex interactions among the sex steroids, cytokines, GnRH, and growth factors. GnRH is synthesized by placental cells; GnRH receptors are present on placental cells, and GnRH stimulates the secretion of HCG and the steroid hormones in *in vitro* studies of placental cells.^{98, 99} and ¹⁰⁰ Similar responses can be demonstrated with other peptides, such as interleukin-1b.¹⁰¹ Similar to opiate action in the hypothalamus, the endorphins are a major inhibiting influence on HCG secretion.¹⁰² Also similar to the pituitary secretion of gonadotropins, inhibin restrains and activin enhances the GnRH-HCG system, with a positive influence of estrogen and a negative impact by progesterone.^{103, 104} Follistatin, by binding activin, prevents the stimulatory activity of activin. Other growth factors, specifically IGF-I, IGF-II, TGF- α , and EGF, also influence HCG secretion.

Although a relatively clear story can be constructed into a working concept regarding the autocrine/paracrine interactions in the regulation of the menstrual cycle (Chapter 6), placental function is more complex, and a simple presentation of the many interactions cannot be produced. For example, epidermal growth factor stimulates HCG secretion, but also stimulates inhibin secretion in placental cells, and inhibin suppresses GnRH stimulation of HCG.¹⁰⁵ Inhibin secretion in the placenta is further stimulated by prostaglandins.¹⁰⁶

Can the cytotrophoblast-syncytiotrophoblast relationship be compared with the hypothalamic-pituitary axis? It does appear that hypothalamic-like peptides (CRH, GnRH) originate in the cytotrophoblast and influence the syncytiotrophoblast to secrete pituitary-like hormones (HCG, HPL, ACTH). Unraveling the interaction is made more difficult by the incredible complexity of the syncytiotrophoblast, a tissue that produces and responds to steroid and peptide hormones, growth factors, and neuropeptides. The best we can say is that locally produced hormones, growth factors, and peptides work together to regulate placental function.

To this day, the only definitely known function for HCG is support of the corpus luteum, taking over for LH on about the 8th day after ovulation, one day after implantation, when b-HCG first can be detected in maternal blood. HCG has been detected at the 8-cell stage in the embryo using molecular biology techniques.¹⁰⁷ Continued survival of the corpus luteum is totally dependent on HCG, and, in turn, survival of the pregnancy is dependent upon steroids from the corpus luteum until the 7th week of pregnancy.¹ From the 7th week to the 10th week, the corpus luteum is gradually replaced by the placenta, and by the 10th week, removal of the corpus luteum will not be followed by steroid withdrawal abortion.

It is very probable, but not conclusively proven, that HCG stimulates steroidogenesis in the early fetal testes, so that androgen production will ensue, and masculine differentiation can be accomplished.¹⁰⁸ It is also possible that the function of the inner fetal zone of the adrenal cortex depends on HCG for steroidogenesis early in pregnancy. The b-HCG gene is expressed in fetal kidney and fetal adrenal, suggesting that HCG may affect the development and function of these organs.¹⁰⁹

HCG gene expression is present in both cytotrophoblast and syncytiotrophoblast, but it is synthesized mainly in the syncytiotrophoblast.¹¹⁰ The maternal circulating

HCG concentration is approximately 100 IU/L at the time of the expected but missed menses. A maximal level of about 100,000 IU/L in the maternal circulation is reached at 8–10 weeks of gestation. Why does the corpus luteum involute at the time that HCG is reaching its highest levels? One possibility is that a specific inhibitory agent becomes active at this time. Another is down-regulation of receptors by the high levels of HCG. In early pregnancy, down-regulation may be avoided because HCG is secreted in an episodic fashion.¹¹¹ For unknown reasons, the fetal testes escape desensitization; no receptor down-regulation takes place.¹⁰⁸

HCG levels decrease to about 10,000–20,000 IU/L by 18–20 weeks and remain at that level to term. It is not certain why HCG levels are decreased in the second half of pregnancy. Advancing gestation is associated with increasing amounts of “nicked” HCG molecules in the maternal circulation.¹¹² These molecules are missing a peptide linkage on the beta-subunit, and therefore, they dissociate into free α - and β -subunits. At any one point in time, the maternal circulation contains HCG, nicked HCG, free subunits, and fragments of HCG. In addition, the carbohydrate content of HCG varies throughout pregnancy, with more glycosylation present in early pregnancy. Overall, there are about 20–30 isoforms in the maternal blood, and the production of normal molecules is maximal in early gestation when the biologic actions of HCG are so important.¹¹³ A major route of clearance for HCG is renal metabolism in which a final reduced fragment of the β -subunit is produced, known as the β -core fragment.

In the complex process of HCG regulation, several inhibiting factors have been identified, including inhibin and progesterone. The decline in HCG occurs at the time of increasing placental progesterone production, and a direct inhibition by this steroid could explain the lower levels of HCG after the 10th week of gestation.¹¹⁴

HCG levels close to term are higher in women bearing female fetuses. This is true of serum levels, placental content, urinary levels, and amniotic fluid concentrations. The mechanism and purpose of this difference are not known.

There are two clinical conditions in which blood HCG titers are very helpful: trophoblastic disease and ectopic pregnancies. Early pregnancy is characterized by the sequential appearance of HCG, followed by β -HCG and then α -HCG. The ratio of β -HCG to whole HCG remains constant after early pregnancy. Trophoblastic disease is distinguished by very high β -HCG levels (3–100 times higher than normal pregnancy). Ectopic production of α - and β -HCG by nontrophoblastic tumors is rare. Previous studies with polyclonal antisera suggesting ectopic production were not accurate. The production of whole HCG in such tumors may not occur.

In the United States, hydatidiform moles occur in approximately 1 in 600 induced abortions and 1 in 1000–2000 pregnancies. About 20% of patients with hydatidiform moles will develop malignant complications. Following molar pregnancies, the HCG titer should fall to a nondetectable level by 16 weeks in patients without persistent disease. Patients with trophoblastic disease show an abnormal curve (a titer greater than 500 IU/L) frequently by 3 weeks and usually by 6 weeks.^{115, 116} A diagnosis of gestational trophoblastic disease is made when the β -HCG plateaus or rises over a 2-week period, or a continued elevation is present 16 weeks after evacuation. In the United States, the rare occurrence of this disease mandates consultation with a certified subspecialist in gynecologic oncology. Following treatment, HCG should be measured monthly for at least a year, then twice yearly for 5 years. In order to avoid missing the diagnosis of nonmolar trophoblastic disease, abnormal bleeding after any pregnancy should be evaluated with an HCG measurement, and all patients with elevated HCG levels and early pregnancy losses should be followed with serial HCG testing.

In order to avoid unnecessary treatment (prophylactic chemotherapy) of the 80–85% of patients who undergo spontaneous remission, there is a need to identify those at high risk for persistent trophoblastic disease. A radioimmunoassay for the free β -subunit of HCG may serve this need in that persistent trophoblastic disease is associated with excessive production of the free β -subunit.^{117, 118}

Virtually all ectopic pregnancies are associated with detectable HCG. The HCG level increases at different rates in normal and ectopic pregnancies, and the quantitative measurement of HCG combined with pelvic ultrasonography has had an enormous impact on the diagnosis and management of ectopic pregnancy. This important clinical problem is discussed fully in [Chapter 32](#). The contributions of HCG measurement can be summarized as follows:

1. The quantitative measurement of HCG can assess pregnancy viability. A normal rate of rise usually indicates a normal pregnancy.
2. When the HCG titer exceeds 1000–1500 IU/L, vaginal ultrasonography should identify the presence of an intrauterine gestation.
3. Declining HCG levels are consistent with effective treatment, and persistent or rising levels indicate the presence of viable trophoblastic tissue.

With the use of modern sensitive assays, it is now appreciated that virtually all normal human tissues produce the intact HCG molecule. HCG can be detected in the blood of normal men and women, where it is secreted in a pulsatile fashion in parallel with LH, and apparently the source of this circulating HCG is the pituitary gland.^{119, 120, 121} and ¹²² The concentration of this pituitary HCG normally reaches the sensitivity of the usual modern assay only in a rare postmenopausal woman with high LH levels. HCG produced in sites other than the placenta has little or no carbohydrate, and, therefore, it has a very short half-life and is rapidly cleared from the circulation. Significant levels of free α -subunit are also present in the circulation of healthy individuals; however, the levels of the β -subunit are extremely low.

Human Placental Lactogen (HPL)

Human placental lactogen (sometimes called human chorionic somatomammotropin), also secreted by the syncytiotrophoblast, is a single-chain polypeptide of 191 amino acids held together by two disulfide bonds. It is very similar in structure to human growth hormone (HGH), but has only 3% of HGH somatotropin activity. The growth hormone-HPL gene family consists of 5 genes on chromosome 17q22–q24. Two genes encode for HGH and 3 for HPL; however, only 2 of the HPL genes are abundantly active in the placenta, each producing the same HPL hormone.¹²³ The third HPL gene does generate a protein in the placenta, but its activity is limited.¹²⁴

Although HPL has about 50% of the lactogenic activity of sheep prolactin in certain bioassays, its lactogenic contribution in human pregnancy is uncertain. Its half-life is short, about 15 minutes; hence its appeal as an index of placental problems. The level of HPL in the maternal circulation is correlated with fetal and placental weight, steadily increasing until plateauing in the last 4 weeks of pregnancy (5–7 mg/mL). There is no circadian variation, and only minute amounts of HPL enter the fetal circulation. Very high maternal levels are found in association with multiple gestations; levels up to 40 mg/mL have been found with quadruplets and quintuplets. An abnormally low level is anything less than 4 mg/mL in the last trimester.

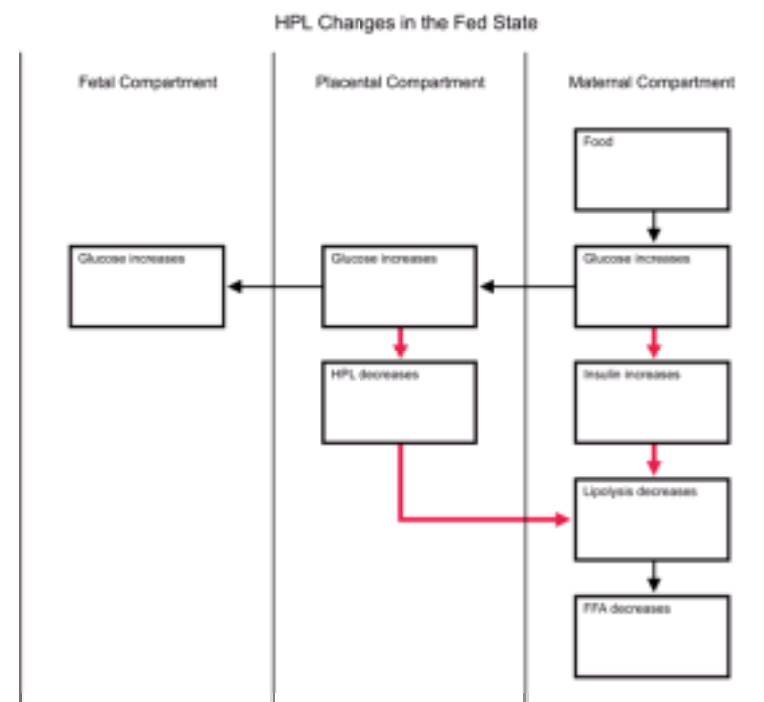

Physiologic Function

Although similar in structure to growth hormone, neither growth hormone-releasing hormone nor somatostatin influence placental HPL secretion. One would expect the regulatory mechanism to involve placental growth factors and cytokines, as is the case with other placental steroids and peptides.

In the mother, HPL stimulates insulin secretion and IGF-I production and induces insulin resistance and carbohydrate intolerance. Experimentally, the maternal level of HPL can be altered by changing the circulating level (chronically, not acutely) of glucose. HPL is elevated with hypoglycemia and depressed with hyperglycemia. This information and studies in fasted pregnant women have led to the following formulation for the physiologic function of HPL. [125](#), [126](#), [127](#), [128](#), [129](#), [130](#) and [131](#)

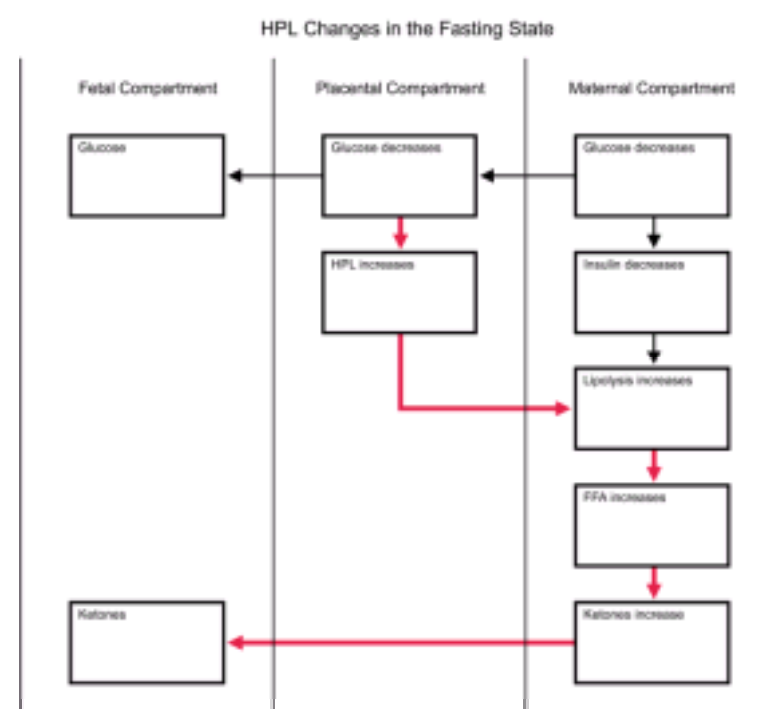

The metabolic role of HPL is to mobilize lipids as free fatty acids. In the fed state, there is abundant glucose available, leading to increased insulin levels, lipogenesis, and glucose utilization. This is associated with decreased gluconeogenesis and a decrease in the circulating free fatty acid levels, because the free fatty acids are utilized in the process of lipogenesis to deposit storage packets of triglycerides (see Chapter 19, [Obesity](#)).

Pregnancy has been likened to a state of “accelerated starvation,” characterized by a relative hypoglycemia in the fasting state. [128](#) This state is due to two major influences:

1. Glucose provides the major, although not the entire, fuel requirement for the fetus. A difference in gradient causes a constant transfer of glucose from the mother to the fetus.
2. Placental hormones, specifically estrogen and progesterone, and especially HPL, interfere with the action of maternal insulin. In the second half of pregnancy when HPL levels rise approximately 10-fold, HPL is a major force in the diabetogenic effects of pregnancy. The latter is characterized by increased levels of insulin associated with decreased cellular response (peripheral insulin resistance and hyperinsulinemia).

As glucose decreases in the fasting state, HPL levels rise. This stimulates lipolysis leading to an increase in circulating free fatty acids. Thus, a different fuel is provided for the mother so that glucose and amino acids can be conserved for the fetus. With sustained fasting, maternal fat is utilized for fuel to such an extent that maternal ketone levels rise. There is limited transport of free fatty acids across the placenta. Therefore, when glucose becomes scarce for the fetus, fetal tissues utilize the ketones that do cross the placenta. Thus, decreased glucose levels lead to decreased insulin and increased HPL, increasing lipolysis and ketone levels. HPL also may enhance the fetal uptake of ketones and amino acids. The mechanism for the insulin antagonism by HPL may be the HPL-stimulated increase in free fatty acid levels, which, in turn, directly interfere with insulin-directed entry of glucose into cells. These interactions significantly involve growth factors, particularly insulin-like growth factor, at the cellular level.

This mechanism can be viewed as an important means to provide fuel for the fetus between maternal meals. However, with a sustained state of inadequate glucose intake, the subsequent ketosis may impair fetal brain development and function. Pregnancy is not the time to severely restrict caloric intake. Indeed, impaired fetal growth and development are now recognized to correlate with adverse cardiovascular risk factors and disease in adult life. [47](#), [132](#)

The lipid, lipoprotein, and apolipoprotein changes during pregnancy are positively correlated with changes in estradiol, progesterone, and HPL. [133](#) The lipolytic activity of HPL is an important factor because HPL is also linked to the maternal blood levels of cholesterol, triglycerides, phospholipids, and insulin-like growth factor-I.

When glucose is abundant, as in pregnant women with diabetes mellitus, the flow of nutritional substrates (in this case, glucose and amino acids) is in the direction of the fetus. The subsequent hyperinsulinemia in the fetus becomes a strong stimulus to growth, perhaps compounded by maternal hyperinsulinemia caused by obesity as well as the hyperinsulinemia due to the peripheral resistance produced by the hormones of pregnancy. [134](#) Fetal undernutrition lowers fetal IGF-I levels, and this is associated with a high prevalence of insulin resistance later as adults. [135](#) In vitro studies indicate that HPL, despite its lower levels in the fetus, directly affects fetal tissue metabolism, including synergistic actions with insulin, especially on glycogen synthesis in the liver. The failure of fetal growth hormone to affect fetal growth (e.g., normal growth in anencephalics) further indicates that HPL may be the fetal growth hormone.

HPL Clinical Uses

Blood levels of HPL are related to placental function. Although some studies indicated that HPL was valuable in screening patients for potential fetal complications, others did not support the use of HPL measurements. Even though utilization of the HPL assay can have an impact on perinatal care, fetal heart rate-monitoring techniques are more reliably predictive and sensitive for assessing fetal well-being. Furthermore, totally uneventful pregnancies have been reported, despite undetectable HPL. [136](#), [137](#)

Previous suggestions that a low or declining level of HPL and a high level of HCG are characteristic of trophoblastic disease were not accurate. Because of the rapid clearance of HPL (half-life of about 20 minutes), aborting molar pregnancies are likely to have low levels of HPL, whereas the level of HCG is still high. However, intact molar pregnancies can have elevated levels of both HPL and HCG. [138](#)

Human Chorionic Thyrotropin (HCT)

The human placenta contains two thyrotropic substances. One is called human chorionic thyrotropin (HCT), similar in size and action to pituitary TSH. The content in the normal placenta is very small, and it is unlikely that it has any physiologic importance. HCT differs from the other glycoproteins in that it does not appear to share the common α -subunit. Antiserum generated to α -HCG does not neutralize the biologic activities of HCT, but it does neutralize that of HCG and pituitary TSH.

Rarely, patients with trophoblastic disease have hyperthyroidism. Studies have indicated that HCG has intrinsic thyrotropic activity, suggesting that HCG is the second placental thyrotropic substance.^{139, 140 and 141} It has been calculated that HCG contains approximately 1/4000th of the thyrotropic activity of human TSH. In conditions with very elevated HCG levels, the thyrotropic activity can be sufficient to produce hyperthyroidism, and this can even be encountered in normal pregnancy.¹⁴² There is a correlation between elevated thyroid function and hyperemesis gravidarum. These clinical manifestations in normal pregnancies may be linked to a specific subpopulation of HCG molecules with greater thyrotropic bioactivity (because highly purified, standard HCG has only trivial TSH-like activity).¹⁴³ Specifically, HCG with reduced sialic acid content is increased in pregnant patients with hyperemesis and hyperthyroidism.¹⁴⁴ The thyroid hormone changes in pregnancy and the role of HCG as a thyroid stimulator are discussed in [Chapter 20](#).

Human Chorionic Adrenocorticotropin

The rise in maternal free cortisol that takes place throughout pregnancy is due to ACTH and corticotropin-releasing hormone (CRH) production and secretion into the maternal circulation by the placenta.^{145, 146 and 147} The placental content of ACTH is higher than can be accounted for by the contribution of sequestered blood. In addition, cortisol levels in pregnant women are resistant to dexamethasone suppression, suggesting that there is a component of maternal ACTH and CRH that does not originate in the maternal pituitary gland. The placental production of ACTH in the syncytiotrophoblast (and the increase in maternal ACTH levels) is probably due to stimulation by the locally produced CRH in the cytotrophoblast.¹⁴⁸ Placental pro-opiomelanocortin (POMC) gene expression and ACTH content are present throughout pregnancy and increase in the weeks before term.¹⁴⁹ One can speculate that placental ACTH and CRH raise maternal adrenal activity in order to provide the basic building blocks (cholesterol and pregnenolone) for placental steroidogenesis. There is no passage of ACTH between the fetal and maternal compartments.

The maternal ACTH response to the administration of CRH during pregnancy is blunted, indicating a high level of endogenous CRH and ACTH activity. Vasopressin stimulates ACTH secretion in the pituitary, both directly and indirectly by potentiating the action of CRH. In contrast to the blunted response to CRH during pregnancy, the ACTH response to vasopressin is increased.¹⁵⁰ This is further evidence that placental CRH produces a state of chronic stimulation for the maternal pituitary-adrenal axis. Thus, in contrast to nonpregnant women, CRH levels in maternal plasma are relatively high, rising in the second trimester to peak values at term.^{151, 152} In contrast to the hypothalamic-pituitary axis, placental CRH and ACTH are not suppressed by glucocorticoids, and, therefore, maternal ACTH levels are little affected by corticosteroid administration to the mother. Oxytocin is a potent stimulator of CRH and ACTH placental production, a logical mechanism to meet the stress of labor and delivery. The fall in CRH-binding protein near term further increases the cortisol availability during labor and delivery.

Both maternal and fetal levels of CRH are further elevated in pathologic states such as premature labor, hypertension, fetal asphyxia, and intrauterine growth retardation.¹⁵³ Because CRH also stimulates prostaglandin synthesis in the placenta and fetal membranes, it is implicated in the premature labor that accompanies pathologic conditions.¹⁵⁴

Growth Hormone, Growth Hormone-Releasing Hormone, and Somatostatin

Growth hormone-releasing hormone (GHRH) and somatostatin are found in the placenta, and somatostatin is present in decidua.^{78, 155} The amount of somatostatin decreases with increasing gestation. Pregnancy GHRH and somatostatin do not contribute to maternal circulating levels of these peptides. One of the two growth hormone genes on chromosome 17 is expressed only in the syncytiotrophoblast of the placenta.¹²⁴ The placental growth hormone is not identical to pituitary growth hormone, and after 15–20 weeks of pregnancy, placental growth hormone gradually replaces pituitary growth hormone in the maternal circulation.^{124, 156} Indeed, by term, maternal pituitary growth hormone is undetectable. Placental growth hormone is not present in fetal blood. The changes in maternal levels of insulin-like growth factors and insulin-like growth factor binding proteins reflect regulation by this placental growth hormone.¹⁵⁷ Maternal IGF-I levels in the circulation increase during pregnancy in a pattern similar to that of placental growth hormone. Placental growth hormone is not regulated by placental GHRH, but responds inversely to maternal glucose levels, protecting glucose availability for the fetus.¹²⁴ Placental growth hormone can also stimulate gluconeogenesis and lipolysis in maternal organs. It is believed, therefore, that placental growth hormone influences fetal growth by affecting maternal metabolism.

Alpha-Fetoprotein

Alpha-fetoprotein (AFP) is a relatively unique glycoprotein (590 amino acids and 4% carbohydrate) derived largely from fetal liver and partially from the yolk sac until it degenerates at about 12 weeks. In early pregnancy (5–12 weeks), amniotic fluid AFP is mainly from yolk sac origin, whereas maternal circulating AFP is mainly from the fetal liver.¹⁵⁸ Its function is unknown, but it is comparable in size to albumin and contains 39% sequence homology; it may serve as a protein carrier of steroid hormones in fetal blood. AFP may also be a modulator of cell proliferation, synergizing with various growth factors.¹⁵⁹

Peak levels of AFP in the fetal blood are reached at the end of the first trimester; then levels decrease gradually until a rapid decrease begins at 32 weeks. Maternal blood levels are much lower than fetal levels, rising until week 32 (probably because of the great increase in trophoblast villous surface area during this time period) and then declining. Because AFP is highly concentrated in the fetal central nervous system, abnormal direct contact of CNS with the amniotic fluid (as with neural tube defects) results in elevated amniotic fluid and maternal blood levels. Other fetal abnormalities, such as intestinal obstruction, omphalocele, and congenital nephrosis, are also associated with high levels of AFP in the amniotic fluid. Besides indicating a variety of fetal anomalies, elevated maternal AFP levels are also present with multiple pregnancies and associated with an increased risk of spontaneous miscarriage, stillbirth, preterm birth, preeclampsia, neonatal death, and low birth weight (probably reflecting an increase in villous surface area in response to an adverse intrauterine environment).^{160, 161}

Multiple Marker Screening

Down syndrome is a very common genetic cause of abnormal development. The majority of cases are due to trisomy 21, an extra chromosome usually due to nondisjunction in maternal meiosis. A low maternal level of AFP is associated with trisomy 21. However, there is extensive overlap between normal and affected pregnancies responsible for a significant false-positive rate. Several placental products are secreted in increased amounts in pregnancies with trisomy 21, including HCG and HPL, whereas the maternal circulating level of unconjugated estriol is lower in affected pregnancies. The free β -subunit of HCG usually circulates in low concentrations, but in the presence of a fetus with Down syndrome, the levels are high. With trisomy 18, all markers are decreased. Modern screening for fetal aneuploidy combines three markers: AFP, HCG, or β -HCG, and unconjugated estriol.^{162, 163 and 164} This protocol will detect 85% of open neural tube defects and 80% of Down syndrome. However, Down syndrome represents only about 50% of the chromosomal abnormalities that can be detected.

The multiple marker screening protocol measures AFP, HCG, and unconjugated estriol in maternal serum at 16–18 weeks gestation, the optimal time for neural tube defect detection. Using the patient's age and the laboratory results, patients are provided a statistical estimation of risks for both neural tube defects and Down syndrome. Corrections are applied for race and weight. A pattern similar to that of Down syndrome has also been reported to be associated with hydropic fetal Turner syndrome.¹⁶⁵ A comparison trial concluded that a combination of AFP and the free β -subunit of HCG is more accurate and less expensive than the utilization of the 3 markers, AFP, HCG, and unconjugated estriol.¹⁶⁶

The most critical factor for correct risk assessment is accurate gestational dating. A two-week error in dating can change the calculated risk for Down syndrome ten-fold. Therefore, ultrasound confirmation of gestational dating is essential. In addition, ultrasonography will indicate fetal number and assess the fetus for anomalies.

The multiple marker protocol is for screening a low-risk population regardless of age, and amniocentesis is necessary for final diagnosis. Genetic amniocentesis is still recommended for older women; however, although multiple marker screening does not detect all chromosomal abnormalities, some have argued that the detection rate is so high that screening as an option should be offered even to older women.^{163, 167}

The detection of a very low unconjugated estriol level in the second trimester is associated with an increased risk of early fetal demise.¹⁶⁸ In addition, a low estriol can

be a marker for placental sulfatase deficiency.

Relaxin

Relaxin is a peptide hormone produced by the corpus luteum of pregnancy, which is not detected in men or nonpregnant women. It is composed of two short peptide chains (24 and 29 amino acids, respectively) linked by disulfide bridges. While it has been argued that the human corpus luteum is the sole source of relaxin in pregnancy, it has also been identified in human placenta, decidua, and chorion. ^{169, 170 and 171} The maternal serum concentration rises during the first trimester when the corpus luteum is dominant and declines in the second trimester. ¹⁷² This suggests a role in maintaining early pregnancy, but its function is not really known. In animals, relaxin softens the cervix (ripening), inhibits uterine contractions, and relaxes the pubic symphysis. The animal cervical changes are comparable to those seen with human labor, and in *in vitro* studies of human cervical stromal cells, relaxin induces changes consistent with clinical ripening. ^{173, 174} To examine the contribution of the corpus luteum, normally pregnant women were compared with women pregnant with donated oocytes (and therefore without corpora lutea). ¹⁷⁵ Relaxin was undetectable in the women without functioning ovaries, confirming that its major source is the corpus luteum. No effect on prolactin secretion was observed, but it did appear that relaxin enhanced growth hormone secretion by the pituitary. Obviously, relaxin is not necessary for the maintenance of pregnancy and labor because the rest of pregnancy and the outcomes did not differ between those women with circulating levels of relaxin and those with undetectable levels. However, recombinant relaxin is being tested for ripening of the cervix.

Prolactin

Following ovulation, the endometrium becomes a secretory organ and remains so throughout pregnancy. Decidualized endometrium secretes renin, which may be involved in the regulation of water and electrolytes in the amniotic fluid, and relaxin, which may influence prostaglandin production in the membranes. One of the best studied special endocrine functions of the decidual endometrium is the secretion of prolactin. Prolactin is synthesized by endometrium during a normal menstrual cycle, but this synthesis is not initiated until histologic decidualization begins about day 23. ^{176, 177} The control of prolactin secretion by decidual tissue has not been definitively established. Some argue that once decidualization is established, prolactin secretion continues in the absence of either progesterone or estradiol, although there is evidence for an inhibitory feedback by decidual proteins (perhaps prolactin itself). ^{176, 178} Others indicate that endometrial prolactin production requires the combined effects of progestin and estrogen hormones plus the presence of other placental and decidual factors, including relaxin, IGF-I, and specific stimulatory and inhibitory proteins. ¹⁷⁹

During pregnancy, prolactin secretion is limited to the fetal pituitary, the maternal pituitary, and the uterus. Neither trophoblast nor fetal membranes synthesize prolactin, but both the myometrium and endometrium can produce prolactin. The endometrium requires the presence of progesterone to initiate prolactin, whereas progesterone suppresses prolactin synthesis in the myometrium. Prolactin derived from the decidua is the source of prolactin found in the amniotic fluid. ¹⁸⁰ The prolactin in the fetal circulation is derived from the fetal pituitary. Decidual prolactin is transcribed by a gene with an additional exon compared with the pituitary, accounting for a different system of regulation. ¹⁸¹

During pregnancy, prolactin levels rise from the normal level of 10–25 ng/mL to high concentrations, beginning about 8 weeks and reaching a peak of 200–400 ng/mL at term. ^{182, 183} The increase in prolactin parallels the increase in estrogen beginning at 7–8 weeks gestation, and the mechanism for increasing prolactin secretion (discussed in [Chapter 5](#)) is believed to be estrogen suppression of the hypothalamic prolactin inhibiting factor, dopamine, and direct stimulation of prolactin gene transcription in the pituitary. ^{184, 185} There is marked variability in maternal prolactin levels in pregnancy, with a diurnal variation similar to that found in nonpregnant persons.

Amniotic fluid concentrations of prolactin parallel maternal serum concentrations until the 10th week of pregnancy, rise markedly until the 20th week, and then undergo a decrease until delivery. The maternal and fetal blood levels of prolactin are derived from the respective pituitary glands, and, therefore, dopamine agonist suppression of pituitary secretion of prolactin throughout pregnancy produces minimal maternal and fetal blood levels, yet there is normal fetal growth and development, and amniotic fluid levels are unchanged. ¹⁸⁶ Fortunately, decidual secretion of prolactin is unaffected by dopamine agonist treatment because decidual prolactin is important for fluid and electrolyte regulation of the amniotic fluid. This decidual prolactin is transported across the membranes in a process that requires the intact state of amnion and chorion with adherent decidua. The prolactin receptor is expressed in fetal and maternal tissues in the following descending order of intensity: chorionic cytotrophoblast, decidua, amnion, and syncytiotrophoblast. ¹⁸⁷ This molecular expression is consistent with local actions.

No clinical significance can be attached to maternal and fetal blood levels of prolactin in abnormal pregnancies. Decidual and amniotic fluid prolactin levels are lower, however, in hypertensive pregnancies and in patients with polyhydramnios. ^{188, 189} Prolactin receptors are present in the chorion laeve, and their concentration is lower in patients with polyhydramnios. ¹⁹⁰ Prolactin reduces the permeability of the human amnion in the fetal to maternal direction. This receptor-mediated action takes place on the epithelium lining the fetal surface. ¹⁹¹ There is also evidence that prolactin derived from the fetal pituitary contributes to the regulation of fetal water and electrolyte balance by acting as an antidiuretic hormone. ¹⁹²

The increase in maternal levels of prolactin represents maternal pituitary secretion in response to estrogen as the fetus prepares the mother for breastfeeding. The mechanisms for pituitary secretion of prolactin are discussed in [Chapter 2](#), [Chapter 5](#), and [Chapter 16](#).

Cytokines and Growth Factors

The placenta synthesizes many proteins that are part of the normal composition of cells throughout the body. Local placental cytokine production is believed to be important for embryonic growth, and in the maternal immune response essential for survival of the pregnancy. ¹⁹³ Interleukin-1b is produced in the decidualized endometrium during pregnancy, and colony-stimulating factor-1 (CSF-1) is produced by both decidua and placenta. CSF-1 gene expression in response to interleukin-1b has been localized to mesenchymal fibroblasts from the core of placental villi. ¹⁹⁴ Thus, a system of communication is present between maternal decidual and fetal tissue to provide growth factor support for the placenta which would include fetal hematopoiesis, a known response to CSF-1. The placenta also produces interleukin-6, and both interleukins stimulate HCG release by activation of the interleukin-6 receptor. ¹⁹⁵ Thus, the interleukin-1 influence on HCG secretion is mediated by the interleukin-6 system. Both trophoblast derived interleukin-1 and tumor necrosis factor- α (TNF- α) synergistically release interleukin-6 and activate the interleukin-6 system to secrete HCG. ¹⁹⁶ Interferons and their receptors are present in virtually all cells, and thus, it is not surprising that they are found in the tissues of pregnancy.

The insulin-like growth factors, IGF-I and IGF-II, are involved in prenatal and postnatal growth and development. These growth factors do not cross the placenta into the fetal circulation; however, they may be involved in placental growth. ¹⁹⁷ The maternal levels of IGF-I are significantly regulated by growth hormone-dependent liver synthesis. The fetus can influence maternal IGF-I levels by means of the placental secretion of HPL. An increase in maternal IGF-I levels during pregnancy with a rapid decrease after delivery indicates a significant placental influence. There is no major change in maternal IGF-II levels throughout pregnancy.

The 6 IGF binding proteins transport IGFs in the circulation, protect IGFs against metabolism and clearance, and, importantly, affect the biologic activity of IGFs by modulating IGF availability at the cellular level. Pregnancy is marked by a rise in maternal levels of insulin-like growth factor binding protein-1 (IGFBP-1), beginning at the end of the first trimester and reaching a peak at term. ¹⁹⁸ IGFBP-1 is now recognized to be the same as placental protein-12, a decidual protein. Thus, IGFBP-1 originates in the decidua, regulated by progesterone, as well as in the liver. The prominence of IGFBP-1 in the pregnant state is in contrast to the nonpregnant state

when IGFBP-3 is the main circulating IGFBP. During pregnancy, the levels of IGFBP-3 and IGFBP-2 decrease, apparently due to the activity of a pregnancy-associated serum protease (IGFBP-3 protease).¹⁹⁸ These changes would promote the bioavailability of IGF-I in maternal tissues, and this may be important in enhancing nutrient transfer from the mother to the placenta. There is evidence to indicate that the mother can alter IGFBP-3 proteolytic activity according to her nutritional state; thus increased proteolysis would decrease IGFBP-3 levels increasing the bioavailability of maternal IGF-I.¹⁹⁹

How these changes interact to regulate growth and development of different organs and tissues is a new area of research activity. For example, in the pregnant ewe and fetal lamb, glucose and other nutritional factors regulate the gene expression and, therefore, the circulating levels of IGF binding proteins.²⁰⁰ Fasting and feeding increased and decreased, respectively, the IGFBP concentrations, perhaps partly a response to insulin levels and the effect of insulin on liver synthesis of IGFBPs. These changes are consistent with IGF and IGFBP involvement in the responses to nutrition and stress. Because IGFBP-1 appears to be the principal binding protein in pregnancy, attention is focused on the changes in IGF-I and IGFBP-1. IGF-I, produced in the placenta, regulates transfer of nutrients across the placenta to the fetus and, thus, enhances fetal growth; IGFBP-1, produced in the decidua, interferes with IGF-I action and inhibits fetal growth.²⁰¹ Thus, newborn birth weight correlates directly with maternal levels of IGF-I and inversely with levels of IGFBP-1.

Intrauterine growth retardation is associated with reduced fetal blood levels of IGF-I and IGFBP-3 and increased levels of IGFBP-1 and IGFBP-2.²⁰² In view of the strong relationship between the IGF system and fetal nutrition, it is logical that fetal glucose availability and insulin are the principal regulating agents. In experimental animals, an increase in fetal insulin or glucose elevates IGF-I levels, whereas nutritional restriction causes an increase in IGFBP-1 and IGFBP-2, and a decrease in IGFBP-3.²⁰³ Insulin is believed to influence growth by promoting cellular uptake of nutrients and by increasing IGF-I production. The fetal blood levels of IGF-II parallel those of IGF-I, and IGF-II promotes fetal growth by means of the IGF-I receptor. IGF-II appears to be important early in embryonic growth, and then after organ development is complete, IGF-I becomes the dominant factor.

Epidermal growth factor (EGF) is present in both cytotrophoblast and syncytiotrophoblast, but more intensely in syncytiotrophoblast, and probably is involved in the differentiation of cytotrophoblast into syncytiotrophoblast. EGF is well known as a mitogen. Other growth factors isolated from human placenta include platelet-derived growth factor, nerve growth factor, fibroblast growth factor, and transforming growth factors. These factors are probably all involved in the proliferation and growth associated with pregnancy.

Inhibin, Activin, and Follistatin

The placenta produces inhibin, which is responsible for the marked increase in maternal inhibin levels throughout pregnancy.^{204,205} Inhibin A is the principal bioactive inhibin secreted during pregnancy, rising in the maternal circulation at the time of the emergence of placental function, peaking at 8 weeks gestation, and then decreasing before increasing again in the third trimester to reach a level at term that is 100 times greater than that during the normal menstrual cycle.^{206,207 and 208} Undoubtedly, the high levels of inhibin and estrogen during pregnancy account for the profound suppression of maternal gonadotropins. Trophoblastic inhibin synthesis is inhibited by activin A and stimulated by HCG, GnRH, epidermal growth factor, transforming growth factor- α , and PGE₂ and PGF₂, the major placental prostaglandins.²⁰⁵ Activin A, the major trophoblastic activin product, also increases in the maternal circulation, with elevated but stable levels from 8 to 24 weeks, and then increasing to reach a level at term that is 100 times greater than that during the normal menstrual cycle.²⁰⁹

Similar to their action in the ovarian follicle, inhibin and activin are regulators within the placenta for the production of GnRH, HCG, and steroids; as expected, activin is stimulatory, and inhibin is inhibitory.¹⁰³ GnRH and the subunits for inhibin and activin can be found in the same placental cells, in both cytotrophoblast and syncytiotrophoblast, but not in all cells.²¹⁰ The maternal levels of inhibin B are very low throughout pregnancy; however, inhibin B is significantly expressed in the amnion where it is believed to influence prostaglandin synthesis.²¹¹ Trophoblast synthesis and release of inhibin and activin are part of the complex placental story, involving many hormones and locally produced factors. The placental and decidual appearance of inhibin and activin occurs early in pregnancy in time for possible roles in embryogenesis and local immune responses. The measurement of inhibin A has promise as a screening test for Down syndrome.^{212,213}

Follistatin is an activin-binding protein expressed in placenta, membranes, and decidua.²¹⁴ Because follistatin binds activin, it antagonizes the stimulatory effects of activin on placental steroid and peptide production.

Endogenous Opiates

Fetal and maternal endogenous opiates originate from the pituitary glands and are secreted in parallel with ACTH, in response to corticotropin-releasing hormone, which is, in part, derived from the placenta.²¹⁵ There is reason to believe that in pregnancy the intermediate lobe of the maternal pituitary gland is a major source of elevated circulating endorphin levels. However, the syncytiotrophoblast in response to CRH produces all of the products of proopiomelanocortin (POMC) metabolism, including β -endorphin, enkephalins, and dynorphins. The placenta and membranes are richly endowed with G protein opioid receptors.²¹⁶ The presence of CRH in the placenta and placental opiate production in response to CRH and oxytocin indicate an interaction similar to that in the hypothalamic-pituitary axis.²¹⁷

It is not certain whether maternal blood levels of endogenous opiates increase with advancing gestation.⁷⁸ However, a marked increase in maternal values is reached during labor, coinciding with full cervical dilatation. The maternal levels also correlate with the degree of pain perception and use of analgesia. On the fetal side, hypoxia is a potent stimulus for endorphin release.

There are many hypotheses surrounding the function of endogenous opiates in pregnancy. These include roles related to stress; inhibition of oxytocin, vasopressin and gonadotropins; the promotion of prolactin secretion; and, of course, a natural analgesic agent during labor and delivery.

The Renin-Angiotensin System

The circulating levels of prorenin, the inactive precursor of renin, increase (10-fold) during early pregnancy, the result of ovarian stimulation by HCG.^{218,219} This increase in prorenin from the ovary is not associated with any significant change in the blood levels of the active form, renin. Possible roles for this ovarian prorenin-renin-angiotensin system include the following: stimulation of steroidogenesis to provide androgen substrate for estrogen production, regulation of calcium and prostaglandin metabolism, and stimulation of angiogenesis. This system may affect vascular and tissue functions both in and outside the ovary. Prorenin also originates in chorionic tissues and is highly concentrated in the amniotic fluid. The highest biologic levels of prorenin are found in gestational sacs in early pregnancy; its possible roles in embryonic growth and development remain speculative.²¹⁹ Renin and angiotensinogen (the renin substrate) are expressed by the following fetal tissues: chorion, amnion, and placenta.²²⁰ This system responds to a variety of factors, affecting vascular resistance and blood volume.²²¹ Maternal renin activity is increased four-fold by midgestation, partly a response to an estrogen-induced increase in angiotensinogen, but largely a compensatory response to maintain blood pressure in the presence of vasodilatation.²²² There is little evidence that fetal or uterine prorenin or renin contribute to the maternal circulation.

Atrial Natriuretic Peptide

Atrial natriuretic peptide (ANP) is derived from human atrial tissue and the placenta.²²³ It is a potent natriuretic, diuretic, and smooth muscle-relaxant peptide that circulates as a hormone. Maternal ANP increases in the third trimester and during labor, and cord levels on the arterial side suggest that ANP is a circulating hormone in the fetus.²²⁴ In the mother, ANP release is stimulated by atrial stretch, and this is another mechanism for regulating the volume and electrolyte changes associated with pregnancy and delivery.²²⁵

Other Proteins

The mother responds to a pregnancy even before implantation. Remarkably, early pregnancy factor (EPF) can be detected in the maternal circulation within 1–2 days after coitus results in a pregnancy.²²⁶ It remains throughout pregnancy, but interestingly, disappears before parturition. EPF prior to implantation is apparently produced by the ovary in response to a signal from the embryo. After implantation, EPF is no longer secreted by the ovary but now is derived from the embryo. EPF is a protein associated with cell proliferation and growth and, therefore, is present in many nonpregnant tissues such as neoplasms. EPF has immunosuppressive properties and is abundant in platelets. We are just beginning to learn about this fetal and maternal protein. Neuropeptide Y, a peptide extensively distributed in the brain, is found in trophoblast, membranes, and decidua, with higher but nonchanging maternal blood levels during pregnancy.⁷⁸

Pregnancy-specific α_1 -glycoprotein (PSG) was previously known as Schwangerschaftsprotein 1. The physiologic function of PSG produced by the placenta is unknown, but it has been used as a test for pregnancy and a marker for malignancies, including choriocarcinoma. Molecular studies have revealed that PSG consists of a family of closely related glycoproteins encoded by genes on chromosome 19.²²⁷ The PSG family is closely related to the carcinoembryonic antigen (CEA) proteins. Pregnancy-associated plasma protein-A (PAPP-A) is a placental protein that is similar to a macroglobulin in the serum and still in search of specific functions. Progesterone-associated endometrial protein, previously called placental protein 14, is now recognized to originate in secretory endometrium and decidua. No role for this protein has been described thus far.

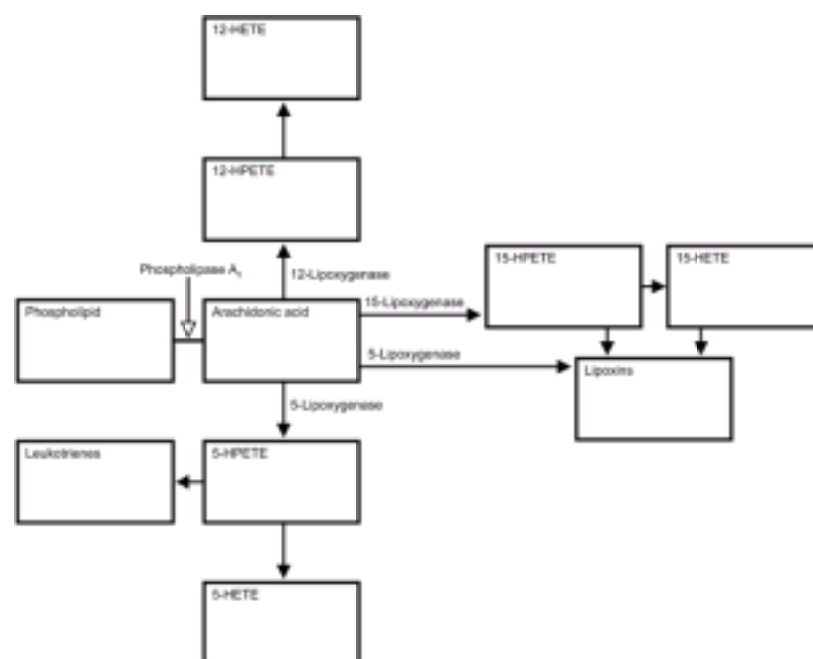

Prostaglandins

Prostaglandin Biosynthesis

The family of prostaglandins with the greatest biologic activity is that having two double bonds, derived from arachidonic acid.^{228, 229} Arachidonic acid can be obtained from two sources, directly from the diet (from meats) or by formation from its precursor linoleic acid, which is found in vegetables. In the plasma, 1–2% of the total free fatty acid content is free arachidonic acid. The majority of arachidonic acid is covalently bound in esterified form as a significant proportion of the fatty acids in phospholipids and in esterified cholesterol. Arachidonic acid is only a minor fatty acid in the triglycerides packaged in adipose tissue.

The rate-limiting step in the formation of the prostaglandin family is the release of free arachidonic acid. A variety of hydrolases may be involved in arachidonic acid release, but phospholipase A_2 activation is an important initiator of prostaglandin synthesis because of the abundance of arachidonate in the 2 position of phospholipids. In addition, phospholipase C activity can provide arachidonic acid. Types of stimuli that activate such lipases include burns, infusions of hypertonic and hypotonic solutions, thrombi and small particles, endotoxin, snake venom, mechanical stretching, catecholamines, bradykinin, angiotensin, and the sex steroids.

“Eicosanoids” refer to all the 20-carbon derivatives, whereas “prostanoids” indicate only those containing a structural ring. After the release of arachidonic acid, the synthetic path can go in two different directions: the lipoxygenase pathway or the cyclooxygenase (prostaglandin endoperoxide H synthase) pathway, depending upon the local cellular context. There are 3 lipoxygenase enzymes that lead to active compounds. Arachidonic acid is first converted to hydroperoxyeicosatetraenoic acids (HPETEs), and then to hydroxyeicosatetraenoic acids (HETEs), lipoxins, or leukotrienes. The leukotrienes are formed by 5-lipoxygenase oxygenation of arachidonic acid at C-5, forming an unstable intermediate, LTA_4 .²³⁰ LTB_4 is formed by hydration and LTC_4 by the addition of glutathione. The remaining leukotrienes are metabolites of LTC_4 . The previously known slow reacting substance of anaphylaxis consists of a mixture of LTC_4 , LTD_4 , and LTE_4 . The leukotrienes are involved in the defense reactions of white cells and participate in hypersensitivity and inflammatory responses. LTB_4 acts primarily on leukocytes (stimulation of leukocyte emigration from the bloodstream), whereas LTC_4 , LTD_4 , and LTE_4 affect smooth muscle cells (bronchoconstriction in the lungs and reduced contractility in the heart). All leukotrienes increase microvascular permeability. Thus, the leukotrienes are major agonists, synthesized in response to antigens provoking asthma and airway obstruction. Leukotrienes are 100–1000 times more potent than histamine in the pulmonary airway. Asthma can now be treated with a specific leukotriene receptor antagonist.

The 12-lipoxygenase pathway leads to 12-hydroxyeicosatetraenoic acid (12-HETE). Little is known about 12-HETE other than its function as a leukostatic agent. The lipoxins (LXA and LXB), products of the 5- and 15-lipoxygenase pathways, inhibit natural killer cell cytotoxicity and are vasodilators.²³⁰

The cyclooxygenase pathway leads to the prostaglandins. The first true prostaglandin (PG) compounds formed are PGG_2 and PGH_2 (half-life of about 5 minutes), the mothers of all other prostaglandins. The numerical subscript refers to the number of double bonds. This number depends on which of the three precursor fatty acids has been utilized. Besides arachidonic acid, the other two precursor fatty acids are linoleic acid, which gives rise to the PG_1 series, and pentanoic acid, the PG_3 series. The latter two series are of less importance in physiology, hence, the significance of the arachidonic acid family. The prostaglandins of original and continuing relevance to reproduction are PGE_2 and PGF_{2a} and possibly PGD_2 . The a in PGF_{2a} indicates the a steric configuration of the hydroxyl group at the C-9 position. The A, B, and C prostaglandins either have little biologic activity or do not exist in significant concentrations in biologic tissues. In the original work, the prostaglandin more soluble in ether was named PGE, and the one more soluble in phosphate (spelled with an F in Swedish) buffer was named PGF. Later, naming became alphabetical.

The cyclooxygenase enzyme (prostaglandin synthase) exists in two forms, COX-1 and COX-2, products of separate genes.^{231, 232 and 233} Prostacyclin is produced by COX-1, the constitutive form of the enzyme found in virtually all tissues, whereas COX-2 is induced in responses to inflammatory stimuli. COX-2 is expressed only after stimulation by various growth factors, cytokines, and endotoxins, and, therefore, it is called the inducible form. Thus selective inhibition of COX-2 would be therapeutically advantageous, possibly avoiding the side effects associated with inhibition of COX-1.

Thromboxane and Prostacyclin

Thromboxanes are not true prostaglandins because of the absence of the pentane ring, but prostacyclin (PGI₂) is a legitimate prostaglandin. Thromboxane (TX) (half-life about 30 seconds) and PGI₂ (half-life about 2–3 minutes) can be viewed as opponents, each having powerful biologic activity that counters or balances the other. TXA₂ is the most powerful vasoconstrictor known, whereas PGI₂ is a potent vasodilator. These two agents also have opposing effects on platelet function. Platelets, lungs, and the spleen predominately synthesize TXA₂, while the heart, stomach, and blood vessels throughout the body synthesize PGI₂. The lungs are a major source of prostacyclin. Normal pulmonary endothelium makes prostacyclin while TXA₂ appears in response to pathologic stimuli.²³⁴ The pulmonary release of prostacyclin may contribute to the body's defense against platelet aggregation.

Let's take a closer look at platelets. The primary function of platelets is the preservation of the vascular system. Blood platelets stick to foreign surfaces or other tissues, a process called adhesion. They also stick to each other and form clumps; this process is called aggregation. Because platelets synthesize TXA₂, a potent stimulator of platelet aggregation, the natural tendency of platelets is to clump and plug defects and damaged spots. The endothelium, on the other hand, produces PGI₂ and its constant presence inhibits platelet aggregation and adherence, keeping blood vessels free of platelets and ultimately clots. Thus, prostacyclin has a defensive role in the body. It is 4 to 8 times more potent a vasodilator than the E prostaglandins, and it prevents the adherence of platelets to healthy vascular endothelium. However, when the endothelium is damaged, platelets gather, beginning the process of thrombus formation. Even in this abnormal situation, prostacyclin strives to fulfill its protective role because increased PGI₂ can be measured in injured endothelium, thrombosed vessels, and in the vascular tissues of hypertensive animals.

It is believed that endothelial production of prostacyclin plays an important role in the impressive vasodilatation that is associated with pregnancy. The placenta is a major source of thromboxane, and preeclampsia may, in part, reflect an imbalance between the vasodilator, prostacyclin, and the vasoconstrictor, thromboxane.²³⁵

Conditions associated with vascular disease can be understood through the prostacyclin-thromboxane mechanism.²³⁶ For example, atheromatous plaques and nicotine inhibit prostacyclin synthesis. Increasing the cholesterol content of human platelets increases the sensitivity to stimuli that cause platelet aggregation due to increased thromboxane production. The well-known association between low-density and high-density lipoproteins (LDL-cholesterol and HDL-cholesterol) and cardiovascular disease may also be partly explained in terms of PGI₂. LDL from men and postmenopausal women inhibits and HDL stimulates prostacyclin production.²³⁷ Platelets from diabetics and from class A diabetic pregnant women make more TXA₂ than platelets from normal pregnant women. Smokers who use oral contraceptives have increased platelet aggregation and an inhibition of prostacyclin formation.²³⁸ Incidentally, onion and garlic inhibit platelet aggregation and TXA₂ synthesis.²³⁹ Perhaps the perfect contraceptive pill is a combination of progestin, estrogen, and some onion or garlic.

In some areas of the world, there is a low incidence of cardiovascular disease. This can be directly attributed to diet and the protective action of prostacyclin.²⁴⁰ The diet of Eskimos and Japanese has a high content of pentanoic acid and low levels of linoleic and arachidonic acids. Pentanoic acid is the precursor of prostaglandin products with 3 double bonds, and, as it happens, PGI₃ is an active agent while TXA₃ is either not formed, or it is inactive. The fat content of most common fish is 8–12% pentanoic acid, and more than 20% in the more exotic (and expensive) seafoods such as scallops, oysters, and caviar.

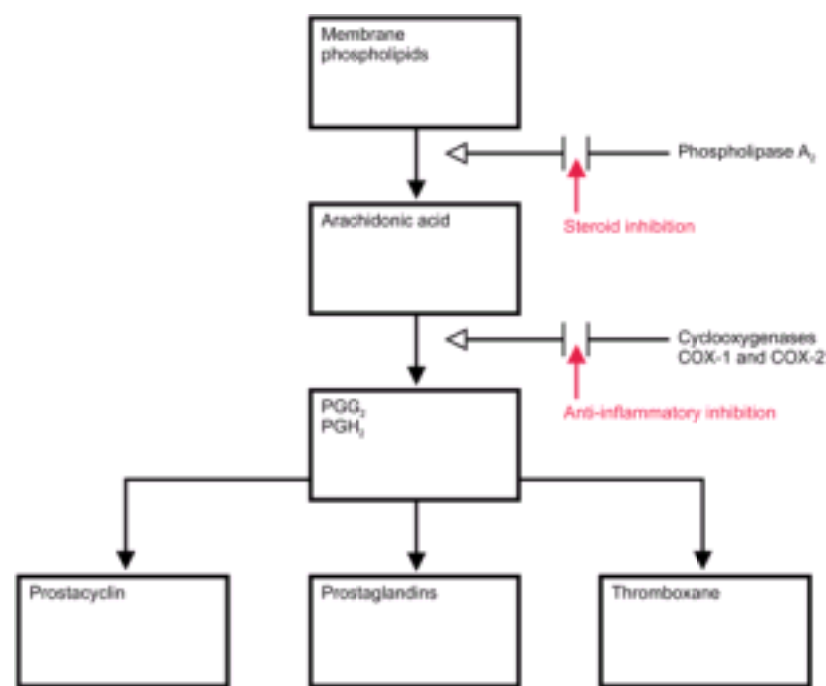

Metabolism

Prostaglandin metabolism is initiated by 15-hydroxyprostaglandin dehydrogenase. The metabolism of prostaglandins occurs primarily in the lungs, kidneys, and liver. The lungs are important in the metabolism of E and F prostaglandins. Indeed, there is an active transport mechanism that specifically carries E and F prostaglandins from the circulation into the lungs. Nearly all active prostaglandins in the circulation are metabolized during one passage through the lungs. Therefore, members of the prostaglandin family have a short half-life, and in most instances, exert autocrine/paracrine actions at the site of their synthesis. Because of the rapid half-lives, studies are often performed by measuring the inactive end products, for example 6-keto-PGF_{1α}, the metabolite of prostacyclin, and TXB₂, the metabolite of thromboxane A₂.

Prostaglandin Inhibition

A review of prostaglandin biochemistry is not complete without a look at the inhibition of the biosynthetic cascade of products. Corticosteroids were thought to inhibit the prostaglandin family by stabilizing membranes and preventing the release of phospholipase. It is now proposed that corticosteroids induce the synthesis of proteins called lipocortins (or annexins) which block the action of phospholipase.²⁴¹ Thus far, corticosteroids and some local anesthetic agents are the only substances known to work at this step. Because corticosteroids reduce the availability of arachidonic acid for both the lipoxygenase and cyclooxygenase pathways, they are very effective anti-inflammatory agents and antihypersensitivity agents, especially for the treatment of asthma.

Aspirin is an irreversible inhibitor, selectively acetylating the cyclooxygenase involved in prostaglandin synthesis. The other inhibiting agents, nonsteroidal anti-inflammatory agents such as indomethacin and naproxen, are reversible agents, forming a reversible bond with the active site of the enzyme. Acetaminophen inhibits cyclooxygenase in the central nervous system, accounting for its analgesic and antipyretic properties, but has no anti-inflammatory properties nor does it affect platelets. However, acetaminophen does reduce prostacyclin synthesis; the reason for this preferential effect is unknown.²⁴² The analgesic, antipyretic, and anti-inflammatory actions of these agents are mediated by inhibition of the cyclooxygenase enzymes, COX-1 and COX-2. Aspirin, indomethacin, and ibuprofen are more potent inhibitors of COX-1 than COX-2.²⁴³ Diclofenac, acetaminophen, and naproxen inhibit both enzymes equally. The side effects associated with each agent are a reflection of the degree of selectivity towards the two enzymes; inhibition of COX-1, the constitutive form, being associated with significant side effects, and inhibition of COX-2, the inducible form, being therapeutic. Part of the anti-inflammatory activity of glucocorticoids is due to inhibition of COX-2 formation. The well-known gastric ulcerogenic side effect of anti-inflammatory drugs is due to the fact that PGE₂ protects the gastric mucosa by inhibiting gastric acid secretion, and COX-1 is the predominant enzyme in the gastric mucosa.

Because of the irreversible nature of the inhibition by aspirin, aspirin exerts a long lasting effect on platelets, maintaining inhibition in the platelet for its lifespan (8–10 days). Prostacyclin synthesis in the endothelium recovers more quickly because the endothelial cells can resynthesize new cyclooxygenase. Platelets, lacking nuclei, cannot produce new enzyme, probably exclusively COX-1. The sensitivity of the platelets to aspirin may explain the puzzling results in the early studies in which aspirin was given to prevent subsequent morbidity and mortality following thrombotic events. It takes only a little aspirin to effectively inhibit thromboxane synthesis in platelets. Going beyond this dose will not only inhibit thromboxane synthesis in platelets, but also the protective prostacyclin production in blood vessel walls. Some suggest that a dose of 3.5 mg/kg (about half an aspirin tablet) given at 3-day intervals effectively induces maximal inhibition of platelet aggregation without affecting prostacyclin production by the vessel walls.²⁴⁴ Others indicate that the dose which effectively and selectively inhibits platelet cyclooxygenase is 20–40 mg daily.^{245 246} The major handicap with the use of inhibitors of PG synthesis is that they strike blindly and with variable effect from tissue to tissue. Obviously, drugs that selectively inhibit TXA₂ synthesis would be superior to aspirin in terms of antithrombotic effects.

The Endocrinology of Parturition

Perhaps the best example of the interplay among fetus, placenta, and mother is the initiation and maintenance of parturition. Hormonal changes in the uteroplacental environment are the principal governing factors accounting for the eventual development of uterine contractions. The sequence of events has been repeatedly reviewed in detail, where references to the original work are available.^{247 248 and 249}

Extensive work in the sheep has implicated the fetal pituitary-adrenal axis in normal parturition. The sequence of events in the sheep begins about 10 days prior to labor with elevation of fetal cortisol in response to fetal pituitary ACTH, in turn a response to increased release of hypothalamic CRH. Fetal adrenalectomy or hypophysectomy prolongs pregnancy, whereas infusion of ACTH or glucocorticoids into the sheep fetus stimulates premature labor. Maternal stimulation of the fetal adrenal is not a factor because in sheep (and in women) there is little or no placental transfer of maternal ACTH into the fetal circulation. Thus, parturition in the ewe is initiated by a signal in the fetal brain activating ACTH secretion.

Increased cortisol secretion by the fetal adrenal gland starts a chain of events associated with labor. The sequence of events continues in the sheep with a decline in progesterone. This change is brought about by the induction of 17 α -hydroxylase, 17,20-lyase enzyme activity (P450c17) in the sheep placenta. The up-regulation of P450c17 may be mediated by PGE₂. COX-2 activity is stimulated by cortisol, while at the same time, cortisol inhibits the activity of 15-hydroxyprostaglandin dehydrogenase. Thus, an increase in PGE₂ correlates with the increasing activity of P450c17.

Glucocorticoid treatment of sheep placental tissue specifically increases the rate of production of 17 α ,20 α -dihydroxyprog-4-en-3-one. This dihydroxyprogesterone compound also has been identified in sheep placental tissue obtained after spontaneous labor. Thus, direct synthesis of progesterone does not decline, but increased metabolism to a 17 α -hydroxylated product results in less available progesterone. Progesterone withdrawal is associated with a decrease in the resting potential of myometrium; i.e., an increased response to electric and oxytocic stimuli. Conduction of action potential through the muscle is increased, and the myometrial excitability is increased.

Dihydroxyprogesterone also serves as a precursor for the rise in estrogen levels, which occurs a few days prior to parturition. Estrogens enhance rhythmic contractions, as well as increasing vascularity and permeability, and the oxytocin response. Thus, progesterone withdrawal and estrogen increase lead to an enhancement of conduction and excitation.

The final event in the ewe is a rise in PGF_{2 α} production hours before the onset of uterine activity. A cause-and-effect relationship between the rise in estrogen and the appearance of PGF_{2 α} has been demonstrated in sheep. These events indicate that the decline in progesterone, the rise in estrogen, and the increase in PGF_{2 α} are all secondary to direct induction of a placental enzyme by fetal cortisol.

Human Parturition

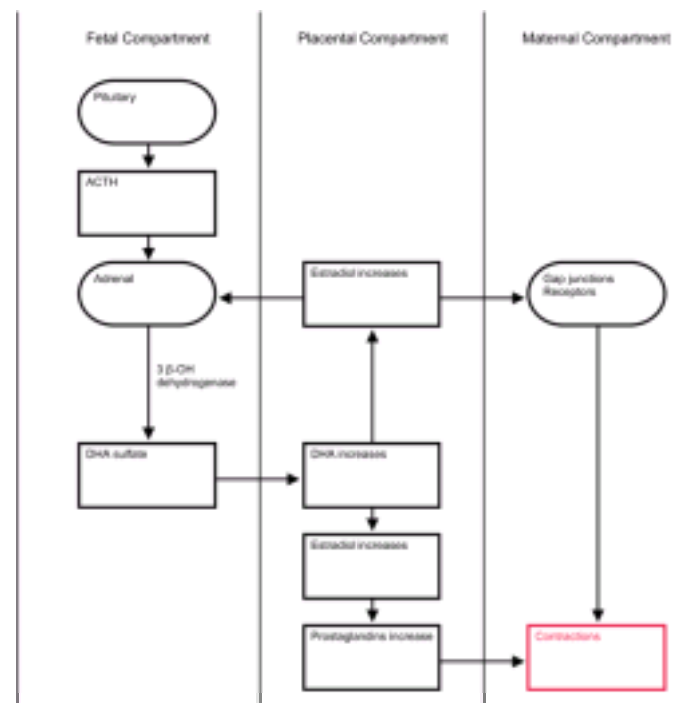

The steroid events in human pregnancy are not identical to events in the ewe. In addition, there is a more extended time scale. Steroid changes in the sheep occur over the course of several days, while in human pregnancy the changes begin at approximately 34–36 weeks and occur over the last 5 weeks of pregnancy. However, if the time course is expressed as a percentage of gestational length, the percentages in sheep and primates are impressively comparable.

Cortisol rises dramatically in amniotic fluid, beginning at 34–36 weeks, and correlates with pulmonary maturation. Cord blood cortisol concentrations are high in infants born vaginally or by cesarean section following spontaneous onset of labor. In contrast, cord blood cortisol levels are lower in infants born without spontaneous labor, whether delivery is vaginal (induced labor) or by cesarean section (elective repeat section). In keeping with the extended time scale of events, administration of glucocorticoids is not followed acutely by the onset of labor in pregnant women (unless the pregnancy is past due).

It is unlikely that the cortisol increments in the fetus represent changes due to increased adrenal activity in the mother in response to stress. Although maternal cortisol crosses the placenta readily, it is largely (85%) metabolized to cortisone in the process. This, in fact, may be the mechanism by which suppression of the fetal adrenal gland by maternal steroids is avoided. In contrast to the maternal liver, the fetal liver has a limited capacity for transforming the biologically inactive cortisone

to the active cortisol. On the other hand, the fetal lung does possess the capability of changing cortisone to cortisol, and this may be an important source of cortisol for the lung. Cortisol itself induces this conversion in lung tissue. Increased fetal adrenal activity is followed by changes in steroid levels as well as important developmental accomplishments (e.g., increased pulmonary surfactant production and the accumulation of liver glycogen). In human parturition an important contribution of the fetal adrenal, in addition to cortisol, is its effect on placental estrogen production. The common theme in human pregnancies associated with failure to begin labor on time is decreased estrogen production; e.g., anencephaly and placental sulfatase deficiency.²⁵⁰ In contrast, mothers bearing fetuses who cannot form normal amounts of cortisol, such as those with congenital adrenal hyperplasia, deliver on time.²⁵¹

Progesterone maintenance of uterine quiescence and increased myometrial excitability associated with progesterone withdrawal are firmly established as mechanisms of parturition in lower species. In primates, the role of progesterone is less clear, largely because of the inability to demonstrate a definite decline in peripheral blood levels of progesterone prior to parturition.²⁵² Nevertheless, pharmacologic treatment with progesterone or synthetic progestational agents has some effect in preventing premature labor, although not labor at term.^{253, 254} There is also reason to believe that progesterone concentration is regulated locally, especially in the fetal membranes and the decidua, and progesterone withdrawal can be accomplished by a combination of binding and metabolism.²⁵⁵ Interruption of exposure to progesterone (e.g., with the antiprogestone, RU486) leads to uterine contractions.²⁵⁶ Furthermore, inhibition of progesterone production in the second trimester of human or the third trimester of monkey pregnancies is followed by a decrease in maternal, fetal and amniotic fluid progesterone concentrations and preterm labor and delivery.^{257, 258} Perhaps multiple mechanisms exist, which affect in a subtle fashion the local concentration and actions of progesterone, as well as the production of progesterone in fetal membranes.²⁵⁹

An increase in estrogen levels in maternal blood begins at 34–35 weeks of gestation, but a late increase just before parturition (as in the sheep) has not been observed in human pregnancy. Perhaps a critical concentration is the signal in human pregnancy rather than a triggering increase. Or the changes are taking place at a local level and are not reflected in the maternal circulation.²⁶⁰ Although it has not been definitely demonstrated, increased or elevated estrogen levels, as well as a local decrease in progesterone production, are thought to play a key role in increasing prostaglandin production.

Evidence for a role of prostaglandin in parturition includes the following:

1. Prostaglandin levels in maternal blood and amniotic fluid increase in association with labor.
2. Arachidonic acid levels in the amniotic fluid also rise in labor, and arachidonate injected into the amniotic sac initiates parturition.
3. Patients taking high doses of aspirin have a highly significant increase in the average length of gestation, incidence of postmaturity, and duration of labor.
4. Indomethacin prevents the normal onset of labor in monkeys and stops premature labor in human pregnancies.
5. Stimuli known to cause the release of prostaglandins (cervical manipulation, stripping of membranes, and rupture of membranes) augment or induce uterine contractions.
6. The process of cervical ripening and softening is mediated by prostaglandins.
7. Prostaglandins induce labor.

The precursor fatty acid for prostaglandin production in part may be derived from storage pools in the fetal membranes, the decidua, or both.²⁴¹ Phospholipase A₂ has been demonstrated in both human chorioamion and uterine decidua. Although the precise mechanism for initiating prostaglandin synthesis, presumably by activation of the enzyme phospholipase A₂, remains unknown, the availability of arachidonic acid for prostaglandin production during parturition follows the stimulation of hydrolysis of phosphatidylethanolamine and phosphatidylinositol in decidual, amnion, and chorion laeve tissues.^{261, 262 and 263} Microsomes from amnion, chorion laeve, and decidua vera tissues contain lipases that hydrolyze fatty acids esterified in the 2 position. Specific phospholipase activity (phospholipase A₂ acting on phosphatidylethanolamine and phospholipase C acting on phosphatidylinositol) combined with a diacylglycerol lipase that also has a specificity for arachidonic acid provides a mechanism for the release of arachidonic acid. The activity of these enzymes in fetal membranes and decidua vera tissue increases with increasing length of gestation.

The key may be the increasing formation of estrogen (both estradiol and estrone) in the maternal circulation as well as in the amniotic fluid or, more importantly, locally within the uterus. The marked rise in estrogen near term may affect the activity of the lipase enzymes, leading to the liberation of arachidonic acid. The activity of these phospholipases is increased by increasing concentrations of calcium, and, therefore, the regulation of intracellular calcium is an important mechanism. Nevertheless, a role for local progesterone withdrawal in the activation of prostaglandin production cannot be discounted.²⁵⁸

The human fetal membranes and decidua are incredibly active. Human chorion and decidua produce estrogen utilizing a variety of substrates, especially estrone sulfate and dehydroepiandrosterone sulfate (DHAS), and this activity is increased around the time of parturition.^{264, 265} In addition, the human fetal membranes synthesize and metabolize progesterone.¹⁴ The membranes contain a 17,20-hydroxysteroid dehydrogenase system. One active site converts 20 α -dihydroxyprogesterone to progesterone, while another active site on this enzyme converts estrone to estradiol. Thus, this enzyme can play an important role in altering the estrogen:progesterone ratio. The membranes and the decidua contain distinct cell populations with different biochemical activities (which change with labor).²⁶⁶ Steroidogenic and prostaglandin interactions among these cells could produce the changes necessary for parturition without affecting the concentrations of circulating hormones. In addition, relaxin derived from decidua and/or chorion may exert a paracrine action on amnion prostaglandin production.¹⁷¹ Throughout most of pregnancy, the amnion and chorion may exert an inhibitory influence over the myometrium by suppressing calcium channel activity.²⁶⁷ Finally, the fetus may take a very direct role in this scenario by secreting substances into the amniotic fluid, which interact with the fetal membranes to signal the initiation of parturition.

The following observations support an important role for placental corticotropin-releasing hormone (CRH):

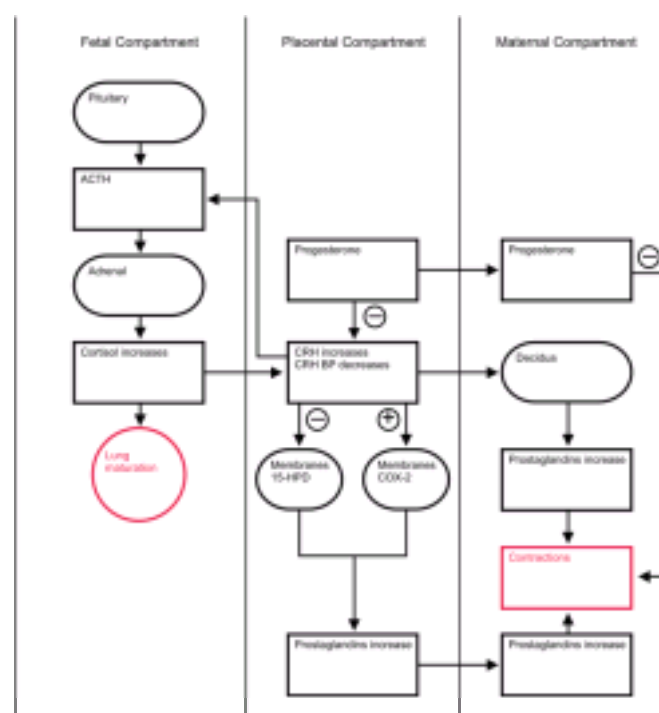

1. CRH is produced in trophoblast, the fetal membranes, and decidua.⁷⁸
2. During pregnancy, CRH levels in the amniotic fluid and the maternal circulation progressively increase, and although amniotic fluid levels do not further increase with labor, the highest maternal levels are found at labor and delivery.
3. Levels of the CRH-binding protein (also produced in trophoblast, membranes, and decidua) are decreased in the amniotic fluid and maternal circulation prior to labor.^{266, 268} This decrease in the CRH-binding protein would allow an increase in CRH activity.
4. CRH stimulates prostaglandin release in fetal membranes, decidua, and myometrium.^{90, 269}
5. Increased CRH and decreased CRH-binding protein have been measured in women with preterm labor and in women with threatened preterm labor who subsequently deliver within 24 hours.^{270, 271 and 272}
6. Cortisol, in the presence of progesterone, stimulates (probably by blocking progesterone inhibition) trophoblastic CRH synthesis.^{50, 273}

These observations are consistent with a key mechanism involving CRH activity in the initial triggering events of parturition. Although in the sheep the CRH signal begins in the fetal brain, in women, it appears to begin in the uterus. Progesterone is the only major inhibiting factor for CRH production in placental tissues. It has been hypothesized that rising fetal cortisol secretion competes with progesterone for the glucocorticoid receptor in the placenta, thus blocking the inhibitory action of progesterone on CRH synthesis, leading to an increase in CRH.⁵⁰ The increase in CRH would augment fetal ACTH secretion, producing more fetal cortisol as well as more DHAS to serve as precursor for the increase in estrogen that occurs prior to parturition; this indicates the important role of the fetal brain in the overall process. The competitive inhibition of progesterone would in effect be a mechanism of progesterone withdrawal. This sequence of events could be started by an increase in CRH or a decrease in CRH-binding protein, or both. On the other hand, consistent with the sheep studies, the initiating step in this sequence of events could be an increase in fetal ACTH secretion; e.g., in response to relative hypoxemia. Regardless of the specific triggering event, it is increasingly clear that the fetus plays a pivotal, if not controlling, role in parturition.

The Role of Prostaglandins

With labor, the arachidonic acid pathway in the fetal membranes shifts toward the cyclooxygenase direction with a large increase in the production of PGE₂ due to the induction of COX-2 activity. This COX-2 activity is a response to the increase in cortisol that in turn is a response to CRH. In addition, CRH can directly stimulate prostaglandin production in the membranes.

Specific protein inhibitors of prostaglandin synthase have been demonstrated in placenta, amnion, and chorion, and these proteins cannot be found in tissue from patients who have established labor.^{241, 274} The link between infection and the onset of labor (especially preterm labor) may be due to the conversion by bacterial medium (with factors such as the interleukins) of arachidonic metabolism in the membranes and decidua to a condition associated with labor marked by the production of PGE₂.^{241, 275, 276} In this case, prostaglandin production may be a consequence of inflammatory induction of the second cyclooxygenase enzyme, COX-2.²⁷⁷

Undoubtedly, prostaglandin production during pregnancy reflects the usual complex interaction of a host of autocrine/paracrine factors. Platelet-activating factor, epidermal growth factor, and transforming growth factor- α stimulate prostaglandin production by the fetal membranes apparently by regulating intracellular calcium concentrations.^{278, 279} Secretory products of the fetal membranes themselves are active stimulators of membrane prostaglandin production, including renin derived from chorion prorenin.²⁸⁰ Decidual PGF_{2 α} production is enhanced by bradykinin, epidermal growth factor and transforming growth factor- α , and these responses are further increased by interleukin-1b.^{281, 282} Prostaglandin production by amnion, chorion, and decidual cells is stimulated by corticotropin-releasing hormone and modulated by progesterone.^{8c} The ubiquitous substances, activin and inhibin, are involved here as well. Amnion and chorion produce the activin and inhibin subunits, and activin stimulates prostaglandin PGE₂ release from amnion cells.²¹¹

During labor the maternal circulating levels of PGE₂, PGF_{2 α} , and the PGF_{2 α} -metabolite are increased, a change which can be directly attributed to uterine production in that the gradient across the uterus for these substances is also increased. This increase in production of prostaglandins within the uterus must be the key factor, because the concentration and affinity of prostaglandin receptors do not change at parturition.²⁸³ Meanwhile, prostacyclin and its metabolite are not increased. Prostacyclin is produced (at least in vitro) by a variety of tissues involved in pregnancy: endometrium, myometrium, placenta, amnion, chorion, and decidua. Prostacyclin and thromboxane are probably more important in the vascular responses of mother and fetus, and in all likelihood do not play a role in initiating or maintaining uterine contractions.²⁸⁴

Decidua produces both PGE₂ and PGF_{2 α} , but the amnion and chorion produce primarily PGE₂.²⁸⁵ The inducible cyclooxygenase, COX-2, is expressed at a high level at term in the amnion and chorion.²⁸⁶ As in sheep, prostaglandin synthesis in membranes and decidua is probably stimulated by cortisol; glucocorticoid receptors are present in the same cells that contain cyclooxygenase.²⁸⁷

There is evidence for the transfer of prostaglandin E₂ across the membranes to the decidua and possibly the myometrium.²⁸⁸ The paradox of PGE₂ production in the amnion being matched not by a PGE₂-metabolite in the maternal circulation, but by a PGF_{2 α} -metabolite, is explained by transfer across the membranes and conversion of PGE₂ to PGF_{2 α} in the decidua.²⁸⁹ However, continued study of this issue strongly indicates that prostaglandins produced on one side of the membranes do not contribute to the prostaglandins on the other side, arguing that uterine contractions must be primarily influenced by decidual or myometrial prostaglandins.²⁹⁰ On the other hand, there is reason to believe that the myometrial exposure to prostaglandins is governed by the activity of a catabolic enzyme in the chorion.

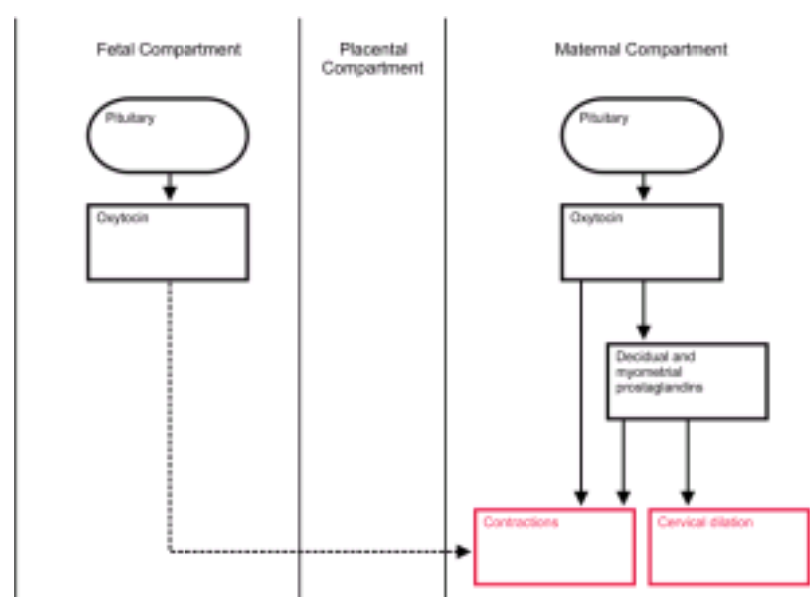

At term, prostaglandin synthesis occurs mainly in the amnion and decidua, and throughout pregnancy the chorion forms a barrier preventing passage of bioactive prostaglandins to the myometrium because of a large capacity to catabolize prostaglandins via 15-hydroxyprostaglandin dehydrogenase.²⁹¹ The activity of this enzyme is decreased in the presence of labor, including preterm labor, and after premature rupture of membranes or when infection is present.²⁹² Thus, a combination of increased biosynthesis and a decrease in chorionic 15-hydroxyprostaglandin dehydrogenase achieve the increase in prostaglandins associated with parturition, probably mediated by the local changes in estrogen and progesterone bioavailability and activity, with a key role also played by CRH and cortisol. Cortisol decreases and progesterone increases 15-hydroxyprostaglandin dehydrogenase in placental tissues.³³⁰

Oxytocin and Myometrial Responses

Using sensitive assays, an increase in maternal levels of oxytocin can be detected prior to parturition, occurring at first only at night.^{293, 294} Once labor has begun, oxytocin levels rise significantly, especially during the second stage. Thus, oxytocin may be important for developing the later, more intense uterine contractions. Extremely high concentrations of oxytocin can be measured in the cord blood at delivery, and release of oxytocin from the fetal pituitary may also be involved in labor. However, this is controversial, and studies in monkeys fail to indicate a role for fetal oxytocin in parturition.²⁹⁴ Part of the contribution of oxytocin to parturition is the stimulation of prostaglandin synthesis in decidua and myometrium.²⁹⁵ Cervical dilatation appears to be dependent on oxytocin stimulation of prostaglandin production, probably in the decidua. The greater frequency of labor and delivery at night may be due to greater nocturnal oxytocin secretion.²⁹³ In addition, oxytocin is synthesized in the amnion, chorion, and significantly, in the decidua.^{293, 296, 297} This locally produced oxytocin may be a significant stimulus for myometrial and membrane production of prostaglandins.

It is likely that oxytocin action during the initial stages of labor may depend on myometrial sensitivity to oxytocin in addition to the levels of oxytocin in the blood. The concentration of oxytocin receptors in the myometrium is low in the nonpregnant state and increases steadily throughout gestation (an 80-fold increase), and during

labor, the concentration doubles. This receptor concentration correlates with the uterine sensitivity to oxytocin.²⁹⁸ The mechanism for the increase is unknown, but it likely is due to a change in the prostaglandin and hormonal milieu of the uterus. The local production and effects of oxytocin, estrogen, and progesterone combine in a complicated process of autocrine, paracrine, and endocrine actions to result in parturition. In mice lacking the prostaglandin F receptor, the sequence of progesterone withdrawal, appearance of oxytocin receptors, and parturition fails to occur, indicating a key role for prostaglandin initiation of luteolysis in mice as a requisite for labor and delivery.²⁹⁹ Mice lacking oxytocin, however, undergo normal parturition, but fail to nurse their offspring.³⁰⁰

Animal studies have implicated the formation of low-resistance pathways in the myometrium, called **gap junctions**, as an important action of steroids and prostaglandins during labor.³⁰¹ In the gap junction, a pore forms, which allows communication from cytoplasm to cytoplasm between two cells. The pore is a cylinder-shaped channel formed of 6 special proteins called **connexins**. Either substances or electrical current (ions) can follow this pathway without leakage into extracellular space. Thus, gap junctions provide a means of communication between myometrial cells, allowing enhancement of electrical conductivity and synchronization of activity. Gap junction formation is related to the estrogen/progesterone ratio (estrogen is stimulatory and progesterone is inhibitory) and to the presence of the stimulating prostaglandins, PGE₂ and PGF_{2α}. Therefore it is not surprising that the number of gap junctions increases in the final weeks of pregnancy, especially just before labor. The modulation of the number and the permeability of gap junctions is another contributing factor in the control of uterine contractility.

The final contraction of uterine muscle results from increased free calcium concentrations in the myofibril, the result of prostaglandin action, an action opposed to that of progesterone which promotes calcium binding in the sarcoplasmic reticulum.³⁰² Thus, prostaglandins and oxytocin increase while progesterone decreases intracellular calcium levels. The intracellular calcium concentration is affected by cellular entry and exit of calcium as well as binding in the sarcoplasmic reticulum. It is the intracellular concentration of calcium which determines the rate of myosin phosphorylation and the contractile state of the myometrium. Tocolytic therapy (the use of beta-adrenergic agents) stimulates adenylate cyclase activity, which increases the levels of cellular cyclic AMP, which, in turn, decreases intracellular calcium concentration as well as inhibiting actin-myosin interaction by modulating kinase phosphorylation.

Ducsay and colleagues propose that the coordination of this complex relationship of physiologic, endocrine, and molecular mechanisms is expressed in rhythms.⁶⁷ Both mother and fetus experience 24-hour rhythms in hormone secretions, and uterine activity is correlated with day and night (photoperiod regulation). The coordination and enhancement of this rhythmicity play a role in parturition. Improved detection and measurement of this activity could contribute to better prevention and treatment of preterm labor.

Concluding Thought

Imagine yourself as a fetus within a pregnant uterus. Your growth, development, and survival require keeping the uterus quiescent for most of pregnancy. This is accomplished by maintaining progesterone inhibitory dominance of the myometrium. When ready to begin extrauterine life or when your environment becomes inhospitable, you are able to prepare or “activate” the parturition mechanisms by means of hormonal and autocrine/paracrine messengers. Ultimately, uterine contractions and cervical ripening are stimulated, and amazingly, even if you are incapable of initiating these events, the sequence will eventually begin, and delivery will ensue. The extraordinary experience and wonder of labor and birth, as perceived by parents and birth assistants, are matched by your ability and the complexity of the systems you influence.

Treatment of Labor With Prostaglandin Inhibition

The key role for prostaglandins in parturition raises the potential for treatment of premature labor with inhibitors of prostaglandin synthesis. The concern has been that such treatment would result in intrauterine closure of the ductus arteriosus and pulmonary hypertension. Clinical studies, however, indicate that use of the nonsteroidal anti-inflammatory agents for short periods of time (3 days) yields good results and does not result in this complication.³⁰³ Beyond 34 weeks, the fetus is more sensitive to this pulmonary action, and treatment should be limited to pregnancies less than 32 weeks and with caution from 32–34 weeks. Perhaps it is the treatment of choice for the inhibition of labor during a maternal transport. If the drug is failing, it should not be maintained because increased blood loss can occur at delivery. Because indomethacin inhibits the synthesis of all members of the prostaglandin family, including the vasodilating prostacyclin, it should be used with caution in hypertensive patients.³⁰⁴ Sulindac is just as effective as a tocolytic but does not affect urine output and amniotic fluid, and it has a lesser impact on the fetal ductus arteriosus.^{305, 306}

Treatment of pregnant women with indomethacin reduces the amniotic fluid volume due to a decrease in fetal urine output. This is reversible with a decrease in dose. This treatment has been used for polyhydramnios with good response and no effect on the newborn despite treatment for 2 to 11 weeks.³⁰⁷

Induction of Labor and Cervical Ripening

Pharmacologically and physiologically, prostaglandins have two direct actions associated with labor: ripening of the cervix and myometrial stimulation. Successful parturition requires organized changes in both the upper uterus and in the cervix. The cervical changes are in response to the estrogen/progesterone ratio and the local release of prostaglandins. Whether relaxin plays a role in human parturition is not established; however, recombinant relaxin is being tested for cervical ripening.

Ripening of the cervix is the result of a change that includes an increase in hyaluronic acid and water and a decrease in dermatan sulfate and chondroitin sulfate (these compounds hold the collagen fibers in a rigid structure). How prostaglandins operate in this change is unknown, but enzyme activation must be involved. For ripening of the cervix, PGE₂ is very effective, while PGF_{2α} has little effect. The purpose of pharmacologically achieving ripening of the cervix is to increase the success rate with induction of labor and lower the proportion of cesarean sections. Intravaginal prostaglandin E₂ administered as tablets, suppositories, and mixed in gels has been very effective for cervical ripening. The commercial formulation currently available in the U.S. consists of 0.5 mg PGE₂ dissolved in a triacetin viscous gel base, also containing a colloid silicone dioxide, provided in a prefilled syringe for application.³⁰⁸ A synthetic PGE₁ analogue, misoprostol, is also safe and effective when used intravaginally for cervical ripening and labor induction.³⁰⁹

A major clinical application for the induction of labor in the United States is the use of intravaginal PGE₂ in cases of fetal demise and anencephalic fetuses. Based on our own experience, certain precautions have been developed. The patient should be well hydrated with an electrolyte solution to counteract the induced vasodilatation and decreased peripheral resistance. If satisfactory uterine activity is established, the next application should be withheld. And, finally, because there is a synergistic effect when oxytocin is used shortly after prostaglandin administration, there should be a minimum of 6 hours between the last prostaglandin dose and beginning oxytocin augmentation.

Prostaglandins are used to induce term labor. Intravenous prostaglandins are not an acceptable method due to the side effects achieved by the high dosage necessary to reach the uterus. The intravaginal and oral administration of PGE₂ is as effective as intravenous oxytocin, even including patients with previous cesarean sections.^{310, 311} The intravaginal administration of misoprostol, the synthetic prostaglandin E₁ analogue, is safe, effective, and relatively inexpensive.³¹² These

methods, plus intracervical administration, are in routine use in many parts of the world.

Induced Abortion

Prostaglandins are effective for postcoital contraception and first trimester abortion but impractical because of the high incidence of side effects, including an unacceptable rate of incomplete abortions. For midtrimester abortions, intra-amniotic prostaglandin, intramuscular methyl esters, and vaginal PGE suppositories are available. The major clinical problems have been the efficacy in accomplishing complete expulsion and the high level of systemic side effects. Overall, there is a higher risk of hemorrhage, fever, infection, antibiotic administration, readmission to the hospital, and more operative procedures when compared with saline abortions. The surgical procedure, D&E (dilatation and evacuation) is safer and less expensive than medical methods, and it is better tolerated by patients.

The combination of prostaglandin's oxytocic action with the antiprogesterone effect of RU486 (mifepristone) has proved to be a safe and effective medical treatment for the induction of therapeutic abortion prior to 9 weeks gestation.^{113,114 and 115} An orally active methyl ester of prostaglandin E₁ is only 20% effective as an abortifacient when administered by itself. Combining the prostaglandin with RU486 achieves greater than 95% efficacy, safely and inexpensively.

Prostaglandins and Postpartum Hemorrhage

When routine methods of management for postpartum hemorrhage caused by uterine atony have failed, an analogue of prostaglandin F_{2a} has been used with excellent results (80–90% successful).³¹⁶ Prostin 15 M is (15-S)-15-methyl prostaglandin F_{2a}-tromethamine. The dose is 0.25–0.5 mg, repeated up to 4 times and given with equal efficacy either intramuscularly or directly into the myometrium. It can also be used after the replacement of an inverted uterus. Failures are usually associated with infections or magnesium sulfate therapy. It should not be used in patients with severe hypertension or symptomatic asthma. Diarrhea is a frequent side effect.

Prostaglandins and the Fetal Circulation

The predominant effect of prostaglandins on the fetal and maternal cardiovascular system is to maintain the ductus arteriosus, renal, mesenteric, uterine, placental, and probably the cerebral and coronary arteries in a relaxed or dilated state. The importance of the ductus arteriosus can be appreciated by considering that 59% of the cardiac output flows through this connection between the pulmonary artery and the descending aorta.

