The presence of ovarian cancer within a family and 3 or more cases of breast cancer within a family are strong predictors of *BRCA1* mutations. Thus, genetic screening should be reserved for patients with high-risk families.

Family History Characteristics Associated With the Presence of *BRCA1*

- Early age of onset of breast cancer within a family.
- Relatives with ovarian cancer.
- 3 or more relatives with breast cancer.
- Ashkenazi ancestry.

Moderate risk families are characterized by a less striking family history, the absence of ovarian cancer, and an age of onset at the time of diagnosis that is older. High risk families have the presence of multiple cases of breast cancer in close relatives (usually at least 3 cases) that follows an autosomal dominant pattern of inheritance; breast cancer is usually diagnosed before age 45; there may be cases of ovarian cancer in the family as well. Many of the cases, but not all, can be attributed to the susceptibility genes, *BRCA1* and *BRCA2*.

High risk families have the following cumulative breast cancer risk by the age of 80 as determined by the analysis of family histories. ¹²⁶

Affected Relative	Age of Affected Relative	Cumulative Breast Cancer Risk by Age 80
One first-degree relative	< 50 years old	13–21%
	50 or more years old	9–11%
One second-degree relative	< 50 years old	10–14%
	50 or more years old	8–9%
Two first-degree relatives	Both < 50 years old	35–48%
	Both 50 years or older	11–24%
Two second-degree relatives but both parental or maternal	Both < 50 years old	21–26%
	Both 50 years or older	9–16%

BRCA1 and *BRCA2* direct DNA screening is now possible. Each child of a carrier has a 50% chance of inheriting the mutation. Although it is recognized that this may be an over estimation, the studies indicate that women who are carrying the *BRCA1* mutation have an 87% cumulative life-time risk of developing breast cancer—about 20% by age 40, 51% by age 50, and 85% by age 70, and a 20–65% risk for ovarian cancer (closer to 20% in more recent studies of less highly selected groups). In addition, the male relatives who are carrying this mutation have approximately a 3-fold increased risk of prostate cancer and 4-fold increased risk of colon cancer. The breast cancer risk is similar for women with *BRCA2* mutations. Breast cancer associated with *BRCA1* mutations is histologically different (more often aneuploid and receptor negative) compared to *BRCA2* mutations and sporadic cancers, and appears to grow faster, but paradoxically, may have a better survival. ¹²⁹ Outcome results, however, have not been consistent. A well-done Dutch study could not detect a difference in disease-free and overall survival comparing breast cancer cases from families with proven *BRCA1* mutations to patients with sporadic breast cancer. ¹³⁰

Because not all families with breast cancer carry mutations of *BRCA1* or *BRCA2*, these families probably have breast cancer susceptibility genes yet to be identified. In addition, the current screening methods do not detect all *BRCA* mutations. **When 3 or more closely related individuals within a family have been diagnosed with breast cancer, the likelihood that an inherited dominant genetic mutation is present is very high.** The affected women need not be first-degree relatives, but they must be related either all on the mother's side or the father's side. **The family presence of just one case of ovarian cancer further increases the likelihood of the *BRCA1* mutation.** Identifying the families that carry the *BRCA2* gene uses the same historical criteria as that for the *BRCA1* gene. In contrast to *BRCA1* families, *BRCA2* families have only a moderately increased incidence of ovarian cancer.

P>Identification and counseling for families who have the appropriate history but fail to demonstrate *BRCA1* or *BRCA2* mutations should be exactly the same as when the mutations are found.

Once it has been determined that a family is at high risk for a breast cancer gene mutation, it is recommended that this family be referred to an appropriate laboratory and service that can be identified through the medical genetics department at a regional referral institution. Although blood samples can be mailed by over-night mail, involvement with an appropriate center is highly urged because of the importance of accurate informed consent, counseling, and follow-up care. The way in which information is communicated to patients has a profound impact on decision-making and compliance with surveillance.

A problem exists when it comes to deciding what to do. While we have good data indicating prevalence and risk in these high-risk families, we do not have studies telling us what the risk reduction is from prophylactic surgery, nor do we know the efficacy of increasing surveillance programs for these identified individuals. Because the mutation is present in every cell, and prophylactic mastectomy does not remove all tissue, there is no guarantee that breast cancer will be totally prevented. The same situation applies with prophylactic oophorectomy in that a carcinoma can arise from peritoneal cells. However, prophylactic removal of the bulk of the tissue at risk should be effective. ¹³¹ The first follow-up study of high risk women who have undergone prophylactic mastectomy indicated a major reduction in the number of breast cancers in the mastectomy group, although total prevention was not achieved. ¹³²

Current recommendations from experts in this field are as follows. ^{126, 133} For an individual identified to be at high risk, clinical breast examination and mammography

are recommended every 6–12 months beginning between ages 25 and 35. Evaluation every 6 months is appropriate because the *BRCA1*-related tumors have been demonstrated to be faster growing tumors. Although the evidence for the precise degree of protection offered by prophylactic mastectomy is not available, support should be provided for those women who choose this option. Pelvic examination, serum CA-125 levels, and transvaginal ultrasonography with color Doppler are recommended every 6–12 months for women under age 40. Prophylactic oophorectomy is recommended at the completion of child-bearing, preferably before age 35. It is of benefit to take oral contraceptives to reduce the ovarian cancer risk. A case-control study indicated that the use of oral contraceptives in women with *BRCA1* or *BRCA2* mutations was associated with a 50% reduction in the risk of ovarian cancer (increasing with duration of use, from 20% for less than 3 years of use, up to 60% with 6 or more years of use).¹³⁴ The magnitude of this protection is identical with that previously observed in the general population. In our view, postmenopausal estrogen therapy is not contraindicated for these women (see [Chapter 18](#)).

Dietary Factors

The geographic variation in incidence rates of breast cancer is considerable (the United States has the highest rates and Japan the lowest), and it has been correlated with the amount of animal fat in the diet.¹³⁵ Lean women, however, have an increased incidence of breast cancer, although this increase is limited to small, localized, and well-differentiated tumors.¹³⁶ Furthermore, studies have failed to find evidence for a positive relationship between breast cancer and dietary total or saturated fat or cholesterol intake.^{137, 138 and 139} On the other hand, there is evidence that dietary fat is a stronger risk factor for postmenopausal breast cancer than for premenopausal breast cancer.¹⁴⁰ Although a cohort study concluded that dietary fat is a determinant of postmenopausal breast cancer, the association did not achieve statistical significance.¹⁴¹ Thus, the epidemiologic literature provides little support for a major contribution of dietary fat to the risk of breast cancer. Nevertheless, there is a correlation between intra-abdominal fat (android obesity) and the risk of breast cancer, a consequence of excessive caloric consumption, however, not a specific dietary component.¹⁴² Presumably, the connection between android obesity and breast cancer is through the metabolic perturbations associated with excessive body weight.

There is no argument that the incidence of breast cancer is increased in countries associated with affluent, unfavorable diets (high fat content) and a lack of physical exercise. The common denominator may be the peripheral insulin resistance and hyperinsulinemia that become prevalent with aging in affluent, modern societies. This specific metabolic change is becoming a common theme in various clinical conditions, particularly noninsulin-dependent diabetes mellitus, anovulation and polycystic ovaries, hypertension, and dyslipidemia. Hyperinsulinemia is found more often in women with breast cancer.¹⁴³ In this subgroup of women, the risk of breast cancer may be unfavorably influenced by hormonal changes (such as a decrease in sex hormone-binding globulin and an increase in unbound, free estradiol). There are, indeed, many reasons to avoid excess body weight. The risk of breast cancer is reduced in women who exercise regularly.¹⁴⁴

In women, soy consumption produces a reduction in the circulating levels of estradiol.¹⁴⁵ In the parts of the world where soy intake is high, there is a lower incidence of breast, endometrial, and prostate cancers. For example, a case-control study concluded that there was a 54% reduced risk of endometrial cancer, and another case-control study indicated a reduction in the risk of breast cancer, in women with a high consumption of soy and other legumes.^{146, 147} It is by no means certain, however, that there is a direct effect of soy intake.¹⁴⁸ Soy intake may be a marker for other factors in lifestyle or diet that are protective.

It is well recognized that the incidence of breast cancer is higher in the U.S. than in China or Japan. It has been further observed that after migration to the U.S., Asian women gradually increase (6-fold) their risk of breast cancer over several generations, eventually reaching the level of white women. Evidence indicates that this reflects a change in diet and lifestyle, with an increase in risk associated with a gain in height and weight.^{149, 150} Recent weight gain is especially associated with increased risk. A reduced risk, however, is observed in heavy, younger women.