Control of ductal patency and closure is mediated through prostaglandins. The arterial concentration of oxygen is the key to the caliber of the ductus. With increasing gestational age, the ductus becomes increasingly responsive to increased oxygen. In this area, too, attention has turned to PGI₂ and TXA₂.

Fetal lamb ductus homogenates produce mainly PGI₂ when incubated with arachidonic acid. PGE₂ and PGF_{2a} are formed in small amounts and TXA₂ not at all. Although PGE₂ is less abundant than PGI₂ in the ductus, it is a more potent vasodilator of the ductus and is more responsive to oxygen (decreasing vasodilatation with increasing oxygen).³¹⁷ Thus, PGE₂ appears to be the most important prostaglandin in the ductus from a functional point of view, while PGI₂, the major product in the main pulmonary artery, appears to be the major factor in maintaining vasodilatation in the pulmonary bed. The ductus is dilated maximally in utero by production of prostaglandins, and a positive vasoconstrictor process is required to close it. The source of the vasoconstrictor is probably the lung. With increasing maturation, the lung shifts to TXA₂ formation. This fits with the association of ductal patency with prematurity. With the onset of pulmonary ventilation at birth leading to vascular changes that deliver blood to the duct directly from the lungs, TXA₂ can now serve as the vasoconstrictor stimulus. The major drawback to this hypothesis is the failure of inhibitors to affect the constriction response to oxygen.

Administration of vasodilating prostaglandins can maintain patency after birth, while preparing an infant for surgery to correct a congenital lesion causing pulmonary hypertension. Infants with persistent ductus patency may be spared thoracotomy by treatment with an inhibitor of prostaglandin synthesis. The use of indomethacin to close a persistent ductus in the premature infant is successful about 40% of the time.³¹⁷ An important factor is early diagnosis and treatment because with increasing postnatal age the ductus becomes less sensitive to prostaglandin inhibitors, probably because of more efficient clearance of the drug.³¹⁸ The highest incidence of successful indomethacin ductus closure has been with infants less than 30 weeks gestation and less than 10 days old.

This aspect of the use of prostaglandin inhibitors is of concern in considering the use of agents to inhibit premature labor. The drug half-life in the fetus and newborn is prolonged because the metabolic pathways are limited, and there is reduced drug clearance because of immature renal function. In utero constriction of the ductus can cause congestive heart failure and fetal pulmonary hypertension.³¹⁹ Prolonged ductus constriction leads to subendocardial ischemia and fibrotic lesions in the tricuspid valve muscles. Infants with persistent pulmonary hypertension have hypoxemia, cardiomegaly, and right to left shunting through the foramen ovale or the ductus. Infants of mothers given either indomethacin or salicylates chronically have been reported to have this syndrome. Duration of exposure and dosage are critical. It takes occlusion of the ductus for more than 2 weeks to produce fetal pulmonary hypertension and cardiac hypertrophy. This side effect is rare in pregnancies less than 27 weeks gestation; the ductus arteriosus usually begins to respond at 27–30 weeks, and after 30 weeks, this is an important side effect which can be minimized if long-term use is avoided.³²⁰

Prostaglandins and Fetal Breathing

Prior to parturition, fetal breathing is very shallow. It is proposed that placental PGE₂ suppresses breathing by acting in the fetal brain.³²¹ Occlusion of the umbilical cord is rapidly followed by a loss of this PGE₂ influence and the onset of air breathing. The administration of indomethacin to fetal sheep increases, while infusion of PGE suppresses, fetal breathing movements. This may be the explanation for the decrease in fetal breathing movements observed during human labor (associated with an increase in prostaglandin levels).

Fetal Lung Maturation

The pulmonary alveoli are lined with a surface-active phospholipid-protein complex called pulmonary surfactant, which is synthesized in the type II pneumocyte of mature lungs. It is this surfactant that decreases surface tension, thereby facilitating lung expansion and preventing atelectasis. In full-term fetuses, surfactant is present at birth in sufficient amounts to permit adequate lung expansion and normal breathing. In premature fetuses, however, surfactant is present in lesser amounts, and when insufficient, postnatal lung expansion and ventilation are frequently impaired, resulting in progressive atelectasis, the clinical syndrome of respiratory distress.

Phosphatidylcholine (lecithin) has been identified as the most active and most abundant lipid of the surfactant complex. The second most active and abundant material is phosphatidylglycerol (PG), which significantly enhances surfactant function. Both are present in only small concentrations until the last 5 weeks of pregnancy. Beginning at 20–22 weeks of pregnancy, a less stable and less active lecithin, palmitoylmyristoyl lecithin, is formed. Hence, a premature infant does not always develop respiratory distress syndrome; however, in addition to being less active, synthesis of this lecithin is decreased by stress and acidosis, making the premature infant more susceptible to respiratory distress. At about the 35th week of gestation, there is a sudden surge of dipalmitoyl lecithin, the major surfactant lecithin, which is stable and very active. Because secretion by the fetal lungs contributes to the formation of amniotic fluid and the sphingomyelin concentration of amniotic fluid changes relatively little throughout pregnancy, assessment of the lecithin/sphingomyelin (L/S) ratio in amniotic fluid at approximately 34–36 weeks of pregnancy can determine the amount of dipalmitoyl lecithin available and thus the degree to which the lungs will adapt to newborn life.

Gluck and colleagues were the first to demonstrate that the L/S ratio correlates with pulmonary maturity of the fetal lung.³²² In normal development, sphingomyelin concentrations are greater than those of lecithin until about gestational week 26. Prior to 34 weeks, the L/S ratio is approximately 1:1. At 34–36 weeks, with the sudden increase in lecithin, the ratio rises acutely. In general, a ratio of 2.0 or greater indicates pulmonary maturity and that respiratory distress syndrome will not develop in the newborn. Respiratory distress syndrome associated with a ratio greater than 2.0 usually follows a difficult delivery with a low 5-minute Apgar score, suggesting that severe acidosis can inhibit surfactant production. A ratio in the transitional range (1.0–1.9) indicates that respiratory distress syndrome may develop but that the fetal lung has entered the period of lecithin production, and a repeat amniocentesis in 1 or 2 weeks usually reveals a mature L/S ratio. The rise from low to high ratios may actually occur within 3–4 days.

An increase in the surfactant content of phosphatidylglycerol at 34–36 weeks marks the final maturation of the fetal lung. When the L/S ratio is greater than 2.0 and

PG is present, the incidence of respiratory distress syndrome is virtually zero. The assessment of PG is especially helpful when the amniotic fluid is contaminated because the analysis is not affected by meconium, blood, or vaginal secretions.

Abnormalities of pregnancy may affect the rate of maturation of the fetal lung, resulting either in an early mature L/S ratio or a delayed rise in the ratio. Accelerated maturation of the ratio is associated with hypertension, advanced diabetes, hemoglobinopathies, heroin addiction, and poor maternal nutrition. Delayed maturation is seen with diabetes (without hypertension) and Rh sensitization. In general, accelerated maturation is associated with reductions in uteroplacental blood flow (and presumably increased fetal stress). With vigorous and effective control of maternal diabetes, the risk of respiratory distress syndrome in the newborns is not significantly different from infants born to nondiabetics.

Since Liggins observed survival of premature lambs following the administration of cortisol to the fetus, it has become recognized that fetal cortisol is the principal requisite for surfactant biosynthesis. This is true despite the fact that no increase in fetal cortisol can be demonstrated to correlate with the increases in fetal lung maturation. For that reason, fetal lung maturation can be best viewed as the result of not only cortisol, but the synergistic action of cortisol, prolactin, thyroxine, estrogens, prostaglandins, growth factors, and perhaps other yet unidentified agents.³²³ Insulin directly inhibits surfactant protein expression in fetal lung tissue, which explains the increase in respiratory distress syndrome associated with hyperglycemia in pregnancy (although this effect can be overcome by the stress associated with advanced diabetes).³²⁴

Corticosteroid therapy of pregnant women threatened with preterm delivery reduces neonatal mortality, respiratory distress syndrome, and intraventricular hemorrhage.³²⁵ In general, maximal benefit in terms of enhanced fetal pulmonary maturity has been demonstrated with glucocorticoid administration at 24–32 weeks of gestational age, with some benefit between 32–34 weeks, and no benefit beyond 34 weeks. The optimal effect requires that 48 hours elapse after initiation of therapy, and this benefit is lost after 7 days; however, it is recommended that treatment be limited to 2 doses. The effect of antenatal corticosteroid treatment is additive to that of postnatal surfactant. Although every case of respiratory distress syndrome and subsequent chronic lung disease cannot be prevented, a significant impact can be achieved on infant mortality, and the incidence and severity of respiratory distress syndrome. Additional treatment with thyrotropin-releasing hormone (TRH) was initially believed to be beneficial; however, clinical trials indicate that TRH does not further reduce the incidence of chronic lung disease in glucocorticoid-treated very low birth weight infants.^{326, 327}

The Postpartum Period

The immediate postpartum period is a time of rapid readjustment to the nonpregnant endocrine state. About 10–15% of women become clinically depressed during this time, and an endocrine mechanism has been suggested.³²⁸ The clinician should always have a high index of suspicion for thyroid dysfunction because of the 5–10% incidence of postpartum thyroiditis in the 3–6 months after delivery. Because of the relative hypercortisolism in the last trimester of pregnancy, it has been suggested that persistent suppression of hypothalamic CRH secretion (and thus the pituitary-adrenal axis) in the postpartum period is a characteristic finding in women with postpartum depression, and that this suppression also contributes to a greater vulnerability to autoimmune diseases, like thyroiditis.³²⁹

Abnormalities of sexual differentiation are seen infrequently in an individual clinician's practice. There are, however, few practitioners who have not been challenged at least once by a newborn with ambiguous genitalia or by a young woman with primary amenorrhea on a genetic basis. The categorization of the various syndromes in this area has been confusing, requiring constant reference to multiple textbooks, and dependence upon memory of eponym-laden, seemingly endless lists of syndromes. Happily, this "catalogue" state of affairs has changed; major advances in reproductive science have yielded clarification and consolidation. As a result, an informed basis for clinical practice has emerged and is readily applicable.

This chapter will present classification of the major problems and our clinical approach to diagnosis. Normal sexual differentiation will be considered in order to provide a basis of understanding for the various types of abnormal development. This is followed by a section on the diagnosis and management of ambiguous genitalia. Some subjects are discussed in other chapters, but brief descriptions will be repeated here in order to present a complete picture. It will be seen that analysis of phenotypic ambiguity follows a fundamental, pervasive theme: too little androgen effect in males, too much androgen effect in females. Whereas androgen biologic "availability" may be excessive in females because of abnormally high levels of intake or production, reduced androgen effects in males can be the result of defects in synthesis, peripheral and target organ conversion, abnormalities in androgen receptor or receptor-DNA interactions, as well as defective gonadal development and function.

Normal Sexual Differentiation

The gender identity of a person (whether an individual identifies as a male or a female) is the end result of genetic, hormonal, and morphologic sex as influenced by the environment of the individual. It includes all behavior with any sexual connotation, such as body gestures and mannerisms, habits of speech, recreational preferences, and content of dreams. Sexual expression, both homosexual and heterosexual, can be regarded as the result of all influences on the individual, both prenatal and postnatal. Specifically, gender identity is the result of the following determinants: genetic sex, gonadal sex, the internal genitalia, the external genitalia, the secondary sexual characteristics that appear at puberty, and the role assigned by society in response to all of these developmental manifestations of sex.

Prenatally, sexual differentiation follows a specific sequence of events. First is the establishment of the genetic sex. Second, under the control of the genetic sex the gonads differentiate, determining the hormonal environment of the embryo, the differentiation of internal duct systems, and the formation of the external genitalia. It has become apparent that the embryonic brain is also sexually differentiated, perhaps via a control mechanism very similar to that which determines the sexual development of the external genitalia. The inductive influences of hormones on the central nervous system may have an effect on the patterns of hormone secretion

and sexual behavior in the adult.^{1, 2, 3, 4, 5 and 6}

Gonadal Differentiation

In human embryos, the gonads begin development during the 5th week of gestation as protuberances overlying the mesonephric ducts. The migration of primordial germ cells into these gonadal ridges occurs between weeks 4 and 6 of gestation. Although germ cells do not induce gonadal development, if the germ cells fail to arrive, gonads do not develop and only the fibrous streak of gonadal agenesis will exist ([Chapter 3](#)). At 6 weeks of gestation (4 weeks after ovulation) the gonads are indifferent but bipotential, possessing both cortical and medullary areas, and are capable of differentiation into either testes or ovaries. They are composed of germ cells, special epithelia (potential granulosa/Sertoli cells), mesenchyme (potential theca/Leydig cells), and the mesonephric duct system. Wolffian and müllerian ducts exist side by side; external genitalia are undifferentiated.⁷ Subsequent sexual differentiation requires direction by various genes, with a single gene determinant on the Y chromosome (testes determining factor — TDF) necessary for testicular differentiation, beginning at 6–7 weeks gestation.⁸

The distal ends of the short arms of the X and Y chromosomes are called the pseudoautosomal regions because during meiosis the homologous distal short arms of the X and Y chromosomes pair, and interchange of genetic material occurs as in autosomes. The genes in the pseudoautosomal regions are doubly present in both sexes, and therefore escape X inactivation. Gene deletions in this area of the X chromosome (Xp22.3) are associated with various conditions, known as contiguous gene syndromes: short stature, mental retardation, X-linked ichthyosis, Kallmann's syndrome. The testes-determining gene is located on the distal short arm of the Y, immediately adjacent to the pseudoautosomal region. Loss of the TDF gene causes gonadal dysgenesis. Transfer of the TDF gene to the X results in an XX male.

Since the identification of the Y chromosome's importance to male differentiation over 4 decades ago, three proteins have been suggested as the Y-encoded, gene expressed, testes determining factor. The first was the H-Y histocompatibility antigen and the second, ZFY (a zinc finger protein). Both were abandoned because of inconsistencies of expression in various cell types (in XX males and XY females), as well as absent expression in indisputable males with testes. More recently, SRY (Sex determining Region Y) has been isolated, almost certainly the true sex-determining region on the short arm of the Y chromosome, the only gene on the Y chromosome required for sex determination.⁹

SRY is a single copy gene located in the smallest Y chromosome region capable of sex reversal. It is expressed in the genital ridge only during the appropriate time of embryonic development when testicular cords form; it is deleted or mutated in cases of human XY females, and present in 46,XX males, and it can sex-reverse XX mice into males.^{10, 11 and 12} The 204 amino acid protein product contains an 80 amino acid domain with a motif shared by a recognized family of transcription factors (the high mobility group) that bind to DNA and regulate gene transcription. Investigations of the DNA binding properties of the SRY high mobility group (HMG) box in the promoter regions of P450 aromatase (conversion of testosterone to estradiol which is down-regulated in the male embryo) and anti-müllerian hormone (responsible for regression of the müllerian ducts) support the hypothesis that SRY directly controls male development through sequence-specific regulation of target genes.¹³

SRY participation in morphogenesis leading to a testis from the bipotential genital ridge is a model "genetic switch" between alternative inherent programs. Whereas testes formation is an active event, female sex determination is the default pathway occurring if SRY is absent or deficient. Genes other than SRY are also required for proper gonadogenesis.^{14, 15} In the human, autosomal genes are essential for gonadal development. These autosomal genes regulate migration of the germ cells and coding of the steroidogenic enzymes. The formation of the testicle precedes any other sexual development in time, and a functionally active testis controls subsequent sexual development, therefore SRY presumably controls these autosomal genes. Thus, testicular hormones activate or repress genes to direct development away from an otherwise predetermined course of female differentiation.

Steroidogenic factor-1 (SF-1) and DAX-1 (named for the location of its gene on the X chromosome) are nuclear receptors for which specific ligands have not been identified ("orphan receptors"). SF-1 influences the expression of genes that encode steroidogenic enzymes, and when genetic expression of SF-1 is disrupted in mice, gonads and adrenal glands fail to develop.^{16, 17} SF-1 is also believed to be involved in the production of anti-müllerian hormone.¹⁸ Mutations in the DAX-1 gene result in adrenal hypoplasia, and DAX-1 is believed to work with SF-1 in regulating development and function of steroid-producing tissues.¹⁹

The *WT1* gene is named after the Wilms' tumor nephroblastoma because it is one of the genes on chromosome 11 deleted in patients with this tumor. Mutant mice lacking *WT1* fail to develop kidneys and gonads. *WT1* mutations, however, could not be detected in 25 patients with a congenital absence of the uterus and vagina, indicating that *WT1* may be necessary for normal renal and gonadal development, but not for early müllerian duct development.²⁰

Testicular differentiation begins at 6–7 weeks; first with Sertoli cells that aggregate to form spermatogenic cords, then seminiferous tubules, followed by Leydig cell formation a week later. Human chorionic gonadotropin (HCG) stimulation produces Leydig cell hypertrophy, and peak fetal testosterone levels are seen at 15–18 weeks.¹⁴ It is very probable, but not conclusively proven, that HCG stimulates steroidogenesis in the early fetal testes, so that androgen production will ensue and masculine differentiation can be accomplished.²¹

In an XX individual, without the active influence of a Y chromosome, the bipotential gonad develops into an ovary about 2 weeks later than testicular development. The cortical zone develops and contains the germ cells, while the medullary portion regresses with its remnant being the rete ovarii, a compressed nest of tubules and Leydig cells in the hilus of the ovary. The germ cells proliferate by mitosis, reaching a peak of 5–7 million by 20 weeks. By 20 weeks, the fetal ovary achieves mature compartmentalization with primordial follicles containing oocytes, initial evidence of follicle maturation and atresia, and an incipient stroma. Degeneration (atresia) begins even earlier, and by birth, approximately 1–2 million germ cells remain. These have become surrounded by a layer of follicular cells, forming primordial follicles with oocytes that have entered the first meiotic division. Meiosis is arrested in the prophase of the first meiotic division until reactivation of follicular growth that may not occur until years later. Excessively rapid atresia (germ cell attrition) in gonadal dysgenesis (45,X) accounts for the streak gonad seen in these cases.²² A complete 46,XX chromosomal complement is necessary for normal ovarian development.²³ The second X chromosome, therefore, contains elements essential for ovarian development and maintenance.

Duct System Differentiation

Caspar Wolff described the mesonephros in 1759 in his doctoral dissertation when he was 26 years old.²⁴ The paired structures of the mesonephros of the early vertebrate embryo were named wolffian bodies by the 19th century embryologist, Rathke, in recognition of Wolff's initial discovery and description. Johannes Müller, a German physiologist with a prodigious academic output, described the embryology of the genitalia in 1830. The paramesonephric ducts received his name, not because of his original contributions, but because of his ability to synthesize current knowledge in his effective writings. His physiology text was a standard in many

European countries.

Renal development goes through 3 stages: pronephric, mesonephric, and metanephric. The mesonephric ducts remain for development as internal genitalia. At this stage the mesonephric ducts are called the wolffian ducts. The paired paramesonephric ducts are the müllerian ducts. The wolffian and müllerian ducts are discrete primordia which temporarily coexist in all embryos during the ambisexual period of development (up to 8 weeks). Thereafter, one type of duct system persists normally and gives rise to special ducts and glands, whereas the other disappears during the 3rd fetal month, except for nonfunctional vestiges.

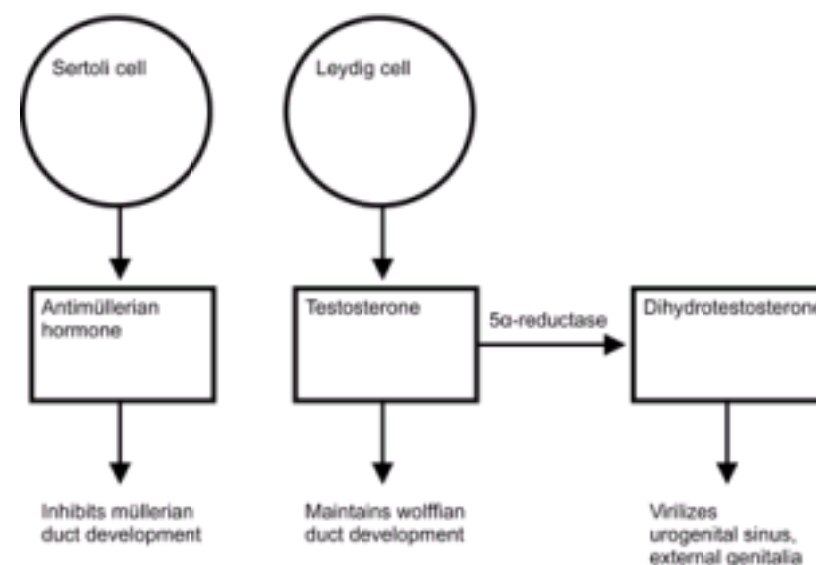

Hormonal control of mammalian somatic sex differentiation was established by the classic experiments of Alfred Jost.²⁵ In Jost's landmark studies, the active role of male determining factors was defined as the directing feature of sex differentiation. This principle applies not only to the internal ducts but to the gonad, external genitalia, and perhaps even the brain. The critical factors in determining which of the duct structures stabilize or regress are the secretions from the testes: testosterone and anti-müllerian hormone (AMH), also known as müllerian inhibiting substance or müllerian inhibiting factor.

AMH is a member of the transforming growth factor- β family of glycoprotein differentiation factors that includes inhibin and activin.^{26, 27} The gene for AMH has been mapped to the short arm of chromosome 19, and the AMH receptor gene is on chromosome 12. AMH is synthesized by Sertoli cells (activated by SRY) soon after testicular differentiation and is responsible for the ipsilateral regression of the müllerian ducts by 8 weeks, before the emergence of testosterone and stimulation of the wolffian ducts.²⁸ Despite its presence in serum up to puberty, lack of regression of the uterus and tubes is the only consistent expression of AMH gene mutations. Knockout mice for AMH develop normal testes and ovaries.²⁹ In the absence of AMH, the fetus will develop fallopian tubes, uterus, and upper vagina from the paramesonephric ducts (the müllerian ducts). **This development requires the prior appearance of the mesonephric ducts, and for this reason, abnormalities in the renal system are associated with abnormalities in development of the tubes, uterus, and upper vagina.**

AMH has extra müllerian functions. AMH exerts an inhibitory effect on oocyte meiosis, plays a role in the descent of the testes, and inhibits surfactant accumulation in the lungs.³⁰ Proteolytic cleavage of AMH produces fragments which have the ability to inhibit growth of various tumors (a potential therapeutic application). Testicular descent occurs in stages. Transabdominal movement of the testes is the result of rapid gubernacular growth, apparently under AMH control. Movement through the inguinal canal is mediated by androgens.

AMH, secreted by the Sertoli cells, is detectable in the serum of males during infancy, childhood, adolescence, and adulthood (with a decline to barely detectable levels after puberty). In contrast, AMH, secreted by granulosa cells, is not measurable until puberty in females. This difference allows serum measurement to be a sensitive marker for the presence of testicular tissue in intersex anomalies.³¹ After puberty, testosterone, with an added contribution from meiotic germ cells, suppresses AMH secretion in males, and, therefore, individuals with the androgen insensitivity syndrome (androgen receptor defects) have very high AMH levels after puberty.³² The failure of testosterone to suppress AMH secretion during fetal and newborn life is explained by the absence of the androgen receptor in Sertoli cells until later in life.

Testosterone is secreted by the fetal testes soon after Leydig cell formation (at 8 weeks) and rapidly rises to peak concentrations at 15–18 weeks. This testosterone secretion stimulates development of the wolffian duct system into epididymis, vas deferens, and seminal vesicles. Testosterone levels in the male fetus correlate with Leydig cell development, overall gonadal weight, 3 β -hydroxysteroid dehydrogenase activity, and chorionic gonadotropin (HCG) concentrations. As HCG declines (approximately 20 weeks) the fetal pituitary luteinizing hormone (LH) assumes control of Leydig cell testosterone secretion; anencephalics and other forms of congenital hypopituitarism display diminished androgen effects on internal and external genitalia. Dihydrotestosterone

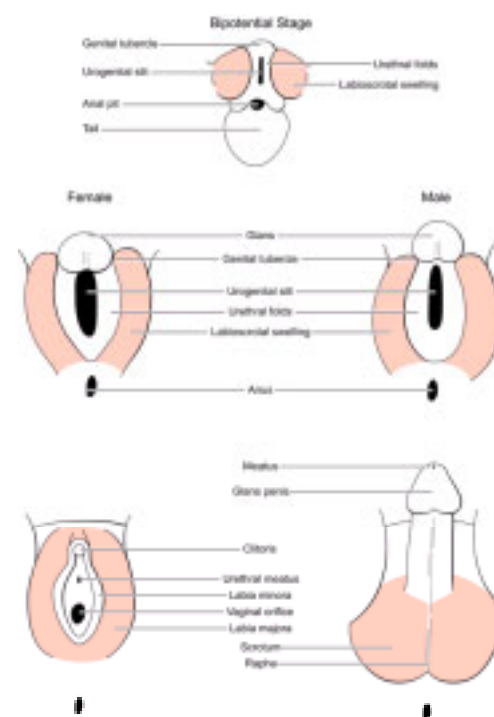

The wolffian ducts receive testosterone signals directly from nearby Leydig cells as well as the general fetal circulation. This local paracrine effect is essential to the stimulation of ipsilateral differentiation into the epididymis, vas deferens, and seminal vesicles. Duct system differentiation will proceed, therefore, according to the nature of the adjacent gonad. The wolffian ducts do not form dihydrotestosterone, so the direct high concentration is crucial for normal development.³³ Because of this local paracrine action, wolffian development cannot be stimulated in females exposed to adrenal or exogenous androgens.

The internal genitalia possess the intrinsic tendency to feminize. In the absence of a Y chromosome and a functional testis, the lack of AMH allows retention of the müllerian system and development of fallopian tubes, uterus, and upper vagina. In the absence of testosterone, the wolffian system regresses. In the presence of a normal ovary or the absence of any gonad, müllerian duct development takes place. These classic roles for the presence and absence of testosterone are undisputed; however, estrogen may make a contribution in this process. Knockout mice for the estrogen receptor- α have a marked retention of wolffian tubules, indicating that estrogen plays a role in the degeneration of the wolffian system.³⁴

External Genitalia Differentiation

In the bipotential state (6th gestational week), the external genitalia consist of a genital tubercle, a urogenital sinus, and two lateral labioscrotal swellings. Unlike the internal genitalia where both duct systems initially coexist, the external genitalia are neutral primordia able to develop into either male or female structures depending on gonadal steroid hormone signals. Normally, this differentiation is under the active influence of androgen from the Leydig cells of the testis. The genital tubercle forms the penis, labioscrotal folds fuse to form a scrotum, and folds of the urogenital sinus form the penile urethra. The testis begins androgen secretion by 8–9 weeks; masculinization of the external genitalia is manifest 1 week later and is completed by 14 weeks. To achieve this morphologic change, external genitalia target tissue cells must convert testosterone to dihydrotestosterone (DHT) by the intracellular enzyme 5 α -reductase. In the male, DHT mediates the following androgen events: temporal hairline recession, growth of facial and body hair, development of acne, and development of the external genitalia and prostate.

In the absence of this androgen effect (the absence of a Y chromosome, the presence of an ovary, the absence of a gonad, abnormalities in androgen receptor or postreceptor events, or defects of the 5 α -reductase enzyme), the folds of the urogenital sinus remain open, forming the labia minora, the labioscrotal folds form the labia majora, the genital tubercle forms the clitoris, and the urogenital sinus differentiates into the vagina and the urethra. Thus, the lower vagina is formed as part of the external genitalia.

Exposure to androgens at critical time periods leads to variable masculinization. Androgen exposure at 9–14 weeks superimposes variable external ambiguity on the basic female phenotype (clitoral hypertrophy, hypospadias, scrotalization of nonfused labia). By the same token, incompletely masculinized genitalia will result if sufficient local androgen concentration or activity is not achieved by the 12th week in the male. Because of shared common tissue origin, male-female external genital structural ambiguities reflect abnormal androgen impact: males too little, females too much.

Central Nervous System Differentiation

At the same time the presence or absence of androgens is playing a critical role in genitalia development, the neuroendocrine mechanism of the central nervous system (CNS) is also being influenced. Androgens present in sufficient amounts during the appropriate critical stage of development may program the central nervous system (CNS) to induce the potential for male sexual behavior.^{3, 5, 6, 35, 36 and 37} Experimental and analytical evidence suggests that a behavioral effect can be traced to this early androgen influence. Inappropriate fetal hormonal programming may contribute, therefore, to the spectrum of psychosexual behavior seen in humans. In addition, gender role is heavily influenced by assignment of sex of rearing followed by social interaction based upon genital appearance and the development of secondary sexual characteristics.

Abnormal Sexual Differentiation

The standard classification of individuals with intersexuality (hermaphroditism) proceeds according to gonadal morphology. In this terminology, a **true hermaphrodite** possesses both ovarian and testicular tissue. A

male pseudohermaphrodite has testes, but external and sometimes internal genitalia take on female phenotypic aspects. A **female pseudohermaphrodite** has ovaries, but genital development displays masculine characteristics. These classifications are modified to reflect gonadal abnormalities due to abnormal sex chromosome constitution or abnormalities of phenotype attributable to an inappropriate fetal hormone environment. Hypospadias in the absence of any other deformity is not included in this classification.

Disorders of Fetal Endocrinology

Masculinized females (female pseudohermaphroditism)

Congenital adrenal hyperplasia

- 21-Hydroxylase (P450c21) deficiency
- 11 β -Hydroxylase (P450c11b) deficiency
- 3 β -Hydroxysteroid dehydrogenase deficiency

Elevated androgens in the maternal circulation

- Drug intake
- Maternal disease

Aromatase (P450arom) deficiency

Incompletely masculinized males (male pseudohermaphroditism)

- Androgen insensitivity syndromes
- 5 α -Reductase deficiency
- Testosterone biosynthesis defects

3 β -Hydroxysteroid dehydrogenase deficiency
17 α -Hydroxylase (P450c17) deficiency
17 β -Hydroxysteroid dehydrogenase deficiency

Gonadotropin resistant testes
Anti-müllerian hormone deficiency

Disorders of Gonadal Development

Male pseudohermaphroditism

Primary gonadal defect — Swyer syndrome
Anorchia

True hermaphroditism

Gonadal dysgenesis

Turner syndrome
Mosaicism
Normal karyotype — Noonan syndrome

Masculinized Females

Masculinized females possess ovaries and are female by genetic sex (XX), but the external genitalia are not those of a normal female. Of all infants with ambiguous genitalia, 40–45% have adrenal hyperplasia. Rarer causes of female pseudohermaphroditism are excess maternal androgen caused by drug ingestion, tumor secretion, or possibly aromatase deficiency.

Congenital Adrenal Hyperplasia (the Adrenogenital Syndrome)

Congenital adrenal hyperplasia in females is characterized by masculinized external genitalia, and is diagnosed by demonstrating excessive androgen production by the adrenal cortex, caused by either tumor or hyperplasia. ^{3E}, ^{3E} and ^{4C} The syndrome may appear in utero or develop postnatally.

Depending on the time of onset, quantity available, and duration of exposure, the presence of excessive androgens is manifested by varying degrees of fusion of the labioscrotal folds, clitoral enlargement, and anatomical changes of the urethra and vagina. Generally, the urethra and vagina share a urogenital sinus formed by the fusion of labial folds. This sinus opens at the base of the clitoris, which is usually enlarged. The degree of urogenital sinus deformity is related to the timing in prenatal development of the onset of masculinizing androgen effect. Because there is no anomalous secretion of anti-müllerian hormone in females with congenital adrenal hyperplasia, the fallopian tubes, uterus, and upper vagina develop normally. Since wolffian duct development and maintenance depend on high local androgen levels provided by the male gonad, the excessive androgens of adrenal hyperplasia origin cannot stimulate this process, and no wolffian development is retained. The external genitalia on the other hand can be substantially altered by adrenal hyperplasia. After the 10th week, when the vagina and urethra have separated, the emerging excess androgen effect may be limited to clitoral hypertrophy. High androgen levels earlier than the 12th week of fetal age, however, can cause progressive fusion of the labia, formation of a urogenital sinus, and even variable closure of the urethra along the phallus (hypospadias). The absence of palpable testes may be the only clinical marker suggesting female pseudohermaphroditism.

Excessive adrenal activity does not affect internal genitalia differentiation. This is because the internal genitalia are completely formed by the 10th week of gestation, whereas the adrenal cortex does not reach a level of significant function until 10–12 weeks.

Because the female external genitalia phenotype is not completed until 20 weeks of fetal age, early androgen excess (10–12 weeks gestation) may fully masculinize, whereas late (18–20 weeks gestation) androgen may create limited ambiguity of the basically female appearance of the urogenital sinus and genital folds. The size of the clitoris depends on the quantity rather than timing of androgen excess. Cases of incorrect sex assignment in the female are due to the similarity between these external genitalia and hypospadias and bilateral cryptorchidism in a male infant.

If untreated, the female with adrenal hyperplasia will develop signs of progressive virilization postnatally. Pubic hair will appear by age 2–4, followed by axillary hair, then body hair and beard. Bone age is advanced by age 2, and because of early epiphyseal closure, height in childhood is achieved at the expense of shortened stature in adulthood. Progressive masculinization continues with the development of the male habitus, acne, deepened voice, and primary amenorrhea and infertility.

In addition to sexual changes, patients can present with metabolic disorders such as salt-wasting, hypertension, or rarely, hypoglycemia. An electrolyte imbalance of the salt-losing type is usually apparent within a few days of birth and occurs in approximately two-thirds of patients with virilizing adrenal hyperplasia. A salt-losing crisis usually begins 5–15 days after birth. Beginning with a refusal to feed, failure to thrive, apathy, and vomiting, the infant goes on to an Addisonian-like crisis with hyponatremia, hyperkalemia, and acidosis. Rapid diagnosis and treatment are necessary to save these infants. Less frequent is hypertension, which occurs in approximately 5% of patients with virilizing adrenal hyperplasia.

Virilizing adrenal hyperplasia is the result of an inherited abnormality of steroid biosynthesis that results in an inability to synthesize glucocorticoids. The hypothalamic-pituitary axis reacts to the low level of cortisol by elevated ACTH secretion in a homeostatic response to achieve normal levels of cortisol production. This stimulation induces a hyperplastic adrenal cortex that produces androgens as well as corticoid precursors in abnormal quantities. Therefore, one can see a well-compensated infant who has achieved normal cortisol levels but at the expense of extensive masculinization. In summary, the clinical picture resulting from a specific enzyme deficiency is due to the effects of both the inadequate production of cortisol/aldosterone and excess accumulation of precursors, with diversion into biosynthetic pathways yielding androgens.

The most common enzymatic defects are the 21-hydroxylase (P450c21), the 11 β -hydroxylase (P450c11), and the 3 β -hydroxysteroid dehydrogenase types. Very rarely, blocked synthesis of cortisol can be due to a defect in P450c17.

Enzyme Defect in Adrenal Only: Deficient 21-Hydroxylase (P450c21). The 21-hydroxylase block is the most common form of congenital adrenal hyperplasia (95% of cases), the most frequent cause of sexual ambiguity, and the most frequent endocrine cause of neonatal death. With severe uncompensated blocks of this type, salt-wasting and shock accompany significant virilization. In less severe variations, when sufficient cortisol can be produced, virilization due to excess androgen is still present in utero, at birth, or later in life. Three different clinical forms are recognized representing the spectrum of severity: the salt-wasting, the simple virilizing, and the nonclassical (previously known as the late-onset, attenuated, or acquired adrenal hyperplasia). The first and second are associated with female pseudohermaphroditism at birth, while the third usually becomes apparent at adolescence or beyond and causes hirsutism, menstrual irregularities, and infertility.

Developments in molecular biology and genetics have greatly expanded our understanding of this condition. ⁴¹

1. The disorder is inherited as a monogenic autosomal recessive trait.
2. Two 21-hydroxylase genes exist, designated CYP21A and CYP21B, located on chromosome 6, in tandem duplication with the genes encoding the fourth component of complement. Only CYP21B is active in adrenal steroidogenesis; CYP21A is not involved (a pseudogene, also known as CYP21P, because it is inactive).
3. A variety of mutations affecting CYP21B lead to 21-hydroxylase deficiency, but 85% are gene conversions. Most patients are compound heterozygotes, having a different genetic lesion on each copy of chromosome 6, one from each parent. The severity of the condition is determined by the activity of the least affected

allele.

The 21-hydroxylase genes are located in the midst of the human leukocyte antigen (HLA) complex on the short arm of chromosome 6. By combined HLA genotyping and ACTH stimulation testing (see [17-OHP](#) nomogram in Chapter 13) of families that contained patients with nonclassical and classical disease, a concept of variations in 21-hydroxylase activity evolved.^{42, 43} Salt-wasting, simple virilizing, and nonclassical clinical manifestations, respectively, are due to the most, less, and the least deficiency of 21-hydroxylase. Some family members exhibit abnormal responses to ACTH, and, although some of these have clinical evidence of androgen excess, others are entirely normal and represent a “cryptic” form of 21-hydroxylase deficiency. Finally, heterozygotes for either the mild or severe deficiency exhibit the mildest enzyme deficiency and are clinically asymptomatic.

Enzyme Defect in Adrenal Only: Deficient 11b-Hydroxylase (P450c11). The final step in cortisol synthesis is blocked in this condition. In classic 11b-hydroxylase deficiency, 11-deoxycortisol is not converted to cortisol. Accumulated precursors are shunted into androgen biosynthesis with virilization similar to that seen with 21-hydroxylase deficiency. However, a parallel defect also exists so that deoxycorticosterone (DOC) is not converted to corticosterone. This pathway is used in the zona glomerulosa to synthesize aldosterone, and the degree to which aldosterone levels are affected lends clinical heterogeneity to the classic presentation of 11b-hydroxylase deficiency (virilization, hypertension, volume overload). About 5–8% of cases of

congenital adrenal hyperplasia are due to 11b-hydroxylase deficiency, about 1 in 100,000 births, with a higher incidence in Jewish people who originated in Morocco.⁴⁴

Usually as a result of 11b-hydroxylase deficiency, metabolically active precursors of corticosterone and cortisol add to excess androgen synthesis as further liabilities of ACTH-induced hyperplasia. Hypertension and hypokalemic alkalosis are induced by elevated deoxycorticosterone with reduced renin and aldosterone. Virilization is caused by androgens of the “deoxy” type (dehydroepiandrosterone, dehydroepiandrosterone sulfate, and androstenedione). The diagnosis is confirmed by high plasma deoxycorticosterone and compound S (11-deoxycortisol) levels.

About two-thirds of untreated patients with 11b-hydroxylase deficiency become hypertensive, usually of mild to moderate degree (150/90 mm Hg) and only after several years of life. A mild nonclassic form of 11b-hydroxylase deficiency, as in 21-hydroxylase defects, has also been documented; it is characterized by mild biochemical abnormalities, and the patients are only slightly virilized and rarely hypertensive.

Contrary to 21-hydroxylase deficiency, the 11b-hydroxylase deficiency locus is remote from the HLA complex. The gene for the enzyme is on the long arm of chromosome 8, and the deficiency is inherited in autosomal recessive fashion.⁴⁵ Actually there are two isozymes with 11b-hydroxylase activity, encoded by two genes on chromosome 8.⁴⁴ One, CYP11B1 or P450c11, is the enzyme classically referred to as 11b-hydroxylase and regulated by ACTH. The other, CYP11B2 or P450c18 (or P450aldo), has been called aldosterone synthase and is regulated by angiotensin II. P450c18 has strong 11b-hydroxylase activity, but also hydroxylates and oxidizes at the C-18 position. Deficiency in 11b-hydroxylase results from mutations in P450c11 (CYP11B1).⁴⁴

Enzyme Defects in Adrenal and Ovary: Deficient 3b-Hydroxysteroid Dehydrogenase. Lack of this essential step in the formation of all biologically active steroids affects both the adrenal cortex and the ovary and is also inherited in autosomal recessive fashion. Thus, there is decreased synthesis of glucocorticoids, mineralocorticoids, androgens, and estrogens. These infants are severely ill at birth and rarely survive. The external genitalia ambiguity results from the massive increase in dehydroepiandrosterone that is androgenic when available in excess, and also can be utilized to form more potent androgens in peripheral tissues. Thus, females may be slightly virilized and males incompletely masculinized with a variable degree of hypospadias. The spectrum of clinical phenotypes also includes both salt wasting and non-salt wasting forms. The degree of the enzyme defect cannot be extrapolated from the degree of external genitalia ambiguity. As in 21-hydroxylase deficiency, milder nonclassic cases may occur with mild hirsutism and elevated dehydroepiandrosterone and dehydroepiandrosterone sulfate being the only distinguishing features. Some argue that late-onset 3b-hydroxysteroid dehydrogenase deficiency is encountered more frequently than 21-hydroxylase deficiency.⁴⁶ However, although an exaggerated 17a-hydroxypregnenolone response to ACTH stimulation is common in women with hyperandrogenism, the response is consistent with adrenal hyperactivity and not an enzyme deficiency.⁴⁷ Furthermore, molecular studies fail to find mutations in the genes for the two 3b-hydroxysteroid dehydrogenase enzymes in patients with apparent mild to moderate 3b-hydroxysteroid dehydrogenase deficiency.^{48, 49}

Enzyme Defect in Adrenal and Ovary: Deficient 17a-Hydroxylase (P450c17). With block of the 17a-hydroxylase enzyme (P450c17), synthesis of cortisol, androgens, and estrogens is curtailed. Only the non-17-hydroxylated corticoids, deoxycorticosterone and corticosterone, are formed.⁵⁰ The molecular basis for this enzyme deficiency is due to a variety of mutations which result in multiple base deletions and duplications in the CYP17 gene on chromosome 10q24–25.^{51, 52} The resulting syndrome is composed of hypertension (due to hypernatremia and hypervolemia), hypokalemia, infantile female external genitalia, which do not mature at puberty, and primary amenorrhea with elevated follicle-stimulating hormone (FSH) and luteinizing hormone (LH). Genital ambiguity is a problem only in male infants.

Epidemiology

Only the 21-hydroxylase deficiency has been studied extensively, in part because it is not only the most frequent cause of genital ambiguity and congenital adrenal hyperplasia but also because of the high prevalence of the nonclassical, late onset forms of the disease. Within families, the clinical picture is uniform, the type of syndrome (simple, salt-wasting, hypertensive) is usually, but not always, the same in affected siblings. The genetic defect in virilizing adrenal hyperplasia is an autosomal recessive gene. The ratio in offspring of unaffected parents is one affected to three nonaffected individuals. Treated patients have a 1:100 to 1:200 chance of producing an affected infant. Males and females are at equal risk. The classic form is a relatively common inborn error of metabolism. One out of every 100 Caucasians is likely to be a genetic carrier of the classic type, and neonatal screening tests indicate an incidence of 1 in 14,000 births. The highest frequency for congenital adrenal hyperplasia is in Alaskan Yupik Eskimos.

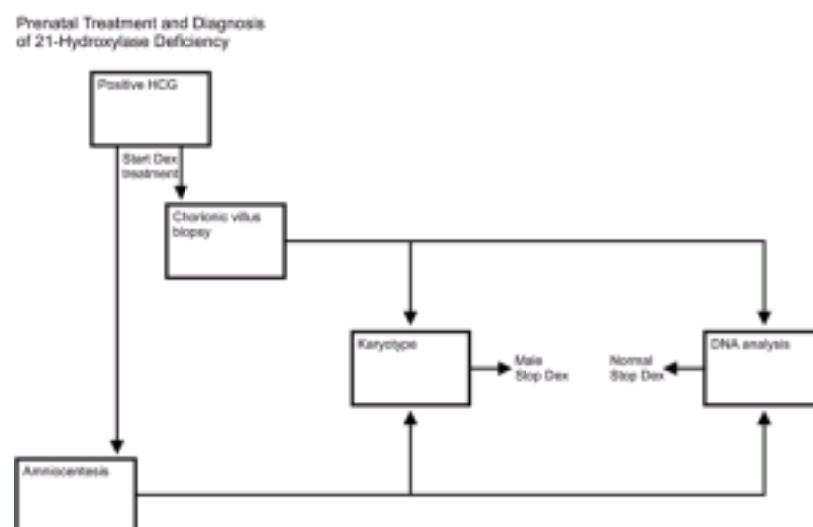

For the nonclassical types, frequency rates established by the usual methodology (neonatal screening, case surveys) are likely to markedly underestimate what may be one of the most common autosomal recessive disorders in humans. Extrapolations from ACTH testing suggest the following frequency:⁵³

	Nonclassical Disease	Heterozygous Carrier
Eastern European Jews	1 in 30	1 in 3
Hispanics	1 in 40	1 in 4
Slavs	1 in 50	1 in 5

Prenatal Diagnosis

The diagnosis of congenital adrenal hyperplasia due to 21-hydroxylase deficiency can be obtained prenatally by demonstrating elevated levels of 17-hydroxyprogesterone (17-OHP), 21-deoxycortisol, and androstenedione in the amniotic fluid. 17-OHP may be elevated only in the salt-losing form of adrenal hyperplasia, but androstenedione is usually increased with all forms. The 11 β -hydroxylase deficiency is associated with elevated levels of 11-deoxycortisol in amniotic fluid and tetrahydro-11-deoxycortisol in maternal urine.⁵⁴ Because amniotic fluid steroids may be within the normal range with less severe deficiencies, hormonal measurements have been replaced by molecular genetic diagnosis.

Prenatal diagnosis of the 21-hydroxylase deficiency by chorion villus biopsy utilizing DNA probes offers the timely options of termination or in utero therapy.⁵⁵ With chorion villus biopsy, diagnosis can be made and therapy instituted before the critical period of fetal genital differentiation with avoidance of genital ambiguity in affected female fetuses. In addition, masculinization of the fetal brain can be avoided which might have an impact on gender identity and adult sexual behavior.^{2, 4, 5} Despite the fact that prenatal diagnosis is not 100% accurate, prenatal treatment beginning at 4–5 weeks gestation has been administered with dexamethasone in fetuses at risk for 21-hydroxylase deficiency.^{56, 57, 58, 59 and 60} Using multiple daily doses of dexamethasone (total no greater than 1.5 mg/day), complete prevention has been achieved in some newborns and diminished virilization in others. No congenital malformations or low birth weight or height have resulted from pregnancy-long cortisol derivative therapy. However, this treatment is associated with significant maternal side effects, such as severe striae with permanent scarring, hyperglycemia, hypertension, gastrointestinal symptoms, and emotional lability.⁶¹ A reduction in dosage during the second half of pregnancy is recommended; dosage can be titrated by maintaining the maternal serum estriol levels in the normal range.

Given that only one in four siblings is at risk and one-half will be males (who do not suffer genital ambiguity from the excess androgen associated with 21-hydroxylase deficiency) then only 1 of 8 fetuses requires treatment. Therefore 7 of 8 fetuses will be exposed to very high glucocorticoid doses unnecessarily. Until the long-term effects and safety of this therapy are established, treatment should be governed by appropriate research-type institutional protocols.

Diagnosis of Adrenal Hyperplasia

For years the demonstration of a metabolic defect and its location depended upon the study of urinary steroid excretion. Today, the immunoassay of blood 17-hydroxyprogesterone (17-OHP) has become the primary assessment for the diagnosis and management of congenital adrenal hyperplasia. With the 21-hydroxylase and 11 β -hydroxylase deficiencies, the 17-OHP level will be 50–400-fold above normal. In addition, plasma renin activity is measured to assess the degree of mineralocorticoid deficiency.

During delivery of normal infants, the concentration of 17-OHP is elevated in cord blood (1000–3000 ng/dL), but it rapidly decreases to 100–200 ng/dL after 24 hours. A delay in measurement gains accuracy. In contrast to 17-ketosteroids in the urine where the delay must be several days, with 17-OHP the delay need be only a day or two. In affected infants, 17-OHP ranges from 3000 to 40,000 ng/dL. Measurement of 17-OHP is the basis for the newborn screening programs currently in place in many countries and some states in the U.S. In Texas, the screening program detected classic congenital adrenal hyperplasia in 1 in 16,000 births, with a ratio of salt-wasting to simple virilizing of 2.7:1.⁶²

In adults, 17-OHP must be measured first thing in the morning to avoid later elevations due to the diurnal pattern of ACTH secretion. The baseline 17-OHP level should be less than 200 ng/dL. Levels greater than 200 ng/dL, but less than 800 ng/dL, require ACTH testing (discussed in [Chapter 13](#)). Levels over 800 ng/dL are virtually diagnostic of the 21-hydroxylase deficiency. The dehydroepiandrosterone sulfate level is usually normal. The hallmarks of nonclassical adrenal hyperplasia are elevated levels of 17-OHP and a dramatic increase after ACTH stimulation. The elevated levels of 17-OHP are often not impressive (e.g., overlapping with those found in women with polycystic ovaries due to anovulation), and a simple ACTH stimulation test must be utilized. **To distinguish the 21-hydroxylase deficiency from other disorders, all of the following in addition to 17-OHP should be measured at zero and 60 minutes after ACTH stimulation: pregnenolone, 17-hydroxypregnenolone, dehydroepiandrosterone, 11-deoxycortisol, cortisol, and testosterone.**

Of course, in patients with 3 β -hydroxysteroid dehydrogenase or 17-hydroxylase blocks, the 17-OHP level will not be elevated. With the 3 β -hydroxysteroid dehydrogenase block, the blood levels of DHA and DHA sulfate (DHAS) will be markedly increased. In the 11 β -hydroxylase deficiency, in addition to elevated 17-OHP, elevation of 11-deoxycortisol is diagnostic. In this deficiency, plasma renin activity will be low, whereas in 21-hydroxylase and 3 β -hydroxysteroid dehydrogenase deficiencies plasma renin activity is elevated in the salt losing forms.

Treatment

Treatment of adrenal hyperplasia is to supply the deficient hormone, cortisol. This decreases ACTH secretion and lowers production of androgenic precursors. The addition of salt-retaining hormone to glucocorticoid therapy has improved the control of the disease. When the plasma renin activity is normalized, ACTH and androgen levels are further decreased, and a decrease in the glucocorticoid dose is also possible. Therefore, the modern management of hormonal control requires the measurement of the blood levels of 17-OHP, androstenedione, testosterone, and plasma renin activity.^{36, 38} The drugs of choice are hydrocortisone (cortisol), approximately 10 mg per day, and 9-fluorohydrocortisone, approximately 100 mg/day. This method of treatment and monitoring applies to all forms of adrenal hyperplasia. The standard dose of cortisol is 12–18 mg/m² or 3.5–5 mg/m² of prednisone, but larger doses given on alternate days (14 mg/m² of prednisone, about 20 mg) can maintain adrenal androgen suppression and perhaps achieve better growth and pubertal development, despite higher levels of 17-hydroxyprogesterone.⁶³ The 17-OHP level should be maintained in the range of 500 to 4000 ng/dL, thereby avoiding both overtreatment and undertreatment. Minor stresses will cause brief elevations of adrenal androgens but usually do not require readjustment of dosage. With major stress, such as surgery, additional hormonal support is necessary.

The surgical treatment of the anatomical abnormalities should be carried out in the first few years of life, when the patient is still too young to remember the procedure and too young to have developed psychological problems centered about the abnormal external genitalia. If clitoridectomy is necessary, the clitoral recession procedure, conserving the glans and its innervation, should be employed. It is important to know that women who undergo total clitoral amputations have no subsequent impairment of erotic responsiveness or capacity for orgasm. Significant vaginal reconstruction, if necessary, is best accomplished after puberty when mature compliance is possible.

Normal reproduction is possible with replacement therapy of the cortisol deficiency. Unfortunately, poor compliance with therapy and less than satisfactory surgical reconstruction of the vagina result in decreased fertility and sexuality.² Greater attention to these factors is needed to improve the sexual experience and fertility of these women. Many cases come to cesarean section because normal anatomy of the perineum may be obscured by scar tissue from earlier plastic surgery; therefore, greater blood loss and the risk of a hematoma with a vaginal delivery are significant factors. A masculine pelvis is not expected since the adult form and size of the inlet of the pelvis are assumed largely during the growth spurt in puberty. However, a small pelvis might be anticipated if the bone age is up to age 13–14 when treatment is initiated. Fertility in women with nonclassical adrenal hyperplasia is only slightly reduced, dependent upon the degree of hormonal dysfunction (which is

promptly corrected with glucocorticoid therapy).⁶⁴ Consistent with the belief that androgens can program sexual behavior during fetal development, women with congenital adrenal hyperplasia report a decrease in heterosexual activity and an increase in homosexual activity.^{2,4}

The maintenance steroid dose usually does not need to be changed during pregnancy. The dosage of steroids used in the treatment of this syndrome replaces the approximate amount normally produced and, therefore, is a physiologic dose. At these low doses, teratogenic effects would be unlikely, and none have been noted. The need for additional steroids during the stress of labor and delivery is obvious and is usually met by the administration of cortisone acetate intramuscularly and cortisol intravenously. Infection and impaired wound healing have not been problems. Aside from the liability associated with genetic transmission of this syndrome, the children born to patients with adrenal hyperplasia have been normal. The newborn should be closely observed for adrenal insufficiency due to steroid crossover and suppression of the fetal adrenal in utero.

Treatment Problems

Overtreatment causes Cushing's syndrome and poor growth; undertreatment is associated with short stature, hirsutism, and infertility. In some cases, undertreatment and increased androgen secretion lead to premature pubertal maturation that may require treatment with a gonadotropin-releasing hormone (GnRH) agonist. The adult height achieved by most patients is less than normal, testimony to overtreatment and undertreatment (which both compromise growth). Mineralocorticoid therapy should be maximized (maintaining the plasma renin activity at its lower limit of normal) to eliminate hypovolemia as a stimulus for ACTH secretion, via the angiotensin II pathway.

Because it is now recognized that estrogen is the primary regulator of bone response in both males and females,⁶⁵ low-dose hydrocortisone and fludrocortisone treatment was combined with flutamide (an antiandrogen) and testolactone (an inhibitor of androgen to estrogen aromatization). In a preliminary study, normalization of growth was achieved.⁶⁶

Masculinization Due to Elevated Androgens in the Maternal Circulation

Masculinization of the female fetus, although in most cases due to fetal virilizing adrenal hyperplasia, can be produced by an androgen-secreting maternal tumor or can be due to the intake of exogenous androgenic substances, such as progestins and danazol. When not caused by an error in the metabolism of the fetal adrenal gland, virilization is not progressive, blood steroids are not elevated, and no hormonal therapy is needed. Subsequent development will be normal. Therefore, surgical correction of abnormalities in the external genitalia is the only indicated treatment.

The occurrence of an androgen-secreting tumor in a mother during pregnancy is rarely seen. On the other hand, the iatrogenic cause of masculinization is a well known story. The majority of these cases resulted from antenatal maternal treatment of threatened or recurrent miscarriage with various progestin compounds. In view of the lack of evidence for positive results with such therapy, progestin compounds, other than progesterone, are no longer administered to pregnant women.

Aromatase (P450arom) Deficiency

P450arom is encoded by the CYP19 gene on chromosome 15p21.1. A deficiency in this enzyme is very uncommon, and only rare mutations in P450arom have been reported.^{65, 67, 68 and 69} An individual with this deficiency will be first affected by the failure to achieve normal levels of aromatization within the placenta. A placental deficiency in aromatase activity would allow an accumulation of the fetal androgen precursors utilized in placental estrogen synthesis. This condition is associated with virilization of the mother during the second half of pregnancy, low estrogen levels in the mother, and a female newborn with masculinization. Accurate prenatal diagnosis requires a loading test with DHA and DHAS. A patient with a placental sulfatase deficiency will increase her estrogen levels in response to DHA and not to DHAS. A patient with an aromatase deficiency will respond to neither steroid. Pubertal development is prevented because the ovary cannot aromatize androgens in order to produce estrogen; a patient can present with primary amenorrhea (hypergonadotropic hypogonadism) and mild virilization.

Incompletely Masculinized Males

Incompletely masculinized males are male by genetic sex (XY) and possess testicles, but the external genitalia are not normally male. Male pseudohermaphrodites may arise in one of four ways:

1. Defective responses in androgen dependent tissues — Androgen Insensitivity Syndromes.
2. Abnormal androgen synthesis.
3. Gonadotropin resistant testes.
4. Absent or defective anti-müllerian hormone.

Syndromes of Androgen Insensitivity

Factors that influence the response to androgens in specific target cells include the following:

1. The intracellular concentration of androgen.
2. The relative binding affinity of these steroids to their nuclear androgen receptors.
3. The binding capacity of the receptor.
4. The nuclear content of androgen receptors.
5. The cellular concentrations of catabolic and/or synthetic enzymes (e.g., 5 α -reductase, aromatase, 17 β -hydroxysteroid dehydrogenase).
6. The adequacy of the nuclear (chromatin) acceptor site.
7. The adequacy of regulatory molecules (adapter proteins) controlling chromatin "read" of the androgen message.
8. RNA processing and translation.
9. The quality of the protein gene product.

Defects in androgenization of targets theoretically can occur as a result of failure in any of these steps. Three major clinical conditions are worthy of detailed review.

Complete Androgen Insensitivity — Testicular Feminization

Complete androgen insensitivity was first described in detail by Morris at Yale, who provided the descriptive term, testicular feminization.⁷⁰ The phenotype of this condition (also discussed in [Chapter 11](#)) is female, despite the normal male karyotype, 46,XY. There is a congenital insensitivity to androgens, transmitted by means of a maternal X-linked recessive gene responsible for the androgen intracellular receptor.⁷¹ Therefore, androgen induction of wolffian duct development does not occur. However, anti-müllerian hormone activity is present, and the individual does not have müllerian development (a natural experiment that indicates the presence of an anti-müllerian hormone). Frequently the testes have descended to the inguinal ring because AMH mediates the transabdominal descent of the testes. The vagina is short (derived from the urogenital sinus only) and ends blindly. The uterus and tubes are absent. The testes are normally developed but abnormally positioned. Testosterone production is normal or slightly increased. There is no problem of sex assignment because there is no trace of androgen activity. The diagnosis is likely when an individual presents following breast development at puberty, with primary amenorrhea, absent pubic and axillary hair, a short vagina, and an absent cervix and uterus. Males with enzyme defects that prevent testosterone synthesis will have a female phenotype, but breast development does not occur. Individuals with complete androgen insensitivity have augmented breast development because of a total absence of androgen influence. Androgen insensitivity accounts for about 10% of all cases of primary amenorrhea, third most common after gonadal dysgenesis and congenital absence of the vagina. The hormone profile in these individuals is typical: high LH, normal to slightly elevated male testosterone levels, high estradiol (for men), and normal to elevated FSH. Individuals with complete androgen insensitivity perform less well in tests of visual-spatial ability, suggesting that androgens exert an organizing effect in the brain during development.⁷²

An absent uterus in a normal appearing female is encountered in only two conditions: androgen insensitivity and müllerian agenesis (the Mayer-Rokitansky-Kuster-Hauser syndrome). The latter is easily diagnosed because of the presence of pubic and axillary hair and a normal 46,XX karyotype (discussed in [Chapter 11](#)).

The “complete” form indicates that there is no androgen response; therefore, normal external female development occurs, and these infants should be reared as females. The testes (azoospermic with hyperplastic Leydig cells) may be present in the inguinal canals. Children with inguinal hernias and/or inguinal masses should be suspected of testicular feminization. There is no virilization at puberty because of the lack of androgen response. In contrast to dysgenetic gonads with a Y chromosome, the occurrence of gonadal tumors is relatively late, rarely before age 25, and the overall incidence is less, about 5–10%.^{73, 74, 75 and 76} Therefore, gonadectomy should be performed at approximately age 16–18, to allow endogenous hormonal changes and a smooth transition through puberty.

Because of the importance of prophylactic gonadectomy, detection of this syndrome demands careful investigation for other affected family members. This syndrome follows an X-limited recessive pattern of inheritance. Apparent sisters of affected individuals have a 1 in 3 chance of being XY. Female offspring of a normal sister of an affected individual have a 1 in 6 chance of being XY. About a third of the patients have negative family histories and presumably represent new mutations.

In the past, conventional wisdom warned against unthinking and “needless” disclosure of the gonadal and chromosomal sex to a patient with complete androgen insensitivity. This attitude has changed as, more and more, patients desire and appreciate a full understanding of themselves. Although infertile, these patients are certainly completely female in their gender identity, and this should be reinforced rather than challenged. We now strongly advocate combining a truthful education with appropriate psychological counseling of patient and parents. A good resource is the international support group, A⁴S, that is headquartered in the United Kingdom (2 Shirburn Avenue, Mansfield, Nottinghamshire, NG18 2BY, UK); <http://www.medhelp.org/www/ais/>.

Incomplete Androgen Insensitivity

A spectrum of disorders, all due to an X-linked recessive trait, are known as incomplete forms of testicular feminization. Incomplete androgen insensitivity is one-tenth as common as the complete syndrome.⁷⁶ The clinical presentation ranges from almost complete failure of virilization to essentially complete phenotypic masculinization. Between these poles exist examples of mild clitoromegaly and slight labial fusion to significant genital ambiguity. Reifenstein’s syndrome is now applied to all the intermediate forms that were initially given individual names (such as Lubs syndrome). Males have been described whose only indication of androgen insensitivity was azoospermic or severe oligospermic infertility. Indeed, the incidence may approach 40% or more of men with infertility due to azoospermia or severe oligospermia. However, the defect in androgen receptor function may be so subtle that some affected men are fertile.⁷⁷ The undervirilized fertile male syndrome is another manifestation of this androgen receptor disorder. The diversity of presentation represents variable manifestations of the same mutant gene. The biochemical abnormality depends upon the degree of function of the androgen receptor or postreceptor events.

Molecular analysis of the androgen receptor gene in individuals with androgen insensitivity has demonstrated a spectrum of disorders in which both the complete and partial forms result from androgen receptor gene mutations.⁷¹ The gene encoding the androgen receptor is localized to the q11–12 region (the long arm) of the X chromosome.^{78, 79} About 200 unique mutations have been identified.⁸⁰

Two types of defective androgen receptor function are recognized: abnormalities of androgen binding and abnormalities of DNA binding. The molecular defects responsible for these deficiencies have been identified and characterized. These include major structural abnormalities of the androgen receptor gene in which complete deletion of the gene or deletions of the exons encoding the androgen binding domain or the DNA binding domain each result in the clinical picture of complete androgen insensitivity.^{81, 82, 83 and 84} In addition, point mutations that result in a defective receptor or alter receptor mRNA and cause reduced receptor protein production also result in complete androgen insensitivity.⁸⁵ On the other hand, single base mutations that change a single amino acid yield subjects displaying either complete or partial androgen insensitivity.⁸⁶ Alterations in receptor function, therefore, range from complete loss to subtle qualitative changes in the stimulation and transcription of androgen dependent target genes. Less understandable, however, is the poor correlation between receptor levels (and androgen binding affinity) with the degree of masculinization seen in partial androgen insensitivity. Nevertheless, the same mode of inheritance, despite differences in androgen receptor functioning, indicates that all forms originate in changes in the structural gene responsible for the androgen receptor.

Some men with partial androgen insensitivity can respond to androgen treatment with enhanced virilization. For example, a man with Reifenstein syndrome due to a mutation in the DNA-binding domain of the androgen receptor responded to high-dose testosterone administration with normal virilization.⁸⁷ However, there is no test or measurement that will predict response, and only a few of these patients are able to respond to androgen therapy.

Sex assignment may be a problem when ambiguous genitalia exist because of a partial response of the receptor. If sex assignment is female, early gonadectomy is performed to avoid neoplasia. In Reifenstein syndrome, the phallus may be large enough to allow a male sex assignment at birth, despite the perineal hypospadias. After puberty, however, the inadequate androgen receptor function becomes evident. The receptor function is inadequate to respond to the surge of androgen at puberty; without androgen effect, estrogen activity prevails, and feminization with gynecomastia occurs. These individuals are infertile and cannot react to exogenous androgen. The karyotype is male XY, distinguishing it from other feminizing syndromes of puberty in phenotypic males (e.g., Klinefelter’s syndrome).

The endocrine profiles of both the complete and incomplete forms are similar: normal to elevated FSH levels, mildly elevated LH (due to absence of negative androgen feedback), and high blood levels of testosterone and estradiol (increased testicular response to LH and increased peripheral conversion).

The Androgen Insensitivity Syndromes⁷⁶

	5a-reductase	Complete	Incomplete	Reifenstein	Infertile
Inheritance	Autosomal recessive	X-linked recessive	X-linked recessive	X-linked recessive	X-linked recessive

Spermatogenesis	Decreased	Absent	Absent	Absent	Decreased
Müllerian	Absent	Absent	Absent	Absent	Absent
Wolffian	Male	Absent	Male	Male	Male
External	Female	Female	Female clitoromegaly	Male hypospadias	Male
Breasts	Male	Female	Female	Gynecomastia	Gynecomastia

5 α -Reductase Deficiency

This form of familial incomplete male (46,XY) pseudohermaphroditism is due to an autosomal recessive trait that leads to a deficiency of the 5 α -reductase enzyme (and, in some individuals, enzyme that is present but unstable) and is characterized by severe perineal hypospadias and underdevelopment of the vagina.⁸⁸ In the past it was known as pseudovaginal perineoscrotal hypospadias (PPH). It differs from the incomplete forms of testicular feminization because, at puberty, masculinization occurs (the breasts remain male). Normal testicular function occurs, and there is no lack of response to endogenous or exogenous androgen. At birth, however, the external genitalia are similar to that of incomplete androgen insensitivity; i.e., hypospadias, varying failure of fusion of labioscrotal folds and a urogenital opening, or separate urethral and vaginal openings. The cleft in the scrotum appears to be a vagina (there are no müllerian ducts), and these patients have been reared as girls with an enlarged clitoris. At birth, steroid levels are normal, ruling out adrenal disorders.

Diagnosis can be established by demonstrating an elevated T:DHT ratio based upon the blood levels of testosterone and dihydrotestosterone, especially after HCG stimulation. The karyotype is XY, and, as with other incompletely masculinized males, the sex assignment is female if the phallus is inadequate. Gonadectomy is necessary to avoid not only neoplasia but the virilization that is certain to appear at puberty. On the other hand, early correction of cryptorchidism and hypospadias can preserve fertility and allow a male life. The deficiency is believed to be due to the homozygous state, manifest clinically only in males. Homozygous 46,XX females have reduced body hair, and although menarche may be delayed, fertility is normal.⁸⁹

At least 3 “types” of enzyme deficiency have been described in affected families:

1. Abnormally low concentration of enzyme.
2. Reduced enzyme activity due to enzyme instability.
3. Normal enzyme concentration but defective affinity for testosterone and/or essential cofactors leading to reduced enzyme activity.

Two 5 α -reductase genes have been cloned.⁹⁰ One isoenzyme (5 α -reductase-1) is encoded on chromosome 5; mutations in the other isoenzyme (5 α -reductase-2) encoded on chromosome 2 are responsible for male pseudohermaphroditism due to 5 α -reductase deficiency. Because this deficiency in females does not affect fertility, this contributes to the high incidence of the disorder. The relatively easy switch of individuals reared as girls to boys at puberty suggests that the other 5 α -reductase gene is operative in the brain.

Study of this syndrome points out important lessons in intersexuality.⁹¹ In this condition, the wolffian duct virilizes in a normal male fashion, but the urogenital sinus and genital tubercle persist as female structures. The failure is due to inadequate DHT formation intracellularly in these external genitalia tissues at the time the normal male fetus virilizes. In the 5 α -reductase deficiencies, the seminal vesicles, ejaculatory ducts, epididymis, and vas deferens, which are all testosterone-dependent, are present, whereas the DHT-dependent structures, external genitalia, urethra, and prostate, do not develop along male lines. Affected men have less facial and body hair, less temporal hairline recession, and no problems with acne. However, spermatogenesis, muscle mass, male libido, and deepening of the voice do occur in these men. DHT presence is a requirement only in the fetus, as indicated by the significant genital virilization these patients undergo at puberty and thereafter.⁹² These individuals require surgical correction of hypospadias and cryptorchidism. Whereas the conversion from male to female role is exceedingly traumatic psychologically, the reversal of sex identity (female to male) some of these patients have undergone at puberty was apparently uncomplicated.³⁵ In one such case, a “double-life” was conducted. Although functioning in all public respects as a female, one 5 α -reductase individual conducted numerous and prolonged heterosexual affairs, which were quite satisfactory, albeit clandestine. He had known of his male sexual identity since puberty but delayed medical assistance for fear that exposure would bring shame and guilt to his religiously devoted elderly “old world” mother. He decided to keep his secret until his mother died. He finally sought diagnostic help at age 65, however, because his mother at age 93 continued to enjoy good health.

Abnormal Androgen Synthesis

Defective male development may stem from a secretory failure of the testes during the critical period of sex differentiation. In addition to the obvious specific and often familial defects in enzymatic steps leading to testosterone biosynthesis, a variety of other intrinsically testicular problems can lead to male pseudohermaphroditism. In all, the following conditions account for 4% of male pseudohermaphroditism:

1. Aberrations in testicular organogenesis (dysgenetic testes).
2. Gonadotropin resistant testes (LH receptor mutations).
3. Congenital lipoid adrenal hyperplasia.
4. Defective synthesis, secretion, or response to anti-müllerian hormone.

Defects in testosterone synthesis can be at any one of the 3 required enzymatic reactions that lead from cholesterol to testosterone: 3 β -hydroxysteroid dehydrogenase, P450c17, and 17 β -hydroxysteroid dehydrogenase. These defects are inherited as autosomal recessive traits, and the phenotypes range from partial to complete male pseudohermaphroditism.

Patients with male pseudohermaphroditism who are considered variants of testicular feminization upon partial virilization at puberty may actually have a defect in androgen synthesis. The diagnosis is made by demonstrating elevated blood levels of androstenedione and estrogens, while the blood level of testosterone is low or low-normal. When the enzyme involves a reaction that is active in the adrenal gland (all but the 17 β -hydroxysteroid dehydrogenase), the adrenal blocks are usually severe with adrenal failure and death in the newborn period.

The male pseudohermaphrodite due to deficient testicular 17 β -hydroxysteroid dehydrogenase activity because of mutations in the encoding gene has male internal genitalia and no müllerian structures. The characteristic clinical findings in these patients are external female genitalia at birth with testes usually located in the inguinal canal. Raised as females, these individuals can undergo virilization at puberty because of an increase in testosterone levels. This increase in pubertal testosterone is derived by conversion of elevated circulating levels of androstenedione (in response to the increase in LH at puberty) by unaffected 17 β -hydroxysteroid dehydrogenase isoenzymes.⁹³ In individuals being raised as girls, early gonadectomy is required to avoid virilization at puberty and testicular neoplasia.

Gonadotropin Resistant Testes

Male pseudohermaphrodites, due to agenesis or abnormal differentiation of Leydig cells, are characterized by reduced responsiveness to LH/HCG. All these cases can be termed “gonadotropin resistant testes.” In general, the characteristics of the syndrome include basically female but ambiguous genitalia, male cryptorchid testes with degenerated Leydig cells (Leydig cell hypoplasia or agenesis), no müllerian ducts but present vas deferens and epididymis, elevated gonadotropins (FSH rises further after gonadectomy, indicating the presence of inhibin).⁹⁴

Molecular studies have revealed that these XY gonadotropin resistant individuals with varying degrees of masculinization (from total feminization to nearly normal male genitalia) reflect the amount of Leydig cell function allowed by mutations in the LH receptor.^{95,96} These mutations are inherited by recessive transmission, and, therefore, heterozygous parents have no characteristic affected phenotypes.⁹⁷

Congenital Lipoid Adrenal Hyperplasia

Most of the cholesterol used for steroid synthesis is derived from the mobilization and transport of intracellular stores.^{98,99} Indeed, the rate-limiting step in

steroidogenesis is the transfer of cholesterol from the outer mitochondrial membrane to the inner mitochondrial membrane where fully active P450_{scc} waits for substrate. The rate-limiting transfer of hydrophobic cholesterol through the aqueous space between the outer and inner mitochondrial membranes is mediated by protein activation stimulated by tropic hormones. Long-term, chronic steroidogenesis requires gene transcription and protein synthesis, but short-term, acute responses occur independently of new RNA synthesis, although protein synthesis is still necessary, specifically the proteins that regulate cholesterol transfer across the mitochondrial membrane.

Several proteins have been characterized and proposed as regulators of acute intracellular cholesterol transfer. Sterol carrier protein 2 (SCP2) is able to bind and transfer cholesterol between compartments within a cell. Another candidate is a small molecule, steroidogenesis activator polypeptide (SAP), and still another is peripheral benzodiazepine receptor (PBR), which affects cholesterol flux through a pore structure. But the most studied and favored protein as a regulator of acute cholesterol transfer is **steroidogenic acute regulator (StAR) protein**.^{100,101} StAR messenger RNA and protein are induced concomitantly with acute steroidogenesis in response to cyclic AMP stimulation; StAR increases steroid production; and StAR is imported and localized in the mitochondria. But most impressively, congenital lipoid adrenal hyperplasia (an autosomal recessive disorder) has been demonstrated to be a failure in adrenal and gonadal steroidogenesis due to a mutation in the StAR gene, which results in premature stop codons.^{102,103} With this mutation, a low level of steroidogenesis is possible, even permitting feminization at puberty, but continuing tropic hormonal stimulation results in an accumulation of intracellular lipid deposits that destroy steroidogenic capability.¹⁰⁴

StAR mediates the transport of cholesterol into mitochondria in adrenal and gonadal steroidogenesis, but not in the placenta and brain. It is synthesized in a precursor form as a 285-amino acid protein that has a 25-residue sequence cleaved from the NH₂-terminal after transport into mitochondria.¹⁰⁵ The mutant forms of StAR undergo premature truncation that prevents this proteolytic cleavage. Mutations of the StAR gene, located on chromosome 8p11.2, are the only inherited disorder of steroidogenesis not caused by a defect in one of the steroidogenic enzymes. The absence of StAR expression in placenta and brain indicates the presence of different mechanisms for cholesterol transport in those tissues.

Abnormal Anti-Müllerian Hormone

Hernia Uterine Inguinale (Uterine Hernia Syndrome)

Individuals with this syndrome appear to be normal males, but relatively well-differentiated müllerian duct structures are found, usually a uterus and tubes in an inguinal hernia sac. This is due to a failure of AMH function either as a result of failure of Sertoli cell secretion of this polypeptide or an inability of the müllerian ducts to respond to AMH. Therefore, this syndrome is due to mutations in either the gene for AMH or its receptor. The mutation is inherited as a recessive trait, either X-linked or autosomal. Fertility is usually preserved.

Disorders of Gonadal Development

The proper development and eventual function of the gonad depend on the presence of germ cells, the appropriate sex chromosome constitution, and appropriate gonadal ridge somatic cells. Errors in meiotic division can cause aneuploidy and abnormal sex chromosomes. These occur by nondisjunction, anaphase lag, translocation, breakage, rearrangements, or deletions. Mitosis can also be marred by nondisjunction and anaphase lag leading to mosaicism. Two or more different cell lines can persist and appear in different tissues. Finally, abnormal gonadogenesis may occur as a result of structural or disease related catastrophes leading to loss of fetal gonadal function.

Bilateral Dysgenesis of the Testes (Swyer Syndrome)

Affected individuals have an XY karyotype but normal (infantile) female external and internal genitalia.¹⁰⁶ There are fibrous bands in place of the gonads yielding primary amenorrhea and lack of secondary sexual development at puberty. It is a matter of prudent practice to avoid the possibility of virilization or neoplasm; therefore, removal of these band areas is advocated as soon as the diagnosis is made. Presumably, testes failed to develop or were eliminated (testicular regression) before internal or external genital differentiation.¹⁰⁷ At least one cause of this syndrome is a mutation in the SRY gene.¹⁰⁸ Estrogen and progestin sequential therapy supports female secondary sex development.

Anorchia

Affected XY individuals have infantile unambiguous male external genitalia, and male wolffian ducts and lack müllerian ducts. There are, however, no detectable testes. Early testis function did occur (wolffian presence, AMH function) but was not sustained in sufficient amounts or duration to develop a normal size phallus. It is frequently called "the disappearing testis syndrome." Sex of assignment depends on the extent of external genitalia development.

True Hermaphroditism

Hermaphroditus, the Greek god with bisexual attributes, was the son-daughter of Hermes, the god of athletics, secrets, and occult philosophy, and Aphrodite, the goddess of love. The bisexual theme was immortalized in countless statues by the Greeks and Romans, depicting a normal woman with normal male external genitalia (not a combination commonly encountered in real life). Pliny (23–79 AD) was the first to apply the term hermaphrodite to humans, presenting a description in his massive work, *Historia Naturalis*.

Abnormal sexual differentiation can occur as a result of a mixture of gonadal sex (true hermaphroditism) or complete uncertainty of gonadal sex (gonadal dysgenesis with some virilization).^{109,110} A true hermaphrodite possesses both ovarian and testicular tissue. Both types may be contained in one gonad (ovotestis) or less often, one side may be an ovary, the other a testis. The internal structures correspond to the adjacent gonad. In the majority, external genitalia are ambiguous with sufficient male character to allow male sex assignment. However, three-fourths develop gynecomastia and half menstruate after puberty. Sixty percent are genetic females (XX), few are XY, the rest are mosaics with at least one cell line XX. 46,XX individuals without SRY may have a mutation of an autosomal gene that permits testicular determination in the absence of the testes determining factor.¹¹¹

Gonadal Dysgenesis

Gonadal dysgenesis with bilateral rudimentary streak gonads due to an abnormality in or absence of one of the X chromosomes in all cell lines is called Turner syndrome. Approximately 60% of Turner patients have the total loss of one X chromosome; the remainder have either a structural abnormality in one of the X chromosomes or mosaicism with an abnormal X. Henry Hughbert Turner, born in 1892, became chief of endocrinology and associate dean of the University of Oklahoma school of medicine. He was president of the Endocrine Society in 1968, and died in 1970. Turner's clinical description of this syndrome was presented to the annual meeting of the Association for the Study of Internal Secretions in 1938.¹¹²

In the absence of gonadal development, these individuals are phenotypic females. The well-known characteristics are short stature (142–147 cm, 56–58 inches), sexual infantilism, and streak gonads. The streak gonad is composed of white fibrous stromal tissue, 2–3 cm long and about 0.5 cm wide, containing no va or follicular derivatives. Other congenital problems in this syndrome are a webbed neck, a high arched palate, cubitus valgus, a broad shield-like chest with widely spaced nipples, a low hairline on the neck, short fourth metacarpal bones, disproportionately short legs, and renal abnormalities (horseshoe kidney, unilateral pelvic kidney, rotational abnormalities, and partial or complete duplication of the collecting system). Autoimmune disorders are common, such as Hashimoto's thyroiditis, Addison's disease, alopecia, and vitiligo. Hypothyroidism is present in about 10% of young patients and may reach 50% later in life. Mild insulin resistance and hearing loss are also common. Patients with Turner syndrome are very prone to keloid formation. One-third of patients with Turner syndrome have cardiovascular abnormalities, including bicuspid aortic valves, coarctation of the aorta, mitral valve prolapse, and aortic aneurysms. Often the diagnosis is not made until puberty when amenorrhea and lack of sexual development become apparent. At birth, however, lymphedema (due to hypoplasia of superficial vessels) of the extremities may indicate the condition. It is important to assess the aorta, aortic root, and aortic valve with ultrasonography at least in infancy and again during the teens. Patients with Turner syndrome have normal intelligence; however, there may be difficulty with mathematical ability, visual-motor coordination, and spatial-temporal processing, problems that remain throughout life.

Almost all (99%) of conceptuses with only one X chromosome abort. The remaining 1% account for an incidence of Turner syndrome between 1 in 2500 and 1 in 5000

liveborn girls.¹¹³

Because of the high incidence of assorted abnormalities in patients with Turner syndrome, the following evaluations should be performed, some only once at the time of diagnosis, and others annually as part of on-going surveillance: thyroid function testing (annually) and antibodies (at least once), intravenous pyelogram or renal ultrasonography (once if normal), echocardiography, audiometry, and annual evaluation of the lipid profile and glucose metabolism.

Spontaneous puberty has been reported in 10–20% and spontaneous menstruation in 2–5% of girls with Turner syndrome.¹¹⁴ Rare pregnancies have been reported in those who have had spontaneous menstruation.¹¹⁵ The presence of menstrual function and reproduction in a patient with Turner phenotype may be due to an undetected mosaic complement, such as a 46,XX line in addition to 45,X. When pregnancy does occur in an X deficient subject, the infant has a 30% chance of congenital anomalies, including Down syndrome, spina bifida, and congenital heart disease.

A large variety of mosaic patterns is seen with gonadal dysgenesis. From analysis of the various combinations, it is apparent that short stature is related to loss of regions on the short arm of one X chromosome. Distal long arm deletions of one of the X chromosomes are associated with amenorrhea (usually secondary after some ovarian function) and streak gonads, but the patients are not always growth compromised nor do they display other Turner somatic malformations. Long arm deletions near the centromere are associated with primary amenorrhea. Thus, loss of material from the short arms of the X chromosome leads to short stature and the other stigmata of Turner syndrome. This suggests that normal ovarian development requires two loci, one on the long arm and one on the short arm; loss of either results in gonadal failure. Thyroid autoimmunity is common in Turner syndrome, but Hashimoto's thyroiditis may be specific to 46,XXq1 cases. It should be emphasized that any of the Turner syndrome characteristics can be seen with any karyotype.

Just as X chromosome monosomy, with deletion of the second X chromosome, results in Turner's phenotype, the same will apply to loss of the Y chromosome. The 45,X karyotype derived from leukocyte culture does not guarantee that a mosaic does not exist with a gonadal line containing XY. For this reason, annual pelvic examinations and appropriate screening are required to detect incipient signs of gonadal neoplasia as an adnexal mass. If a presumed 45,X patient develops breasts or sexual hair without exogenous therapy, a gonadoblastoma or dysgerminoma should be considered and ruled out. Heterosexual signs require scrutiny in all 45,X individuals. **Expert consultation should be obtained to pursue further analysis with X- and Y-specific DNA probes.** Why not screen all patients with some form of gonadal dysgenesis with molecular techniques? For example, 3–4% of 45,X patients had Y-derived DNA detected by polymerase chain reaction analysis.¹¹⁶ In one series of 40 Turner syndrome patients, one patient had identifiable Y chromosome material using polymerase chain reaction of the gene from the SRY region of the Y chromosome.¹¹⁷ In 3 of 18 patients (none of whom had evidence of Y chromosomal material by cytogenetic analysis), Y chromosomal segments from the SRY region were detected by polymerase chain amplification and Southern blot analysis.¹¹⁸ Therefore the prevalence of undetected Y material is low.¹¹⁹ Furthermore, is it necessary to know of the presence of silent Y mosaicism?

The problem is that we do not know if there is any clinical significance to Y-derived material detected only by molecular techniques. Another shortcoming of this approach is that polymerase chain reaction and in situ hybridization identify only those DNA sequences that correspond to the probes used in the analysis. There may be a sequence from a Y chromosome that does not correspond to the selected probes. A totally reliable method awaits identification of the gene responsible for tumor formation or the complete mapping of the Y chromosome sequences. Until then, **the recommendation is to seek Y chromosomal material in patients with virilization or when a chromosomal fragment of uncertain origin is identified on the karyotype.**

The term "gonadal dysgenesis" is frequently used to describe all subjects with female genitalia, normal müllerian structures and streak gonads (with either 46,XX or 46,XY karyotypes). Not all possess the spectrum of Turner phenotype anomalies, and some show none of these characteristics. The latter groups are referred to as "pure gonadal dysgenesis." Ovarian development and subsequent internal and external genitalia development proceed normally. However, at variable times thereafter, the gonads undergo accelerated germ cell loss, and premature degeneration of the ovaries ensues. A similar morphologic consequence of premature ovarian degeneration exists in 46,XX gonadal dysgenesis. In these instances, a mutation in an autosomal gene is considered the likely etiologic factor, inherited in autosomal recessive fashion.⁷⁵ Perrault syndrome is the combination of XX gonadal dysgenesis and neurosensory deafness.

Subjects with 46,XY karyotype can also have gonadal dysgenesis; most, but not all, with the pure gonadal dysgenesis form are without Turner stigmata.¹²⁰ The 46,XY gonadal dysgenesis patients are diagnosed in early adolescence with delayed pubertal development. As expected they show elevated gonadotropins, normal female levels of androgen, and low levels of estrogens, female external genitalia, a uterus, and fallopian tubes. Minimal breast enlargement reflects peripheral aromatization of androgens. Menstrual function suggests tumor development in the streak gonad. These streaks often display ovarian stroma but no follicles. Their propensity to tumor development is significant, a 20–30% incidence. Patients with mosaic patterns in the karyotype have a reduced risk of tumor, but it still amounts to 15–20%. The most common tumor is the often bilateral gonadoblastoma, but dysgerminomas and even the more threatening embryonal carcinoma are also seen. Intraabdominal testes should be removed as early in life as possible because of the known risk of tumor development. If well visualized, streak gonads can be removed by laparoscopy.^{121, 122, and 123} The uterus and tubes should be retained for the possibility of pregnancy with donor oocytes.

The etiology of this defect is thought to be a short arm Y chromosome deletion involving SRY, a mutation in other genes that leads to inhibition of SRY function, or a XXq1 mutation of SRY.¹² There is evidence to suggest that some cases of 46,XY gonadal dysgenesis are due to impaired function of a gene on the X chromosome that is necessary for normal SRY function.^{124, 125} The absence of Turner stigmata in these patients suggests the preservation of a nearby gene that protects XY individuals from developing Turner features.¹²⁶ In 46,XY partial gonadal dysgenesis individuals there is some testicular development, and therefore, they present as newborns with ambiguous genitalia.¹²⁷ The degree of external masculinization and the relative proportions of müllerian and wolffian duct structures present correlate with the extent of testes differentiation.

Curiously, to date analysis of a large number of 46,XY gonadal dysgenesis patients has not demonstrated mutations of the coding region of the SRY gene. The association of this form of gonadal dysgenesis with duplications of the short arm of the X chromosome, and various inherited syndromes of multiple congenital anomalies, indicate the role of several genes other than SRY in testes development. There are several reports of 46,XY male pseudohermaphroditism because of mutations in the LH receptor gene.^{128, 129} The 46,XX sisters of these individuals present with primary amenorrhea and a normal female phenotype.

Males who have a 46,XX karyotype usually have SRY present, probably by translocation from the Y to an X chromosome.¹²⁶ Some subjects, however, lack SRY, indicating that more than one genetic defect yields 46,XX maleness.

Multiple X females (47,XXX) have normal development and reproductive function, although mental retardation may be more frequent. Secondary amenorrhea and/or eunuchoidism can be seen.

Mixed Gonadal Dysgenesis

Mosaicism involving the Y chromosome can be associated with abnormalities of sex differentiation. Of the variety of karyotypes possible from loss of the Y by nondisjunction, 45,X/46,XY is the most common. A wide variety of phenotypes is displayed by these individuals from newborns with ambiguous genitalia to normal fertile males or normal female phenotype with bilateral streak gonads. Most have short stature, and one-third have other Turner stigmata.

In the "typical" mixed gonadal dysgenesis case presenting with abnormal sex differentiation, the usual gonadal pattern is a streak gonad on one side and a dysgenetic or normal appearing testis on the other side of the abdomen. Müllerian and wolffian duct development correlates with the character of the ipsilateral gonad. All possible permutations combining streaks, and dysgenetic and apparently normal testes have been encountered. The diversity of presentation is presumed to reflect

the relative proportion of 45,X and 46,XY cells in the gonadal ridge. The incidence of gonadal tumors is 25%.

Surgical Removal of Gonadal Tissue

There is no debate that gonadal tissue having any Y chromosome component in phenotypic females requires removal as soon as the diagnosis is made to avoid the risk of malignant gonadal tumors. There is one exception to this rule. Because gonadal tumors occur relatively late in patients with complete androgen insensitivity, surgery is delayed until after puberty. An accomplished laparoscopist can attempt this procedure, with the option of laparotomy if the gonads prove to be inaccessible. Streak gonads have been removed in this fashion, as well as the testes in androgen insensitivity.^{121, 122, and 123} With androgen insensitivity, the gonads can be close to the external iliac artery and herniated into the inguinal canals. The procedure is more difficult, and care must be taken to extract the gonad from the inguinal canal to secure complete excision. It may also be necessary to make a small abdominal incision or a culdotomy to extract the gonad in order to avoid morcellation. Preoperative magnetic resonance imaging can be helpful in order to accurately localize gonadal tissue and select the correct operative approach.

The uterus and tubes should be preserved for the possibility of pregnancy with donor oocytes.

Hormone Treatment of Patients Without Ovaries

When ovaries are absent in individuals being reared as females, either because of surgery or streak gonads, hormonal treatment will be necessary at puberty and thereafter. Estrogen will initiate and sustain maturation and function of secondary sexual characteristics, and promote the achievement of the full height potential. The adolescent increase in bone density is a very important determinant of an individual's later risk for osteoporosis. This alone is sufficient reason for treatment.¹³⁰ Very small amounts of estrogen will promote growth and development. Early treatment with estrogen, however, can reduce overall growth.¹³¹ Start at about age 12–14 with unopposed estrogen (0.3 mg conjugated estrogens or 0.5 mg estradiol daily). After 6 months to 1 year, move to a sequential program with 0.625 mg conjugated estrogens or 1.0 mg estradiol daily and 5 mg medroxyprogesterone acetate or an equivalent progestin for the first 14 days each month (if a uterus is present). Although not proven by appropriate studies, most clinicians believe an increase in estrogen dose to 1.25 mg conjugated estrogens or 2.0 mg estradiol is warranted (along with adequate calcium intake) to maximize bone and breast responses. Adequacy of treatment can be assessed by following bone age changes, although this is unnecessary in most cases. In patients with genetic shortness in stature (e.g., Turner syndrome), estrogen treatment is not started until bone age is greater than 12 to avoid epiphyseal closure and to allow a longer period of time for long bone growth. Clinicians should strive for good compliance with life-long hormone therapy in order to protect against osteoporosis and cardiovascular disease. Patients can receive helpful education and support from the Turner's Syndrome Society of the United States, 1313 SE Fifth St., Suite 327, Minneapolis, MN 55414, <http://www.turner-syndrome-us.org/>

Stimulation of Growth

Short stature occurs in virtually all patients with a 45,X karyotype and nearly all patients with Turner syndrome who have other karyotypes.¹³² This growth impairment begins in utero, is apparent throughout childhood, and results in a short adult height (a mean of 143 cm, about 4 feet 8 inches).¹³³ This attenuation of growth is partly due to insufficient growth hormone secretion due to the deficiency in sex steroids and also to an end organ resistance to insulin-like growth factor-I.¹³⁴ Anabolic steroids have been used to stimulate growth, especially in patients with Turner syndrome. Short-term growth can be stimulated by anabolic steroids; however, the effect on final adult height is equivocal because epiphyseal maturation is also enhanced. Furthermore, virilizing side effects are a drawback. The combination of low doses of an anabolic steroid (e.g., oxandrolone) and recombinant growth hormone under the direction of a pediatric endocrinologist offers the best prospect. Treatment with growth hormone (50 µg/kg/day) yields significant growth acceleration that can be sustained for at least 6 years, achieving an adult height as much as 10 cm over the initial predicted height, and most patients can achieve a height that is greater than 150 cm (about 4 feet 11 inches).^{131, 135} The future may see effective use of growth hormone-releasing hormone for this purpose. It is worth noting that adolescents with Turner syndrome either treated with growth hormone or not do not lose bone mineral density prior to estrogen treatment; hence, it is unnecessary to begin estrogen treatment at an early age (when it might counteract the goal of growth hormone therapy: achieving maximal height).^{132, 136}

Now that the success of growth hormone treatment is recognized and accepted, an argument can be made for chromosomal screening by molecular analysis of all growth-retarded girls. In a screening of 375 mildly growth-retarded girls, 18 cases of Turner syndrome were identified; 14 of whom had none of the typical clinical features.¹³⁷

The Possibility of Pregnancy

In women who have variants of gonadal dysgenesis and who menstruate, pregnancy can occur. However, there is a 30% incidence of congenital anomalies in the offspring, including spina bifida and Down syndrome. Sex chromosome abnormalities are frequent in the children born to mosaic mothers.¹¹⁵ Prenatal diagnosis by amniocentesis or chorionic villus biopsy is highly advised. Assisted reproductive technology with donated oocytes yields excellent results in women with streak gonads (see [Chapter 31](#)). There is an important consideration in regards to those patients who become pregnant. ***Fatal aortic events (aneurysm, dissection, or rupture) can occur during pregnancy in patients with gonadal dysgenesis. A cardiology consultation with an echocardiogram is strongly advised for these women prior to pregnancy.***

Noonan Syndrome

Both affected males and females with Noonan syndrome have apparently normal chromosome complements and normal gonadal function. The phenotypic appearance of the female is that of a patient with Turner syndrome: short stature, webbed neck, shield chest, and cardiac malformations.¹³⁸ The cardiac lesions, however, are different. Pulmonic stenosis is most frequent in Noonan syndrome as opposed to aortic coarctation in Turner syndrome. In the past these patients have been referred to as male Turner's or Turner's with normal chromosomes. Noonan's are fertile and transmit the trait as an autosomal dominant with variable expression.

Diagnosis of Ambiguous Genitalia

Ambiguous external genitalia in a newborn infant represents not only a major diagnostic challenge, but a social and medical emergency. The physician is involved in a pressure-filled situation because of the necessity for making such an influential decision as the sex of sexual rearing. Rapid and organized evaluation must be initiated to assign the appropriate gender, identify a possible life-threatening medical condition, and begin necessary medical, surgical, and psychological interventions.¹³⁹ Input from a team of experts in endocrinology, genetics, neonatology, psychology, surgery, and urology is essential. Nevertheless, the primary clinician should be the sole contact with the family. Diagnostic procedures may delay the decision, but it is well recognized that a period of delay is far better than later reversal of the sex assignment. Naming of the child should be delayed until a gender is firmly assigned. Parental education and guidance are essential in this anxiety-ridden situation.

The most important point to remember when confronted with a newborn infant with ambiguous genitalia, or an apparently male infant with bilateral cryptorchidism, is that the prime diagnosis until ruled out is congenital adrenal hyperplasia. The reason is clear: adrenal hyperplasia is the only condition that is life threatening. Signs of adrenal failure such as vomiting, diarrhea, dehydration, and shock may develop rapidly. Furthermore, most infants with ambiguous genitalia are virilized females, and most of these have congenital adrenal hyperplasia.

The history of a previously affected relative may aid in the diagnosis of testicular feminization or any of its variants. Similarly, the history of a sibling with genital ambiguity or the history of a previous neonatal death in a sibling strongly suggest the possibility of adrenal hyperplasia. A history of maternal exposure to androgenic compounds may be difficult to elicit. The mother may be unaware of the nature of her medications, and the obstetrician should be consulted to determine if medication was used for threatened or recurrent miscarriage or endometriosis.

Although the appearance of the external genitalia in intersex infants may be similar regardless of etiology, and a definitive diagnosis unachievable by physical examination alone, certain useful clues can be discerned.

Are gonads palpable? Palpation of the genital and inguinal regions is the most important part of the physical examination. Gonads in the inguinal regions or in scrotal folds are almost certainly testes. Ovaries are not found in scrotal folds or in the inguinal regions. The testicles, however, may be intraabdominal. If testicles are

not palpable, the infant should be considered to have congenital adrenal hyperplasia until demonstrated otherwise.

What is the phallus length and diameter? Measured from the pubic ramus to the tip of the glans, a stretched penile length of less than 2.5 cm is 2.5 standard deviations below the mean for infants at 40 weeks of gestational age (2.0 cm for 36 weeks and 1.5 cm for 32 weeks).¹³⁹ The normal newborn clitoris measures less than 1 cm long; a normal newborn penis measures 2.8–4.2 cm in length.

What is the position of the urethral meatus? The urethral meatus can range from a mild hypospadias to an opening in the perineal area into a urogenital sinus. Hypospadias is almost always accompanied by chordee, which is a ventral curvature of the phallus resulting from a shortened urethra.

To what degree are the labioscrotal folds fused? The findings can range from unfused labia majora of a normal female through labia with variable degrees of posterior fusion, a bifid scrotum, to a fully fused normal appearing male scrotum. The distance from the anus to the edge of the vagina divided by the distance from the anus to the base of the clitoris is a ratio which is less than 0.5 in normal females. A ratio greater than 0.5 indicates some degree of labioscrotal fusion.

Is there a vagina, vaginal pouch, or urogenital sinus? Does the rectal examination suggest a midline structure that might be a uterus? A uterus can be palpable, especially shortly after birth when the uterus is a little enlarged in response to maternal estrogen.

Further important physical signs include evidence of hyperpigmentation due to the melanocyte stimulation associated with high levels of ACTH in adrenal hyperplasia, dehydration, hypotension, hypertension, and the manifestations of Turner syndrome such as webbed neck, low hairline, edema of hands and feet, and cardiac and renal anomalies. Careful examination of the phallus may differentiate between a clitoris and a penis. The penis has a midline ventral frenulum, while the clitoris has two folds which extend from the lateral aspects of the clitoris to the labia minora.

All patients with ambiguous genitalia require pelvic ultrasonography (to detect a uterus and ovaries or undescended testes) and a retrograde injection of contrast media into the urogenital orifice to outline the urethra and/or vaginal anatomy, the existence of a urogenital sinus, and the presence of a cervix.¹⁴⁰ Magnetic resonance imaging of the newborn pelvis can supplant both of these procedures.¹⁴¹

Rapid testing of blood leukocytes for karyotype analysis, serum electrolytes, serum androgens (androstenedione, testosterone, dehydroepiandrosterone, dehydroepiandrosterone sulfate), 17-hydroxyprogesterone, 11-deoxycorticosterone, and 11-deoxycortisol is an essential laboratory component in the evaluation of intersex. In selected circumstances, ACTH testing and genital skin biopsy provide specific amplifying information. Currently, there is no rapid test using DNA probes for diagnosing the etiology of ambiguous genitalia.

Differential Diagnosis

The presence or absence of palpable gonads, the presence or absence of a uterus, and the karyotype places the patient in one of four categories: female pseudohermaphroditism, male pseudohermaphroditism, true hermaphroditism, or gonadal dysgenesis.

Clinical signs of adrenal failure indicate that the newborn has some form of adrenal enzyme defect regardless of the steroid pattern. The diagnosis is certain if such an infant is hyperkalemic and hyponatremic (due to aldosterone deficiency) or hypertensive and hypokalemic (secondary to elevated deoxycorticosterone).

In the absence of maternal androgen excess, the diagnosis of genetic females with excess androgen (female pseudohermaphroditism) must distinguish 3 forms of congenital virilizing adrenal hyperplasia. The diagnosis of 21-hydroxylase deficiency is confirmed by finding an elevated level of 17-hydroxyprogesterone in the serum. Elevated levels of 11-deoxycorticosterone and 11-deoxycortisol are found in 11 β -hydroxylase deficiency, while the precursors to cortisol and androgen, 17-hydroxypregnenolone and dehydroepiandrosterone, are high in the 3 β -hydroxysteroid dehydrogenase deficiency. Marginal basal aberrations can be accentuated by an ACTH stimulation test.

Male pseudohermaphroditism (genetic males with too little androgen) can be the result of one of the relatively rare enzyme disorders. Four derive from enzymatic errors in the biosynthesis of testosterone. P450c17 deficient patients display elevated progesterone, whereas individuals with 3 β -hydroxysteroid dehydrogenase deficiency have elevated DHA and 17-hydroxypregnenolone levels. Again, ACTH testing can be useful in amplifying compensated defects. A testosterone biosynthetic error which leads to deficient masculinization involves an enzyme not required for glucocorticoid or mineralocorticoid synthesis. Thus no evidence of adrenal insufficiency with electrolyte disturbance is seen in 17 β -hydroxysteroid dehydrogenase deficiency. Using HCG stimulation testing, elevated androstenedione and DHA are abnormally high. In Leydig cell hypoplasia, HCG stimulation reveals very low circulating testosterone and its precursors, but no adrenal defects, confirming a specific cellular defect in the testes.

HCG stimulation tests and cultures of genital skin fibroblasts are useful in the laboratory differentiation of 5 α -reductase deficiency and partial androgen insensitivity in the newborn. An elevated ratio of testosterone to dihydrotestosterone after HCG stimulation suggests 5 α -reductase deficiency that can be confirmed in culture. On the other hand, patients with androgen insensitivity will have normal ACTH and HCG stimulation tests and abnormal androgen binding or androgen receptor gene mutations in cultured cells.

Although laparotomy is not necessary for assignment of sex, it may be the only way to arrive at a definitive diagnosis. Laparotomy is indicated in the following situations (laparoscopic evaluation is inadequate because gonads may be small and hidden in the inguinal canal).

1. The XX infant with ambiguous genitalia, normal androgens, in apparent good health, and no history of maternal androgen exposure. This is either a true hermaphrodite or a variant of mixed gonadal dysgenesis, and gonadectomy is indicated.
2. The XY patient with ambiguous genitalia, without palpable gonads, and normal androgens. The possibilities are incompletely masculinized males (variants of testicular feminization), a true hermaphrodite, mixed gonadal dysgenesis, and 5 α -reductase deficiency. Sex of rearing will be female, and gonadectomy is necessary to avoid virilization at puberty and the propensity to develop gonadal neoplasia.

Only laparotomy, gonadal biopsy, and/or gonadectomy confirm the diagnosis of true hermaphroditism in individuals with ambiguous genitalia and 46,XY or 45X/46,XY karyotypes. It should be emphasized that evaluations for mutations in the SRY gene are powerful research tools, but these tests are not currently available for clinical determinations.¹⁴²

Assignment of Sex of Rearing

In a newborn who presents a problem of correct sex assignment, it is better to delay than to reverse the sex assignment at a later date. Generally, the decision can be made within a few days, at most a few weeks. In dealing with the parents, terms with unfortunate connotations, such as hermaphrodite, should be avoided. An easy way to explain ambiguous genital development to parents is to indicate that the genitals are unfinished, rather than abnormal from a sexual point of view.

Despite the wealth of knowledge derived from the world of molecular biology, the decision regarding sex of rearing remains a clinical judgment. When all the information is in place, gender assignment will rest on:

1. Future fertility,
2. The projected appearance of genitalia after puberty,
3. Penile adequacy for coital function.

The future fertility in all masculinized females is unaffected. With proper treatment, reproduction is possible, since the internal genitalia and gonads are those of a normal female. Therefore, all masculinized females should be reared as females.

The only other category of patients with ambiguous genitalia with reproductive capability consists of males with 1) isolated hypospadias, 2) the male with repaired isolated cryptorchidism, and 3) the male with the uterine hernia syndrome.

All other patients with ambiguous genitalia will be sterile. Except for salt-wasting adrenal hyperplasia, the physician's prime concern is not with physical survival, but to enable the patient to grow into a psychologically normal, healthy, and well-adjusted adult. The sex of assignment depends upon only one judgment: can the phallus ultimately develop into a penis adequate for intercourse. The success of a penis is dependent upon erectile tissue, and the genitalia should not only be serviceable but also erotically sensitive. Technically, the construction of female genitalia is easier, and therefore the physician must be convinced that a functional penis is possible.^{143, 144}

All decisions regarding sex of rearing and the overall treatment program should be made early in life. If a case has been neglected, sex reassignments must be made according to the gender identity in which a child has developed. Reassignment of sex can probably be made safely up to age 18 months.

Socialization and hormone therapy are important for gender identity and sexual function. Future gender role and identity can be in accord with assigned sex if 4 conditions are met:

1. The parents are comfortable in their ability to raise their child and their resolution of any doubts or uncertainty about the sex of the child. In this acceptance and adaptation, the parents must have participated in and agreed to the sex reassignment decision. Ambiguous names should be discouraged to ensure normal gender identity.
2. Genital reconstruction should take place as early as possible, certainly well before 18 months. Thereafter, sex reassignment is difficult and adjustment impaired.
3. Properly timed hormonal and/or additional surgical interventions must be provided at puberty.
4. The patient should be informed about his or her condition as deemed age-appropriate.

Sex Testing in Athletics

Gender verification tests were introduced into competitive sports in the 1960s because of the concern that individuals might masquerade as the opposite sex to gain a competitive advantage. Sex testing can be based on chromosomal or other histological assays, hormone measurements, or anatomical criteria. Such testing could identify 3 potential groups of problem athletes: transsexuals who have undergone sex change operations, impersonators, and individuals with intersex conditions. Neither sex changed individuals nor masqueraders have been a problem in athletic events. However, sex testing creates the possibility of public exposure and embarrassment for intersex individuals. In addition, sex testing has the potential for revealing to an unaffected individual an underlying diagnosis in a shocking, difficult manner. For all of these reasons, it is argued that physical examination alone should suffice, and any individual with a female phenotype should be allowed to compete as a woman.¹⁴⁵ Even individuals with mild disorders would be able to pass the physical examination requirement. Gender testing of athletes is unnecessary and fraught with potential harm. Gender testing was eliminated in 1992 by the International Amateur Athletic Federation, but it is still required in the Olympic Games.

In many societies throughout history, puberty has been a time of celebration. The changes of puberty announce the acquisition of fertility. However, it is precisely these psychological, social, and cultural forces that make this a stressful, difficult transition for many individuals. Unfortunately, the earlier age of puberty in modern times has made it difficult to cope with an earlier sexuality. Early teenage pregnancies are a relatively new problem (previously they were a biological impossibility). This change in modern life, probably due to improved nutrition and living conditions, makes it all the more important to understand puberty.

The ability to diagnose and manage disorders of female pubescence requires a thorough understanding of the physical and hormonal events that mark the evolution of the child into a sexually mature adult capable of reproduction. Abnormalities in this process of developmental endocrinology either lead to premature, attenuated, or retarded (delayed) puberty. This chapter reviews the important landmarks and mechanisms of normal female maturation as well as the abnormalities which lead to precocious or delayed puberty.

The Physiology of Puberty

The Period of Infancy and Childhood

The hypothalamus, anterior pituitary gland, and gonads of the fetus, neonate, the prepubertal infant and child are all capable of secreting hormones in adult concentrations. Even during fetal life, serum concentrations of follicle-stimulating hormone (FSH) and luteinizing hormone (LH) reach adult levels at midgestation but fall thereafter as the high level of pregnancy steroid hormones exerts inhibitory feedback.¹ Separation of the newborn from its sources of maternal and placental estrogen and progesterone releases newborn FSH and LH from this negative feedback. A prompt rise in gonadotropin secretion follows (along with an increase in inhibin B levels) that, in female neonates, may occasionally reach levels greater than those in the normal adult menstrual cycle.^{2,3} As a result, transient estradiol secretion equivalent to the level of the midfollicular phase of the menstrual cycle is induced and is associated with waves of ovarian follicle maturation and atresia. Full negative feedback is rapidly attained; ovarian steroids and gonadotropins decline and remain at very low levels until 6–8 years of age. During this period, the hypothalamic-pituitary system controlling gonadotropins (the "gonadostat") is highly sensitive to negative feedback of estrogen (estradiol concentration in these years remains low at 10 pg/mL). Studies on gonadal dysgenesis and other hypogonadal infants indicate that the "gonadostat" is 6–15 times more sensitive to negative feedback at this period than in the adult.⁴ Therefore, gonadotropin secretion is in part restrained by even extraordinarily low levels of estrogen.

This reduction in the infant's gonadotropins is not entirely due to exquisite sensitivity to negative feedback. Low levels of FSH and LH even exist in hypogonadal children (with gonadal dysgenesis) between the ages of 5 and 11 years and are similar to the low levels in normal infants of this age.⁵ Because gonadotropin-releasing hormone (GnRH) infusion stimulates moderate LH and FSH secretion in these hypogonadal subjects, a central nonsteroidal suppressor of endogenous GnRH and gonadotropin synthesis appears to be operative.⁶

Although peptide hormone concentrations are low throughout infancy and the prepubertal child, FSH and LH display evidence of pulsatile secretion.^{7,8} and ⁹ As noted, pituitary gonadotropins react with small but significant responses to exogenously administered GnRH, which although quantitatively less than those achieved in puberty are nevertheless capable of inducing the immature gonad to respond with modest steroid secretion. Immaturity of the various endocrine components is not the rate-limiting factor in the onset of puberty.

The Prepubertal Period

As puberty approaches, three critical changes in the low endocrine homeostatic function of childhood emerge:

1. Adrenarche.
2. Decreasing repression of the "gonadostat."
3. Gradual amplification of the peptide-peptide and peptide-steroid interactions leading to "gonadarche."

Adrenarche

The growth of pubic and axillary hair is due to an increased production of adrenal androgens at puberty. Thus, this phase of puberty is often referred to as adrenarche (or pubarche). **Premature adrenarche** by itself is occasionally seen; i.e., pubic and axillary hair without any other sign of sexual development. **Premature thelarche** (breast development) without other signs of puberty is very rare, but does occur. Increased adrenal cortical function, expressed by a rise in circulating

dehydroepiandrosterone (DHA), dehydroepiandrosterone sulfate (DHAS), and androstenedione associated with increased adrenal 17 α -hydroxylase and 17,20-lyase activity (the P450c17 enzyme), occurs progressively in late childhood from about age 6–7 to adolescence (13–15 years of age).¹⁰ This steroid secretion is associated with an increase in size and differentiation of the inner zone (zona reticularis) of the cortex. Generally, the beginning of adrenarche precedes by 2 years the linear growth spurt, the rise in estrogens and gonadotropins of early puberty, and menarche at midpuberty. Because of this temporal relationship, activation of adrenal androgen secretion has been suggested as a possible initiating event in the ontogeny of the pubertal transition.

Considerable evidence, however, supports a *dissociation* of the control mechanisms that initiate adrenarche and those governing GnRH-pituitary-ovarian maturation (“gonadarche”).¹¹ Premature adrenarche (precocious appearance of pubic and axillary hair before age 8 years) is not associated with a parallel abnormal advancement of gonadarche.¹² In hypergonadotropic hypogonadism (gonadal dysgenesis) or in hypogonadotropic states such as Kallmann's syndrome, adrenarche occurs despite the absence of gonadarche. When adrenarche is absent, as in children with cortisol-treated Addison's disease (hypoadrenalism), gonadarche still occurs. Finally, in true precocious puberty occurring before 6 years of age, gonadarche precedes adrenarche.

Plasma levels of adrenal androgens change without corresponding changes in cortisol and ACTH during fetal life, puberty, and aging. Furthermore, in other circumstances such as chronic disease, surgical stress, recovery from secondary adrenal insufficiency, and anorexia nervosa, changes in ACTH-induced cortisol secretion are not accompanied by corresponding changes in plasma adrenal androgen levels.¹³ Thus, adrenarche does not appear to be under direct control of gonadotropins or ACTH.

A pituitary adrenal androgen stimulating factor formed by cleavage of a high molecular weight precursor, proopiomelanocortin (POMC), which also contains ACTH and b-lipotropin, acting on an ACTH prepared and maintained adrenal, has been suggested as the agent stimulating adrenarche. A large glycoprotein has been identified that also displayed adrenal androgen stimulating activity.¹⁴ However, in a study confirming the dissociation between plasma adrenal androgens and cortisol in children and adolescents with Cushing's disease and ectopic ACTH producing tumors, all known proopiomelanocortin-related peptides, including ACTH, b-endorphin, and b-lipotropin did not have a determinative role in the initiation of adrenarche.¹⁵ Studies fail to demonstrate a relationship between melatonin secretion and adrenarche.¹⁶

A study of the kinetics of the 3 β -hydroxysteroid dehydrogenase enzyme in human adrenal microsomes suggests that the changes in adrenal secretion from fetal life to adulthood can be explained by local steroid inhibition of key enzymes within the adrenal, acting to a variable degree in different layers of the cortex and at different stages of development.¹⁷ Puberty is associated with the emerging prominence of a zona reticularis (the source of DHA and DHAS) that is relatively deficient in 3 β -hydroxysteroid dehydrogenase activity, a state that is maintained during adult life.^{18,19} The factors that regulate and suppress this enzyme activity remain unknown. Another hypothesis suggests that serine phosphorylation of P450c17 is necessary for 17,20-lyase activity, and that this phosphorylation, stimulated by a yet unknown mechanism, is responsible for the initiation of adrenarche.²⁰ It is fair to say that the factors controlling adrenarche remain obscure.

Decreasing Repression of the “Gonadostat”

Regardless of its relation to adrenarche, factors which induce gonadarche in late prepuberty involve derepression of the central nervous system (CNS)-pituitary gonadostat, progressive responsiveness of the anterior pituitary to exogenous (and presumably endogenous) GnRH, and follicle reactivity to FSH and LH.

For approximately 8 years, from early infancy to the prepubertal period, LH and FSH are suppressed to very low levels. The mechanisms for this restraint on gonadotropin secretion are a highly sensitive negative feedback of low level gonadal estrogen on hypothalamic and pituitary sites, and an intrinsic central inhibitory influence on GnRH that reduces basal gonadotropin concentrations even in agonal children. Gonadal dysgenesis patients display marked elevations of gonadotropins for the first 2–3 years of life. Thereafter, a striking decline in concentrations of FSH and LH occurs, reaching a nadir at 6–8 years. By age 10–11 (at the time puberty would have occurred), however, gonadotropins are elevated once again to the postmenopausal range. The overall pattern of basal gonadotropin secretion in agonal children is qualitatively similar to that observed in normal females.

Whereas negative feedback inhibition may play the more important role in early childhood, the central intrinsic inhibitor becomes functionally dominant in midchildhood and persists up to prepuberty. Suppression of, or damage to, the neural source of this inhibition has been postulated in the pathogenesis of the precocious puberty secondary to hypothalamic lesions that compress or destroy posterior hypothalamic areas.²¹ Thus, normal pubertal timing of gonadarche, with the reactivation of gonadotropin synthesis and secretion, results from the combined reduction in intrinsic suppression of GnRH and decreased sensitivity to the negative feedback of estrogen.²²

It has been suggested that the reversal of central intrinsic suppression is due to a reduction in melatonin secretion by the pineal gland. In lower animals affected by photoperiodicity, pineal melatonin appears to inhibit hypothalamic-pituitary gland secretion. While melatonin may play a role in the altered timing of puberty associated with pineal tumors and in the pathophysiology of central precocious puberty, there is no evidence that it is important in the physiologic onset of normal puberty in humans.²³ In two large studies of circadian rhythms of serum melatonin from infancy to adulthood (1–18 years) the decline in the nocturnal surge of melatonin, thought to have been exclusively related to the pubertal conversion, was observed to begin in infancy and progressively decline through pubescence.^{24,25} Pinealectomy in agonal primates does not prevent the inhibition of FSH and LH seen during transition from infancy to childhood nor the return of gonadotropins with the advent of puberty.²⁶

The fascinating search for the factor(s) involved in the derepression of the “gonadostat” so crucial to the timing of puberty continues. POMC-related peptides do not appear to change during the transitional period.²⁷ The ontogeny of the GnRH gene and its expression, so elegantly demonstrated in rodents, is yet to be extended to the primate.

Alteration and Amplification of GnRH-Gonadotropin and Gonadotropin-Ovarian Steroid Interactions

FSH and LH levels increase during the progress through the stages of puberty. Rhythmic pulses of GnRH given to immature rhesus monkeys will initiate activity of the pituitary-gonadal apparatus, supporting the primacy of endogenous GnRH in the establishment and maintenance of puberty. Similar effects have been demonstrated in prepubertal girls.²⁸ Normal pubertal maturation in girls is also accompanied by changes in the pattern of gonadotropin responses to the hypothalamic-releasing hormone GnRH. FSH responses to GnRH are initially pronounced but decrease steadily throughout the onset of puberty. In contrast, LH responses are low in prepubertal girls and increase strikingly during puberty.²⁹ This is the basis of the observation that in general FSH rises initially and plateaus in midpuberty while LH tends to rise more slowly and reaches adult levels in late puberty. The increased amplitude and frequency of pulsatile GnRH are believed to provoke progressively enhanced responses of FSH and LH secretion. GnRH acts as a self-primer on the gonadotrope cells of the anterior pituitary by inducing cell surface receptors specific for GnRH and necessary for its action (up-regulation). Thus, gonadotrope cells increase their capacity to respond to GnRH first by synthesis and later by secretion of gonadotropins. As gonadotropin secretion appears, ovarian follicle steroid synthesis is stimulated and estrogen secretion rises.

Elsewhere ([Chapter 5](#) and [Chapter 6](#)), the evidence for the dichotomous effects of estrogen feedback on the anterior pituitary has been reviewed. Suffice to say, by midpuberty estrogen enhances LH secretory responses to GnRH (positive feedback) while combining with inhibin to maintain relative inhibition (negative feedback) of FSH response.

The amplification of peptide-steroid interactions during pubescence is not restricted to the GnRH impact on gonadotropin or steroid feedback on the pituitary and hypothalamus. As the pubertal transition advances there is a disproportionate rise of biologically potent LH beyond the increase seen in immunologic LH. This marked increase in the bioactive to immunoreactive ratio is due to molecular alterations in the glycosylation pattern of LH, as reviewed in Chapter 2 under “[Heterogeneity](#).”³⁰

Prior to puberty, gonadotropin levels are low but still associated with pulses.⁹ The onset of augmented GnRH pulses first occurs during sleep. There is sleep-associated release of LH in both sexes, a consequence of LH responses to endogenous GnRH. The early stages of puberty are associated with a marked nocturnal augmentation of FSH and LH pulses (both amplitude and frequency, but especially frequency); this difference between nighttime and daytime switches by late puberty with an increase in daytime and a decrease in sleep pulsatility.^{8,31,32 and 33} It should be noted that day-night differences exist before puberty, but the differences become more marked with the onset of puberty. This change is not abrupt with the onset of puberty. Very sensitive assays can detect an increase in FSH and LH (both day and night) in the months preceding the beginning of breast development.³¹

Sleep-related LH pulses also are seen in children with idiopathic precocious puberty, in anorexia nervosa patients during intermediate stages of exacerbation and

recovery, and also in agonadal patients during the pubertal age period when their gonadotropins are returning from midchildhood reductions. ³⁴ GnRH pulses appear and are maintained independent of steroid feedback.

Puberty

The cascade of events initiated by the release of pulsatile GnRH from prepubertal feedback and central negative inhibition results in increased levels of gonadotropins and steroids with appearance of secondary sexual characteristics and eventual adult function (menarche and, later, ovulation). Between the ages of 10 and 16 the endocrine sequence observed includes, first, increased pulsatile patterns of LH during sleep, followed by similar pulses of less amplitude occurring throughout the 24-hour day. Episodic peaks of estradiol result and menarche appears. By mid to late puberty, maturation of the positive feedback relationship between estradiol and LH is established, leading to ovulatory cycles.

Timing of Puberty

Although the major determinant of the timing of puberty is genetic, other factors appear to influence the time of initiation and the rate of progression of puberty: geographic location, exposure to light, general health and nutrition, and psychologic factors. For example, children with a family history of early puberty start early. ³⁵ Children closer to the equator, at lower altitudes, those in urban areas, and mildly obese children start earlier than those in Northern latitudes, at higher elevations above sea level, in rural areas, and normal weight children, respectively. There is a fairly good correlation between the times of menarche of mothers and daughters and between sisters. ³⁵ There is a correlation between age of onset and duration of puberty; the earlier the onset, the longer the duration. ³⁶

The decline in the age of menarche displayed by children in developed countries undoubtedly reflects improved nutritional status and healthier living conditions. Frisch argued that a critical body weight (47.8 kg) must be reached by a girl to achieve menarche. ³⁷ Possibly more important than total weight is the shift in body composition to a greater percent fat (from 16.0 to 23.5%), which in turn is influenced by the nutritional state. ³⁸ Indeed, moderately obese girls (20–30% over normal weight) have earlier menarche than normal weight girls. ³⁹ Conversely, anorexics and intense exercisers (low weight or low percent fat component of weight) have delayed menarche or secondary amenorrhea. That other factors are involved is indicated by the delayed menarche experienced by morbidly obese girls (greater than 30% overweight), diabetics, and intense exercisers of normal weight. Intriguingly, blind girls experience earlier menarche. ⁴⁰ Furthermore, girls with idiopathic central precocious puberty may undergo menarche at a total body fat of 19%, and girls with no signs of puberty may have measured total body fat of 27%. ⁴¹

It is reasonable to hypothesize that central mechanisms bring about maturation of the hypothalamic-pituitary-ovarian axis, which in turn stimulates growth to the critical weight as well as the increases in body fat composition. However, not all auxologic studies have found a relationship between the onset of puberty and either body fat mass or body fat distribution. ⁴² Nevertheless, the identification of leptin (discussed in [Chapter 19](#)) has revitalized the importance of a relationship between body fat and reproductive function.

Leptin is a peptide secreted in adipose tissue that circulates in the blood bound to a family of proteins, and acts on the central nervous system neurons that regulate eating behavior and energy balance. Several observations support a role for leptin in reproductive physiology.

1. Leptin administration accelerates the onset of puberty in rodents. ⁴³
2. Leptin levels increase at puberty in boys. ⁴⁴
3. Low leptin levels are present in athletes and in patients with anorexia, or delayed puberty. ⁴⁵
4. Mice lacking leptin undergo normal sexual development, but remain prepubertal and never ovulate, but fertility is restored with leptin administration. ⁴³

Leptin levels increase during childhood until the onset of puberty, suggesting that a threshold level of leptin (and, therefore, a critical amount of adipose tissue, the source of leptin) is necessary for puberty to begin. ⁴⁶ The higher the level of leptin, the earlier the age of menarche. ⁴⁷ Girls with idiopathic precocious puberty have higher levels of leptin. ⁴⁸ These relationships support the existence of communication between the central nervous system and body fat in the process of puberty, with leptin serving as the messenger.

After puberty, leptin levels in boys return to the prepubertal range (apparent suppression by testosterone). In girls, leptin levels are higher than in boys and decrease with increasing Tanner stages of puberty. ⁴⁹ Thus with puberty, there is increasing sensitivity to leptin. Or, in another way to look at this relationship, a decrease in leptin during puberty may allow greater food intake for growth by lowering the satiety signal.

Stages of Pubertal Development

On the average, the pubertal sequence of accelerated growth, breast development, adrenarche, and menarche requires a period of 4.5 years (range 1.5 to 6 years). The largest body of data was accumulated in healthy European girls; current North American standards are approximately 6 months earlier for each stage. ^{50, 51, 52, 53, 54, 55 and 56} Secondary sex characteristics develop earlier in black girls than in white girls.

In the early 1990s, the American Academy of Pediatrics performed a cross-sectional study of pubertal development in American girls seen in pediatric office practices. ⁵⁷ Although this study was handicapped by deriving data from office practices rather than a randomized population sampling, it is the largest study available, containing 17,077 girls (9.6% black Americans and 90.4% white). The important findings are as follows:

	Black Americans	White Americans
Breast and/or pubic hair at age 7:		
	27.2%	6.7%
	at age 8:	14.7%
Menarche at age 11:	27.9%	13.4%
	at age 12:	35.2%
Mean age for thelarche:	8.87 years	9.96 years
Mean age for adrenarche:	8.78 years	10.51 years
Mean age for menarche:	12.16 years	12.88 years

The data from the American Academy of Pediatrics study indicates that a substantial number of girls display development 6 months to one year earlier than previously documented, although the age of menarche has remained stable. On average, black American girls begin puberty between ages 8 and 9, and white American girls by age 10.

In general, the first sign of puberty is an acceleration of growth followed by breast budding (thelarche). Breast development follows a well-recognized sequence of events. Breast budding is a change distinguished by enlargement and elevation of the nipples and areolae. This is followed by elevation of the breast by the building of the breast mound. Just prior to the formation of the final adult contours, the areolae form secondary mounds.

Although the sequence may be reversed, adrenarche usually appears after the breast bud with axillary hair growth 2 years later. In approximately 20% of children, pubic hair growth is the first sign of puberty. Menarche is a late event, occurring after the peak of growth has passed.

Growth

An adolescent girl's growth spurt occurs 2 years earlier (at 11–12 years) than that of a boy, and in 1 year, her rate of growth doubles, yielding a height increment of between 6 and 11 cm (2.4–4.3 inches).⁵⁸ The average girl reaches this growth peak about 2 years after breast budding and 1 year prior to menarche. Evidence suggests that growth acceleration is due to estrogen and concomitant increases in growth hormone production and secondary stimulation of insulin-like growth factor-I (IGF-I) levels.⁵⁹ Adrenal androgens are not involved because cortisol-repleted Addisonian patients display normal pubertal growth patterns.

In a remarkable study of African pygmies, it was discovered that the short stature of adult pygmies is due primarily to a failure of growth to accelerate during puberty, and that the principal factor responsible for normal pubertal growth is insulin-like growth factor-I (IGF-I).⁶⁰ Growth hormone exerts its action through a locally produced mediator, insulin-like growth factor-I. In addition, growth hormone can directly stimulate epiphyseal cartilage growth. Normal growth at puberty requires the concerted action of growth hormone, insulin-like growth factor-I, and sex steroids. The increase in circulating insulin-like growth factor-I at puberty correlates with sexual development and results from the interaction between sex steroids and growth hormone. Specifically, the increase in sex steroids in turn increases the secretion of growth hormone, which stimulates the production of insulin-like growth factor-I.⁶¹ However, studies also indicate that the sex steroids can have a direct effect on bone growth independent of growth hormone.⁶² Thus, Laron-type dwarfs (who have a genetic defect in the growth hormone receptor and cannot stimulate IGF-I secretion) can undergo a growth spurt at puberty in response to the sex steroids. However, normal pubertal growth velocities require the combined action of the sex steroids and growth hormone. The sex steroid hormones also limit the ultimate height attained by stimulating epiphyseal fusion. The principal sex steroid involved in pubertal growth is probably estrogen in both boys and girls, with aromatization of androgens being the source of estrogen in boys.⁶³

The most abundant hormone produced by the pituitary gland is growth hormone, which is secreted not as a single substance but as one predominant form and one smaller variant.⁶⁴ Growth hormone is encoded by 5 genes located on chromosome 17q22-q24. One gene is for the predominant form in the pituitary; 3 of the genes are expressed in the placenta. The pituitary gene is regulated by growth hormone-releasing hormone, thyroid hormone, and glucocorticoids. Besides the stimulation of IGF-I in cartilage, growth hormone also stimulates IGF-I production in a variety of tissues throughout the body, especially in the liver (the main source of circulating IGF-I).

The hepatic production of insulin-like growth factor binding protein-1 (IGFBP-1) is regulated by insulin. The circulating levels of IGFBP-1 decrease throughout puberty, in response to the relative hyperinsulinemia that accompanies puberty in response to increasing insulin resistance.⁶⁵ This change would allow greater metabolic activity of IGF-I, an important mediator of growth.

Like the gonadotropins, growth hormone is secreted in pulsatile fashion, and during puberty, the amplitude of the pulses increases, especially during sleep. Your grandmother was right when she said: sleep and you'll grow. The age at which an increase in pulse amplitude first occurs corresponds to the age of most rapid growth. The growth response to growth hormone is correlated with the increases in pulse amplitude, not a change in baseline levels.^{66, 67} Slower growing children display fewer and smaller pulses of growth hormone. The pulsatile pattern of growth hormone secretion is regulated by stimulation from growth hormone-releasing hormone and inhibition from somatotropin release-inhibiting hormone, both released into the hypothalamic-pituitary portal circulation from hypothalamic nuclei. This mechanism is influenced at multiple levels by estrogens and androgens. Prior to puberty, the sex steroid hormones are not involved with growth hormone secretion, beyond a low maintenance effect on secretion. At puberty, however, the dynamics of growth hormone secretion are critically dependent on the gonadal sex steroid hormones. Growth hormone secretion must be very sensitive to the stimulatory effect of estrogens because growth hormone levels increase before any signs of sexual development appear.

The amounts of estrogen required to stimulate long-bone cortical growth are incredibly small. Doses of 100 nanograms of estradiol per kilogram body weight per day increase the amplitude of growth hormone pulsatile secretion and produce maximal growth in agonadal recipients. These doses are insufficient to cause breast budding, vaginal cornification, or an increase in sex hormone-binding globulin.^{68, 69} These low dose effects are consistent with the observation that girls attain peak height velocity early in puberty at a serum estradiol concentration of 20 pg/mL which is one-sixth the mean level of adult women. Furthermore, at low doses, estrogen stimulates growth hormone-induced IGF-I secretion, while high doses suppress IGF-I levels.

Estrogen is a critical hormone in both males and females. Males with mutations in the estrogen receptor alpha or who have aromatase deficiencies grow slowly and have markedly reduced bone densities.^{70, 71} Analysis of the decline in testosterone and estrogen circulating levels with aging indicates that the amount of bioavailable estrogen circulating in the blood is the most consistent predictor of bone density in men and women.⁷² And most impressively, a man with an aromatase deficiency, treated with estrogen, demonstrated that both androgens and estrogens are necessary in order to for males to reach optimal bone mass.⁷³

Osteoporosis and vertebral fractures are less common in black than in white women. Vertebral bone density increases rapidly and significantly during adolescence, and the increase is greater in black girls, providing one explanation for the racial difference in osteoporosis.⁷⁴ The pubertal increase in bone density ranges from 10% to 20%, an accumulation which provides 10–20 years of protection against the normal age-related loss of skeletal mass. Calcium supplementation during adolescence results in a significant increase in bone density and skeletal mass, providing even greater protection against future osteoporosis.⁷⁵ Optimal growth has both immediate and long-term consequences. Adolescents with abnormal menstrual function (suppressed estrogen levels) should not be ignored, but properly evaluated and treated. The influence of the sex steroid levels on bone mass is underscored by the fact that almost all of the bone mass in the hip and the vertebral bodies will be accumulated in young women by late adolescence (age 18), and the years immediately following menarche^{11, 12, 13 and 14} are especially important.^{76, 77}

Menarche

As mentioned previously, environmental factors are important in the onset of puberty. Improved living standards and nutrition in the mother antenatally, and in children postnatally, have played a significant role in producing taller, heavier children with earlier maturation. Studies of identical twins and nonidentical twins indicate that the age at menarche is chiefly controlled by genetic factors when the environment is optimal. In affluent cultures, the trend toward lowering of the menarcheal age and puberty halted around 1960.⁵¹ In the 1700s, the mean age of voice change in the Boys' Bach Choir in Leipzig was 18, now it is 13.5 years. Recent studies have indicated a very slight upward trend in the age of menarche, perhaps a response to some environmental deterioration.⁷⁸

The relationship between menarche and the growth spurt is relatively fixed: menarche occurs after the peak in growth velocity has passed. Hence slower growth, totaling no more than 6 cm (2.4 inches) is noted after initiation of menses.

The normal age range of menarche in U.S. girls is 9.1–17.7 years with a median of 12.8. ^{51, 52} The final endocrine hallmark of puberty is the development of positive estrogen feedback on the pituitary and hypothalamus. This feedback stimulates the midcycle surge of LH required for ovulation. Thus, the menses following menarche are usually anovulatory, irregular, and occasionally heavy. Anovulation lasts as long as 12–18 months after menarche, but there are reports of pregnancy before menarche. Ovulation increases in frequency as puberty progresses, but it is common for 25–50% of adolescents to still be anovulatory 4 years after menarche. ^{53, 54}

Summary of Pubertal Events

The onset of puberty is an evolving sequence of maturational steps. The hypothalamic-pituitary-gonadal system differentiates and functions during fetal life and early infancy. Thereafter, it is suppressed to low activity levels during childhood by a combination of hypersensitivity of the “gonadostat” to estrogen negative feedback and an intrinsic CNS inhibitor. All the components located below GnRH (below the CNS) are competent to respond at all ages (as will be seen in the pathogenesis of precocious puberty). After a decade of functional GnRH insufficiency (between late infancy and the onset of puberty), GnRH secretion is resumed and gonadarche (the reactivation of the CNS-pituitary-ovarian apparatus) appears. Prolongation of intrinsic CNS suppression or disability in any of the components of the gonadarche cascade leads to delayed or absent pubescence.

1. FSH and then LH levels rise moderately before the age of 10 and are followed by a rise in estradiol. An increase in LH pulses is first seen only in sleep but gradually extends throughout the day. In the adult, they occur at roughly 1.5–2 hourly intervals.
2. As gonadal estrogen increases (gonadarche), breast development, female fat distribution, and vaginal and uterine growth occur. Skeletal growth rapidly increases as a result of initial gonadal secretion of low levels of estrogen, which increases the secretion of growth hormone, which in turn stimulates the production of IGF-I.
3. Adrenal androgen (adrenarche) and, to a lesser degree, gonadal androgen secretion cause pubic and axillary hair growth. Adrenarche plays little, if any, part in skeletal growth. While temporarily related to gonadarche, adrenarche is an independent, functionally unrelated biological event.
4. At midpuberty, sufficient gonadal estrogen secretion proliferates the endometrium, and the first menses (menarche) occurs.
5. Postmenarcheal cycles are initially anovulatory. Sustained, predictable positive LH surge responses to estradiol with ovulation are late pubertal events.

Blood Hormone Concentrations During Female Puberty^{79, 80, 81, 82, 83, 84 and 85}

Tanner Stage	FSH IU/L	LH IU/L	Estradiol pg/mL	DHA ng/dL
Stage 1	0.9–5.1	1.8–9.2	<10	19–302
Stage 2	1.4–7.0	2.0–16.6	7–37	45–1904
Stage 3	2.4–7.7	5.6–13.6	9–59	125–1730
Stage 4	1.5–11.2	7–14.4	10–156	153–1321
Adult: follicular	3–20	5–25	30–100	162–1620

Precocious Puberty

Puberty is the biologic transition between immature and adult reproductive function. Its timing, endocrine milieu, and physical expressions have been characterized sufficiently to set clinically reasonable time limits for the normal appearance of female maturity and to allow recognition of the pathogenesis and pathophysiology of most of the causes of premature or delayed pubescence.

If one accepts the mean ± 2.5 standard deviations as encompassing the normal range, then pubertal changes before the age of 8 are regarded as precocious. However, the most recent cross-sectional study (by the American Academy of Pediatrics) indicates that a substantial number of normal girls begin pubertal development before age 8.⁵⁷ Certainly, thelarche and adrenarche before age 6 deserves evaluation. From age 6 to age 8, the clinician's response will be influenced by the anxiety and distress in patient and parents, and the clinical presentation. Increased growth is often the first change in precocious puberty. This is usually followed by breast development and growth of pubic hair. On occasion, adrenarche, thelarche, and linear growth occur simultaneously. Menarche, however, can be the first sign.

Traditionally, precocious puberty has been divided into two classifications:

1. **GnRH-Dependent Precocious Puberty.** Complete, isosexual, central (or specifically GnRH- and gonadotropin-dependent) precocity — also known as **true precocious puberty**. These terms all refer to early activation of the hypothalamic-pituitary-gonadal axis.

2. **GnRH-Independent Precocious Puberty.** Incomplete, isosexual or heterosexual, peripheral or **precocious pseudopuberty.** Sexual maturation in these instances may be due to extra pituitary secretion of human chorionic gonadotropin (HCG) or sex steroid secretion independent of hypothalamic-pituitary gonadotropin stimulation. Thus, this mechanism is GnRH-independent.

In clinical practice, these classifications are of little practical use. Precocity occurs in girls 5 times more frequently than boys, and almost three-quarters of precocity in girls is idiopathic. Nevertheless, in the face of any precocious development, the clinician is obligated to rule out a serious disease process in central or peripheral sites. In girls over 4 years old a specific etiology is rarely found. In younger girls, a CNS lesion is usually present.

A classification of sexual precocity is presented to provide a guide to the possible conditions and the relative incidences encountered. It should be noted that a GnRH-dependent cause is found in up to 80% of girls, with a lesser occurrence in boys. Ovarian tumors, adrenal disease, and the McCune-Albright syndrome make up the majority of noncentral precocity in girls.

Classification and Relative Occurrence of Precocious Puberty^{86, 87 and 88}

	Female	Male
GnRH-Dependent (True Precocity)	74.0%	41.0%
Idiopathic		
CNS problem	7.0%	26.0%
GnRH-Independent (Precocious Pseudopuberty)	11.0%	—
Ovarian (cyst or tumor)		
Testicular	—	10.0%
McCune-Albright syndrome	5.0%	1.0%
Adrenal feminizing	1.0%	0.0%
Adrenal masculinizing	1.0%	22.0%
Ectopic gonadotropin production	0.5%	0.5%

Particular attention should be given to the following possibilities: drug ingestion, cerebral problems such as cranial trauma or encephalitis, retarded growth with symptoms of hypothyroidism, and a pelvic or abdominal mass. A left hand-wrist film (for use with atlases) should be obtained for bone age. Determination of thyroid function is indicated, and blood levels of gonadotropins and steroids should be measured. CT or MRI imaging of the brain is indicated in patients with precocious puberty, even in the face of a normal overall evaluation, including normal routine skull x-rays. Other procedures should be dictated by the clinical findings. Virilization, of course, demands a full adrenal evaluation.

Sexual development does not require ovulatory capability. Evaluation of a patient's possible fertility, for example, with basal body temperatures or progesterone assays, is an unnecessary procedure. More importantly, complete sexual precocity with potential fertility and adult levels of gonadotropins does not rule out the possibility of a serious disease process (e.g., a CNS tumor). While it is true that the most common form of sexual precocity in females is idiopathic or constitutional precocity (true sexual precocity), this must be a diagnosis by exclusion with prolonged follow-up in an effort to detect slowly developing lesions of the brain, ovary, or adrenal gland.

GnRH-Dependent Precocious Puberty (Precocious Development Due to Stimulation of Gonadotropin Secretion, True Precocious Puberty)

The signs of *constitutional* sexual precocity are due to premature maturation of the hypothalamic-pituitary-ovarian axis, resulting in production of gonadotropins and sex steroids. These patients experience an increase in growth that is associated with pubertal levels of insulin-like growth factor-I. Constitutional precocity runs in families and usually occurs very close to the "borderline" age of 8 years. On the other hand, *idiopathic* precocious puberty does not run in families and occurs much earlier in childhood. It must be reemphasized that these benign diagnoses should be made only by exclusion and deserve long-term follow-up, because cerebral abnormalities may not become apparent until adulthood.

Clinical presentation of true precocity may not follow the usual progression of breast and pubic hair growth, acceleration of growth rate and then menses. It is not unusual for adrenarche or menarche to be the first sign (or an adult body odor) with others following. This progression is variable, usually slower in idiopathic cases, but telescoped in precocity due to central disease.

Sexual precocity is consistent with normal reproductive life and it is not associated with premature menopause. The most serious effect of precocity is the resultant adult short stature. Because the skeleton is very sensitive to even the lowest levels of estrogen, these children are transiently tall for their age, but as a result of early epiphyseal fusion, eventually short stature results. Fifty percent are less than 5 feet tall (152 cm).

Intellectual and psychosocial development are also commensurate with chronologic age rather than stage of puberty. Expectations of emotional, social, sexual, and intellectual competence corresponding to their pubertal state leave these youngsters and their families with potentially serious difficulties on all levels of social and emotional function.

A number of CNS problems, including abnormal skull development due to rickets, can cause true precocious development. Various tumors can induce precocity, including hamartomas in the hypothalamus (the most common lesion in very young girls), craniopharyngioma, astrocytoma, glioma, neurofibroma, ependymoma, and suprasellar teratoma — all usually near the hypothalamus. Pineal tumors, for unknown reasons, have been seen only in male precocious puberty. Nontumorous causes include encephalitis, meningitis, hydrocephalus, and von Recklinghausen's disease. An injury to the skull may stimulate sexual development.⁸⁹ The mechanism is unknown, and a latent period of 1–2 months is usually seen. A hamartoma is a hyperplastic congenital malformation in the floor of the third ventricle that usually produces precocity in the first few years of life; magnetic resonance imaging is the most sensitive method for the detection of small tumors like a hamartoma. Patients with true precocious puberty and known CNS lesions or a history of cranial irradiation should be evaluated for growth hormone deficiency because of the recognized association of these defects.⁶²

There is no unifying pathophysiologic mechanism linking this diverse spectrum of etiologies for central precocity. Increased intracerebral pressure and a predilection for posterior hypothalamic lesions have suggested numerous theories. The finding that transforming growth factor- α (TGF- α) accumulates in areas of brain injury as a result of trauma-induced activation of gene expression in glial cells presents an intriguing model in that TGF- α stimulates GnRH release.⁹⁰ Hamartomas can produce gonadotropin-releasing hormone pulses, just as the normal hypothalamic tissue from which they are derived.

Ectopic gonadotropin production is a rare cause of sexual precocity accounting for less than 0.5% of cases. The most common tumors producing human chorionic gonadotropin (HCG) are chorioepithelioma and dysgerminoma of the ovary, and liver hepatoblastoma.^{91, 92} Tumor spread may be present at the time of pubertal development; pelvic and abdominal masses accompanied by ascites are usually detectable.

True sexual precocity occurs in a small number of children with long-standing hypothyroidism. There is evidence to support the possibility that high levels of thyroid-stimulating hormone (TSH) can stimulate the FSH receptor.⁹³ In addition to short stature (but not bone age acceleration), galactorrhea may be present. The sella turcica is frequently enlarged, but with thyroid replacement pubertal development will stop and even regress. The sella films will return to normal. Although reported cases have been severe and, therefore, clinically obvious, laboratory evaluation of thyroid function is indicated in all cases of sexual precocity.

GnRH-Independent Precocious Puberty (Development Due to Availability of Sex Steroids, Precocious Pseudopuberty)

Eleven percent of girls with precocious puberty have an ovarian tumor. The tumor is usually an estrogen-producing neoplasm or cyst. Five percent of granulosa cell tumors and 1% of theca cell tumors occur before puberty. However, gonadoblastomas, teratomas, lipoid cell tumors, cystadenomas and even ovarian cancers have been reported as causes of precocity. Bleeding is irregular and menorrhagic — clearly anovulatory. A pelvic mass is readily palpable in 80% of cases. The palpation of a pelvic or abdominal mass demands surgical exploration. Increasing use has been made of pelvic ultrasonography and whole body (abdominal) imaging for the

work-up of precocious puberty. In addition to estrogen and androgens, these tumors can secrete HCG.

A feminizing adrenal tumor is very rare (1% of cases) and is associated with increased blood levels of DHAS.

Drug ingestion should be suspected in all cases of precocity, especially when there is dark pigmentation of the nipples and breast areolae, an effect of certain synthetic estrogens such as stilbestrol. Common sources are oral contraceptives, anabolic steroids, and hair or facial creams.

McCune-Albright syndrome (polyostotic fibrous dysplasia) accounts for 5% of female precocity and consists of multiple disseminated cystic bone lesions that easily fracture, cafe au lait skin spots of various sizes and shapes, and sexual precocity. In addition, this syndrome can be associated with ovarian cysts, growth hormone- and prolactin-secreting adenomas, hyperthyroidism, adrenal hypercortisolism, and osteomalacia. Premature menarche may be the first sign of the syndrome. Skeletal abnormalities may become evident following the onset of puberty. The combination of multiple bone fractures, cafe au lait patches, and premature development should lead to the diagnosis. But remember that the manifestations of this syndrome can be varied and sometimes subtle. A technetium-99 bone scan may be necessary to demonstrate the areas of bony fibrous dysplasia.

Sexual precocity in McCune-Albright syndrome is now demonstrated to be the result of autonomous early production of estrogen by the ovaries.⁹⁴ FSH and LH levels are low, respond poorly to GnRH stimulation, and there is an absence of nocturnal gonadotropin pulsations (all unlike central precocity). In addition, Cushing's disease, acromegaly, hyperparathyroidism, and hyperthyroidism have been reported in this syndrome. The protean manifestations of this disorder suggested that the pathophysiology results from a basic defect in cellular regulation at the level of the G protein-cAMP-kinase function in affected tissues.⁹⁵ A mutation in the alpha-subunit (G_sa) of the G protein that stimulates cAMP formation (as described in [Chapter 2](#)) has been identified in all affected tissues in patients with McCune-Albright syndrome. This mutation attenuates GTPase activity that is necessary to terminate adenylate cyclase activation; thus, affected tissues have autonomous activity. Somatic mosaicism of the alpha-subunit accounts for the fact that this mutation is not lethal and for the variation in site and activity throughout the body. This mutation can also occur in nonendocrine tissues in patients with McCune-Albright syndrome, thus explaining the occurrence of hepatitis, intestinal polyps, and cardiac arrhythmias. It is possible that this mechanism is responsible for childhood diseases other than McCune-Albright syndrome. For this reason, it has been suggested that this genetic disorder should be called inherited G_sa deficiency.⁹⁶ Eventual fertility is unimpaired, and adult height is usually normal. These positive factors must be considered in the choice of management of the syndrome. In keeping with the autonomous nature of the gonadal activity, treatment with a GnRH agonist fails to suppress gonadal hormone secretion or reverse the sexual precocity.⁹⁷

Familial male precocious puberty is inherited in an autosomal dominant fashion and is caused by mutations in the LH receptor gene that lead to activation.⁹⁸ Thus far, no effects in females of activating mutations of either the LH receptor gene or the FSH receptor gene have been reported.

Yet another example of precocity due to GnRH-independent gonadal secretion of estrogen is by autonomous benign ovarian follicular or luteal cysts.⁹⁹ These children demonstrate an absence of gonadotropin pulsations, variable responses to GnRH, and a lack of suppression of puberty by a long-acting GnRH agonist. The cysts may enlarge and involute and then recur so that signs of sexual precocity and vaginal bleeding remit and exacerbate.¹⁰⁰ The cysts are unusually large and therefore palpable. GnRH testing is useful in differentiating the autonomous (nonreactive) cyst from those secondary to the FSH and LH stimulation of central true precocity (reactive).

It is now understood that nearly every cause of peripheral precocious puberty may *secondarily activate* the hypothalamic-pituitary-gonadal axis with development and superimposition of a central GnRH-dependent true precocity process. Presumably the central mechanism controlling the onset of puberty can be activated once a critical threshold of somatic development has been achieved by the premature production of estrogen *regardless* of source of secretion. This explains the previously paradoxical observations of continuing progressive puberty despite effective treatment of specific causative disease as well as the variable effectiveness of GnRH agonist therapy in McCune-Albright and the syndrome of recurrent ovarian cyst formation. GnRH testing to determine the level of activation will dictate the need for additional GnRH agonist suppression, inhibition of steroidogenesis, or peripheral aromatase inhibition therapy in these cases.

Laboratory Findings in Disorders Producing Precocious Puberty

Gonadal Size	Basal FSH/LH	Estradiol or Testosterone	DHAS	GnRH Response
Idiopathic Increased	Increased	Increased	Increased	Pubertal
Cerebral Increased	Increased	Increased	Increased	Pubertal
Gonadal Unilat. incr.	Decreased	Increased	Increased	Flat
Albright Increased	Decreased	Increased	Increased	Flat
Adrenal Small	Decreased	Increased	Increased	Flat

Special Cases of Precocious Development

Special cases of precocious development include the isolated appearance of one sexual characteristic: premature adrenarche or pubarche (pubic hair), premature thelarche (breast development), or premature isolated menarche. These cases present a special dilemma for the concerned clinician. Are they benign, self-limited variants of normal sexual development that do not require treatment or the first sign of a potentially accelerating process in which early exhaustive diagnosis and long-term therapy may be necessary?

Typically linear growth and skeletal maturation are not advanced, and baseline hormone levels are normal for age and sexual development. However, there is a spectrum of conditions of premature sexual maturation defined by idiopathic central precocious puberty at one end and isolated premature thelarche or premature adrenarche at the other. Between these poles are examples of mixed atypical problems with variable tendencies for stability or progression. Guidelines are emerging that address the issues of when sophisticated diagnostic testing (ACTH stimulation, GnRH testing, ultrasonography, bone assessments) is indicated.

Premature Thelarche

Premature thelarche usually occurs in the first few years of life and is usually self-limited, requiring no therapy. Follow-up has revealed that these children experience normal puberty and growth and, eventually, normal reproduction.¹⁰¹ The breast growth may regress after a few months, wax and wane for years, or last until puberty. Premature thelarche can be unilateral.

Premature Menarche

Isolated premature menarche without other evidence of maturation is an exceedingly rare presentation of precocity; infection, the presence of a foreign body, abuse and trauma, and local neoplasms should be considered. Normal growth, development, and fertility are not affected.¹⁰²

Premature Adrenarche

Premature adrenarche, the appearance of pubic hair before age 8 in girls, is the consequence of an early modest increase in the adrenal androgens, androstenedione, dehydroepiandrosterone and dehydroepiandrosterone sulfate. Normal levels according to stage of puberty are available in the literature.¹⁰³ An adrenal enzyme deficit should be excluded by appropriate laboratory testing, but it is rarely discovered in a prepubertal child who presents only with early growth of pubic hair.^{104, 105} Thus, an ACTH stimulation test is not necessary; a measurement of the circulating early morning level of 17-hydroxyprogesterone will suffice. Treatment is not necessary because the transient acceleration in growth and bone maturation has no major influence on puberty or final height.^{106, 107} Surveillance of these patients should be continued because, although not certain, it has been suggested that they have an increased incidence of anovulation, hirsutism, and hyperinsulinemia.^{108, 109 and 110} Sparse hair growth on the vulva does not represent precocious pubarche.

An ACTH stimulation test should be performed in patients who have an advanced bone age and circulating androgen levels that are greater than those seen in the early stages of puberty. ACTH testing of all children with premature adrenarche will yield results in some that are consistent with mild errors of steroidogenesis.

However, even if present, these mild enzyme changes do not require treatment, and hence, exact diagnosis is not necessary. Treatment is indicated only for unequivocal cases of 21-hydroxylase deficiency, in whom baseline 17-hydroxyprogesterone levels will be diagnostic.

Tanner Staging		
	Breast	Pubic Hair
Stage 1 (prepubertal)	Elevation of papilla only	No pubic hair
Stage 2	Elevation of breast and papilla as small mound, areola diameter enlarged. Median age: 9.3 years	Sparse, long, pigmented hair chiefly along labia majora. Median age: 10.5 years
Stage 3	Further enlargement without separation of breast and areola. Median age: 11.2 years	Dark, coarse, curled hair sparsely spread over mons. Median age: 11.4 years
Stage 4	Secondary mound of areola and papilla above the breast. Median age: 12.1 years	Adult-type hair, abundant but limited to the mons. Median age: 12.0 years
Stage 5	Recession of areola to contour of breast. Median age: 14.6 years	Adult-type spread in quantity and distribution. Median age: 13.7 years

Diagnosis of Precocious Puberty

The cause of precocious development may be obvious by findings in the history or physical examination. Familial occurrence helps to exclude certain disease processes (tumors). Clinically, the nature of precocity dictates certain diagnostic priorities.

1. **Rule out life-threatening disease.** This includes neoplasms of the CNS, ovary, and adrenal.
2. **Define the velocity of the process.** Is it progressing or stabilized? Management decisions hinge on this determination. Isolated, nonendocrine causes of vaginal bleeding (trauma, foreign body, vaginitis, genital neoplasm) must be excluded.

Differential Diagnostic Steps

Physical Diagnosis:

Record of growth, Tanner stages, height and weight percentiles.
 External genitalia changes.
 Abdominal, pelvic, neurologic examination.
 Signs of androgenization.
 Special findings: McCune-Albright, hypothyroidism.

Laboratory Diagnosis:

Bone age.
 Head CT scan or MRI, ultrasonography of abdomen and pelvis.
 FSH, LH, HCG assay.
 Thyroid function tests (TSH and free T₄).
 Steroids (serum DHAS, testosterone, estradiol, progesterone, 17-hydroxyprogesterone).
 GnRH testing.

If the full signs of sexual precocity are present, and basal or GnRH-stimulated gonadotropins are in the pubertal range, a pituitary source of gonadotropins is suspected. A simplified GnRH test can be used as follows: [111](#)

GnRH, 100 µg, administered subcutaneously;
Serum LH level 40 minutes after injection should be less than 8 IU/L.

Any abnormality on neurologic exam or imaging points toward central (CNS in origin) precocious puberty. If these are all normal, idiopathic sexual precocity is the most likely diagnosis. It should be emphasized that basal serum gonadotropins may be in the prepubertal range in the early stages of idiopathic or central precocious puberty; with time and progression of sexual development these will rise to the pubertal range. However, an ectopic source of HCG should be considered if serum gonadotropins are suppressed while estradiol is markedly elevated; a situation easily confirmed by an immunoassay specific for the b-subunit of HCG. The rare feminizing adrenal tumor may be present if the laboratory picture is more one of elevated adrenal androgens with only slightly elevated serum estradiol and suppressed serum gonadotropins. Abdominal and pelvic ultrasonography or magnetic resonance imaging (MRI) is indicated.

When signs of sexual precocity are associated with accelerated growth and skeletal maturation, in the absence of virilization, the etiology may be an ovarian tumor or cyst. A pelvic mass is usually palpable. In this situation, serum FSH and LH are suppressed, while serum estradiol is usually elevated. An elevated serum progesterone suggests an ovarian luteoma. Pelvic ultrasound or imaging can help to confirm the presence of an ovarian mass. Laparotomy is indicated to confirm the diagnosis and carry out surgical resection.

Adrenal hyperplasia or a virilizing adrenal or ovarian tumor must be considered if signs of sexual precocity are accompanied by virilization. With elevation of serum 17-hydroxyprogesterone (17-OHP) and adrenal androgens, the diagnosis of 21-hydroxylase deficient adrenal hyperplasia is established, whereas an elevation of serum 11-deoxycortisol leads to the diagnosis of 11b-hydroxylase deficient adrenal hyperplasia. If these two serum hormones are normal, while serum DHAS or androstenedione is elevated, an adrenal tumor or a virilizing ovarian tumor is suspect. Ultrasound examination and abdominal imaging can be utilized to further localize the tumor.

Breast development usually correlates with a bone age of 11 and menarche with a bone age of 13. If breast and genital development, pubic hair growth, and vaginal bleeding are seen in a short child with a *delayed* bone age, primary hypothyroidism is the most likely diagnosis. This can be confirmed by finding a low serum T₄ and elevated TSH concentration. Serum FSH and LH levels may be in the pubertal range, but these will decrease following thyroid treatment. Galactorrhea may be present along with elevated serum prolactin concentrations. These return to normal with thyroid treatment.

Treatment of Precocious Development

The objectives of management and treatment of precocious puberty include:

1. Diagnose and treat intracranial disease.
2. Arrest maturation until normal pubertal age.
3. Attenuate and diminish established precocious characteristics.
4. Maximize eventual adult height.
5. Avoidance of abuse, reduction of emotional problems, and contraception if necessary.

A number of therapies have been used to achieve these goals. These have included medroxyprogesterone acetate, cyproterone acetate, and danazol. In addition to undesirable side effects, bone maturation and growth were not regularly or sufficiently controlled. Major progress has been made with the use of GnRH analogues for the treatment of true precocious puberty.

The short half-life of GnRH is due to rapid cleavage of bonds between amino acids 5–6, 6–7, and 9–10. Substitution of amino acids at position 6 and replacement of the C-terminal glycine amide has produced effective GnRH agonists. Agents can be chosen that are administered subcutaneously, intranasally daily, or in long-acting depot forms.

After an initial short-term “flare” stimulation of gonadotropin release, desensitization and down-regulation follow, yielding profound reduction in gonadotropins, steroid production, and biologic effects. Substantial regression of pubertal characteristics, amenorrhea, and reduction in growth velocity are rapidly achieved and maintained within the first year of treatment.¹¹² Final bone height is increased but is dependent upon the stage at which medication is begun, the bone age at which the drug is stopped, and the adequacy of the dose regimen.^{113, 114} Even individuals with advanced bone ages will achieve greater growth because suppression of gonadal steroids will delay epiphyseal fusion and prolong the duration of growth. Treatment is more effective if begun before bone age exceeds 12 years.¹¹⁵ With idiopathic GnRH-dependent precocious puberty, height predictions are more accurate using the Bayley-Pinneau tables for average girls, despite advanced bone ages in patients. Some patients will demonstrate a marked slowing of growth with GnRH agonist treatment, and in these patients, the addition of growth hormone will produce an excellent growth response.¹¹⁶

GnRH Agonists in Clinical Use

Position	1	2	3	4	5	6	7	8	9	10
Native GnRH	p	Glu	His	Trp	Ser	Tyr	Gly	Leu	Arg	ProGly-NH ₂
Leuprolide						D-Leu				NH-Ethylamide
Buserelin						D-Ser (tertiary butanol)				NH-Ethylamide
Nafarelin						D-Naphthylalanine (2)				
Histrelin						D-His (tertiary benzyl)				NH-Ethylamide
Goserelin						D-Ser (tertiary butanol)				Aza-Gly
Deslorelin						D-Trp				NH-Ethylamide
Tryptorelin						D-Trp				

The dose of GnRH agonist treatment can be monitored by measuring estradiol levels. Because estradiol is the hormone that triggers growth and development, the objective is to maintain an estradiol less than 10 pg/mL, a prepubertal range.¹¹⁷ Because many commercial estradiol assays lack sensitivity in this range, it may be necessary to confirm adequate suppression by demonstrating a lack of gonadotropin response to the administration of GnRH. In general, children require higher doses of GnRH agonists to achieve suppression compared to adults. Even with treatment, adrenarche will probably continue, true to its independent control system.

Sustained release pellets (goserelin) or sustained release injections (leuprolide) allow once a month dosing.¹¹⁸ Treatment is maintained until the epiphyses are fused or until appropriate pubertal and chronological ages are matched. Discontinuation of therapy is followed by prompt reactivation of the pubertal process and the development of regular ovulatory function in a pattern similar to that of normal adolescents.¹¹⁹ GnRH agonist treatment is also recommended for GnRH-secreting hamartomas of the hypothalamus.^{120, 121} The progress of the tumor can be monitored by imaging, and risky surgery can be avoided.

GnRH agonist treatment is not effective for noncentral forms of precocious puberty such as McCune-Albright syndrome, GnRH-independent sexual precocity, or congenital adrenal hyperplasia. However, should patients with McCune-Albright syndrome or congenital adrenal hyperplasia mature their hypothalamic-pituitary-gonadal axis and develop true sexual precocity, then supplementary GnRH agonist therapy is helpful.^{122, 123} Primary treatment in these cases is directed toward suppression of gonadal steroidogenesis. Medroxyprogesterone acetate can be utilized in depot form to suppress LH secretion, or testolactone, an aromatase inhibitor, can be administered.

If a specific etiology for precocious puberty is identified, treatment is aimed at curing the underlying disorder. Neurosurgical excision of hypothalamic, pituitary, cerebral, or pineal tumors must be individualized in each patient. If these tumors are small and do not extend around or into vital brain structures, their removal may be successful. If complete surgical excision is not possible, radiation therapy should be considered. Although many tumors are said not to be radiosensitive, this may

be the only treatment available, although new chemotherapy protocols are of benefit with some tumors. The tumors that secrete ectopic HCG, such as chorioepitheliomas, teratomas, hepatomas, should be managed in a manner consistent with current specific treatment protocols for HCG-secreting neoplasms.

If an ovarian or adrenal tumor is identified, surgical excision is the treatment of choice. In the case of an ovarian cyst, it may be difficult to know whether the cyst is an autonomous source of estrogens or whether its growth is secondary to gonadotropin stimulation. GnRH testing is useful in resolving this question. If multiple bilateral cysts are discovered, these are usually secondary to central gonadotropin secretion. If the cyst is solitary and the contralateral ovary appears immature, then cyst resection is justified. With primary hypothyroidism, thyroid replacement will prevent further progression of sexual precocity. If adrenal hyperplasia is identified, treatment with appropriate doses of glucocorticoids (and mineralocorticoids if salt-wasting is present) will also prevent further progression of pubertal development. If these patients have a bone age of 11–12 years, glucocorticoid therapy may result in onset of true sexual precocity.

Careful consideration must be given to the management of psychosocial problems in all children with precocious puberty. As mentioned previously, these children have intellectual, behavioral and psychosexual maturation in keeping with their chronological age, not their physical or pubertal age. They do not have early heterosexual activity or abnormal sexual libido. Unfortunately, parents, teachers, and peers may have unrealistic expectations of their intellectual and athletic abilities, and these children may even inappropriately be labeled as retarded. Careful explanation of these considerations must be given to parents. The children should be counseled that their secondary sexual characteristics are normal albeit early. If the child is bright, advancement in school may be possible with special tutoring and this may prove beneficial. Children with precocious puberty may place a stress on the marital or family relationship, and in these situations formal psychological counseling can be useful.

Prognosis

The prognosis for precocious puberty depends on the underlying cause. With primary hypothyroidism, the prognosis is excellent. Children with adrenal hyperplasia tend to be short as adults. Removal of benign ovarian tumors and adrenal tumors carries a good prognosis, while malignant carcinomas often have metastatic disease at the time of presentation, with consequent poor prognosis. Approximately 20% of granulosa cell tumors are malignant, and the prognosis is guarded for recurrences as late as 25 years after removal. Approximately 25% of ovarian Sertoli-Leydig cell tumors are malignant.

With CNS causes of sexual precocity, the prognosis again depends on the exact etiology. If tumors of the CNS are completely resectable, the prognosis is good; however, this tends to be the exception rather than the rule. Some tumors, though, such as hamartomas, are slow growing and may only be discovered during a routine autopsy following death due to other causes. Other tumors, such as craniopharyngiomas, are developmental remnants rather than true neoplasms, and with partial resection and radiation therapy patients may go into remission for many years. With other conditions, such as congenital cysts, hydrocephalus, encephalitis, McCune-Albright syndrome, and neurofibromatosis, the prognosis is related to associated neurologic deficits.

Psychometric testing indicates that girls with precocious puberty have higher verbal IQ scores. Behavioral testing demonstrates that a majority of girls do not have problems; a minority may show a tendency toward social difficulties related to apparent age and physical maturation, such as depression, social withdrawal, moodiness, aggression and hyperactivity. However, with the exception of short stature as an adult, the prognosis for idiopathic sexual precocity remains good if the children enter adult life without psychosexual scars. The mean height in adult women is approximately 152 cm (5 feet). Even with prompt GnRH agonist treatment final adult height is likely to be somewhat compromised because some stimulation to epiphyseal closure will already have occurred before treatment is initiated. One can consider adding growth hormone to patients who appear to be falling short of their predicted height, however the expense of growth hormone is a factor (discussed in [Chapter 9](#)). Most women have normal menstrual cycles and fertility, and they do not have premature menopause. ¹²⁴

Delayed Puberty

Since there is such a wide variation in normal development it is difficult to define the patient with abnormally delayed sexual maturation. Nearly all U.S. white girls and all U.S. black girls have entered puberty by age 13. ⁵² However, some evaluation is needed whenever a patient and parents are concerned enough to seek a clinician's advice. Patients who have not developed signs of puberty by age 17 are very likely to have a specific problem and not physiological delay of puberty.

Delayed puberty is a rare condition in girls, and a genetic problem or hypothalamic-pituitary disorder must be suspected. In addition, anatomic abnormalities of the target organ (uterus and endometrium) or outflow tract are unique but important elements to consider in amenorrheic but otherwise normal pubertal adolescents.

The history and physical examination are very useful in the diagnostic work-up of delayed puberty. Special note should be taken of past general health, height and weight records, and the height and pubertal milestone experience of older siblings and parents, and relevant behavior such as extreme exercise or abnormal eating habits. Physiological delayed puberty tends to be familial. On physical examination, in addition to body measurements and Tanner staging of any secondary sexual characteristics present, a search for signs of hypothyroidism, gonadal dysgenesis, hypopituitarism, or chronic illness should be made. Persistent deciduous teeth are typical of hypothyroidism. The absence of pubic hair in a patient with a uterus and vagina indicates hypopituitarism. The absence of pubic hair in a patient with a vaginal pouch indicates that the patient has androgen insensitivity syndrome.

The failure of growth in stature suggests several possibilities. Isolated growth hormone deficiency is associated with somewhat delayed sexual maturity. Menarche may eventually occur, albeit delayed, but with bone age still several years below chronologic age. More global pituitary hormone deficiency will result in total pubertal delay. Finally, gonadal dysgenesis (45,X) will be associated with decreased height and sexual infantilism with normal to slightly reduced bone age and hypergonadotropism.

Neurologic examination is important; evidence of intracranial disease, restricted visual fields, or absent sense of smell are key findings. Anatomic defects of the müllerian ducts must be sought, especially when a disparity between normal puberty and absent menses is encountered.

As will be seen in the discussion of the work-up, the diverse etiologic possibilities for delayed puberty are best classified by the level of gonadotropin encountered. The distribution of diagnostic frequencies in the three categories — hypergonadotropic hypogonadism, hypogonadotropic hypogonadism and eugonadism — are depicted below, representing the findings in 326 patients. ¹²⁵

Relative Frequency of Delayed Pubertal Abnormalities¹²⁵

Hypergonadotropic Hypogonadism	43.0%
Ovarian failure, abnormal karyotype	26.0%
Ovarian failure, normal karyotype	17.0%
46, XX	15.0%
46, XY	2.0%
Hypogonadotropic Hypogonadism	31.0%
Reversible	18.0%
Physiologic delay	10.0%
Weight loss/anorexia	3.0%
Primary hypothyroidism	1.0%
Congenital adrenal hyperplasia	1.0%
Cushing's syndrome	0.5%
Prolactinomas	1.5%
Irreversible	13.0%
GnRH deficiency	7.0%
Hypopituitarism	2.0%
Congenital CNS defects	0.5%

Other pituitary adenomas	0.5%
Craniopharyngioma	1.0%
Malignant pituitary tumor	0.5%
Eugonadism	26.0%
Müllerian agenesis	14.0%
Vaginal septum	3.0%
Imperforate hymen	0.5%
Androgen insensitivity syndrome	1.0%
Inappropriate positive feedback	7.0%

Laboratory Assessments of Delayed Puberty

Laboratory work-up of delayed puberty usually includes x-rays for bone age, skull imaging (if hypogonadotropic), gonadotropin and prolactin levels, appropriate adrenal and gonadal steroid measurements, and assessment of thyroid function. In addition, general laboratory screening for systemic disorders is worthwhile. Evaluation according to the program outlined in [Chapter 11](#) will lead to the proper diagnosis. Patients with elevated gonadotropins require a karyotype. Measurements of serum IGF-I, IGFBP-3, and IGFBP-2 can distinguish between delayed puberty and growth hormone deficiency; normal levels according to age, body mass index, and stage of puberty are available in the literature. ^{126, 127}

Hypergonadotropic Hypogonadism

If gonadotropins are increased into the postmenopausal range (hypergonadotropic hypogonadism), then some type of gonadal deficiency usually is the basis of delayed maturation. The most common disorder of this type is gonadal dysgenesis. In the 45,X patient, the typical phenotypic stigmata of Turner syndrome will be displayed. However, these may be minimal or absent in sex chromosome mosaicism or structural deletions of the X chromosome. A Y-bearing cell line requires gonadal excision as prophylaxis against the risk of gonadal malignancy. Intersex patients ([Chapter 9](#)) can present with delayed puberty.

A hypergonadotropic 46,XX individual presents interesting possibilities. If hypertension, sexual infantilism, and an elevated serum progesterone are found, 17 α -hydroxylase deficiency in steroid synthesis is likely. Acquired ovarian damage from torsion or inflammation should be ruled out. In sickle cell disease, approximately 20% of patients have delayed puberty and hypergonadotropism. Finally, the 46,XX patient may have pure gonadal dysgenesis (gonadal streaks) or the resistant ovary syndrome. See the discussion in Chapter 11 under "[Premature Ovarian Failure.](#)"

Hypogonadotropic Hypogonadism

Decreased secretion of LH (less than 6 IU/L), associated with depressed FSH, is seen in hypothalamic amenorrhea, amenorrhea and anosmia — Kallmann's syndrome, pituitary (tumor) disorders, hyperprolactinemia, or nonpathologic constitutional (physiologic) delay in development. Physiological delayed puberty can be regarded as a physiologic variant in development. The typical patient with physiological delay is short with appropriate bone maturation delay. Physiological delay accounts for only 10% of cases with delayed puberty, emphasizing the need to seek another diagnosis. As previously noted, physiological delay is frequently seen in a familial pattern with the expectation of a late but otherwise normal growth pattern and adult reproductive function.

Poor nutrition (anorexia nervosa, malabsorption, chronic illness, regional ileitis, renal disease) can lead to hypogonadotropic delayed growth and development. Exercise and/or stress-induced amenorrhea can also delay puberty. Unfortunately, illegal drug use (especially marijuana) must be considered.

In the presence of normal olfaction and normal prolactin levels, exclusion of pituitary, paraspinal, or hypothalamic tumor by specialized neuroradiologic procedures is necessary. If tumor or vascular malformation is not found, the diagnosis is (by exclusion) physiological delayed puberty.

Craniopharyngioma. This tumor is the most common neoplasm associated with delayed puberty. Craniopharyngioma is a tumor of Rathke's pouch, originating from the pituitary stalk with suprasellar extension. The peak incidence is between ages 6 and 14. ¹²⁸ Imaging reveals an abnormal sella and calcifications in 70% of cases. Treatment consists of a combination of surgery and irradiation.

Eugonadism

Müllerian tube segmental discontinuities, müllerian agenesis, or androgen insensitivity syndrome will present as delayed menarche despite normal development of an adult female phenotype ([Chapter 11](#)). Müllerian agenesis accounts for one-seventh of cases of prolonged primary amenorrhea. Other obstructive anomalies of the müllerian ducts are less frequently seen. Anovulation and polycystic ovaries, and androgen-producing adrenal disease, can present as primary amenorrhea. Virilization raises the possibility of adrenal hyperplasia or an intersex problem.

Treatment of Sexual Infantilism (Delayed Puberty)

The first priority in therapy is removal or correction of primary etiology when possible. In this regard, thyroid therapy for hypothyroidism, growth hormone for isolated growth hormone deficiency, and treatment of ileitis are examples of specific therapy. In XY individuals, properly timed gonadectomy followed by sex hormone treatment is required. In physiological delay, reassurance that the anticipated development will occur is the only management step needed, especially when there is a family history of delayed puberty. Early hormone treatment is worthwhile in order to minimize psychological stress.

In hypogonadism, hormonal therapy will initiate and sustain maturation and function of secondary sexual characteristics and promote the achievement of full height potential. The importance of the adolescent increase in bone density should not be underrated. This is sufficient reason to recommend hormone treatment.

Hormone treatment should conform to what we have learned about the early stages of puberty. Very small amounts of estrogen will promote growth and development. Start with unopposed estrogen, 0.3 mg conjugated estrogens or 0.5 mg estradiol daily. After 6 months to 1 year, move to a sequential program with 0.625 mg conjugated estrogens or 1.0 mg estradiol daily and 5 mg medroxyprogesterone acetate or an equivalent progestin for the first 14 days each month. Patients with physiological delay of puberty will continue development on their own when bone age has advanced to 13 years.

Monthly menstruation is an important experience for adolescents. Regular and visible bleeding serves to reinforce the young patient's identification with the feminine gender role. However, remember that the doses used for this therapy will not protect against pregnancy in the event the hypothalamic-pituitary-ovarian axis is activated. In a sexually active patient, it would be wiser to use oral contraception to provide the missing estrogen.

Treatment with pulsatile GnRH is both a logical and effective means of inducing a physiologic puberty. ¹²⁹ However, this treatment regimen is not practical. Although its expense is an important consideration, the technical aspects associated with the parenteral administration of GnRH pulses make this method too cumbersome and difficult.

Growth Problems in Normal Adolescents

Perhaps the worst thing about an adolescent growth problem is that it makes the individual "different." It is probably true that more than anyone else the adolescent does not like to be different. Therefore, excessive or insufficient growth is not a problem to be dismissed lightly, and psychologic support and reassurance are key features in the management of such problems. A willingness to listen to problems, together with an adult-to-adult attitude, will place the adolescent-clinician relationship at the proper level of mutual respect.

The basic and essential laboratory procedure is a left hand-wrist x-ray for bone age. The Bayley-Pinneau tables predict future adult height, utilizing the bone age and present height. ¹³⁰ To use the tables, one needs a measurement of height, the patient's age, and an x-ray of the left hand and wrist for bone age. All of the hand

epiphyses and those of the distal end of the arm are used to determine the skeletal age. The Bayley-Pinneau tables begin at the end of this chapter.

To predict a patient's adult height, use the tables as follows. Go down the left column to the patient's present height, follow this horizontal row to the column under the bone age which is given by 6-month intervals across the top. The number at the intersection represents the predicted adult height. The predicted height can be easily extrapolated if figures do not fall at the 1-inch or 6-month intervals used on the tables.

It is important to use the table suitable for the rate of maturing. If the bone age is within 1 year of the chronologic age, use the table for average girls; if the bone age is accelerated 1 year or more, use the table for accelerated girls; if the bone age is retarded 1 year or more, use the table for retarded girls. Girls with idiopathic central precocious puberty are an exception to this recommendation. With idiopathic GnRH-dependent precocious puberty, despite advanced bone age, height predictions are more accurate using the Bayley-Pinneau tables for average girls. ¹¹⁵

The tables are for use with bone age films of the hand and wrist only in conjunction with the Greulich-Pyle Atlas. Use with bone age determined by any other method is less accurate.

Short Stature

Thorough medical history and physical examination will eliminate the usual disorders associated with short stature: malnutrition, chronic urinary tract disease, chronic infectious disease, hypothyroidism, mental illness, panhypopituitarism, and gonadal dysgenesis. In the history, the heights and weights of parents, siblings, and relatives should be obtained along with timing of growth in the family, dietary history, daily activities, and sleep habits. Normal history and examination in an individual with a bone age only 1 year behind the chronologic age suggest a constitutional pattern that does not require treatment.

Endocrine disease is an uncommon basis for impairment of growth. Congenital hypothyroidism is the most frequent problem of this type, followed by hypopituitarism, hypothyroidism with onset during childhood, and excess cortisol.

It is unlikely that a patient with congenital hypothyroidism will present undiagnosed and untreated as an adolescent. However, juvenile hypothyroidism must be suspected in an adolescent with obesity and short stature and normal early childhood development. Similarly, an adolescent with hypopituitarism due to a slow growing pituitary tumor may present with a failure to develop secondary sexual characteristics and a failure to grow. Cortisol excess may be due to Cushing's disease (rare in childhood) or to therapy with corticosteroids. Excess endogenous or exogenous corticosteroids suppress skeletal maturation and growth. Moderate overdosage of cortisol; e.g., when treating children with adrenal hyperplasia, can suppress growth.

Treatment of Short Stature. Support and observation are indicated if the physician concludes that an adolescent suffers from a delay of normal growth and no disease process is present. Reassurance is essential if the bone age is more than 1 year below the chronologic age, but the family history reveals a consistent pattern of retarded but eventual normal growth. It is helpful to point out the x-ray, indicating that the individual has 1 year or more of unused potential in which to catch up with her friends.

Hormone treatment can be considered when continued failure to grow is evident in the absence of disease. Presently the use of growth hormone is limited to use in growth hormone deficiency. The increment in height achieved with growth hormone treatment of short, but normal, children is too small (about 2.5 cm) to warrant such treatment.¹³¹ Illicit sources of growth hormone have been administered by parents and young people eager to "grow" to achieve greater athletic prowess. This dangerous practice all too often leads to growth but of fragile bones unsupported by the sought-after muscular capacities.

Anabolic-androgenic steroids are illegally utilized by both adolescent males and females to increase athletic performance and even in an effort to look better. ¹³² Response to these agents ranges from increased strength and libido (virilization and menstrual dysfunction in women) to liver diseases, impotence, and oligospermia. Excessive androgen use by adolescents can prevent individuals from reaching their genetic height potential. Although not well studied, most experts believe that there are significant psychological and behavioral effects (such as enhanced aggression), as well as psychological dependence. In addition, adolescents who use anabolic steroids are more likely to use other drugs and to share needles (a major risk factor for human immunodeficiency virus infection). ¹³³

Fortunately, it is rare to see a female adolescent complaining of short stature. More commonly it is an adolescent boy who is sensitive to reduced growth, and in whom the use of testosterone may be indicated. In cases of gonadal failure, estrogen can be used in a female to stimulate epiphyseal growth, bringing the bone age to match the chronologic age. Conjugated estrogens (0.3 mg) or estradiol (0.5 mg) administered daily are effective in hypogonadal individuals (this is a much smaller dose than previously used). Patients should be observed at monthly intervals to document the pattern of growth and development. Hormone treatment may be discontinued when the bone age matches the chronologic age.

Tall Stature

This is rarely a problem in boys. Basketball has provided a ready outlet, and fortunately participation in sports is now appealing to girls as well. But girls who are the daughters of very tall parents may come for help. The Bayley-Pinneau tables are accurate in predicting the height of tall girls. A predicted height greater than 6 feet probably deserves treatment.

A hand-wrist x-ray for bone age is necessary. The degree of development of secondary sexual characteristics is important, because the more mature a girl is, the less effective treatment is in influencing her eventual height.

Treatment of Tall Stature. It is difficult to make a decision for treatment, and parental participation in the decision is essential. In a case where some success can be achieved, the patient is relatively young and may find it hard to know what to think about the future problem.

Because the adolescent growth spurt precedes menarche, treatment must begin before menarche in order to be optimally successful. ¹³⁴ This would be as early as 8 or 9 years, and certainly before the age of 12. However, treatment begun after menarche may still achieve up to an inch of growth reduction. ^{135, 136} Once begun, treatment must continue until epiphyses are fused. If treatment is stopped earlier, further growth will occur. ¹³⁷ The parents and patient must be informed of possible problems with menorrhagia, breast symptoms, and water retention.

A simple regimen that provides high doses of estrogen is to use oral contraceptives; a 50 µg ethinyl estradiol oral contraceptive provides 10 times the estrogen usually administered to postmenopausal women. Hand-wrist films should be taken every 6 months until epiphyseal closure is demonstrated. In view of the sensitivity of growth physiology to low levels of estrogen, it is not certain that these high doses are necessary. Although 10-year follow-up of a large number of women treated with high doses of estrogens did not detect any adverse consequences on reproductive function, ¹³⁸ it would be reasonable to consider the usual replacement dose (0.625–1.25 mg conjugated estrogens or 1–2 mg estradiol), especially if the high doses elicit unpleasant symptoms.

Bayley-Pinneau Table for Accelerated Girls

To predict height, find vertical column corresponding to skeletal age and horizontal row for the present height. The number at the intersection is the predicted height in inches. If figures do not fall at the whole inch or 6-month intervals, the predicted height must be extrapolated.

Skeletal Age	7.0	7.5	8.0	8.5	9.0	9.5	10.0	10.5	11.0	11.5	12.0	12.5	13.0	13.5	14.0	14.5	15.0	15.5	16.0	16.5	17.0	17.5	18.0

Few problems in gynecologic endocrinology are as challenging or taxing to the clinician as amenorrhea. The clinician must be concerned with an array of potential diseases and disorders involving, in many instances, unfamiliar organ systems, some carrying morbid and even lethal consequences for the patient. Not infrequently, the otherwise confident and experienced clinician dismisses the problem as too complex for a busy practice and refers the patient to a "specialist" in the field. In doing so, the nonavailability of sophisticated laboratory techniques is often cited as necessitating the costly and frequently inconvenient transfer of the patient.

The intent of this chapter is to provide a simple mechanism for the differential diagnosis of amenorrhea of all types and chronology, using procedures available to all clinicians. Strict adherence to this design will unerringly pinpoint the organ system locus of disorder leading to the presenting symptom of amenorrhea. Once this is accomplished, the detailed evidence confirming the diagnosis can be sought and the assistance of appropriate specialists (neurosurgeon, internist, endocrinologist, psychiatrist) confidently chosen. In the end, the patient receives the most reliable diagnosis and therapy at minimum cost and optimum convenience. The majority of patients with amenorrhea have relatively simple problems that can be managed easily by the patients' primary care clinicians. This happy outcome is also consistent with the modern health care emphasis on cost-effectiveness.

The "workup" to be described is not new. With minor modifications, it has been continuously and successfully applied for several decades. Before presenting the diagnostic workup in detail, it is necessary to provide a definition of amenorrhea, designating the appropriate selection of patients. In addition, a brief review of the physiologic mechanisms by which a menstrual flow is produced is presented to clarify the logic of the various steps in the diagnostic procedures.

Definition of Amenorrhea

Any patient fulfilling the following criteria should be evaluated as having the clinical problem of amenorrhea:

1. No period by age 14 in the absence of growth or development of secondary sexual characteristics.
2. No period by age 16 regardless of the presence of normal growth and development with the appearance of secondary sexual characteristics.
3. In a woman who has been menstruating, the absence of periods for a length of time equivalent to a total of at least 3 of the previous cycle intervals or 6 months of amenorrhea.

Having affirmed the traditional criteria, let us now point out that strict adherence to these criteria can result in improper management of individual cases. There is no reason to defer the evaluation of a young girl who presents with the obvious stigmata of Turner syndrome. Similarly, the 14-year-old girl with an absent vagina who is otherwise completely normal should not be told to return in 2 years. A patient deserves a considerate evaluation whenever her anxieties, or those of her parents, bring her to a clinician. Finally, the possibility of pregnancy should always be considered.