The effect of body weight on the risk of breast cancer differs in premenopausal and postmenopausal women. In premenopausal women who are overweight, the risk of breast cancer is lower compared with normal weight individuals, and in postmenopausal women, excess weight is associated with either an unchanged or slightly increased risk.^{150, 151 and 152} This is attributed to a more marked increase in total and free estrogen levels in overweight postmenopausal women, in contrast to lower levels with increasing weight in premenopausal women. Postmenopausal obese women have later menopause, higher estrone production rates and free estradiol levels (lower sex hormone-binding globulin), and a slightly greater risk for breast cancer.¹⁵³ A large Swedish case-control study suggested that the principal factor is weight gain during adulthood, and that the impact on breast cancer emerges 10 years after menopause.¹⁵⁴ As noted, this weight gain may be the important determinant in the increasing risk experienced by migrants from low-risk parts of the world who move to high-risk areas.

Alcohol in the Diet

There is a modest increase in the risk for breast cancer with the consumption of one or more alcoholic drinks of all forms per day.¹⁵⁵ Almost all of many studies conclude that two drinks daily increase the risk by about 30–40%.¹⁵⁶ It is tempting to speculate that breast cancer and alcohol are linked through estrogen, either a direct or an indirect effect (e.g., on hepatic enzymes) on estrogen metabolism. An effect of alcohol ingestion by premenopausal women was not demonstrated on circulating levels of estrone, estradiol, dehydroepiandrosterone sulfate (DHEAS), or sex hormone-binding globulin in a cross-sectional study that depended upon a questionnaire to assess alcohol intake.¹⁵⁷ However, when alcohol is administered under experimental conditions, circulating estrogen concentrations are raised to high levels.^{158, 159} And in a prospective cohort study of premenopausal women in Italy, higher estradiol levels were correlated with an increased alcohol intake over a 1-year period of time.¹⁶⁰

Specific Endocrine Factors

Adrenal Steroids

Subnormal levels of etiocholanolone (a urinary excretion product of androstenedione) were found from 5 months to 9 years before the diagnosis of breast cancer in women living on the island of Guernsey, off the English coast.¹⁶¹ A subnormal excretion of this 17-ketosteroid was also found in sisters of patients with breast cancer. A 6-fold increase in the incidence of breast cancer was found between women excreting less than 0.4 mg of etiocholanolone and those excreting over 1 mg/24 hours. Measurement of this 17-ketosteroid might be a useful screening procedure to detect a high-risk group of patients because approximately 25% of the population excretes less than 1 mg/24 hours.

Endogenous Estrogen

Epidemiologic and other information continue to suggest some estrogen-related promoter function. These include the following: 1) the condition is 100 times more common in women than in men; 2) breast cancer invariably occurs after puberty; 3) untreated gonadal dysgenesis and breast cancer are mutually exclusive; 4) a 65% excess rate of breast cancer has been observed among women who have had an endometrial cancer; and 5) breast tumors contain estrogen receptors which are biologically active as indicated by the presence of progesterone receptors in tumor tissue. Taken together, these data suggest an element of estrogen dependence, if not provocation, in many breast cancers.

Estril generally has failed to produce breast cancer in rodents, and in fact, estril protects the rat against breast tumors induced by various chemical carcinogens.¹⁶² The hypothesis is that a higher estril level protects against the more potent effects of estrone and estradiol. This might explain the protective effect of early pregnancies. Women having had an early pregnancy continue to excrete more estril than nulliparous women. Premenopausal healthy Asiatic women have a lower breast cancer risk than Caucasians and also have a higher rate of urinary estril excretion.¹⁶³ When Asiatic women migrate to the United States, however, the risk of breast cancer increases, and their urinary excretion of estril decreases, perhaps a consequence of dietary changes as noted above. A major factor in the potency differences among the various estrogens (estradiol, estrone, estril) is the length of time the estrogen-receptor complex occupies the nucleus. The higher rate of dissociation with the weak estrogen (estril) can be compensated for by continuous application to allow prolonged nuclear binding and activity. Estril has only 20–30% affinity for the estrogen receptor compared to estradiol; therefore, it is rapidly cleared from a cell. But if the effective concentration is kept equivalent to that of estradiol, it can produce a similar biologic response.¹⁶⁴ In pregnancy, where the concentration of estril is very great, it can be an important hormone, not just a metabolite. Thus, higher estril levels are not necessarily protective. Indeed, antagonism of estradiol occurs only within a very narrow range of the ratio of estradiol to estril, a range rarely encountered either physiologically or pharmacologically.¹⁶⁵ Below this range, estradiol is unimpeded, above this range estril itself exerts estrogenic activity.