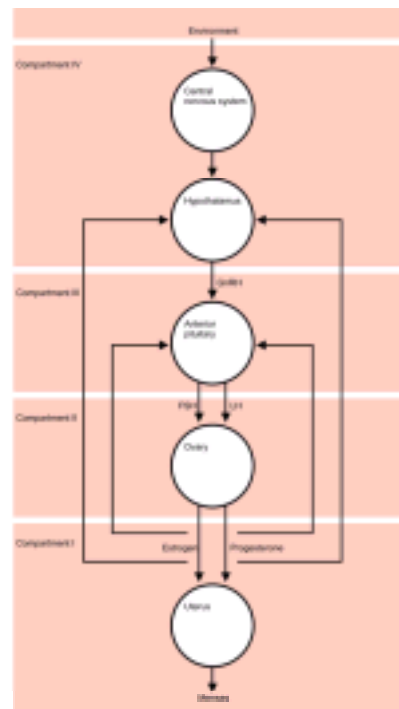

Another tradition has been to categorize amenorrhea as primary or secondary in nature. Although these stipulations are inherent in the classic definitions noted above, experience has shown that premature categorization of this sort leads to diagnostic omission in certain instances, and frequently, unnecessary and expensive diagnostic procedures. Because the prescribed workup to be detailed here applies comprehensively to all forms of amenorrhea, the classic definitions are not retained.

Basic Principles in Menstrual Function

The clinical demonstration of menstrual function depends on visible external evidence of the menstrual discharge. This requires an intact outflow tract that connects the internal genital source of flow with the outside. As such, the outflow tract requires patency and continuity of the vaginal orifice, the vaginal canal, and the endocervix with the uterine cavity. The presence of a menstrual flow depends on the existence and development of the endometrium lining the uterine cavity. This tissue is stimulated and regulated by the proper quantity and sequence of the steroid hormones, estrogen and progesterone. The secretion of these hormones

originates in the ovary, but more specifically, in the evolving spectrum of follicle development, ovulation, and corpus luteum function. This essential maturation of the follicular apparatus is guided by the stimuli provided by the sequence and magnitude of the gonadotropins, follicle-stimulating hormone (FSH) and luteinizing hormone (LH), originating in the anterior pituitary. The secretion of these hormones is in turn dependent on gonadotropin-releasing hormone (GnRH), the specific peptide-releasing hormone produced in the basal hypothalamus and blood borne via the portal vessels of the stalk to receptive cells within the anterior pituitary. The entire system is regulated by a complex mechanism that integrates biophysical and biochemical information composed of interactive levels of hormonal signals, autocrine/paracrine factors, and target cell reactions.

At 6–8 weeks of gestation, the first signs of ovarian differentiation are reflected in the rapid mitotic multiplication of germ cells, reaching 6–7 million oogonia by 16–20 weeks.^{1,2} This represents the maximal oogonial content of the gonad. From this point in time germ cell content will irretrievably decrease until, some 50 years later, the store of oocytes will be finally exhausted. Chromosomal anomalies can accelerate germ cell loss. Individuals with Turner syndrome (45,X) experience normal migration and mitosis of germ cells, but the oogonia do not

undergo meiosis, and rapid loss of oocytes leaves the gonad without follicles by birth, and it appears as a fibrous streak.

The basic principles underlying the physiology of menstrual function permit formulation of several discrete compartmental systems on which proper menstruation depends. It is useful to employ a diagnostic evaluation that segregates causes of amenorrhea into the following compartments:

Compartment I:

Disorders of the outflow tract or uterine target organ.

Compartment II:

Disorders of the ovary.

Compartment III:

Disorders of the anterior pituitary.

Compartment IV:

Disorders of central nervous system (hypothalamic) factors.

Evaluation of Amenorrhea

A careful history and physical examination should seek the following: evidence for psychological dysfunction or emotional stress, family history of apparent genetic anomalies, signs of a physical problem with a focus on nutritional status, abnormal growth and development, the presence of a normal reproductive tract, and evidence for CNS disease. A patient with amenorrhea is then exposed to a combined therapeutic and laboratory dissection according to the depicted flow diagrams. Because a significant number of patients with amenorrhea also have galactorrhea (nonpuerperal breast secretion), and there are similarities in the evaluation of these two conditions, the workup as described is appropriate for patients who have amenorrhea, galactorrhea, or both. Galactorrhea is an important clinical physical sign, whether it is spontaneous or present only with careful expression by the examiner, unilateral or bilateral, persistent or intermittent. **Hormonal secretions usually come from multiple duct openings in contrast to pathologic discharge that usually comes from a single duct.** Galactorrhea is considered in greater detail in [Chapter 16](#).

Amenorrhea and galactorrhea need be the sole pertinent initial items of information. Although additional data are undoubtedly available at this time, derived from history and physical examination and evaluation of other endocrine glands such as the thyroid and adrenal, these items should not be utilized for diagnostic purposes until the entire workup is completed. Experience has shown that premature diagnostic bias at this point, while frequently accurate, not uncommonly leads to erroneous judgments as well as inappropriate, costly, and useless testing.

Step 1

The initial step in the workup of the amenorrheic patient after excluding pregnancy begins with a measurement of thyroid-stimulating hormone (TSH), a prolactin level, and a progestational challenge. The initial step in the patient presenting with galactorrhea, regardless of menstrual history, also includes TSH and prolactin measurements but adds a coned-down, lateral x-ray view of the sella turcica. The x-ray can be safely omitted in those patients who have galactorrhea, but also have regular, ovulatory menstrual cycles.

Only a few patients presenting with amenorrhea and/or galactorrhea will have hypothyroidism that is not clinically apparent. Although it seems rather extravagant to measure TSH in such a large number of patients for such a small return, because treatment for hypothyroidism is so simple and is rewarded by such a prompt return of ovulatory cycles, and, if galactorrhea is present, by a disappearance of the breast secretions (a slower process that can take several months), TSH measurement is warranted.

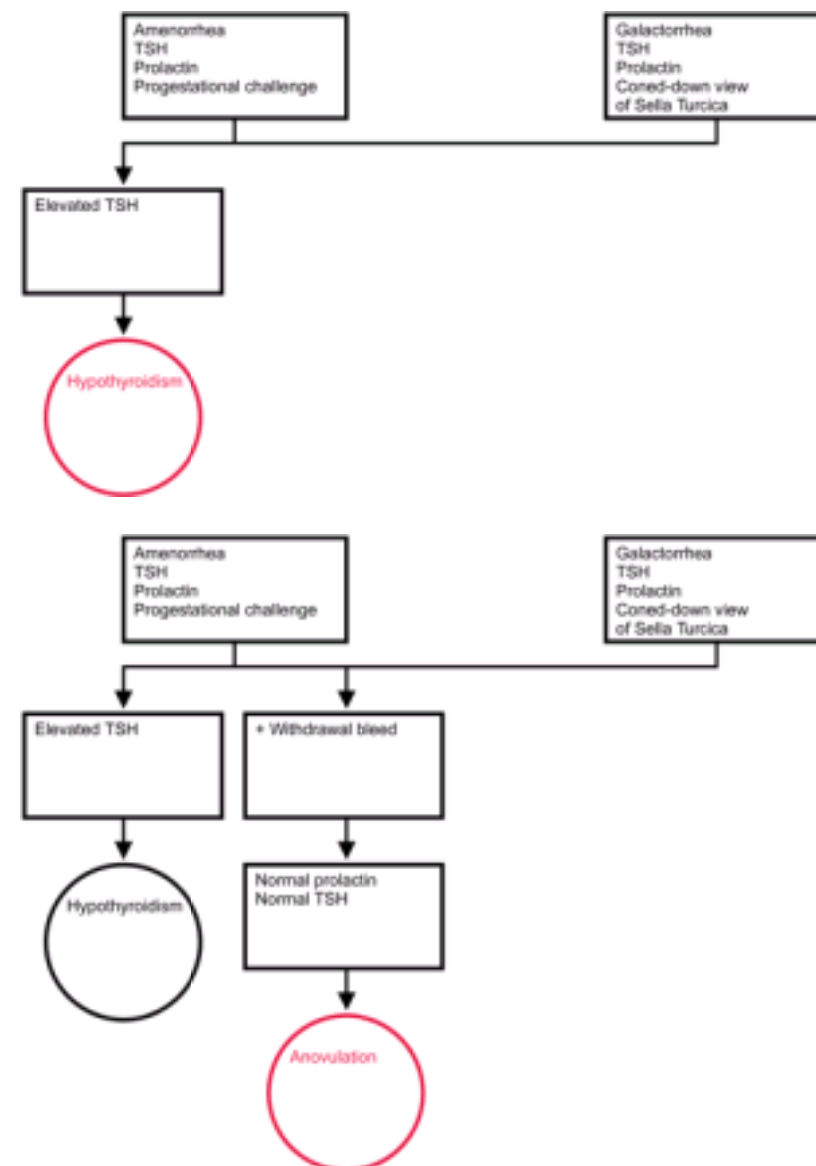

The duration of the hypothyroidism is important with regard to the mechanism of the galactorrhea; the longer the duration the higher the incidence of galactorrhea and the higher the prolactin levels.³ This is thought to be associated with declining hypothalamic content of dopamine with on-going hypothyroidism. This would lead to an unopposed thyrotropin-releasing hormone (TRH) stimulatory effect on the pituitary cells that secrete prolactin. In our experience, prolactin levels associated with primary hypothyroidism have always been less than 100 ng/mL.

Constant stimulation by hypothalamic-releasing hormones can result in hypertrophy or hyperplasia of the pituitary. The imaging picture of a tumor (distortion, expansion, or erosion of the sella turcica) can be seen, therefore, with primary hypothyroidism and in patients with elevated GnRH and gonadotropin secretion due to

premature ovarian failure.^{4,5} Appropriate treatment is followed by rapid normalization of the initial image. Patients with primary hypothyroidism and hyperprolactinemia can present with either primary or secondary amenorrhea.⁶

The purpose of the progestational challenge is to assess the level of endogenous estrogen and the competence of the outflow tract. A course of a progestational agent totally devoid of estrogenic activity is administered. There are 3 choices: parenteral progesterone in oil (200 mg), the oral administration of micronized progesterone (300 mg), or orally active medroxyprogesterone acetate, 10 mg daily for 5 days. The use of an orally active agent avoids an unpleasant intramuscular injection (although this might be necessary when compliance is a concern). The dose of micronized progesterone is relatively high and should be administered at bedtime to avoid side effects. Other hormonal preparations, such as oral contraceptives, are not appropriate because they do not exert a purely progestational effect.

Within 2–7 days after the conclusion of progestational medication, the patient will either bleed or not bleed. If the patient bleeds, a diagnosis of anovulation has been reliably and securely established. The presence of a functional outflow tract and a uterus lined by reactive endometrium sufficiently prepared by endogenous estrogen is confirmed. With this demonstration of the presence of estrogen, minimal function of the ovary, pituitary, and CNS is established. In the absence of galactorrhea, with a normal prolactin level, and a normal TSH, further evaluation is unnecessary.

How much bleeding constitutes a positive withdrawal response? The appearance of only a few blood spots following progestational medication implies marginal levels of endogenous estrogen. Such patients should be followed closely and periodically reevaluated, because the marginally positive response may progress to a clearly negative response, placing the patient in a new diagnostic category. Bleeding in any amount beyond a few spots is considered a positive withdrawal response.

There are two rare situations associated with a negative withdrawal response, despite the presence of adequate levels of endogenous estrogen. In both situations, the endometrium is decidualized, and, therefore, it will not be shed following the withdrawal of exogenous progestin. The first condition finds the endometrium decidualized in response to high androgen levels, e.g., due to the anovulatory state (with polycystic ovaries). In the second unusual clinical situation, the endometrium is decidualized by high progesterone levels associated with a specific adrenal enzyme deficiency.

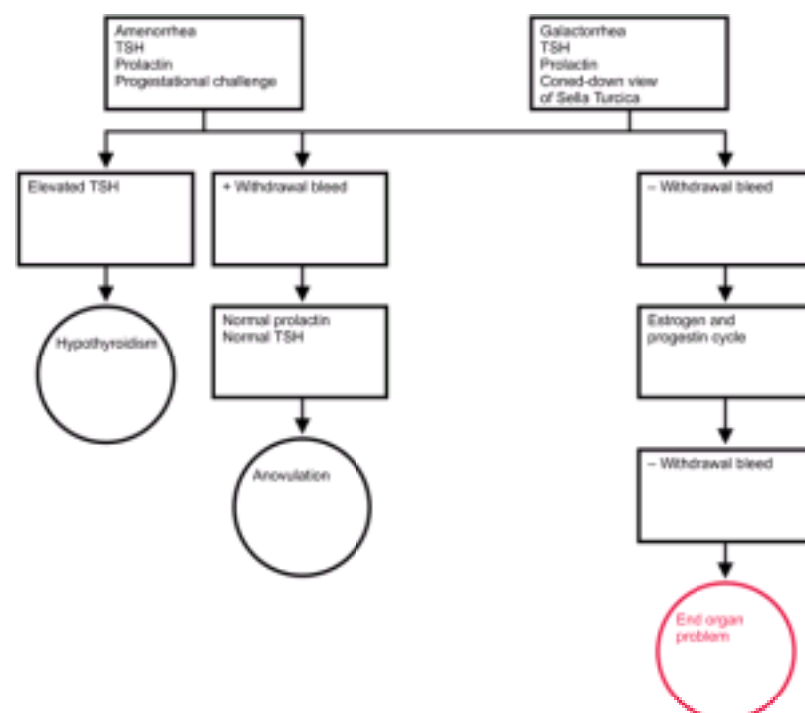

All anovulatory patients require therapeutic management, and with this minimal evaluation, therapy can be planned immediately. Because of the short latent period in the progression from normal endometrial tissue to atypia to cancer, clinicians are sensitive to the issue of endometrial cancer. But all too often, the clinician believes that this is a problem limited to older age. The critical feature is the duration of exposure to constant, unopposed estrogen. Therefore, even young women, anovulatory for relatively long periods of time, can develop endometrial cancer. If there is any concern, evaluation of the endometrium (with aspiration curettage) is in order. On the other hand, the latent phase for breast cancer is long, perhaps as long as 20 years. Women who are anovulatory when they are young may have an increased risk of breast cancer when they are postmenopausal.⁷ This could reflect exposure to unopposed estrogen, or it could be the consequence of infertility and the absence of the protection against breast cancer that pregnancy early in the reproductive years confers. However, some studies have not observed a link between anovulation and the risk of breast cancer (discussed with full references in [Chapter 16](#)).

Minimal therapy of anovulatory women requires the monthly administration of a progestational agent. An easily remembered program is to prescribe 10 mg medroxyprogesterone acetate daily for the first 10 days of each month. Experience with the endometrium in estrogen therapy programs has established the importance of a time period of at least 10 days to provide adequate protection against the growth-promoting effects of constant estrogen. When reliable contraception is essential, the use of low-dose oral contraceptive pills in the usual cyclic fashion is appropriate. Attempts to demonstrate a relationship between pill use and subsequent postpill amenorrhea have not been successful. Anovulation with amenorrhea or oligomenorrhea should not be viewed as a contraindication to the use of oral contraception.

If, at any time, an anovulatory patient fails to have withdrawal bleeding on a monthly progestin program, this is a sign (providing the patient is not pregnant) that she has moved to the negative withdrawal bleed category, and the remainder of the workup must be pursued. The progestational challenge will occasionally trigger an ovulation in an anovulatory patient. The tip-off will be a later withdrawal bleed, 14 days after the progestational challenge!

In the absence of galactorrhea and if the serum prolactin level is normal (less than 20 ng/mL in most laboratories), further evaluation for a pituitary tumor is unnecessary provided the patient has undergone a withdrawal bleed. Random single samples for prolactin are sufficient, because variations in the amplitude of the spikes of secretion and the sleep-related and food-related increases appear to be attenuated in both functional and tumor hyperprolactinemic states. If the prolactin is elevated, imaging evaluation of the sella turcica is essential (as discussed below). At this point in the workup, the following statement is a useful clinical rule of thumb: **A positive withdrawal bleeding response to progestational medication, the absence of galactorrhea, and a normal prolactin level together effectively rule out the presence of a significant pituitary tumor.**

Ectopic production of prolactin is rarely encountered. Increased prolactin secretion should draw attention to the pituitary gland. However, to be complete, we should mention case reports with ectopic secretion associated with pituitary tissue in the pharynx, bronchogenic carcinoma, renal cell carcinoma, a gonadoblastoma, and women with amenorrhea and hyperprolactinemia due to a prolactinoma in the wall of an ovarian dermoid cyst or teratoma.^{8,9,10,11 and 12}

Step 2

If the course of progestational medication does not produce withdrawal flow, either the target organ outflow tract is inoperative or preliminary estrogen proliferation of the endometrium has not occurred. Step 2 is designed to clarify this situation. Orally active estrogen is administered in quantity and duration certain to stimulate endometrial proliferation and withdrawal bleeding provided that a completely reactive uterus and patent outflow tract exist. An appropriate dose is 1.25 mg conjugated estrogens or 2 mg estradiol daily for 21 days. The terminal addition of an orally active progestational agent (medroxyprogesterone acetate 10 mg daily for the last 5 days) is necessary to achieve withdrawal. In this way the capacity of Compartment I is challenged by exogenous estrogen. In the absence of withdrawal flow, a validating second course of estrogen is a wise precaution.

As a result of the pharmacologic test of Step 2, the patient with amenorrhea will either bleed or not bleed. If there is no withdrawal flow, the diagnosis of a defect in the Compartment I systems (endometrium, outflow tract) can be made with confidence. If withdrawal bleeding does occur, one can assume that Compartment I systems have normal functional abilities if properly stimulated by estrogen.

From a practical point of view, in a patient with normal external and internal genitalia by pelvic examination, and in the absence of a history of infection or trauma (such as curettage), an abnormality of the outflow tract is unlikely. Outflow tract problems include either destruction of the endometrium, generally the result of an overzealous curettage or the result of an infection, or primary amenorrhea resulting from the discontinuity or disruption of the müllerian tube. **Abnormalities in the systems of Compartment I are not commonly encountered, and in the absence of a reason to suspect a problem, Step 2 can be omitted.**

Step 3

With the elucidation of the amenorrheic patient's inability to provide adequate stimulatory amounts of estrogen, the physiologic mechanisms responsible for the elaboration of this steroid must be tested. In order to produce estrogen, ovaries containing a normal follicular apparatus and sufficient pituitary gonadotropins to stimulate that apparatus are required. Step 3 is designed to determine which of these two crucial components (gonadotropins or follicular activity) is functioning improperly.

This step involves an assay of the level of gonadotropins in the patient. Because Step 2 involved administration of exogenous estrogen, endogenous gonadotropin levels may be artificially and temporarily altered from their true baseline concentrations. Hence, a delay of 2 weeks following Step 2 must ensue before doing Step 3, the gonadotropin assay. One should keep in mind that the midcycle surge of LH is approximately 3 times the baseline level. Therefore, if the patient does not bleed 2 weeks after the blood sample was obtained, a high level can be safely interpreted as abnormal.

Step 3 is designed to determine whether the lack of estrogen is due to a fault in the follicle (Compartment II) or in the CNS-pituitary axis (Compartments III and IV). The result of the gonadotropin assay in the amenorrheic woman who does not bleed following a progestational agent will be abnormally high, abnormally low, or in the normal range.

Clinical State	Serum FSH	Serum LH
Normal adult female	5–20 IU/L, with the ovulatory midcycle peak about 2 times the base level	5–20 IU/L, with the ovulatory midcycle peak about 3 times the base level
Hypogonadotropic state: Prepubertal, hypothalamic, or pituitary dysfunction	Less than 5 IU/L	Less than 5 IU/L
Hypergonadotropic state: Postmenopausal, castrate, or ovarian failure	Greater than 20 IU/L	Greater than 40 IU/L

High Gonadotropins

The clinical implications of elevated gonadotropins are very significant, and, therefore, repeated measurements, several months apart, are worthwhile to document a more than transient state. The association between castrate or postmenopausal levels of gonadotropins and absent ovarian follicles due to accelerated atresia is very reliable, but not totally reliable. There are rare situations in which high gonadotropins can be accompanied by ovaries that contain follicles.

1. On rare occasions, tumors can produce gonadotropins. This situation is usually associated with lung cancer and is so infrequent that, with a normal history and physical examination, routine chest x-ray is not warranted in amenorrheic patients.
2. There have been a handful of reports of a single gonadotropin deficiency. The importance of measuring both FSH and LH can be appreciated because a high level of one and a baseline or undetectable level of the other would reveal this rare condition. The rare cases of a true single gonadotropin deficiency are probably due to homozygous mutations in the gonadotropin genes. A case of hypogonadism due to an LH b-subunit mutation and a woman with primary amenorrhea due to a mutation in the FSH b-subunit have been reported.^{13, 14} The mutated b-subunit genes produce alterations in the b-subunits that yield no immunoreactivity or bioactivity. Hence, hypogonadism will be associated with one high and one low gonadotropin level. Heterozygote carriers have a problem of relative infertility. Treatment with exogenous gonadotropins will achieve pregnancy in these rare patients. When a high FSH and a normal or low LH are encountered, an elevated level of a-subunit and the presence of a pituitary mass indicate a gonadotroph adenoma.
3. Elevated gonadotropins can be due to a gonadotropin-secreting pituitary adenoma. However, gonadotropin-secreting adenomas are **NOT** associated with hypogonadism (amenorrhea), and, therefore, are hard to diagnose.^{15, 16 and 17} There is no specific symptom or symptom complex associated with hypersecretion of gonadotropins. Thus, these tumors are usually diagnosed because of tumor growth that results in headaches and visual disturbances. Previously it was believed that these tumors were very rare and more common in men. This belief was due to the difficulty in recognizing these adenomas, especially in women. However, tumors of the pituitary are relatively common, and most are not nonsecreting, but, in fact, they arise from gonadotroph cells, and they are active.¹⁸ In addition to secreting FSH and, rarely, LH, these tumors secrete high levels of the a-subunit of the glycopeptide hormones, and sometimes only the a-subunit. Patients suspected of having a pituitary tumor, the nature of which is uncertain or puzzling, should have their gonadotropin and a-subunit levels measured.

4. During the perimenopausal period, it is normal for FSH levels to begin to rise even before bleeding has ceased.¹⁹ This is true whether the perimenopausal period is premature at age 25–35 or at the usual time. This increase in FSH is associated with a decrease in inhibin. During the perimenopausal period, the remaining follicles may be viewed as the least sensitive of all follicles because they have remained in place and failed to respond to gonadotropins for many years. The rise in FSH prior to menopause is due to the declining inhibin production by either the less competent ovarian follicles or because the cohort of follicles is reduced in number. Attention must be paid to this situation because a period of elevated levels of FSH can be followed by a pregnancy. An elevated FSH level is not an absolute indicator of infertility. It is not unusual to encounter a pregnancy in a woman after a diagnosis of premature ovarian failure.²⁰
5. In the resistant or insensitive ovary syndrome, the patient with amenorrhea and normal growth and development has elevated gonadotropins, despite the presence of ovarian follicles. In this condition, the ovarian follicles are unresponsive to stimulation compared with premature depletion of follicles in the most common type of premature ovarian failure. This syndrome may be due to absent or defective gonadotropin receptors on the follicles or a postreceptor-signaling defect.²¹ Molecular biology studies of patients with premature ovarian failure are discovering rare cases of point mutations; e.g., mutations in the gonadotropin receptor genes that prevent ovarian response.^{22, 23} We anticipate that more and more such cases will be identified. In addition, translocations between regions on X and Y chromosomes that share sequence homology have been reported in patients with secondary amenorrhea and ovarian failure.²⁴ It is also possible that this is a subtle form of autoimmune ovarian failure. In these cases, laparotomy is the only definitive way to evaluate the ovaries, because follicles are contained deep within the ovary, yielding only to a full thickness biopsy.²⁵ Because this condition is very rare, and the chance of achieving pregnancy is probably impossible, even with large doses of exogenous gonadotropins, laparotomy is **NOT** recommended for every patient with amenorrhea and high gonadotropins.
6. Secondary amenorrhea caused by premature ovarian failure can be due to autoimmune disease.²⁶ The ovaries contain normal-appearing primordial follicles, but developing follicles are surrounded by nests of lymphocytes and plasma cells with lymphocytic infiltration of the thecal layer of cells. The exact mechanism of resistance to gonadotropins is not known. Antibodies blocking FSH and LH receptors cannot be demonstrated in immunoglobulin G from women with premature ovarian failure.²⁷ Most commonly, evidence of abnormal thyroid function is detected, and, therefore, complete thyroid testing (with antibodies) is necessary in all patients with premature ovarian failure. The extensive polyglandular syndrome (autoimmune polyglandular syndrome) that includes hypoparathyroidism, adrenal insufficiency, thyroiditis, and moniliasis, is rare; at least one gene mutation has been identified in this autosomal recessive disorder.²⁸ In patients with adrenal insufficiency and ovarian failure, antibodies have been detected directed against P450_{scc}, the cholesterol side-chain cleavage enzyme essential for steroidogenesis.²⁹ It is believed that antibodies can be directed against any of the vital enzymes involved in steroidogenesis. Other rare conditions associated with premature ovarian failure include myasthenia gravis, idiopathic thrombocytopenic purpura, rheumatoid arthritis, vitiligo, and autoimmune hemolytic anemia. Classically, premature ovarian failure precedes adrenal failure, and, thus, a case can be made for continuing adrenal surveillance.³⁰ Frequently, various endocrine disorders will be present among family members. Very rare pregnancies have been reported in women with ovarian failure and autoimmune disease. Ovulation has been restored temporarily with corticosteroid treatment, and at least one patient had a temporary spontaneous return of menstrual ovarian activity.³¹ Because pregnancy is extremely unlikely, consideration should be given to donor oocytes. However, an impressive pregnancy rate has been reported by one group combining suppression with a GnRH agonist, corticosteroid treatment, and induction of ovulation with high doses of exogenous gonadotropins.³²
7. Galactosemia is a rare inherited autosomal recessive disorder of galactose metabolism due to a deficiency of galactose-1-phosphate uridyl transferase.³³ The problem in patients with galactosemia is primarily gonadal; fewer oogonia may be the result of a direct toxic effect of galactose metabolites on germ cell migration to the genital ridge.³⁴ Premature ovarian failure is common and usually irreversible.
8. The final rare clinical situation associated with high gonadotropins despite the presence of ovarian follicles is that associated with specific enzymatic deficiencies. The 17-hydroxylase deficiency (P450_{c17}) is present in both ovaries and the adrenal gland. A patient with a deficiency of 17-hydroxylase is readily detectable because she would present with absent secondary sexual development (sex steroids cannot be produced due to the enzyme block in the adrenal glands and the ovaries), and hypertension, hypokalemia, and high blood levels of progesterone. A deficiency in the aromatase enzymes is another rare cause of hypergonadotropic amenorrhea and a failure of pubertal development.

The Need for Chromosome Evaluation

All patients under the age of 30 who have been assigned the diagnosis of ovarian failure on the basis of elevated gonadotropins must have a karyotype determination. The presence of mosaicism with a Y chromosome requires excision of the gonadal areas because the presence of any testicular component within the gonad carries with it a significant chance of malignant tumor formation. These are highly malignant secondary tumors from germ cells: gonadoblastomas, dysgerminomas, yolk sac tumors, and choriocarcinoma. Approximately 30% of patients with a Y chromosome will not develop signs of virilization. Therefore, even the normal-appearing adult woman with elevated gonadotropin levels must be karyotyped. Even if the karyotype is normal, as an added precaution all patients with ovarian failure should have an annual pelvic examination. Such preventive care is also indicated because these patients will be receiving hormone therapy. Over the age of 30, amenorrhea with high gonadotropins is best labeled premature menopause. Genetic evaluation is unnecessary because it is essentially unheard of to have a gonadal tumor appear in these patients after the age of 30. Most of these tumors appear before age 20, but a significant number are detected from age 20 to 30.^{35, 36}

The clinician and patient should give consideration to whether it is worth obtaining an expensive karyotype to seek identification of chromosomal abnormalities that have clinical implications for other family members. Deletions of the X chromosome can be responsible for premature ovarian failure.³⁷ Accurate diagnosis of these deletions is not essential for decision making regarding the patient; however, the presence of such abnormalities within a family is associated with infertility due to premature ovarian failure. Having this information can influence the family planning decisions of family members. We recommend that women with premature ovarian failure who are less than 63 inches tall (160 cm) be karyotyped because of the close conjunction of the genes responsible for stature and normal ovarian function.

Because an individual with a mosaic karyotype (e.g., XX/XO) can experience normal pubertal development, menses, and even pregnancy before the onset of a premature menopause, it is appropriate to consider obtaining a karyotype, regardless of menstrual pattern, in an adolescent or young woman less than 60 inches tall.

Spontaneous puberty has been reported in 10–20% and spontaneous menstruation in 2–5% of girls with Turner syndrome.³⁸

Premature Ovarian Failure: A Clinical Dilemma

Patients with repeatedly elevated gonadotropin levels can be reliably diagnosed as having ovarian failure and can be considered sterile. In the past this was a diagnosis made with great confidence, and careful explanation was given to the patient indicating that future pregnancy was impossible. However, as many as 10–20% of patients presenting with secondary amenorrhea and elevated gonadotropins (with normal karyotypes), several months later, have demonstrated resumption of normal function.^{20, 39, 40} Often, this has been associated with the use of estrogen therapy, suggesting that the estrogen may activate receptor formation on follicles, and the high gonadotropins may, thus, stimulate follicular growth and development. On the other hand, spontaneous recovery of ovarian function may be the reason for apparent success with treatment. In some patients, return of normal ovarian function with pregnancy has occurred in the absence of any

treatment. Indeed, careful study of estrogen treatment in women with hypergonadotropic amenorrhea could detect no impact on ovarian folliculogenesis.⁴¹ Although resumption of normal function is extremely rare, it is now necessary to tell patients who fit into this category that there is a very remote possibility of future pregnancy

(but it should be emphasized this is very unlikely). In addition the feasibility of pregnancy with the transfer of a fertilized donated ovum should be presented as a possible option ([Chapter 31](#)).

A number of cases of ovarian failure have been reported with autoimmune disorders. Indirect immunofluorescence has been used for the detection of ovarian antibodies, but the results have been variable and of little clinical meaning. Comparing several methodologies currently available, only a small number of women with premature ovarian failure test positively, results are inconsistent, and a need or indication for ovarian antibody testing cannot be established. ⁴² The search for antibodies to gonadotropin receptors has been equally unrewarding. ²⁷

A reasonable empiric approach is to perform a few selected blood tests for autoimmune disease. These tests should also be obtained periodically (perhaps every few years) as part of the long-term surveillance against associated autoimmune disorders.

- Calcium
- Phosphorus
- Fasting glucose
- A.M. cortisol
- Free T₄
- TSH
- Thyroid antibodies, if thyroid function is abnormal
- Complete blood count and sedimentation rate
- Total protein, albumin:globulin ratio
- Rheumatoid factor
- Antinuclear antibody

Testing for adrenocorticotrophic hormone (ACTH) reserve (with corticotropin stimulation or metyrapone) is not necessary if clinical appearance and other laboratory tests are normal. Periodic surveillance for adrenal failure is in order because ovarian failure usually precedes adrenal failure. It is not worthwhile to seek the presence of antiovarian antibodies in serum or antibodies to the gonadotropins; there is no correlation between the clinical state and the results from such testing. ³⁰

Other than hypothyroidism, it is uncommon to encounter other disorders associated with premature ovarian failure. In a series of 119 patients with premature ovarian failure and normal karyotypes, recruited by the National Institute of Child Health and Human Development in Bethesda, 10 new cases of hypothyroidism and 3 new cases of diabetes mellitus were discovered; there were no new cases of adrenal insufficiency, hypoparathyroidism, or pernicious anemia. ⁴³

It has been suggested that blood gonadotropins and estradiol should be measured weekly on 4 occasions. ^{2c} If FSH is not higher than LH (an FSH:LH ratio less than 1.0), and if estradiol is greater than 50 pg/mL, induction of ovulation can be considered. Prior to treatment with exogenous gonadotropins, no advantage has been demonstrated to first bringing the elevated gonadotropins down to normal range with administration of a GnRH agonist. ⁴⁴ The experience with this approach has been unrewarding, and we do not recommend it.

The clinician needs to compare the choice of a full-thickness ovarian biopsy with empirical treatment. In our view, empirical treatment appears to outweigh the cost and risk of laparotomy, since only a very rare woman with hypergonadotropic amenorrhea can be expected to conceive. In other words, even if there is some gonadotropic and estradiol evidence of follicular activity, the response to exogenous gonadotropin stimulation has been very disappointing. We believe that ovarian biopsy is not indicated or necessary.

Transvaginal ultrasonography can identify ovarian follicular activity in many of these patients. However, the meaning of this finding is uncertain. Are patients with ovarian follicles present on ultrasonography more likely to respond to treatment and achieve pregnancy? In time, clinical studies should provide us with an answer.

This clinical problem requires scientific study. Ovarian failure may be the consequence of more than one abnormal condition. One recognized example is ovarian failure due to an accelerated rate of follicular atresia leading to the premature depletion of the follicular supply. Other cases may be due to a failure in the gonadotropin receptor mechanism. Unsuccessful binding can be due to defective receptors, blockage of receptors (e.g., by autoantibodies), or to genetic mutations that direct the production of gonadotropins of altered structure which are incapable of binding. Molecular studies of these patients should bring important clinical clarification in the coming years.

Normal Gonadotropins

Why is it that hypoestrogenic (negative progesterational withdrawal) patients will frequently have normal circulating levels of FSH and LH as measured by immunoassay? If normal gonadotropins were truly present in the circulation, follicular growth should be maintained and estrogen levels would be adequate to provide a positive withdrawal bleed. The answer to this paradox lies in the heterogeneity of the glycoprotein hormones (as discussed in [Chapter 2](#)).

The molecules of gonadotropins produced by these amenorrheic patients have increased amounts of sialic acid in the carbohydrate portion. Therefore, the molecules are qualitatively altered and biologically inactive. The antibodies in the immunoassay, however, are able to recognize a sufficient portion of the molecule to return a normal answer. Another very rare possibility is an inherited disorder of gonadotropin synthesis leading to the production of immunologically active but biologically inactive hormones. ⁴⁵

The significant clinical point is the following: FSH and LH levels in the normal range in a patient with a negative progesterational withdrawal test are consistent with pituitary-CNS failure. Indeed, this is the most commonly encountered clinical situation. Extremely low or nondetectable gonadotropins are seldom found, usually only with large pituitary tumors or in patients with anorexia nervosa. Further evaluation, therefore, is in order and follows the recommendations for low gonadotropins.

Low Gonadotropins

If the gonadotropin assay is abnormally low, or in the normal range, one final localization is required to distinguish between a pituitary (Compartment III) or CNS-hypothalamic (Compartment IV) cause for the amenorrhea. This is achieved by imaging evaluation of the sella turcica for signs of abnormal change.

Imaging of the Sella Turcica

The diagnostic modality of choice is either thin-section coronal computed tomography (CT scan) with intravenous contrast enhancement or magnetic resonance imaging (MRI) with gadolinium enhancement. CT scanning (capable of high-resolution 1.5 mm cuts) is able to evaluate the contents of the sella turcica as well as the suprasellar area; however, total accuracy is not achieved. ⁴⁶ Magnetic resonance imaging is even more sensitive than the CT scan, but it is also more expensive, and it requires a lengthy period of time to obtain the images. MRI provides highly accurate assessments without biologic hazard, and it is better for evaluation of extrasellar extensions and the empty sella turcica. ⁴⁷ Most neuroradiologists and neurosurgeons prefer MRI,

as do we. The intention of this workup is to be conscious of cost and to isolate those few patients who require sophisticated but expensive imaging.

There has been growing conservatism in the management of small pituitary tumors because of an appreciation that the majority of these tumors never change.^{48, 49} and⁵⁰ We have adopted the conservative approach of close surveillance, recommending dopamine agonist treatment for those prolactin-secreting tumors that display rapid growth, or those tumors that are already large, and reserving surgery only for those tumors that are unresponsive to medical therapy. This means that small tumors (microadenomas are less than 10 mm in diameter) need not be treated at all. Hence, the initial x-ray evaluation for amenorrheic patients with or without galactorrhea is the coned-down lateral view of the sella turcica. This will detect the presence of a large tumor, although an incredibly rare suprasellar extension might escape this method. The coned-down lateral view of the sella is also a good screen for other lesions, such as a craniopharyngioma. Combining this screening technique with the prolactin assay, we are able to select those few patients who require more sensitive sellar imaging. If the prolactin level is greater than 100 ng/mL, or if the coned-down view of the sella turcica is abnormal, we recommend CT scan evaluation or MRI. **A double floor of the sella is often seen on the coned-down view and, in the absence of enlargement and/or demineralization, is interpreted as a normal variation rather than asymmetrical depression of the sellar floor by a tumor.**

The presence of visual problems and/or headaches should also encourage CT scan or MRI evaluation. Headaches are definitely correlated with the presence of a pituitary adenoma.⁵¹ Although they are usually bifrontal, retro-orbital, or bitemporal, no locations or features are specific for pituitary tumors.

The prolactin level of 100 ng/mL for determining a more aggressive approach has been empirically chosen. Both in our own experience, and that of others, large tumors are most frequently associated with prolactin levels greater than 100 ng/mL. **Large masses associated with prolactin levels less than 100 ng/mL are more likely to be tumors other than prolactin-secreting adenomas, causing stalk compression and interruption of the normal dopamine regulation of prolactin secretion. These tumors will be associated with abnormal changes present in the coned-down view of the sella turcica.**

If imaging rules out an empty sella syndrome, or a suprasellar problem, treatment is dictated by the patient's desires, the size of the tumor, and the rapidity of growth of the tumor.

The above approach to the problem of pituitary tumors implies that patients with prolactin levels less than 100 ng/mL and with normal coned-down views of the sella turcica can be offered a choice between treatment and surveillance. An annual prolactin level and a periodic coned-down view (at first annually, and then at increasing intervals) are indicated for continued observation to detect an emerging and slow-growing tumor. Dopamine agonist therapy is recommended for patients wishing to achieve pregnancy and for those patients who have galactorrhea to the point of discomfort. Thus far, long-term therapy with a dopamine agonist has not been proven to be successful in producing a complete reversal of the problem (with either permanent suppression of elevated prolactin levels or elimination of small tumors). Thus, a very strong argument can be made for a "need not to know" the presence of a pituitary microadenoma. If treatment and management are not changed, it is not necessary to document the presence of a microadenoma.

Reasons Why the Diagnosis of Microadenoma Is Not Necessary

1. **Microadenomas are very common.**
2. **Microadenomas very rarely grow during pregnancy.**
3. **Microadenomas very rarely progress to a macroadenoma (10 mm or more in diameter).**
4. **There is a significant recurrence rate after surgery.**
5. **The natural course is unaffected by dopamine agonist treatment.**
6. **There is no contraindication to hormone therapy or oral contraception.**
7. **It is better to avoid the problem of the pituitary incidentaloma.**

Contemporary reviews point out the shortcomings of the coned-down view of the sella turcica, citing the limitation of excluding only macroadenomas.⁵² Indeed, reviews of our text have faulted this chapter for being less than the state-of-the-art, emphasizing that where we use the coned-down view, MRI should be uniformly obtained. We would argue that the state-of-the-art approach is to use the MRI when necessary, to avoid the compulsion to document the presence of a microadenoma for the reasons stated above, to be cost-effective. This takes strength of conviction when your radiologist reports that a coned-down view of the sella turcica is not sufficient.

The Pituitary Incidentaloma

The percentage of pituitary glands found to contain unsuspected adenomas, all microadenomas, ranged from 9% to 27% in autopsy series.^{53, 54, 55, 56} and⁵⁷ Therefore, many individuals, probably 10%,⁵⁸ have silent pituitary masses that are endocrinologically inactive and have no adverse effects on well-being. These lesions are being found incidentally because of the increased use of CT scanning and MRI. Silent microadenomas (less than 10 mm diameter) do not grow, and even macroadenomas (10 mm or more diameter) grow slowly and only rarely.^{49, 50} This benign course argues against immediate intervention in patients who have no evidence of hormonal disturbances; long-term surveillance is appropriate.⁵⁹ Imaging reassessment of a microadenoma should be obtained at 1, 2, and 5 years, and if there is no change, no further studies are necessary. Imaging reassessment of a macroadenoma should be obtained at 0.5, 1, 2, and 5 years. Growth, of course, requires treatment. Although it is reasonable to screen hormonal function in the presence of a macroadenoma, the value of hormonal screening in a normal individual with a microadenoma is debatable. Minimal hormonal screening includes prolactin, TSH, IGF-I, and a 24-hour urinary cortisol or the overnight dexamethasone suppression test (Chapter 13).

Evaluation of the Abnormal Sella Turcica and/or High Prolactin

The high incidence of pituitary tumors in patients with amenorrhea has prompted a search for a reliable method of diagnosing the condition. Expectations for the utilization of endocrine testing to discriminate between disorders of the hypothalamus and the anterior pituitary have not been realized. These endocrine maneuvers include GnRH stimulation, TRH stimulation, and other steps to alter prolactin, growth hormone, and ACTH secretion. TRH stimulation of the prolactin response is the most consistently abnormal response (a blunter response of prolactin), but some patients with tumors respond normally. Variability in response to all maneuvers is the rule.

Frankly, the endocrine maneuvers yield no more useful information than the two major screening procedures, the blood prolactin and the coned-down view of the sella

turcica. Visual field examination is not useful in screening for pituitary tumors because abnormalities are seen only with large tumors that are evident by prolactin, x-ray evaluation, and/or visual symptoms and headaches.

If the coned-down view is abnormal and/or the prolactin level is over 100 ng/mL, further evaluation and treatment require consultation with expert endocrine resources. These patients are rare, and accumulated experience that can provide the necessary clinical judgment can be found only with the referral resource. On the other hand, our workup easily deals with the vast majority of patients, and the few who require a multidisciplinary team approach are readily identified.

Hypogonadotropic Hypogonadism

Patients with amenorrhea and without galactorrhea who have reached this point in the workup and have normal imaging studies are classified as **hypothalamic amenorrhea**. The mechanism of the amenorrhea is suppression of pulsatile GnRH secretion below its critical range. This is a diagnosis by exclusion because we can identify probable causes (e.g., anorexia and weight loss) but we cannot test, manipulate, or measure the hypothalamus to prove our diagnosis.

Specific Disorders Within Compartments

With only modest effort, expense, and time, the problem of amenorrhea has been dissected into compartments of dysfunction which positively correlate with specific organ systems. At this point, with the specific anatomic locus of the defect defined, the clinician can now undertake steps to elucidate the specific disorder leading to amenorrhea. Congenital abnormalities are limited to amenorrhea that presents in the pubertal period of life. In a collection of 262 patients with secondary amenorrhea of adult onset, the following diagnostic frequencies were most often observed:⁶⁰

Compartment I	7.0%
Asherman's syndrome	
Compartment II	0.5%
Abnormal chromosomes	10.0%
Normal chromosomes	
Compartment III	7.5%
Prolactin tumors	
Compartment IV	28.0%
Anovulation	10.0%
Weight loss/anorexia	10.0%
Hypothalamic suppression	1.0%
Hypothyroidism	

Compartment I: Disorders of the Outflow Tract or Uterus

Asherman's Syndrome

Secondary amenorrhea follows destruction of the endometrium (Asherman's syndrome).⁶¹ This condition generally is the result of an overzealous postpartum curettage resulting in intrauterine scarification. A typical pattern of multiple synechiae is seen on a hysteroqram. Diagnosis by hysteroscopy is more accurate and will detect minimal adhesions that are not apparent on a hysteroqram. In the presence of normal ovarian function, the basal body temperature will be biphasic. The adhesions may partially or completely obliterate the endometrial cavity, the internal cervical os, the cervical canal, or combinations of these areas. Surprisingly, despite stenosis or atresia of the internal os, hematometra does not inevitably occur. The endometrium, perhaps in response to a buildup of pressure, becomes refractory, and simple cervical dilatation cures the problem. Asherman's syndrome also can occur following uterine surgery, including cesarean section, myomectomy, or metroplasty. Very severe adhesions have been noted following postpartum curettage and postpartum hypogonadism; e.g., in Sheehan's syndrome.

Patients with Asherman's syndrome can present with other problems besides amenorrhea, including miscarriages, dysmenorrhea, or hypomenorrhea. They can even have normal menses. Infertility can be present with mild adhesions, an association not readily explainable. Patients with repeated miscarriages, infertility, or pregnancy wastage should have investigation of the endometrial cavity by hysteroqram or hysteroscopy.

Impairment of the endometrium resulting in amenorrhea can be caused by tuberculosis, a condition that is rare in the United States. Diagnosis is made by culture of the menstrual discharge or tissue obtained by endometrial biopsy. Uterine schistosomiasis is another rare cause of end organ failure, and eggs of the parasite may be found in urine, feces, rectal scrapings, menstrual discharge, or endometrium. We have seen the syndrome following intrauterine device (IUD)-related infections and severe, generalized pelvic infections.

Asherman's syndrome in the past was treated with a dilatation and curettage to break up the synechiae and, if necessary, an on-the-table hysteroqram to ensure a free uterine cavity. Hysteroscopy with direct lysis of adhesions by cutting, cautery, or laser yields better results than the "blind" dilatation and curettage. Following operation, a method should be utilized to prevent the sides of the uterine cavity from adhering. Previously an IUD was used for this purpose; however, a pediatric Foley catheter appears to be a better option. The bag is filled with 3 mL fluid, and the catheter is removed after 7 days. A broad-spectrum antibiotic is started preoperatively and maintained for 10 days. An inhibitor of prostaglandin synthesis can be used if uterine cramping is a problem. The patient is treated for 2 months with high stimulatory doses of estrogen (e.g., conjugated estrogens 2.5 mg daily 3 of 4 weeks with medroxyprogesterone acetate 10 mg daily added during the 3rd week). When the initial attempt fails to re-establish menstrual flow, repeated attempts are worthwhile. Persistent treatment with repeated procedures may be necessary to regain reproductive potential. Approximately 70–80% of patients with this condition have achieved a successful pregnancy. Pregnancy is frequently complicated, however, by premature labor, placenta accreta, placenta previa, and/or postpartum hemorrhage.

Müllerian Anomalies

In primary amenorrheas, discontinuity by segmental disruptions of the müllerian tube should be ruled out. Thus, imperforate hymen, obliteration of the vaginal orifice, and lapses in continuity of the vaginal canal must be ruled out by direct observation. The cervix or the entire uterus may be absent. Far less common, the uterus may be present, but the cavity absent, or, in the presence of a cavity, the endometrium may be congenitally lacking. With the exception of the latter abnormalities, the clinical problem of amenorrhea due to obstruction is compounded by the painful distension of hematocolpos, hematometra, or hematoperitoneum. In all instances, an effort must be made to incise and drain from below at the points of closure of the müllerian tube. Even in complicated circumstances reestablishment of müllerian duct continuity usually can be achieved surgically. The unfortunate consequences of operative extirpation of painful masses from above with damage to bladder, ureter, and rectum, as well as irretrievable loss of distended but otherwise healthy reproductive organs, are rare but well remembered.

Knowing what to expect prior to attempting surgical correction is a great advantage. Imaging (MRI) can be utilized to accurately delineate the anatomical abnormality.^{62, 63} A correct preoperative diagnosis will certainly facilitate the planning and execution of surgery.

Müllerian Agenesis

Lack of müllerian development (**Mayer-Rokitansky-Kuster-Hauser syndrome**) is the diagnosis for the individual with primary amenorrhea and no apparent vagina.⁶⁴ This is a relatively common cause (about 1 in 4000 female births) of primary amenorrhea, more frequent than congenital androgen insensitivity and second only to gonadal dysgenesis. These patients have an absence or hypoplasia of the internal vagina, and usually an absence of the uterus and fallopian tubes. However, rarely, the uterus may be normal, but lacking a conduit to the introitus, or there may only be rudimentary, bicornuate cords present. If a partial endometrial cavity is present, cyclic abdominal pain may be a complaint. Because of the similarity to some types of male pseudohermaphroditism, it is worthwhile to demonstrate the normal female karyotype. Because the ovaries are not müllerian structures, ovarian function is normal and can be documented with basal body temperatures or peripheral levels of progesterone. Growth and development are normal.

The exact cause of müllerian agenesis is unknown; however, likely causes are mutations of the gene for antimüllerian hormone or the gene for the antimüllerian

hormone receptor. The underlying mechanism would be unwanted exposure to antimüllerian hormone activity. Thus far, no activating mutations have been reported, in contrast to inactivating mutations that cause persistence of müllerian structures.⁶⁵ Although usually sporadic, occasional occurrence may be noted within a family. A mutation has been identified in galactose-1-phosphate uridyl transferase in daughters with müllerian agenesis and their mothers.⁶⁶ This is different from classic galactosemia; however, it is postulated that increased intrauterine exposure to galactose because of this error in galactose metabolism can be a biologic basis for müllerian agenesis. High-galactose feeding of pregnant mice delays vaginal opening in female offspring. In this group of patients with müllerian agenesis, oocyte depletion (and premature ovarian failure) may be more common.

Further evaluation should include radiologic studies. Approximately one-third of patients have urinary tract abnormalities, and 12% or more have skeletal anomalies, most involving the spine, although absent digits and syndactyly (webbing or fusion of fingers or toes) can occur. Renal tract abnormalities include ectopic kidney, renal agenesis, horseshoe kidney, and abnormal collecting ducts. When the presence of a uterine structure is suspected on examination, ultrasound can be utilized to depict the size and symmetry of the structure. When the anatomic picture on ultrasonography is not certain, MRI is indicated.^{67,68} Laparoscopic visualization of the pelvis is not necessary. MRI is more accurate than ultrasonography and less expensive and invasive than laparoscopy. Extirpation of the müllerian remnants is certainly not necessary unless they are causing a problem such as uterine fibroid growth, hematometra, endometriosis, or symptomatic herniation into the inguinal canal.

Because of the difficulties and complications experienced in surgical series, we favor, when possible, an alternative to the surgical construction of an artificial vagina. Instead, we encourage the use of progressive dilatation as initially described by Frank⁶⁹ and later by Wabrek et al.⁷⁰ Beginning first in a posterior direction, and then after 2 weeks changing upward to the usual line of the vaginal axis, pressure with commercially available vaginal dilators is performed for 20 min daily to the point of modest discomfort. Utilizing increasingly larger dilators, a functional vagina can be created in several months.⁷¹ Plastic syringe covers can be used instead of the expensive commercial glass dilators. An easier and very effective technique is to hold the dilator in place with a tight garment, maintaining pressure by sitting on a racing bicycle seat (mounted on a special stool or even on a bicycle).⁷²

In patients who are unwilling or unable to undergo the dilatation program, the Vecchiotti operation applies a traction device either transabdominally or by laparoscopy.⁷³ Postoperative traction creates a functional vagina in 7–9 days.

Operative treatment should be reserved for those women in whom the Frank method is unacceptable, or fails, or when a well-formed uterus is present and fertility might be preserved. The symptoms of retained menstruation should identify these patients. One recommendation is to perform an initial laparotomy to evaluate the cervical canal; if the cervix is atretic, the uterus should be removed.⁷⁴ If it is the relatively simple problem of an imperforate hymen or a transverse vaginal septum, surgery is indicated. Most have recommended against trying to preserve fertility in the presence of complete vaginal agenesis. The morbidity subsequent to this surgery argues for removal of the müllerian structures at the time of construction of a neovagina.

Patients with a transverse vaginal septum, which is a failure of canalization of the distal third of the vagina, usually present with symptoms of obstruction and urinary frequency. A transverse septum can be differentiated from an imperforate hymen by a lack of distension at the introitus with Valsalva's maneuver. A transverse vaginal septum can be accompanied by abnormalities of the upper reproductive tract; e.g., absent segments or atresia of the fallopian tubes or unilateral absence of the fallopian tube and ovary.⁷⁵

Distal obstruction of the genital tract is the only condition in this category that can be considered an emergency. Delay in surgical treatment can lead to infertility due to inflammatory changes and endometriosis. Definitive surgery should be accomplished as soon as possible. Diagnostic needling should be avoided because a hematocolpos can be converted into a pyocolpos.

Reassurance and support are necessary to carry a patient through these procedures. Problems with body image and sexual enjoyment can be avoided, and, although infertile, a full and normal life as a woman can be achieved. Furthermore, genetic offspring can be achieved by collection of oocytes from the genetic mother, fertilization by the genetic father, and placement into a surrogate carrier.⁷⁶ An analysis of 34 surrogacy live births resulting from oocytes retrieved from 58 women with congenital absence of the uterus and vagina could find no indication of inheritance in a dominant fashion, making surrogate pregnancy a reasonable option for patients with this disorder.⁷⁷

Androgen Insensitivity (Testicular Feminization)

Complete androgen insensitivity (testicular feminization) is the likely diagnosis when a blind vaginal canal is encountered and the uterus is absent (also discussed in [Chapter 9](#)). This is the third most common cause of primary amenorrhea after gonadal dysgenesis and müllerian agenesis. The patient with testicular feminization is a male pseudohermaphrodite. The adjective male refers to the gonadal sex; thus, the individual has testes and an XY karyotype. Pseudohermaphrodite means that the genitalia are opposite of the gonads; thus, the individual is phenotypically female but with absent or meager pubic and axillary hair.

Differences between Müllerian Agenesis and Testicular Feminization		
	Müllerian Agenesis	Testicular Feminization
Karyotype	46,XX	46,XY
Heredity	Not known	Maternal X-linked recessive; 25% risk of affected child, 25% risk of carrier
Sexual hair	Normal female	Absent to sparse
Testosterone level	Normal female	Normal to slightly elevated male
Other anomalies	Frequent	Rare
Gonadal neoplasia	Normal incidence	5% incidence of malignant tumors

The male pseudohermaphrodite is a genetic and gonadal male with failure of virilization. Failures in male development can be considered a spectrum with incomplete forms of androgen insensitivity being represented by some androgen response. Transmission of this disorder is by means of an X-linked recessive gene that is responsible for the androgen intracellular receptor (see [Chapter 9](#) for a discussion of the androgen receptor defect). Clinically, the diagnosis should be considered in:

1. A female child with inguinal hernias because the testes are frequently partially descended.
2. A patient with primary amenorrhea and an absent uterus.
3. A patient with absent body hair.

These patients appear normal at birth except for the possible presence of an inguinal hernia, and most patients are not seen by a physician until puberty. Growth and development are normal, although overall height is usually greater than average, and there may be an eunuchoidal tendency (long arms, big hands, and big feet). The breasts, although large, are abnormal; actual glandular tissue is not abundant, nipples are small, and the areolae are pale. More than 50% have an inguinal hernia, the labia minora are usually underdeveloped, and the blind vagina is less deep than normal. Rudimentary fallopian tubes are composed of fibromuscular tissue with only occasional epithelial lining. Horseshoe kidneys have been reported.

The testes may be intra-abdominal, but often are in a hernia. They are similar to any cryptorchid testis except that they may be nodular. After puberty, the testis displays immature tubular development, and tubules are lined by immature germ cells and Sertoli cells. There is no spermatogenesis. The incidence of neoplasia in these gonads is high. In 50 reported cases, there were 11 malignancies, 15 adenomas, and 10 benign cysts: a 22% incidence of malignancy and a 52% incidence of neoplasia.⁷⁸ More recent series indicate a lower overall incidence of gonadal tumors, about 5–10%.^{35, 79, 80 and 81} Therefore, once full development is attained after puberty, the gonads should be removed at approximately age 16–18, and the patient should receive hormone therapy. **This is the only exception to the rule that gonads with a Y chromosome should be removed as soon as a diagnosis is made.** There are two reasons: first, the development achieved with hormone treatment does not seem to match the smooth pubertal changes due to endogenous hormones, and second, gonadal tumors in these patients have not been encountered prior to puberty. Removal of gonadal tissue can be accomplished by a skilled operator through the laparoscope, reserving the option of laparotomy if the gonads are inaccessible.⁸²

When testicular feminization was first studied, it was found that the urinary 17-ketosteroids were normal, and it was suggested that there might be a resistance to

androgen action rather than an absence of androgens — a congenital androgen insensitivity. Indeed, the plasma levels of testosterone are in the normal to high male range, and the plasma clearance and metabolism of testosterone are normal. Thus, these patients produce testosterone, but they do not respond to androgens, either their own or those given locally or systemically. Therefore, the critical steps in sexual differentiation, which require androgens, fail to take place, and development is totally female. Because antimüllerian hormone is present, development of the müllerian duct is inhibited, hence the absence of uterus, tubes, and upper vagina.

This syndrome is marked by a unique combination:

1. Normal female phenotype.
2. Normal male karyotype, 46,XY.
3. Normal or slightly elevated male blood testosterone levels and a high LH.

Cases of **incomplete androgen insensitivity** (one-tenth as common as the complete syndrome) represent individuals with some androgen effect. These individuals may have clitoral enlargement, or a phallus may even be present. Axillary hair and pubic hair develop along with breast growth. Gonadectomy should not be deferred in such cases because it will obviate unwanted further virilization. Patients with a deficit in testicular 17 β -hydroxysteroid dehydrogenase activity will have impaired testosterone production and present clinically as incomplete androgen insensitivity. Because treatment (gonadectomy) is the same, precise diagnosis is not essential.

In the past, conventional wisdom warned against unthinking and “needless” disclosure of the gonadal and chromosomal sex to a patient with complete androgen insensitivity. This attitude has changed as, more and more, patients desire and appreciate a full understanding of themselves. Although infertile, these patients are certainly completely female in their gender identity, and this should be reinforced rather than challenged. We now strongly advocate combining a truthful education with appropriate psychological counseling of patient and parents. A good resource is the international support group, A⁴S, that is headquartered in the United Kingdom (2 Shirburn Avenue, Mansfield, Nottinghamshire, NG18 2BY, UK); <http://www.medhelp.org/www/ais/>.

Compartment II: Disorders of the Ovary

Problems in gonadal development can present with either primary or secondary amenorrhea. From 30 to 40% of primary amenorrhea cases have gonadal streaks due to abnormal development: gonadal dysgenesis. These patients can be grouped according to the following karyotypes:

- 50% — 45,X
- 25% — Mosaics
- 25% — 46,XX

Women with gonadal dysgenesis can also present with secondary amenorrhea. The karyotypes associated with this presentation are, in order of decreasing frequency:

- 46,XX (most common).
- Mosaics (e.g., 45,X/46,XX).
- Deletions in X short and long arms.
- 47,XXX
- 45,X

Both X chromosomes must be present and active in oocytes to avoid the accelerated loss of follicles. The finding of a normal karyotype in patients with ovarian failure, the most common situation, is most perplexing, suggesting subtle reasons for loss of activity, probably due to specific gene alterations. There is reason to believe that specific genes confined to a portion of the X chromosome are necessary for normal ovarian function.⁸³

Gonadal dysgenesis associated with a normal karyotype is also linked to neurosensory deafness (Perrault syndrome). Auditory evaluation should be considered in all 46,XX gonadal dysgenesis cases.

Pure gonadal dysgenesis indicates the presence of bilateral streak gonads, regardless of karyotype. Mixed gonadal dysgenesis indicates testicular tissue on one side and a streak gonad on the other.

Turner Syndrome

Turner syndrome (an abnormality in or an absence of one of the X chromosomes) is a well known and thoroughly studied entity. (See [Chapter 9](#) for a full discussion.) The characteristics of short stature, webbed neck, shield chest, and increased carrying angle at the elbow, combined with hypergonadotropic hypogonadism, make a diagnosis possible on the most superficial evaluation. Due to a lack of ovarian follicles, there is no gonadal sex hormone production at puberty, and thus patients present with primary amenorrhea. However, special attention must be given to the less common variations of this syndrome. Autoimmune disorders, cardiovascular abnormalities, and various renal anomalies must be ruled out. A karyotype should be performed on all patients with elevated gonadotropins, despite the appearance of a typical case of Turner syndrome. The presence of a pure syndrome, 45,X chromosome single-cell line, should be confirmed. This expensive test cannot be viewed just as a step toward academic perfection. Forty percent of individuals who appear to have Turner syndrome are mosaics or have structural aberrations in the X or Y chromosome.

Mosaicism

The presence of mosaicism (multiple cell lines of varying sex chromosome composition) must be ruled out for a very important reason. The presence of a Y chromosome in the karyotype requires excision of the gonadal areas because the presence of any medullary (testicular) component within the gonad is a predisposing factor to tumor formation and to heterosexual development (virilization). Only in the patient with the complete form of androgen insensitivity can laparotomy be deferred until after puberty, because the individual is resistant to androgens and gonadal tumors occur late. In all other patients with a Y chromosome, gonadectomy should be performed as soon as the diagnosis is made to avoid virilization and early tumor formation. One should be aware that approximately 30% of patients with a Y chromosome will not develop signs of virilization. Therefore, even the normal-appearing adult patient with elevated serum levels of gonadotropins must be karyotyped to detect a silent Y chromosome so that prophylactic gonadectomy can be performed before neoplastic changes occur. The fully stained and banded karyotype continues to be the best method to detect the presence of testicular tissue or other mosaic combinations. When standard cytogenetic analysis is uncertain, expert consultation should be obtained to pursue further analysis with X- and Y-specific DNA probes.⁸⁴ Probing for Y chromosomal material is also indicated when virilization occurs, despite no apparent Y on the karyotype and when a chromosomal fragment of uncertain origin is identified (discussed in [chapter 9](#)).

The impact of mosaicism, even in the absence of a Y-containing line, is significant. With an XX component (e.g., XX/XO), functional cortical (ovarian) tissue can be found within the gonad, leading to a variety of responses, including some degree of female development, and, on occasion, even menses and reproduction. These individuals may appear normal, attaining normal stature before premature menopause is experienced. More commonly, these patients are short. Most patients with missing sex chromosome material are less than 63 inches (160 cm) in height. The menopause is early, because the functioning follicles undergo an accelerated rate of atresia.

This complex array of gonadal dysgenesis variations, from the typical pure form to an otherwise normal-appearing and functioning woman with premature menopause, is the result of a variety of mosaicism, which produces a complex mixture of cortical and medullary gonadal tissue. The clinical importance of this information justifies obtaining karyotypes in all cases of elevated gonadotropins in women under age 30. Although more uncommon, even autosomal abnormalities can be associated with hypergonadotropic ovarian failure; e.g., a 28-year-old woman with secondary amenorrhea and elevated gonadotropins has been reported with trisomy 18 mosaicism.⁸⁵ All patients with absent ovarian function and quantitative alterations in the sex chromosomes are categorized as having **gonadal dysgenesis** ([Chapter 9](#)).

XY Gonadal Dysgenesis

A female patient with an XY karyotype who has a palpable müllerian system, normal female testosterone levels, and lack of sexual development has **Swyer's**

syndrome. Tumor transformation in the gonadal ridge can occur at any age, and extirpation of the gonadal streaks should be performed as soon as the diagnosis is made.

Gonadal Agenesis

No complicated clinical problems accompany the gonadal failure due to agenesis. Without precise information, only conjecture about the causes of absent development can be made. Thus, viral and metabolic influences in early gestation or undiscovered genetic mutations are suspected. Nevertheless, the final result is irretrievable — hypergonadotropic hypogonadism. In the absence of gonadal function, development is female. Surgical removal of the gonadal streaks is necessary to avoid the possibility of neoplasia.

The Resistant Ovary Syndrome

There is a rare patient with amenorrhea and normal growth and development who has elevated gonadotropins despite the presence of unstimulated ovarian follicles, and there is no evidence of autoimmune disease. Laparotomy is necessary to arrive at a correct diagnosis by obtaining adequate histological evaluation of the ovaries. This can demonstrate not only the presence of follicles but the absence of the lymphocytic infiltration seen with autoimmune disease. Because of the rarity of this condition and the very low chance of achieving pregnancy even with high doses of exogenous gonadotropins, we do not believe it is worthwhile to perform a laparotomy for the purpose of ovarian biopsy on every patient with amenorrhea, high gonadotropins, and a normal karyotype. These patients are excellent candidates for oocyte donation.

Premature Ovarian Failure

Premature ovarian failure (the early depletion of ovarian follicles) is surprisingly common. Approximately 1% of women will experience ovarian failure before the age of 40, and in women with primary amenorrhea, the prevalence ranges from 10% to 28%.^{26,86} The etiology of premature ovarian failure is unknown in most cases. It is useful to explain to the patient that it is probably a genetic disorder with an increased rate of follicle disappearance. Often, specific sex chromosome anomalies can be identified.⁸⁷ The most common abnormalities are 45,X and 47,XXY, followed by mosaicism and specific structural abnormalities on the sex chromosomes. Searching for 45,X/46,XX mosaicism using fluorescence in situ hybridization, a higher percentage of cells containing a single X chromosome can be detected in women who present with premature ovarian failure.⁸⁸ The cause of ovarian failure is most likely accelerated follicular atresia because even 45,X (Turner syndrome) patients begin with a full complement of germ cells. In addition, premature ovarian failure can be due to an autoimmune process, or perhaps to destruction of follicles by infections, such as mumps oophoritis, or a physical insult, such as irradiation or chemotherapy.

The problem can present at varying ages, depending on the number of follicles left. It is useful to view the various presentations as representing a stage in the process of perimenopausal change, no matter what the chronological age of the patient. If loss of follicles has been rapid, then primary amenorrhea and lack of sexual development will be present. If loss of follicles takes place during or after puberty, then the extent of adult phenotypic development and the time of onset of secondary amenorrhea will vary accordingly.

In view of the many case reports documenting resumption of normal function in patients with normal karyotypes (10–20% of these patients), we cannot be certain that these patients will be sterile forever. On the other hand, laparotomy and full-thickness ovarian biopsy surely are not necessary for all of these patients. We believe that a minimal approach, with a survey for autoimmune disease (recognizing that there is no practical clinical method to accurately diagnose autoimmune ovarian failure) and an assessment of ovarian-pituitary activity, is sufficient. As with other hypogonadal patients, hormone therapy is recommended. However, because of spontaneous ovulations, an oral contraceptive is a better treatment regimen choice if pregnancy is not desired. The best prospect for pregnancy is with donated oocytes; however, it should be noted that pregnancy rates are reduced when using a sibling's donated oocytes.⁸⁹

Molecular Explanations for Ovarian Failure

A group of patients with ovarian failure and normal chromosomes has been identified in Finland, displaying a recessive inheritance pattern.⁹⁰ A point mutation was detected in the FSH receptor gene and demonstrated to be the cause of ovarian failure in this population.²² This mutation accounted for 29% of 75 Finnish women with ovarian failure. Ovarian follicles were present in these women, as detected by ultrasonography, although the ovaries were small in volume.²³ Finland is known to harbor an increased number of inherited conditions. A search for this same mutation in American and Brazilian women could not detect a single case in women presenting with premature ovarian failure.^{91,92}

As more women with premature ovarian failure undergo genetic studies, we anticipate the identification of multiple subgroups, each with a different biologic basis for the ovarian failure, results that would be consistent with a heterogeneous condition with multiple causes. For example, a case of hypergonadotropic primary amenorrhea has been reported due to a point mutation in the LH receptor gene; FSH and LH were only slightly elevated and multiple ovarian follicles were present with development and steroidogenesis up to an early antral stage.⁹³ The almost normal gonadotropin levels were probably due to inhibition by inhibin, because inhibin secretion by granulosa cells is FSH-dependent and not influenced by LH. This patient had two siblings who were 46,XY male pseudohermaphrodites due to Leydig cell hypoplasia because of the same LH receptor gene mutation. In another example, translocations between regions on X and Y chromosomes that share sequence homology have been reported in patients with secondary amenorrhea and ovarian failure.²⁴ Sequences on the long arm of the X chromosome (Xq27–28) share homology with sequences on the long arm of the Y chromosome (Yq11.22) allowing errors in the process of crossing-over. In addition, less than complete mutations (so-called premutations) of the site that transmits the fragile X syndrome have been reported to occur at a greater frequency in women with premature ovarian failure.⁹⁴

The Effect of Radiation and Chemotherapy

The effect of radiation is dependent upon age and the x-ray dose.^{95,96} Steroid levels begin to fall and gonadotropins rise within 2 weeks after irradiation to the ovaries. The higher number of oocytes in younger age is responsible for the resistance to total castration in young women exposed to intense radiation. Function can resume after many years of amenorrhea. On the other hand, the damage may not appear until later in the form of premature ovarian failure. If pregnancy does occur, the risk of congenital abnormalities is no greater than normal. When the irradiation field excludes the pelvis, there is no risk of premature ovarian failure.⁹⁷ For this reason, elective transposition by laparoscopy of the ovaries out of the pelvis prior to irradiation provides a good prospect for future fertility.⁹⁸ Gonads are not in danger in the kitchen; microwave ovens utilize wavelengths with low tissue-penetrating power.

The following table indicates the risk of sterilization according to dose.⁹⁹

Ovarian Dose Sterilization Effect	
60 rads	No effect
150 rads	Some risk over age 40
250–500 rads	Ages 15–40: 60% sterilized
500–800 rads	Ages 15–40: 60–70% sterilized
over 800 rads	100% permanently sterilized

Alkylating agents are very toxic to the gonads. As with radiation, there is an inverse relationship between the dose required for ovarian failure and age at the start of therapy.¹⁰⁰ Other chemotherapeutic agents have the potential for ovarian damage, but they have been less well studied. The effect of combination chemotherapies is similar to those of the alkylating agents. Approximately two-thirds of premenopausal women with breast cancer and treated with cyclophosphamide, methotrexate, and fluorouracil lose ovarian function.¹⁰¹ Resumption of menses and pregnancy can occur, but there is no way to predict which patient will reacquire ovulatory function. As with radiotherapy, damage may present late with premature ovarian failure.¹⁰²

Is it possible that maintenance of ovarian follicles in a “dormant” state by suppressing FSH secretion can prevent ovarian failure? In a monkey model, gonadotroph suppression by treatment with a GnRH agonist during radiation did not protect against loss of ovarian follicles.¹⁰³ In contrast, GnRH agonist treatment of monkeys did

protect the ovarian follicles against damage by cyclophosphamide.¹⁰⁴

The harvesting and cryopreservation of oocytes prior to irradiation and/or chemotherapy will, in our opinion, ultimately prove to be best means of preserving fertility for these patients.

Compartment III: Disorders of the Anterior Pituitary

A consideration of the disorders of the hypothalamic-pituitary axis must first focus on the problem of the pituitary tumor. Fortunately, malignant tumors are almost never encountered. Through 1997, there were approximately 40 reported cases of prolactin cell metastatic carcinomas (mostly in men) and through 1989, no more than 40 cases of primary pituitary cancer in the world literature,^{105, 106, 107, 108, 109, 110 and 111} but growth of a benign tumor can cause problems because it expands in a confined space. The tumor grows upward, compressing the optic chiasm and producing the classic findings of bitemporal hemianopsia. With small tumors, however, abnormal visual fields are rarely encountered. In contrast, other tumors of this region (e.g., craniopharyngioma, usually marked by calcifications on x-ray) may be associated with the early development of blurring of vision and visual field defects because of their close proximity to the optic chiasm. Besides craniopharyngioma, other very rare tumors include meningiomas, gliomas, metastatic tumors, and chordomas. Increased melatonin secretion, probably from a cystic pineal lesion, has been reported as a cause of delayed puberty.¹¹² **Hypogonadism and delayed puberty deserve brain evaluation by MRI.**

Sometimes, the suspicion of a pituitary tumor is increased because of clinical signs of acromegaly caused by excessive secretion of growth hormone, or Cushing's disease due to excessive secretion of ACTH. Rarely, a TSH-secreting tumor (less than 1–3% of pituitary tumors) will cause secondary hyperthyroidism.^{113, 114} Amenorrhea and/or galactorrhea may precede the eventual full clinical expression of a tumor that secretes ACTH or growth hormone. If clinical criteria suggest Cushing's disease, ACTH levels and the 24-hour urinary levels of free cortisol should be measured, and the rapid suppression test (Chapter 13) should be utilized. If acromegaly is suspected, growth hormone should be measured during an oral glucose tolerance test (lack of suppression of growth hormone levels is diagnostic), and the circulating level of IGF-I should be measured. However, the 2 most common tumors are prolactin-secreting adenomas and clinically nonfunctioning tumors. Though usually a problem in adult life, prolactin-secreting tumors can be seen in preadolescent and adolescent children, and, thus, can be a cause of failure of growth and development or of primary amenorrhea.¹¹⁵

Because acromegaly can initially present with an elevated prolactin level and amenorrhea, the circulating level of IGF-I should be measured in all patients with a macroadenoma (>10 mm diameter).

The majority of clinically nonfunctioning (null) adenomas (30–40% of all pituitary tumors) are of gonadotroph origin and actively secrete FSH, free α -subunit, and rarely, LH (all of which do not exert clinical effects, and, therefore, patients with these tumors usually present with symptoms due to mass effects).¹⁷ The α -subunit can be used as a tumor marker; however, in postmenopausal women (the age at which most gonadotroph adenomas present) the situation can be confusing because increased free α -subunit secretion accompanies increased secretion of gonadotropins. One premenopausal woman with a gonadotroph adenoma has been reported, distinguished by multiple ovarian cysts, high estradiol levels, and endometrial hyperplasia.¹¹⁶ In contrast to patients with normal pituitary glands, patients with pituitary adenomas usually fail to down-regulate gonadotropin secretion in response to GnRH agonist treatment, and repeated GnRH agonist administration is associated with persistent elevations in either FSH or α -subunit. Most patients with these tumors, however, have reduced secretion of gonadotropins (and amenorrhea) because of tumor compression of the pituitary stalk and interference with the delivery of hypothalamic GnRH. For this reason, these patients often present with modest elevations of prolactin (due to the inability of dopamine to reach the anterior pituitary).

Elevated gonadotropins in the presence of a pituitary microadenoma in a woman with amenorrhea are not a consequence of secretion by the tumor; another explanation must be pursued.

Not all intrasellar masses are neoplastic. Cysts, tuberculosis, sarcoidosis, and fat deposits have been reported as causes of pituitary compression leading to hypogonadotropic amenorrhea. Lymphocytic hypophysitis is a rare autoimmune infiltration of the pituitary that can mimic a pituitary tumor, often occurring during pregnancy or in the first 6 months postpartum.¹¹⁷ In the initial phase of hypophysitis, hyperprolactinemia is common, followed by hypopituitarism. Transsphenoidal surgery is both diagnostic and therapeutic for this potentially lethal condition.

Nearby lesions, such as internal carotid artery aneurysms and obstruction of the aqueduct of Sylvius, can also cause amenorrhea. Pituitary insufficiency can be secondary to ischemia and infarction and appear as a late sequela to obstetrical hemorrhage — the well known Sheehan's syndrome. These problems, as well as genetic disorders such as Laurence-Moon-Biedl and Prader-Willi syndromes, are so rarely encountered that consultation with textbooks and colleagues is necessary. In a large transsphenoidal surgical series, 91% of sellar and parasellar masses were pituitary adenomas.¹¹⁸ Diabetes insipidus is not associated with pituitary adenomas, but commonly accompanies masses not of pituitary origin.

Treatment of Nonfunctioning Adenomas

If imaging discovers a microadenoma (less than 10 mm in diameter) in an asymptomatic patient, no treatment is necessary. These tumors are often incidental findings. A follow-up imaging is recommended in a year or two to be sure there is no growth. If a macroadenoma (greater than 10 mm in diameter) is present and symptomatic, surgery is necessary; these tumors are commonly not detected until the onset of symptoms (headaches and visual disturbances). Because of their large size and the high risk of recurrence, adjunctive irradiation is recommended if residual tumor and elevated gonadotropins and α -subunit are present after surgery. Follow-up imaging is obtained every 6 months for 1 year, and then yearly for 3–5 years. The radiation dose is high (4500 rads), and the incidence of hypopituitarism may reach 50% over a 10-year period.¹⁷ Ongoing surveillance of adrenal and thyroid function is necessary. With careful imaging follow-up after surgery, postoperative irradiation can be avoided in some patients.¹¹⁹ Although a response to dopamine agonist therapy has been reported, in general, results are not satisfactory.^{15, 120} The response to the somatostatin analogue, octreotide, has also been disappointing.¹²¹ Nevertheless, because good tumor size reduction occasionally occurs, the option of medical treatment should be considered.

Pituitary Prolactin-Secreting Adenomas

Prolactin-secreting adenomas are the most common pituitary tumors, and they account for 50% of all pituitary adenomas identified at autopsy. Classically, pituitary adenomas have been grouped according to their staining ability as eosinophilic, basophilic, or chromophobic. This classification is misleading and of no clinical usefulness. Pituitary adenomas should be classified according to their function; e.g., prolactin-secreting adenoma.

With the utilization of the serum prolactin assay and the increased sensitivity of the new imaging techniques, the association of amenorrhea and small pituitary tumors has become recognized as a relatively common problem. This is not a new phenomenon, rather it reflects more sensitive diagnostic techniques. Attempts to link the problem to oral contraceptive use have proved negative.¹²²

The exact incidence of this clinical problem is unknown. In autopsy series the percentage of pituitary glands found to contain microadenomas ranged from 9% to 27%.^{53, 54, 55, 56 and 57} The age distribution ranged from 2 to 86, with the greatest incidence in the 6th decade of life. The sex distribution was equal. However, clinical manifestations, mainly a disruption of the reproductive mechanism, occur more commonly in women and are probably due to estrogen-induced activity of the pituitary lactotrophs.

A high prolactin level is encountered in about one-third of women with no obvious cause of amenorrhea.¹²³ Only one-third of women with high prolactin levels will have galactorrhea, probably because the low estrogen environment associated with the amenorrhea prevents a normal response to prolactin. Another possible explanation again focuses on the heterogeneity of peptide hormones. Prolactin circulates in various forms with structural modifications, which are the result of glycosylation, phosphorylation, deletions, and additions. The various forms are associated with varying bioactivity (manifested by galactorrhea) and immunoreactivity (recognition by immunoassay). The predominant variant is little prolactin (80–85%), which also has more biological activity than the larger sized variants. Therefore, it is not surprising that big prolactins compose the major form of circulating prolactin in women with normal menses and minimal galactorrhea.¹²⁴ This is not always the case, however, because a high blood level (350–400 ng/mL) of prolactin composed predominantly of high molecular weight prolactin has been reported in a woman with oligomenorrhea and galactorrhea but with no evidence of a pituitary tumor.¹²⁵ These high levels of relatively inactive prolactin in the absence of a tumor may be due to the creation of macromolecules of prolactin by antiprolactin autoantibodies.¹²⁶ Explanations for clinically illogical situations can be found in the variable molecular heterogeneity of the peptide hormones. At any one point in time, the bioactivity and the immunoreactivity of prolactin represent the cumulative effect of the circulating

family of structural variants.

Very high prolactin levels (greater than 1000 ng/mL) are associated with invasive tumors. These very rare tumors do not yield themselves to surgery, but, fortunately, they can usually be effectively treated and controlled with a dopamine agonist.

Approximately one-third of women with galactorrhea have normal menses.^{127, 128} As the prolactin concentration increases, a woman can progress sequentially from normal ovulation to an inadequate luteal phase to intermittent anovulation to total anovulation to complete suppression and amenorrhea.

Probably as many as one-third of patients with secondary amenorrhea will have a pituitary adenoma, and if galactorrhea is also present, half will have an abnormal sella turcica.¹²³ The clinical symptoms do not always correlate with the prolactin level, and patients with normal prolactin levels can have pituitary tumors.¹²⁸ The highest prolactin levels, however, are associated with amenorrhea, with or without galactorrhea.

The amenorrhea associated with elevated prolactin levels is due to prolactin inhibition of the pulsatile secretion of GnRH. The pituitary glands in these patients respond normally to GnRH, or in augmented fashion (perhaps due to increased stores of gonadotropins), thus indicating that the mechanism of the amenorrhea is a decrease in GnRH.^{129, 130} Short-term administration of an opioid antagonist suggests that this inhibition is mediated by increased opioid activity.¹³¹ However, chronic administration of naltrexone (a long-acting opioid antagonist) does not restore menstrual function.¹³² Nevertheless, treatment that lowers the circulating levels of prolactin restores ovarian responsiveness and menstrual function. This is true whether the treatment consists of removal of a prolactin-secreting tumor or suppression of prolactin secretion. Interestingly, postmenopausal women with elevated levels of prolactin do not experience vasomotor symptoms (hot flashes) until prolactin levels are restored to normal.¹³³

The increased ability to detect pituitary tumors has been accompanied by the development of a surgical technique that effectively removes the small tumors with a high margin of safety. Utilizing the operating microscope, the transsphenoidal technique approaches via a sublabial incision (under the upper lip), with dissection under the nasal mucosa, removal of the nasal septum to expose the sphenoidal sinus, and resection of the floor of the sphenoid sinus to expose the sella turcica. Tumor tissue is usually distinguishable from the yellow-orange, firm tissue of the normal anterior pituitary. However, because pituitary adenomas do not have a capsule, the borderline between tumor and normal tissue is often vague. The ideal time for excision is when the adenoma is a small nodule. When enlarged, it becomes more difficult to distinguish normal from pathological tissue. Once the adenoma grows beyond the sella, total removal is essentially impossible.

The development of transsphenoidal surgery was paralleled by the availability and clinical application of the drug, bromocriptine, which specifically suppresses prolactin secretion. Initially, appropriate decisions between the surgical approach and medical treatment were difficult to make. With increasing experience, clinical perspective has been achieved, and reasonable judgments are now possible. Let us first consider results with surgery, and then examine dopamine agonist treatment.

Results With Surgery

Transsphenoidal neurosurgery achieves immediate resolution of hyperprolactinemia with resumption of cyclic menses in approximately 30% of patients with macroadenomas and 70% of patients with microadenomas. Besides an inability to achieve a complete cure, surgery may be followed by recurrence of tumor (long-term cure rate is about 50% overall, ranging from as high as 70% for microadenomas to as low as 10% for macroadenomas), depending upon the skill and experience of the neurosurgeon and the size of the tumor, and a still unknown but significant percentage (perhaps as high as 10–30% after surgery for macroadenomas) of development of panhypopituitarism.^{134, 135} Other complications of surgery include cerebrospinal fluid leaks, an occasional case of meningitis, and the frequent postoperative problem of diabetes insipidus. The diabetes insipidus is usually a transient problem, rarely lasting as long as 6 months, but it can be permanent. There is a mortality rate of less than 1%. Although initial follow-up reports of the results of transsphenoidal adenomectomy were discouraging (high recurrence rates), other authors have argued that surgical techniques improved with time, and recurrent hyperprolactinemia is relatively low.¹³⁶ The best results are in patients with prolactin levels in the 150–500 ng/mL range; the higher the prolactin the lower the cure rate. In the largest series (409 women) with long-term follow-up, the recurrence rate was 26% when postoperative prolactin levels were 20 ng/mL or less.¹³⁷ The higher the postoperative prolactin level, the lower the cure rate. Overall, approximately 50% of both microadenomas and macroadenomas were cured by surgery. There were no deaths, but adrenal hormone replacement (hypopituitarism) was necessary in 4%. Importantly, pregnancy (achieved by 88% within 1 year in those desiring conception) did not cause exacerbation or recurrence in a single patient.

There are 3 possible explanations for the recurrence or persistence of hyperprolactinemia after surgery.

1. The prolactin-producing tumor looks like the surrounding normal pituitary, and it is difficult to resect completely.
2. The tumor may be multifocal in origin.
3. There may be a continuing abnormality of the hypothalamus giving rise to chronic stimulation of the lactotrophs. In other words, this is a problem of recurrent hyperplasia, not adenomas. However, molecular biology studies indicate that pituitary tumors are monoclonal.¹³⁸ If dysfunction were the etiologic factor, one would expect the tumors to be polyclonal.

When persistent or recurrent tumors are treated with repeat surgery, only about one-third are cured and the complication rate is high.¹³⁹ Irradiation after surgery has many problems, including the possibility of stroke and other brain tumors.^{140, 141}

We recommend the following management for those patients who have had surgery:

1. If cyclic menses return: periodic evaluation for the problem of anovulation.
2. If amenorrhea or oligomenorrhea and hyperprolactinemia persist or recur: prolactin levels every 6 months and imaging yearly for 2 years, and then a coned-down view every few years. If tumor growth becomes evident, control of growth should be achieved with dopamine agonist treatment. In addition, a dopamine agonist can be used to induce ovulation if pregnancy is desired. If the reason for surgery was lack of response or side effects with bromocriptine, one of the other dopamine agonists should be used.

Results With Radiation

Results with radiation therapy are less satisfactory than with surgery. In addition, response is very slow; prolactin concentrations may take several years to fall. After radiation, panhypopituitarism can occur as long as 10 years after treatment.¹⁴² Patients who have been treated with radiation should be followed for a long time, and any symptoms suggestive of pituitary failure require investigation. It is not yet known whether focusing the delivery of radiation (stereotactic radiotherapy) can avoid the problem of hypopituitarism, presumably by sparing the hypothalamus from radiation. Furthermore, it is believed that focused irradiation is better for small tumors or small amounts of residual tumor after surgery. Irradiation should be reserved as adjunctive therapy for controlling postoperative persistence or regrowth of large tumors and shrinking large tumors that are unresponsive to medical treatment. Overall, a small number of irradiated women return to normal hormonal function.¹³⁷

Dopamine Agonist Treatment

Bromocriptine is a lysergic acid derivative with a bromine substitute at position 2.¹⁴³ It is available as the methane-sulfonate (mesylate) in 2.5 mg tablets. It is a dopamine agonist, binding to dopamine receptors and, therefore, directly mimicking dopamine inhibition of pituitary prolactin secretion. Prolactin-secreting tumors do not have inactivating mutations in the dopamine receptor gene; thus, dopamine agonists can bind and exert inhibiting activity.¹⁴⁴ Absorption from the gastrointestinal tract is rapid but not complete; 28% is absorbed and 94% metabolized in the first pass through the liver. Bromocriptine is metabolized into at least 30 excretory products. Excretion is mainly biliary, and more than 90% appears in the feces over 5 days after a single dose of 2.5 mg. A small part, 6–7%, is excreted unchanged or as metabolites in the urine.

The oral dose that suppresses prolactin is 10 times lower than that which improves the symptoms of Parkinson's disease. For some patients, one pill a day (or half a pill bid) will be effective. On the other hand, an occasional patient will require 7.5 mg or 10 mg daily in order to suppress adenoma secretion of prolactin.

Bromocriptine is also available in a long-acting form (depot-bromocriptine) for intramuscular injection and as a slow-release oral form. Depot-bromocriptine is administered in a dose of 50–75 mg monthly; the dose of the oral slow-release formulation is 5–15 mg daily. These forms are equally effective as the standard oral

preparation and are associated with the same side effect severity and prevalence.¹⁴⁵ The response to the intramuscular form appears to be more rapid, and thus this preparation would offer an advantage in cases with large tumors with visual field impairment.^{146, 147}

Approximately 10% of patients cannot tolerate oral bromocriptine. Nausea, headache, and faintness are the usual initial problems. The faintness is due to orthostatic hypotension, which can be attributed to relaxation of smooth muscle in the splanchnic and renal beds, as well as inhibition of transmitter release at noradrenergic nerve endings and central inhibition of sympathetic activity. Neuropsychiatric symptoms, occasionally with hallucinations, occur in less than 1% of patients. This may be due to hydrolysis of the lysergic acid part of the molecule. Other side effects include dizziness, fatigue, nasal congestion, vomiting, and abdominal cramps.

Side effects can be minimized by slowly building tolerance toward the usual dose, 2.5 mg bid. Treatment should be started with an initial dose of 2.5 mg given at bedtime. It may help to take the tablet with a glass of milk and snack. The peak level is achieved 2 hours after ingestion, and the biological half-life is about 3 hours. If intolerance occurs with this initial dose, then the tablet should be cut in half, and an even slower program should be followed. Usually a week after the initial dose, the second 2.5 mg dose can be added at breakfast or lunch. Patients who are extremely sensitive to the drug should be instructed to divide the tablets and to devise their own schedule of increasing dosage in order to achieve tolerance. A very small percentage of patients cannot tolerate any dosage.

Vaginal administration of bromocriptine is an excellent method to avoid side effects. One 2.5 mg tablet is inserted high into the vagina at bedtime. This dose will provide excellent clinical results and few side effects.^{148, 149} In contrast to oral bromocriptine which is not absorbed completely and that which is absorbed is largely metabolized in the first pass through the liver, vaginal absorption is nearly complete, and avoidance of the liver first-pass effect (with longer maintenance of systemic levels) allows achievement of therapeutic results at a lower dose.

There are two bromocriptine treatment methods to follow in those patients seeking pregnancy. The first is simply daily administration of 2.5 mg bid until the patient is pregnant as judged by the basal body temperature chart. In the second method, bromocriptine is administered during the follicular phase, and the drug is stopped when a basal body temperature rise indicates that ovulation has occurred, thus avoiding high drug levels early in pregnancy. The drug is resumed at menses when it is apparent the patient is not pregnant. No comparative study has been performed to tell us whether the follicular phase only method is as effective as the daily method. Furthermore, there has been no evidence that bromocriptine ingestion during early pregnancy is harmful to the fetus.^{150, 151}

Results of Treatment. In 22 clinical trials, 80% of patients with amenorrhea/galactorrhea, associated with hyperprolactinemia but no demonstrable tumors, had menses restored.¹⁵² The average treatment time to the initiation of menses was 5.7 weeks. Complete cessation of galactorrhea occurred in 50–60% of patients in an average time of 12.7 weeks, and a 75% reduction of breast secretions was achieved in 6.4 weeks. ***It is important to advise patients that the cessation of galactorrhea is a slower and less certain response than restoration of ovulation and menses.*** Amenorrhea recurred in 41% of the patients within an average of 4.4 weeks of discontinuing treatment; galactorrhea recurred in 69% at an average of 6.0 weeks. Approximately 5% of patients terminated treatment because of adverse reactions.

Regression of Tumors With Bromocriptine. There is no question that macroadenomas will regress with bromocriptine treatment.^{120, 143, 153} In some, there is prompt shrinkage with low-dose treatment (5–7.5 mg daily); in others, prolonged treatment is required with higher doses. If a prolactin adenoma fails to shrink with 10 mg daily, further increases in dose are not useful. Visual improvement may be noted within several days. Reduction in tumor size can take place in several days to 6 weeks, but in some cases it is not observed until 6 months or more. In most cases, rapid shrinkage occurs during the first 3 months of therapy, followed by slower reduction.¹⁵⁴ Very high prolactin levels, greater than 2000–3000 ng/mL, are probably the result of invasion of the cavernous sinuses with release directly into the bloodstream. Levels greater than 1000 ng/mL are associated with locally invasive tumors. Even these cases show remarkable resolution with bromocriptine treatment. Indeed, surgical results with invasive tumors are so poor that long-term control with a dopamine agonist is recommended. Although tumor shrinkage is always preceded by a decrease in prolactin levels, the overall response cannot be predicted by the basal prolactin level, the absolute or relative fall in prolactin, or even the attainment of normal prolactin levels. Visual impairment improves rapidly, but maximal effects may take several months. However, a prolactin level nonresponder will be a tumor size nonresponder.

The response of macroadenomas to bromocriptine is impressive, and a most compelling reason in favor of its use is that it has been successful when previous surgery or radiation has failed.¹²⁰ The problem, however, is that it probably must be taken indefinitely, because there is yet to be a convincing report of complete disappearance and resolution of tumor that can be attributed to drug therapy and not spontaneous resolution. Light and electron microscopic, immunohistochemical, and morphometric analyses all indicate that bromocriptine causes not only a reduction in the size of individual cells but also necrosis of the cells with replacement fibrosis.¹⁵⁴ Nevertheless, prolactin levels generally return to an elevated state after discontinuation of the drug. There are cases of improvement in sellar imaging; however, the occurrence of spontaneous regression of prolactin-secreting tumors makes it impossible to attribute “cures” to bromocriptine. Recurrence of hyperprolactinemia has been observed following as many as 4–8 years of treatment.

Other Dopamine Agonists

Other ergoline derivatives with dopaminergic activity are available throughout the world. Pergolide is more potent, longer-lasting, and better tolerated by some patients than bromocriptine. Pergolide is given in a single daily dose of 50–150 mg, and it may be effective in bromocriptine-resistant patients.¹⁵⁵ Others are lysuride, terguride, metergoline, and cabergoline. Quinagolide (CV 205–502) is a nonergot long-acting dopamine agonist given in a daily bedtime dose of 75–300 mg. Because quinagolide has a higher affinity for the dopamine receptor, tumors resistant to bromocriptine have responded to this drug.¹⁵⁶ Side effects are reduced with quinagolide, and it appears to have antidepressive properties.¹⁵⁷ Side effects and intolerance with one of these drugs is often solved by using another. ***A patient who fails to respond to one dopamine agonist may respond to another.***

Cabergoline. Cabergoline is also an ergot-derived dopamine agonist.¹⁵⁸ Patients resistant to both bromocriptine and quinagolide have been reported to respond to cabergoline.¹⁵⁹ Cabergoline can be administered orally at doses of 0.5 to 3.0 mg only once weekly, although it can be given twice weekly if necessary, with minimal dopamine agonist side effects (headache being the most common complaint).^{160, 161, 162 and 163} ***The low rate of side effects and the once weekly dosage make cabergoline an attractive choice for initial treatment, replacing bromocriptine.*** The only reservation (a small one) is a more limited experience documenting fetal safety for patients being treated for infertility.¹⁶⁴ Cabergoline can also be administered vaginally for the rare patient who cannot tolerate it orally.¹⁶⁵

Summary: Therapy of Pituitary Prolactin-Secreting Adenomas

Macroadenomas

Currently dopamine agonist treatment is advocated for the treatment of macroadenomas, utilizing as low a dose as possible. Shrinkage of a tumor may require 5–10 mg bromocriptine daily, but once shrinkage has occurred, the daily dose should be progressively reduced until the lowest maintenance dose is achieved. The serum prolactin level can be utilized as a marker, checking levels every 3 months until stable. In many (but not all) patients, control of tumor growth correlates with maintenance of a baseline prolactin level and can be achieved in some patients with as little as one-quarter of a tablet (0.625 mg) daily.¹⁶⁶ Withdrawal of the drug is usually associated with regrowth or reexpansion of the tumor, and, therefore, treatment must be long-term if not indefinite. If there is a good response in prolactin levels, and if present, visual field defects, the MRI should be repeated after 1 year of treatment to establish size reduction of the tumor. Some patients will prefer surgery rather than long-term medical treatment, and it is certainly a legitimate option. In view of better results claimed in more recent times, this choice should be presented to the patient. Transsphenoidal surgery is recommended when suprasellar extension or visual impairment persists after dopamine agonist treatment of a macroadenoma. For some patients, side effects with dopamine agonist treatment and difficulty with medication compliance make surgery a reasonable alternative. Because tumor recurrence is high, radiotherapy should be considered.¹⁶⁷ All patients receiving radiotherapy require ongoing surveillance for the development of hypopituitarism. Surgery should be considered as a debulking procedure for very large tumors with or without invasion prior to long-term dopamine agonist therapy.

Short-term treatment (several weeks) with a dopamine agonist can make surgery easier because of a reduction in size (although not all neurosurgeons agree); however, long-term treatment (3 months or more) is associated with fibrosis, which makes complete surgical removal more difficult and more likely to be associated with the sacrifice of other pituitary hormonal function.¹⁶⁸ Even though prolactin levels usually increase when dopamine agonist treatment is discontinued after several years, many tumors (70–80%) do not regrow.¹⁶⁹ Pregnancy should be deferred until repeat imaging confirms shrinkage of the macroadenoma.

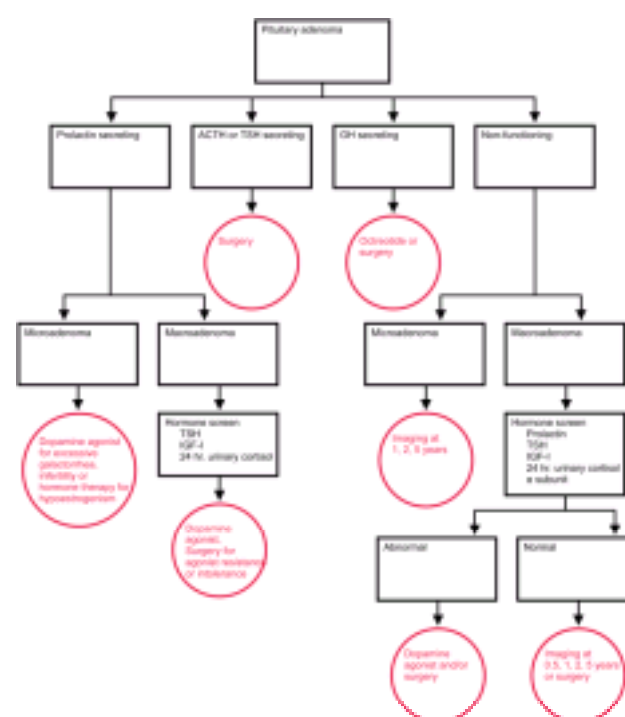

Approximately 10% of macroadenomas do not shrink with dopamine agonist therapy. **The failure of a tumor to shrink significantly in size despite a normalization of prolactin levels is consistent with a nonfunctioning tumor that is interrupting the supply of dopamine to the pituitary by stalk compression. Early surgery is indicated.** A tumor that continues to grow despite dopamine agonist treatment may be a rare carcinoma.

Microadenomas

The treatment of microadenomas should be directed to alleviating one of two problems: infertility or breast discomfort. Treatment with a dopamine agonist is the method of choice. Again, some patients, deliberately and understandably, choose the surgical approach in hopes of achieving a cure and avoiding the worry and annoyance of continuing surveillance.

The major therapeutic dilemma can be expressed by the following question: should chronic dopamine agonist treatment be utilized to retrieve ovarian function in those patients with hypoenestrogenic amenorrhea, or should estrogen treatment be offered? Until a clear-cut benefit is demonstrated by clinical studies, we cannot advocate widespread dopamine agonist therapy for those patients not interested in becoming pregnant. This conservative approach is supported by documentation of a benign clinical course with spontaneous resolution in many patients.^{170, 171 and 172} Patients with hypoenestrogenic amenorrhea are encouraged to be on an estrogen therapy program to maintain the health of their bones and the vascular system. Low-dose oral contraception is recommended for those patients who require contraception.

Estrogen-induced tumor expansion or growth has not been a problem in both our experience and in that of others.^{173, 174}

Long-Term Follow-Up

Because these tumors can grow slowly, it is appropriate in the absence of symptoms to evaluate patients with microadenomas annually for 2 years. The evaluation consists of a measurement of the prolactin level and a coned-down view of the sella turcica. If the course is unchanged, annual evaluation can be limited to measurement of the prolactin level. More sophisticated sellar imaging is reserved for patients with a change in the coned-down x-ray view, an increasing prolactin, or the development of headaches and/or visual complaints. It should be noted that progressively increasing prolactin levels have been observed **without** associated tumor growth of a microadenoma.¹⁷⁵ The rare microadenoma that grows deserves treatment. Patients with macroadenomas deserve an initial period of follow-up after treatment every 6 months, and if the adenoma appears to be clinically stable, prolactin levels should be measured annually. CT scanning or MRI is reserved for situations suggestive of tumor expansion. If clinician and patient need reassurance regarding tumor size, imaging intervals can be prolonged if the tumor is stable; e.g., at 1 year, 2 years, 4 years, 8 years. Tumor expansion and recurrent tumors after surgery or radiotherapy deserve a trial of treatment with a dopamine agonist.

Patients who have been on dopamine agonist treatment for 5–10 years with successful tumor size reduction can have a gradual reduction, and then stopping of treatment, followed by monitoring of prolactin levels every 3 months. If a normal prolactin level is maintained, we recommend an imaging study 1 year later. Of course, tumor reexpansion requires resumption of treatment with the gradual program that should always be used when starting therapy.

Pregnancy and Prolactin Adenomas

Approximately 80% of hyperprolactinemic women achieve pregnancy with dopamine agonist treatment.¹⁷⁶ **Breastfeeding, if desired, can be experienced normally without fear of stimulating tumor growth.** There is no increase in the normal rates of spontaneous miscarriages, ectopic pregnancies, and complications of pregnancy.

Interestingly, some women resume cyclic menses after pregnancy. This spontaneous improvement may be due to tumor infarction brought about by the expansion and shrinkage during and after pregnancy, or there may be a correction of a hypothalamic dysfunction followed by a disappearance of the associated pituitary hyperplasia.

A very small percentage (less than 2%) of women with hyperprolactinemia and microadenomas will develop signs or symptoms suggestive of tumor growth during pregnancy.¹⁷⁶ Approximately 5% of these patients will develop asymptomatic tumor enlargement (determined by radiologic techniques), and essentially none will ever require surgical intervention. The risk is higher with macroadenomas, approximately 15%. Headaches usually precede visual disturbances, and both may occur in any trimester. There is no characteristic headache; they are variable in intensity, location, and character. Bitemporal hemianopsia is the classic visual field finding, but other defects can occur. It has been argued in the past that a desire for pregnancy was a reason for the surgical approach. This argument hinged on the risk of tumor enlargement during pregnancy due to the well known stimulatory effects of estrogen on the pituitary lactotrophs. As noted above, however, experience has indicated that very few patients develop problems. In a series of 65 consecutive pregnant women with untreated pituitary adenomas, not one with a microadenoma developed visual loss; however, 6 of 8 women with macroadenomas did develop some visual field loss.¹⁷⁷

It is impossible to identify which patient is at risk for symptomatic expansion during pregnancy. Other than a very large tumor, the size is not critical because both microadenomas and macroadenomas can undergo uneventful pregnancies. There is no increase in miscarriages, or perinatal mortality or morbidity. It is virtually

unheard of to develop a problem that results in perinatal damage or serious maternal sequelae. Nevertheless, an occasional serious event can occur; e.g., hemorrhage of the tumor with diabetes insipidus and the potential for permanent visual impairment or life-threatening sequelae. ¹⁷⁸

Surveillance during pregnancy at first consisted of monthly visual field and prolactin measurements. With experience, this proved to be unnecessary. The patient and the clinician can be guided by the development of symptoms. Assessment of visual fields, prolactin, and the sella turcica by imaging can await the onset of headaches or visual disturbances. Even macroprolactinomas with suprasellar extension can be followed closely; discontinuation of a dopamine agonist after conception is usually not associated with tumor growth during the pregnancy. ¹⁷⁹ With repeated pregnancies, tumor regression often occurs with the development of an empty sella.

Definite evidence of tumor expansion, as well as the symptoms of headaches and visual changes, promptly regresses with dopamine agonist treatment. ¹²⁰

Termination of pregnancy or neurosurgery, therefore, should rarely, if ever, be necessary. Although bromocriptine treatment profoundly lowers both maternal and fetal blood levels of prolactin, no adverse effects on the pregnancy or the newborn have been noted. ^{150, 176, 180, 181 and 182} Fortunately, amniotic fluid prolactin (and its presumed action on regulation of amniotic fluid water and electrolytes) is derived from decidual tissue, and its secretion is controlled by estrogen and progesterone, not dopamine. Therefore, dopamine agonist treatment does not affect amniotic fluid levels of prolactin.

The Empty Sella Syndrome

A patient may have an abnormal sella turcica, but rather than a tumor, she may have the empty sella syndrome. In this condition, there is a congenital incompleteness of the sellar diaphragm that allows an extension of the subarachnoid space into the pituitary fossa. The pituitary gland is separated from the hypothalamus and is flattened. The sella floor may be demineralized due to pressure from the cerebrospinal fluid, and the x-ray picture on coned-down views will be similar to a tumor. The empty sella syndrome can also occur secondary to surgery, radiotherapy, or infarction of a pituitary tumor.

An empty sella is found in approximately 5% of autopsies, and approximately 85% are in women, previously thought to be concentrated in middle-aged and obese women. ¹⁸³ A closer look at the sella turcica, brought about by our pursuit of elevated prolactin levels, has revealed an incidence of empty sellas in 4–16% of patients who present with amenorrhea/galactorrhea. ^{123, 128} Galactorrhea and elevated prolactin levels can be seen with an empty sella, and there may be a coexisting prolactin-secreting adenoma. This suggests that the empty sella in these patients may have arisen because of tumor infarction.

This condition is benign; it does not progress to pituitary failure. The chief hazard to the patient is inadvertent treatment for a pituitary tumor. Even though enlargement of the sella turcica with a normal shape is more likely associated with an empty sella than a tumor, all patients should have examination by imaging for confirmation.

Because of the possibility of a coexisting adenoma, patients with elevated prolactin levels or galactorrhea and an empty sella should undergo annual surveillance (prolactin assay and coned-down view) for a few years to detect tumor growth. It is totally safe and appropriate to offer hormone treatment or induction of ovulation.

Sheehan's Syndrome

Acute infarction and necrosis of the pituitary gland due to postpartum hemorrhage and shock is known as Sheehan's syndrome. ¹⁸⁴ The symptoms of hypopituitarism are usually seen early in the postpartum period, especially failure of lactation and loss of pubic and axillary hair. Deficiencies in growth hormone and gonadotropins are most common, followed by ACTH, and last, by TSH in frequency. ¹⁸⁵ Diabetes insipidus is not usually present. This can be a life-threatening condition, but fortunately, because of good obstetrical care, this syndrome is never encountered by most of us.

Compartment IV: Central Nervous System Disorders

Hypothalamic Amenorrhea

Patients with hypothalamic amenorrhea (hypogonadotropic hypogonadism) have a deficiency in GnRH pulsatile secretion. Hypothalamic problems are usually diagnosed by exclusion of pituitary lesions and are the most common category of hypogonadotropic amenorrhea, a functional suppression of reproduction, often a psychobiologic response to life events. ¹⁸⁶ Frequently, there is an association with a stressful situation, such as in business or in school. There is also a higher proportion of underweight women and a higher occurrence of previous menstrual irregularity. Indeed, many women with hypothalamic amenorrhea display the endocrine and metabolic characteristics associated with eating disorders and athletics, suggesting the presence of a subclinical eating disorder. ¹⁸⁷ Nevertheless, the clinician is obliged to go through the process of exclusion prior to prescribing hormone therapy or attempting induction of ovulation to achieve pregnancy.

The degree of GnRH suppression determines how these patients present clinically. Mild suppression can be associated with a marginal effect on reproduction, specifically an inadequate luteal phase. Moderate suppression of GnRH secretion can yield anovulation with menstrual irregularity, and profound suppression is manifested by hypothalamic amenorrhea.

Patients with hypothalamic amenorrhea are categorized by low or normal gonadotropins, normal prolactin levels, a normal imaging evaluation of the sella turcica, and a failure to demonstrate withdrawal bleeding. A good practice is to evaluate such patients annually. This annual surveillance should include a prolactin assay and the coned-down view of the sella turcica. The x-ray is necessary only every 2–3 years after several years with no change. In the only long-term follow-up of a large group of women with secondary amenorrhea, it was noted that amenorrhea associated with psychological stress or weight loss demonstrated a spontaneous recovery after 6 years in 72% of the women. ¹⁸⁸ This still leaves a significant percentage of women who require ongoing surveillance. In patients with eating disorders, the return of menstrual function is associated with a gain in body weight, an obvious marker for clinical improvement in the underlying condition. ¹⁸⁹

Experimental evidence in the monkey indicates that corticotropin-releasing hormone (CRH) inhibits gonadotropin secretion, probably by augmenting endogenous opioid secretion. ¹⁹⁰ This is the probable pathway by which stress interrupts reproductive function. Women with hypothalamic amenorrhea have reduced secretion of FSH, LH, and prolactin, but increased secretion of cortisol. ^{191, 192 and 193} There is also evidence to indicate that some patients with hypothalamic amenorrhea have dopaminergic inhibition of GnRH pulse frequency. ¹⁹⁴ The suppression of GnRH pulsatile secretion may be the result of increases in both endogenous opioids and dopamine. Thus far, abnormalities in the genes for GnRH and the beta-subunits for FSH and LH have not been detected in patients with hypothalamic amenorrhea. ^{195, 196}

Even though a patient may not be currently interested in pursuing pregnancy, it is important to assure these patients that, at the appropriate time, treatment for the induction of ovulation will be available and that fertility can be achieved. Concern with potential fertility is often an unspoken fear, especially in the younger patients, even teenagers. On the other hand, induction of ovulation should be performed only for the purpose of producing a pregnancy. There is no evidence that cyclic hormone administration or induction of ovulation will stimulate the return of normal function.

Weight Loss, Anorexia, Bulimia

St. Wilgefortis was the 7th daughter of the King of Portugal, living around the year 1000. ¹⁹⁷ When confronted with an arranged marriage (she had made a vow of virginity to become a nun), she turned to intense prayer. The intensity of the prayer was marked by anorexia and the growth of body hair. Confronted with this new appearance, the King of Sicily changed his mind about the marriage, and Wilgefortis's father had her crucified. Around 1200, the legend of Wilgefortis spread throughout Europe.

St. Wilgefortis became a symbol, a woman who liberated herself of female problems, and she became a protectress of women with sexual problems, including problems associated with childbirth. Indeed, women who wished to rid themselves of their husbands prayed to her, because she had successfully resisted both a father and a potential husband. In England, rather than St. Wilgefortis, she was known as St. Uncumber because women believed she could uncumber them of their husbands.

Thus emerged the medieval dark ages explanation (with ascendancy to sainthood) of a girl's response (anorexia nervosa) to her fears of marriage and sexuality. Our understanding of the reason for this extraordinary behavior continues today to focus on an inability to cope with the onset of adult sexuality, with a return to the

prepubertal state. Both anorexia nervosa and bulimia nervosa (binge eating) are distinguished by a morbid fear of fatness.

Obesity can be associated with amenorrhea, but amenorrhea in an obese patient is usually due to anovulation, and a hypogonadotropic state is not encountered unless the patient also has a severe emotional disorder. Conversely, acute weight loss, in some unknown way, can lead to the hypogonadotropic state. Again, the clinician must pursue the presence of a pituitary tumor, and the diagnosis of hypothalamic amenorrhea is made by exclusion.

Clinically a spectrum is encountered that ranges from a limited period of amenorrhea associated with a crash diet, to the severely ill patient with the life-threatening attrition of anorexia nervosa. It is a common experience for a clinician to be the first to recognize anorexia nervosa in a patient presenting with the complaint of amenorrhea. It is also not infrequent that a clinician will evaluate and manage an infertility problem due to hypogonadotropism and not be aware of a developing case of anorexia. Because the mortality rate associated with this syndrome is significant (5–15%), it warrants close attention. [198, 199](#)

Diagnosis of Anorexia Nervosa

1. Onset between ages 10 and 30.
2. Weight loss of 25% or weight 15% below normal for age and height.
3. Special attitudes:
 - Denial,
 - Distorted body image,
 - Unusual hoarding or handling of food.
4. At least one of the following:
 - Lanugo,
 - Bradycardia,
 - Overactivity,
 - Episodes of overeating (bulimia),
 - Vomiting, which may be self-induced.
5. Amenorrhea.
6. No known medical illness.
7. No other psychiatric disorder.
8. Other characteristics:
 - Constipation,
 - Low blood pressure,
 - Hypercarotenemia,
 - Diabetes insipidus.

Anorexia nervosa has been recognized to occur frequently in young white middle to upper class females under age 25, but it is now apparent that this problem occurs at all socioeconomic levels in about 1% of young women. [200](#) The families of anorectics are success-achievement-appearance oriented. Serious problems may be present within the family, but the parents make every effort to maintain an apparent marital harmony, glossing over or denying conflicts. In one psychiatric interpretation, each parent, in secret dissatisfaction with the other, expects affection from their “perfect” child. Anorexia begins when the role of the perfect child becomes too difficult. The pattern usually starts with a voluntary diet to control weight. This brings a sense of power and accomplishment, soon followed by a fear that weight cannot be controlled if discipline is allowed to relax. A reasonable view is to consider anorexia as a mechanism that identifies a generally disturbed family. [201](#) The symptom pattern is the expression of the various psychological, familial, and cultural factors involved.

At puberty, the normal weight gain may be interpreted as excessive, and this can trip the teenager over into true anorexia nervosa. Excessive physical activity can be the earliest sign of incipient anorexia nervosa. The children are characteristically overachievers and strivers. They seldom give any trouble, but are judgmental and demand that others live up to their rigid value system, often resulting in social isolation. Patients with eating disorders usually demonstrate delayed psychosexual development marked by sexual experiences occurring at a later age. [202](#)

The cultural value our society places on thinness definitely plays a role in eating disorders. Both occupational and recreational environments that stress thinness put women at greater risk for anorexia nervosa and bulimia. But basically, an eating disorder is a method being utilized to solve a psychological dilemma.

Besides amenorrhea, constipation is a common symptom, often severe and accompanied by abdominal pain. The preoccupation with food may manifest itself by large intakes of lettuce, raw vegetables, and low-calorie foods. Hypotension, hypothermia, rough dry skin, soft lanugo-type hair on the back and buttocks, bradycardia, and edema are the most commonly encountered signs. Long-term diuretic and laxative abuse may produce significant hypokalemia. An elevation of the serum carotene is not always associated with a large intake of yellow vegetables, suggesting that a defect in vitamin A utilization is present. The yellowish coloration of the skin is usually seen on the palms. Hypercarotenemia should be regarded as a metabolic marker, but not every woman with hypercarotenemia will be amenorrheic or anovulatory. [203](#)

Bulimia is a syndrome marked by episodic and secretive binge eating followed by self-induced vomiting, fasting, or the use of laxatives and diuretics. [198, 204](#) It appears to be a growing problem among young women; however, careful study indicates that although bulimic behaviors may be relatively common, clinically significant bulimia is not (approximately 1.0% of female students and 0.1% of male students in a college sample), and the overall prevalence of eating disorders may be declining. [205, 206](#) and [207](#) Bulimic behavior is frequently seen in patients with anorexia nervosa (about half), but not in all. Patients with bulimia have a high incidence of depressive symptoms, and a problem with shoplifting (usually food). Little is known about the long-term outcome. There is a growing tendency to divide patients with anorexia nervosa into bulimic anorectics and dieters. Bulimic anorectics are older, less isolated socially, and have a higher incidence of family problems. Body weight in a “pure” bulimic fluctuates, but it does not fall to the low levels seen in anorectics.

The serious case of anorexia nervosa is seen more often by an internist. However, the borderline anorectic frequently presents to a gynecologist, pediatrician, or family physician as a teenager who has low body weight, amenorrhea, and hyperactivity (excellent grades and many extracurricular activities). The amenorrhea can precede, follow, or appear coincidentally with the weight loss.

The various problems associated with anorexia represent dysfunction of the body mechanisms regulated by the hypothalamus: appetite, thirst and water conservation, temperature, sleep, autonomic balance, and endocrine secretion. [208](#) Endocrine studies can be summarized as follows: FSH and LH levels are low, cortisol levels are elevated, prolactin levels are normal, TSH and thyroxine (T_4) levels are normal, but the 3,5,3 α -triiodothyronine (T_3) level is low, and reverse T_3 is high. Indeed, many of the symptoms can be explained by relative hypothyroidism (constipation, cold intolerance, bradycardia, hypotension, dry skin, low metabolic rates, hypercarotenemia). There appears to be a compensation to the state of undernourishment, with diversion from formation of the active T_3 to the inactive metabolite, reverse T_3 . With weight gain, all of the metabolic changes revert to normal. Even though normal gonadotropin secretion may be restored with weight gain, 30% of patients remain amenorrheic, a good sign of ongoing psychological conflict. [206](#)

The central origin for the amenorrhea is suggested by the demonstration that the response to GnRH is regained at approximately 15% below the ideal weight, and this return to normal responsiveness occurs before the resumption of menses. [209](#) Patients with anorexia nervosa have persistent low levels of gonadotropins similar to prepubertal children. With weight gain, sleep-associated episodic secretion of LH appears, similar to the early pubertal child. With full recovery, the 24-hour pattern is similar to that of an adult, marked by fluctuating peaks. This sequence of changes with increasing and decreasing weight is explained by increasing and decreasing pulsatile secretion of GnRH. Neuropeptide Y may be a link between the control of food intake and GnRH secretion. [210](#) Neuropeptide Y cell bodies are located in the arcuate nucleus of the hypothalamus. This peptide both stimulates feeding behavior and inhibits gonadotropin secretion (presumably by suppressing GnRH pulses, although a direct action on the pituitary is also possible). In response to food deprivation, the endogenous levels of neuropeptide Y increase, and elevated concentrations of neuropeptide Y can be measured in the cerebrospinal fluid of anorexic women. This is consistent with the known actions of leptin, as discussed with full references in [Chapter 19](#).

This is one of the rare conditions in which gonadotropins may be undetectable (large pituitary tumors and genetic deficiencies are the others). If necessary, a high plasma cortisol can differentiate this condition from pituitary insufficiency. However, extensive laboratory testing in these patients is not necessary. Adherence to our scheme for the evaluation of amenorrhea is indicated to rule out other pathological processes. Further endocrine assessment, however, is not essential for patient

management.

A careful and gentle revelation to the patient of the relationship between the amenorrhea and the low body weight is often all that is necessary to stimulate the patient to return to normal weight and normal menstrual function. Occasionally, it is necessary to see the patient frequently and become involved in a program of daily calorie counting (a minimum intake of 2600 calories) in order to break the patient's established eating habits. If progress is slow, hormone therapy should be initiated. In an adult weighing less than 100 pounds, continued weight loss requires psychiatric consultation. Some would argue that any patient with an eating disorder requires psychiatric intervention.

Going away to school or the development of a relationship with a male friend often are turning points for young women with mild to moderate anorexia. A failure to respond to these life changes is relatively ominous, predicting a severe problem with a protracted course.

It is disappointing that despite the impressive studies on anorexia, there is no specific or new therapy available. This only serves to emphasize the need for early recognition to allow psychologic intervention before the syndrome is entrenched in its full severity.²¹¹ The use of serotonin antagonists or uptake blockers is restricted to patients who, as is frequently the case, have the comorbidity of clinical depression.²¹² Clinicians (and parents) should pay particular attention to weight and diet in young women with amenorrhea. Even in amenorrheic adolescents of normal or above-normal body weights, disordered eating patterns (fasting and purging) are often present, a sign of an underlying stressful disorder.²¹³

Exercise and Amenorrhea

Soranus of Ephesus in the 1st century AD observed in his famous treatise, "On the Diseases of Women," that amenorrhea is frequently observed in the youthful, the aged, the pregnant, in singers, and in those who take much exercise. Late in the 20th century, there was a new awareness that competitive female athletes, as well as women engaged in strenuous recreational exercise and women engaged in other forms of demanding activity, such as ballet and modern dance, have a significant incidence of menstrual irregularity and amenorrhea, in the pattern called hypothalamic suppression. The extent of this problem has perhaps been underestimated because of a lack of attention to anovulatory cycles. As many as two-thirds of runners who have menstrual periods have short luteal phases or are anovulatory.²¹⁴ When training starts before menarche, menarche can be delayed by as much as 3 years, and the subsequent incidence of menstrual irregularity is higher. In some individuals, secondary amenorrhea is associated with delayed menarche even though training did not begin until after menarche. It is suggested that some girls with these characteristics may be socially influenced to pursue athletic training. Contrary to the female situation, exercise has little effect on the timing of puberty in boys. Although changes in testicular function can be demonstrated in males, the changes are more subtle and less meaningful clinically.²¹⁵

There appear to be two major influences: a critical level of body fat and the effect of stress itself. Young women who weigh less than 115 pounds and lose more than 10 pounds while exercising are the women most likely to develop the problem,²¹⁶ an association that supports the critical weight concept of Frisch.²¹⁷

The critical weight hypothesis states that the onset and regularity of menstrual function necessitate maintaining weight above a critical level, and, therefore, above a critical amount of body fat. In dealing with patients, it is helpful to use the nomogram derived from Frisch, which is based on the calculation of the amount of total body water as a percentage of body weight. This relates to the percentage of body fat and, therefore, is an index of fatness. The 10th percentile at age 16 is equivalent to about 22% body fat, the minimal weight for height necessary for sustaining menstruation, and the 10th percentile at age 13 is equivalent to 17% body fat, the minimum for initiating menarche. A loss of body weight in the range of 10–15% of normal weight for height represents a loss of approximately one-third of the body fat, which will result in a drop below the 22% line and may result in abnormal menstrual function.²¹⁸

Although the nomogram is useful to show these relationships to patients, individual variation is such that the nomogram cannot be utilized to predict without fail the return of menses for an individual patient. Indeed, the accuracy of the nomogram has been challenged.²¹⁹ The fat criteria were derived from the indirect estimation of body fat from predicted total body water, with a regression equation that employs height and weight. There is no question that the most reliable and accurate method for estimating body fatness is hydrostatic weighing of body density, although dual-energy x-ray absorptiometry (DEXA) is also excellent. But one can hardly maintain a small pool for this purpose in a clinical office. Granted that the nomogram, and specifically the 22% body fat criterion, are not absolutely accurate; nevertheless, the concept is useful, and the nomogram remains helpful to illustrate the concept to patients.

The competitive female athlete has about 50% less body fat than the noncompetitor, very much under the 10th percentile for secondary amenorrhea (the 22% body fat line). This change in body fat can occur with no discernible change in total body weight, because fat is converted to lean muscle mass.²²⁰ A critical look at the critical weight hypothesis argues that there is not a cause-and-effect relationship between body fat and menstrual function, only a correlation.^{221, 222} For this reason, considerable variation is seen with many examples of normal and abnormal menstrual function at all levels of body fat content. On the other hand, the correlation does exist, and body fat content and body weight are useful guides to the relationship between menstrual function and the energy balance of the body. Indeed, the leptin story (Chapter 19) has restored credibility to the critical weight hypothesis. It has always been a mystery how total body fat could talk with the brain. A mystery no longer! Fat talks to the brain via leptin, and the leptin system affects reproduction.

In addition to the role of body fat, stress and energy expenditure appear to play an independent role. Warren has pointed out that dancers will have a return of menses during intervals of rest, despite no change in body weight or percent body fat.²²³ High-energy output and stress, therefore, can act independently, as well as additively, to low body fat in suppressing reproductive function. It is not surprising that a woman with low body weight who is engaged in competitive activity (athletic or aesthetic) is highly susceptible to anovulation and amenorrhea.

Running in the dark is even more risky. Studies indicate that ovarian activity can be affected independently by strenuous activity and seasonal variation.²²⁴ Decreased ovarian activity in autumn could be related to a greater dark photoperiod with increased pineal secretion of melatonin. Indeed, the conception rate of women living in northern Scandinavia is higher during the summer than in the winter. The practical conclusion is that serious runners can expect to encounter more problems with menstrual function in autumn and winter.

This menstrual disruption is similar to the hypothalamic dysfunction which is more marked in the classic cases of anorexia nervosa. Acute exercise decreases gonadotropins and increases prolactin, growth hormone, testosterone, ACTH, the adrenal steroids, and endorphins as a result of both enhanced secretion and reduced clearance.²²⁵ The prolactin increase is in contrast to the absence of prolactin changes in undernourished women. The prolactin increases are variable, small in amplitude, and exceedingly short in duration. Thus, it is unlikely that the prolactin increase is responsible for the suppression of the menstrual cycle. Most importantly, insignificant differences occur in prolactin when amenorrheic runners are compared with eumenorrheic runners or nonrunners.²²⁶ In addition, women athletes have elevated daytime melatonin levels, and amenorrheic athletes have an exaggerated nocturnal secretion of melatonin.²²⁷ The nocturnal increase in

melatonin is also seen in women with hypothalamic amenorrhea and appears to reflect suppression of GnRH pulsatile secretion.²²⁸ Another contrast to undernourished women is found in the thyroid axis. Athletes have relatively low T_4 levels, but amenorrheic athletes have an overall suppression of all circulating thyroid hormones, including reverse T_3 .²²⁹

It has been suggested that a suboptimal amount of body fat adversely affects estrogen metabolism, specifically leading to an increased conversion of biologically active estrogens to relatively inactive catecholestrogens.²³⁰ The conversion of estradiol to its catecholestrogens rapidly yields 2-hydroxyestrone and 4-hydroxyestrone, relatively inactive metabolites, that are metabolized further by methylation to 2-methoxyestrogen and 4-methoxyestrogen. These products, and, thus, this metabolic pathway, are increased by physical exercise.^{231, 232} The extent of 2-hydroxylation correlates inversely with body fat, increasing with decreasing adiposity.^{220, 233} This could be a mechanism that interferes with the important feedback and local roles for estradiol in pituitary-ovarian interactions.

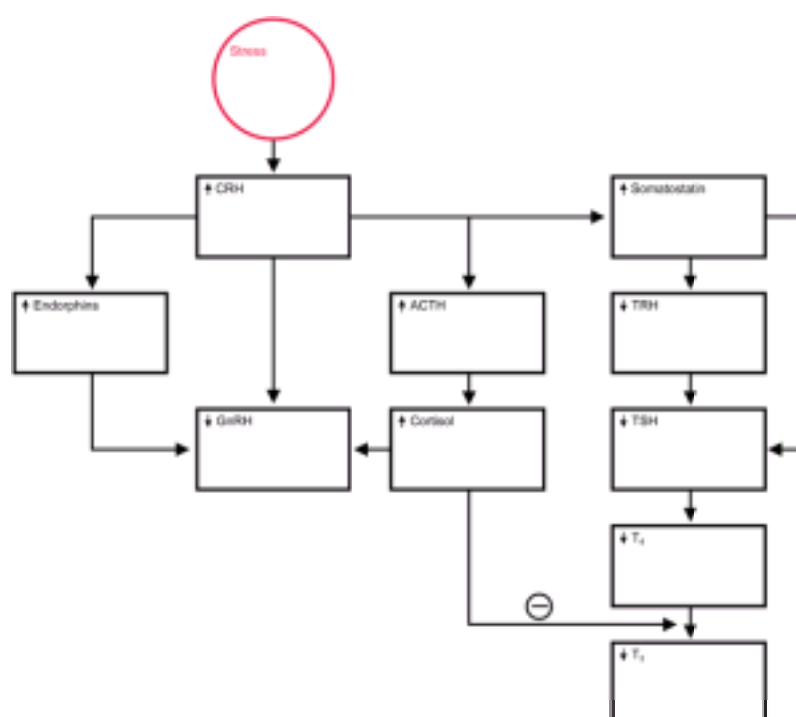

Among runners, there is frequent talk about the runner's "high," the feeling of euphoria and exhilaration after competition or an extensive workout. It is still not clear whether this is a psychologic reaction or whether it is due to an increase in endogenous opiates. The site of GnRH secretion, the arcuate nucleus area in the hypothalamus, is rich in opioid receptors and endorphin production. There is considerable evidence indicating that endogenous opiates inhibit gonadotropin secretion by suppressing hypothalamic GnRH. Women studied during a period of endurance conditioning demonstrated a steadily increasing endorphin output after exercise.^{234, 235, 236} and ²³⁷ This link of endorphins to the menstrual suppression associated with exercise is very plausible. Naltrexone, a long-acting opioid receptor blocker, restores menstrual function when administered long-term to women with amenorrhea associated with weight loss; this indicates a key role of endorphins in stress-related hypothalamic amenorrhea.²³⁸ The measurement of circulating b-endorphin levels may not reflect central mechanisms; both eumenorrheic and amenorrheic athletes have exercise-induced increases in the blood levels of b-endorphin.²³⁷

Corticotropin-releasing hormone (CRH) directly inhibits hypothalamic GnRH secretion, probably by augmenting endogenous opioid secretion.^{239, 240} Women with hypothalamic amenorrhea (including exercisers and women with eating disorders) demonstrate hypercortisolism (due to increased CRH and ACTH), suggesting that this is the pathway by which stress interrupts reproductive function.^{192, 241, 242} Indeed, amenorrheic athletes who have cortisol levels that return to normal range regain menstrual function within 6 months, in contrast to athletes who maintain elevated cortisol levels and continue to be amenorrheic.²⁴³

Amenorrheic athletes are in a state of negative energy balance, further distinguished by elevated levels of insulin-like growth factor binding protein-1 (IGFBP-1), increased insulin sensitivity, decreased insulin levels, and increased growth hormone levels.²⁴⁴ The increase in IGFBP-1 can limit IGF activity in the hypothalamus and thus provide another mechanism for suppression of GnRH secretion.

A unifying hypothesis focuses on energy balance.²²² When available energy is excessively diverted, as in exercise, or when insufficient, as with eating disorders, reproduction is suspended in order to support essential metabolism for survival. Thus reproduction is not directly affected by the level of body fat, rather body fat is a marker of the metabolic energy state. From a teleologic point of view, there is sense to these relationships; the responses that assist the body to withstand stress also inhibit menstrual function because a stressful period is not the ideal time for reproduction.

The effect of leptin on reproduction can be viewed as an additional role in maintaining responses to stress. Weight loss is known to be associated with an increased adrenal response and a decrease in thyroid function; these endocrine changes, along with suppression of the estrous cycle, occur in fasted mice and are reversed by treatment with leptin.²⁴⁵

The puzzle is why CRH is elevated in stress amenorrhea (especially that associated with weight loss) in contrast to fasting in normal and obese individuals. One possibility is that the decrease in leptin and increase in NPY associated with stress-related weight loss is the expected response, but it is inadequate to suppress the stress-induced increase in CRH. The blunted patterns in amenorrheic athletes support this. The increase in CRH and resulting hypercortisolism further increases metabolism and weight loss.

Athletes with cyclic menses demonstrate a normal diurnal rhythm in leptin levels. However, amenorrheic athletes do not have a diurnal pattern.²⁴⁶ Both cycling athletes and amenorrheic athletes have low leptin levels (3-fold reduction) that correlate with reduced body fat, but the levels are further lowered by hypoinsulinemia and hypercortisolemia. In addition, amenorrheic athletes have a blunted leptin response to the increase in insulin following meals. An increase in menstrual irregularity and amenorrhea is correlated with a decrease in body fat below 15% of body weight and leptin levels that are less than 3 ng/ml.²⁴⁷

Because of the high levels of leptin present in overweight people, the purpose of leptin function may be limited to an effect at low levels. A low circulating level of leptin may serve as a signal that fat stores are not sufficient for growth and reproduction. Thus low levels would ordinarily stimulate hyperphagia, reduce energy expenditure, and suppress gonadotropin secretion and reproduction. The high levels of leptin and the apparent resistance to leptin action associated with excess body weight and fat would then reflect not resistance, but a lack of physiologic effect.

In regards to reproduction, the final pathway is suppression of GnRH, a response to multiple inputs indicating the availability of metabolic fuel.²⁴⁸ Even in runners with regular menstrual patterns, LH pulsatile frequency and amplitude are significantly reduced.^{249, 250} A central inhibition of GnRH can be discerned even before there is perceptible evidence of menstrual irregularity. The clinical presentation (inadequate luteal phase, anovulation, or amenorrhea) will depend on the degree of GnRH suppression. Insufficient estrogen secretion at a critical time during growth can impede the growth spurt and yield short stature.

The characteristics of women in the subculture of exercise and amenorrhea strikingly remind one of anorexia nervosa: significant physical exercise, a necessity for control of the body, striving for artistic and technical proficiency, and the consequent preoccupation with the body, combined with the stressful pressures of performing and competition.^{251, 252} Individuals in this lifestyle are prone to develop what can be called the anorectic reaction.²⁵³ Fries has described four stages of dieting behavior that can form a continuum.²⁵⁴

1. Dieting for cosmetic reasons.
2. Dieting due to neurotic fixation on food intake and weight.
3. The anorectic reaction.
4. True anorexia nervosa.

There are several important distinctions between the anorectic reaction and true anorexia nervosa. Psychologically, the patient with true anorexia nervosa has a misperception of reality and a lack of insight into the disease and her problem. She does not consider herself underweight and displays an impressive lack of concern

over her dreadful physical condition and appearance. The clinician—patient relationship is difficult with no visible emotional involvement and a great deal of mistrust. Patients with the anorectic reaction have the capability for self-criticism. They can see the problem and describe it with insight and an absence of denial. The exercising woman and the competing athlete or dancer can develop an anorectic reaction. The anorectic reaction develops consciously and voluntarily, just as in anorexia nervosa, as the exercising woman deliberately makes an effort to decrease body weight. A clinician may be the first to be aware of the problem having encountered the patient because of the presenting complaint of either amenorrhea or now uncontrolled weight loss. Early recognition, concentrated counseling, and confidential support can intercept and prevent a progressive problem. The high prevalence of eating disorders among female athletes indicates that the threat of progression should not be underrated.²⁵² It is estimated that the prevalence (in the general population, not just athletes) of the early or partial disorder is twice that of the full syndrome, and progression from pathologic dieting to the full syndrome can occur in some individuals in as short a time period as 1–2 years.²⁵⁵

Prognosis is excellent with early recognition, and simple weight gain may reverse the state of amenorrhea. The degree of reversibility is unknown, although general experience indicates that the majority of women regain ovulation when stress and exercise diminish or cease.^{256, 257} However, these patients are often unwilling to give up their routines of exercise, and a sensitive clinician can perceive that the exercise is an important means for coping with daily life. Hormone therapy is, therefore, encouraged for these hypoenestrogenic patients to provide protection against the loss of bone and cardiovascular changes. However, in patients with an eating disorder, restoration of normal hormonal levels is not sufficient to return bone density to normal; resumption of an adequate diet and weight gain are essential.^{258, 259} and²⁶⁰ When pregnancy is desired, a reduction in the amount of exercise and a gain in weight should be recommended, or induction of ovulation must be pursued.

Eating Disorders and Pregnancy

It has been estimated that a typical pregnancy requires approximately 300 extra calories per day above that needed in the nonpregnant state.²⁶¹ With sufficient caloric intake, weight gain during pregnancy averages 10–12 kg (22–26 lb). Women who are underweight prior to pregnancy need to increase their energy intake and gain 12–15 kg (26–33 lb). Imagine the reaction of a patient with an eating disorder when confronted with these facts. This is fuel for the fire (the morbid fear of fatness).

Prior to the 1970s, obstetricians vigorously advised their patients to limit weight gain during pregnancy. This sadly misplaced advice can be traced to the false belief that excessive weight gain caused preeclampsia, made labor more difficult, and had a permanently detrimental impact on a woman's figure. More appropriate recommendations emerged in the 1970s, based upon a growing body of information derived from scientific studies. These studies documented the importance of prepregnancy weight as well as weight gain during pregnancy as two very important determinants for infant birth weight.

The critical issue is the relationship between the diet of the mother and the well-being of the fetus. There are three classic studies of acute famine in Leningrad, Holland, and Wuppertal during the worst days of World War II.^{262, 263} and²⁶⁴ The mean birth weight during the siege of Leningrad declined 550 g to 2,789 g. During the Dutch famine, mean birth weight decreased by 300 g; there was no decrease in the birth weight of infants conceived during the famine whose mothers received adequate rations during the third trimester. In Wuppertal, mean birth weight was depressed by 170–227 g. These differences were proportional to the level of official rations, the conditions being the worst in Leningrad.

Studies of restriction of calories during pregnancy have indicated a ready achievement of lesser maternal weight gain, at the expense of lighter birth weights.²⁶⁵ Women who gain less than 20 pounds compared with those who gain more than 20 pounds are 2.3 times more likely to deliver infants of low birth weight and 1.5 times more likely to have a fetal death.²⁶⁶ These studies finally led to the abandonment of caloric limitation.

In general, studies of dietary supplementation have indicated increases in mean birth weights.²⁶⁶ The Special Supplemental Food Program for Women, Infants, and Children (WIC) was begun in the U.S. in 1973. A review of this program found a significant impact on decreasing preterm labor and delivery, an increase in mean birth weight, and a reduction in late fetal death.²⁶⁷ These improvements are attributed to an improved maternal physiologic status, not upgraded health care. The head circumferences of infants of mothers who participated in WIC were significantly larger, presumably reflecting accelerated brain growth.

Gradually it came to be appreciated that there is a linear relationship between birth weight and maternal weight gain at all levels of prepregnancy weight.^{268, 269, 270, 271, 272} and²⁷³ However, as prepregnancy weight increases, the importance of maternal weight gain diminishes.²⁷⁴ Thus, in underweight women, the importance of each factor, prepregnancy weight and the weight gain during pregnancy, is magnified.

Now that the many circumstances that influence infant birth weight are better recognized, a modern look at this subject is especially helpful. After adjusting for maternal age, race, parity, weight gain, socioeconomic status, cigarette consumption, and gestational age, there continues to be a statistically significant linear relationship between prepregnancy body mass and birth weight, as well as between prenatal weight gain and birth weight.^{275, 276} Furthermore, the fetal death rate increases exponentially as birth weight decreases at each gestational age.²⁷⁷ Most importantly, a low prepregnancy weight can be overcome; weight gain during pregnancy (beginning in the first trimester) in underweight women can bring an infant into the normal range for birth weight.²⁷⁸

Low birth weight in an infant can be directly attributed mainly to two influencing factors: prematurity and fetal growth retardation. Underweight status before pregnancy and inadequate weight gain during the second half of pregnancy each separately increase the risk of preterm birth.²⁷⁹ In patients with eating disorders, the outcome of pregnancy is significantly influenced by both preterm delivery and intrauterine growth retardation.

In view of the well-recognized correlation between maternal weight (pregnancy weight and pregnancy weight gain) and infant size, it is certainly logical to expect a problem with pregnancy outcome in patients with eating disorders. Older reports were anecdotal in nature and usually failed to provide birth weights, because our awareness of the importance of body weight to pregnancy outcome is a relatively recent development.^{280, 281, 282, 283, 284, 285} and²⁸⁶

More recent reports have documented problems with intrauterine growth retardation and preterm labor. The average weight gain in 7 pregnancies in patients with anorexia nervosa was 8 kg; all infants demonstrated intrauterine growth retardation in the third trimester, followed by accelerated growth after birth.²⁸⁷ A review of 23 pregnancies in 74 women treated for anorexia or bulimia documented the importance of the severity of the disorder.²⁸⁸ Women in remission gained more weight and had higher birth weights and 5-minute Apgar scores. Women with active disease had worsening symptoms and psychological problems during pregnancy. The smallest birth weights were born to those with anorexia and bulimia. All the women who were ill at conception continued to be ill. Nine of the 10 women who successfully breastfed for 6 months were in remission. The rate of preterm labor and delivery in patients with eating disorders is twice the normal incidence, and in a study of 50 Danish anorectic women, the perinatal mortality rate was 6 times the normal rate.²⁸⁹ In an Australian review of 14 consecutive women who failed to respond to clomiphene, all the women had a history of an eating or exercise disorder, and one-third of the eventual live births weighed less than 2500 g.²⁹⁰ There is a suggestion in retrospective data that the risk of spontaneous miscarriage is increased in pregnant women who are actively bulimic.²⁹¹

Some patients with eating disorders do well during pregnancy; however, even during pregnancy, many patients continue their abnormal eating behavior, and characteristically minimize or lie about their eating behaviors to clinicians, family, and friends.²⁹² After the pregnancy, rapid deterioration usually takes place.²⁹³ In contrast, normal women are more accepting of their body size and weight gain during pregnancy, and dieting is unusual.²⁹⁴ Ultimately, the impact on weight is the key. There is no evidence that psychological distress independently influences fetal growth.²⁹⁵

Expert help during the pregnancy is highly recommended. Some useful warning signs are the following:

1. Unusual concern regarding body shape.
2. Aversion to being weighed.
3. Lack of weight gain.

Approximately 25% of patients with amenorrhea are underweight due to self-imposed dietary restriction.²⁹⁶ Because underweight women frequently are anovulatory, it is not surprising that they represent a significant population in whom ovulation is induced. Comparing the outcome of pregnancy in underweight women after spontaneous and induced ovulation, it is apparent that inadequate weight has serious consequences.²⁹⁷ Underweight women who undergo induction of ovulation often fail to gain weight adequately during pregnancy despite care and counseling. As expected, intrauterine growth retardation and preterm labor are significant problems.

The seriousness of the problem is heightened because of its presence at conception and during the first trimester. A study of adolescent pregnancy concluded that inadequate weight gain before 24 weeks gestation was associated with a significantly increased risk of having a small for gestational age infant, *even when later*

weight gains brought the cumulative weight gain within normal adult standards.²⁹⁸ Later inadequate weight gain was associated with an increased risk of preterm delivery. These results suggest that prevention of preterm delivery and intrauterine growth retardation requires an effort encompassing the entire pregnancy, best beginning prior to conception. A rise in weight of more than 6 kg by the 28th week of pregnancy has predictive value, indicating with a high degree of probability that the rest of pregnancy will progress normally.²⁹⁹

In summary, dietary restriction decreases birth weight and can have as great an impact as a serious famine. The impact on perinatal morbidity and mortality has been poorly assessed, but there is reason to believe that preterm labor is increased and that children with intrauterine growth retardation have more problems later in life. Although the impact of the eating disorder on parenting after the delivery has not been well studied, there is evidence that the children of parents with eating disorders are not adequately nourished.^{300, 301 and 302} Mealtimes for these children are often filled with conflict, interfering with the important communication between parent and infant that usually takes place during feeding.³⁰³ The critical factor affecting the parental-infant interaction is the mother's preoccupation with her own body and shape.

Because intrauterine growth retardation before the third trimester is associated with significant long-term morbidity, clinicians treating amenorrhea associated with weight loss should consider solving the dietary problem before subjecting a fetus to a struggle during intrauterine life. Patients with an active eating disorder should wait for remission before getting pregnant. These messages, therefore, especially apply to two groups of physicians: obstetricians and reproductive endocrinologists.

When encountering a patient who is pregnant and has an eating disorder, the obstetrician should seek expert consultation in order to achieve and maintain remission of the disorder during the pregnancy. Careful monitoring of maternal weight gain and fetal growth is essential. Consideration should be given to special dietary supplementation, especially when delayed fetal growth is demonstrated. Full exploitation of the pregnancy is warranted to provide motivation for effective resolution of this psychodynamic disorder.

The best results can be achieved with stabilization of the disorder prior to pregnancy. The reproductive endocrinologist should hesitate before embarking on a program of ovulation induction. The reward of pregnancy should be offered as an inducement to reach a normal prepregnancy weight. Patients with an eating disorder who are considering pregnancy must be made aware of the potential adverse impact on fetal growth and development. The persistence of amenorrhea is not a good sign. Persistent amenorrhea is associated with longer duration of the eating disorder and more affective disorders.¹⁸⁹

The timing of psychiatric intervention is important. The prospect of pregnancy should stimulate a preconceptual effort by the patient's physicians. At no other time will the patient's physicians have such a strong ally, the motivating force behind the desire for pregnancy.

Inherited Genetic Defects

Specific inherited defects that cause hypogonadotropic hypogonadism have not been commonly recognized; however, with the increasing sophistication of molecular biology, this may change.³⁰⁴ No mutations of the α -subunit have been reported. Deficient secretion of GnRH is a consequence of Kallmann's syndrome and the inherited disorder of adrenal hypoplasia. A case of hypogonadism due to an LH β -subunit mutation and women with primary amenorrhea and delayed puberty due to a mutation in the FSH β -subunit have been reported.^{13, 14, 305} The mutated β -subunit genes produce alterations in the β -subunits that yield no immunoreactivity or bioactivity. Hence, hypogonadism will be associated with one high and one low gonadotropin level. Treatment with exogenous gonadotropins will achieve pregnancy in these rare patients; transmission is autosomal recessive. **When a high FSH and a normal or low LH are encountered, an elevated level of α -subunit and the presence of a pituitary mass indicate a gonadotroph adenoma.**

Amenorrhea and Anosmia, Kallmann's Syndrome

A rare condition in females is the syndrome of congenital hypogonadotropic hypogonadism due to deficient secretion of GnRH, associated with anosmia or hyposmia, known as Kallmann's syndrome. There is a chronology of eponyms assigning credit for original descriptions of this syndrome, but with all due respect to the physicians who first recognized this association, it is far easier to remember it in a descriptive way, as a syndrome of amenorrhea and anosmia.^{306, 307, 308 and 309} In the female, this problem is characterized by primary amenorrhea, infantile sexual development, low gonadotropins, a normal female karyotype, and the inability to perceive odors; e.g., coffee grounds or perfume. Often the affected individuals are not aware of their olfactory defect. The gonads can respond to gonadotropins, therefore induction of ovulation with exogenous gonadotropins is successful. However, clomiphene is ineffective.

Kallmann's syndrome is associated with a specific anatomic defect. Magnetic resonance imaging (as well as postmortem examination) demonstrates hypoplastic or absent olfactory sulci in the rhinencephalon.³¹⁰ This defect is a consequence of the failure of both olfactory axonal and GnRH neuronal migration from the olfactory placode in the nose. The cells that produce GnRH originate in the olfactory area and migrate during embryogenesis along fibers of the cranial nerve I complex (the terminal nerve) that connect the nose and the forebrain.³¹¹

Three modes of transmission have been documented: X-linked, autosomal dominant, and autosomal recessive.³¹² The 5–7-fold increased frequency in males indicates that X-linked transmission is the most common. X-linked Kallmann's syndrome can be associated with other disorders due to deletions or translocations of contiguous genes on the distal short arm of the X chromosome (such as X-linked short stature or ichthyosis and sulfatase deficiency).

The X-linked mutations (there is no consistent mutation) responsible for this syndrome involve a single gene (KAL) on the short arm of the X chromosome (at Xp22.3) that encodes a protein responsible for functions necessary for neuronal migration.^{313, 314 and 315} This protein has been named anosmin-1.³¹⁶ The syndrome of anosmia and amenorrhea associated with X-linked mutations results from the failure of this nerve complex to penetrate the forebrain, preventing the successful migration of GnRH neurons. Other neurologic abnormalities (mirror movements, hearing loss, cerebellar ataxia) can be present, suggesting more widespread neurologic defects. Renal and bone abnormalities, hearing deficit, color blindness, and cleft lip and palate (the most common associated abnormality) also occur in affected individuals, probably reflecting the fact that the gene is expressed in tissues other than the hypothalamus.³¹⁷ The syndrome occurs as an inherited or sporadic defect.

Molecular Explanations for Hypogonadotropic Amenorrhea

It is possible that patients with hypothalamic amenorrhea due to isolated deficiency of GnRH secretion (and no other abnormalities) have a defect similar to that of Kallmann's syndrome. With a lesser penetrance, only the GnRH migratory defect is expressed. In some individuals with amenorrhea and a normal sense of smell, family members can be identified with anosmia. Some patients with GnRH deficiency, but without anosmia, have an autosomal mode of transmission; however, a defect in the GnRH gene has not been commonly detected and X-linked mutations are uncommon.^{195, 312}

A brother and sister have been described with hypogonadotropic hypogonadism due to mutations of the GnRH receptor gene.³¹⁸ The parents and one sister were heterozygotes and normal; thus, the mutations were transmitted as an autosomal recessive trait. Screening 46 men and women with hypogonadotropic hypogonadism revealed the existence of an autosomally inherited GnRH gene receptor mutation in one of the 14 families with an affected female.³¹⁹ This mutation produces an interference in signal transduction resulting in resistance to GnRH stimulation. Thus this infrequent mutation causes hypogonadotropic amenorrhea that is not readily treated with GnRH, but response to exogenous gonadotropins is unimpaired. **Because most individuals with hypogonadotropic amenorrhea respond to GnRH, this genetic defect is not common, and worth pursuing only in patients who have family members with similar presentations.** This approach is supported by the failure to detect GnRH receptor gene deletions or rearrangements in patients with idiopathic hypogonadotropic hypogonadism.³²⁰

Adrenal Hypoplasia

Adrenal hypoplasia is an X-linked inherited disorder that results in adrenal insufficiency, and in survivors, hypogonadotropic hypogonadism.³²¹ This condition is caused by mutations in the DAX-1 gene, a gene that encodes a protein that is similar in structure to receptors that have no identified ligands (orphan receptors). These rare patients have both deficient secretion of GnRH and impaired response to GnRH.

Postpill Amenorrhea

In the past, it was assumed that secondary amenorrhea reflected persistent suppressive effects of oral contraceptive medication or the use of the intramuscular depot form of medroxyprogesterone acetate (Depo-Provera). It is now recognized that the fertility rate is normal following discontinuance of either of these forms of contraception ([Chapter 22](#)), and attempts to identify a cause-effect relationship in case-control studies have failed. Therefore, amenorrhea following the use of

steroids for contraception requires investigation as described in order to avoid missing a significant problem. This investigation should be pursued if a patient is amenorrheic 6 months after discontinuing oral contraception or 12 months after the last injection of Depo-Provera.

Hormone Therapy

The patient who is hypoestrogenic and who is not a candidate for induction of ovulation deserves hormone therapy. This includes patients appropriately evaluated and diagnosed as having gonadal failure, patients with hypothalamic amenorrhea, and postgonadectomy patients. The long-term impact of the hypoestrogenic state in terms of cardiovascular disease has long been recognized. To some degree, the beneficial impact of exercise on the lipoprotein profile is reversed by estrogen deficiency; however, athletes have high, exercise-induced levels of HDL-cholesterol, which should be cardioprotective. ^{322, 323}

We want to emphasize that the bone density in women is dependent on normal reproductive age levels of estrogen and progesterone. Even the most strenuous of exercise does not balance the consequences of hypoestrogenism on the bones, especially in adolescents. ^{324, 325, 326 and 327} The degree of bone loss is influenced by the specific athletic activity; e.g., gymnasts have a higher bone density than runners despite similar menstrual patterns and body fat. ³²⁸ In one study, ballet dancers were able to maintain bone density at weight-bearing sites, despite oligomenorrhea and reduced body weight, whereas another study found reduced bone mass in weight-bearing bones. ^{208, 329} It makes sense that different exercises have different osteogenic effects according to the mechanical forces generated. In addition, the effect of bone loss is greater in the spine because trabecular bone is more sensitive to the loss of estrogen. Whether specific individuals and activities are threatened with osteoporosis-related fractures later in life requires follow-up data that are not available at this point in time.

In the absence of estrogen, the normal response of bone to stress (to become stronger) is impaired. ³³⁰ The same arguments that apply to hormone treatment in older women ([Chapter 17](#) and [Chapter 18](#)) can be convincingly used to encourage these younger women to replace the estrogen they are lacking. The amenorrheic exerciser should be made aware that the hypoestrogenic state is associated with a greater risk of stress fractures. ^{331, 332, 333, 334, 335 and 336} Indeed, the loss of bone in amenorrheic athletes, with some exceptions as noted above, occurs at all skeletal sites that are weight bearing and subject to stress fractures. ³³⁷ Ballet dancers with delayed menarche are more prone to scoliosis as well as stress fractures. ³³⁵ It is not certain, however, whether this greater risk of stress fractures is influenced solely by bone density changes in that some studies fail to correlate fractures with reductions in bone density. ³³⁸ It should be noted that bone loss in amenorrheic women shows the same pattern over time as seen in postmenopausal women. ³³⁹ The loss is most rapid in the first few years, emphasizing the need for early treatment. The bone density increase in response to estrogen-progestin treatment of women with exercise-induced amenorrhea is impressive and worth achieving. ³⁴⁰ Long-term estrogen treatment of women with Turner syndrome effectively maintains bone density. ³⁴¹

It is worth emphasizing the importance of bone mineralization early in life. The subsequent risk of fracture from osteoporosis will depend upon bone mass at the time of menopause and the rate of bone loss following menopause. There is only a relatively narrow window of opportunity for acquiring bone mass. Almost all of the bone mass in the hip and the vertebral bodies will be accumulated by late adolescence (age 18), and the years following menarche (11–14) are especially important. ^{342, 343} The importance of a normal diet and normal hormonal support during adolescence cannot be overrated.

In patients with eating disorders, bone density correlates with body weight. ³⁴⁴ The response to hormone therapy will be impaired as long as an abnormal weight is maintained. ²⁶⁰ The failure to respond to estrogen treatment with an increase in bone density may be due to the adverse bone effects of the hypercortisolism associated with stress disorders. Furthermore, because the pubertal gain in bone density is so significant, individuals who fail to experience this adolescent increase may continue to have a deficit in bone mass despite hormone treatment. Reduced menstrual function for any reason early in life (even beyond adolescence) may leave a residual deficit in bone density that cannot be totally retrieved with resumption of menses or with hormone treatment. ^{345, 346} Interventions that improve diet and reduce overtraining can restore hormonal function, and even improve athletic performance (presumably because of better energy balance). ³⁴⁷

Several reports have indicated that patients with hyperprolactinemia are at risk for osteoporosis. At first this appeared not to be related to estrogen status, suggesting an independent effect of prolactin. Results have been confusing for several reasons. Controls in various studies were matched in different fashions; e.g., only for age, ignoring height and weight. Photon absorptiometry, the method of study in some reports, has a reduced sensitivity and significant variation when used to assess the axial skeleton. And finally, the estrogen status of the hyperprolactinemic patients was not always carefully quantified. It is now recognized that the bone density changes observed in hyperprolactinemic amenorrheic women are due to the hypoestrogenic state. ^{348, 349 and 350}

The standard program for estrogen therapy should be used. A good schedule is the following: 0.625 mg conjugated estrogens or 1 mg estradiol daily with 5 mg medroxyprogesterone acetate for two weeks every month. If the progestational agent is responsible for side effects, patients do well upon changing to 0.7 mg norethindrone. In a few individuals, the estrogen dosage may have to be increased in order to achieve menstrual bleeding. Whether a flow-provoking dose of estrogen is necessary for optimal protection of the bones has not been addressed in a clinical study. In patients who have not undergone pubertal development, a lower dose regimen should be used initially, as outlined in [Chapter 10](#). **Periodic measurements of bone density are worthwhile to assess adequacy of hormonal treatment and to provide evidence of lifestyle and dieting changes.**

Menstruation generally occurs 3 days after the last day of progestin medication. Bleeding that occurs at any time other than the usual expected time may be a sign that endogenous function has returned. The hormone treatment program should be discontinued and the patient monitored for the resumption of ovulation.

The importance of monthly menstruation to a young woman cannot be overemphasized. Regular and visible menstrual bleeding is often a gratifying experience in the young patient with gonadal dysgenesis and serves to reinforce her identification with the feminine gender role. On the other hand, serious exercisers (such as athletes and dancers) may want to avoid menstrual bleeding. One can provide hormone therapy to these women utilizing the daily combination approach: 0.625 mg conjugated estrogens and 2.5 mg medroxyprogesterone acetate or equivalent preparations given together every day without a break.

If for some reason, a hypoestrogenic woman refuses hormone treatment, supplemental calcium (1000–1500 mg daily) should be strongly encouraged. High calcium intake when combined with a high level of exercise is more effective in protecting the vertebral bone density than either exercise or calcium alone. ³⁵¹ Even patients receiving hormone therapy should be cautioned to maintain a normal intake of calcium and vitamin D, and this usually requires supplementing the teenage diet.

Patients with hypothalamic amenorrhea must be cautioned that hormone therapy will not protect against pregnancy in the event that normal function unknowingly returns. In the patient who desires effective contraception, it is reasonable to utilize a low-dose oral contraceptive to provide the missing estrogen. ³⁵² This is an excellent option in patients with premature ovarian failure because a spontaneous resumption of ovarian function can occur without warning. Athletes and others interested in avoiding menstruation can take oral contraceptives every day without a pill-free interval.

It is not enough to provide hormone therapy when disturbed menstrual function is secondary to psychobiologic stress responses. Appropriate support and counseling are necessary to help patients develop coping mechanisms other than extreme dieting and exercise. All available skills and resources should be utilized to promote healthy attitudes and healthy behaviors. The presence of amenorrhea in athletes and recreational exercisers should be regarded as a sign of negative energy balance, a condition requiring appropriate interventions.

[Chapter References](#)

Anovulation is a very common problem that presents in a variety of clinical manifestations, including amenorrhea, irregular menses, and hirsutism. Serious consequences of chronic anovulation are infertility and a greater risk for developing carcinoma of the endometrium and perhaps the breast. There is a new appreciation for the role of hyperinsulinemia in this condition and for the clinical effect of hyperinsulinemia and hyperandrogenism on the risks of developing cardiovascular disease and diabetes mellitus. The clinician must recognize the clinical impact of anovulation and undertake therapeutic management of all anovulatory patients to avoid these unwanted consequences. We cannot overemphasize the importance of a new attitude toward this common female problem. Concern for anovulation and the polycystic ovary is a legitimate component of modern preventive health care.

Normal ovulation requires coordination of the menstrual system at all levels: the central hypothalamic-pituitary axis, the feedback signals, and local responses within the ovary. The loss of ovulation can be due to any one of an assortment of factors operating at each of these levels. The end result is a dysfunctional state: anovulation and the polycystic ovary. In this chapter, we will discuss the variety of mechanisms by which dysfunction of the ovulatory cycle can occur and how the clinical expressions of the resulting abnormal menstrual function are produced.

Pathogenesis of Anovulation

Just before and during menses, escape from the negative feedback of estrogen, progesterone, and inhibin results in increased follicle-stimulating hormone (FSH) secretion by the anterior pituitary. This initial increase in FSH is essential for follicular growth and steroidogenesis. With continued growth of the follicle, autocrine/paracrine factors produced within the follicle maintain follicular sensitivity to FSH, allowing conversion from a microenvironment dominated by androgens to one dominated by estrogen, a change necessary for a complete and successful follicular lifespan. Continuing and combined action of FSH and activin leads to the appearance of luteinizing hormone (LH) receptors on the granulosa cells, a prerequisite for ovulation and luteinization. Ovulation is triggered by the rapid rise in circulating levels of estradiol. A positive feedback response at the level of the anterior pituitary (and perhaps at the hypothalamus as well) results in the midcycle surge of LH necessary for expulsion of the egg and formation of the corpus luteum. A rise in progesterone follows ovulation along with a second rise in estradiol, producing the 14-day luteal phase characterized by low FSH and LH levels. The demise of the corpus luteum, concomitant with a fall in hormone levels, allows FSH to increase again, thus initiating a new cycle.

In the early follicular phase, activin produced by granulosa in immature follicles enhances the action of FSH on aromatase activity and FSH and LH receptor formation, while simultaneously suppressing thecal androgen synthesis. In the late follicular phase, increased production of inhibin by the granulosa (and decreased activin) promotes androgen synthesis in the theca in response to LH and insulin-like growth factor-II (IGF-II) to provide substrate for even greater estrogen production in the granulosa. Refinements in assay techniques have revealed that inhibin B is the form of inhibin predominantly secreted by granulosa cells in the follicular phase of the cycle.¹ In the mature granulosa, activin serves to prevent premature luteinization and progesterone production.

The successful follicle is the one that acquires the highest level of aromatase activity and LH receptors in response to FSH. The successful follicle is characterized by the highest estrogen (for central feedback action) and the greatest inhibin production (for both local and central actions). This accomplishment occurs in synchrony with the appropriate activin and growth factor expression. The activin proteins (which enhance FSH activity) are produced in greatest amounts early in follicular development to enhance follicle receptivity to FSH.

The right concentration of androgens in granulosa cells promotes aromatase activity and inhibin production, and, in turn, inhibin promotes LH stimulation of thecal androgen synthesis. LH stimulation of androgen production in thecal cells is further enhanced by the autocrine activity of insulin-like growth factor. Evidence indicates that the endogenous insulin-like growth factor in the human ovarian follicle is IGF-II in both the granulosa and the thecal cells.² Studies indicating activity of IGF-I with human ovarian tissue can be explained by the fact that both IGF-I and IGF-II activities can be mediated by the type I IGF receptor, which is structurally similar to the insulin receptor. With development of the follicle, inhibin expression comes under control of LH. A key to successful ovulation and luteal function is conversion of the inhibin production to LH responsiveness, to maintain FSH suppression centrally and enhancement of LH action locally.

This recycling mechanism is regulated by substances functioning as classic hormones (FSH, LH, estradiol, and inhibin) transmitting messages between the ovary and the hypothalamic-pituitary axis, and autocrine/paracrine factors (IGF-II, inhibin, and activin, among others), which coordinate sequential activities within the follicle destined to ovulate. The negative feedback relationship between corpus luteum products (estradiol, progesterone, and inhibin) and FSH results in the critical initial rise in FSH during menses, and the positive feedback relationship between estradiol and LH is the ovulatory stimulus. Within the ovary, IGF-II, inhibin, and activin modify follicular receptor responses necessary for growth and function. Dysfunction in the cycle can be due to an abnormality in one of the various roles for any one of these substances or an inability to respond to signals.

Central Defects

The hypothalamic-pituitary axis may be unable to respond, even if given adequate and appropriately timed feedback signals. A pituitary tumor represents an obvious example of a central defect in menstrual function and is discussed in Chapter 11, [Amenorrhea](#).

Although difficult to demonstrate definitively, malfunction within the hypothalamus is both a likely, as well as a favorite, explanation for ovulatory failure. Normal pituitary ovulatory response to the follicle's steroid signals requires the presence of gonadotropin-releasing hormone (GnRH) pulsatile secretion within a critical range. The teenager between menarche and the onset of ovulation cannot generate a normal cycle until full GnRH pulsatile secretion is achieved. Increasing intensity of GnRH suppression is associated with increasing dysfunction and a changing clinical presentation. A variety of problems, such as stress and anxiety, borderline anorexia nervosa, and acute weight loss after a crash diet, is associated with an inhibition of normal GnRH pulsatile secretion. The mechanism for this suppression of GnRH is excessive hypothalamic activity of corticotropin-releasing hormone (CRH), a response to stress.³ These patients present more commonly with amenorrhea, as discussed in [Chapter 11](#). However if GnRH is only partially suppressed, homeostatic pituitary-ovarian function is maintained, and the patients will be anovulatory.⁴

At least one specific clinical syndrome of central anovulatory dysfunction has been recognized: hyperprolactinemia. Increasing levels of prolactin can cause a woman to progress through a spectrum, beginning with an inadequate luteal phase to anovulation to the amenorrhea associated with complete GnRH suppression. **A search for galactorrhea and measurement of the prolactin level are important screening procedures for all women who are not ovulating normally.** The presence of galactorrhea or elevated prolactin levels dictates a choice of dopamine agonist treatment for the induction of ovulation. Indeed, even in women with normal prolactin levels, long-term treatment with a dopamine agonist can reduce androgen levels and restore menstrual function, either through a direct central dopaminergic effect or because of further suppression of normal prolactin levels.⁷

Anovulatory women with polycystic ovaries have a higher LH (and presumably GnRH) pulse frequency and amplitude when compared to the normal midfollicular phase.⁸ Central opioid tone appears to be suppressed because there is no difference in response to naloxone.⁹ The enhanced pulsatile secretion of GnRH can be attributed to a reduction in hypothalamic opioid inhibition because of the chronic absence of progesterone.¹⁰ Interaction at the dopamine-endorphin sites may be altered because pretreatment with a dopamine precursor leads to a naloxone-induced increase in LH in anovulatory women compared with controls.

Abnormal Feedback Signals

Abnormal cycles can be due to failures within the system or due to the introduction of confounding factors. In order to achieve the appropriate changes within the cycle, estradiol levels must rise and fall in synchrony with morphologic events. Therefore, two possible signal failures may occur: 1) estradiol levels may not fall low enough to allow sufficient FSH response for the initial growth stimulus, and 2) levels of estradiol may be inadequate to produce the positive stimulatory effects necessary to induce the ovulatory surge of LH.

Loss of FSH Stimulation

In order to achieve recycling, a nadir in blood sex steroid levels must occur so that the initial event in the cycle, the rise in FSH, can take place. Sustained estrogen at such a key moment would not permit FSH stimulation of follicular growth and maturation, and recycling would be thwarted. The necessary decline in blood estrogen requires reduction of secretion, appropriate clearance and metabolism, and the absence of a significant contribution of estrogen to the circulation by extragonadal sources.

Persistent Estrogen Secretion. The most common clinical example of anovulation associated with continued secretion of sex steroids is pregnancy. Persistent and elevated secretion of estrogen can be encountered rarely with an ovarian or adrenal tumor. In such a case, anovulation or amenorrhea may bring the patient to a clinician's attention.

Abnormal Estrogen Clearance and Metabolism. The clearance and metabolism of estrogen can be impaired by other pathologic conditions, such as thyroid or hepatic disease. It is for this reason that a careful history and physical examination are important elements in the differential diagnosis of anovulation. Both hyperthyroidism and hypothyroidism can cause persistent anovulation by altering not only metabolic clearance but also the peripheral conversion rates among the various steroids. **The subtle presence of hypothyroidism, which may be associated with elevated prolactin levels, demands screening of anovulatory and amenorrheic women with a thyroid-stimulating hormone (TSH) level.**

Extraglandular Estrogen Production. Extragonadal contribution to the blood estrogen level can reach significant proportions. Although the adrenal gland does not secrete appreciable amounts of estrogen into the circulation, it indirectly contributes to the total estrogen level. This is accomplished by the extragonadal peripheral conversion of C-19 androgenic precursors, mainly androstenedione, to estrogen. In this manner, psychological or physical stress may increase the adrenal contribution of estrogenic precursor, and subsequent conversion to estrogen may sustain the blood level of estrogen at a time when a decline is necessary for successful recycling of the menstrual cycle. Adipose tissue is capable of converting androstenedione to estrogen; hence, the percent conversion increases with increasing body weight.¹¹ This is at least one mechanism for the well-known association between obesity and anovulation.

Loss of LH Stimulation

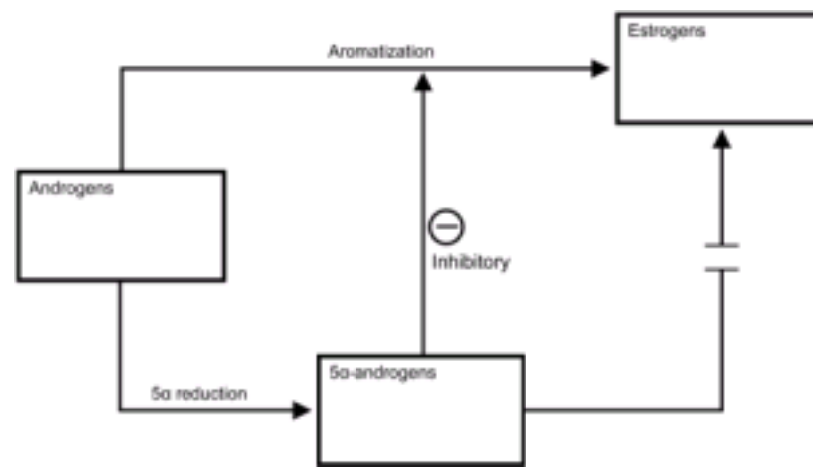

A failure in gonadal production of estrogen need not be absolute. Obviously, the patient with gonadal dysgenesis and ovarian failure will present with amenorrhea and infertility because of a total lack of estrogen secretion. More commonly, the clinician is concerned with the patient who has gonadotropin and estrogen production but does not ovulate. The failure to achieve a critical midcycle level of estradiol necessary to trigger the gonadotropin surge may be due to a relative deficiency in steroid production. The perimenopausal woman undergoes a terminal period of anovulation, which may represent steroidogenic refractoriness within the remaining elderly follicles. This inadequacy may be due to intrinsic follicular weaknesses or impairment in the follicular-gonadotropin interaction. In any case, the end result is the same—a failure to achieve critical signal levels of estradiol at the appropriate time in midcycle.

Local Ovarian Conditions

An understanding of the critical balances within the follicle indicates possible points of failure that may lead to anovulation. Local autocrine/paracrine factors prevent atresia despite declining FSH levels by enhancing the action of FSH in increasing the number of FSH receptors within the follicle, thus increasing follicular sensitivity to FSH. In addition, these factors enhance the induction of LH receptors by FSH, making it possible for the follicle to respond to the LH surge at midcycle. A follicle can fail to grow and ovulate because of inadequate expression or impaired function of any of the following local ovarian activities (described in detail in [Chapter 6](#)):

1. Selection of the dominant follicle is established during days 5–7, and consequently, peripheral levels of estradiol begin to rise significantly by cycle day 7.
2. Derived from the dominant follicle, estradiol levels increase steadily and, through negative feedback effects, exert a progressively greater suppressive influence on FSH release.
3. Insulin-like growth factor-II (IGF-II) is produced in theca cells in response to gonadotropin stimulation, and this response is enhanced by estradiol and growth hormone. In an autocrine action, IGF-II increases LH stimulation of androgen production in thecal cells.
4. IGF-II stimulates granulosa cell proliferation, aromatase activity, and progesterone synthesis.
5. FSH inhibits IGF binding protein synthesis and thus maximizes growth factor availability.
6. FSH stimulates inhibin and activin production by granulosa cells.
7. Activin augments FSH activities: FSH receptor expression, aromatization, inhibin/activin production, and LH receptor expression.
8. Inhibin enhances LH stimulation of androgen synthesis in the theca to provide substrate for aromatization to estrogen in the granulosa.
9. While directing a decline in FSH levels, the midfollicular rise in estradiol exerts a positive feedback influence on LH secretion. LH levels rise steadily during the late follicular phase, stimulating androgen production in the theca.
10. The positive action of estrogen also includes modification of the gonadotropin molecule, increasing the quality (the bioactivity) as well as the quantity of LH at midcycle.
11. Inhibin and, less importantly, follistatin, secreted by the granulosa cells in response to FSH, directly suppress pituitary FSH secretion.
12. FSH induces the appearance of LH receptors on granulosa cells.

The factors that control follicular growth and development are now understood in terms of the two-cell explanation described in [Chapter 2](#) and [Chapter 6](#). A very precise coordination is necessary between morphologic development and hormone stimulation. Perturbations may arise from an infectious process, from the presence of endometriosis, or by abnormal qualitative or quantitative changes in tropic hormone receptors (ovarian insensitivity), or the necessary biologic effects may be blocked by an improper molecular constitution of the gonadotropins (heterogeneity of the glycopeptide hormones).

A Critical Role for the Concentration of Androgens in the Ovarian Follicle

Serving as substrate for FSH-induced aromatization, the androgens in low concentrations enhance aromatase activity and estrogen production. At higher concentrations, the granulosa cells favor the conversion of androgens to more potent 5 α -reduced androgens, that cannot be converted to estrogen and, in addition, are capable of inhibiting aromatase activity and FSH induction of LH receptors (Chapter 6). Thus, raising the local androgen concentration above a critical level inhibits the emergence of a dominant follicle and leads to follicular atresia. Although this action in the normal cycle may be important in ensuring that only one follicle reaches the point of ovulation, an excessive concentration of androgens (no matter what the source) can prevent normal cycling and cause chronic anovulation.

Excess Body Weight

The frequency of obesity in women with anovulation and polycystic ovaries has been reported to be from 35% to 60%.^{12, 13, 14 and 15} Obesity is associated with three alterations that interfere with normal ovulation, and weight loss improves all three:

1. Increased peripheral aromatization of androgens to estrogens.
2. Decreased levels of sex hormone-binding globulin (SHBG), resulting in increased levels of free estradiol and testosterone.
3. Increased insulin levels that can stimulate ovarian stromal tissue production of androgens.

Precise Etiology

The normal ovulatory function of the menstrual system relies on a dynamic coordination of complex actions. Abnormal function may represent discordance at all of the levels reviewed in the above paragraphs. Thus, a minor deficiency in the estradiol signal will be associated with a subnormal central response and an impaired or inappropriate degree of follicular growth and function. Dysfunction is sustained by the internal feedback mechanisms within the system, and anovulation can become a persistent problem.

It is usually impossible to reduce the issue of etiology to a single factor of abnormal menstrual function, except in severe states such as pituitary tumors, anorexia nervosa, gonadal dysgenesis, and perhaps hyperprolactinemia and obesity. Not only is it often impossible, but it is usually unnecessary to define the precise etiology. Regardless of the nature of the initial cause of the problem, the final clinical statement of the dysfunction is predictable, and easily diagnosed and managed. In patients who have abnormal or absent menstrual function, but are otherwise medically normal, the diagnosis will fall into one of three categories:

1. Ovarian Failure. Hypergonadotropic hypogonadism, the inability of the ovary to respond to any gonadotropic stimulation, usually due to the absence of follicular tissue on a genetic basis (discussed in Chapter 11).
2. Central Failure. Hypogonadotropic hypogonadism, hypothalamic or pituitary suppression as expressed in abnormal low or normal serum gonadotropins (discussed in Chapter 11).
3. Anovulatory Dysfunction. The patient who has asynchronous gonadotropin and estrogen production and does not ovulate presents with a variety of clinical manifestations. The associated clinical signs and symptoms depend on the level of gonadal function preserved and are represented by the following principal problems:

- Amenorrhea (Chapter 11).
- Hirsutism (Chapter 13).
- Dysfunctional uterine bleeding (Chapter 15).
- Endometrial hyperplasia and cancer (Chapter 18).
- Breast disease (Chapter 16).
- Infertility and induction of ovulation (Chapter 30).
- The polycystic ovary (this chapter).

The Polycystic Ovary

In 1935, Irving F. Stein and Michael L. Leventhal first described a symptom complex associated with anovulation.¹⁶ Both gynecologists were born in Chicago, both were graduates of Rush Medical College, and both spent their entire professional careers at Michael Reese Hospital.¹⁷ Stein and Leventhal described 7 patients (4 of whom were obese) with amenorrhea, hirsutism, and enlarged, polycystic ovaries. They reported the results of bilateral wedge resection, removing one-half to three-fourths of each ovary; all 7 patients resumed regular menses, and 2 became pregnant. Stein and Leventhal developed the wedge resection after they observed that several of their amenorrheic patients menstruated after ovarian biopsies. They reasoned that the thickened tunic was preventing follicles from reaching the surface of the ovary.

Acceptance of this syndrome as a singular clinical entity led to a rather rigid approach to this problem for many years. Only those women qualified who had a history of oligomenorrhea, hirsutism, and obesity, together with a demonstration of enlarged, polycystic ovaries, a clinical state now recognized to be characteristic of extreme cases. It is far more useful clinically to avoid the use of eponyms and even the term polycystic ovary syndrome or disease. It is better to consider this problem as one of persistent anovulation with a spectrum of etiologies and clinical manifestations, that now includes insulin resistance and hyperinsulinemia, as well as hyperandrogenism. Of course, specific conditions must be pursued and excluded, such as adrenal hyperplasia, Cushing's syndrome, hyperprolactinemia, and androgen-producing tumors.

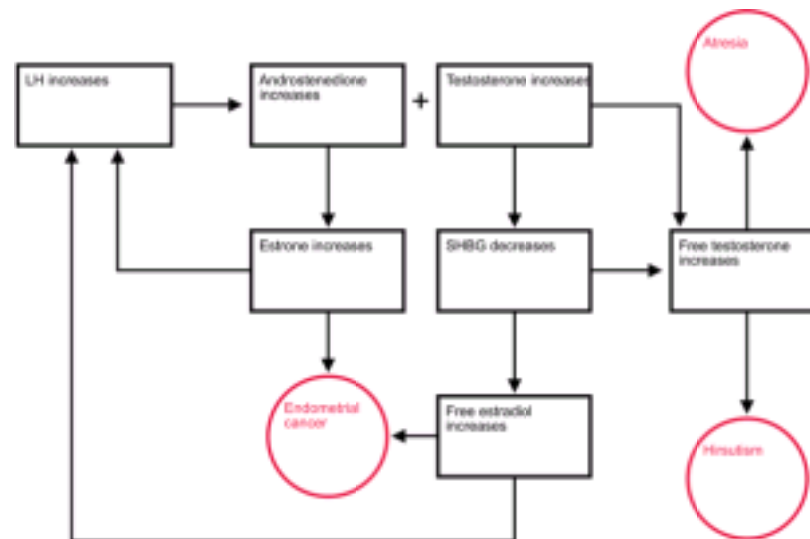

A question that has puzzled gynecologists and endocrinologists for many years is what causes polycystic ovaries. There is an answer that is appealing in its logic and clinical applicability. **The characteristic polycystic ovary emerges when a state of anovulation persists for any length of time.** Whether diagnosis is by ultrasonography or by the traditional clinical and biochemical criteria, a cross section of anovulatory women at any one point of time will reveal that approximately 75% will have polycystic ovaries.^{15, 18} Because there are many causes of anovulation, there are many causes of polycystic ovaries. A similar clinical picture and ovarian condition can reflect any of the dysfunctional states discussed above. In other words, the polycystic ovary is the result of a functional derangement, not a specific central or local defect.

Insistence on a specific endocrine or clinical criterion for the diagnosis of the polycystic ovary syndrome results in the inclusion of a collection of patients that represents a focused segment isolated from the broad clinical spectrum in which these patients really belong. This especially applies to the use of ultrasonography to make the diagnosis of the polycystic ovary syndrome (the presence of an increased number of ovarian follicles, often in a necklace-like pattern, and an increase in ovarian volume, largely due to an increase in stroma). From 8% to 25% of normal women will demonstrate ultrasonographic findings typical of polycystic ovaries! ^{19, 20, 21 and 22} Even 14% of women on oral contraceptives have been found to have this ultrasonographic picture. ²⁰ Ultrasonography as a diagnostic tool for this condition is unnecessary, and we vigorously discourage its use for this purpose. Magnetic resonance studies further confirm the unreliability of the imaging finding presumed to be diagnostic of this condition. ²³

It is argued that normally ovulating women with polycystic ovaries on ultrasonography have underlying metabolic abnormalities. ^{14, 19} However, the great majority of ovulatory women with polycystic ovaries on ultrasonography are endocrinologically normal, and only occasionally is an androgen level minimally elevated. ²⁴ We are not convinced that such subtle changes are of clinical importance. Even if this argument were correct and a basic disorder is present, but homeostatic adjustments allow the maintenance of normal physiologic mechanisms and there are no clinical consequences, it is hard to justify medical interventions.

In contrast to the characteristic picture of fluctuating hormone levels in the normal cycle, a “steady state” of gonadotropins and sex steroids can be depicted in association with persistent anovulation. This steady state is only relative, and is being exaggerated in the diagram to present a concept of this clinical problem. In patients with persistent anovulation, the average daily production of estrogen and androgens is both increased and dependent on LH stimulation. ^{25, 26} This is reflected in higher circulating levels of testosterone, androstenedione, dehydroepiandrosterone (DHA), dehydroepiandrosterone sulfate (DHAS), 17-hydroxyprogesterone (17-OHP), and estrone. ²⁷ The testosterone, androstenedione, and DHA are secreted directly by the ovary, whereas the DHAS, elevated in about 50% of anovulatory women with polycystic ovaries, is almost exclusively an adrenal contribution. ^{28, 29}

Treatment of women with polycystic ovaries with a GnRH agonist (to produce a hypogonadotropic hypogonadal state) is associated with the following helpful observations: ^{25, 30, 31}

1. The increases in androstenedione and testosterone are almost exclusively from the ovary.
2. The increase in 17-OHP is also from the ovary.
3. Secretion of DHA, DHAS, and cortisol are not influenced by short-term GnRH agonist treatment; however, long-term treatment is associated with a decrease in DHAS in some but not all women with polycystic ovaries. ^{30, 31} It is suggested that increased adrenal androgen production in some women is secondary to P450c17 17,20 lyase hyperactivity, and in others it is an acquired response due to the anovulatory hormonal steady state. ^{31, 32}

The ovary does not secrete increased amounts of estrogen, and estradiol levels are equivalent to early follicular phase concentrations. ³³ Circulating estrone levels are slightly elevated. The increased total estrogen is due to peripheral conversion of the increased amounts of androstenedione to estrone. That is not to say that there is no ovarian secretion of estrogen. Both estrone and estradiol continue to be secreted in significant, although low, amounts. ³⁴

When compared with levels found in normal women, patients with persistent anovulation have higher mean concentrations of LH, but low or low-normal levels of FSH. ^{35, 36} The elevated LH levels are partly due to an increased sensitivity of the pituitary to releasing hormone stimulation, manifested by an increase in LH pulse amplitude and frequency, but mainly amplitude. ^{33, 37, 38} This is consistent with the concepts discussed in Chapter 5, linking a high estrogen environment with anterior pituitary secretion of LH and suppression of FSH. It is noteworthy that this high level of LH is characterized by an increased level of LH bioactivity. ^{26, 37}

The gonadotropin pattern (high LH and low FSH) can also be due to increased frequency of GnRH pulsatile secretion. ^{38, 39} Central opioid tone appears to be suppressed because there is no difference in response to naloxone. ⁹ Indeed, the enhanced pulsatile secretion of GnRH can be attributed to a reduction in hypothalamic opioid inhibition because of the chronic absence of progesterone. ^{10, 40} This is associated with an increase in amplitude and frequency of LH secretion that is correlated with the level of circulating estrogen. ⁴¹ It is likely that this increased activity is taking place at both hypothalamic and pituitary sites. This altered state is also associated with a change in the circadian pattern with the highest LH values occurring in late afternoon rather than at night. ³³

The increase in LH pulse frequency and pituitary response to GnRH are characteristic of the anovulatory state, and are independent of obesity. ⁴² Obesity attenuates the LH response to GnRH, and LH pulse amplitude is relatively normal in overweight women with polycystic ovaries, although the increase in pulse frequency is maintained. ^{43, 44} The overall LH reduction may be a direct effect of the greater hyperandrogenism in obese women. ^{45, 46}

The increased pituitary and hypothalamic sensitivity can be attributed to the increased estrone levels, ⁴⁷ but an important contributing factor is the impact of the decreased SHBG concentration. The levels of sex hormone-binding globulin (SHBG) are controlled by a balance of hormonal influences on its synthesis in the liver; testosterone is inhibitory, estrogen and thyroxine are stimulatory. In anovulatory women with polycystic ovaries, there is an approximately 50% reduction in circulating levels of SHBG, a response to the increased testosterone, and in patients with hyperinsulinemia, due to a direct insulin effect on the liver (discussed later in this chapter). Despite no increase in estradiol secretion, free estradiol levels are increased because of the significant decrease in SHBG. The clinical consequences of uninterrupted estrogen stimulation (endometrial and perhaps breast cancer) as well as the increased LH are the result of the two estrogenic influences, estrone and free estradiol.