Stanley G. Korenman promulgated a most interesting hypothesis concerning the endocrinology of breast cancer.^{166, 167} Recognizing that the endocrine changes thought to be related to the promotion or provocation of breast cancer were small, inconsistent, and could hardly account for the differential risk of breast cancer

among populations, Korenman concluded that endocrine status is related to breast cancer by influencing the patient's susceptibility to environmental carcinogens. Called the "Open Window Hypothesis," Korenman argued that unopposed estrogen stimulation is the most favorable state for tumor induction (the "open" window). Susceptibility to breast cancer declines with the establishment of normal luteal phase progesterone secretion and becomes very low during pregnancy; the open window is closed.

The two main open window periods are the pubertal years prior to the establishment of regular ovulatory menstrual cycles and the perimenopausal period of waning follicle maturation and ovulation. The prolongation of these open windows by obesity, infertility, delayed pregnancy, earlier menarche, and later menopause would be associated with greater susceptibility. This argument is supported by observational studies indicating that anovulatory and infertile women (exposed to less progesterone) have an increased risk of breast cancer later in life. ^{168, 169, 170 and 171} However, the statistical power of these observational studies was limited by small numbers (all fewer than 15 cases).

Although theoretically appealing on the basis of presumed correlation with epidemiologic risks (infertility, late menopause) clinical research has not always confirmed the thesis. Young women at high genetic risk for breast cancer had normal luteal phases, and a group of premenopausal women with breast cancer also had normal luteal phases. ¹⁷² Others have failed to find a link between anovulation and the risk of breast cancer. ^{173, 174 and 175} Indeed, women with the most irregular menstrual cycles (and thus presumably anovulatory) in the Nurses' Health Study appeared to have a reduced risk of breast cancer. ¹⁷⁶

Studies seeking a correlation between circulating levels of sex hormones and breast cancer have yielded conflicting results. In the Rancho Bernardo cohort, no relationship between estrogen, androgen, and sex hormone-binding globulin levels with the incidence of breast cancer could be demonstrated. ¹⁷⁷ Using serum collected earlier in life, no differences in endogenous hormones could be detected in 51 women who subsequently developed breast cancer; including the various estrogens, progesterone, androstenedione, and even sex hormone-binding globulin. ¹⁷⁸ On the other hand, in a very large prospective study in Italy, estradiol, testosterone, and sex hormone-binding globulin levels were higher in postmenopausal women who subsequently developed breast cancer. ¹⁷⁹ In a British report, women who subsequently developed breast cancer had higher levels of estradiol. ¹⁸⁰ Two North American prospective studies also found higher levels of estrogen in women who subsequently developed breast cancer, and most impressively, an increasing risk of breast cancer correlated with increasing levels of free estradiol. ^{181, 182} In another study, women who developed breast cancer displayed higher levels of non-bound, free estradiol and lower levels of sex hormone-binding globulin (SHBG). ¹⁸³ In the Nurses' Health Study, an association was reported between an increased risk of breast cancer and higher levels of estradiol, estrone, and dehydroepiandrosterone sulfate; however, no association could be demonstrated with the percent free or bioavailable levels of estradiol, androstenedione, testosterone, or dehydroepiandrosterone. ¹⁸⁴

Bone mass is generally regarded as a marker of estrogen exposure, and women with the highest bone densities have a greater risk of breast cancer compared with women who have low bone densities. ¹⁸⁵ Another attempt to link the risk of breast cancer to the endogenous estrogen level focused on prenatal exposure. A reduced risk for breast cancer is observed for women born to mothers with pregnancy-induced hypertension, suggesting that this finding is due to the lower estrogen levels associated with preeclampsia. ^{186, 187}

The biologic plausibility and epidemiologic support for an estrogen link are impressive arguments. Whether the important factor is the total amount of estrogen, the amount of estrogen unopposed by progesterone, the amount of free (unbound) estradiol, the duration of exposure to estrogen, or some other combination is not known. The discrepancies among the various studies reflect the fact that the differences are very small, and it is a struggle to achieve statistical significance.

Endogenous Progesterone

Because mitotic activity in the breast reaches its peak during the progesterone dominant luteal phase of the menstrual cycle, ^{188, 189 and 190} it can be argued that progesterone is the key to influencing the risk of breast cancer. This would be consistent with experimental demonstrations in mice that progesterone is the primary hormonal stimulus for mammary growth and differentiation. ² However, studies do not support a major role for a progestational influence. Indeed, evidence indicates that with increasing duration of exposure, progesterone can limit breast epithelial growth as it does with endometrial epithelium. ^{11, 12 and 13} In vitro studies of normal breast epithelial cells reveal that progestins inhibit proliferation. ¹⁹¹ Human breast tissue specimens removed after the patients were treated with estradiol and progesterone indicate that progesterone inhibits in vivo estradiol-induced proliferation. ^{13, 192} As noted, women who ultimately develop breast cancer do not have different blood levels of progesterone. ¹⁷⁸ In addition, several clinical observations would argue against progesterone as a key factor. Although there is some disagreement, most studies indicate that the high levels of estrogen and progesterone during pregnancy have no adverse impact on the course of breast cancer diagnosed during pregnancy or when pregnancy occurs subsequent to diagnosis and treatment (discussed with references in [Chapter 18](#)). Medroxyprogesterone acetate is not associated with an increased risk of breast cancer when used for contraception over long durations ([Chapter 23](#)).

Exogenous Estrogen and Progestin

The relationship between the postmenopausal use of exogenous estrogens and the risk of breast cancer has been intensively studied (reviewed with complete references in [Chapter 18](#)). At the present time there is no conclusive evidence that estrogen doses known to protect against osteoporosis and cardiovascular disease (0.625 mg conjugated estrogens, 1.0 mg estradiol, or equivalent doses of other products) increase the risk of breast cancer. Some have concluded that a slight increase is noted with long duration of use; however, notable studies have failed to document such an increase. The extensive literature on this subject can be summarized as follows:

Some epidemiologic case-control and cohort studies conclude that long-term (5 or more years) of current use of postmenopausal hormone therapy is associated with a slight increase in the risk of breast cancer. This conclusion might be due to confounding biases, particularly detection and surveillance bias.

All epidemiologic studies fail to find an increased risk of breast cancer associated with short-term (less than 5 years) use or past use of postmenopausal hormone therapy.

The epidemiologic data agree that the addition of a progestin to the treatment regimen neither increases nor decreases the risk observed in individual studies.

The epidemiologic data indicate that a positive family history of breast cancer should not be a contraindication to the use of postmenopausal hormone therapy.

Women who develop breast cancer while using postmenopausal hormone therapy have a reduced risk of dying from breast cancer. This is because of two factors: (1). Increased surveillance and early detection; and (2). Acceleration of tumor growth so that tumors appear at a less virulent and aggressive stage.

Thyroid, Prolactin, Various Nonestrogen Drugs

Despite isolated suggestions of increased risk, hypothyroidism, reserpine, and prolactin excess, whether spontaneous or drug-induced, are not related to an enhanced risk of breast cancer. ^{193, 194}

Oral Contraception and Breast Cancer

The large number of women taking or having taken oral contraceptive steroids, combined with the belief that steroids provoke or promote abnormal breast growth and possibly cancer, has provided a source of major concern for years. The Royal College of General Practitioners, Oxford Family Planning Association, and Walnut Creek studies have indicated no significant differences in breast cancer rates between users and nonusers. However, patients were enrolled in these studies at a time when oral contraceptives were used primarily by married couples spacing out their children. Because this population did not reflect use by younger women for long durations to delay their first pregnancy, case-control studies in the last decade have focused on the contemporary use of oral contraceptives. This subject is reviewed in detail with complete references in [Chapter 22](#).