The increased LH secretion as expressed by the LH:FSH ratio is positively correlated with the increased free estradiol. ^{35, 48} The lower FSH levels represent the sensitivity of the FSH negative feedback system to the elevated estrogen, both free estradiol and the estrone formed from peripheral conversion of androstenedione. In addition, the altered pattern of GnRH secretion can contribute to this characteristic LH:FSH ratio. ³⁹ There is no evidence to support a role for inhibin suppression of FSH. ^{49, 50} In fact, consistent with impaired granulosa cell function, inhibin production in granulosa cells from polycystic ovaries is reduced. ^{51, 52} However, it is possible that these early findings with inhibin reflect the lack of precision associated with the first immunoassays. A sensitive assay for inhibin B has detected high levels in women with polycystic ovaries, suggesting that multiple small follicles can suppress FSH levels by increasing the circulating levels of inhibin B. ⁵³

Because the FSH levels are not totally depressed, new follicular growth is continuously stimulated, but not to the point of full maturation and ovulation. ⁵⁴ Despite the fact that full growth potential is not realized, follicular lifespan may extend several months in the form of multiple follicular cysts, 2–10 mm in diameter (some can be as large as 15 mm). These follicles are surrounded by hyperplastic theca cells, often luteinized in response to the high LH levels. The accumulation of follicular tissue in various stages of development allows an increased and relatively constant production of steroids in response to the gonadotropin stimulation. This condition is self-sustaining. As various follicles undergo atresia, they are immediately replaced by new follicles of similar limited growth potential.

The tissue derived from follicular atresia is also sustained by the steady state and now contributes to the stromal compartment of the ovary. In terms of the two-cell explanation of follicular steroidogenesis, atresia is associated with a degenerating granulosa, leaving the theca cells to contribute to the stromal compartment of the ovary. It is not surprising, therefore, that this functioning stromal tissue secretes significant amounts of androstenedione and testosterone, the usual products of theca

cells. In response to the elevated LH levels, the androgen production rate is increased. In turn, in a vicious cycle, the elevated androgen levels compound the problem through the process of extraglandular conversion as well as the suppression of SHBG synthesis, resulting in elevated estrogen levels. In addition, the decrease in SHBG is associated with a two-fold increase in free testosterone.

The elevated androgens contribute to the morphologic effect within the ovary preventing normal follicular development and inducing premature atresia. Indeed, in another aspect of the vicious cycle, the local androgen block is a major obstacle that maintains the steady state of persistent anovulation. When ovarian androgen concentrations are high, they can be converted to 5 α -reduced metabolites that inhibit aromatase activity and estrogen production.⁵⁵ A sustained reduction in androgen levels following surgical wedge resection of the ovaries precedes the return of ovulatory cycles, indicating that the intraovarian androgen effect is a principal factor in preventing normal cycling.^{56, 57, 58 and 59} The success of wedge resection is directly proportional to the volume of androgen-producing tissue removed. Tissue removal and destruction are the key factors, not the shape and procedure of the "wedge." Indeed, even a unilateral oophorectomy is followed by resumption of ovulation in anovulatory women with polycystic ovaries.⁶⁰

This is further supported by the results of treatment with flutamide, an antiandrogen at the receptor level. In 8 young anovulatory, hirsute women with polycystic ovaries, treatment with flutamide restored ovulation in every subject.⁶¹ In addition, testosterone can have a direct inhibitory action on the hypothalamic-pituitary axis.⁶²

In this manner, the classic picture of the polycystic ovary is attained, displaying numerous follicles in the early stages of development and atresia and dense stromal tissue. The loss of recycling has resulted in a hormonal steady state causing persistent anovulation that can be associated with an increase in the production of androgens and the bioavailability of estrogen.

The polycystic ovary is the result of a "vicious cycle," which can be initiated at any one of many entry points. Altered function at any point in the cycle leads to the same result: the polycystic ovary. Recent studies, in an effort to be accurate, have usually included only patients fulfilling strict criteria. Thus, only certain subgroups of a large heterogeneous clinical population have been characterized. **Don't lose sight of the fact that the polycystic ovary is a sign, not a disease.**

The polycystic ovary is usually enlarged and is characterized by a smooth pearly white capsule. For years, it was erroneously believed that the thick sclerotic capsule acted as a mechanical barrier to ovulation. A more accurate concept is that the polycystic ovary is a consequence of the loss of ovulation and the achievement of the steady state of persistent anovulation. The characteristics of the ovary reflect this dysfunctional state:⁶³

1. The surface area is doubled, giving an average volume increase of 2.8 times.
2. The same number of primordial follicles is present, but the number of growing and atretic follicles is doubled. Each ovary may contain 20–100 cystic follicles.
3. The thickness of the tunica (outermost layer) is increased by 50%.
4. A one-third increase in cortical stromal thickness and a 5-fold increase in subcortical stroma are noted. The increased stroma is due both to hyperplasia of thecal cells and to increased formation subsequent to the excessive follicular maturation and atresia.
5. There are 4 times more ovarian hilus cell nests (hyperplasia).

Hyperthecosis refers to patches of luteinized theca-like cells scattered throughout the ovarian stroma. It is characterized by the same histologic findings as seen in polycystic ovaries.⁶⁴ The clinical picture of more intense androgenization is a result of greater androgen production. This condition is associated with lower LH levels, which is a possible consequence of the higher testosterone levels blocking estrogen action at the hypothalamic-pituitary level.^{45, 46} It seems appropriate to view hyperthecosis as a manifestation of the same process, persistent anovulation, but with greater intensity. A greater degree of insulin resistance is correlated with the degree of hyperthecosis.⁴⁶ And in turn, because insulin and IGF-I stimulate proliferation of thecal interstitial cells, hyperinsulinemia may be an important incitement toward hyperthecosis.⁶⁵

The typical histologic changes of the polycystic ovary can be encountered with any size ovary. There is a spectrum of time involved in the development of this condition, and it is useful to view the attainment of large ovaries as a stage of maximal effect of persistent anovulation. Increased size of the ovaries is not a critical feature, nor is it necessary for diagnosis. The key to understanding this clinical problem is an appreciation for the disruption in ovulatory recycling function.

There is no specific pathophysiologic defect. The hypothalamic-pituitary response is entirely appropriate, a response to chronically elevated estrogen feedback. The changes are a functional derangement brought about by accumulated and increased androgen due to a failure of ovulation, whatever the reason. Hence, the polycystic ovary may be associated with extragonadal sources of androgens,^{66, 67} or with ovarian androgen-producing tumors,^{68, 69} and even with the administration of exogenous androgens to female-to-male transsexuals.⁷⁰

The functional problem can be understood in terms of the two-cell explanation of steroidogenesis ([Chapter 6](#)). The follicles are unable to successfully change their microenvironment from androgen dominance to estrogen dominance, the change that is essential for continued follicular growth and development.⁷¹ Measurement of the insulin-like growth factor binding proteins (IGFBPs) in follicular fluid reveals that the profile in polycystic ovaries is the same as that found in atretic follicles, higher levels of IGFBP-2 and -4.^{72, 73} This is consistent with limitation of IGF-I and IGF-II activity, reducing the expression of aromatase action and allowing androgenic dominance in the microenvironment. However, there is a striking difference comparing polycystic granulosa cells with granulosa cells from atretic follicles. Granulosa cells from polycystic ovaries are very sensitive to FSH; granulosa cells from atretic follicles are not.⁷⁴ Thus, the granulosa cells from the follicles in polycystic ovaries are not apoptotic (atretic), but simply arrested in development, and capable of responding to FSH stimulation.^{75, 76}

The functional picture that emerges (arrested granulosa cells and very active theca cells) corresponds to the morphologic histology of underdeveloped granulosa and hyperplastic and luteinized theca. Granulosa cells obtained from the small follicles of polycystic ovaries produce negligible amounts of estradiol but show a dramatic increase in estrogen production when FSH or IGF-I is added and a synergistic action when FSH and IGF-I are added together.^{77, 78} In terms of the two-cell explanation, this behavior is consistent with a blockage of FSH response (probably through various growth factors), not an intrinsic steroid synthesis enzyme defect. Successful treatment depends, therefore, on altering the ratio of FSH to androgens; either increasing FSH (with clomiphene) or decreasing androgens (wedge resection) to overcome the androgen block at the granulosa level. This permits development of aromatization to bring about conversion of the microenvironment to estrogen dominance. Because anovulation with polycystic ovaries is a functional derangement, it is not surprising that these patients occasionally may ovulate spontaneously. Indeed, ovulation is unpredictable, and contraception may be necessary.

Genetic Considerations

The familial clustering of anovulation and polycystic ovaries suggests an underlying genetic basis.^{79, 80 and 81} At least one group of patients with this condition has been described inheriting the disorder, possibly by means of an X-linked dominant transmission. There was a two-fold higher incidence of hirsutism and oligomenorrhea with paternal transmission but with marked variability of phenotypic expression.⁸² On the other hand, studies of large families suggested inheritance in an autosomal dominant fashion, with premature balding as the phenotype in males.^{83, 250} The strong link between hyperinsulinemia and hyperandrogenism also suggests that the stimulatory effect of insulin on ovarian androgen production is influenced by a genetic predisposition or susceptibility. Family members of women with anovulation, hyperandrogenism, and polycystic ovaries have an increased incidence of hyperinsulinemia in females and premature baldness in males.⁸⁴ Initial searches for genes that are associated with a susceptibility to anovulation and polycystic ovaries have implicated a locus on the insulin gene and the gene encoding P450scc (*CYP11a*), but not the gene encoding P450c17a (*CYP17*).^{85, 86} **These studies imply an autosomal dominant mode of inheritance, directing clinicians to counsel families that theoretically 50% of mothers and sisters within a family can manifest this disorder.** The actual expression is less (perhaps 40%) due to modification by both genetic and environmental factors.

P450c17 Dysregulation

A popular hypothesis in the 1990s explained this ovarian hyperandrogenic state as a consequence of an enzymatic dysregulation, specifically of P450c17, the enzyme responsible for both 17 α -hydroxylase and 17,20-lyase activities.⁸⁷ Abnormal hyperactivity of this enzyme would account for the altered steroidogenesis in both the ovaries and the adrenal glands. Indeed, the adrenal gland is involved in this clinical problem. Higher circulating levels of DHAS, almost exclusively an adrenal product, testify to adrenal participation. The mechanism and the clinical importance of this involvement will be further discussed in [Chapter 13](#), Hirsutism. It is difficult, if not impossible, to know whether abnormal enzyme activity comes first or is a reflection of the anovulatory dysfunctional state. Indeed, in 92 consecutive women with hirsutism, the steroidogenic response to ACTH stimulation was not consistent with an inherent disorder in P450c17.⁸⁸ Testing both ovarian and adrenal responses to stimulation fails to delineate a clear-cut or characteristic disorder of P450c17.⁸⁹ Genetic screening of anovulatory women with polycystic ovaries has not

detected sequence variations in the promoter or coding regions of the P450c17 gene.⁹⁰ In our view, a more straight forward and clinically manageable concept is to consider enzyme changes as secondary to the dysfunctional state.

Insulin Resistance, Hyperinsulinemia, and Hyperandrogenism

The first recognition of an association between glucose intolerance and hyperandrogenism was the famous report of the bearded diabetic woman by Archard and Thiers in 1921.⁹¹ The association between increased insulin resistance and polycystic ovaries is now well recognized. This clinical association of hyperinsulinemia and anovulatory hyperandrogenism is commonly found throughout the world and among different ethnic groups.^{92, 93 and 94} In addition, hyperandrogenism and insulin resistance are often associated with acanthosis nigricans.⁹⁵ Acanthosis nigricans is a gray—brown velvety, sometimes verrucous, discoloration of the skin, usually at the neck, groin, axillae, and under the breasts, which is a marker for insulin resistance. Hyperkeratosis and papillomatosis are the histological characteristics of acanthosis nigricans. The presence of acanthosis nigricans in hyperandrogenic women is dependent on the presence and severity of hyperinsulinemia.⁹⁶ It is most highly correlated with the magnitude of peripheral insulin resistance and less well with the hyperinsulinemia measured by a glucose tolerance test. The mechanism responsible for the development of acanthosis nigricans is uncertain. Conflicting studies suggest mediation through various growth factor receptors, not just insulin or insulin-like growth factor. Because acanthosis nigricans can be present in normal women, its presence is not an absolute marker for hyperandrogenism and hyperinsulinemia.

Insulin resistance is defined as a reduced glucose response to a given amount of insulin. Resistance to insulin-stimulated glucose uptake is a relatively common phenomenon, sometimes referred to as syndrome X.⁹⁷ The majority of patients with noninsulin-dependent diabetes mellitus have peripheral insulin resistance, but not all women who are insulin resistant are hyperandrogenic. The state of chronic hyperinsulinemia represents a compensatory response to the target tissue problem. These relationships involve changes in plasma free fatty acid concentrations. If the insulin levels necessary to suppress free fatty acid levels cannot be achieved, then the increase in free fatty acids leads to increased hepatic glucose production and hyperglycemia.

There are several mechanisms for the state of insulin resistance: peripheral target tissue resistance, decreased hepatic clearance, or increased pancreatic sensitivity.⁹⁸ The **euglycemic clamp technique** establishes a steady state of hyperinsulinemia with a normal glucose level at which point the glucose infusion rate equals glucose utilization. Adding insulin will measure the glucose uptake rate (the more insulin required, the greater the peripheral resistance, also referred to as a measure of **insulin sensitivity**). Studies with this technique indicate that hyperandrogenic women with hyperinsulinemia have peripheral insulin resistance and, in addition, a reduction in the insulin clearance rate due to decreased hepatic insulin extraction.^{98, 99}

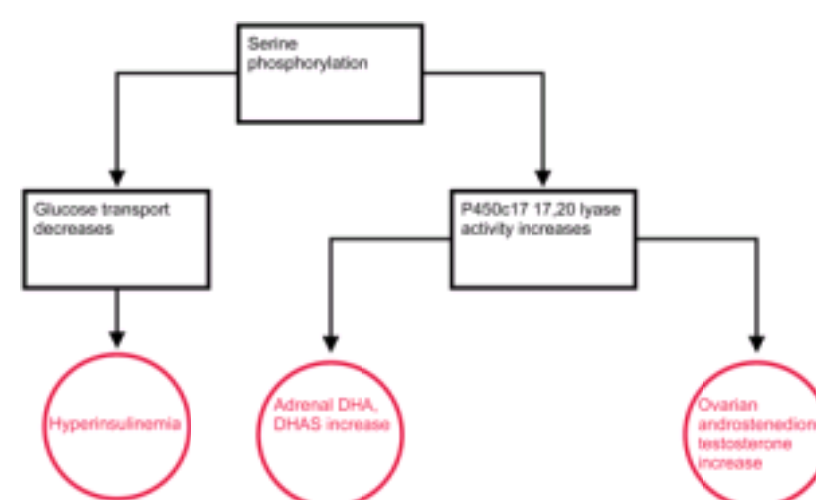

The clinical presentation of patients with insulin resistance (whether they have impaired glucose tolerance or diabetes mellitus) depends on the ability of the pancreas to compensate for the target tissue resistance to insulin. At first, compensation is effective, and the only metabolic abnormality is hyperinsulinemia. In many patients, the beta cells of the pancreas eventually fail to meet the challenge, and declining insulin levels lead to impaired glucose tolerance and type II noninsulin-dependent diabetes mellitus. Indeed, beta cell dysfunction can be detected in women with polycystic ovaries even before the appearance of glucose intolerance.¹⁰⁰

Hyperinsulinemia leads to hypertension and an increased risk of coronary heart disease; a direct relationship exists between plasma insulin levels and blood pressure.¹⁰¹ Resistance to insulin is further associated with increased triglycerides and decreased HDL-cholesterol levels, a potent bad combination that promotes coronary heart disease.¹⁰² Although the adverse lipid effect is present in anovulatory women with polycystic ovaries, hypertension is not encountered in these women until later in life, not in their reproductive years.^{103, 104 and 105}

Hyperinsulinemia and polycystic ovaries are also associated with an increased production of plasminogen activator inhibitor type 1 (PAI-1).^{105, 106} Increased PAI-1 levels are correlated with an increased risk of coronary heart disease; impaired fibrinolysis may affect vascular tissue changes associated with vascular disease.

There are rare causes of hyperinsulinemia and hyperandrogenism that are congenital in origin. Peripheral insulin resistance associated with hyperandrogenism and acanthosis nigricans, known as “type A syndrome,” can be due to mutations of the insulin receptor gene (which leads to decreased numbers of insulin receptors in target tissues).¹⁰⁷ Leprechaunism is a rare syndrome in young girls with a mutation in the insulin receptor gene and perhaps defects in growth factor receptors; it is associated with severe insulin resistance, polycystic ovaries, hyperandrogenism, and acanthosis nigricans.¹⁰⁸ Another subgroup, “type B syndrome,” consists of patients with autoantibodies to insulin receptors. This leaves a large collection of women with neither reduced nor abnormal insulin receptors nor autoantibodies, the most common clinical entity encountered, anovulatory women with hyperandrogenism and hyperinsulinemia. Possible mechanisms for the hyperinsulinemia include functional problems in the insulin receptor (which could also be a consequence of insulin receptor gene mutations) and inhibitors, which can interfere with insulin-receptor function after binding.¹⁰⁹ Thus, there are at least 3 categories for peripheral target tissue insulin resistance: decreased insulin receptor numbers, decreased insulin binding, and post receptor failures.

There is experimental evidence to indicate that in women with polycystic ovaries, the peripheral insulin resistance is due to a defect beyond activation of the receptor kinase, specifically leading to reduced tyrosine autophosphorylation of the insulin receptor.^{110, 111} The phosphorylation of serine and threonine residues on the insulin receptor reduces signal transmission, and excessive serine phosphorylation (by a mechanism extrinsic to the insulin receptor) has been demonstrated as a possible postreceptor defect in these patients, changing signal transduction.¹¹¹ It has been suggested that serine phosphorylation of the beta chain of the insulin receptor and at the same time of the adrenal and ovarian P450c17 enzyme (the origin or cause of serine phosphorylation is uncertain, but presumably it would have a genetic basis) would explain both the hyperinsulinemia and hyperandrogenism (serine phosphorylation increases and dephosphorylation decreases 17,20-lyase activity and androgen production).³² Stated simply, serine instead of tyrosine phosphorylation is an “off” mechanism for glucose transport, but an “on” mechanism for P450c17 enzyme activity.

This change in phosphorylation would be consistent with no abnormality in the number of receptors or in receptor function; the impaired insulin signal for glucose transport would be due to a postreceptor problem. Indeed, structural defects in the insulin receptor cannot be identified.^{112, 113} Of course, different patients with the same clinical presentation may have different reasons for the insulin resistance, a spectrum of etiologies with a common clinical expression. The defect in insulin action is limited to glucose metabolism; other biologic actions of insulin are not impaired.

Because of the tight connection between insulin and leptin levels in mice, and the now well-recognized prevalence of hyperinsulinemia in women with polycystic ovaries, it makes sense to examine leptin levels in these women. Although an initial study reported increased leptin levels in women with polycystic ovaries, the study was criticized for not adjusting for body weight.¹¹⁴ At least 4 studies, controlling for weight, have detected no differences in leptin levels comparing women with and without polycystic ovaries.^{115, 116, 117 and 118} In women with polycystic ovaries, the relationship between leptin and body weight is maintained. Thus, in contrast to the rodent model, hyperinsulinemia and insulin resistance do not affect leptin levels in these women.

However, a role for leptin in the changes associated with polycystic ovaries should not yet be discounted. There may be subtle differences that have biologic consequences. At least one study demonstrated a correlation between leptin levels and 24-hour insulin levels in women with polycystic ovaries.¹¹⁵ Furthermore, a drug that lowers insulin resistance, troglitazone, inhibits transcription of the leptin gene and may be especially suited for obese women with polycystic ovaries.¹¹⁹

Is the Link Between Hyperinsulinemia and Hyperandrogenism Explained Solely by the Presence of Obesity in Hyperandrogenic Patients?

Overweight, anovulatory women with hyperandrogenism have a characteristic distribution of body fat known as android obesity.^{120, 121 and 122} Android obesity is the result of fat deposited in the abdominal wall and visceral mesenteric locations. This fat is more sensitive to catecholamines, less sensitive to insulin, and more active metabolically. This fat distribution is associated with hyperinsulinemia, impaired glucose tolerance, diabetes mellitus, and an increase in androgen production rates resulting in decreased levels of sex hormone-binding globulin and increased levels of free testosterone and estradiol.^{120, 121 and 122}

Central body (android) obesity is associated with cardiovascular risk factors, including hypertension and unfavorable cholesterol-lipoprotein profiles.¹²³ The waist:hip ratio is the variable most strongly and inversely associated with the level of HDL₂, the fraction of HDL-cholesterol most consistently linked with protection from cardiovascular disease.¹²⁴ A waist:hip ratio greater than 0.85 indicates android fat distribution. The adverse impact of excess weight in adolescence can be explained by the fact that deposition of fat in adolescence is largely central in location.^{125, 126} Weight loss in women with lower body obesity is mainly cosmetic, whereas loss of central body weight is more important for general health because an improvement in cardiovascular risk is associated with loss of central body fat.

Hyperinsulinemia and hyperandrogenism, however, are not confined to anovulatory women who are overweight. It is important to note that the combination of increased androgen secretion and insulin resistance has been reported in both obese and nonobese anovulatory women.^{42, 127, 128, 129 and 130} However, insulin levels are higher and LH, SHBG, and IGFBP-1 levels are lower in obese women with polycystic ovaries compared to nonobese women with polycystic ovaries.^{42, 131, 132} For this reason, some have suggested that hyperandrogenic women with polycystic ovaries could be divided into two groups: those with obesity, insulin resistance, hyperinsulinemia, and normal or minimally elevated LH levels; and those with elevated LH, no insulin resistance, and normal insulin levels.^{133, 134} In our view, these two groups represent the ends of a spectrum, and division of this clinically broad spectrum of patients is artificial and unhelpful.

Hyperinsulinemia and hyperandrogenism are not explained, therefore, solely by obesity, and specifically, android obesity. **However, the presence of obesity adds the insulin resistance and hyperinsulinemia associated with obesity to that which is specifically unique to the anovulatory, polycystic ovary state.**^{42, 135, 136}

Which Comes First, the Hyperinsulinemia or the Hyperandrogenism?

There are studies indicating that androgens can induce hyperinsulinemia. However, most of the evidence supports hyperinsulinemia as the primary factor, especially the experiments in which turning off the ovary with a GnRH agonist does not change the hyperinsulinemia or insulin resistance.^{98, 137, 138 and 139} This indicates that disordered insulin action precedes the increase in androgens. Large doses of insulin were administered to a 16-year-old female with insulin resistance secondary to insulin receptor autoantibodies; the increased insulin levels increased her circulating testosterone levels.¹⁴⁰ With resolution of her insulin resistance, her testosterone levels returned to normal, indicating that the hyperinsulinemia stimulates and increases testosterone and not vice versa. Indeed, there are 6 reasons to believe that hyperinsulinism causes hyperandrogenism:

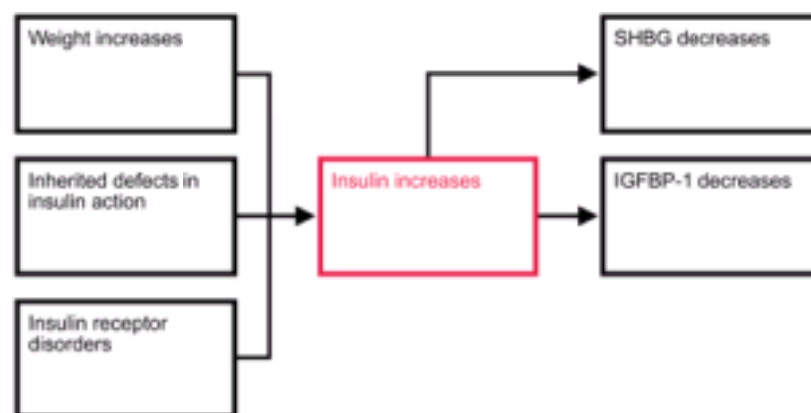

1. The administration of insulin to women with polycystic ovaries increases circulating androgen levels.¹⁴¹
2. The administration of glucose to hyperandrogenic women increases the circulating levels of both insulin and androgens.¹⁴²
3. Weight loss decreases the levels of both insulin and androgens, and increases the levels of IGFBP-1.¹⁴³
4. In vitro, insulin stimulates thecal cell androgen production.^{144, 145}
5. The experimental reduction of insulin levels in women reduces androgen levels in women with polycystic ovaries, but not in normal women.¹⁴⁶
6. After normalization of androgens with GnRH agonist treatment, the hyperinsulin response to glucose tolerance testing remains abnormal in obese women with polycystic ovaries.^{139, 147}

Nevertheless, antiandrogen treatment and prolonged androgen suppression can ameliorate the degree of insulin resistance.^{148, 149} However, the effect is not great, and may be limited to lean patients with mild hyperinsulinemia.

How Does Hyperinsulinemia Produce Hyperandrogenism?

There is an impressive correlation between the degree of hyperinsulinemia and hyperandrogenism.^{127, 129, 130} At higher concentrations, insulin binds to the type I IGF receptors (which are similar in structure to insulin receptors; both IGF and insulin transmit their signals by initiating tyrosine autophosphorylation of their receptors). Thus, when insulin receptors are blocked or deficient in number, it is to be expected that insulin would bind to the type I IGF receptors.¹⁵⁰ In view of the known actions of IGF-I in augmenting the thecal androgen response to LH, activation of IGF-I receptors by insulin would lead to increased androgen production in thecal cells.¹⁵¹ **It should be noted that evidence indicates that the endogenous insulin-like growth factor in the human ovarian follicle is IGF-II in both the granulosa and the thecal cells.**² **Studies indicating activity of IGF-I with human ovarian tissue can be explained by the fact that both IGF-I and IGF-II activities can be mediated by the type I IGF receptor, which is structurally similar to the insulin receptor.**

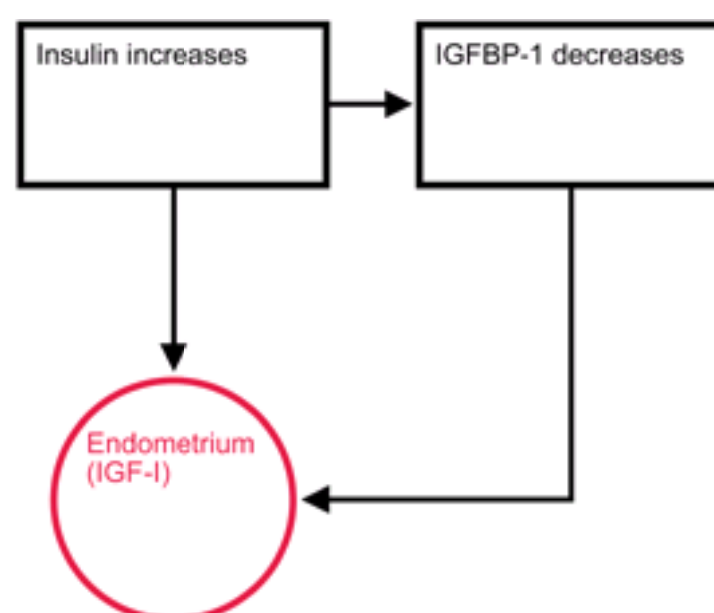

Because the increase in insulin is not always extreme, it has been proposed that insulin activates a signaling system separate from glucose transport, specifically, that insulin operates via inositolphosphoglycan to stimulate steroidogenesis.¹⁵² This pathway would operate by means of insulin binding to its own receptor, not the IGF receptor, a pathway supported by in vitro studies of both granulosa cells and thecal cells.^{153, 154 and 155}

There are two other important actions of insulin which contribute to hyperandrogenism in the presence of hyperinsulinemia: inhibition of hepatic synthesis of sex hormone-binding globulin and inhibition of hepatic production of insulin-like growth factor binding protein-1.

Independently of any effect on sex steroids, increased insulin will inhibit the hepatic synthesis of sex hormone-binding globulin.¹⁵⁶ In vitro studies indicate that both insulin and IGF-I directly inhibit SHBG secretion by human hepatoma cells.^{157, 158} This is now known to be the mechanism for the inverse relationship between body weight and the circulating levels of SHBG. Because SHBG is regulated by insulin, decreased SHBG levels in women represent an independent risk factor for noninsulin-dependent diabetes mellitus, regardless of body weight and fat distribution.¹⁵⁹ Of course, a decrease in SHBG allows more androgen and estrogen to be bioavailable.

Nutritional intake decreases the circulating levels of insulin-like growth factor binding protein-1 (IGFBP-1) because of the increase in insulin, which then directly inhibits IGFBP-1 production in the liver.¹⁶⁰ Obese individuals with increased insulin levels and women with polycystic ovaries and hyperinsulinemia have lower circulating levels of IGFBP-1.¹⁶¹ This lower level of IGFBP-1 allows an increase in circulating levels of IGF-I and greater local activity of IGF-I and/or IGF-II in the ovary. In addition, greater IGF-I activity in the endometrium due to reduced levels of IGFBP-1 and direct insulin activation of IGF receptors or its own receptor are possible mechanisms for endometrial growth (and the increased risk for endometrial cancer) in these patients. On the other hand, a greater IGF binding protein capacity in the follicular fluid from polycystic ovaries would yield a reduced bioavailability of IGFs within the follicle.^{72, 73} Although these findings (increased circulating IGF availability and decreased follicular IGF availability) at first seem paradoxical, they are compatible with increased thecal androgen production by the IGF pathway and disrupted follicular maturation by the FSH system. It is likely that these characteristics of polycystic ovaries are secondary to increased anovulation, hyperinsulinemia, and increased androgens, rather than indicating a primary, etiologic role.

Finally, there is evidence that insulin can increase LH secretion in some anovulatory, overweight women.¹⁶²

Why are not all patients with hyperinsulinemia also hyperandrogenic; e.g., many women with noninsulin-dependent diabetes mellitus? The answer to this question is not known, but a logical speculation is that an ovarian genetic susceptibility is required,¹⁶³ although it may be that the existence of long-term anovulation must be present and even precede hyperinsulinemia.

Can Ovarian Hyperandrogenism be Treated with Diabetes Drugs?

There is a variety of pharmacologic agents available to reduce insulin levels. Diazoxide and octreotide, the long-acting analogue of somatostatin, both inhibit insulin secretion, but are accompanied by worsening glucose intolerance.^{146, 164} The best approach is to improve peripheral insulin sensitivity, thus achieving reductions in insulin secretion and stability of glucose tolerance. Metformin and troglitazone, oral agents used to treat diabetes mellitus, have been administered to anovulatory women with polycystic ovaries.

Metformin improves insulin sensitivity, but the primary effect is a significant reduction in gluconeogenesis, thus decreasing hepatic glucose production. Metformin treatment (500 mg tid) reduces hyperinsulinemia, basal and stimulated LH levels, free testosterone concentrations, and PAI-1 levels in overweight women with polycystic ovaries.^{165, 166 and 167} A significant number of these anovulatory women ovulate and achieve pregnancy.^{168, 169} In a group of obese women with polycystic ovaries, 90% of the women treated with metformin and 50 mg clomiphene ovulated compared with 8% in the group treated with placebo and clomiphene.¹⁷⁰ However, there has been controversy, suggesting that the improvement was the result of the weight loss that often accompanies the use of metformin.¹⁷¹ In a study designed to control the effect of body weight, the administration of metformin was without effect on insulin resistance in extremely overweight women with polycystic ovaries.¹⁷² In another well-designed study, metformin again had no effect on insulin resistance when body weights remained unchanged, and in this study baseline weights and hyperinsulinemia were only modestly increased.¹⁷³ In lean, anovulatory women with hyperinsulinemia, metformin treatment reduced hyperandrogenemia although there was no change in body weight; however, a decrease in the waist to hip ratio accompanied a reduction in the hyperinsulinemia.¹⁷⁴ This study indicates that both obese and nonobese patients with hyperinsulinemia respond to metformin treatment. The reasons for the differences among the studies are not apparent. Perhaps

only certain patients will respond to metformin, and, thus, patient selection could influence the reported results.

The thiazolidinediones markedly improve insulin sensitivity and insulin secretion (improved peripheral glucose utilization and β -cell function) without weight changes. Troglitazone (400 mg daily) decreases hyperinsulinemia, and improvements in metabolic abnormalities (decreased androgens, increased SHBG, decreased PAI-1 consistent with improved fibrinolytic capacity, and decreased LH) and a return to ovulation in very obese women have been reported with this agent. [175, 176](#)

There is little doubt that these drugs can produce significant and beneficial improvements in this condition, although metformin may be effective only when weight loss occurs. However, is short-term use better than our standard methods of the induction of ovulation, and are these drugs safe during pregnancy and lactation? Is long-term use for preventive health care cost-effective and compatible with good drug compliance? How effective are these agents in women who are of normal or only slightly elevated body weight? Are there any unwanted effects associated with long-term use (liver enzyme changes have occurred in rare patients with troglitazone)? Appropriate clinical trials are required to answer these questions.

We believe there will be rapid progress in this area. It is our prediction that during the clinical lifetime of this text, metformin and troglitazone (and perhaps new related drugs) will be increasingly used for anovulatory women resistant to clomiphene treatment and to prevent the cardiovascular and metabolic consequences of hyperinsulinemia.

The Clinical Consequences of Persistent Anovulation

Anovulation is the key feature of this condition and presents as amenorrhea in approximately 50% of cases and with irregular, heavy bleeding (dysfunctional uterine bleeding) in 30%. [12, 177](#) True virilization is rare, but 70% of anovulatory patients complain of cosmetically disturbing hirsutism. The development of hirsutism depends not only on the concentration of androgens in the blood but on the genetic sensitivity of hair follicles to androgens. Thus, anovulatory, hyperandrogenic women can be free of the clinical sign of hirsutism. Alopecia and acne can also be consequences of hyperandrogenism. [14, 178](#) Obesity has been classically regarded as an important feature, but in view of the concept of persistent anovulation arising from many causes, its presence is extremely variable (about 35–60% of anovulatory women with polycystic ovaries) and has no diagnostic value. [12, 13 and 14](#) However, the greater the body mass index, the higher the testosterone levels, and, therefore, hirsutism is more common in overweight anovulatory women.

How many anovulatory women with polycystic ovaries have hyperinsulinemia? It is impossible to provide an accurate estimate. It does appear that the more aggressively clinicians pursue hyperinsulinemia in these patients the more often it is being demonstrated. Certainly not every anovulatory patient has hyperinsulinemia, not even every overweight, anovulatory patient. However, subtle abnormalities in insulin dynamics may be present early in the course of this condition, and appear more prominently with time. [179](#) Thus, when anovulation and hyperandrogenism are present, hyperinsulinemia may be an underlying disorder in most, if not all. As an anovulatory woman gains weight, the insulin resistance and hyperinsulinemia associated with obesity are now added to the underlying problem, and the abnormality is now more easily detected. [42, 135, 136](#)

Although an elevated LH value in the presence of a low or low-normal FSH may be diagnostic, the diagnosis is easily made by the clinical presentation alone. About 20–40% of patients with this condition do not have elevated LH levels with reversal of the LH:FSH ratio. [180, 181 and 182](#) We do not routinely measure FSH and LH levels in anovulatory patients. The selection of a specific criterion to make this diagnosis will inevitably fail to include many patients with this clinical problem that covers a broad spectrum of manifestations. This failing also applies to the diagnostic use of ultrasonographic criteria. [22](#)

The Clinical Consequences of Persistent Anovulation

1. **Infertility.**
2. **Menstrual bleeding problems, ranging from amenorrhea to dysfunctional uterine bleeding.**
3. **Hirsutism, alopecia, and acne.**
4. **An increased risk of endometrial cancer and, perhaps, breast cancer.**
5. **An increased risk of cardiovascular disease**
6. **An increased risk of diabetes mellitus in patients with insulin resistance.**

There are potentially severe clinical consequences of the steady state of hormone secretion. Besides the problems of bleeding, amenorrhea, hirsutism, and infertility, the effect of the unopposed and uninterrupted estrogen is to place the patient at considerable risk for cancer of the endometrium and, perhaps, cancer of the breast. [183, 184, 185 and 186](#) The risk of endometrial cancer is increased 3-fold, while chronic anovulation during the reproductive years has been reported to be associated with a 3–4 times increased risk of breast cancer appearing in the postmenopausal years. However, the statistical power of these observational studies on breast cancer was limited by small numbers (all fewer than 15 cases). Others have failed to find a link between anovulation and the risk of breast cancer. [187, 188 and 189](#) Women with the most irregular menstrual cycles (and thus presumably anovulatory) in the Nurses' Health Study appeared to have a reduced risk of breast cancer. [190](#)

If left unattended, patients with persistent anovulation develop clinical problems, and, therefore, appropriate therapeutic management is essential for all anovulatory patients. In a long-term follow-up of women with polycystic ovaries, the problems of android obesity and hyperinsulinemia were observed to persist into the postmenopausal years. [103](#) Although it is yet to be documented by appropriate epidemiologic studies, it is logical to expect postmenopausal women who have previously been anovulatory, hyperandrogenic, and hyperinsulinemic to experience a reduction in life expectancy because of cardiovascular disease and diabetes mellitus. These women will derive important benefits from an aggressive preventive health care attitude on the part of the clinician that results in amelioration of adverse metabolic risk factors.

Growing support for an inherited basis for this disorder (autosomal dominant) makes it important to consider appropriate family counseling. Sisters and daughters may have a 50% chance of having the same problems as the patient.

The typical patient presents with anovulation and irregular menses or amenorrhea with withdrawal bleeding after a progestational challenge. Documentation of anovulation is usually unnecessary, especially in the presence of menstrual irregularity with periods of amenorrhea. In the patient who has long-standing anovulation, an endometrial biopsy (with extensive sampling) is a wise precaution. The well-known association between this condition and abnormal endometrial changes must be kept in mind. Endometrial cancer can be encountered in young, anovulatory women. [191, 192 and 193](#) **The decision to perform an endometrial biopsy should not be influenced by the patient's age. It is the duration of exposure to unopposed estrogen that is critical.**

Therapy of most anovulatory patients can be planned at the first visit. If the patient desires pregnancy, she is a candidate for the medical induction of ovulation ([Chapter 30](#)). When pregnancy is achieved, patients with polycystic ovaries appear to have an increased risk of spontaneous miscarriage. [194, 195 and 196](#) This increased risk has been attributed to elevated levels of LH that may produce an adverse environment for the oocyte, perhaps even inducing premature maturation and completion of the first meiotic division. For this reason, consideration should be given to pretreatment suppression prior to the induction of ovulation ([Chapter 30](#)).

If the patient presents with amenorrhea, an investigation must be pursued as outlined in [Chapter 11](#). The management of significant dysfunctional uterine bleeding is discussed in [Chapter 16](#) and hirsutism in [Chapter 13](#).

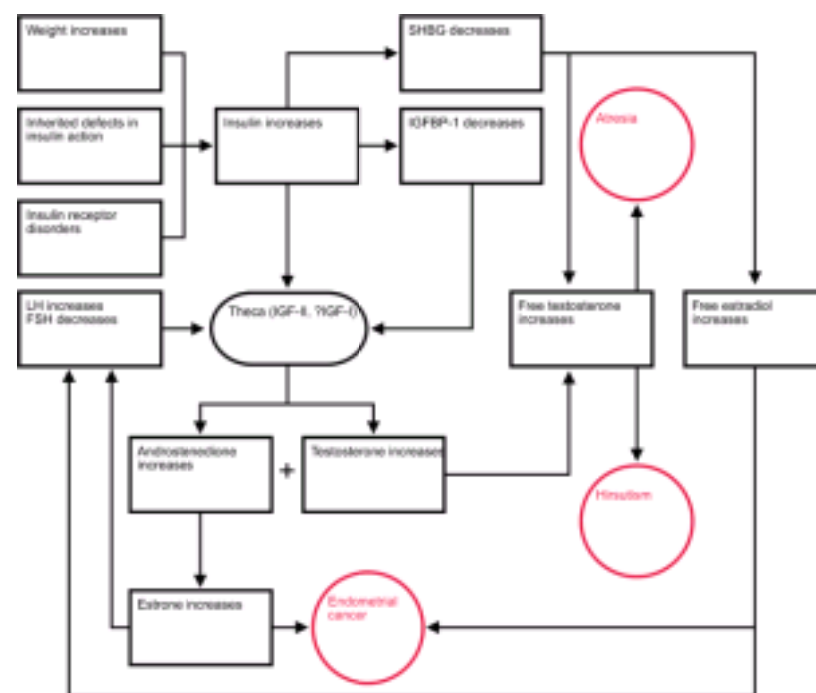

For the patient who does not wish to become pregnant and does not complain of hirsutism, but is anovulatory and has irregular bleeding, therapy is directed toward interruption of the steady state effect on the endometrium and breast. The use of medroxyprogesterone acetate (5–10 mg daily for the first 10 days of every month) is favored to ensure complete withdrawal bleeding and to prevent endometrial hyperplasia and atypia. The monthly 10-day duration has been demonstrated to be essential to protect the endometrium from cancer in women on postmenopausal estrogen therapy. Until specific clinical data are available, it seems logical that young, anovulatory women also require at least 10 days of progestational exposure every month. The patient will be aware of the onset of ovulatory cycles because bleeding will occur at a time other than the expected withdrawal bleed. In our opinion, when reliable contraception is essential, the use of low-dose combination oral contraception in the usual cyclic fashion is appropriate.

Besides contraception, there is another argument in favor of continuous suppression with low-dose oral contraceptives rather than periodic progestational interruption. The lipid profile in androgenized women with polycystic ovaries (who are also exposed to relatively lower estrogen levels over time) is similar to the male pattern with higher levels of cholesterol, triglycerides, and LDL-cholesterol, and lower levels of HDL-cholesterol, and this abnormal pattern is independent of body weight. [197, 198, 199](#)

²⁰⁰ and ²⁰¹ Although the elevated androgens associated with polycystic ovaries and anovulation offer some protection against osteoporosis, the adverse impact on the risk for cardiovascular disease is a more important consideration. ²⁰² An adverse lipid profile is a distinguishing feature of these patients even when body mass index, insulin, and age are controlled in case-control studies. ²⁰³ Subclinical atherosclerosis can be demonstrated by carotid ultrasonography to be prevalent in premenopausal women with a history of anovulation and polycystic ovaries. ²⁰⁴ In women undergoing coronary angiography, the prevalence of polycystic ovaries is increased, and women with polycystic ovaries have more extensive coronary atherosclerosis. ²⁰⁵ Thus anovulatory women with polycystic ovaries develop risk factors for atherosclerosis and ultimately clinical disease, comparable with that found in older, very overweight, postmenopausal women.

Monthly periodic treatment with a progestational agent has no significant effect on the androgen production by polycystic ovaries. Thus, if contraception is not required and hirsutism is not a complaint, assessment of the lipoprotein profile is a reasonable clinical response, and in the presence of a male pattern, serious consideration should be given to suppression with oral contraceptives. Short-term studies with low-dose oral contraceptives have not revealed an adverse effect on the already abnormal lipid profile. ²⁰⁶ Indeed, one would expect an improvement in the lipid profile to accompany suppression of androgen production. Similarly, interference with androgen actions with an agent like flutamide improves the lipid profile. ²⁰⁷ Long-term suppression of hyperandrogenism should be beneficial; however, epidemiologic data on this important question are not available.

Because older, high-dose oral contraceptives increased insulin resistance, it has been suggested that this treatment should be avoided in anovulatory, overweight women. However, low-dose oral contraceptives have minimal effects on carbohydrate metabolism, and the majority of hyperinsulinemic, hyperandrogenic women can be expected to respond favorably to treatment with oral contraceptives. ²⁰⁸ Insulin and glucose changes with low-dose (less than 50 µg ethinyl estradiol) oral contraceptives are so minimal, that it is now believed that they are of no clinical significance. ²⁰⁹ Long-term follow-up studies have failed to detect any increase in the incidence of diabetes mellitus or impaired glucose tolerance (even in past and current users of high-dose pills). ^{210, 211} Furthermore, there is no evidence of an increase in risk of cardiovascular disease among past users of oral contraceptives. ^{212, 213} In addition, low-dose oral contraceptives have been administered to women with recent gestational diabetes without an adverse impact, and in women with insulin-dependent diabetes mellitus, low-dose oral contraceptives have not produced deterioration of lipid and biochemical markers for cardiovascular disease or increased the development of retinopathy or nephropathy. ^{214, 215, 216} and ²¹⁷ And finally, the administration of a low-dose oral contraceptive to women with extreme obesity and insulin resistance resulted in only a mild deterioration of glucose tolerance. ²¹⁸

This experience supports the safety of oral contraceptive treatment for anovulatory, hyperandrogenic, hyperinsulinemic women. Patients resistant to oral contraceptive treatment may require suppression with a GnRH agonist. Because glucocorticoids increase insulin resistance, they should be used with caution in patients with hyperinsulinemia. Spironolactone and flutamide do not affect insulin sensitivity in anovulatory women. ^{219, 220}

A contributing factor to the abnormal lipid pattern in many of these patients is hyperinsulinemia, ^{201, 221} and therefore, a major effort must be directed to control of body weight in those patients who are overweight.

Hyperandrogenic and hyperinsulinemic, anovulatory women must be cautioned regarding their increased risk of future diabetes mellitus. Not only are anovulatory, hyperinsulinemic women at greater risk for noninsulin-dependent diabetes, but the age of onset is about 30 years earlier than the general population. ^{222, 249} Not surprising, these patients are more likely to develop glucose tolerance problems in pregnancy. ²²³ And patients who have experienced gestational diabetes are more likely to demonstrate the entire metabolic syndrome (hyperandrogenism and hyperinsulinemia) later in life. ²²⁴ In a long-term follow-up study, anovulatory women with polycystic ovaries had a 5-fold increased risk of diabetes mellitus compared with age-matched controls. ¹⁰³ **It is appropriate, and indeed essential, to monitor glucose tolerance testing.**

Hyperinsulinemia also contributes to the increased risk of cardiovascular disease both by means of a direct atherogenic action and indirectly by adversely affecting the lipoprotein profile. Insulin resistance may be a more significant factor than androgens in determining the abnormal lipoprotein profile in overweight, anovulatory women. ²⁰¹ It has also been suggested that the increased insulin stimulation of IGF-I could produce bone changes similar to that seen in acromegaly. ²²⁵ Hyperinsulinemia may be a factor contributing to the higher risk of endometrial cancer in these patients by increasing IGF-I activity in the endometrium. ²²⁶

The best therapy for these women is weight loss. Both the hyperinsulinemia and the hyperandrogenism can be reduced with weight loss, which is at least more than 5% of the initial weight. ^{143, 227, 228, 229, 230} and ²³¹ Increased PAI-1 levels associated with hyperinsulinemia also improve with weight loss. ²³⁰ These metabolic improvements are associated with an impressive rate of resumption of ovulation and pregnancy. ^{232, 233} In one study, 60 of 67 anovulatory women, who lost from 4 to 15 kg, resumed ovulation. ²³⁴ A goal for weight loss that correlates with a good chance of achieving pregnancy (improved menstrual function), a reduction in insulin levels, and a decrease in free testosterone levels is a body mass index of less than 27 (see the nomogram for calculating body mass index in [Chapter 19](#)). Insulin resistance is not detected in normal women with a body mass index less than 27. ¹³⁵ However, it is likely that women with this condition can still manifest some degree of insulin resistance despite weight loss. Nevertheless, the impact of mild or incipient hyperinsulinemia is uncertain, and a major improvement in clinical consequences can be achieved by weight loss, and it should be emphasized, that only a relatively small percentage of weight (5–10%) need be lost to have a beneficial impact upon insulin resistance and cardiovascular hemodynamic function. ²³⁵

The best application of drugs, such as metformin and troglitazone, remains to be determined by data from appropriate clinical trials; however, the mechanism of action and the logic behind this treatment offer impressive potential for preventive health benefits for these women. Clinical (ovulatory) and laboratory responses can be expected within 3 months. **As we have previously noted, we believe these drugs will prove to be an important component of the health care of anovulatory women with polycystic ovaries.**

Although changes are uncommon, liver function must be monitored during troglitazone treatment. The pharmaceutical company's package information should be consulted for the currently recommended monitoring regimen of serum alanine aminotransferase levels. Troglitazone was found to be associated with a 30% decrease in the circulating estrogen and progestin levels in oral contraceptive users in a small number of women who have been studied in clinical trials (pharmaceutical company data), an effect probably secondary to troglitazone's stimulation of hepatic enzyme activity; however, it is by no means certain that this will result in a loss of contraceptive efficacy. Lactic acidosis is a rare complication in patients treated with metformin; however, virtually all cases have occurred in patients with complicated medical problems, such as sepsis, renal insufficiency, and congestive heart failure. Patients who become ill should discontinue metformin treatment, and metformin should not be administered to women who have abnormal renal chemistries.

Treatment with low doses of dehydroepiandrosterone to increase insulin sensitivity is effective in the short-term, but well-designed studies are necessary to demonstrate long-term efficacy and safety. ²³⁶

Overall Goals of Treatment

1. Reduce the production and circulating levels of androgens.
2. Protect the endometrium against the effects of unopposed estrogen.
3. Support lifestyle changes to achieve normal body weight.
4. Lower the risk for cardiovascular disease.
5. Avoid the effects of hyperinsulinemia on the risks of cardiovascular disease and diabetes mellitus.
6. Induction of ovulation to achieve pregnancy.

Who Should Be Tested for Hyperinsulinemia?

Do all anovulatory patients require testing for hyperinsulinemia? Both lean and obese women with polycystic ovaries can be found to have hyperinsulinemia, but not all hyperandrogenic women with polycystic ovaries (lean and obese) have hyperinsulinemia.^{14, 147, 237} However, it is more common and severe in overweight women and androgenic effects are more intense. Furthermore, lean women with hyperinsulinemia do not appear to have the same risk of future diabetes mellitus, although clinical follow-up may in time document an onset later in life of noninsulin-dependent diabetes mellitus compared to an earlier onset in obese women. It has been reported that anovulatory women with polycystic ovaries who have a parent with noninsulin-dependent diabetes mellitus are more likely to have impaired beta cell secretion of insulin in addition to insulin resistance.²³⁸

Because of the probable inherited susceptibility for anovulation and insulin resistance, consideration should be given to a glucose tolerance and insulin evaluation for family members of already diagnosed patients. Both brothers and sisters of anovulatory, hyperandrogenic women can be insulin resistant.⁸⁴

What about those women who are ovulatory and have no clinical complaints, yet supposedly have an underlying hyperinsulinemic disorder? In our view, if this is real, it is a homeostatic compensatory state, and until appropriate data reveal adverse outcomes in these women, diagnostic and therapeutic interventions are not indicated.

It would be ideal if all patients with android obesity were tested for hyperinsulinemia. The waist:hip ratio is a means of estimating the degree of upper to lower body obesity; the ratio accurately predicts the amount of intra-abdominal fat (which is greater with android obesity).^{239, 240} However, studies have demonstrated that the more easily determined circumference of the waist is a better predictor of central, android abdominal fat.^{241, 242} **A waist circumference greater than 100 cm (about 40 inches) in men and 90 cm (about 35 inches) in women is predictive of abnormal endocrinologic and metabolic function and is associated with an increased risk of cardiovascular disease.**²⁴¹

Teenagers who present with persistent anovulation would also be good candidates for hyperinsulinemia testing. During puberty, insulin resistance develops, probably because of the increase in sex steroids and growth hormone, resulting in a secondary increase in insulin and IGF-I.^{243, 244} The increase in insulin leads to a decrease in SHBG, which would allow greater sex steroid activity for pubertal development. There is reason to believe that some teenagers fail to normalize the hyperinsulinemia associated with the growth hormone increase in early puberty.¹⁷⁹ It would be important to identify these teenagers who are at an increased risk for the development of diabetes mellitus and are destined to struggle with all of the problems associated with anovulation and polycystic ovaries. There is also reason to believe that many cases of premature adrenarche are due to hyperinsulinemia, and these patients go on to develop the full characteristics of anovulation, hyperandrogenism, and polycystic ovaries.^{245, 246}

When clinical circumstances are encountered that do not seem to make sense, give consideration to the presence of hyperinsulinemia. We have experienced several examples where hyperinsulinemia proved to be the underlying answer. Several instances involved women in the reproductive age range, with significant hirsutism and very high testosterone levels. Evaluation failed to reveal an ovarian tumor or an adrenal lesion. The demonstration of hyperinsulinemia has avoided unnecessary surgical exploration for a "small tumor." Another example was the onset of hirsutism in elderly women associated with testosterone levels greater than 200 ng/mL and normal imaging evaluations of the ovaries and adrenal glands. Again, hyperinsulinemia was the cause, not a hidden tumor.

Unfortunately, it is not certain what levels of insulin in the fasting state or in response to an oral glucose tolerance test are correlated with clinical outcome. However, in individuals with normal glucose tolerance, the fasting insulin level is strongly correlated with insulin resistance.²⁴⁷ In most laboratories, the upper limit of normal for a fasting insulin level is 10–20 U/mL. Because there is considerable overlap between normal women and patients with anovulation and polycystic ovaries, it is reasonable to assume that all overweight, anovulatory women with polycystic ovaries are hyperinsulinemic. Nevertheless we recommend the measurement of the ratio of fasting glucose to fasting insulin in order to provide evidence that lends credence and importance to counseling efforts. **A ratio of less than 4.5 is consistent with insulin resistance.**²⁴⁸

Based upon the information reviewed in this chapter, we offer the following recommendations:

All anovulatory women who are hyperandrogenic should be assessed for insulin resistance and glucose tolerance with measurements of:

1. The fasting glucose:insulin ratio, followed by
 2. The 2-hour glucose level after a 75 g glucose load:
- | | |
|--|----------------------|
| normal | less than 140 mg/dL |
| impaired | 140–199 mg/dL |
| noninsulin-dependent diabetes mellitus | 200 mg/dL and higher |

Anovulatory women who do not exhibit signs of hyperandrogenism should be evaluated for the presence of a metabolic abnormality by measuring the free testosterone level; if elevated, insulin resistance and glucose tolerance should be assessed. However, a fasting glucose:insulin ratio is about one-third the cost of a free testosterone level. It may be more economical to measure this ratio in all anovulatory women.

In women who continue to manifest this disorder, periodic surveillance is necessary. The frequency is uncertain, but annual assessment is appropriate in women who continue to be obese.

Conclusion

We are truly entering a new era in our understanding and management of women with polycystic ovaries and hyperandrogenism. In the past we have effectively treated the specific problems of infertility, dysfunctional uterine bleeding, and hirsutism. We now have an opportunity to have an impact on the quality and quantity of life to be experienced by these patients. By creating and supporting a preventive health care attitude in anovulatory women, we can not only correct specific clinical consequences of anovulation, we can reduce major adverse effects on overall health.

Hirsutism, excessive facial and body hair caused by excess androgen production, is usually associated with anovulatory ovaries and loss of cyclic menstrual function. The more severe states of virilism (clitoromegaly, deepening of the voice, balding, and changes in body habitus) are rarely seen and usually are secondary to adrenal hyperplasia or androgen-producing tumors of adrenal or ovarian origin. Although these are rare, diagnostic evaluation is required.

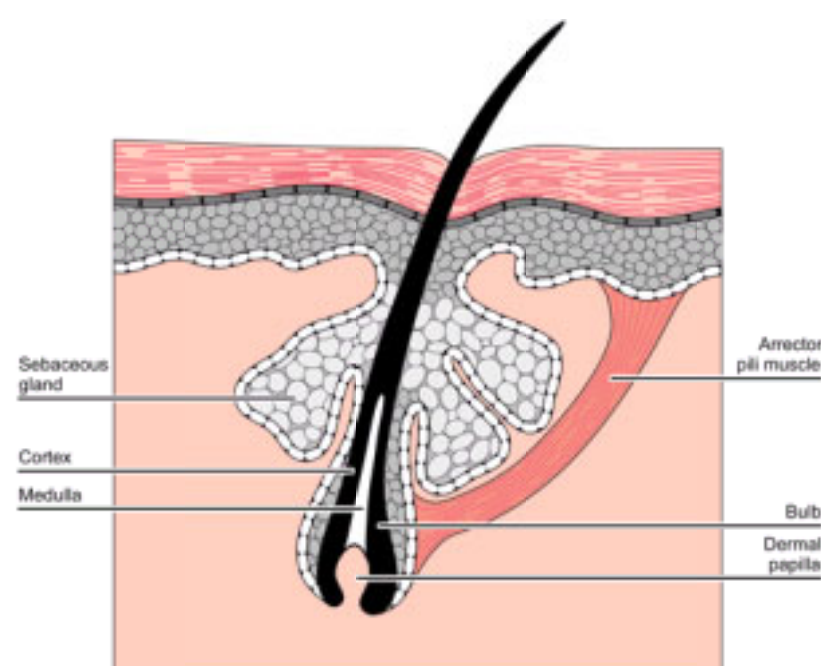

A concerned and sympathetic approach must be offered to women who complain of hirsutism. The responsible clinician must view hirsutism both as an endocrine problem and as a cosmetic problem. To the affected woman, hair growth over the face, abdomen, or breasts is disturbing on several levels. Is there disease? Is sexuality changing? Is social acceptance altered? Is fertility impaired?

This chapter reviews the biology of hair growth and the endocrine causes that can yield hirsutism. An uncomplicated, effective program for diagnostic evaluation and therapeutic management is presented.

The Biology of Hair Growth¹

Embryology

Each hair follicle develops at about 8–10 weeks of gestation as a derivative of the epidermis. It is composed initially of a solid column of cells that proliferates from the basal layers of the epidermis and protrudes downward into the dermis. As the column elongates it encounters a cluster of mesodermal cells (the dermal papilla) that it envelops at its bulbous tip (bulb). The solid epithelial column then hollows out to form a hair canal, and the pilosebaceous apparatus (a hair follicle, sebaceous glands, and arrector pili muscles) is laid down.

Hair growth begins with proliferation of the epithelial cells at the base of the column in contact with the dermal papilla. The *lanugo hair* that covers the fetus is lightly pigmented, thin in diameter, short in length, and fragile in attachment. Important to note is the fact that the total endowment of hair follicles is made at an early gestational stage (by 22 weeks) and no new hair follicles will be produced de novo. The concentration of hair follicles laid down per unit area of facial skin does not differ materially between sexes but does differ between races and ethnic groups (Caucasian > Oriental; Mediterranean > Nordic). In addition, hair growth differences between races probably reflect hair follicle differences in 5 α -reductase activity (the production of the active androgen, dihydrotestosterone).² The pattern of hair growth is genetically predetermined.

Structure and Growth

Hair does not grow continuously but, rather, in a cyclic fashion with alternating phases of activity and inactivity. The cycles are referred to by the following terms:

Anagen—the growing phase.
Catagen—rapid involution phase.
Telogen—quiescent phase.

In the resting phase (telogen), the hair is short and loosely attached to the base (the bulb) of the epithelial canal. As growth begins (anagen), epithelial matrix cells at the base begin to proliferate and extend downward into the dermis. The epithelial column elongates some 4–6 times from the resting state. Once downward extension is completed, continued rapid growth of the matrix cells pushes upward to the skin surface. The tenuous contact of the previous hair is broken, and that hair is shed. The superficial matrix cells differentiate forming a keratinized column. Growth continues as long as active mitoses persist in the basal matrix cells. When finished (catagen), the column shrinks, the bulb shrivels, and the resting state is reached (telogen).

The length of hair is primarily determined by duration of the growth phase (anagen). Scalp hair remains in anagen for 3 years and has only a relatively short resting phase. Elsewhere (forearm) a short anagen and long telogen will lead to short hair of stable nongrowing length. The appearance of continuous growth (or periodic shedding) is determined by the degree to which individual hair follicles act asynchronously with their neighbors. Scalp hair is asynchronous and, therefore, always seems to be growing. The resting phase that some hairs (10–15%) are in is not apparent. If marked synchrony is achieved, then all hairs may undergo telogen at the same time leading to shedding that is called **telogen effluvium**. Occasionally, women will complain of marked hair loss from the scalp, but this time period of shedding is usually limited (6–8 months), and growth resumes when asynchrony is re-established. **However, it is worthwhile to rule out thyroid disease with a TSH measurement.**

Hypertrichosis is a generalized increase in hair of the fetal lanugo type, associated with the use of drugs or malignancy. **Vellus hair** is the downy, unpigmented hair associated with the prepubertal years. **Terminal hair** is the coarse, pigmented hair that grows on various parts of the body during the adult years. Hirsutism implies a vellus to terminal hair transformation.

Factors That Influence Hair Growth

The dermal papilla is the director of the events that control hair growth. Despite major injury to the epithelial component of the follicle (such as freezing, x-rays, or a skin graft), if the dermal papilla survives, the hair follicle will regenerate and regrow hair. Injury to or degeneration of the dermal papilla (such as that achieved with properly performed electrolysis) is the crucial factor in permanent hair loss.

Sexual hair is defined as hair that responds to the sex steroids. Sexual hair grows on the face, lower abdomen, anterior thighs, the chest, the breasts, the pubic area, and in the axillae. Once androgen influences hair follicles in sexual areas and larger, longer, more pigmented hair is induced, these final hair characteristics recur in typical cycles of activity and inactivity, even in the absence of sustaining androgen. Androgenic stimulation of the hair follicle requires the conversion of testosterone to dihydrotestosterone, and therefore the sensitivity of the hair follicle to androgens is determined by the level of 5 α -reductase activity. The individual variability in hair response is believed to reflect genetic differences in 5 α -reductase activity.

From animal studies and human disease patterns, the following list of hormonal effects can be compiled:

1. Androgens, particularly testosterone, initiate growth, increase the diameter and pigmentation of the keratin column, and probably increase the rate of matrix cell mitoses in all but scalp hair.
2. Estrogens act essentially opposite from androgens, retarding the rate and initiation of growth, and leading to finer, less pigmented and slower growing hair. In the mouse, estrogen arrests hair follicles in the telogen phase of the cycle.³
3. Progestins have minimal direct effects on hair.
4. Pregnancy (high estrogen and progesterone) can increase the synchrony of hair growth, leading to periods of growth or shedding.

An important clinical characteristic of hair growth can be understood from studies of the effects of castration. If castration occurs before puberty, the male will not grow a beard. If castration occurs after puberty with beard and sexual hair distribution fully developed, then these hairs continue to grow albeit more slowly and with finer caliber. Androgen stimulates sexual hair follicle conversion from lanugo to terminal adult hair growth patterns, but **once established, these patterns persist despite withdrawal of androgen.**

Sexual and nonsexual hair growth can be affected by endocrine problems. In hypopituitarism, there is marked reduction of hair growth. Acromegaly will be associated with hirsutism in 10–15% of patients. Although the impact of thyroid hormone is not clear, hypothyroid individuals sometimes display scalp alopecia as well as less axillary, pubic, and curiously, lateral eyebrow hair. 5 α -Reductase activity is stimulated by insulin-like growth factor-I (IGF-I).⁴ Increased IGF-I activity in anovulatory patients with insulin resistance and hyperinsulinemia can intensify the hirsute response in these hyperandrogenic patients.

Hair growth can be influenced by nonhormonal factors, such as local skin temperature, blood flow, and edema. Hair grows faster in the summer than in the winter.⁵ Hair growth can be seen in association with central nervous system (CNS) pathology such as encephalitis, cranial trauma, multiple sclerosis, and with certain drugs.

Androgen Production

The production rate of testosterone in the normal female is 0.2 to 0.3 mg/day. Approximately 50% of testosterone is derived from peripheral conversion of androstenedione, whereas the adrenal gland and ovary contribute approximately equal amounts (25%) to the circulating levels of testosterone, except at midcycle when the ovarian contribution increases by 10–15%. Dehydroepiandrosterone sulfate (DHAS) arises almost exclusively from the adrenal gland, while 90% of dehydroepiandrosterone (DHA) is from the adrenal.

About 80% of circulating testosterone is bound to a beta-globulin known as sex steroid hormone-binding globulin (SHBG). In women, approximately 19% is loosely bound to albumin, leaving about 1% unbound. Androgenicity is dependent mainly on the unbound fraction and partly upon the fraction associated with albumin. DHA, DHAS, and androstenedione are not significantly protein bound, and routine immunoassay reflects their biologically available hormone activity. This is not the case with testosterone because routine assays measure the total testosterone concentration, bound and unbound.

SHBG production in the liver is decreased by androgens. Hence, the binding capacity in men is lower than in normal women, and 2–3% of testosterone circulates in the free, active form in men. SHBG is decreased by insulin, and increased by estrogens and thyroid hormone. Therefore, binding capacity is increased in women with hyperthyroidism, in pregnancy, and by estrogen-containing medication. In a hirsute woman, the SHBG level is depressed by the excess androgen (and, when present, by hyperinsulinemia), and the percent free and active testosterone is elevated as is the metabolic clearance rate of testosterone. The total testosterone concentration, therefore, can be in the normal range in a woman who is hirsute. However, there is little clinical need for a specific assay for the free portion of testosterone. The very presence of hirsutism or masculinization indicates increased androgen effects. One can reliably interpret a normal total testosterone level in these circumstances as being compatible with decreased binding capacity and increased free testosterone.

In hirsute women, only 25% of the circulating testosterone arises from peripheral conversion, and most is due to direct glandular secretion. Indeed, data overwhelmingly indicate that the ovary is the major source of increased testosterone and androstenedione in hirsute women.⁶ The most common cause of hirsutism in women is persistent anovulation and excessive androgen production by the ovaries. Adrenal causes are most uncommon.

3a-Androstenediol Glucuronide

Although testosterone is the major circulating androgen, dihydrotestosterone (DHT) is the major nuclear androgen in many sensitive tissues, including hair follicles and the pilosebaceous unit in skin. 3a-Androstenediol is the peripheral tissue metabolite of DHT, and its glucuronide, 3a-androstenediol glucuronide (3a-AG) has been utilized as a marker of target tissue cellular action.^{6,7,8} There is an excellent correlation between the serum levels of 3a-AG and the clinical manifestations of androgens. Specifically, 3a-AG correlates with the level of 5a-reductase activity (testosterone and androstenedione to dihydrotestosterone) in the skin.

Thus, there are 3 principal laboratory measurements of *potential* clinical use for the evaluation of androgen excess:

1. Testosterone — a measure of ovarian and adrenal activity.
2. DHAS — a measure of adrenal activity.
3. 3a-AG — a measure of peripheral target tissue activity.

Hirsutism is not a disorder of hair; rather, it reflects increased 5a-reductase activity which produces more DHT, leading to the stimulation of hair growth. This enzyme activity is increased by an increased availability of precursor (the circulating level of testosterone, therefore, is a primary factor) or by still unknown local tissue mechanisms. Measurement of 3a-AG has revealed that true idiopathic hirsutism may not exist (or at least it is very rare). In the presence of other laboratory measurements that are normal, increased levels of 3a-AG indicate an increased activity of 5a-reductase in the peripheral compartment.⁹ However, 3a-AG also reflects hepatic conjugation activity and the impact of major precursors that are derived from the adrenal gland and not from peripheral sources.¹⁰ Therefore 3a-AG is not solely a measure of cutaneous androgen metabolism.

There are 2 reasons why the measurement of 3a-AG is not part of the routine clinical approach to the problem of hirsutism. First, it is not an absolute measurement. Values in hirsute women overlap the normal range by about 20%. Second, and most importantly, the ultimate diagnosis and therapy of the problem are not affected by this test.

Prostate-Specific Antigen

The prostate-specific antigen (PSA) is a serine protease, produced in the prostate gland, and used as a tumor marker for the diagnosis and management of prostate cancer. PSA has also been detected in female tissues, and using a very sensitive assay, circulating levels of PSA can be measured in women. Because androgens increase the expression of the PSA gene, it is reasonable to expect hyperandrogenic women to have increased circulating levels of PSA. Indeed, circulating levels of PSA are higher in hirsute women and are correlated with 3a-AG levels.¹¹ These elevated levels do not respond to ovarian and adrenal stimulation or ovarian suppression, indicating a widespread origin.¹² However, at the present time, there is no clinical application for PSA measurements in women.

Evaluation of Hirsutism

Cosmetically disturbing hirsutism is the end result of a number of factors:

1. The number of hair follicles present (Asian women bearing androgen-producing tumors rarely are hirsute because of the low concentration of hair follicles per unit skin area).
2. The degree to which androgen has converted resting vellus hair to terminal adult hair.
3. The ratio of the growth to resting phases in affected hair follicles.
4. The asynchrony of growth cycles in aggregates of hair follicles.
5. The thickness and degree of pigmentation of individual hairs.

The primary factor in hirsutism is an increase in androgen levels (usually testosterone) that produces an initial growth stimulus and then acts to sustain continued growth. Essentially, every woman with hirsutism will have an increased production rate of testosterone and androstenedione.¹³

Anovulatory women who are not hirsute can often be found to have laboratory evidence of increased androgen production.¹⁴ However, the most common complaint voiced by women and associated with increased androgen production is hirsutism. This is followed in order by acne and increased oiliness of the skin, increased libido, clitoromegaly, and, finally, masculinization. Masculinization and virilization are terms reserved for extreme androgen effects (usually, but not always, associated with a tumor) leading to the development of a male hair pattern, clitoromegaly, deepening of the voice, increased muscle mass, and general male-like body habitus. The Ferriman-Gallwey scoring system used to quantify the amount of hirsutism is of little clinical use, and it is reserved for studies of hirsutism, but even for this

purpose, it is limited by subjective variability.¹⁵

Alopecia can be a vexing problem for patient and clinician. In many instances, alopecia is a temporary phenomenon, a response of the scalp hair to some change that has induced a period of synchronous hair growth and loss. This can be a response to acute, stressful events. Telogen effluvium often occurs near the end of a pregnancy or postpartum. With time, usually 6 months to a year, the scalp hair becomes asynchronous again and the hair thickens. In a series of consecutive patients presenting with diffuse alopecia, the majority had no evidence of hirsutism or menstrual dysfunction; however, anovulation with polycystic ovaries was the most common problem, and nearly 40% demonstrated hyperandrogenism.¹⁶ Patients complaining of alopecia deserve evaluation for hyperandrogenism because a significant number of them can be appropriately treated. In addition, a laboratory survey is indicated for thyroid dysfunction or chronic illness. However, because alopecia reflects increased scalp 5 α -reductase activity, normal circulating hormone levels should not preclude treatment.^{17, 18} Hair loss is also a consequence of aging, beginning in both sexes about the age of 50.¹⁹

Acne is another sign of increased androgen activity. Up to 60% of women with acne who have normal circulating levels of androgens display evidence of increased 5 α -reductase activity in the pilosebaceous unit.²⁰ These are the women who benefit from antiandrogenic treatment.

Acanthosis nigricans in an overweight patient with hirsutism is a reliable clinical marker of insulin resistance and hyperinsulinemia. This gray—brown velvety discoloration of the skin is usually present at the neck, groin, and axillae; however, the vulva is a very common site in hirsute women.²¹ Acanthosis nigricans indicates the need to determine the state of glucose metabolism, as discussed in [Chapter 12](#). Serious consideration should be given to the presence of hyperinsulinemia in hyperandrogenic women.

The most common clinical problem is the hirsute woman with irregular menses, with the onset of hirsutism during teenage years or in the early 20s, and long, gradual worsening of the condition. About 70% of anovulatory women develop hirsutism. The picture is so characteristic that a careful history is often sufficient for the diagnosis.

A good history can reveal some of the rare causes of hirsutism: environmental factors producing chronic irritation or reactive hyperemia of the skin, the use of drugs, changes associated with Cushing's syndrome or acromegaly, or even the presence of pregnancy (indicating the possibility of a luteoma). Hair-stimulating drugs include methyltestosterone, anabolic agents such as Nilevar or Anavar, phenytoin, diazoxide, danazol, cyclosporin, and minoxidil. Hirsutism associated with drugs that are not androgens typically consists of fine hairs distributed diffusely over the trunk and face (hypertrichosis). The 19-nortestosterones in the current low-dosage oral contraceptives rarely (if ever) cause acne or hirsutism. Postmenopausal women being treated with androgens can develop hirsutism despite low doses. Dehydroepiandrosterone, available as a food supplement, increases testosterone levels in women and can cause hirsutism and acne, even at the lowest doses.

Especially important in the history is the rapidity of development. A woman who develops hirsutism after the age of 25 and demonstrates very rapid progression of masculinization over several months usually has an androgen-producing tumor.

Late-onset adrenal hyperplasia caused by an enzymatic deficiency *presenting* in adult life is rare. Classical congenital adrenal hyperplasia that can lead to hirsutism is usually diagnosed and treated prior to puberty. Hirsutism in childhood is usually caused by classical congenital adrenal hyperplasia or androgen-producing tumors. Genetic problems, such as Y-containing mosaics or incomplete androgen sensitivity, will produce signs of androgen stimulation at puberty.

Virilization during pregnancy raises the suspicion of a luteoma, which is not a true tumor but an exaggerated reaction of the ovarian stroma to normal levels of chorionic gonadotropin.²² The solid luteoma is unilateral in 45% of cases and associated with a normal pregnancy. Theca-lutein cysts (also called ***hyperreactio luteinalis***) seen with trophoblastic disease are virtually always bilateral. Maternal virilization occurs in 30% of pregnancies with theca-lutein cysts. Hyperreactio luteinalis can also be seen with the high human chorionic gonadotropin (HCG) titers associated with multiple gestation. Because a luteoma regresses postpartum, the only risk is masculinization of a female fetus; a risk not reported with theca-lutein cysts.^{23, 24} Luteomas cause maternal virilization in 35% of the cases, and in these pregnancies, about 80% of female fetuses will exhibit some signs of masculinization. Subsequent pregnancies are usually normal, but maternal virilization is occasionally recurrent.²⁵ There have been several rare case reports of recurrent maternal virilization during pregnancy associated with hyperthecosis or polycystic ovaries.²⁶ These cases should also be regarded as examples of hyperreactio luteinalis.

Androgen-secreting ovarian tumors are very rarely encountered during pregnancy, probably because the excess androgen usually suppresses ovulation.^{23, 24} Ultrasonographic evaluation of the pelvis in women experiencing virilization in pregnancy is very helpful. Malignancy is frequently encountered when a solid unilateral ovarian lesion is present.

Hirsutism, therefore, is usually associated with persistent anovulation ([Chapter 12](#)). Although anovulatory ovaries are usually the source of excess androgens, a minimal workup is necessary, dedicated to ruling out the adrenal sources and tumors. It should be emphasized that hospitalization for extensive evaluation of hirsutism is required only rarely.

The Diagnostic Workup for Hirsutism

The initial laboratory evaluation of hirsutism consists of assays for the blood levels of testosterone and 17 α -hydroxyprogesterone (17-OHP). We no longer consider the measurement of DHAS to be necessary (discussed later). As part of the evaluation for anovulation, prolactin levels and thyroid function should be assessed, careful examination of the breasts for the presence of galactorrhea is important, and an aspiration endometrial biopsy should be considered. A thyroid-stimulating hormone (TSH) screen is also indicated in women complaining of alopecia. In addition, consideration should be directed to the possible presence of hyperinsulinemia. ***Patients with intense androgen action may be amenorrheic due to endometrial suppression (with a decidual response) and may not demonstrate withdrawal bleeding after a progestational challenge.***

Cushing's syndrome can present with hirsutism, and later, masculinization. Remember that one of the most common referral diagnoses is Cushing's syndrome, but this is one of the least common final diagnoses. When clinical suspicion is high, a screen for Cushing's syndrome is indicated.

The Screen for Cushing's Syndrome

Cushing's syndrome is the persistent oversecretion of cortisol. It can develop in 5 different ways: pituitary adrenocorticotropic hormone (ACTH) overproduction (Cushing's disease), ectopic ACTH overproduction by tumors, autonomous cortisol secretion by the adrenal or, very rarely, ovarian tumors, or a fifth extremely rare possibility, the secretion of corticotropin-releasing hormone (CRH) by a tumor. A clinician must first make the diagnosis of Cushing's syndrome (excessive cortisol secretion) before determining the etiology.²⁷

The most useful measurements in the basal state to detect Cushing's syndrome are the 24-hour urinary free cortisol excretion (10–90 μ g) and the late evening plasma cortisol level (less than 15 μ g/dL). The urinary excretion of 17-ketosteroids and 17-hydroxysteroids and measurement of morning and afternoon plasma cortisol levels are less reliable because of a significant overlap between normal and abnormal patients.

We prefer to start with the single-dose overnight dexamethasone test. Dexamethasone (1 mg) is given orally at 11 PM, and a plasma cortisol is drawn at 8:00 the next morning. A value less than 5 μ g/dL rules out Cushing's syndrome. Cushing's syndrome is unlikely with intermediate values between 5 and 10 μ g/dL, whereas a value higher than 10 μ g/dL is diagnostic of adrenal hyperfunction. The number of patients with Cushing's syndrome who show a normal suppression in the single-dose overnight test is negligible (less than 1%).²⁸ Obese patients, however, have a false-positive rate up to 13%.

If the single-dose overnight test is abnormal, establish the diagnosis by measuring the 24-hour urinary free cortisol. The low-dose, 2-day suppression test provides final confirmation. Dexamethasone (0.5 mg every 6 hours) is administered for 2 consecutive days after 2 days of baseline 24-hour urinary 17-hydroxysteroid and free cortisol measurements. Patients with Cushing's will not lower their urinary 17-hydroxysteroids below 2.5 mg/day and the free cortisol below 10 μ g on the second day of dexamethasone suppression. Combining the low-dose test with the 24-hour urinary free cortisol should definitely provide the diagnosis of Cushing's syndrome. A 24-hour urinary free cortisol greater than 250 μ g is virtually diagnostic of Cushing's syndrome, and a urinary free cortisol greater than 200 μ g/day provides 90% diagnostic accuracy.

Pseudo-Cushing's states exist in patients with mild hypercortisolism due to conditions such as alcoholism, response to stress, anorexia and bulimia nervosa, severe obesity, and depression. Although usually not necessary, combining the low-dose dexamethasone suppression test with CRH stimulation is an accurate method to distinguish the real syndrome from the hypercortisolism associated with these other conditions.²⁹ After two days of low-dose dexamethasone

suppression, a single plasma cortisol level is obtained 15 minutes after administering CRH (1 µg/kg) intravenously. A 15-minute cortisol level greater than 1.4 µg/dL requires further evaluation.

The etiology of Cushing's syndrome can be established by combining a high dose dexamethasone suppression test with measurement of the basal state blood ACTH level. Dexamethasone (2 mg every 6 hours) is administered for 2 days, and the urinary 17-hydroxysteroid and cortisol levels on the second day are compared with basal levels. If basal ACTH is less than 5 pg/mL, and the urinary steroids do not decrease by at least 40%, an adrenal tumor is likely. When ACTH is measurable in the blood (more than 20 pg/mL), an ectopic ACTH-producing tumor is unlikely if the urinary steroids decrease by at least 40%. Cushing's disease is present when the blood ACTH level is in the normal range, a chest x-ray is normal, and imaging detects an abnormal sella turcica. A level of plasma ACTH greater than 50 pg/mL suggests ectopic ACTH release; a level less than 5 pg/mL suggests an autonomous cortisol-secreting tumor.

Imaging is very accurate and reliable in detecting adrenal tumors.³⁰ In addition, imaging reliably predicts which patients have ectopic ACTH-producing tumors by detecting bilateral adrenal enlargement in such patients. CT scanning of the adrenal glands provides better resolution and is preferred over MRI and ultrasonography.

The evaluation of a patient with Cushing's syndrome can yield inconclusive results, and a failure to recognize an occult, ectopic ACTH-secreting neoplasm can lead to unnecessary pituitary or adrenal surgery. Bilateral venous sampling from the inferior petrosal sinus (sampling the blood draining from the pituitary gland) for the measurement of ACTH before and after CRH stimulation is an effective means to achieve accurate diagnosis of a pituitary origin for the ACTH.^{31, 32 and 33} Approximately 15% of patients with ACTH-dependent Cushing's syndrome will have an occult, ectopic source for the ACTH. Most of these ACTH-secreting lesions are in the thorax (usually small-cell lung carcinoma), some in the abdomen.³⁴ Petrosal sinus sampling is recommended in all patients with ACTH-dependent Cushing's syndrome who do not have an obvious adrenal tumor on imaging.³⁵

A very rare cause of Cushing's syndrome is the autonomous production of cortisol by an ovarian tumor.³⁶ Chest and abdominal imaging is recommended for all atypical presentations.

Assessment of Insulin Secretion

Hyperandrogenism and hyperinsulinemia are commonly associated, as discussed in detail with complete references in [Chapter 12](#). In many patients, a disorder in insulin action precedes the increase in androgens. Hyperinsulinemia can directly augment thecal cell androgen production in the ovary, and in addition, hyperinsulinemia contributes to the hyperandrogenism by inhibiting hepatic synthesis of sex hormone-binding globulin and insulin-like growth factor binding protein-1, actions that increase free testosterone levels and augment IGF-I stimulation of thecal androgen synthesis, respectively.

Weight loss reduces both hyperinsulinemia and hyperandrogenism, and is often followed by a return to ovulatory function. The use of oral agents such as troglitazone and metformin for the treatment of these patients offers great promise. Overweight, hyperandrogenic and hyperinsulinemic, anovulatory women must be counseled regarding their increased risk of future diabetes mellitus and cardiovascular disease.

The mechanism of hyperandrogenism can be attributed to hyperinsulinemia in an occasional case in which the circumstances are hard to understand; for example, the onset of hirsutism in an elderly woman who is found to have hyperthecosis in the ovaries. The appearance of hirsutism in such a case is not due to an ovarian response to hypergonadotropism but, rather, to the development of hyperinsulinemia.

For these reasons, we make the following recommendations:

All anovulatory women who are hyperandrogenic should be assessed for insulin resistance and glucose tolerance with measurements of:

- | | |
|---|----------------------|
| 1. The fasting glucose:insulin ratio, followed by | |
| 2. The 2-hour glucose level after a 75 g glucose load: | |
| normal | less than 140 mg/dL |
| impaired | 140–199 mg/dL |
| noninsulin-dependent diabetes mellitus | 200 mg/dL and higher |

In women who continue to manifest this disorder, periodic surveillance is necessary. The frequency is uncertain, but annual assessment is appropriate in women who continue to be obese.

Unfortunately, testing for hyperinsulinemia is not straightforward. Clinical guidelines for the interpretation of insulin levels and response to glucose loading have not been established. Because there is considerable overlap between normal women and patients with anovulation and polycystic ovaries, it is reasonable to assume that all overweight, anovulatory women with polycystic ovaries are hyperinsulinemic. Nevertheless, we recommend the measurement of the ratio of fasting glucose to fasting insulin in order to provide evidence that lends credence and importance to counseling efforts. **A ratio of less than 4.5 is consistent with insulin resistance.**³⁷

The DHAS Level

DHAS circulates in higher concentration than any other steroid and is derived almost exclusively from the adrenal gland. It is, therefore, a direct measure of adrenal androgen activity, correlating clinically with the urinary 17-ketosteroids.³⁸ The upper limit of normal in most laboratories is 350 µg/dL, but, because of laboratory variation, attention must be paid to the local range of normal.

A random sample of DHAS is sufficient for the evaluation of hirsutism, needing no corrections for body weight, creatinine excretion, or episodic variation. Variations

are minimized because of its high circulating concentration and its long half-life. A slow turnover rate results in a large and stable pool in the blood with insignificant variation. Elevated levels of DHAS contribute to the clinical problem of hirsutism because DHAS serves as a prohormone in hair follicles, providing substrate for the hair follicle synthesis of androgens.³⁹

Aging is associated with a decrease in the blood concentration of DHAS. The decrease accelerates after menopause, and DHAS is almost undetectable after age 70.⁴⁰ This decline is 4 times greater than the age-related decline in cortisol, which is further support for the contention that cortisol and DHAS secretion are separately controlled.

Both 17-ketosteroids and circulating levels of DHAS are elevated in association with hyperprolactinemia.^{40, 41, 42} The levels return to normal with prolactin suppression by dopamine agonist treatment. In addition, increased free testosterone levels associated with decreased SHBG are often found in hyperprolactinemic women.^{43, 44} This underscores the need to search for galactorrhea and to obtain a prolactin measurement in all anovulatory women. The androgen changes are probably secondary to the persistent anovulatory state induced by the elevated prolactin, although direct prolactin effects on the adrenal, ovary, or SHBG are possible.

When the DHAS level is normal, adrenal disease is most unlikely, and the diagnosis of excess androgen production by the ovaries is likely. There are only rare cases of adrenal tumors with normal DHAS levels, and further evaluation of such cases would be indicated by the presence of markedly elevated blood levels of testosterone.⁴⁵ These rare tumors are responsive to luteinizing hormone (LH), suggesting that they are derived from embryonic rest cells. Nonclassical (late-onset) adrenal hyperplasia commonly is not associated with an increased level of DHAS; the diagnosis of this condition relies on the measurement of 17-OHP for screening.

The clinical problem with DHAS measurements in the evaluation of hirsutism is the frequent finding of a moderately elevated DHAS level in anovulatory patients with polycystic ovaries. This is similar to the moderate elevations of 17-ketosteroids encountered in these patients. If the 17-OHP level is normal, we believe that it is not worthwhile to subject these patients to a search for an adrenal enzyme defect. Clinical experience has established that moderate elevations of DHAS are associated with anovulation; suppression of ovarian function restores the DHAS level to normal.

A DHAS level of 700 µg/dL or greater has been accepted as a marker for abnormal adrenal function. But how often is a DHAS of this level encountered? ***DHAS levels of 700 µg/dL or more are confronted so rarely that we must now question the clinical usefulness of measuring DHAS. We cannot identify a single case in our experience in which the DHAS level changed patient management. Even if a DHAS of 700 µg/dL or greater is encountered, we believe that the adrenal secretion of extremely high levels of DHAS will be associated with high levels of testosterone, either by direct secretion or by peripheral conversion of the DHAS. Therefore, in the absence of Cushing's syndrome, we believe that measurement of testosterone will suffice to screen for adrenal abnormalities. An imaging assessment of the adrenal glands whenever a markedly elevated testosterone is encountered will be more cost-effective than measuring DHAS in all hirsute women.***

Nonclassical Adrenal Hyperplasia

Congenital adrenal hyperplasia is due to an enzyme defect leading to excessive androgen production. This severe condition, with its prenatal onset, is inherited in an autosomal recessive fashion (discussed in [Chapter 9](#)). A milder form of the disease, appearing later in life, has been designated by a variety of adjectives, including late-onset, partial, nonclassical, attenuated, and acquired adrenal hyperplasia.^{46, 47} An asymptomatic form, cryptic adrenal hyperplasia, is revealed only with biochemical testing.

Although each of the enzymatic steps from cholesterol to cortisol can be affected in specific clinical disease, the most common enzymes to be deficient are 21-hydroxylase (p450c21), 11b-hydroxylase (p450c11), and 3b-hydroxysteroid dehydrogenase.

The 21-Hydroxylase Defect

Women with late-onset adrenal hyperplasia due to a 21-hydroxylase deficiency respond to ACTH stimulation in a moderate fashion, between the classical homozygote response and the mild heterozygote reaction (see the [17-OHP](#) nomogram). A 21-hydroxylase deficiency is now recognized to be the most common autosomal recessive disorder, surpassing cystic fibrosis and sickle cell anemia.⁴⁸ The clinical presentation is extremely variable, and the symptoms may appear and disappear over time. Therefore, the diagnosis requires laboratory evaluation as discussed under "The 17-OHP Level." The genetic diagnosis for known mutations in the CYP21 gene is discussed in [Chapter 9](#).

There are at least 3 reasons that make it worthwhile to seek the correct diagnosis:

1. Therapy should be accurately applied because it must be long-term.
2. Pregnant couples with this condition require genetic counseling for the prenatal diagnosis and possible treatment of the congenital form of the disease, as well as the assessment of asymptomatic offspring. However, without knowing the father's carrier status, an accurate estimate of risk is impossible. Although the risk of having a child with congenital adrenal hyperplasia is very low, the couple should consider paternal testing for heterozygosity. If the father tests positively, prenatal diagnosis and treatment would be reasonable.
3. Theoretically, these patients might be subject to cortisol deficiency during severe stress; however, to our knowledge this has not been a clinical problem.

Other Enzyme Defects

The 3b-hydroxysteroid (type II) dehydrogenase deficiency exists in both the ovaries and adrenals. This defect precludes significant androgen production; however, this enzyme activity appears to remain intact in peripheral tissues. Therefore, hirsutism seen with this deficiency is probably due to target tissue conversion of the increased secretion of precursors.⁴⁹ Unlike 21-hydroxylase deficiency, no genetic markers are currently available; diagnosis requires ACTH stimulation and demonstration of an altered 17a-hydroxypregnenolone to 17-OHP ratio. Some argue that late-onset 3b-hydroxysteroid dehydrogenase deficiency is encountered more frequently than 21-hydroxylase deficiency.⁵⁰ However, although an exaggerated 17a-hydroxypregnenolone response to ACTH stimulation is common in women with hyperandrogenism, the response is consistent with adrenal hyperactivity and not an enzyme deficiency.⁵¹ Furthermore, molecular studies fail to find mutations in the genes for the two 3b-hydroxysteroid dehydrogenase enzymes in patients who appear to have mild to moderate deficiencies in 3b-hydroxysteroid dehydrogenase.^{52, 53} We believe that this deficiency is so subtle that accurate diagnosis is not essential. Our usual therapeutic approach to hirsutism will be effective. The 11b-hydroxylase deficiency is quite rare, and it is usually diagnosed at a younger age ([Chapter 9](#)). It is not worth measuring the 11-deoxycortisol response to ACTH stimulation in adult hirsute women in an effort to detect this rare deficiency.⁵⁴

The 17-OHP Level

From 1 to 5% of women who complain of hirsutism display a biochemical response that is consistent with the less severe form of adrenal hyperplasia of the 21-hydroxylase variety.^{55, 56 and 57} This relative frequency of late-onset adrenal hyperplasia dictates routine 17-OHP screening of women who complain of hirsutism. On the other hand, the routine use of the ACTH stimulation test is not warranted.^{55, 58} Heterozygosity for CYP21 mutations does not increase the risk of clinically significant hirsutism.⁵⁹

Besides using the 17-OHP screen to make a cost-effective decision regarding ACTH stimulation, one can be swayed by pertinent clinical findings.⁶⁰ A strong family history of androgen excess suggests the presence of an inherited disorder. Hirsutism due to an adrenal enzyme defect usually is more severe and begins at a young age, typically at puberty. Short stature and very high blood levels of androgens also signify a more severe problem. Finally, it is worth considering the following: ***With normal baseline steroid levels, even if a woman has a subtle enzyme defect, the management of the problem does not require its discovery.***

17-OHP must be measured first thing in the morning to avoid later elevations due to the diurnal pattern of ACTH secretion. The baseline 17-OHP level should be less than 200 ng/dL.⁵⁸ Levels greater than 200 ng/dL, but less than 800 ng/dL, require ACTH testing. Levels over 800 ng/dL are virtually diagnostic of the 21-hydroxylase deficiency. The DHAS level is usually normal. The hallmarks of late-onset adrenal hyperplasia are elevated levels of 17-OHP and a dramatic increase after ACTH stimulation.⁵⁶ However, the elevated baseline levels of 17-OHP are often not impressive (e.g., overlapping with those found in women with polycystic ovaries due to anovulation), and a simple ACTH stimulation test must be utilized.

The ACTH Stimulation Test

Synthetic ACTH (Cortrosyn) is administered intravenously in a dose of 250 µg. Blood samples for the measurement of 17-OHP are obtained at time 0 and again at 1 hour. The testing must be performed in the morning (8 AM), but it can be scheduled at any time during the menstrual cycle. The 1 hour value is plotted on the nomogram which predicts the genotype of homozygote and heterozygote forms of the 21-hydroxylase deficiency.⁶¹ Dexamethasone pretreatment the night before is not necessary.⁶² Heterozygote carriers for 21-hydroxylase deficiency have ACTH-stimulated levels of 17-OHP up to 1000 ng/dL; patients with late-onset deficiency have stimulated levels above 1200 ng/dL.

For the diagnosis of the 3β-hydroxysteroid dehydrogenase deficiency, the same ACTH stimulation test is utilized, measuring 17-OHP and 17-hydroxypregnenolone. An abnormal 17-hydroxypregnenolone/17-OHP ratio is usually greater than 6.0.⁴⁹ This deficiency is also usually marked by a significant elevation of DHAS in the face of normal or mildly elevated testosterone levels. In the 11β-hydroxylase deficiency, the level of 11-deoxycortisol will be increased; it is normal with the 21-hydroxylase defect.

The Adrenal Gland and Anovulation

Adrenal involvement in the syndrome of anovulation and hirsutism has long been recognized. Adrenal suppression, for example, will induce regular menses and ovulation in some patients, and empiric treatment with glucocorticoids has been advocated in the past.

Late-onset adrenal hyperplasia does not explain every anovulatory woman encountered with a moderate elevation in DHAS. The important clinical question is the following: is excessive androgen secretion by the adrenal gland a primary disorder in these women, or is it a secondary reaction to the hormonal milieu associated with anovulation?

One possibility is that the adrenal hyperactivity (as indicated by elevated DHAS levels) is due to an estrogen-induced 3β-hydroxysteroid dehydrogenase insufficiency. Considerable effort has been devoted to demonstrating an estrogen influence on adrenal androgen secretion. Unfortunately there is no clear-cut conclusion, with both positive^{63, 64, 65, 66} and negative^{68, 69, 70, 71} results reported.

This picture may be similar to that of the fetal adrenal gland. Studies have demonstrated that the low level of 3β-hydroxysteroid dehydrogenase activity and high secretion of DHAS by the fetal adrenal cortex are due to estrogen.^{73, 74} Inconsistent with this explanation is the fact that ACTH levels in adult anovulatory women are not elevated;^{75, 76} however, the period of increased ACTH response would exist only until normal cortisol levels are re-achieved (a new set point). Indeed, studies of anovulatory women with elevated levels of DHAS indicate that the increase in adrenal activity is because of a mechanism within the adrenal gland, not because of an increase in pituitary response to CRH and not because of increased adrenal response to ACTH stimulation.⁷⁷

The activity of 3β-hydroxysteroid dehydrogenase is inhibited by both androgens and estrogens in concentrations to be expected within the adrenal gland but difficult to achieve with exogenous administration; changes in adrenal secretion, therefore, can reflect varying action of steroids, especially estrogen, in different layers of the adrenal cortex.⁷⁸ The failure to affect adrenal steroidogenesis with the exogenous administration of androgens is consistent with this hypothesis.⁷⁹ Thus, it remains attractive to explain adrenal hyperactivity seen in anovulatory women as a secondary reaction induced and maintained by the constant estrogen state associated with persistent anovulation. Indeed, in patients with polycystic ovaries and increased adrenal androgen activity, a correlation can be demonstrated between adrenal sensitivity to ACTH and estrogen levels.⁸⁰ This relationship, however, may be the result of mechanisms other than inhibition of 3β-hydroxysteroid dehydrogenase (see discussion of the fetal adrenal gland in [Chapter 8](#)).

Suppression of ovarian function by treatment with a GnRH agonist has been utilized in hopes of bringing clarity to this puzzle by assessing adrenal function after elimination of ovarian steroid production. Short-term suppression (3–6 months) has been reported to have no impact on adrenal androgen production.^{81, 82} However, these studies did not include women with high levels of DHAS. When anovulatory women with levels of DHAS greater than normal are treated with a gonadotropin-releasing hormone (GnRH) agonist for at least 3 months, in some women, but not all, the elevated DHAS levels are suppressed.^{83, 84} Thus, the exact

nature of the adrenal-ovarian relationship in these women may vary, consistent with the clinical heterogeneity characteristic of these patients. It has been suggested that increased adrenal androgen production in some women is secondary to P450c17 17,20 lyase hyperactivity, and in others it is an acquired response due to the anovulatory hormonal steady state.^{84, 85 and 86} In those women with P450c17 hyperactivity, the underlying disorder may be hyperinsulinemia.⁸⁷

Regardless of differences in weight, diet, race, and environmental factors, excess adrenal androgen activity is present in one-half to two-thirds of anovulatory women and hyperinsulinemia in approximately 70%.⁸⁸ It makes sense that similar growth factor modulation takes place in adrenal steroid-producing cells as in the ovary. Women with polycystic ovaries (both obese and nonobese) and hyperinsulinemia have a greater steroidogenic response to ACTH than anovulatory patients with normal insulin levels.⁸⁹

Insulin and IGF-I receptors are present on adrenal cells. The infusion of insulin into women causes a decrease in DHAS, and hyperinsulinemia inhibits adrenal 17,20 lyase (P450c17) activity, suggesting that insulin decreases the production of this adrenal androgen.^{90, 91} It is further suggested that the age-related decline in DHAS may be related to increasing insulin resistance.⁹² How do these changes relate to DHAS levels in anovulatory women, levels that range from normal to moderately elevated? A simple inverse relationship between insulin and adrenal androgen levels in anovulatory women does not exist.⁹³ Furthermore, in a study of 92 consecutive women with hirsutism, the steroidogenic response to ACTH stimulation was not consistent with an inherent disorder of P450c17.⁹⁴

An ovulatory response following the treatment of anovulatory women with dexamethasone can be explained in part by a contribution made to ovarian androgen production by circulating DHAS. A significant percentage of testosterone production by the ovarian follicle can be attributed to circulating DHAS serving as a substrate or prehormone.⁹⁵ Thus, dexamethasone suppression cannot separate adrenal and ovarian testosterone secretion in that the two glands are involved in a complex interaction, with DHAS providing at least one mechanism for this interaction.

The inconclusiveness of this situation and the rarity of a true adrenal enzyme deficiency in adult women make a cost-effective argument against routine endocrine testing. Accordingly, we have adopted a 17-OHP level of 200 ng/dL, below which we do not pursue the possibility of a primary adrenal enzyme problem, and we now find little use for DHAS measurements. Mild adrenal enzyme defects can be treated by our usual methods and do not require glucocorticoid administration.

The Testosterone Level

Plasma testosterone levels (normal 20–80 ng/dL) are elevated in the majority of women (70%) with anovulation and hirsutism. Individual variation is great, however, largely because of the changes in the testosterone-binding capacity of the sex hormone-binding globulin in the blood. Because the binding globulin levels are depressed by androgen and insulin, the total testosterone concentration can be in the normal range in a woman who is hirsute even though the percent unbound and active testosterone is elevated. Indeed, the unbound or free testosterone is approximately twice normal (an increase from 1% to 2%) in women with anovulation and polycystic ovaries.⁹⁶ Therefore, a normal total testosterone level in hirsute women is still consistent with elevated androgen production rates.

It is not necessary to measure the free testosterone (a technically difficult and expensive assay) because a routine total testosterone assay adequately serves the purpose of screening for testosterone-secreting tumors. Such tumors are associated with testosterone levels that are usually in the male range, and, therefore, the fine discrimination of the free testosterone level is unnecessary.^{97, 98} **If the testosterone level exceeds 200 ng/dL, an androgen-producing tumor must be suspected.**

The arbitrary cutoff point has been challenged because variations in secretion can yield misleading values, and not all androgen-producing tumors will be this active, and some women with polycystic ovaries (especially hyperthecosis) will have testosterone levels greater than 200 ng/dL.^{99, 100} Nevertheless, the combination of the patient's historical chronology of the development of hirsutism, the pelvic examination, and the 200 ng/dL testosterone level will provide accurate diagnosis in virtually all cases. **A patient with an acute, rapid course of virilizing symptoms requires a full evaluation for the presence of an androgen-producing tumor even if the testosterone concentration is less than the cutoff level.**

Be aware that testosterone levels are significantly elevated during normal pregnancy. Levels are greater than 100 ng/dL in the first trimester and reach 500 to 800 ng/dL by term.¹⁰¹ This is mainly due to the estrogen-induced increase in sex hormone-binding globulin; however, even the free testosterone level is elevated in the third trimester. Mother and fetus are protected from these high androgen levels by many mechanisms, including binding to sex hormone-binding globulin and placental aromatization of androgens to estrogens.

Androgen-Producing Tumors

There are two findings that should stimulate the clinician to suspect the presence of an androgen-producing tumor. One is a history of rapidly progressive masculinization. Hirsutism associated with anovulation is generally slow to develop, usually covering a time period of at least several years. Tumors are associated with a short time course, measured in months. The second finding that should arouse suspicion is a testosterone level greater than 200 ng/dL.

In our view, androgen-producing tumors are one of medicine's vastly overrated problems. First, they are incredibly rare, yet they attract an inordinate amount of attention at our meetings and a disproportionate number of printed pages in texts and journals. Second, there is an endocrine mystique surrounding the functioning tumor. Actually it is a straightforward problem.

Functioning ovarian tumors are almost all palpable, and like any ovarian mass, rapid laparotomy and surgical removal are in order. It is well recognized, however, that very small ovarian tumors (usually in the hilus of the ovary) can secrete testosterone. And occasionally, virilization is encountered with a nonfunctional tumor due to tumor stimulation of androgen secretion in the surrounding stromal tissue.¹⁰²

The only diagnostic dilemma is when to explore the patient in whom a mass is not palpable. Suppression and stimulation tests are known to falsely lead to oophorectomy in the presence of a virilizing adrenal adenoma.⁹⁸ In addition, suppression and stimulation methods do not specifically isolate ovarian or adrenal function.^{102, 103} Ovarian androgen-producing tumors are responsive to LH and, therefore, will respond to ovarian suppression and stimulation.^{104, 105 and 106}

Selective angiography with venous sampling and measurement of adrenal and ovarian steroids is not without problems. It is technically difficult to achieve bilateral catheterization of the ovaries, steroid secretion is episodic (especially by the adrenal glands), and the technique is not without risk. Selective retrograde catheterization of ovarian and adrenal veins by an expert should be reserved for those few patients who have been imaged with negative findings and yet the clinical

history is suggestive of a tumor. Surgical exploration and bivalving of the ovaries may be necessary if the catheterization studies are negative. However, a surgical approach requires the presence of an appropriately rapid appearance of virilizing signs.

In postmenopausal women with hyperandrogenism, it is usually appropriate to be more aggressive surgically; however, keep in mind that hyperinsulinemia in the postmenopausal years can stimulate hyperthecosis, which would simulate the presentation of a tumor.¹⁰⁷ GnRH agonist treatment can avoid surgery in these patients because insulin-induced steroidogenic activity in the ovary is still LH-dependent.

When an androgen-producing tumor is suspected and an adnexal mass is not palpable, imaging of the adrenal glands and ovaries should be obtained. Imaging of the adrenal is a sensitive diagnostic technique for small tumors that produce Cushing's syndrome as well as for virilizing adrenal adenomas.^{30,98} For adrenal imaging, CT scanning provides better resolution and is preferred over MRI and ultrasonography. For ovarian imaging, transvaginal ultrasonography is the method of choice.

The Incidental Adrenal Mass

Adrenal masses will be discovered incidentally in approximately 10% of postmortem examinations, and therefore, it is to be expected that an incidental adrenal mass will be discovered occasionally with abdominal imaging.¹⁰⁸ Bilateral lesions are more serious. Common causes of bilateral lesions are metastatic cancer (most commonly from breast, kidney, or lung), infection (tuberculous and fungal), and adrenal hyperplasia; hence, surgery is rarely indicated. A primary malignancy of the adrenal is usually associated with excess secretion of glucocorticoids and androgens. The size of a lesion is significant.¹⁰⁹ The probability of malignancy roughly parallels the diameter of the lesion. Bilateral lesions less than 3 cm usually are due to metastatic disease. Thus, the current recommendation is to excise unilateral masses if they are of significant size, usually greater than 4 cm in diameter. Fine needle aspiration is also recommended for all unilateral adrenal lesions, after excluding a pheochromocytoma, to rule out metastatic lesions.¹⁰⁸ When following a mass, imaging should be performed at 3, 9, and 18 months. Any mass that is stable after 18 months can be left in place.

Incidental adrenal masses require evaluation for biochemical function. The presence of hypertension raises the suspicion of Cushing's syndrome, hyperaldosteronism, or pheochromocytoma. The evaluation should include a screening test for pheochromocytoma (24-hour urinary catecholamines), electrolyte, aldosterone, and renin activity assessment for aldosteronism, a 24-hour urinary free cortisol, and a testosterone level. If these tests are normal, subclinical hormone secretion can be present. A relatively high incidence of cortisol-secreting tumors in the presence of normal 24-hour urinary free cortisol excretion indicates the need to perform an overnight dexamethasone suppression test in patients with asymptomatic incidental adrenal masses.¹¹⁰ There appears to be a high incidence of adrenal masses in patients with adrenal hyperplasia, presumably because of chronic excess ACTH stimulation. These need not be removed surgically, but a laboratory evaluation for adrenal hyperplasia is, therefore, indicated in patients with incidental adrenal masses to avoid unnecessary surgery.¹¹¹ Finally, the clonidine suppression test is useful to diagnose a subclinical pheochromocytoma. Adrenal scintigraphy uses radiotracers accumulated by functioning tissue and is recommended when biochemical testing is normal.¹⁰⁹ When uptake in the mass is less than in the contralateral adrenal (a "discordant" pattern), fine-needle aspiration is indicated to rule out a malignant lesion.

Screening Tests for Incidental Adrenal Masses

24-hour urinary catecholamines and free cortisol

Testosterone

Renin activity, aldosterone, and electrolytes

Provocative Tests for Subclinically Active Incidental Adrenal Masses

Dexamethasone overnight suppression test

17-Hydroxyprogesterone response to ACTH

Clonidine suppression test (clonidine, 0.3 mg p.o. in a supine position, followed by plasma norepinephrine levels at 0, 2, and 3 hours; a norepinephrine level above 500 pg/mL or 50% greater than the 0-hour level is a positive result)

Summary of Key Recommendations for the Evaluation of Hirsutism

- 1. The laboratory evaluation of hirsutism consists of the measurement of the circulating levels of testosterone and 17-OHP. When alopecia is present, a TSH screen for thyroid function is also indicated.**
- 2. The single-dose overnight dexamethasone test is used to screen for Cushing's syndrome. Abnormal results are confirmed by measuring the 24-hour urinary free cortisol.**
- 3. A clinician should always consider the possibility of hyperinsulinemia and emphasize preventive health interventions (as discussed in [Chapter 12](#)).**
- 4. Any patient with rapidly progressive virilization must be evaluated for an androgen-secreting tumor regardless of the results of screening laboratory tests.**
- 5. Incidentally discovered adrenal masses require evaluation.**

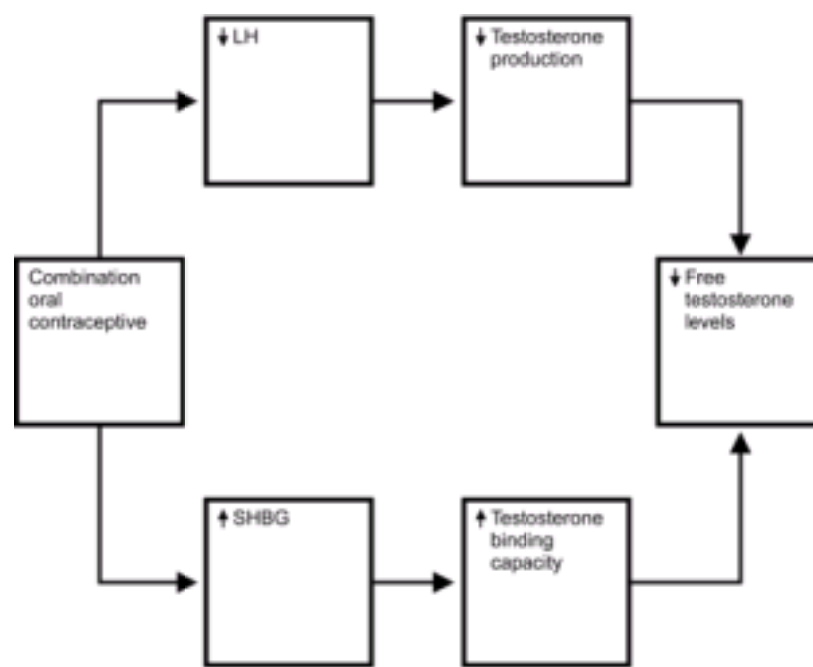

Treatment of Hirsutism

Almost all patients presenting with hirsutism represent excess androgen production in association with the steady state of persistent anovulation. Treatment is directed toward interruption of the steady state. In those patients who wish to become pregnant, ovulation can be induced as discussed in [Chapter 30](#). In patients who do not want to become pregnant, the steady state can be interrupted by suppression of ovarian steroidogenesis by utilizing the potent inhibitory action on LH of progestational agents.

Androgen production in hirsute women is usually an LH-dependent process. Suppression of ovarian steroidogenesis depends upon adequate LH suppression. In addition to the inhibitory action of the progestational component, oral contraceptives provide a further benefit because of the increase in SHBG levels induced by the estrogen component. The increase in SHBG results in a greater androgen-binding capacity with a decrease in free testosterone levels. The progestins in oral contraceptives also inhibit 5 α -reductase activity in skin, further contributing to the clinical impact of oral contraceptives on hirsutism.¹¹²

The low-dose oral contraceptives are effective in treating acne and hirsutism. Suppression of free testosterone levels is comparable with that achieved with higher dosage.^{113,114} The beneficial clinical effect is the same with low-dose preparations containing levonorgestrel, previously recognized to cause acne at high dosage.^{114,115} Formulations with desogestrel, gestodene, and norgestimate are associated with greater increases in sex hormone-binding globulin and significant decreases in free testosterone levels. Comparison studies with oral contraceptives containing these progestins can detect no differences in effects on various androgen measurements among the various products.¹¹⁶ Theoretically, these products would be more effective in the treatment of acne and hirsutism; however, this is not documented by clinical studies. It is likely that all low-dose formulations through the combined effects of an increase in sex hormone-binding globulin and a decrease in testosterone production produce an overall similar clinical response, especially over time (a year or more).

Even in women being treated with antiandrogens, oral contraceptives are important and useful to provide both cycle control and contraception.

In the patient in whom oral contraceptives are contraindicated or unwanted, good results can be achieved with the use of medroxyprogesterone acetate, either 150 mg intramuscularly every 3 months or 10–20 mg orally per day. The mechanism of action of medroxyprogesterone acetate is slightly different from that of the combination oral contraceptive. Suppression of gonadotropins is less intense; hence, ovarian follicular activity continues. LH suppression is significant, however, and testosterone production is decreased, although to a lesser degree than with combined oral contraceptives. In addition, testosterone clearance from the circulation is increased.¹¹⁷ This latter effect is due to an induction of liver enzyme activity. Medroxyprogesterone acetate decreases SHBG so that less testosterone is bound; however, suppression of total testosterone production is so great that the actual amount of free testosterone decreases.¹¹⁸ The overall effect yields a clinical result comparable with that achieved with the combination oral contraceptive.

A noteworthy feature of hirsutism is the slow response to treatment. Because of the hair growth cycle, change takes time. The patient should be cautioned that treatment with hormonal suppression will be necessary for at least 6 months before an observable diminution in hair growth occurs. Combined treatment with electrolysis is not recommended, therefore, until hormonal suppression has been used at least 6 months.

New hair follicles will no longer be stimulated to grow, but hair growth that has been previously established will not disappear with hormone treatment alone. This can be affected temporarily by shaving, tweezing, waxing, or the use of depilatories.¹¹⁹ Contrary to a common belief, these methods do not stimulate growth or increase the rate of growth of hair. None of these tactics alters the inherent growth of the hair; therefore, they must be reapplied at frequent intervals. Permanent removal of hair can be accomplished only by electrocoagulation of dermal papillae. Patients should be counseled to make sure their electrologists use disposable needles.

Some patients return after a period of treatment expressing disappointment because hair is still present. The effect of the treatment (prevention of new hair growth) may not be apparent unless the previously established hair is removed. The combination of ovarian suppression preventing new hair growth and electrolysis removing the old hair yields the most complete and effective treatment of hirsutism.

How long should treatment be continued? After 1–2 years, it is worthwhile to stop the medication and observe the patient for a return of ovulatory cycles. Even in those patients who continue to be anovulatory, testosterone suppression continues for 6 months to 2 years after discontinuing treatment. Of course, if anovulation is still present, one can expect the eventual return of hirsutism.

The really resistant patient deserves further consideration. Combination therapy with one of the methods discussed below is worthwhile, preferably an oral contraceptive combined with either spironolactone or finasteride.

In most patients, DHAS levels are suppressed by progestational treatment.^{120, 121} The mechanism is not definitely known, but there are several possible explanations. If the original stimulus for the increased DHAS secretion is the steady estrogen state of anovulation, then the change in the endocrine milieu of the adrenal gland brought about by the suppression of ovarian steroidogenesis will restore a normal adrenal secretory pattern. Oral contraceptives may also produce subtle but significant alterations in ACTH secretion or response in the adrenal gland.

The effectiveness of adrenal suppression in inducing ovulatory cycles in some anovulatory patients can be attributed to a lowering of circulating androgen levels due to a decrease in the adrenal contribution as well as a reduction in the amount of DHAS available for conversion to testosterone within the ovarian follicle. The intraovarian androgen level is decreased, therefore lowering the inhibitory action of androgens on follicular growth and development. In terms of ovulation, the frequency of successful response with this type of treatment does not match that of the first drug of choice, clomiphene. In terms of treatment of hirsutism, progestin suppression of ovarian steroidogenesis is more effective and should remain the first therapeutic approach. Adrenal suppression should be reserved for patients with a clearly established diagnosis of an adrenal enzyme deficiency.

In an older woman who has no further desire for fertility, and in the woman for whom continued use of steroid medication is disturbing because of increasing risks with increasing age, serious consideration should be given to a surgical solution. A persistent problem of hirsutism, especially if it is progressive in severity, is a reasonable indication for hysterectomy and bilateral salpingo-oophorectomy. Patients with hyperthecosis respond poorly to suppression and are usually older. Surgical treatment for these patients is often very appropriate. Of course, an estrogen regimen is recommended for these patients postoperatively.

Keep in mind the strong association between hyperandrogenism and hyperinsulinemia as discussed in [Chapter 12](#). Treating the problem of hirsutism by suppression of androgen production and action will not restore glucose metabolism to normal; these patients will continue to demonstrate insulin resistance. In overweight, hyperandrogenic patients, a weight control program is essential to reduce the risks of diabetes mellitus and cardiovascular disease, and consideration should be given to the preventive health benefits expected from long-term treatment with metformin or troglitazone. Nevertheless, hirsutism in hyperandrogenic women with hyperinsulinemia will respond favorably to treatment with oral contraceptives.¹²²

Additional Methods of Treatment

Spironolactone

Spironolactone is an aldosterone-antagonist diuretic. In the treatment of hirsutism, spironolactone has multiple actions, inhibiting the ovarian and adrenal biosynthesis of androgens, competing for the androgen receptor in the hair follicle, and directly inhibiting 5 α -reductase activity. The inhibition of steroidogenesis is achieved through an effect on the cytochrome p450 system, but the steroid suppressive effects are so variable that the receptor-blocking action is the most important mechanism.¹²³ It is probably for this reason that cortisol, DHA, and DHAS levels are not significantly changed with spironolactone treatment, even though

androstenedione levels are decreased. ¹²⁴

The impact of spironolactone treatment on hirsutism is related to dosage, and a better effect is seen with a dose of 200 mg daily. ^{125, 126 and 127} After a period of time, one can usually lower the dose of spironolactone to a maintenance dose of 25–50 mg daily. As with progestational agents, the response is relatively slow, and a maximal effect can be demonstrated only after 6 months of treatment. Side effects are minimal, including diuresis in the first few days of use, occasional complaints of fatigue, and dysfunctional uterine bleeding. Remember that the anovulatory state requires progestational management in order to avoid abnormal uterine bleeding (and endometrial hyperplasia). Because of the possibility of hyperkalemia, spironolactone should be used with caution in women who are elderly, diabetic, or using drugs that raise the potassium level.

We use spironolactone when patients find oral contraceptives unacceptable or the response is disappointing. Indeed, it makes sense to combine the peripheral tissue action of spironolactone with oral contraceptives to achieve a more dramatic result; however, the results with combined treatment regimens have not been impressively better than single agent therapy. ^{128, 129} Acne has been effectively treated with the local application of a cream containing 2–5% spironolactone. ¹³⁰ Systemic absorption does not occur, and there are no side effects.

One word of caution: with inhibition of androgen secretion, ovulation can occur, and effective contraception is important. Theoretically, spironolactone interference with testosterone action could result in the feminization of a male fetus; however, a disrupting effect on the external genitalia has not occurred, despite fetal exposure to high doses. ¹³¹ Combined treatment with an oral contraceptive may produce a better clinical effect and, at the same time, prevent menstrual irregularity and provide contraception.

Cyproterone Acetate

Cyproterone is a potent progestational agent that both inhibits gonadotropin secretion and blocks androgen action by binding to the androgen receptor. In many parts of the world, it has been used in an oral contraceptive agent called “Diane” (2 mg cyproterone acetate and 50 µg ethinyl estradiol). “Dianette” or “Diane 35” contains 2 mg cyproterone acetate and 35 µg ethinyl estradiol. In a method for the treatment of hirsutism called the reversed sequential regimen, cyproterone acetate is given in a dose of 50 or 100 mg daily on days 5–14, with 30 or 50 µg of ethinyl estradiol daily on days 5–25. ¹³² In a comparison of Diane with the high dose (100 mg) cyproterone acetate treatment, the therapeutic effect was greater (but probably not of clinical significance) with the higher dose, and there was a similar incidence of side effects with both treatments. ¹³³ In a comparison of Dianette with higher doses of cyproterone acetate (20 and 100 mg), the clinical response with the 2 mg dose of cyproterone in Dianette was equal to that of the higher doses. ¹³⁴ The most common reactions include fatigue, edema, loss of libido, weight gain, and mastalgia. Significant improvement in facial hirsutism is seen by the 3rd month of treatment. In comparisons of spironolactone and cyproterone acetate, a monophasic low-dose oral contraceptive combined with spironolactone 100 mg daily was as effective as the reversed sequential regimen of 50 or 100 mg cyproterone and estrogen. ^{135, 136 and 137}

Dexamethasone

Dexamethasone suppression of endogenous ACTH secretion is used in women who have an adrenal enzyme deficiency. Dexamethasone is given nightly (to achieve maximal suppression of the central nervous system-adrenal axis that peaks during sleep) in a dose of 0.5 mg. An equivalent dose of prednisone is 5–7.5 mg. If this treatment suppresses the morning plasma cortisol level below 2.0 µg/dL, the dose should be reduced to avoid an inability to react to stress. Fortunately, adrenal androgen secretion is more sensitive to suppression by dexamethasone than is cortisol secretion. ¹³⁸ Patients with adrenal hyperplasia may require higher doses to normalize the steroid blood levels. With higher doses, alternate day therapy can still accomplish significant adrenal androgen suppression without affecting cortisol secretion. ¹³⁹ It should be emphasized that moderate elevations of DHAS do not indicate patients who will benefit from dexamethasone treatment. ¹⁴⁰ Maximal effectiveness against hirsutism in patients with an adrenal enzyme deficiency may require treatment besides glucocorticoid supplementation. ^{141, 142} The addition of an oral contraceptive or antiandrogen should be considered.

Treatment With GnRH Agonists

Because ovarian androgen production is LH-dependent, suppression of the pituitary with chronic GnRH agonist treatment improves hirsutism. However, inconsistent results in the literature attest to the fact that sufficient dosage must be administered to achieve effective suppression and clinical response. Therefore, monitoring dosage and response is recommended. A greater dose of GnRH agonist is required to suppress ovarian androgen secretion compared with estradiol secretion. ¹⁴³ We recommend the use of depot administration of a GnRH agonist with monitoring treatment by measuring testosterone levels (the goal being less than 40 ng/dL). To avoid the problems associated with estrogen deficiency, estrogen-progestin add-back should be initiated after the maintenance dose of a long-acting GnRH agonist has been established. We recommend the daily administration of 0.625 mg conjugated estrogens or 1.0 mg estradiol combined with 2.5 mg medroxyprogesterone acetate or 0.35 mg norethindrone, or, even better, an oral contraceptive.

Although a combination of a GnRH agonist and an oral contraceptive produces a greater reduction in free testosterone levels, improvement of hirsutism is similar, comparing the combination to treatment with only an agonist; however, treatment with an agonist has been reported to be more effective than oral contraceptives alone. ^{144, 145 and 146} In one clinical trial, the improved response associated with agonist treatment was observed only in the first 3 months of treatment; by 6 months the combination of oral contraceptives and a GnRH agonist was no more effective than oral contraceptives. ¹⁴⁷ The addition of a long-acting agonist to Dianette (2 mg cyproterone acetate and 35 µg ethinyl estradiol) did not significantly improve clinical results. ¹⁴⁸ After one year, a comparison of GnRH agonist treatment with the high dose cyproterone acetate regimen indicated equal efficacy, although agonist treatment was followed by a more prolonged remission. ¹⁴⁹ These mixed results reflect variability in the severity of the condition and the degree in androgen suppression. The impact of a GnRH agonist-oral contraceptive combination is maximal when testosterone levels are suppressed below 40 ng/dL and in patients who are overweight with severe hirsutism.

This method of treatment is relatively complicated and expensive and should be reserved for the severe case of ovarian hyperandrogenism, which is usually due to significant hyperthecosis and marked hyperinsulinemia (a condition that responds less well to the usual methods of treatment). An alternative that deserves consideration is treatment of the hyperinsulinemia with metformin or troglitazone. Once maximal response has been obtained with one of these more expensive methods, long-term suppression of hair growth can be maintained with an oral contraceptive or an antiandrogen.

Flutamide

Flutamide (Eulexin) is a nonsteroidal antiandrogen at the receptor level. ¹⁵⁰ Flutamide directly inhibits hair growth without many side effects (dry skin is the most common); however, hepatotoxicity is possible. ¹⁵¹ Because of the uncommon but severe toxic effect on the liver, a low-dose approach is recommended. A dose of 250

mg daily can have a marked beneficial impact on hirsutism within 6 months.¹⁵² Despite the use of lower doses, however, it is prudent to monitor liver enzymes. In a comparison study, flutamide (250 mg bid) was not more effective than spironolactone (100 mg/day).¹⁵³ Treatment with flutamide should be combined with a method of contraception; blockage of androgen receptors in a male fetus could interfere with normal male development. In our view, the potential for hepatotoxicity makes flutamide an unsatisfactory choice for treatment of hirsutism.

Finasteride

Finasteride inhibits 5 α -reductase activity, thus blocking conversion of testosterone into dihydrotestosterone. The 5 α -reductase enzyme exists in two forms, type I and II, each encoded by a separate gene, with the type I enzyme found in skin and the type II reductase predominately expressed in reproductive tissues.¹⁵⁴ Finasteride (Proscar), used to treat prostate cancer, effectively inhibits both isoenzymes, and, therefore, can be used to treat hirsutism. A dose of 5 mg per day decreases hirsutism without side effects.¹⁵⁵ A lower dose is probably as effective. Finasteride has been available only as a 5 mg unscored tablet, but it can with care be cut into quarters. A smaller dose, 1 mg (Propecia), has now been approved for the treatment of hair loss in men. In a randomized, clinical trial finasteride and spironolactone (100 mg daily) were equally effective.¹⁵⁶ In another randomized clinical trial, spironolactone in a dose of 100 mg daily was more effective than finasteride.¹⁵⁷ The main advantage of finasteride is the lack of side effects. Because the development of the urogenital sinus and urogenital tubercle into the male external genitalia, urethra, and prostate requires the action of dihydrotestosterone, patients being treated with finasteride should be cautioned regarding this possible risk during pregnancy, and an effective method of contraception must be used.

Other Agents

Cimetidine (300 mg qid) has been used to treat hirsutism, but it is the least potent of the androgen receptor blockers, and the clinical response is disappointing.¹⁵⁸ The use of a skin cream containing progesterone is effective, but it must be applied frequently (because of rapid metabolic clearance) and its action is very concentrated at the point of application.¹⁵⁹ Minoxidil in a topical application produces a moderate increase in hair growth in women with alopecia; however, indefinite, on-going treatment is necessary, and a return to the previous hair pattern cannot be achieved.¹⁶⁰ Ketoconazole in a dose of 400 mg daily blocks androgen synthesis by inhibiting the cytochrome P450 system. Although the impact on hirsutism is significant, there is a high incidence of side effects as well as changes in liver enzymes.¹⁶¹ Ketoconazole, at best, should be a last resort, requiring frequent monitoring of liver function. In addition, chronic treatment with ketoconazole may suppress adrenal corticosteroid production.

End Organ Hypersensitivity (Idiopathic Hirsutism)

There are some patients who present with hirsutism, but ovulate regularly. This category of patients has in the past been labeled idiopathic or familial hirsutism and is more pronounced in certain geographic areas and among certain ethnic groups (especially those from the Mediterranean area). The only satisfactory explanation for this distressing problem is hypersensitivity of the skin's hair apparatus to normal levels of androgens, probably due to increased 5 α -reductase activity.¹⁶² Because of this excessive sensitivity, normal levels of androgen stimulate hair growth. Even in these cases, hirsutism responds to ovarian suppression with a combination oral contraceptive. Suppression of normal female androgen levels to subnormal concentrations diminishes the stimulus to the hair follicles, yielding the same stabilizing results seen in other hirsute women. Spironolactone, flutamide, and finasteride are also effective for this group of patients. Clinical response to pharmacologic treatment correlates with the circulating levels of 3 α -AG, supporting the diagnosis of a target tissue (hair follicle) locus for this problem.¹⁶³ Thus 5 α -reductase inhibition with finasteride may be preferred for this condition (although there have been no comparison studies) because it is directed at the source of the complaint, and there is some evidence that a benefit is sustained after finasteride treatment is discontinued.¹⁶⁴ For this same reason, finasteride may be the treatment of choice for women who have normal circulating androgen levels but suffer from alopecia, a problem due to increased scalp 5 α -reductase activity. Although hirsutism due to an endocrine disorder requires control, end organ hypersensitivity is treated only for the purpose of cosmetic improvement. Electrolysis is a useful adjunct in this group of patients.

Summary of Recommendations for the Treatment of Hirsutism

1. The initial treatment of choice for anovulatory women with hirsutism is a low-dose (less than 50 μ g estrogen) oral contraceptive.
2. Response is relatively slow, and at least 6 months of treatment are required to demonstrate an impact.
3. When patients do not respond well to oral contraceptives, an antiandrogen should be added, preferably (in order) spironolactone or finasteride.
4. There is no overwhelming evidence that one agent is better than another, and choices should be governed by cost and side effects.
5. The addition of a GnRH agonist should be reserved for patients resistant to initial therapy.
6. Finasteride may be more effective for idiopathic hirsutism and androgenic alopecia.

Limitations and Pitfalls

We have outlined a simple, straightforward approach for the evaluation and management of the hirsute woman; however, as in all of medicine, exceptions occur.

1. Occasionally, testosterone levels may be extremely elevated with anovulation, leading to very heavy hair growth and even masculinization. A testosterone level over 200 ng/dL does not absolutely indicate the presence of a tumor.
2. Enlarged ovaries are not necessary for the clinical syndrome of anovulation and excessive androgen production. On the other hand, the presence of enlarged, polycystic ovaries does not ensure the diagnosis of anovulation and excess ovarian production of androgen. They can be associated with adrenal disease or exogenous androgen ingestion.
3. Laparoscopy and ovarian biopsy are not indicated procedures in the evaluation of hirsutism.
4. The association of elevated testosterone production and hirsutism with normal ovulatory cycles should make the clinician suspicious of an adrenal problem.
5. Suppression of elevated androgens by progestin treatment does not rule out the presence of an ovarian tumor. Functional ovarian tumors are gonadotropin-dependent and responsive.
6. Failure of progestin treatment to suppress hair growth and testosterone levels after 6–12 months raises the suspicion of adrenal disease or a very small ovarian tumor.
7. Androgen levels in postmenopausal women are lower. In this age group, a testosterone level greater than 100 ng/dL is suspicious for a tumor.

Since antiquity, the appearance of menses in correlation with lunar phases has inspired names for menses, such as a period or the monthly time. The regularity of this appearance was easily appreciated; more difficult was understanding the purpose of the bleeding. Ancient physicians viewed menstruation as a process of detoxification, and throughout history myths and attitudes toward menstruation have kept alive negative connotations that range from magic to danger and poison. ¹

The health care profession has an obligation to promote menstrual education. This must start with ourselves. We must have an understanding of reproductive physiology in order to impart it to our patients, and we must be sensitive to the need to present a positive attitude regarding sexual and reproductive functions. An educated understanding of these normal events is a powerful mechanism for dealing with perceived discomforts and disorders of menstruation.

Unfortunately, some menstrual disorders are still not well understood (such as the premenstrual syndrome), although others, such as dysmenorrhea, can be physiologically explained in a framework that provides for appropriate pharmacologic treatment. In this chapter we will consider several medical problems that are linked to menstruation and do our best to provide an objective point of view based on physiology.

The Premenstrual Syndrome

The simplest definition of the premenstrual syndrome (PMS) is a commonsense one: the cyclic appearance of one or more of a large constellation of symptoms (over 100) just prior to menses, occurring to such a degree that lifestyle or work is affected, followed by a period of time entirely free of symptoms. The most frequently encountered symptoms include the following: abdominal bloating, anxiety or tension, breast tenderness, crying spells, depression, fatigue, lack of energy, unprovoked anger or irritability, difficulty concentrating, thirst and appetite changes, and variable degrees of edema of the extremities — usually occurring in the last 7 to 10 days of the cycle. The exact collection of symptoms in an individual is irrelevant; the diagnosis is made by prospectively and accurately charting the cyclic nature of the symptoms. However, the symptoms are not to be underrated; the various symptoms of premenstrual syndrome have been recounted time and time again in clinicians' offices in poignant detail, often noting a feeling of being "overwhelmed" or "out of control."

When women's daily moods are prospectively charted, a subgroup emerges in which mood changes demonstrate a cyclic pattern with increasing symptoms during the luteal phase and an elimination of symptoms at or soon after menses. Fewer than 50% of women who complain of premenstrual syndrome can be demonstrated to have a pattern of mood changes with a cyclic pattern. ²

There are two established guidelines for the diagnosis of PMS. The first is from the American Psychiatric Association (APA) and consists of the criteria for what the APA has designated as the **premenstrual dysphoric disorder**. According to the American Psychiatric Association, this disorder should be differentiated as more severe than PMS; however, most assuredly, there is a broad spectrum of severity, and this differentiation is not helpful or useful. The APA criteria for diagnosis (which correspond to our simple definition above) are as follows:

- A. Symptoms are temporally related to the menstrual cycle, beginning during the last week of the luteal phase and remitting after the onset of menses.
- B. The diagnosis requires at least 5 of the following, and one of the symptoms must be one of the first 4:
 1. Affective lability; e.g., sudden onset of being sad, tearful, irritable, or angry.
 2. Persistent and marked anger or irritability.
 3. Anxiety or tension.
 4. Depressed mood, feelings of hopelessness.
 5. Decreased interest in usual activities.
 6. Easy fatigability or marked lack of energy.
 7. Subjective sense of difficulty in concentrating.
 8. Changes in appetite, overeating, or food craving.
 9. Hypersomnia or insomnia.
 10. Feelings of being overwhelmed or out of control.
 11. Physical symptoms, such as breast tenderness, headaches, edema, joint or muscle pain, weight gain.
- C. The symptoms interfere with work or usual activities or relationships.
- D. The symptoms are not an exacerbation of another psychiatric disorder. Thus, PMS is, in part, a diagnosis of exclusion.

The guidelines from the National Institute of Mental Health (NIMH) state that the diagnosis of PMS requires the documentation of at least a 30% increase in severity of symptoms in the 5 days prior to menses compared with the 5 days following menses. ³ Using the NIMH and APA criteria, it is estimated that about 5% of women of reproductive age can be diagnosed with disruptive PMS. ^{4,5}

Approximately 40% of women report problems related to their cycles, and about 2–10% report a degree of impact on work or lifestyle. ⁶ The exact prevalence, however, is difficult to ascertain. The symptoms are variable and difficult to quantitate. A further problem that complicates the evaluation of published studies, as well as dealing with individual cases, is that behavior is usually related to menstruation in a retrospective fashion. This is prone to considerable subjective bias. ⁷ For example, studies in the literature point out that some women do not actually experience problems in relation to menstruation but believe that they do. ⁷ It is argued, rather convincingly, that men and women in our culture have been conditioned to expect symptoms in a woman's premenstrual phase and have been taught to expect fluid retention, pain, and emotional reactions. These stereotypic expectations are precisely what are reported when retrospective charting is utilized. Most importantly, carefully constructed studies (prospective with appropriate statistical analyses) show no significant variation associated with the cycle for cognitive, motor, or social behavior. ⁸

Is PMS due to an individual pathologic problem or is it due to cultural beliefs, beliefs that lead to the menstrual cycle being associated with a variety of negative reactions, or a combination of both? There is a significant correlation between menstrual symptoms in daughters and mothers, and between sisters, suggesting that these are responses that can be learned. ^{9,10} Throughout our recorded history, we find evidence of menstrual taboos. What if our societies and cultures had celebrated menstruation as a time of pleasure (and even public joy) rather than something private (to be hidden) and negative? Would we have PMS today? The answer may lie in the unraveling of the role of our shared beliefs about menstruation in society, rather than the functioning of those beliefs in individuals.

It is generally recognized that R. T. Frank, chief of obstetrics and gynecology at Mt. Sinai Hospital in New York City, first defined premenstrual syndrome in 1931. His

description still stands as a graphic and vivid statement. He wrote the following: ¹¹

The group of women to whom I refer especially complain of a feeling of indescribable tension from 10 to 7 days preceding menstruation which in most instances continues until the time that the menstrual flow occurs. The patients complain of unrest, irritability, like jumping out of their skin and a desire to find relief by foolish and ill considered actions. Their personal suffering is intense and manifests itself in many reckless and sometimes reprehensible actions. Not only do they realize their own suffering, but they feel conscience-stricken toward their husbands and families, knowing well that they are unbearable in their attitude and reactions. Within an hour or two after the onset of the menstrual flow complete relief from both physical and mental tension occurs.

Frank went on to summarize 15 cases. He reported that he could obtain relief by withdrawing blood from his patients, and, therefore, theorized that the problem was due to an excess of female sex hormones because of inadequate excretion. Accordingly, he used treatments to enhance excretion, such as calcium lactate, caffeine, and laxatives. For severe cases, he produced ovarian failure by irradiation. S. Leon Israel, in the 1930s, was the first to propose the counterargument that the syndrome was due to defective luteinization resulting in a progesterone deficiency and only a relative hyperestrogenic state. ¹² The phrase, "premenstrual syndrome," was first used in 1953 by Dalton in a report of 84 cases with Greene. ¹³

For many years, we were handicapped by a lack of knowledge as to what the premenstrual syndrome really is, how to establish a diagnosis, and how best to treat the condition. In the last decade, however, a degree of understanding has emerged, and treatment guidelines are now available derived from clinical studies. ¹⁴

But first let's take a brief look backwards into history where we find reason enough to conclude that we are limited in our reactions to menses, limited by what has been provided by our culture throughout history.

Historical Myths

Recorded beliefs, many of them truly ancient, include magical beliefs, superstitions regarding the milk supply from cows, and beliefs about crops and animals. ¹⁵ It was thought, almost universally, that the menstrual woman was possessed by an evil spirit.

Pliny, born in 23 AD, consulted approximately 2000 available books by physicians in writing his *Historia Naturalis*. Pliny's treatise was a resource throughout the Dark Ages, and there are still more than 100 copies of it, all 37 volumes. The oft-quoted Pliny, who clearly was unencumbered with the burden of objectivity, wrote almost exhaustively on menstruation. ¹⁶

Contact with it turns new wine sour, crops touched by it become barren, grafts die, seeds in gardens are dried up, the fruit of trees falls off, the edge of steel and the gleam of ivory are dulled, hives of bees die, even bronze and iron are at once seized by rust, and a horrible smell fills the air; to taste it drives dogs mad and infects their bites with an incurable poison. If a woman strips herself naked while she is menstruating and walks around a field of wheat, the caterpillars, worms, beetles, and other vermin will fall off from the ears of corn. All plants will turn of a yellow complexion on the approach of a woman who has the menstrual discharge upon her. Bees will forsake their hives at her touch, for they have a special aversion to a thief and a menstros woman, and a glance of her eyes suffices to kill a swarm of bees.

Household articles were not immune. Aristotle said that a menstros woman could dull a mirror with a look, and the next person to look into it would be bewitched. There were numerous tales of women breaking things at the time of menses — needles snapping, glasses breaking, and clocks stopping. In general, there has been a universal horror of blood throughout early history. It is not surprising, therefore, that this (probably) instinctive horror led to taboos on blood and all that came in contact with it. This led in turn to prohibition and seclusion. Almost universally, menstruating women were isolated and prevented from handling food. Most primitive peoples regarded women as unclean during menstruation and subjected menstruating women to segregation and special rituals. Ultimately, with growing sophistication, this led to a generally negative attitude.

The scientific study of menstruation has been hampered by the overpowering influence of traditions and social and cultural beliefs. We have all, men and women, been conditioned to view menstruation in a negative way. Perhaps, it is time to look at menstruation from another point of view. How many fine novels have been finished in a burst of creativity in the premenstrual period? How many great ideas have been born premenstrually? If PMS reflects socially mediated expectations, the answer may lie in social re-education.

The Social Consequences of PMS

It was a common view in Europe in the 19th and early 20th centuries that menstruation was associated with antisocial behavior. ¹⁷ A domestic servant who murdered one of her employer's children in 1845 was acquitted on the grounds of insanity due to obstructed menstruation. In 1851, a woman was acquitted of murdering her baby niece on the grounds of insanity due to disordered menstruation. Acquittals for shoplifting because of suppression of menses date back to 1845. When we consider the fact that PMS (although not known by this specific phrase) has been recognized throughout recorded history, it is not unexpected that it has been used as a defense in the courts before modern times.

Dalton argued that PMS is responsible for an increased incidence of crime, jailing for alcoholism, school misdemeanors, sickness in industry, hospitalization for accidents, and general hospital admissions. ¹⁸ However studies on premenstrual symptoms that have appropriate controls and statistical treatment find no significant variation associated with the menstrual cycle for cognitive or motor behavior. ^{8, 19, 20} Social behavior (including crime and suicide) reveals effects similar to all others seen in self-report studies. When social or psychological expectations are altered, the effect disappears. Today, PMS is accepted by courts in the same manner that factors related to social and psychological stress or physical illness are accepted, and such factors do not absolve the accused of criminal responsibility.

Unfortunately, PMS is still used to explain apparently motiveless and impulsive acts, as well as poor academic performance. In contrast to Dalton's contention that schoolgirls have impaired academic performance during the premenstrual phase, the results of 244 female medical and paramedical students in all examinations taken during one year did not reveal any significant menstrual cycle effects on examination performance. ²¹

One of the biggest problems with the studies that have sought to link behavior with menstrual cycles is an underlying assumption that the premenstrual phase is the crucial variable, ignoring the fact that any phase of the cycle is vulnerable to life stresses. In other words, the premenstrual phase must be controlled for all life stresses in order to conclude that that phase of the cycle has an etiologic influence on some life event.

Etiologies and Treatments

Where scientists have failed to provide proof, practitioners have seldom failed to provide theories. The list of biological theories is impressive:

- Low progesterone levels
- High estrogen levels
- Falling estrogen levels
- Changes in estrogen:progesterone ratios
- Increased aldosterone activity
- Increased renin-angiotensin activity
- Increased adrenal activity
- Endogenous endorphin withdrawal
- Subclinical hypoglycemia
- Central changes in catecholamines
- Response to prostaglandins
- Vitamin deficiencies
- Excess prolactin secretion

Studies prior to 1983 did not incorporate appropriate diagnostic criteria and, therefore, suffer from inaccuracy and heterogeneity. Since 1983, efforts to isolate a

specific pathophysiologic mechanism have failed to demonstrate differences between women with and without symptoms for all hormone levels throughout the menstrual cycle (including estrogens, progesterone, testosterone, follicle-stimulating hormone, luteinizing hormone, prolactin, and sex hormone-binding globulin) or weight gain and measurements of substances involved in fluid regulation, such as aldosterone.²² This further includes both the circulating levels as well as the pattern of secretion over the menstrual cycle. In addition, no connection could be demonstrated between PMS and two endogenous metabolites of progesterone, allopregnanolone and pregnanolone.²³ Dynamic testing has revealed no abnormalities in the hypothalamic-pituitary axis and its relationships with the adrenal glands, the thyroid gland, and the ovaries. No differences can be detected in magnesium, zinc, vitamin A, vitamin E, thiamin, or vitamin B₆.²⁴ Some have argued for a greater change in endorphins, proposing that the luteal phase symptom complex is due to a withdrawal from endogenous opioids (in effect, an autoaddiction and withdrawal), but others have been unable to detect a difference in circulating endorphins in symptomatic patients.^{25, 26 and 27}

Differences have been reported in various biologic factors, but these differences are not always confined to the luteal phases. Some of these factors, besides the endorphins, include the response to thyrotropin-releasing hormone (TRH), melatonin secretion, red blood cell magnesium levels, growth hormone and cortisol responses to tryptophan, cortisol response to corticotropin-releasing hormone, free cortisol secretion, and cortisol secretion patterns. The strongest argument against a luteal phase hormonal change is derived from experiments at the National Institute of Mental Health.²⁸ These experiments utilized the progesterone antagonist, RU486, in combination with human chorionic gonadotropin (HCG) or placebo to induce bleeding at various times during the cycle. Altering the menstrual cycle had no effect on the timing or severity of the PMS symptoms; thus, the neuroendocrine and endocrine events during the luteal phase should not be involved.

In general, thyroid function is normal in patients with PMS.²⁹ About 10% of women with PMS have abnormal thyroid function, but this compares with the prevalence rate of subclinical hypothyroidism. Although there are no differences in thyroid-stimulating hormone (TSH) responses to TRH, patients with PMS do demonstrate more abnormal responses, both exaggerated and blunted (which would balance out in group comparisons).³⁰ However, these abnormal responses occur just as often in the follicular phase as in the luteal phase. Furthermore, there is no evidence of a therapeutic response to thyroxine compared with placebo, even in patients with abnormal responses to TRH.

Various methods of treatment have been proposed, each championing a presumed etiology. All of the following have failed to demonstrate any clear-cut benefits over placebo: oral contraceptives, vitamin B₆, bromocriptine, monamine oxidase inhibitors, and synthetic progestational agents.¹⁴ The use of spironolactone has many advocates, especially for women with a major complaint of bloating; however, appropriate double-blind, placebo-controlled trials have failed to demonstrate a clinical impact (other than on bloatedness) greater than placebo.^{31, 32} It has been argued that patients with PMS have a deficiency in fatty acid metabolism, and evening of primrose oil has been advocated for therapy. Evening of primrose oil is extracted from the seed of the evening primrose; it provides linoleic and gamma-linoleic acids (precursors of prostaglandin E). Appropriately blinded and controlled studies failed to find a difference comparing primrose oil with placebo.^{33, 34 and 35} The one positive study used retrospective assessment of symptoms, a method known to be inaccurate.³⁶ Significant improvement has been noted with the use of prostaglandin synthesis inhibitors, but it is difficult to know if this is influenced by a positive impact on dysmenorrhea.³⁷

In the past, there was an enormous amount of publicity given to the use of progesterone treatment by injection or vaginal suppository, long proposed and promoted by Dalton.¹⁵ Four early studies that failed to detect a positive effect of progesterone were criticized for study size and progesterone dosage.^{38, 39, 40 and 41} A very well-designed study attempted to remove a placebo effect by providing no contact with the investigators or any health care providers during the course of the study; both progesterone and placebo failed to achieve an improvement in symptoms.⁴² The criticism of study size and progesterone dose was effectively answered in a randomized placebo-controlled, double-blind, clinical crossover trial of 168 women.⁴³ Progesterone in doses of 400 mg and 800 mg (doses used by Dalton) did not differ from placebo. A later study by this same group utilizing a very large dose (1200 mg daily) also found no difference between progesterone and placebo treatments.⁴⁴ Only one study has reported beneficial effects with progesterone, a study of only 23 highly motivated women, and the major effect occurred only in the first month of treatment.⁴⁵

Medical and surgical oophorectomy has been described to have dramatic success. A lasting response to surgical hysterectomy and oophorectomy was reported in women unresponsive to medical therapy.^{46, 47} Gonadotropin-releasing hormone (GnRH) agonist treatment can produce hypogonadotropic hypogonadism, in effect, a medical oophorectomy. GnRH agonist treatment has been effective; adding estrogen-progestin to avoid the side effects of the GnRH agonist diminished somewhat the improvement in symptoms. However, the beneficial impact was still considerable.^{48, 49 and 50} While medical and surgical oophorectomy is undoubtedly effective, it is impossible to blind such treatment, and the mechanism is, therefore, uncertain. In the GnRH agonist-steroid add-back study, patients receiving a placebo instead of estrogen-progestin had a return of symptoms (despite continued GnRH agonist treatment), probably in anticipation of a negative reaction to estrogen-progestin. This experience is a strong statement of the power of the placebo response (in this case, a negative response). In general, the response to ovarian suppression with GnRH agonist treatment indicates that the symptoms of PMS represent an abnormal response to normal hormonal changes.⁵¹

The only randomized trials, double-blinded and placebo-controlled, which have had consistent, excellent results are those with the antidepressants, fluoxetine, clomipramine, sertraline, paroxetine, and alprazolam.^{44, 52, 53, 54, 55, 56, 57 and 58} A dose (20–60 mg daily) of fluoxetine (which inhibits neuronal uptake of serotonin) effectively abolished symptoms without side effects.^{52, 53 and 54} Further studies have established that a 20 mg dose of fluoxetine is as effective as higher doses, achieving a rapid response within 2–3 months and avoiding the side effects associated with the higher doses.^{57, 59} For some women, treatment limited to the premenstrual phase can be effective.⁶⁰ Alprazolam is a short-acting benzodiazepine with anxiolytic, antidepressant, and smooth muscle relaxant properties. A dose of 0.25 mg bid-tid during the luteal phase is effective, although some women may require an alprazolam daily dose of 2.5 mg.^{44, 61, 62} In contrast, lithium has no effect.

Problems and Questions

The problems and questions are many:

1. The clinical symptoms are variable, difficult to quantitate, and enormous in number. The symptoms cover emotions, sexual feelings, mood states, behavioral changes, and somatic complaints. Despite multiple questionnaires, we are still not convinced that there exists a reliable, objective method for observing and measuring symptoms that are experienced internally, rather than manifested via external behavior.⁷
2. The discrepancy between retrospective and prospective accounts regarding cyclic changes is now well documented and recognized.⁶³ Women use menses as a marker of time, and unpleasant, easily remembered experiences are attributed to an easily recognized signpost. If women in our culture have been conditioned to expect symptoms in the premenstrual phase and have been taught to expect fluid retention, pain, and emotional reactions, that is precisely what will be reported.⁶³ Our lives are rhythmical. Day alternates with night. There are sleeping and waking, being hungry and being full, the circadian rhythms of our glands, and the ultimate rhythm: the sexual cycle. It is the most natural thing to seek a rhythm for our behavior.

The Ruble study is now a classic.⁶⁴ In this study, 44 undergraduates at Princeton University were deliberately deceived about which phase of the menstrual cycle they were experiencing. A bogus electroencephalogram, complete with electrodes attached to the head, was heralded as a new technique capable of predicting the date of menstruation. Subjects were told they were either premenstrual (due in 1–2 days) or intermenstrual (due in 7–10 days). Only those women who were led to believe that their period would begin in 2 days reported significantly higher symptom ratings on pain, water retention, and eating habit changes. This was interpreted as a realization of stereotypic expectations.

3. Is there a specific syndrome? A syndrome must have a specific pathophysiology; specific signs and symptoms can be documented; and a specific treatment achieves a beneficial response in most patients. One of the basic problems is that we have lumped everything into PMS, including behavioral changes, somatic complaints, and psychological problems, implying the existence of a specific syndrome. Part of the problem is that all the tools of research reflect the way the author of the tool conceptualizes PMS, which, in turn, is based on the background and training of the author.⁶⁵
4. The experimenter expectancy effect has to be properly controlled. Subjects tend to comply with what they think is the experimenter's hypothesis. This has been studied in regard to PMS, and no significant difference in PMS symptomatology can be demonstrated when the purpose of the study is disguised, and, in addition, the responses can be influenced by positive or negative manipulations.^{66, 67 and 68} This relates to findings of negative mood changes when subjects are asked to assess their menstrual distress retrospectively.
5. Studies are complicated by high placebo responses. Clinical studies of premenstrual syndrome typically demonstrate a 30–50% response to placebo and, if a positive effect is anticipated by the subjects, up to 80%. Only well-designed, double-blind, placebo-controlled, randomized trials yield reliable data.

The Placebo Response

The strange sounding word, placebo, comes from the Latin verb meaning “I shall please.” Clinicians and patients have been educated to observe a prescription ritual. Most people seem to feel that their complaints are not taken seriously unless they are in possession of a prescription. But the placebo is not so much a pill as a process.⁶⁹

The process begins with patient confidence in the clinician and extends through to the full functioning of the patient's own healing system. Interaction with the clinician provides a better understanding of what's going on (at least some elimination of unfounded fears) and provides some hope. Many of the treatment modalities for PMS, if not all, provide a woman with a greater sense of control over life; thus, minimal interaction, such as focusing on diet or lifestyle, can yield a positive result. In the process of making detailed, prospective observations of one's own life, a patient can experience an increase in self-control, which is in itself a therapeutic process.

Leon Eisenberg has written the following insightful and helpful thoughts on the placebo: ⁷⁰

So emphatically does the phrase “placebo response” discredit the psychosocial aspects of the therapeutic encounter that it may be time to eradicate it from our language. Let us replace it by some such term as “the response to care,” “the response to the doctor,” or “the healing response” in order to emphasize that it is (a). powerful, (b). no less “real” than drug actions, and (c). embedded in every therapeutic transaction. . . Its mechanisms are some compound of the arousal of hope, the comfort of reassurance, taking an active rather than a passive role in managing the illness experience, and reinterpreting the meaning of the illness. . . It is perverse that “placebo” has almost become an epithet implying charlatanism rather than a descriptor of a fundamental characteristic of medical practice. . . We ought equally to seek an understanding of the healing response rather than disdaining it, as the “hard” scientist does, or being deceived by it, as practitioners often are.

Until PMS is better understood, the placebo response will continue to play an important role in therapy. There is a psychosocial subjective component of medicine that makes the placebo process a legitimate part of every patient–clinician interaction.

Treatment of Premenstrual Syndrome

The first step is to be convinced (both patient and clinician) that the problem is cyclic. The only instrument of diagnosis available at the present time is the menstrual calendar. There is no single calendar that has emerged as superior and acceptable to all; however, several are available in the literature. ^{71, 72} At least 3 months of prospective recording, aided if possible by other observers (such as family members), are necessary in order to document a recurring problem in the luteal phase of the cycle, interfering with work or lifestyle, and followed by a period entirely free of symptoms. This time period should be used to develop a solid patient–clinician relationship and, in so doing, to provide as much education as possible for the patient.

We offer our perspective on this syndrome, suggesting that it is not a single disorder, but rather a collection of different problems. We believe that PMS has a basic psychophysiological origin, tied to the menstrual cycle, primarily biologically, but with a psychosociologic overlay. This can be a learned response or it can be a response in vulnerable individuals triggered by normal neuroendocrine and hormonal changes. The hormonal changes of the menstrual cycle are not an etiologic factor, but they can operate to produce in susceptible women mood changes or a destabilization of mood, and specifically involving the serotonergic system. ⁷³ This may be the reason that elimination of menses with drugs or oophorectomy is often effective. The problem presumably lies within the central nervous system with a mechanism that determines susceptibility.

Often, patients present to the clinician totally focused on complaints that occur premenstrually. With exploration of lifestyle, relationships, and interactions, the focus on a premenstrual syndrome can be shifted to the underlying issues that are producing conflict and lack of control. Helping a patient to come to grips with the subtle nature of this problem, the fundamental psychological response involved, and the need to take charge of one's life represent the type of broad involvement required of a clinician. Without this type of broad involvement, only a short-term response can be achieved with little hope for long-term success.

Any changes that allow individuals to exert greater control over their lives will produce a positive impact. It is for this reason that lifestyle changes are effective in the treatment of PMS. Changes in diet, changes in exercise, changes in work or recreation — all are examples of exerting control over life rather than having life's circumstances control the individual.

If the practitioner is convinced of the cyclic nature of a problem (by a prospective record of at least 3 months duration), try to isolate the specific symptoms and treat with a specific therapy. If fluid retention is perceived by the patient as a principal problem, offer diuretic therapy with spironolactone. If dysmenorrhea is a component of the symptom complex, try one of the inhibitors of prostaglandin synthetase or oral contraceptives. Calcium supplementation (1200 mg daily) was observed in a placebo-controlled, randomized trial to be associated with a 48% reduction in symptom scores (compared with a 30% reduction in the placebo-treated group). ⁷⁴ These are safe and relatively inexpensive approaches that deserve initial consideration.

A failure to identify a specific disorder with a specific mechanism suggests that premenstrual syndrome represents a variety of psychological manifestations triggered by normal, physiologic hormonal changes. This process can be either physiologic in nature or psychosocial and deeply rooted in our cultural history. For that reason, it makes some sense to completely eliminate endogenous sex steroid variability. This can be achieved with daily oral contraceptives, or medroxyprogesterone acetate, 10–30 mg daily, or depot-medroxyprogesterone acetate, 150 mg every 3 months. On occasion, we have induced beneficial and gratifying results in patients with incapacitating emotional swings. But in view of the vague and subjective nature of this syndrome, any such empiric therapeutic treatment must be pursued in a fully informed fashion. If a patient is willing to undergo an empiric trial, we are willing. In doing so, however, neither partner in this contract should be deceived; we must remember that the placebo response may be the underlying basis for any positive response. But keep in mind that the placebo response is another example of an individual exerting control. In this case, it represents the subtle effort of the body at a subconscious level to exert self-healing.

Last resort treatments, in our view, are the expensive and complicated medical oophorectomy by GnRH agonist combined with estrogen-progestin add-back (in doses used for postmenopausal therapy), and the use of the selective serotonin reuptake inhibitors and alprazolam. Because alprazolam can be abused, and because the clinical effect is not impressive, the serotonin reuptake inhibitors are preferred. ⁷⁵ Clinical studies have indicated that ovarian suppression with GnRH agonist treatment is more effective for behavioral and physical symptoms and less effective for psychological symptoms. ^{50, 76} Furthermore, the response is not overwhelming; treatment with a GnRH agonist can be expected to achieve success in 60–70% of women with PMS. ⁵¹ These reasons also favor the use of serotonin reuptake inhibitors. Long-term effectiveness of fluoxetine has been documented, with decreased libido being the most common side effect. ⁷⁷ To minimize side effects, intermittent treatment (7–14 days during the luteal phase) should be assessed first. ⁶⁰

The clinical studies with medical oophorectomy or the use of serotonin reuptake inhibitors are very convincing, but this serious medical therapy does not diminish the important contribution to be made by the clinician in an ongoing relationship and interaction with the patient.

Dysmenorrhea

Dysmenorrhea is pain with menstruation, usually cramping in nature and centered in the lower abdomen. Studies on the prevalence of dysmenorrhea are few. In a random sample of 19-year-old women in Gothenburg, Sweden, 72% reported dysmenorrhea, 15% had to limit their daily activity and the severity was unimproved by analgesics, 8% missed school or work at every menses, and 38.2% regularly used medical treatment. ⁷⁸ Oral contraceptive use and previous vaginal deliveries were associated with less dysmenorrhea. The severity of dysmenorrhea was directly related to the duration and amount of menstrual flow. In a longitudinal American study of 17–19-year-old university students, 13% reported severe pain in more than half of their menstrual periods, and 42% indicated interference with activity at least once. ⁷⁹ A survey in Turkey reported that 25.6% of adolescents missed school because of dysmenorrhea. ⁸⁰ In another older but good prevalence study, 45% of surveyed women had moderate or severe dysmenorrhea. ⁸¹ Most adolescents experience dysmenorrhea in the first 3 years after menarche. In the U.S., about 60% of menstruating adolescents were reported to have some dysmenorrhea, and 14% regularly missed school. ⁸² Menstrual problems, including dysmenorrhea, are more common in individuals who smoke. ^{83, 84} Dysmenorrhea improves in most women after a full-term pregnancy. ⁸⁵

Primary dysmenorrhea, a condition associated with ovulatory cycles, is due to myometrial contractions induced by prostaglandins originating in secretory endometrium, while secondary dysmenorrhea is associated with a variety of pathological conditions. ⁸⁶ Other symptoms associated with menstrual flow, such as headache, nausea and vomiting, backache, and diarrhea, can be explained by entry of the prostaglandins and prostaglandin metabolites into the systemic circulation. There is a 3-fold increase in prostaglandin levels in the endometrium from the follicular phase to the luteal phase, with a further increase during menstruation. ⁸⁷

Women with primary dysmenorrhea have greater endometrial production of prostaglandins than asymptomatic women. Most of the release of prostaglandins during menstruation occurs during the first 48 hours, which coincides with the greatest intensity of the symptoms.

Prostaglandin F_{2a} (PGF_{2a}) is the agent responsible for dysmenorrhea. It always stimulates uterine contractions, whereas the E prostaglandins inhibit contractions in the nonpregnant uterus. Uterine muscle from both normal and dysmenorrheic women is sensitive to PGF_{2a}, but the amount of PGF_{2a} produced is the major differentiating factor.

The clinical benefit derived from the pharmacologic use of inhibitors of prostaglandin synthesis depends on a significant decrease in prostaglandin production in the endometrium, as well as shortened and diminished menstrual flow. An additional role may be attributed to decreased prostaglandins from the platelets participating in the clotting of menstrual blood. The explanation for the benefit seen with oral contraceptives is decreased prostaglandin synthesis associated with the atrophic decidualized endometrium. Oral contraception is a good choice for therapy, combining contraception with a beneficial impact on dysmenorrhea, menstrual flow, and menstrual irregularity.⁸⁸

In women who do not desire hormonal contraception, the best therapy is one of the agents that inhibit prostaglandin synthesis. There are several families of nonsteroidal anti-inflammatory agents. The acetic acid group is associated with more side effects, and these agents are not the drugs of choice for dysmenorrhea; indomethacin belongs to this group. The propionic acid derivatives (ibuprofen, naproxen, ketoprofen) and the fenamates (mefenamic acid, meclofenamate, flufenamic acid) are very effective for the treatment of dysmenorrhea.

The findings in 51 clinical trials of prostaglandin synthetase inhibitors indicated that the fenamates are more effective, but not substantially, for relieving pain.⁸⁸ The fenamates, in addition to inhibiting prostaglandin synthesis, also have an antagonistic action, competing for prostaglandin-binding sites. Side effects associated with these agents are minimal, but can include blurred vision, headaches, dizziness, and gastrointestinal discomfort. The latter can be reduced by taking the medication with milk or food. All of these agents are more potent than aspirin, because the uterus is relatively insensitive to aspirin. The major contraindications to the use of these agents include gastrointestinal ulcers and hypersensitivity to aspirin and similar agents.

Approximately 80% of dysmenorrheic women are relieved by prostaglandin inhibitors. Improvement is noted in the symptoms associated with menses, specifically cramping, backache, nausea, vomiting, dizziness, leg pain, insomnia, and headache. A trial of up to 6 months is warranted, with necessary changes in dosage and inhibitors, before abandoning this therapy. Initially, it was believed that better relief was achieved if treatment was started 2–3 days before menses in order to lower the tissue level of prostaglandins before breakdown of the endometrium. Fortunately, studies have indicated that treatment is just as effective if begun at the sign of first bleeding, thus decreasing the possibility of taking one of these agents early in pregnancy. Another benefit of prostaglandin inhibition is a reduction in the amount of blood lost with periods. Indeed, the agents may be used to treat idiopathic menorrhagia, or the excess flow associated with an intrauterine device (IUD). Most women do not need to take the medication more than 2–3 days.

If dysmenorrhea is not relieved by one of the nonsteroidal, anti-inflammatory analgesics, laparoscopy should be seriously considered to determine the cause of the symptoms. Conditions associated with dysmenorrhea include müllerian duct anomalies, endometriosis, and pelvic inflammatory disease. **We should especially be aware that endometriosis occurs in adolescents; dysmenorrhea caused by endometriosis in adolescents usually begins 3 or more years after menarche.**

Menstrual Headache

Headaches are very common, but it is rare when the cause of the headache is a serious problem. Most headaches are due to vasodilatation, muscle contraction, or psychologic stress. Menstrual headaches include all headaches related in temporal fashion to menses, beginning before or during menstrual flow.⁹⁰ For many women with premenstrual syndrome, headache is part of the constellation of PMS symptoms. Here, we are considering the occurrence of headache as a single, solitary symptom associated with menses.

Migraine headaches have a peak incidence of first occurrence at age 15–19; they are most prevalent in women in their late 30s to early 40s, and rare after menopause.^{91, 92} An association with menses is observed by 60% of women with migraine headaches. In 7–14% of women with migraine, headaches occur exclusively with menses. Because menstrual migraine improves in two-thirds of migraineurs with pregnancy, this type of migraine seems to be due to falling levels of estrogen and progesterone, triggering a host of responses such as release of prostaglandins and changes in neurotransmitters.^{93, 94}

Classic migraine is associated with a visual aura, including bright lights, zigzag lights, or flashes and sparkles. *Common migraine* is not associated with neurologic auras. Complicated migraine refers to headache associated with dramatic focal neurologic features that are transient; e.g, blindness, unilateral paresthesias, or paresis. With increasing age, the focal neurologic phenomena can occur without headache.

Vascular Headaches

Acute and throbbing headaches are due to abnormal vasodilatation. The vasodilatation associated with migraine headaches is believed to follow a period of vasoconstriction. Migraine headaches are usually, but not always, preceded by prodromal symptoms (which may reflect the period of vasoconstriction). Significant vascular headaches can be precipitated by stress, alcohol, or tyramine and tryptophan rich foods (red wine, chocolate, ripe cheeses). Vascular headaches can accompany other problems, such as systemic viral infections, fever, or hypertension. Common migraine headaches are known as “migraine without aura.”⁹¹ Classic migraine is referred to as “migraine with aura.” Migraine headaches associated with menstruation are typically migraine without aura.⁹²

Tension Headaches

The common tension headache is due to prolonged and excessive muscle contraction. The pain is dull, steady, bilateral, and worsens throughout the day. The headaches frequently occur with worry or emotional stress and commonly last for hours or a couple of days; however, everyday minor hassles are a more important factor in the pathogenesis of tension headaches than major stressful events.

Secondary Headaches

This type of headache is due to underlying organic disease. The pain is usually due to pressure or pulling of structures. Headaches associated with brain tumors are usually accompanied by neurologic abnormalities. Other causes are brain abscesses, subdural hematomas, hypertension, drug use, and concussions. The main cause of inflammatory headaches is meningitis.

Evaluation

The acute onset of severe headache pain deserves attention. The following signs suggest the presence of a serious problem: neck stiffness, altered mental status, focal neurologic abnormalities, visual impairment, and fever. Any patient with meningeal signs requires hospitalization. Keep carbon monoxide exposure and drug withdrawal in mind as etiologic agents.

Chronic headaches should be characterized according to location, quality, and course over time. Head trauma in the past is an important piece of information, raising the suspicion of a subdural hematoma. When the headache is cyclic, with periodic complete resolution, one can comfortably ascribe the headache to a vascular origin. Tension headaches are either variable or relatively constant without relentless progression. Any recurrent or chronic headache that gets worse with time deserves a neurologic evaluation.

Management

Menstrually related migraines are more refractory to the battery of therapy used by neurologists, although oral and subcutaneous sumatriptan has been effective.^{91, 92, 95} The nonsteroidal anti-inflammatory agents are also effective, particularly when headaches are associated with dysmenorrhea.

Early studies of menstrual migraine indicated that administration of estrogen could delay the onset of migraine even if menses were not delayed.⁹⁶ Progesterone administration delayed menses, but not the onset of headache. Others have claimed effective treatment of menstrual migraine with maintenance of estrogen levels (there is reason to believe that a relatively high estrogen level is necessary; e.g., the use of the 100 µg transdermal patch).^{97, 98} Still others have reported success with tamoxifen or danazol treatment. Unfortunately this field suffers from a lack of well-designed, double-blind, placebo-controlled studies, and we must make our judgments based on experience.

We have had personal success (anecdotal to be sure) alleviating headaches by eliminating the menstrual cycle, either with the use of *daily* oral contraceptives (not the progestin-only minipill) or the daily administration of a progestational agent (such as 10 mg medroxyprogesterone acetate). Some menstrual migraineurs have extremely gratifying responses.

If menstrual headaches are a reaction to cyclic changes in circulating levels of the sex steroids, it makes sense to avoid cyclicality and maintain a relatively steady state with daily administration of exogenous hormones. A more expensive approach, but one with documented success, is the utilization of a long-acting GnRH agonist combined with estrogen-progestin add-back therapy.⁹⁹ Another option is to use an estrogen transdermal application during the menstrual time period.

The elimination of cyclicality can be applied to postmenopausal women who experience exacerbation or onset of headaches on a sequential hormone regimen. The maintenance of daily, relatively constant hormone levels with the daily, continuous program of combined estrogen-progestin has been effective in our experience.

The run-of-the-mill headache is treated with mild analgesics such as aspirin, acetaminophen, or the nonsteroidal anti-inflammatory agents. A problem of severe headaches on oral contraception requires an immediate response. The conservative reaction is to discontinue the oral contraceptives. On the other hand, the headache can be due to stress or some other reversible condition. We would argue that automatic discontinuation of oral contraception is not necessary with the low-dose preparations. It would be better to evaluate the patient and find out if the patient can continue her contraceptive protection, by discovering an explanation for the headaches. Case-control studies with the old higher dose oral contraceptives indicated that migraine headaches were linked to a risk of stroke. Strokes are essentially no longer seen with low-dose oral contraception. ([Chapter 22](#) with full references) This probably reflects both lower dosage as well as the reluctance of clinicians to prescribe oral contraception to women with severe headaches.

True severe vascular headaches (migraine with aura) represent a contraindication for the use of combined oral contraceptives and their appearance is an indication to discontinue oral contraception. The symptom complex that deserves serious consideration includes headaches that last a long time; dizziness, nausea, or vomiting with headaches; scotomata or blurred vision; episodes of blindness; unilateral, unremitting headaches; and headaches that continue despite medication.

Concern over headaches with oral contraception should be limited to the use of combined oral contraceptives. The progestin-only methods are not associated with problems with headaches. Therefore, the sustained release progestin-only methods are also free of headache concern.

Catamenial Seizures

Catamenial epilepsy in ancient times was attributed to the moon, giving rise to the word, "lunatic."¹⁰⁰ Epileptic seizures increase in frequency during menstruation and decrease during the luteal phase.^{101, 102 and 103} Exacerbation of seizure activity with menses occurs in 50% of epileptic women.¹⁰⁴ In addition, seizure frequency increases at the time of the midcycle peak in estrogen and during anovulatory cycles. In animal experiments, estrogen increases seizure activity, and progesterone is antiepileptic. These observations suggest an antiepileptic effect of progesterone.

Progestational hormones are known to have a sedative effect on the central nervous system. This pharmacologic effect combined with the observations indicating increased seizure activity at times when circulating levels of progesterone are low indicated that treatment with a progestin would have a beneficial impact on seizures. Treatment with orally administered progesterone during the luteal phase has been reported to decrease seizure activity.¹⁰⁵

Antiepileptic drugs enhance hepatic metabolic activity, and, therefore, doses must be relatively high. Oral medroxyprogesterone acetate is relatively ineffective, probably because it is difficult to achieve high blood levels. Intramuscular injections of depot-medroxyprogesterone acetate can improve seizure control. Depot-medroxyprogesterone acetate, 150 mg im every 1–2 months, can decrease seizure frequency by approximately 50%.¹⁰⁶ In a case report of an 8-year-old girl, 150 mg administered every 2 weeks abolished seizure activity.¹⁰⁴ Intravenous progesterone (producing luteal phase levels) can produce a significant decrease in spike frequency.¹⁰⁷

In women with a seizure pattern consistently linked to menses, elimination of cyclic hormonal changes can bring impressive relief. The administration of daily oral contraceptives, or intramuscular depot-medroxyprogesterone acetate, or GnRH agonist treatment with estrogen-progestin add-back can be used for this purpose.

Premenstrual Asthma

Approximately 30–40% of women with asthma have an increase in symptoms associated with menstruation.^{108, 109 and 110} Even asthmatics not aware of a link to menstruation demonstrate a menstrual worsening of pulmonary function.^{111, 112} The mechanism is not known, but obvious effects of menstrual hormonal changes have been suggested, such as prostaglandin release, changes in the immune system, or a direct impact of declining estrogen and progesterone on bronchial smooth muscle. The administration of estrogen (estradiol 2 mg orally daily) improves symptoms and measurements of pulmonary function.¹¹² In another report, the administration of intramuscular progesterone ameliorated premenstrual asthma.¹¹³ Once again, the logic is appealing that the elimination of menstrual periods (with the daily administration of oral contraceptives or intramuscular depot-medroxyprogesterone acetate or with a long-acting GnRH agonist together with an estrogen-progestin supplement) can have a beneficial impact on a menstrual condition, in this case premenstrual asthma, a disorder that can even be lethal.

Catamenial Pneumothorax

Very rarely, recurrent pneumothoraces, often due to pulmonary endometriosis, occur at the time of menses.¹¹⁴ Effective medical treatment requires the long-term suppression of menstruation.¹¹⁵ The two best therapeutic choices are again the daily administration of oral contraceptives or treatment with a long-acting GnRH agonist supplemented with a daily estrogen-progestin combination.

[Summary of Key Points in Therapy of Anovulatory \(Dysfunctional\) Bleeding](#)
[Chapter References](#)

Dysfunctional uterine bleeding is defined as a variety of bleeding manifestations of anovulatory cycles (in the absence of pathology or medical illness). It can be confidently managed without surgical intervention by therapeutic regimens founded on sound physiologic principles. Our formulation is based on knowledge of how the postovulatory menstrual function is naturally controlled, and uses pharmacologic application of sex steroids to reverse the abnormal tissue factors that lead to the excessive and prolonged flow typical of anovulatory cycles.

Three major categories of dysfunctional endometrial bleeding are dealt with:

1. Estrogen withdrawal bleeding,
2. Estrogen breakthrough bleeding, and
3. Progestin breakthrough bleeding.

In each instance, the manner in which the endometrium deviates from the norm is characterized, and specific sex steroid therapy is recommended to counter the difficulties each situation presents.

This mode of clinical management has been in regular use for many years, and failure to control vaginal bleeding with this therapy, despite appropriate application and utilization, excludes the diagnosis of dysfunctional uterine bleeding. If this occurs, attention is directed to a pathologic entity within the reproductive tract as the cause of abnormal bleeding.

Heavy but regular menstrual bleeding can be encountered in ovulating women. In the absence of a specific pathologic cause, it is presumed that this reflects subtle disturbances in the endometrial tissue mechanisms discussed in [Chapter 4](#). In essentially all cases, evaluation and treatment are identical to the approach detailed in this chapter.

Normal Withdrawal (Menstrual) Bleeding

Of all the types of hormonal-endometrial relationships, the most stable endometrium and the most reproducible menstrual function in terms of quantity and duration occurs with postovulatory estrogen-progesterone withdrawal bleeding. It is so controlling that many women over the years come to expect a certain characteristic flow pattern. Any slight deviations, such as plus or minus 1 day in duration or minor deviation from expected napkin or tampon utilization, are causes for major concern in the patient. So ingrained is the expected flow that considerable clinician reassurance may be required in some instances of minor variability. Although variability of menstrual cycles is a common feature during teenage years and the perimenopausal transition, the characteristics of menstrual bleeding do not undergo appreciable change during the reproductive years.¹

Menarche is followed by approximately 5–7 years of relatively long cycles at first, and then there is increasing regularity as cycles shorten to reach the usual reproductive age pattern. In the 40s, cycles begin to lengthen again. The highest incidence of anovulatory cycles is under age 20 and over age 40.^{2,3} At age 25, over 40% of cycles are between 25 and 28 days in length; from 25 to 35, over 60% are between 25 and 28 days. Overall, approximately 15% of reproductive age cycles are 28 days in length. Only 0.5% of women experience a cycle less than 21 days long, and only 0.9% a cycle greater than 35 days.⁴ Most women have cycles that last from 24 to 35 days, but at least 20% of women experience irregular cycles.¹ When women are in their 40s, anovulation becomes more prevalent, and prior to anovulation, menstrual cycle length increases, beginning 2 to 8 years before menopause.⁵

The usual duration of flow is 4–6 days, but many women flow as little as 2 days, and as much as 7 days. The normal volume of menstrual blood loss is 30 mL.⁶ Greater than 80 mL is abnormal. Most of the blood loss occurs during the first 3 days of a period, so excessive flow may exist without prolongation of flow.^{7,8}

Menstrual Period Characteristics

	Normal	Abnormal
Duration of flow	4–6 days	Less than 2; more than 7 days
Volume of flow	30 mL	More than 80 mL
Cycle	24–35 days	

Although the postovulatory phase averages 14 days, greater variability in the proliferative phase produces a distribution in the duration of a menstrual cycle. Based on the normal experience, menstrual bleeding more often than every 24 days or less often than every 35 days deserves evaluation.^{1,5} Flow that lasts 7 or more days also deserves evaluation. A flow that totals more than 80 mL per month usually leads to anemia and should be treated.^{9,10} In general, however, an effort to quantitate menstrual flow beyond historical information is not necessary because evaluation and treatment are responses to a patient's own perceptions regarding duration, amount, and timing of her menstrual bleeding. Although the correlation between a patient's perceptions and actual menstrual blood loss is poor,¹¹ an individual patient's anxiety and concern deserve consideration and evaluation. Midcycle bleeding can be a consequence of the preovulatory fall in estrogen; however, intermenstrual bleeding is often due to pathology.

The histologic changes in the endometrium of a normal, ovulatory menstrual cycle have been detailed in [Chapter 4](#). An understanding of these events provides the foundation and framework to understand abnormal endometrial bleeding. There are three reasons for the self-limited character of estrogen-progesterone withdrawal bleeding.

1. **It is a universal endometrial event.** Because the onset and conclusion of menses are related to a precise sequence of hormonal events, menstrual changes occur almost simultaneously in all segments of the endometrium.
2. **The endometrial tissue that has responded to an appropriate sequence of estrogen and progesterone is structurally stable, and random breakdown of tissue due to fragility is avoided.** The events leading to ischemic disintegration of the endometrium are orderly and progressive, being related to rhythmic waves of vasoconstriction of increasing duration.
3. **Inherent in the events that start menstrual function following estrogen-progesterone are the factors involved in stopping menstrual flow.** Just as waves of vasoconstriction initiate the ischemic events, prolonged vasoconstriction abetted by the stasis associated with endometrial collapse enables clotting factors to seal off the exposed bleeding sites. Additional and significant effects are obtained by resumed estrogen activity.

The withdrawal of estrogen and progesterone initiates important endometrial events: vasomotor reactions, the process of apoptosis, tissue loss, and, finally, menstruation. The most prominent immediate effect of this hormone withdrawal is a modest shrinking of the tissue height and remarkable spiral arteriole vasomotor responses. The following vascular sequence has been constructed from direct observations of rhesus endometrium.^{12,13} With shrinkage of height, blood flow within the spiral vessels diminishes, venous drainage is decreased, and vasodilatation ensues. Thereafter, the spiral arterioles undergo rhythmic vasoconstriction and relaxation. Each successive spasm is more prolonged and profound, leading eventually to endometrial blanching. Within the 24 hours immediately preceding menstruation, these reactions lead to endometrial ischemia and stasis. White cells migrate through capillary walls, at first remaining adjacent to vessels, but then extending throughout the stroma. During arteriolar vasomotor changes, red blood cells escape into the interstitial space. Thrombin-platelet plugs also appear in superficial vessels. The prostaglandin content (PGF_{2a} and PGE₂) in the secretory endometrium reaches its highest levels at the time of menstruation. The vasoconstriction and myometrial contractions associated with the menstrual events are believed to be significantly mediated by PGF_{2a} from glandular cells and the potent vasoconstrictor, endothelin-1, derived from stromal decidual cells.

In the first half of the secretory phase, acid phosphatase and potent lytic enzymes are confined to lysosomes. Their release is inhibited by progesterone stabilization of the lysosomal membranes. With the waning of estrogen and progesterone levels, the lysosomal membranes are not maintained, and the enzymes are released into the cytoplasm of epithelial, stromal, and endothelial cells, and, eventually, into the intercellular space. These active enzymes will digest their cellular constraints, leading to the release of prostaglandins, extravasation of red blood cells, tissue necrosis, and vascular thrombosis. This process is one of **apoptosis** (programmed cell death, characterized by a specific morphologic pattern that involves cell shrinkage and chromatin condensation culminating in cell fragmentation) mediated by cytokines.¹⁴

Endometrial tissue breakdown involves a family of enzymes, matrix metalloproteinases, that degrade components (including collagens, gelatins, fibronectin, and laminin) of the extracellular matrix and basement membrane.¹⁵ The metalloproteinases include collagenases that degrade interstitial and basement membrane collagens, gelatinases that further degrade collagens, and stromelysins that degrade fibronectin, laminin, and glycoproteins. The expression of metalloproteinases in human endometrium follows a pattern correlated with the menstrual cycle, indicating a sex steroid response as part of the growth and remodeling of the endometrium, with a marked increase in late secretory and early menstrual endometrium.¹⁶ Progesterone withdrawal from endometrial cells induces matrix metalloproteinase secretion that is followed by the breakdown of cellular membranes and the dissolution of extracellular matrix.¹⁷ Appropriately, this enzyme expression increases in the decidualized endometrium of the late secretory phase, during the time of declining progesterone levels. With the continuing progesterone secretion of early pregnancy, the decidua is maintained and metalloproteinase expression is suppressed, in a mechanism mediated by TGF- β .¹⁸ In a nonpregnant cycle, metalloproteinase expression is suppressed after menses, presumably by increasing estrogen levels. Metalloproteinase activity is restrained by specific tissue inhibitors, designated as TIMP. Thus progesterone withdrawal can lead to endometrial breakdown through a mechanism that is independent of vascular events (specifically ischemia), a mechanism that involves cytokines.¹⁴

Eventually considerable leakage occurs as a result of diapedesis, and, finally, interstitial hemorrhage occurs due to breaks in superficial arterioles and capillaries. As ischemia and weakening progress, the continuous binding membrane is fragmented, and intercellular blood is extruded into the endometrial cavity. New thrombin-platelet plugs form intravascularly upstream at the shedding surface, limiting blood loss. Increased blood loss is a consequence of reduced platelet numbers and inadequate hemostatic plug formation. Menstrual bleeding is influenced by activation of clotting and fibrinolysis. Fibrinolysis is principally the consequence of the potent enzyme, plasmin, formed from its inactive precursor, plasminogen. Endometrial stromal cell tissue factor (TF) and plasminogen activators and inhibitors are involved in achieving a balance in this process. TF stimulates coagulation, initially binding to factor VII. TF and plasminogen activator inhibitor-1 (PAI-1) expression accompanies decidualization, and the levels of these factors may govern the amount of bleeding.¹⁹ PAI-1, in particular, exerts an important restraining action on fibrinolysis and proteolytic activity.²⁰

With further tissue disorganization, the endometrium shrinks even more, and coiled arterioles are buckled. Additional ischemic breakdown ensues with necrosis of cells and defects in vessels adding to the menstrual effluvia. A natural cleavage point exists between basalis and spongiosum, and, once breached, the loose, vascular, edematous stroma of the spongiosum desquamates and collapses. The process is initiated in the fundus and inexorably extends throughout the uterus. In the end, the typical deflated shallow dense menstrual endometrium results. Within 13 hours, the endometrial height shrinks from 4 mm to 1.25 mm.²¹ Menstrual flow stops as a result of the combined effects of prolonged vasoconstriction, tissue collapse, vascular stasis, and estrogen-induced "healing." In contrast to postpartum bleeding, myometrial contractions are not important for control of menstrual bleeding. Thrombin generation in the basal endometrium in response to extravasation of blood is essential for hemostasis. Thrombin promotes the generation of fibrin, the activation of platelets and clotting cofactors, and angiogenesis.

Platelets and fibrin play a direct part in the hemostasis achieved in a bleeding menstrual endometrium. Deficiencies in these constituents cause the increased blood loss seen in von Willebrand's disease and in thrombocytopenia. The blood loss at menses in afibrinogenemia indicates the importance of fibrin-generating and fibrinolytic factors in the menstrual process. Intravascular thrombi are observed in the functional layers and are localized to the shedding surface of the tissue. These are known as impeding "plugs" because blood may flow past these only partially occlusive barriers. Therefore, thrombi continue to develop within the menstrual blood, accounting for the platelets and large amounts of fibrin found in this effluent. Fibrinolysis occurs in the endometrial tissue, limiting fibrin deposition in the proximal, still unshed layer. Despite large holes in vessel walls, with blood exposed to collagen surfaces, no occlusive surface thrombus is formed. After early dependence on thrombin plugs to restrain blood loss, later generalized vasoconstrictive hemostasis without thrombin plugs occur. The healing endometrium is pale, collapsed, and disorderly, but no thrombi and no fibrin deposits are seen.

Lockwood assigns a key role to decidual cells in both the process of endometrial bleeding (menstruation) and the process of endometrial hemostasis (implantation and placentation).²² Implantation requires endometrial hemostasis and the maternal uterus requires resistance to invasion. Inhibition of endometrial hemorrhage can be attributed, to a significant degree, to appropriate changes in critical factors as a consequence of decidualization; e.g., lower plasminogen activator levels, reduced expression of the enzymes that degrade the stromal extracellular matrix (such as the metalloproteinases), increased levels of plasminogen activator inhibitor-1 and

tissue factor. Withdrawal of estrogen and progesterone support, however, leads to changes in the opposite directions, consistent with endometrial breakdown.

Traditional Definitions

Oligomenorrhea: Intervals greater than 35 days.

Polymenorrhea: Intervals less than 24 days.

Menorrhagia: Regular normal intervals, excessive flow and duration.

Metrorrhagia: Irregular intervals, excessive flow and duration.

Endometrial Responses to Steroid Hormones: Physiologic and Pharmacologic

Obviously, estrogen and progesterone withdrawal is not the only type of endometrial bleeding provoked by the presence of sex steroids and their effects on the endometrium. There are clinical examples for estrogen withdrawal bleeding and estrogen breakthrough bleeding, as well as for progesterone withdrawal and breakthrough bleeding.

Estrogen Withdrawal Bleeding

This category of uterine bleeding can occur after bilateral oophorectomy, radiation of mature follicles, or administration of estrogen to a castrate and then discontinuation of therapy. Similarly, the bleeding that occurs postcastration can be delayed by concomitant estrogen therapy. Flow will occur on discontinuation of exogenous estrogen. Midcycle bleeding can occur secondary to the decrease in estrogen that immediately precedes ovulation.

Estrogen Breakthrough Bleeding

Here a semiquantitative relationship exists between the amount of estrogen stimulating the endometrium and the type of bleeding that can ensue. Relatively low doses of estrogen yield intermittent spotting that may be prolonged, but is generally light in quantity of flow. On the other hand, high levels of estrogen and sustained availability lead to prolonged periods of amenorrhea followed by acute, often profuse bleeds with excessive loss of blood.

Progesterone Withdrawal Bleeding

Removal of the corpus luteum will lead to endometrial desquamation. Pharmacologically, a similar event can be achieved by administration and discontinuation of progesterone or a nonestrogenic synthetic progestin. Progesterone withdrawal bleeding occurs only if the endometrium is initially proliferated by endogenous or exogenous estrogen. If estrogen therapy is continued as progesterone is withdrawn, the progesterone withdrawal bleeding still occurs. Only if estrogen levels are increased 10–20-fold will progesterone withdrawal bleeding be delayed.²³

Progesterone Breakthrough Bleeding

Progesterone breakthrough bleeding occurs only in the presence of an unfavorably high ratio of progesterone to estrogen. In the absence of sufficient estrogen, continuous progesterone therapy will yield intermittent bleeding of variable duration, similar to low-dose estrogen breakthrough bleeding noted above. This is the type of bleeding associated with the long-acting progestin-only contraceptive methods, Norplant and Depo-Provera.²⁴

Suggestions for Why Anovulatory Bleeding Is Excessive

Most instances of anovulatory bleeding are examples of estrogen withdrawal or estrogen breakthrough bleeding. The heaviest bleeding is secondary to high sustained levels of estrogen associated with polycystic ovaries, obesity, immaturity of the hypothalamic-pituitary-ovarian axis as in postpubertal teenagers, and late anovulation, usually involving women in their late 30s and 40s. In the absence of growth-limiting progesterone and periodic desquamation, the endometrium attains an abnormal height without concomitant structural support. The tissue increasingly displays intense vascularity, back-to-back glandularity, but without an intervening stromal support matrix. This tissue is fragile and will suffer spontaneous superficial breakage and bleeding. As one site heals, another, and yet another new site of breakdown will appear. The typical clinical picture is that of a pale frightened teenager who has bled for weeks. Also frequently encountered is the older woman with prolonged bleeding who is deeply concerned over this experience as a manifestation of cancer.

In these instances, the usual endometrial control mechanisms are missing. This bleeding is not a universal event, but, rather, it involves random portions of the endometrium at variable times and in asynchronous sequences. The fragility of the vascular adenomatous hyperplastic tissue is responsible for this experience, in part because of excessive growth, but mostly because of irregular stimulation in which the structural rigidity of a well-developed stroma or stratum compactum does not occur. Finally, the flow is prolonged and excessive not only because there is a large quantity of tissue available for bleeding, but more importantly, because there is a disorderly, abrupt, random, breakdown of tissue with consequent opening of multiple vascular channels. There is no vasoconstrictive rhythmicity, no tight coiling of spiral vessels, no orderly collapse to induce stasis. The anovulatory tissue can only rely on the “healing” effects of endogenous estrogen to stop local bleeds. However, this is a vicious cycle in that this healing is only temporary. As quickly as it rebuilds, tissue fragility and breakdown recur at other endometrial sites.

Alternate Hypothesis

Another explanation for the control of postovulatory endometrial bleeding and regeneration has been presented.²⁵ Based on light and scanning electron microscopy of hysterectomy specimens, this thesis favors nonhormone-related regeneration of surface epithelium from basal glands and cornual area residual tissue with restoration of the continuous binding membrane as the critical events in cessation of blood flow. Endometrial regeneration is viewed as a response to tissue loss, not hormonal changes. By this account, estrogen withdrawal or breakthrough bleeding is uncontrolled because there is insufficient stimulus (loss of tissue) for binding surface restoration to occur. Furthermore, curettage is effective in this condition by reachieving sufficient basal glandular denudation (as is seen also in combined estrogen and progestin withdrawal), which stimulates regeneration of surface integrity and, thus, controls blood flow.

Additional studies are needed to clarify the difference of opinion concerning the pathophysiology of dysfunctional uterine bleeding. Our therapeutic approach favored in this book uses hormonal control of endometrial events and rarely finds it necessary to resort to surgery.

Differential Diagnosis

Dysfunctional uterine bleeding is a diagnosis made by exclusion. A very common cause of abnormal uterine bleeding is pregnancy and pregnancy-related problems such as ectopic pregnancy or spontaneous miscarriage. This category of problems should always receive diagnostic consideration because the most common cause of an abrupt departure from a normal menstrual pattern is pregnancy or a complication of pregnancy. Patients may be using medications unknowingly with an impact on the endometrium. For example, the use of ginseng, an herbal root, has been associated with estrogenic activity and abnormal bleeding.²⁶ Pathology of the menstrual outflow tract includes cancers of the cervix and endometrium, endometrial polyps, leiomyomata uteri, and infections. Although uterine bleeding is a common problem with various contraceptive methods and postmenopausal hormonal therapy, the clinician should always be convinced no pathology is present. Abnormal menstrual cycles are occasionally the first sign of either hypothyroidism or hyperthyroidism.²⁷ Irregular, serious bleeding is often associated with severe organ disease, such as renal failure and liver failure. Finally, careful examination is worthwhile to discover genital injury or a foreign object.

One should keep in mind that as many as 20% of adolescents with dysfunctional uterine bleeding will have a coagulation defect, although the most common cause is anovulation.^{28,29} In 150 women aged 15–50 in Helsinki who were referred for the evaluation of menorrhagia, an inherited bleeding disorder was diagnosed in 26 of the patients; the most common diagnoses were von Willebrand's disease (13%) and factor XI deficiency (4%).³⁰ Bleeding secondary to a blood dyscrasia is usually a heavy flow with regular, cyclic menses (menorrhagia), and this same pattern can be seen in patients being treated with anticoagulants.³¹ Bleeding disorders are usually associated with menorrhagia since menarche and a history of bleeding with surgery or trauma. Menorrhagia may be the only sign of an inherited bleeding disorder.³²

The effects of tubal ligation are still not certain. The first well-controlled studies of this issue demonstrated no change in menstrual patterns, volume, or pain.^{33,34}

Subsequently, these same authors reported an increase in dysmenorrhea and changes in menstrual bleeding.^{35,36} However, these authors failed to agree in their findings (a change found by one group was not confirmed by the other). Adding to the confusion, the incidence of hysterectomy for bleeding disorders in women after tubal sterilization was reported to be increased by some,³⁷ but not by others.³⁸ In a large cohort of women in a group health plan, hospitalization for menstrual disorders was significantly increased; however, the authors believed this reflected bias by patient and physician preference for surgical treatment.³⁹ In the U.S. prospective long-term follow-up study of sterilization, the increased risk of hysterectomy after sterilization was concentrated in women who were treated for gynecologic disorders before tubal sterilization.⁴⁰ These discordant reports do not make patient counseling about the long-term effects of tubal sterilization an easy task. It is possible that extensive electrocoagulation of the fallopian tubes can change ovarian steroid production. Perhaps this is why menstrual changes were detected with longer (4 years) follow-up, while no changes have been noted with the use of rings or clips.^{39,41,42} However, attempts to relate poststerilization menstrual changes with extent of tissue destruction fail to find a correlation, and an increase in hospitalization for menstrual disorders after unipolar cautery cannot be documented.^{39,42} Still another long-term follow-up study (3–4.5 years) failed to document any significant changes in menstrual cycles.⁴³ This inconsistency can reflect differences in sterilization techniques, as well as the fact that a surgical solution is more likely to be chosen if continuing fertility is no longer an issue. The best answer for now is that some women experience menstrual changes, but most do not.

Laboratory tests that can be helpful (but not always necessary) are coagulation studies (prothrombin time, partial thromboplastin time, platelet count, bleeding time, and the ristocetin cofactor assay for the von Willebrand factor), complete blood count, quantitative human chorionic gonadotropin (HCG), prolactin, thyroid function tests, liver function tests, and appropriate cervical cultures.

Treatment Program for Anovulatory Bleeding

The immediate objective of medical therapy in anovulatory bleeding is to retrieve the natural controlling influences missing in this tissue: universal, synchronous endometrial events, structural stability, and vasomotor rhythmicity.

Progestin Therapy

Most women will, at sometime during their reproductive years, either fail to ovulate or not sustain adequate corpus luteum function or duration. But this occurs with increased frequency in adolescence and in the decade prior to menopause. The usual clinical presentation is oligomenorrhea with bouts of heavy bleeding. Women correctly seek medical advice promptly because these menstrual aberrations suggest unplanned pregnancy or uterine pathology. Under most circumstances, progestin therapy will suffice to control the abnormality once uterine pathology is ruled out.

Progesterone and progestins are powerful antiestrogens when given in pharmacologic doses. Progestins stimulate 17 β -hydroxysteroid dehydrogenase and sulfotransferase activity, which convert estradiol to estrone sulfate (which is rapidly excreted from the cell).⁴⁴ Progestins also diminish estrogen effects on target cells by inhibiting the augmentation of estrogen receptors that ordinarily accompanies estrogen action (receptor replenishment inhibition). In addition, progestins suppress estrogen-mediated transcription of oncogenes.⁴⁵ These influences account for the antimitotic, antigrowth impact of progestins on the endometrium (prevention and reversal of hyperplasia, limitation of growth postovulation, and the marked atrophy during pregnancy or in response to combined oral contraceptives).

In the treatment of oligomenorrhea, orderly limited withdrawal bleeding can be accomplished by administration of a progestin such as medroxyprogesterone acetate, 5–10 mg daily for at least 10 days every month. Absence of induced bleeding requires workup. In the treatment of dysfunctional menometrorrhagia or polymenorrhea, progestins are prescribed for 10 days to 2 weeks (to induce stabilizing predecidual stromal changes) followed by a withdrawal flow — the so-called “medical curettage.” Thereafter, repeat progestin is offered cyclically for at least the first 10 days of each month to ensure therapeutic effect. Failure of progestin to correct irregular bleeding requires diagnostic reevaluation. **If contraception is desired, the use of an oral contraceptive is a better choice.**

Oral Contraceptive Therapy

In young women, anovulatory bleeding may be associated with prolonged endometrial buildup, delayed diagnosis, and heavy blood loss. In these cases, combined progestin-estrogen therapy is used in the form of combined oral contraceptives. Any of the low-dose oral combination monophasic tablets are useful. Whatever formulation is available or chosen, therapy is administered as one pill twice a day for 5–7 days. This therapy is maintained despite cessation of flow within 12–24 hours. If flow does not abate, other diagnostic possibilities (polyps, incomplete abortion, and neoplasia) should be reevaluated.

If flow does diminish rapidly, the remainder of the week of treatment can be given over to the evaluation of causes of anovulation, investigation of hemorrhagic tendencies, and blood replacement or initiation of iron therapy. In addition, the week provides time to prepare the patient for the estrogen-progestin withdrawal flow that will soon be induced. For the moment, therapy has produced the structural rigidity intrinsic to the compact pseudodecidual reaction. Continued random breakdown of formerly fragile tissue is avoided and blood loss stopped. However, a large amount of tissue remains to react to estrogen-progestin withdrawal. The patient must be warned to anticipate a heavy and severely cramping flow 2–4 days after stopping therapy. If not prepared in this way, it is certain that the patient will view the problem as recurrent disease or failure of hormonal therapy.

In successful therapy, on the 5th day of flow or in the usual Sunday start fashion, a low dose combination oral contraceptive medication (one pill a day) is started. This will be repeated for several (usually three) 3-week treatments, punctuated by 1-week withdrawal flow intervals. A decrease in volume and pain with each successive cycle is reassuring. Oral contraceptives reduce menstrual flow by at least 60% in normal uteri.⁴⁶ Early application of the estrogen-progestin combination limits growth and allows orderly regression of excessive endometrial height to normal controllable levels. If the estrogen-progestin combination is not applied, abnormal endometrial height and persistent excessive flow will recur.

In the patient not requiring contraception, in whom cyclic estrogen-progestin for 3 months has reduced endometrial tissue to normal height, the oral contraceptive can be discontinued and unopposed endogenous estrogen permitted to reactivate the endometrium. In the absence of spontaneous menses, the recurrence of the anovulatory state is suspected, and a brief preemptive course of an orally active progestin is administered to counter endometrial proliferation. Once pregnancy is ruled out, medroxyprogesterone acetate, 5–10 mg orally daily for at least 10 days, is given monthly. Reasonable flow (progestin withdrawal flow) will occur 2–7 days after the last pill. With this therapy, excessive endometrial buildup is avoided, and an increased risk of endometrial and possibly breast cancer is avoided. If contraception is desired, routine use of oral contraception is warranted and will also be of prophylactic value.

Depot-medroxyprogesterone acetate in the dose used for contraception, 150 mg intramuscularly every 3 months, is a useful option for poorly compliant patients. Breakthrough bleeding is treated with estrogen as discussed below.

Estrogen Therapy

Intermittent vaginal spotting is frequently associated with minimal (low) estrogen stimulation (estrogen breakthrough bleeding). In this circumstance, where minimal endometrium exists, the beneficial effect of progestin treatment is not achieved, because there is insufficient tissue on which the progestin can exert action. A similar circumstance also exists in the younger anovulatory patient in whom prolonged hemorrhagic desquamation leaves little residual tissue.

In these circumstances, when bleeding is acute and heavy, high-dose estrogen therapy is applied by using as much as 25 mg conjugated estrogen intravenously every 4 hours until bleeding abates or for 24 hours.⁴⁷ This is the sign that the “healing” events are initiated to a sufficient degree. The mechanism of action for estrogen is believed to be a stimulus to clotting at the capillary level.⁴⁸ Progestin treatment (usually an oral contraceptive) is started at the same time. Where bleeding is less, lower oral doses of estrogen (1.25 mg of conjugated estrogens or 2.0 mg estradiol daily for 7–10 days) can be prescribed initially. When bleeding is moderately heavy, a more intensive oral program can be utilized, 1.25 mg conjugated estrogens or 2 mg estradiol every 4 hours for 24 hours, followed by the single daily dose for 7–10 days. All estrogen therapy must be followed by progestin coverage and a withdrawal bleed.

Estrogen therapy is also useful in two examples of problems associated with progestin breakthrough bleeding. These are the breakthrough bleeding episodes occurring with use of oral contraception or with depot forms of progestational agents. In the absence of sufficient endogenous and exogenous estrogen, the endometrium shrinks by pharmacologically induced pseudoatrophy. Furthermore, it is composed almost exclusively of pseudodecidual stroma and blood vessels with minimal glands. Peculiarly, experience indicates that this type of endometrium also leads to the fragility bleeding more typical of pure estrogen stimulation.

The usual clinical story is a patient on long-standing oral contraception who, after experiencing marked diminution or absence of withdrawal flow in the pill-free interval, begins to see breakthrough bleeding while on medication. Conjugated estrogens, 1.25 mg, or estradiol, 2.0 mg daily for 7 days during, and, in addition to, the usual birth control pill administration are effective. This treatment rejuvenates the endometrium and intermenstrual flow stops. Another frequently encountered problem is the progestin breakthrough bleeding experienced with chronic depot administration of progestin (Depo-Provera). This therapy is used not only for contraception, but also in the treatment of endometriosis and the prevention of menses during chemotherapy. In 75% of recipients, continuous therapy is not associated with abnormal menstrual bleeding. In the remainder, breakthrough progestin bleeding occurs. Judicious use of estrogen is the appropriate and effective therapy in these instances.

Bleeding problems are common with Norplant, another example of the effect of persistent progestational influence on the endometrium. Patients who can no longer tolerate prolonged bleeding will benefit from a short course of oral estrogen as above.⁴⁹

The Risk Associated with Estrogen Therapy

There is concern that high doses of estrogen could precipitate a thrombotic event. More than one oral contraceptive per day and multiple doses of oral or intravenous estrogen in a 24-hour period certainly should be regarded as high doses. There are no data available, however, to verify or quantitate any risk associated with this use of hormonal therapy. This treatment must be chosen by clinician and patient after weighing the risk-benefit considerations that surround the uterine bleeding problem. As a matter of clinical judgment and prudent practice, lower doses can be used in patients with lifestyle or medical history consistent with an increased risk of vascular complications. In women with a past episode or a positive family history of idiopathic venous thromboembolism, exposure to high doses of estrogen should be avoided.

The Use of Antiprostaglandins

There seems little doubt that prostaglandins (PG) have important actions on the endometrial vasculature and, presumably, on endometrial hemostasis. The concentrations of PGE₂ and PGF_{2α} increase progressively in human endometrium during the menstrual cycle, and nonsteroidal eicosanoid synthesis inhibitors decrease menstrual blood loss perhaps by also altering the balance between the platelet proaggregating vasoconstrictor thromboxane A₂ (TXA₂) and the antiaggregating vasodilator prostacyclin (PGI₂).⁵⁰ Excessive bleeding in women with menorrhagia can be reduced by approximately 40–50%.⁵¹ In a comparison study of ovulating women with menorrhagia, treatment during menses with a prostaglandin synthetase inhibitor was no more effective than high-dose progestin supplementation during the 7 days preceding menstruation, but both treatments were effective.⁵² Occasionally, a woman will demonstrate, for unknown reasons, an anomalous response to this treatment, with an increase in menstrual bleeding.⁵³ A study of postoperative surgical specimens after mefenamic acid treatment revealed evidence of vasoconstriction and improved platelet aggregation.⁵⁴

Whatever the exact mechanism, prostaglandin synthetase inhibitors diminish menstrual bleeding in normal women as well as in the bleeding secondary to intrauterine device (IUD) use. This approach should be considered as a first line of defense in the absence of pathology in those women who are ovulatory but bleed heavily. Side effects are unusual because treatment is limited, usually beginning with the onset of bleeding and continuing for 3–4 days. This treatment will also relieve the other symptoms of menstrual molimina.

Treatment With a Progestin IUD

The delivery of a progestational agent directly to the endometrium in a local fashion is possible with an intrauterine device which releases progesterone or levonorgestrel.^{55, 55, 56} In a comparison trial with a prostaglandin synthase inhibitor and an antifibrinolytic agent, the levonorgestrel-releasing IUD outperformed the medical treatment dramatically.⁵⁶ The reduction in menstrual flow reached 96% after 12 months, and some patients even become amenorrheic. In a comparison of the levonorgestrel-releasing IUD with endometrial ablation, symptomatic response and patient satisfaction were relatively comparable; approximately 20% of patients become amenorrheic and another 50% have a less than normal menstrual flow.⁵⁷ This is an attractive option in patients with intractable bleeding associated with chronic illnesses (such as renal failure). A progestin-releasing IUD is also a good choice for normally ovulating women who have extremely heavy menstrual bleeding.

Treatment with GnRH Agonists

Treatment with a GnRH agonist can achieve short-term relief from a bleeding problem, for example, in a patient with renal failure or a blood dyscrasia. This choice is a good one for patients who experience menstrual bleeding problems after organ transplantation (especially after liver transplantation) where the toxicity of immunosuppressive drugs makes the use of sex steroids less desirable. However, the expense and long-term side effects make this an unlikely choice for chronic therapy. If long-term GnRH agonist therapy is chosen, after gonadal suppression is achieved (2–4 weeks), we recommend add-back treatment with a daily combination of 0.625 mg conjugated estrogens or 1.0 mg estradiol and 2.5 mg medroxyprogesterone acetate or 0.35 mg norethindrone.

Treatment With Desmopressin

Desmopressin acetate is a synthetic analog of arginine vasopressin. It has been used to treat abnormal uterine bleeding in patients with coagulation disorders, especially in patients with von Willebrand's disease.^{58, 59} It can be administered intranasally, but the intravenous route (0.3 µg/kg diluted in 50 mL saline and administered over 15–30 minutes) is more effective. Treatment is followed by a rapid increase in coagulation factor VIII and von Willebrand's factor, which lasts approximately 6 hours. This treatment should be regarded as a last resort for selected patients with coagulation problems. The nasal spray is very effective for patients with von Willebrand's disease type I.⁵⁹

Ablation of the Endometrium

Persistent bleeding despite treatment is both aggravating and concerning. Hysterectomy is an appropriate choice for some of these patients. Others would prefer to avoid a major operation, and still others have conditions that make major surgery a high-risk procedure. Patients and clinicians should consider the option of hysteroscopic endometrial ablation. Ablation of the endometrium can be accomplished with either a laser, a resectoscope with a loop or rolling ball electrode, or radio frequency-induced thermal destruction. A new method employs a uterine balloon to expose the endometrium to an 85°C temperature for 10–15 minutes using the circulation of hot saline.⁶⁰ In a comparison with the rolling ball technique, the thermal balloon was as effective and with fewer side effects.⁶¹ In a randomized comparison of medical treatment of menorrhagia compared with hysteroscopic endometrial ablation, overall results were better with surgical management.⁶² Nevertheless, for most women, medical management is a better first approach (certainly in terms of cost).

Success with these methods is not 100%. Approximately 90% of women with menorrhagia will have an improvement following an ablation procedure; only 40–50% will become amenorrheic.^{63, 64 and 65} Some women will continue to have menorrhagia. In a randomized trial comparing endometrial resection and hysterectomy, subsequent surgery was required by 22% of the women after endometrial resection compared with 9% in the hysterectomy group.⁶⁶ The best results are obtained if the endometrium is first suppressed for 4–6 weeks with either a high dose of a progestin, GnRH agonist treatment, or danazol. Caution must be exercised regarding the possibility of excessive absorption of irrigating fluid with subsequent fluid overload. Despite the advantages of lower risk, fewer complications, and more rapid

recovery with endometrial resection, patients treated by hysterectomy tend to be more satisfied with the outcome. ^{66, 67}

There is concern that obliteration of segments of the uterine cavity can allow isolated, residual endometrium to progress to carcinoma without recognition. ⁶⁸ Endometrial ablation is not recommended for patients who are considered to be at high risk for endometrial cancer. ⁶⁹

Less Appealing Choices

Antifibrinolytic agents (e.g., tranexamine acid) are associated with a large number of side effects. Danazol effectively reduces menstrual blood loss, but treatment requires significant doses maintained for a long time period. The expense and androgenic side effects associated with danazol make it a poor choice. ⁷⁰

Hyperplasia Versus Neoplasia

Ferenczy argues that there are two separate and biologically unrelated diseases: endometrial hyperplasia and endometrial neoplasia. ^{71, 72} He suggests that all hyperplasia without atypia be referred to as **endometrial hyperplasia**, and this is usually not a precursor of carcinoma. He further proposes that lesions with cytologic atypia be referred to as **endometrial intraepithelial neoplasia (EIN)**. In these cases, persistence after multiple curettings or high-dose progestin therapy is approximately 75%. EIN would replace the following terms: atypical adenomatous hyperplasia and carcinoma in situ of the endometrium. This lesion is characterized by nuclear atypia of the cells lining the endometrial glands (enlargement, rounding, and pleomorphism of the nuclei with aneuploid DNA content). Invasive carcinoma is distinguished from EIN by stromal invasion.

EIN is best treated surgically! If future pregnancy is desired, daily progestin therapy (30 mg medroxyprogesterone acetate daily) should be followed by repeat endometrial aspiration curettage in 3–4 months. If EIN is still present, the choice is between surgery and high dose progestin (200 mg medroxyprogesterone acetate daily, 500 mg megestrol acetate biweekly, or depot medroxyprogesterone acetate 1000 mg weekly) with repeat biopsy surveillance.

The benign lesions include all of the following traditional interpretations: anovulatory, proliferative, cystic glandular hyperplasia, simple hyperplasia, adenomatous hyperplasia without atypia. These lesions are basically the same (perhaps exaggerations at most) as preovulatory, proliferative endometrium. This hyperplasia regresses spontaneously, after curettage, or with hormonal treatment. ^{72, 73} **This argument is an important one: benign lesions can be treated hormonally. With one exception, only the presence of cytonuclear atypia should raise immediate and serious concern for progression to cancer. The exception is the patient with an apparently benign lesion that does not respond to progestin therapy. Was the diagnosis accurate? Will clinical data eventually indicate that this type of patient is also at higher risk for progression?**

Summary of Key Points in Therapy of Anovulatory (Dysfunctional) Bleeding

Teenager	Adult
<i>Preliminary:</i>	<i>Preliminary:</i>
Pelvic or rectal examination	Pelvic examination
Rule out pregnancy	PAP smear
Appropriate laboratory tests	Rule out pregnancy
	Appropriate laboratory tests
	Endometrial biopsy

1. Intense estrogen-progestin therapy for 7 days.
2. Cyclic low-dose oral contraceptive for 3 months.
3. If contraception is desired, continue oral contraception.
4. If not exposed to pregnancy, medroxyprogesterone acetate, 5–10 mg daily for at least 10 days every month.

If bleeding has been prolonged, if biopsy yields minimal tissue, if the patient is on progestin medication, or if follow-up is uncertain:

Conjugated estrogens (1.25 mg) or estradiol (2.0 mg) daily for 7–10 days, followed by the daily estrogen combined with 10 mg medroxyprogesterone acetate for 7 days. If acute bleeding is moderately heavy, the oral estrogen dose can be administered every 4 hours during the first 24 hours. For very heavy, acute bleeding, conjugated estrogen, 25 mg intravenously every 4 hours until bleeding stops or significantly slows, and then proceed to Step 1 above. If no response in 24 hours, proceed to D and C.

The clinical problem of dysfunctional bleeding is associated with either anovulation and estrogen withdrawal or breakthrough bleeding, or with anovulation caused by exogenous progestin medication and bleeding due to progestational endometrial breakthrough. These categories of bleeding lack the three important characteristics of normal estrogen-progesterone withdrawal bleeding:

1. Universal, simultaneous change in all segments of the endometrium.
2. An orderly progression of events involving a rigid, compact structure.
3. Vasomotor rhythmicity with vasoconstriction, structural collapse, and clotting.

Questioning should be directed by the differential diagnosis of abnormal uterine bleeding. Clues to the diagnosis may be apparent on physical examination, such as hirsutism, acne, galactorrhea, thyroid enlargement, evidence of an eating disorder, bruises, and, of course, abnormalities on examination of the pelvis. Brown, dark colored bleeding is often secondary to obstruction in a müllerian anomaly. Laboratory tests that can be helpful (but not always necessary) are coagulation studies (prothrombin time, partial thromboplastin time, platelet count, bleeding time, and the ristocetin cofactor assay for von Willebrand's factor), quantitative human chorionic gonadotropin (HCG), prolactin, thyroid function tests, liver function tests, and appropriate cervical cultures. However, it is appropriate to move quickly to empirical hormonal therapy because pathology will eventually declare itself.

Office aspiration biopsy of the endometrium should always be performed in patients considered to be at high risk for endometrial hyperplasia and cancer. Texts and review articles continue to emphasize that endometrial biopsy is in order if the patient is older; e.g., greater than 35 or 40 years old. **It is not the age of the patient that is critical; it is the duration of exposure to unopposed estrogen. Women in their 20s and even teenagers can develop endometrial cancer.** ⁷⁴ The small flexible suction cannulas are preferred for greater patient comfort, and results are comparable with the older, traditional methods. ^{75, 76} and ⁷⁷ Office hysteroscopy is also useful for the direction of biopsies and the detection of polyps and submucous myomas.

Therapy involves an initial choice between intensive estrogen-progestin combination medication or relatively high doses of estrogen. The estrogen-progestin combination will be ineffective unless endometrium of sufficient quantity and responsiveness to allow the formation of pseudodecidual tissue is present. Therefore, the initial choice of therapy should be estrogen in the following situations:

1. When bleeding has been heavy for many days and it is likely that the uterine cavity is now lined only by a raw basalis layer.
2. When the endometrial curet yields minimal tissue.
3. When the patient has been on progestin medication (oral contraceptives, or intramuscular progestins) and the endometrium is shallow and atrophic.
4. When follow-up is uncertain, because estrogen therapy will temporarily stop all categories of dysfunctional bleeding.

If estrogen therapy does not significantly abate flow within 24 hours, reevaluation is mandatory, and the need for curettage is likely. It is believed that patients with coagulation disorders respond better if the uterine cavity is first evacuated with a suction curet. Consideration should be given to the empirical administration of fresh

frozen plasma to adolescents who present with acute, serious bleeding. It is prudent to combine hysteroscopy with curettage in order to achieve full accuracy in diagnosis and treatment.

Once the acute bleeding episode in an anovulatory patient is under control, the patient should not be forgotten. With persistent anovulation, recurrent hemorrhage is a common pattern, and, more importantly, chronic unopposed estrogen stimulation to the endometrium can eventually lead to atypical tissue changes. It is absolutely necessary that the patient undergo periodic progestational withdrawal either with a routine oral contraceptive regimen or if contraception is not desired, a progestational agent (medroxyprogesterone acetate, 5–10 mg daily for at least 10 days) should be administered every month.

Curettage is **not** the first line of defense, but, rather, the last. The use of appropriate steroids for the clinical management of dysfunctional bleeding is based on a physiologic understanding of the endometrium and its responses to hormones. Adherence to this program will avoid D and C except in a rare case of dysfunctional bleeding and except in those cases in which bleeding is due to a pathologic entity within the reproductive tract where D and C is truly indicated and necessary.

Remember to seek pathology if dysfunctional uterine bleeding is persistent or recurrent after hormonal treatment. If a patient has recurrent bleeding despite repeated medical therapy, submucous myomas or endometrial polyps must be suspected. Thorough curettage can miss such pathology, and further diagnostic study can be helpful. Either hysterosalpingography with slow instillation of dye and careful fluoroscopic examination or hysteroscopy (especially with filling of the uterine cavity with fluid) may reveal a myoma or polyp; hysteroscopy can also direct a more accurate biopsy of the endometrium. ^{7E, 7F and 8C} A pathologic problem such as this should especially be suspected in the puzzling case of the patient who has abnormal bleeding and ovulatory cycles.

Patients who are ovulating but have a heavy menstrual flow (menorrhagia) can be effectively treated with prostaglandin inhibitors, progestins administered daily for the 7 days preceding menses, or oral contraceptives in the routine manner. If contraception is not required, we prefer the use of one of the fenamate prostaglandin inhibitors (which block both synthesis and prostaglandin receptors). Women who have menorrhagia but are ovulating should be evaluated for a coagulation disorder (prothrombin time, partial thromboplastin time, platelet count, bleeding time, and the ristocetin cofactor assay for von Willebrand's factor). The IUD that releases progesterone or a progestin is a good choice for ovulating women with menorrhagia, and it should be also considered in patients with chronic illnesses.

The form, function, and pathology of the human female breast are major concerns of medicine and society. As mammals, we define our biologic class by the function of the breast in nourishing our young. Breast contours occupy our attention. As obstetricians, we seek to enhance or diminish function, and as gynecologists, the appearance of inappropriate lactation (galactorrhea) may signify serious disease. Cancer of the breast is the most prevalent cancer in women.

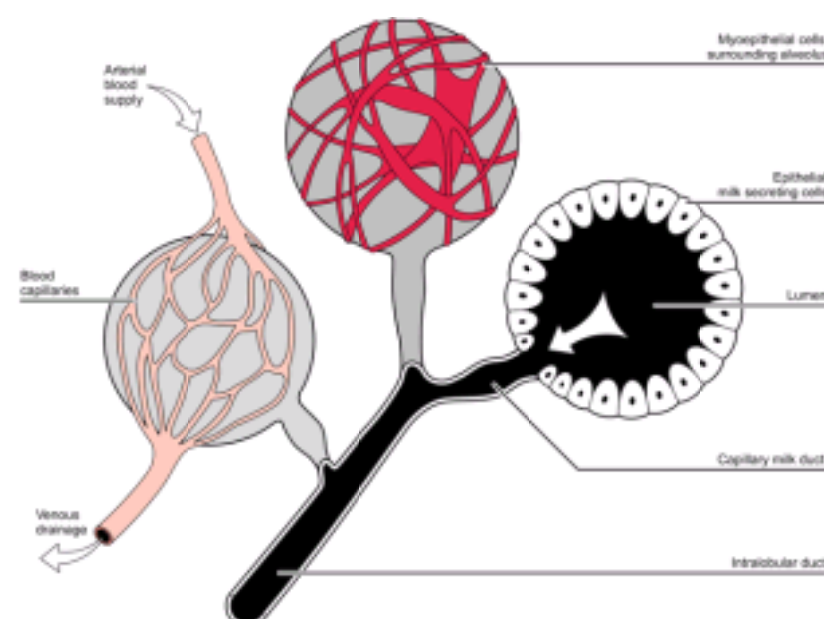

In this chapter, the factors involved in normal growth and development of the breast will be reviewed, including the physiology of normal lactation. A description of the numerous factors leading to inappropriate lactation will follow, and, finally, the endocrine aspects of breast cancer will be considered.

Growth and Development

The basic component of the breast lobule is the hollow alveolus or milk gland lined by a single layer of milk-secreting epithelial cells, derived from an ingrowth of epidermis into the underlying mesenchyme at 10–12 weeks of gestation. Each alveolus is encased in a crisscrossing mantle of contractile myoepithelial strands. Also surrounding the milk gland is a rich capillary network.

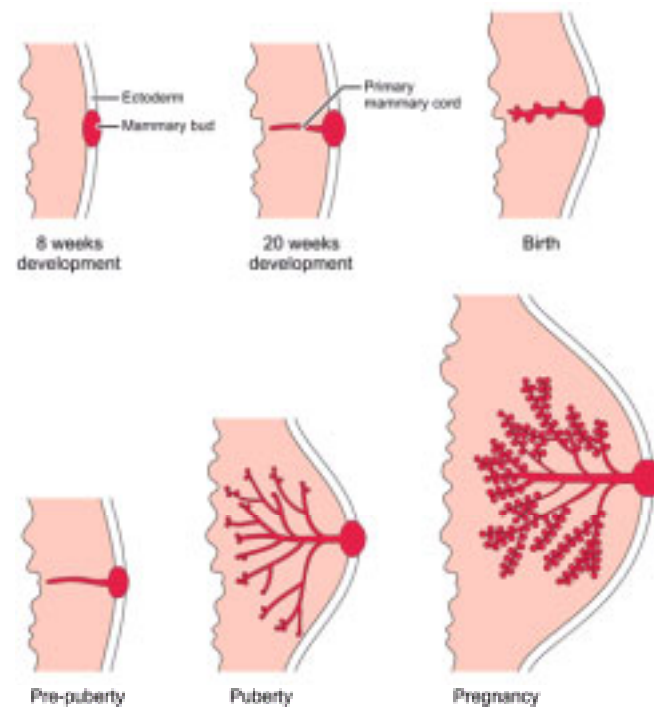

The lumen of the alveolus connects to a collecting intralobular duct by means of a thin nonmuscular duct. Contractile muscle cells line the intralobular ducts that eventually reach the exterior via 15–20 collecting ducts in a radial arrangement, corresponding to the 15–20 distinct mammary lobules in the breast, each of which contains many alveoli.

Growth of this milk-producing system is dependent on numerous hormonal factors that occur in two sequences, first at puberty and then in pregnancy. Although there is considerable overlapping of hormonal influences, the differences in quantities of the stimuli in each circumstance and the availability of entirely unique inciting factors (human placental lactogen and prolactin) during pregnancy permit this chronologic distinction. The strength of the hormonal stimulus to breast tissue during pregnancy is responsible for the fact that nearly half of male and female newborns have breast secretions.

The major influence on breast growth at puberty is estrogen. In most girls, the first response to the increasing levels of estrogen is an increase in size and pigmentation of the areola and the formation of a mass of breast tissue just underneath the areola. Breast tissue binds estrogen in a manner similar to the uterus and vagina. The human breast expresses both estrogen receptors, ER-a and ER-b.¹ The development of estrogen receptors in the breast does not occur in the absence of prolactin. The primary effect of estrogen in subprimate mammals is to stimulate growth of the ductal portion of the gland system. Progesterone in these animals influences growth of the alveolar components of the lobule.² However, neither hormone alone, or in combination, is capable of yielding optimal breast growth and development. Full differentiation of the gland requires insulin, cortisol, thyroxine, prolactin, and growth hormone.³ Of course, the ubiquitous growth factors are also involved, but the molecular mechanisms remain to be determined. Nevertheless, experimental evidence in mice indicates that progesterone is the key hormone required for mammary growth and differentiation; estrogen is necessary because the synthesis of progesterone receptors requires the critical presence of estrogen.²

The pubertal response is a manifestation of closely synchronized central (hypothalamus-pituitary) and peripheral (ovary-breast) events. For example, gonadotropin-releasing hormone (GnRH) is known to stimulate prolactin release, and this action is potentiated by estrogen.⁴ This suggests a paracrine interaction between gonadotrophs and lactotrophs, linked by estrogen, ultimately with an impact on the breast.

Changes occur routinely in response to the estrogen-progesterone sequence of a normal menstrual cycle. Maximal size of the breast occurs late in the luteal phase. Fluid secretion, mitotic activity, and DNA production of nonglandular tissue and glandular epithelium peak during the luteal phase. ^{5,6 and 7} This accounts for cystic and tender premenstrual changes.

During the normal menstrual cycle, estrogen receptors in mammary gland epithelium decrease in number during the luteal phase, whereas progesterone receptors remain at a high level throughout the cycle. ⁸ Studies using tissue from reduction mammoplasties or from breast tissue near a benign or malignant lesion have demonstrated a peak in mitotic activity during the luteal phase. ^{6,9,10} Using fine needle biopsy tissue, an immunocytochemical marker of proliferation was higher in the luteal phase than in the proliferative phase. ⁸ And in this study there was a direct correlation with serum progesterone levels. However, important studies indicate that with increasing duration of exposure, progesterone imposes a limitation on breast cell proliferation. ^{11,12 and 13} Therefore, breast and endometrium epithelial cells may be more similar than initially proposed.

Final differentiation of the alveolar epithelial cell into a mature milk cell is accomplished by the gestational increase in estrogen and progesterone, combined with the presence of prolactin, but only after prior exposure to cortisol and insulin. The complete reaction depends on the availability of minimal quantities of thyroid hormone. Thus, the endocrinologically intact individual in whom estrogen, progesterone, thyroxine, cortisol, insulin, prolactin, and growth hormone are available can have appropriate breast growth and function. During the first trimester of pregnancy, growth and proliferation are maximal, changing to differentiation and secretory activity as pregnancy progresses.

Breast tissue changes with aging. During teenage years the breasts are dense and predominantly glandular. As the years go by, the breasts contain progressively more fat, but after menopause, this process accelerates so that soon into the postmenopausal years, the breast glandular tissue is mostly replaced by fat.

Abnormal Shapes and Sizes

Early differentiation of the mammary gland anlage is under fetal hormonal control. Abnormalities in adult size or shape may reflect the impact of hormones (especially the presence or absence of testosterone) during this early period of development. This prenatal hormonal influence programs the breast development that will occur in response to the increase in hormones at puberty. Occasionally, the breast bud will begin to develop on one side first. Similarly, one breast may grow faster than the other. These inequalities usually disappear by the time development is complete. However, exact equivalence in size may not be attained. Significant asymmetry is correctable only by a plastic surgeon. Likewise hypoplasia and hypertrophy can be treated only by corrective surgery. With one exception, hormone therapy is totally ineffective in producing a permanent change in breast shape or size. Of course in patients with primary amenorrhea due to deficient ovarian function, estrogen treatment will induce significant and gratifying breast growth. Breast size can be increased in current users of oral contraceptives, but there is no lasting effect associated with past use. ¹⁴

Accessory nipples can be found anywhere from the groin to the neck, remnants of the mammary line that extends early in embryonic life (6th week) along the ventral, lateral body wall. They occur in approximately 1% of women and require no therapy.

Pregnancy and Lactation

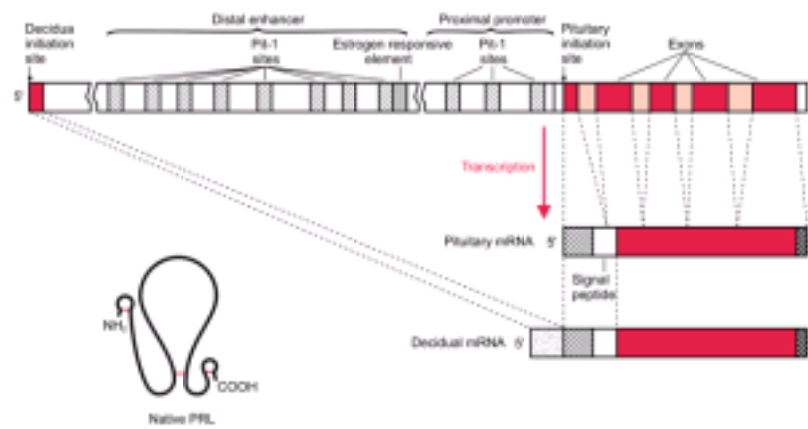

Prolactin Secretion

In most mammalian species, prolactin is a single chain polypeptide of 199 amino acids, 40% similar in structure to growth hormone and placental lactogen. All three hormones are believed to have originated from a common ancestral protein about 400 million years ago.

Prolactin is encoded by a single gene on the short arm of chromosome 6, producing a molecule that in its major form is maintained in 3 loops by disulfide bonds. Simultaneous measurements of prolactin by both bioassay and immunoassay reveal discrepancies. Chemical studies have revealed structural modifications that include glycosylation, phosphorylation, and variations in binding and charge. This heterogeneity is the result of many influences at many levels: transcription, translation, post translational modification, and peripheral metabolism. ^{15,16} Other variations exist. Enzymatic cleavage of the prolactin molecule yields fragments that may be capable of biologic activity. Prolactin that has been glycosylated continues to exert activity; differences in the carbohydrate moieties can produce differences in biologic activity and immunoreactivity. However, the non-glycosylated form of prolactin is the predominant form of prolactin secreted into the circulation. ¹⁷ Modification of prolactin also includes phosphorylation, deamidation, and sulfation. Little prolactin probably results from the proteolytic deletion of amino acids. Big prolactin can result from the failure to remove introns; it has little biologic activity and does not cross react with antibodies to the major form of prolactin. The so-called big big variants of prolactin are due to separate molecules of prolactin binding to each other, either noncovalently or by interchain disulfide bonding. Some of the apparently larger forms of prolactin are prolactin molecules complexed to binding proteins.

At any one point of time, the bioactivity (e.g., galactorrhea) and the immunoreactivity (circulating levels by immunoassay) of prolactin represent the cumulative effect of the family of structural variants. Remember, immunoassays do not always reflect the biologic situation (e.g., a normal prolactin level in a woman with galactorrhea). Nevertheless, the routine radioimmunoassay of prolactin is generally clinically reliable, especially at extremely high levels associated with prolactin-secreting pituitary tumors.

The anterior pituitary cells that produce prolactin, growth hormone, and thyroid-stimulating hormone (lactotrophs, somatotrophs, and thyrotrophs) require the presence of Pit-1, a transcription factor, for development. Pit-1 also binds to the prolactin gene in multiple sites in both the promoter region and in an adjacent region, designated as a distal enhancer; Pit-1 binding is a requirement for prolactin promoter activity and gene transcription. Many hormones, neurotransmitters, and growth factors influence the prolactin gene, involved in a level of function beyond that allowed by Pit-1. Fundamental modulation of prolactin secretion is exerted by estrogen, producing both differentiation of lactotrophs and direct stimulation of prolactin production. ^{18,19} An estrogen response element is adjacent to one of the Pit-1 binding sites in the distal enhancer region, and estrogen stimulation of the prolactin gene involves interaction with this Pit-1 binding site. Estrogen also influences prolactin production by suppressing dopamine secretion. ²⁰

Prolactin is involved in many biochemical events during pregnancy. Surfactant synthesis in the fetal lung is influenced by prolactin, and decidual prolactin modulates prostaglandin-mediated uterine muscle contractility.^{21, 22} Prolactin also contributes to the prevention of the immunologic rejection of the conceptus by suppressing the maternal immune response. Prolactin is both produced and processed in breast cells. The mechanisms and purpose for mammary production of prolactin remain to be determined, but prolactin in milk is believed to be derived from local synthesis. Transmission of this prolactin to the newborn may be important for immune functions.

Prolactin Inhibiting Factor

The hypothalamus maintains suppression of pituitary prolactin secretion by delivering a prolactin inhibiting factor (PIF) to the pituitary via the portal circulation. Suckling suppresses the formation of this hypothalamic substance, which is believed to be dopamine (as discussed in [Chapter 5](#)).²³ Dopamine is secreted by the basal hypothalamus into the portal system and conducted to the anterior pituitary. Dopamine binds specifically to lactotroph cells and suppresses the secretion of prolactin into the general circulation; in its absence, prolactin is secreted. Dopamine binds to a G protein-coupled receptor ([Chapter 2](#)) that exists in a long form and a short form, but only the D₂ (long form) is present on lactotrophs. The molecular mechanism for dopamine's inhibitory action is still not known. There are several other PIFs, but a specific role has been established only for dopamine.

Prolactin Releasing Factor

Prolactin secretion may also be influenced by a positive hypothalamic factor, prolactin-releasing factor (PRF). PRF does exist in various fowl (e.g., pigeon, chicken, duck, turkey, and the tricolored blackbird). While the identity of this material has not been elucidated, or its function substantiated in normal human physiology, it is possible that thyrotropin-releasing hormone (TRH) is a potent stimulant of prolactin secretion in humans. The smallest doses of TRH which are capable of producing an increase in TSH also increase prolactin levels, a finding which supports a physiologic role for TRH in the control of prolactin secretion, at least in response to suckling.²⁴ TRH stimulation of prolactin release involves calcium mechanisms (both internal release and influx via calcium channels) in response to the TRH receptor, also a member of the G protein family. However, except in hypothyroidism, normal physiologic changes as well as abnormal prolactin secretion are easily explained and understood in terms of variations in the prolactin inhibiting factor, dopamine. A large collection of peptides has been reported to stimulate the release of prolactin in vitro. These include growth factors, angiotensin II, GnRH, vasopressin, and others. But it is unknown whether these peptides participate in the normal physiologic regulation of prolactin secretion.

The Prolactin Receptor

The prolactin receptor is encoded by a gene on chromosome 5p13–14 that is near the gene for the growth hormone receptor. The prolactin receptor belongs to a receptor family that includes many cytokines and some growth factors, supporting a dual role for prolactin as a classic hormone and as a cytokine.²⁵

Prolactin receptors exist in more than one form, all containing an extracellular region, a single transmembrane region, and a relatively long cytoplasmic domain. There is evidence for more than one receptor, depending upon the site of action (e.g., decidual and placenta).²⁶ The amino acid identity between prolactin and growth hormone receptors is approximately 30%, with certain regions having up to 70% homology.²⁷ Prolactin receptors are expressed in many tissues throughout the body. Because of the various forms and functions of prolactin, it is likely that multiple signal mechanisms are involved, and for that reason, no single second messenger for prolactin's intracellular action has been identified. A protein also exists that functions as a receptor/transporter, translocating prolactin from the blood into the cerebrospinal fluid, the amniotic fluid, and milk.

Amniotic Fluid Prolactin

Amniotic fluid concentrations of prolactin parallel maternal serum concentrations until the 10th week of pregnancy, rise markedly until the 20th week, and then decrease. Maternal prolactin does not pass to the fetus in significant amounts. Indeed, the source of amniotic fluid prolactin is neither the maternal pituitary nor the fetal pituitary. The failure of dopamine agonist treatment to suppress amniotic fluid prolactin levels, and studies with in vitro culture systems, indicate a primary decidual source with transfer via amnion receptors to the amniotic fluid, requiring the intactness of amnion, chorion, and adherent decidua. This decidual synthesis of prolactin is initiated by progesterone, but once decidualization is established, prolactin secretion continues in the absence of both progesterone and estradiol.²⁸ Various decidual factors regulate prolactin synthesis and release, including relaxin, insulin, and insulin-like growth factor-I (discussed in [Chapter 4](#)). Prolactin produced in extrapituitary sites involves an alternative exon upstream of the pituitary start site, generating a slightly larger RNA transcript compared with the pituitary product. However, the amino acid sequence and the chemical and biological properties of decidual prolactin are identical to those of pituitary prolactin. It is hypothesized that amniotic fluid prolactin plays a role in modulating electrolyte economy not unlike its ability to regulate sodium transport and water movement across the gills in fish (allowing the ocean-dwelling salmon and steelhead to return to freshwater streams for reproduction). Thus prolactin would protect the human fetus from dehydration by control of salt and water transport across the amnion. Prolactin reduces the permeability of the human amnion in the fetal to maternal direction by a receptor-mediated action on the epithelium lining the fetal surface.²⁹

Lactation

During pregnancy, prolactin levels rise from the normal level of 10–25 ng/mL to high concentrations, beginning about 8 weeks and reaching a peak of 200–400 ng/mL at term.^{30, 31} The increase in prolactin parallels the increase in estrogen beginning at 7–8 weeks gestation, and the mechanism for increasing prolactin secretion (discussed in [Chapter 5](#)) is believed to be estrogen suppression of the hypothalamic prolactin-inhibiting factor, dopamine, and direct stimulation of prolactin gene transcription in the pituitary.^{32, 33} There is marked variability in maternal prolactin levels in pregnancy, with pulsatile secretion and a diurnal variation similar to that found in nonpregnant subjects. The peak level occurs 4–5 hours after the onset of sleep.³⁴

Made by the placenta and actively secreted into the maternal circulation from the 6th week of pregnancy, human placental lactogen (HPL) rises progressively reaching a level of approximately 6000 ng/mL at term. HPL, though displaying less activity than prolactin, is produced in such large amounts that it may exert a lactogenic effect.

Although prolactin stimulates significant breast growth, and is available for lactation, only colostrum (composed of desquamated epithelial cells and transudate) is produced during gestation. Full lactation is inhibited by progesterone, which interferes with prolactin action at the alveolar cell prolactin receptor level. Both estrogen and progesterone are necessary for the expression of the lactogenic receptor, but progesterone antagonizes the positive action of prolactin on its own receptor while progesterone and pharmacologic amounts of androgens reduce prolactin binding.^{27, 35, 36} In the mouse, inhibition of milk protein production is due to progesterone suppression of prolactin receptor expression.³⁷ The effective use of high doses of estrogen to suppress postpartum lactation indicates that pharmacologic amounts of estrogen also block prolactin action.

Progesterone can directly suppress milk production. A nuclear peptide (a corepressor) has been identified that binds to specific sites in the promoter region of the casein gene, thus inhibiting transcription.³⁸ Progesterone stimulates the generation of this corepressor. After delivery, the loss of progesterone leads to a decrease in this inhibitory peptide.

The principal hormone involved in milk biosynthesis is prolactin. Without prolactin, synthesis of the primary protein, casein, will not occur, and true milk secretion will be impossible. The hormonal trigger for initiation of milk production within the alveolar cell and its secretion into the lumen of the gland is the rapid disappearance of estrogen and progesterone from the circulation after delivery. The clearance of prolactin is much slower, requiring 7 days to reach non-pregnant levels in a non-breastfeeding woman. These discordant hormonal events result in removal of the estrogen and progesterone inhibition of prolactin action on the breast. Breast engorgement and milk secretion begin 3–4 days postpartum when steroids have been sufficiently cleared. Maintenance of steroidal inhibition or rapid reduction of prolactin secretion (with a dopamine agonist) are effective in preventing postpartum milk synthesis and secretion. Augmentation of prolactin (by TRH or sulpiride, a dopamine receptor blocker) results in increased milk yield.

In the first postpartum week, prolactin levels in breastfeeding women decline approximately 50% (to about 100 ng/mL). Suckling elicits increases in prolactin, which are important in initiating milk production. Until 2–3 months postpartum, basal levels are approximately 40–50 ng/mL, and there are large (about 10–20-fold) increases after suckling. Throughout breastfeeding, baseline prolactin levels remain elevated, and suckling produces a two-fold increase that is essential for continuing milk production.^{39, 40} The pattern or values of prolactin levels does not predict the postpartum duration of amenorrhea or infertility.⁴¹ The failure to lactate within the first 7 days postpartum may be the first sign of Sheehan's syndrome (hypopituitarism following intrapartum infarction of the pituitary gland).

Maintenance of milk production at high levels is dependent on the joint action of both anterior and posterior pituitary factors. By mechanisms to be described in detail shortly, suckling causes the release of both prolactin and oxytocin as well as thyroid-stimulating hormone (TSH).^{42, 43} Prolactin sustains the secretion of casein, fatty acids, lactose, and the volume of secretion, while oxytocin contracts myoepithelial cells and empties the alveolar lumen, thus enhancing further milk secretion and alveolar refilling. The increase in TSH with suckling suggests that thyrotropin-releasing hormone (TRH) may play a role in the prolactin response to suckling. The optimal quantity and quality of milk are dependent upon the availability of thyroid, insulin and the insulin-like growth factors, cortisol, and the dietary intake of nutrients and fluids.

Secretion of calcium into the milk of lactating women approximately doubles the daily loss of calcium.⁴⁴ In women who breastfeed for 6 months or more, this is accompanied by significant bone loss even in the presence of a high calcium intake.⁴⁵ However, bone density rapidly returns to baseline levels in the 6 months after weaning.⁴⁶ The bone loss is due to increased bone resorption, probably secondary to the relatively low estrogen levels associated with lactation. It is possible that recovery is impaired in women with inadequate calcium intake; total calcium intake during lactation should be at least 1500 mg per day. Nevertheless, calcium supplementation has no effect on the calcium content of breast milk or on bone loss in lactating women who have normal diets.⁴⁷ Furthermore, studies indicate that any loss of calcium and bone associated with lactation is rapidly restored, and, therefore, there is no impact on the risk of postmenopausal osteoporosis.^{48, 49}

Antibodies are present in breast milk and contribute to the health of an infant. Human milk prevents infections in infants both by transmission of immunoglobulins and by modifying the bacterial flora of the infant's gastrointestinal tract. Viruses are transmitted in breast milk, and although the actual risks are unknown, women infected with cytomegalovirus, hepatitis B, or human immunodeficiency virus are advised not to breastfeed. Vitamin A, vitamin B₁₂, and folic acid are significantly reduced in the breast milk of women with poor dietary intake. As a general rule approximately 1% of any drug ingested by the mother appears in breast milk. In a study of Pima Indians, exclusive breastfeeding for at least 2 months was associated with a lower rate of adult onset noninsulin-dependent diabetes mellitus, partly because overfeeding and excess weight gain are more common with bottlefeeding.⁵⁰

Frequent emptying of the lumen is important for maintaining an adequate level of secretion. Indeed, after the 4th postpartum month, suckling appears to be the only stimulant required; however, environmental and emotional states also are important for continued alveolar activity. Vigorous aerobic exercise does not affect the volume or composition of breast milk, and therefore infant weight gain is normal.⁵¹

The ejection of milk from the breast does not occur as the result of a mechanically induced negative pressure produced by suckling. Tactile sensors concentrated in the areola activate, via thoracic sensory nerve roots 4, 5, and 6, an afferent sensory neural arc that stimulates the paraventricular and supraoptic nuclei of the hypothalamus to synthesize and transport oxytocin to the posterior pituitary. The efferent arc (oxytocin) is blood-borne to the breast alveolus-ductal systems to contract myoepithelial cells and empty the alveolar lumen. Milk contained in major ductal repositories is ejected from openings in the nipple. This rapid release of milk is called "letdown." This important role for oxytocin is evident in knockout mice lacking oxytocin who undergo normal parturition, but fail to nurse their offspring.⁵²

In many instances, the activation of oxytocin release leading to letdown does not require initiation by tactile stimuli. The central nervous system can be conditioned to respond to the presence of the infant, or to the sound of the infant's cry, by inducing activation of the efferent arc. These messages are the result of many stimulating and inhibiting neurotransmitters. Suckling, therefore, acts to refill the breast by activating both portions of the pituitary (anterior and posterior) causing the breast to produce new milk and to eject milk. The release of oxytocin is also important for uterine contractions that contribute to involution of the uterus.

The oxytocin effect is a release phenomenon acting on secreted and stored milk. Prolactin must be available in sufficient quantities for continued secretory replacement of ejected milk. This requires the transient increase in prolactin associated with suckling. The amount of milk produced correlates with the amount removed by suckling. The breast can store milk for a maximum of 48 hours before production diminishes.

Breastfeeding by Adopting Mothers

Adopting mothers occasionally request assistance in initiating lactation.⁵³ Successful breastfeeding can be achieved by approximately half of the women by ingestion of 25 mg chlorpromazine tid together with vigorous nipple stimulation every 1–3 hours. Milk production will not appear for several weeks. This preparation ideally should be practiced for several months.

Cessation of Lactation

Lactation can be terminated by discontinuing suckling. The primary effect of this cessation is loss of milk letdown via the neural evocation of oxytocin. With passage of a few days, the swollen alveoli depress milk formation probably via a local pressure effect (although milk itself may contain inhibitory factors). With resorption of fluid and solute, the swollen engorged breast diminishes in size in a few days. In addition to the loss of milk letdown the absence of suckling reactivates dopamine (PIF) production so that there is less prolactin stimulation of milk secretion. Routine use of a dopamine agonist for suppression of lactation is not recommended because of reports of hypertension, seizure, myocardial infarctions, and strokes associated with its postpartum use.

Contraceptive Effect of Lactation

A moderate contraceptive effect accompanies lactation and produces child-spacing, which is very important in the developing world as a means of limiting family size. The contraceptive effectiveness of lactation, i.e., the length of the interval between births, depends on the level of nutrition of the mother (if low, the longer the contraceptive interval), the intensity of suckling, and the extent to which supplemental food is added to the infant diet. If suckling intensity and/or frequency is diminished, contraceptive effect is reduced. Only amenorrheic women who exclusively breastfeed (full breastfeeding) at regular intervals, including nighttime, during the first 6 months have the contraceptive protection equivalent to that provided by oral contraception (98% efficacy); with menstruation or after 6 months, the chance of ovulation increases.^{54, 55} With full or nearly full breastfeeding, approximately 70% of women remain amenorrheic through 6 months and only 37% through one year; nevertheless with exclusive breastfeeding, the contraceptive efficacy at one year is high, at 92%.⁵⁵ Fully breastfeeding women commonly have some vaginal bleeding or spotting in the first 8 postpartum weeks, but this bleeding is not due to ovulation.⁵⁶

Supplemental feeding increases the chance of ovulation (and pregnancy) even in amenorrheic women.⁵⁷ Total protection is achieved by the exclusively breastfeeding woman for a duration of only 10 weeks.⁵⁶ Half of women studied who are not fully breastfeeding ovulate before the 6th week, the time of the traditional postpartum visit; a visit during the 3rd postpartum week is strongly recommended for contraceptive counseling.

Rule of 3's for Postpartum Initiation of Contraception

Full breastfeeding: **Begin in 3rd postpartum month.**
Partial or no breastfeeding: **Begin in 3rd postpartum week.**

In nonbreastfeeding women, gonadotropin levels remain low during the early puerperium and return to normal concentrations during the 3rd to 5th week when prolactin levels have returned to normal. In an assessment of this important physiologic event (in terms of the need for contraception), the mean delay before first ovulation was found to be approximately 45 days, while no woman ovulated before 25 days after delivery.⁵⁴ Of the 22 women, however, 11 ovulated before the 6th postpartum week, underscoring the need to move the traditional postpartum medical visit to the 3rd week after delivery. In women who do receive dopamine agonist treatment at or immediately after delivery, return of ovulation is slightly accelerated, and contraception is required a week earlier, in the 2nd week postpartum.^{58, 59}

The mechanism of the contraceptive effect is of interest because a similar interference with normal pituitary-gonadal function is seen with elevated prolactin levels in nonpregnant women, the syndrome of galactorrhea and amenorrhea. Prolactin concentrations are increased in response to the repeated suckling stimulus of breastfeeding. Given sufficient intensity and frequency, prolactin levels will remain elevated. Under these conditions, follicle-stimulating hormone (FSH) concentrations are in the normal range (having risen from extremely low concentrations at delivery to follicular range in the 3 weeks postpartum) and luteinizing hormone (LH) values are in the low normal range. Despite the presence of gonadotropin, the ovary, during lactational hyperprolactinemia, does not display follicular development and does not secrete estrogen.

Earlier experimental evidence suggested that the ovaries might be refractory to gonadotropin stimulation during lactation, and, in addition, the anterior pituitary might be less responsive to GnRH stimulation. Other studies, done later in the course of lactation, indicated, however, that the ovaries as well as the pituitary were responsive to adequate tropic hormone stimulation.⁶⁰

These observations suggest that high concentrations of prolactin can work at both central and ovarian sites to produce lactational amenorrhea and anovulation. Prolactin appears to affect granulosa cell function in vitro by inhibiting the synthesis of progesterone. It also may change the testosterone: dihydrotestosterone ratio, thereby reducing aromatizable substrate and increasing local antiestrogen concentrations. Nevertheless, a direct effect of prolactin on ovarian follicular development does not appear to be a major factor. The central action predominates.

Elevated levels of prolactin inhibit the pulsatile secretion of GnRH.^{61, 62} Prolactin excess has short loop positive feedback effects on dopamine. Increased dopamine reduces GnRH by suppressing arcuate nucleus function, perhaps in a mechanism mediated by endogenous opioid activity.^{63, 64} However, blockade of dopamine receptors with a dopamine antagonist or the administration of an opioid antagonist in breastfeeding women does not always affect gonadotropin secretion.⁶⁵ The exact mechanism for the suppression of GnRH secretion remains to be unraveled. The principle of GnRH suppression by prolactin is reinforced by the demonstration that treatment of amenorrheic, lactating women with pulsatile GnRH fully restores pituitary secretion and normal ovarian cyclic activity.⁶⁶

At weaning, as prolactin concentrations fall to normal, gonadotropin concentrations increase, and estradiol secretion rises. This prompt resumption of ovarian function is also indicated by the occurrence of ovulation within 14–30 days of weaning.

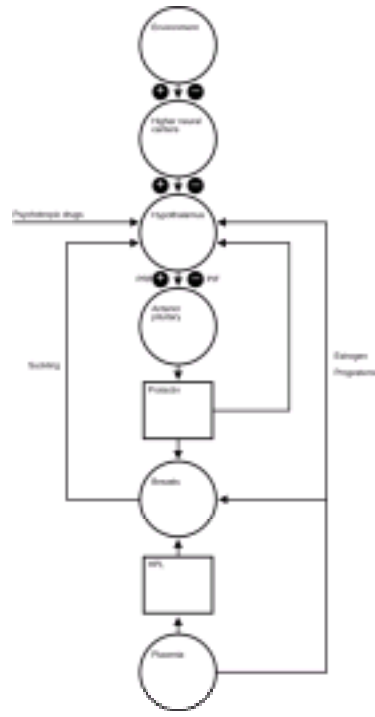

Inappropriate Lactation — Galactorrheic Syndromes

Galactorrhea refers to the mammary secretion of a milky fluid, which is non-physiologic in that it is inappropriate (not immediately related to pregnancy or the needs of a child), persistent, and sometimes excessive. Although usually white or clear, the color may be yellow or even green. In the latter circumstance, local breast disease should be considered. To elicit breast secretion, pressure should be applied to all sections of the breast beginning at the base of the breast and working up toward the nipple. ***Hormonally-induced secretions usually come from multiple duct openings in contrast to pathologic discharge that usually comes from a single duct.*** A bloody discharge is more typical of cancer. The quantity of secretion is not an important criterion. Any galactorrhea demands evaluation in a nulliparous woman and if at least 12 months have elapsed since the last pregnancy or weaning in a parous woman. Galactorrhea can involve both breasts or just one breast. Amenorrhea does not necessarily accompany galactorrhea, even in the most serious provocative disorders.

Differential Diagnosis of Galactorrhea

The differential diagnosis of galactorrhea is a difficult and complex clinical challenge. The difficulty arises from the multiple factors involved in the control of prolactin release. In most pathophysiologic states the final common pathway leading to galactorrhea is an inappropriate augmentation of prolactin release. The following considerations are important:

1. Increased prolactin release may be a consequence of prolactin elaboration and secretion from pituitary tumors which function independently of the otherwise appropriate restraints exerted by PIF from a normally functioning hypothalamus. This infrequent but potentially dangerous tumor, which has endocrine, neurologic, and ophthalmologic liabilities that can be disabling, makes the differential diagnosis of persistent galactorrhea a major clinical challenge. Beyond producing prolactin, the tumor may also suppress pituitary parenchyma by expansion and compression, interfering with the secretion of other tropic hormones. Other pituitary tumors may be associated with lactotroph hyperplasia and present with the characteristic syndrome of hyperprolactinemia and amenorrhea.
2. A variety of drugs can inhibit hypothalamic PIF.⁶⁷ There are nearly 100 phenothiazine derivatives with indirect mammotropic activity. In addition, there are many phenothiazine-like compounds, reserpine derivatives, amphetamines, and an unknown variety of other drugs (opiates, diazepam, butyrophenones, a-methyl dopa, and tricyclic antidepressants) that can initiate galactorrhea via hypothalamic suppression. The final action of these compounds is either to deplete dopamine levels or to block dopamine receptors. Chemical features common to many of these drugs are an aromatic ring with a polar substituent as in estrogen and at least two additional rings or structural attributes making spatial arrangements similar to estrogen. Thus, these compounds may act in a manner similar to estrogens to decrease PIF or to act directly on the pituitary. In support of this conclusion, it has been demonstrated that estrogen and phenothiazine derivatives compete for the same receptors in the median eminence. Prolactin is uniformly elevated in patients on therapeutic amounts of phenothiazines, but essentially never as high as 100 ng/mL. Approximately 30–50% will exhibit galactorrhea that should not persist beyond 3–6 months after drug treatment is discontinued.
3. Hypothyroidism (juvenile or adult) can be associated with galactorrhea. With diminished circulating levels of thyroid hormone, hypothalamic TRH is produced in excess and acts as a PRF to release prolactin from the pituitary. Reversal with thyroid hormone is strong circumstantial evidence to support the conclusion that TRH stimulates prolactin.
4. Excessive estrogen (e.g., oral contraceptives) can lead to milk secretion via hypothalamic suppression, causing reduction of PIF and release of pituitary prolactin, and direct stimulation of the pituitary lactotrophs. Galactorrhea developing during oral contraceptive administration may be most noticeable during the days free of medication (when the steroids are cleared from the body and the prolactin interfering action of the estrogen and progestin on the breast wanes). Galactorrhea caused by excessive estrogen disappears within 3–6 months after discontinuing medication. This is now a rare occurrence with the lower dose pills.⁶⁸ A longitudinal study of 126

women did demonstrate a 22% increase in prolactin values over mean control levels, but the response to low-dose oral contraceptives was not out of the normal range.⁶⁹

5. Prolonged intensive suckling can also release prolactin, via hypothalamic reduction of PIF. Similarly, thoracotomy scars, cervical spinal lesions, and herpes zoster can induce prolactin release by activating the afferent sensory neural arc, thereby simulating suckling.
6. Stresses can inhibit hypothalamic PIF, thereby inducing prolactin secretion and galactorrhea. Trauma, surgical procedures, and anesthesia can be seen in temporal relation to the onset of galactorrhea.
7. Hypothalamic lesions, stalk lesions, or stalk compression (events that physically reduce production or delivery of PIF to the pituitary) allow release of excess prolactin leading to galactorrhea.
8. Increased prolactin concentrations can result from non-pituitary sources such as lung and renal tumors and even a uterine leiomyoma. Severe renal disease requiring hemodialysis is associated with elevated prolactin levels due to the decreased glomerular filtration rate.

The Clinical Problem of Galactorrhea

A variety of eponymic designations have been applied to variants of the lactation syndromes. These were based on the association of galactorrhea with intrasellar tumor (Forbes, Henneman, Griswold, and Albright, 1951), antecedent pregnancy with inappropriate persistence of galactorrhea (Chiari and Frommel, 1852), and in the absence of previous pregnancy (Argonz and del Castillo, 1953). In all, the association of galactorrhea with eventual amenorrhea was noted.

On the basis of currently available information, categorization of individual cases according to these eponymic guidelines is neither helpful nor does it permit discrimination of patients who have serious intrasellar or suprasellar pathology.

Hyperprolactinemia may be associated with a variety of menstrual cycle disturbances: oligoovulation, corpus luteum insufficiency, as well as amenorrhea. About one-third of women with secondary amenorrhea will have elevated prolactin concentrations. Pathologic hyperprolactinemia inhibits the pulsatile secretion of GnRH, and the reduction of circulating prolactin levels restores menstrual function.

Mild hirsutism may accompany ovulatory dysfunction caused by hyperprolactinemia. Whether excess androgen is stimulated by a direct prolactin effect on adrenal cortex synthesis of DHA (dehydroepiandrosterone) and its sulfate (DHAS) or is primarily related to the chronic anovulation of these patients (and hence ovarian androgen secretion) is not settled.

Not all patients with hyperprolactinemia display galactorrhea. The reported incidence is about 33% (Chapter 11). The disparity may not be due entirely to the variable zeal with which the presence of nipple milk secretion is sought during physical examination. The absence of galactorrhea may be due to the usually accompanying hypoestrogenic state. A more attractive explanation focuses on the concept of heterogeneity of tropic hormones (Chapter 2). The immunoassay for prolactin may not discriminate among heterogeneous molecules of prolactin. A high circulating level of prolactin may not represent material capable of interacting with breast prolactin receptors. On the other hand, galactorrhea can be seen in women with normal prolactin serum concentrations. Episodic fluctuations and sleep increments may account for this clinical discordance, or, in this case, bioactive prolactin may be present that is immunoreactively not detectable. Remember that at any one point in time, the bioactivity (galactorrhea) and the

immunoreactivity (immunoassay result) of prolactin represent the cumulative effect of the family of structural and molecular prolactin variants present in the circulation.

In the pathophysiology of male hypogonadism, hyperprolactinemia is much less common, and the incidence of actual galactorrhea quite rare. Hyperprolactinemia in men usually presents with decreased libido and potency.

If galactorrhea has been present for 6 months to 1 year, or hyperprolactinemia is noted in the process of working up menstrual disturbances, infertility, or hirsutism, the probability of a pituitary tumor must be recognized. The workup of hyperprolactinemia is presented in detail in Chapter 11, "Amenorrhea." It is worth reemphasizing the salient clinical issues here.

With the current diagnostic techniques there is no difficulty in discovering and monitoring the size and function of a pituitary prolactin-secreting tumor. With few exceptions the combination of elevation in basal levels of prolactin and radiographic imaging offers complete confidence in diagnosing sellar pathology. The major concern remains in determining management—medical, surgical, or expectant? The considerations that influence management include:

1. Microadenomas, if exclusively prolactin-producing, rarely progress to macroadenoma size. Most are exceedingly slow-growing or stable.
2. Some tumors regress spontaneously. Medical therapy with dopamine agonists shrinks tumors and can prevent growth, although complete elimination of a tumor

- by dopamine agonist treatment does not occur, and rapid regrowth usually follows discontinuation of the drug.
- Transsphenoidal microsurgery is a very safe procedure, but there is a high recurrence rate.
 - The presence of a prolactin-secreting adenoma does not represent a contraindication to pregnancy or the use of exogenous hormones such as oral contraceptives.

As a result of these considerations, many patients can be observed, others treated medically, and, rarely, some treated with surgery, with or without prior medically-induced tumor reduction (see [Chapter 11](#)).

Treatment of Galactorrhea

Galactorrhea as an isolated symptom of hypothalamic dysfunction existing in an otherwise healthy woman does not require treatment. Periodic prolactin levels will, if within normal range, confirm the stability of the underlying process. However, some patients find the presence or amount of galactorrhea sexually, cosmetically, and emotionally burdensome. Treatment with combined oral contraceptives, androgens, danazol, and progestins has met with minimal success. Dopamine agonist treatment, therefore, is the therapy of choice. Even with normal prolactin concentrations and normal imaging, treatment with a dopamine agonist can eliminate galactorrhea.

We have adopted a conservative approach of close surveillance for pituitary prolactin-secreting adenomas, recommending surgery only for those tumors that display rapid growth or those tumors that are already large and do not shrink in response to dopamine agonists. If the prolactin level is greater than 100 ng/mL, or if the coned-down view of the sella turcica is abnormal, we recommend magnetic resonance imaging (MRI) evaluation. If the MRI rules out an empty sella syndrome or a suprasellar problem, surgical intervention after preoperative dopamine agonist treatment is then dictated by the patient's desires, the size of the tumor, and the response of the tumor to a dopamine agonist. In patients with prolactin levels less than 100 ng/mL and with normal coned-down views of the sella turcica, an annual prolactin level and periodic coned-down views are indicated for continued observation to detect a growing tumor. Dopamine agonist therapy is recommended for patients wishing to achieve pregnancy, and for those patients who have galactorrhea to the point of discomfort.

The Management of Mastalgia

The cyclic premenstrual occurrence of breast discomfort is a common problem and is occasionally associated with dysplastic, benign histologic changes in the breast. Neither a specific etiology (although the response is probably secondary to the hormonal stimulation of the luteal phase) nor an adverse consequence (such as an increased risk of breast cancer) has been established.⁷⁰ Approximately 70% of women report premenstrual breast discomfort in surveys, and interference with activities is recorded in 10–30%.⁷⁰

Medical treatment of mastalgia has historically included a bewildering array of options. Several are of questionable value. Diuretics have little impact, and thyroid hormone treatment is indicated only when hypothyroidism is documented. Steroid hormone treatment has been tried in many combinations, mostly unsupported by controlled studies. An old favorite, with many years of clinical experience testifying to its effectiveness, is testosterone. One must be careful, however, to avoid virilizing doses. A good practice is to start with 5 mg methyltestosterone every other day during the time of discomfort. In recent years, however, these methods have been supplanted by several new approaches.

Danazol in a dose of 100–200 mg/day is effective in relieving discomfort as well as decreasing nodularity of the breast.^{71,72} A daily dose is recommended for a period of 6 months. This treatment may achieve long-term resolution of histologic changes in addition to the clinical improvement. Doses below 400 mg daily do not assure inhibition of ovulation, and a method of effective contraception is necessary because of possible teratogenic effects of the drug. Significant improvement has been noted with vitamin E, 600 units/day of the synthetic tocopherol acetate. No side effects have been noted, and the mechanism of action is unknown. Bromocriptine (2.5 mg/day, which can be administered vaginally if side effects are a problem) and antiestrogens such as tamoxifen (10 or 20 mg daily) are also effective for treating mammary discomfort and benign disease.^{72,73 and 74}

Clinical observations had suggested that abstinence from methylxanthines leads to resolution of symptoms. Methylxanthines (caffeine, theophylline, and theobromine) are present in coffee, tea, chocolate, and cola drinks. In controlled studies, however, a significant placebo response rate (30–40%) has been observed. Careful assessments of this relationship have failed to demonstrate a link between methylxanthine use and mastalgia, mammographic changes, or atypia (pre-malignant tissue changes).^{75,76}

Cancer of the Breast

Scope of the Problem

Currently, female American newborns have a lifetime probability of developing breast cancer of 12.5%, about 1 in 8, double the risk in 1940.⁷⁷ The incidence increased over the past 4 decades but plateaued in 1987 (about 180,000 new cases of invasive breast cancer per year). Mortality rates remained disappointingly constant (44,000 deaths per year) until a decline began in 1990. The 5-year survival rate for localized breast cancer (about 60% of breast cancers) has risen from 72% in the 1940s to 97%.⁷⁷ This is attributed to earlier diagnosis because of the greater utilization of screening mammography and increased use of chemotherapy, and a continuing decline in mortality should be observed. With regional spread, the 5-year survival rate for breast cancer is 76%; with distant metastases, the rate is 21%. The overall survival rates (all stages combined) are approximately 84% at 5 years after diagnosis, 67% after 10 years, and 56% after 15 years.⁷⁷

The incidence of breast cancer steadily increased until 1990 throughout the world since breast cancer registration began in the 1930s. The increase was almost entirely due to an increasing incidence in women over age 50. This long-term steady increase was present long before the beginning of widespread mammography screening in the 1980s. From 1982 through 1987, there occurred a more rapid increase in the incidence of breast cancer due to the detection by screening mammography of early stage, small tumors; the incidence of larger tumors and metastatic tumors actually decreased slightly.⁷⁷ For these reasons, the long-term increase (about 1% per year) cannot be attributed solely to the widespread availability of screening mammography. Because the incidence since 1990 has plateaued, the long-term increase over the past decades is attributed to lifestyle and reproductive changes (diet and exercise; reduced parity and delayed child-bearing).

The breast is the leading site of cancer in U.S. women (29.7% of all cancers) and is now, unfortunately, (because smoking is obviously the reason) exceeded by lung cancer as the leading cause of death from cancer in women.⁷⁷

Breast cancer has an increasing frequency with age. Nearly 77% of all breast cancers occur in women over age 50; only 6.5% of all cases occur under age 40, 15% under age 50. A woman at age 70 has almost 16 times the risk as a 40-year-old woman. However, after menopause, although the incidence rate continues to increase, it is less dramatic than the rise before menopause. Over the age of 50, American white women are more likely to develop breast cancer than black American women; under the age of 50, the opposite is true.⁷⁷ The 5-year survival rate for women who develop breast cancer under age 45 is 79% compared to 87% for women ages 65 and older.

The Chances of Developing Breast Cancer According to Age⁷⁸

By age 25	1 in 19,608
By age 30	1 in 2,525
By age 35	1 in 622
By age 40	1 in 217
By age 45	1 in 93
By age 50	1 in 50
By age 55	1 in 33
By age 60	1 in 24
By age 65	1 in 17
By age 70	1 in 14
By age 75	1 in 11
By age 80	1 in 10
By age 85	1 in 9
Lifetime	1 in 8

Over the years, breast cancer has continued its deadly impact despite advances in surgical and diagnostic techniques. Classically, the single most useful prognostic information in women with operable breast cancer has been the histologic status of the axillary lymph nodes.^{79, 80} The survival rate is higher with axillary lymph nodes negative for disease compared with positive nodes. Because of this recognition for the importance of the axillary nodes, the traditional surgical approach to breast cancer was based on the concept that breast cancer is a disease of stepwise progression. **There has been an important change in concept. Breast cancer is now viewed as a systemic disease, with spread to local and distant sites at the same time. Breast cancer is best viewed as occultly metastatic at the time of presentation.** Therefore, dissemination of tumor cells has occurred by the time of surgery in many patients. However, this is not the story for all patients. Surely, some (if not many) cancers prior to invasion (and perhaps even some small invasive cancers) are not systemic at the time of diagnosis. For this reason, surgery is curative for many early cases of breast cancer.

Because we have been dealing with a disease that has already reached the point of dissemination in many patients, we must move the diagnosis forward several years in order to have an impact on breast cancer mortality. Earlier diagnosis requires that we be aware of what it is that makes a high-risk patient. **However, keep in mind that the great majority of women (85%) who develop breast cancer do not have an identifiable risk factor other than age, and, therefore, every woman must be considered at risk.**

Risk Factors

A constellation of factors influences the risk for breast cancer. These include reproductive experience, ovarian activity, benign breast disease, familial tendency, genetic differences, dietary considerations, and specific endocrine factors.

Reproductive Experience

The risk of breast cancer increases with the increase in age at which a woman bears her first full-term child. A woman pregnant before the age of 18 has about one-third the risk of one who first delivers after the age of 35. To be protective, pregnancy must occur before the age of 30. In fact, women over the age of 30 years at the time of their first birth have a greater risk than women who never become pregnant.⁸¹ Indeed, there is reason to believe that the age at the time of birth of the last child is the most important influence (an increasing risk with increasing age).⁸² There is, however, a significant protective effect with increasing parity, present even when adjusted for age at first birth and other risk factors.^{83, 84} Delayed childbearing and fewer children in modern times are believed to have contributed significantly to the increased incidence of breast cancer observed over the last decades.

Data from the Nurses' Health Study indicate that a positive family history for breast cancer overwhelms the protective effect of pregnancy, and women with a mother or sister history of breast cancer actually had an increase in risk enhanced by first pregnancy.⁸⁵

Although pregnancy at an early age produces an overall lifetime reduction in risk, there is evidence that the first few years after delivery are associated with a transient increase in risk.⁸⁶ This increase may reflect accelerated growth of an already present malignancy by the hormones of pregnancy. A very large case-control study concluded that pregnancy transiently increases the risk (perhaps for up to 3 years) after a woman's first childbirth, and this is followed by a lifetime reduction in risk.⁸⁷ And some have found that a concurrent or recent pregnancy (3–4 years previously) adversely affects survival (even after adjustment for size of tumor and number of nodes).^{88, 89} It is argued that breast cells which have already begun malignant transformation are adversely affected by the hormones of pregnancy, while normal stem cells become more resistant.

Conflicting results have been reported in over 20 studies examining the risk of breast cancer associated with the number of abortions (especially induced abortions) experienced by individual patients.^{90, 91} Concern for an adverse effect has been based on the theoretical suggestion that a full-term pregnancy protects against breast cancer by invoking complete differentiation of breast cells, but abortion increases the risk by allowing breast cell proliferation in the first trimester of pregnancy, but not allowing the full differentiation that occurs in later pregnancy. In these studies there has been a major problem of recall bias; women who develop breast cancer are more likely to truthfully reveal their history of induced abortion than healthy women. In studies that avoided recall bias (e.g., by deriving data from national registries instead of personal interviews), the risk of breast cancer was identical in women with and without induced abortions.^{92, 93}

The fact that pregnancy early in life is associated with a reduction in the risk of breast cancer implies that etiologic factors are operating during that period of life. The protection afforded only by the first pregnancy suggests that the first full-term pregnancy has a trigger effect which either produces a permanent change in the factors responsible for breast cancer, or changes the breast tissue and makes it less susceptible to malignant transformation. There is evidence for a lasting impact of a first pregnancy on a woman's hormonal milieu. A small but significant elevation of estriol, a decrease in dehydroepiandrosterone and dehydroepiandrosterone sulfate, and lower prolactin levels all persist for many years after delivery.^{94, 95} These changes take on significance when viewed in terms of the endocrine factors considered below.

Lactation may offer a weak to moderate protective effect (20% reduced risk) only for premenopausal breast cancer.^{96, 97, 98 and 99} There is a unique and helpful study of the Chinese Tanka, who are boat people living on the coast of southern China.¹⁰⁰ The women of the Chinese Tanka wear clothing with an opening only on the right side, and they breastfeed only with the right breast. All breast cancers were in postmenopausal women, and the cancers were equally distributed between the two sides, suggesting a protective effect only for premenopausal breast cancer. The Nurses' Health Study could not detect a protective effect of lactation, and a Norwegian prospective study, including a high percentage of women with long durations of breastfeeding, found no benefit on either premenopausal or postmenopausal breast cancer incidence.^{101, 102} The impact of lactation, if significant, must be small.

In both cohort and case-control studies, there is good evidence that cosmetic breast augmentation does not increase the risk of breast cancer.^{103, 104 and 105} Specifically, studies have failed to indicate an increased risk of breast cancer in women who have had cosmetic breast implants.^{106, 107}

Ovarian Activity

Women who have a premenopausal oophorectomy have a lower risk of breast cancer, and the lowered risk is greater the younger a woman is when ovariectomized. There is a 70% risk reduction in women who have oophorectomy before age 35. There is a small decrease in risk with late menarche and a moderate increase in risk with late natural menopause, indicating that ovarian activity plays a continuing role throughout reproductive life.¹⁰⁸

Benign Breast Disease

Women with prior benign breast disease form only a small proportion of breast cancer patients, approximately 5%. With obstruction of ducts (probably by stromal fibrosis), ductule-alveolar secretion persists, the secretory material is retained, and cysts form from the dilatation of terminal ducts (duct ectasia) and alveoli. There is good reason to eliminate the phrase "fibrocystic disease of the breast." In a review of over 10,000 breast biopsies in Nashville, Tennessee, 70% of the women were found to not have a lesion associated with an increased risk for cancer.¹⁰⁹ The most important variable on biopsies is the degree and character of the epithelial proliferation. Women with atypical hyperplasia had a relative risk of 5.3, while women with atypia and a family history of breast cancer had a relative risk of 11. In the Nurses' Health Study, biopsies with proliferative disease had a relative risk of breast cancer of 1.6, and with atypical hyperplasia, the relative risk was 3.7.¹¹⁰ Only 4–10% of benign biopsies have atypical hyperplasia. The point is that we needlessly frighten patients with the use of the phrase fibrocystic disease. For most women, this is not a disease, but a physiologic change brought about by cyclic hormonal activity. **Let's call this problem FIBROCYSTIC CHANGE OR CONDITION.**

The College of American Pathologists supports this position and has offered this classification.¹¹¹

Classification of Breast Biopsy Tissue According to Risk for Breast Cancer

No increased risk:

- Adenosis
- Duct ectasia
- Fibroadenoma
- Fibrosis
- Mild hyperplasia (3–4 cells deep)
- Mastitis
- Periductal mastitis
- Squamous metaplasia

Slightly increased risk (1.5–2.0 times):

- Moderate or florid hyperplasia
- Papilloma

Risk increased 3–5 times:

- Atypical hyperplasia

Familial Tendency

Most breast cancers are sporadic; i.e., they arise in individuals without a family history of breast cancer. However, female relatives of women with breast cancer have about twice the rate of the general population. There is an excess of bilateral disease among patients with a family history of breast cancer. Relatives of women with bilateral disease have about a 45% lifetime chance of developing breast cancer. In data from the Centers for Disease Control and Prevention (CDC), these relative risks were observed:¹¹²

Affected mother or sister:	2.3 relative risk.
Affected aunt or grandmother:	1.5 relative risk.
Affected mother and sister:	14.0 relative risk

Results from the Nurses' Health Study indicate that the magnitude of risk associations with a positive family history is smaller than previously believed, comparable to the CDC data above, except for a relative risk of only 2.3 when both mother and sister (first-degree relatives) had breast cancer.¹¹³ In general, the size of the increased risk with a positive family history is approximately 2 times the normal incidence. In the Nurses' Health Study, there was no interaction between family history

and alcohol intake; however, a positive mother or sister history of breast cancer eliminated the protective effects of late menarche, multiple births, and early births. ⁸⁵

Using the data from the Cancer and Steroid Hormone Study, the CDC has provided tables which can be used for the purpose of counseling women with a family history of breast cancer.¹¹⁴ These tables estimate the risks according to the various combinations of affected first- and second-degree relatives and the ages at onset of breast cancer for the affected relatives. The risk is higher with early age of onset and more than one relative with breast cancer. For example, the predicted lifetime risk for a woman with two first-degree relatives (sisters and mother) who developed breast cancer before age 40 is approximately 44%, and with one first-degree relative with breast cancer between ages 30 and 39 years, 17%.

The breast and ovarian cancer gene (*BRCA1*) associated with familial cancer is on the long arm of chromosome 17, localized to 17q12—q21. Although other genetic alterations have been observed in breast tumors, mutations in *BRCA1* are believed to be responsible for approximately 45% of familial breast cancer and 80% of families with both early onset breast and ovarian cancer. Inheritance of this gene can be either maternal or paternal; male carriers are at increased risk for colon and prostate cancers.¹¹⁵ A second locus, *BRCA2*, on chromosome 13q12—q13, accounts for up to 35% of families with early onset breast cancer (but a lower rate of ovarian cancer), and in males, for prostate cancer, pancreatic cancer, and male breast cancer. ^{116, 117} Together, *BRCA1* and *BRCA2* account for 80% of families with multiple cases of early-onset breast cancer. ¹¹⁸ About 5–10% of women who develop ovarian cancer have mutations in *BRCA1*.^{119, 120}

BRCA1 encodes an 1863 amino acid protein with a zinc finger domain that is probably a tumor suppressor important in DNA transcription. Mutations in many different regions of the *BRCA1* gene cause a loss or reduction in its function. ^{121, 122} Because not every individual with a mutation in this gene develops cancer, other factors are probably involved, making the accuracy of prediction more difficult and arguing against widespread screening for mutations of this gene. Providing accurate numbers is a difficult task, because breast cancer has a multifactorial etiology with both genetic and environmental factors. The *BRCA1* gene may also play a role in sporadic breast and ovarian cancer, but analysis of tumors has failed to find mutations in sporadic cancers that occur later in life. ¹²³

High-risk families have a high probability of harboring a mutation in a dominant breast cancer susceptibility gene, transmitted by either parent, and accounting for approximately 5% of breast cancer in the general population. It is estimated that approximately 0.04% to 0.2% of women in the U.S. carry the *BRCA1* susceptibility (and *BRCA2* is less common).¹²⁴ Among women of Ashkenazi Jewish descent, the prevalence of *BRCA1* and *BRCA2* mutations is about 2%.¹²⁵ The percentage of breast cancer cases in the general population associated with a family history accounts for only a minor part of the overall prevalence. The best estimates initially ranged from 6% to 19% at most.¹²⁶ Later more representative studies revealed a lower prevalence, as low as 3% in the general population. ^{127, 128} In addition, there appears to be great variability in different parts of the world, and the prevalence in minority populations has not been adequately measured.