Long-term use of oral contraception during the reproductive years is not associated with a significant increase in the risk of breast cancer that occurs later in life, after age 45. There is the possibility that a subgroup of young women who use oral contraceptives early and for more than 4 years has a slightly increased risk (a relative risk of less than 1.2) of breast cancer that occurs earlier in life, before age 45.¹⁹⁵ The re-analysis of data from 54 studies indicated that breast cancers that occurred in women who were previous users of oral contraceptives were more localized, with less metastatic disease.¹⁹⁵ Indeed, the risk of metastatic disease in ever users was significantly reduced. Breast cancer before age 45 is relatively rare, and furthermore, the results of these studies may reflect the same problem observed in studies with postmenopausal hormone therapy, detection/surveillance bias. The reduced risk of later metastatic disease and the increased appearance early in life suggest a situation analogous to pregnancy. Thus, breast cells that have already begun malignant transformation may be accelerated in their growth by exposure to oral contraceptives, and appear early in localized form. With the accumulation of greater numbers of older women previously exposed to oral contraceptives, a protective effect may become evident. Overall, the message is reassuring. The statistical effect, if real, is small, and the data are also consistent with explanations other than an etiologic stimulation.

The use of oral contraception does not further increase the risk of breast cancer in women with positive family histories of breast cancer or in women with proven benign breast diseases. There is no evidence that the use of oral contraceptives prior to the diagnosis of breast cancer has an adverse impact on prognosis.¹⁹⁶

Higher dose oral contraception, used for 2 or more years, protected against benign breast disease, but this protection was limited to current and recent users. It is uncertain whether this same protection is provided by the current low-dose formulations. A French case-control study has indicated a reduction of non-proliferative benign breast disease associated with low-dose oral contraception used before a first full-term pregnancy, but no effect on proliferative disease with use after a pregnancy.¹⁹⁷

Breast Cancer in Diethylstilbestrol (DES)-Exposed Women

From 1940 to 1970, diethylstilbestrol (DES), a potent synthetic estrogen, was prescribed in high doses for a variety of pregnancy-related complications. Exposure to DES occurred in association with 2 million live births; therefore, the risk for induction of breast cancer during a period of breast differentiation could be significant if DES were a true breast carcinogen. The first study on this subject reported on the follow-up of women who participated in a controlled trial of DES in pregnancy between 1950 and 1952 at the University of Chicago. In this study, an increase in breast cancer risk that did not reach significance was observed with DES exposure.¹⁹⁸ A large collaborative study, involving approximately 6000 women, concluded that there is a small but significant increase in the risk of breast cancer many years later in life in women exposed to DES during pregnancy.¹⁹⁹ A longer follow-up (more than 30 years) of this large cohort of DES-exposed women is now available. Exposure to DES is associated with a significant, but modest (less than two-fold), increase in the risk of breast cancer.²⁰⁰ Importantly, the relative risk did not increase with duration of follow-up and remained stable over time. This conclusion was confirmed in a prospective study by the American Cancer Society.²⁰¹ Certainly it is wise to recommend to DES-exposed women that they adhere religiously to screening for breast cancer, including mammography as discussed below.

Receptors and Clinical Prognosis

There is an excellent correlation between the presence of estrogen receptors and certain clinical characteristics of breast cancer, including response to endocrine therapy.²⁰² Premenopausal and younger patients are more frequently receptor negative. Patients with receptor positive tumors survive longer and have longer disease-free intervals after mastectomy than those with receptor negative tumors. The presence of estrogen receptors correlates with increased disease-free interval regardless of the presence of positive axillary nodes or the size and location of the tumors. Similarly, patients without axillary lymph node metastases, but with estradiol receptor negative tumors, have the same high rate of recurrence as do patients with axillary lymph node metastases. Patients with tumors that are positive for estrogen receptors are more likely to respond to endocrine treatment.

It appears that patients with estrogen receptors are those with the more slowly growing tumors. Several reports indicate that estrogen receptor status correlates with the degree of differentiation of the primary tumor. A large proportion of highly differentiated Grade I carcinomas are receptor positive, while the reverse is true of Grade III tumors.

Remember that it takes estrogen to make progesterone receptors. Therefore the presence of progesterone receptors proves that the estrogen receptor in the tumor is biologically active. Thus, the presence of progesterone receptors has a correlation with disease-free survival of patients only second to the number of positive nodes.²⁰² The best prognosis is seen in patients with positive progesterone receptors, even with subsequent disease if the recurrent disease is still progesterone receptor positive. The loss of progesterone receptors is an ominous sign.

Tamoxifen and Breast Cancer

The purpose of adjuvant therapy of breast cancer is to provide treatment in the absence of recognized active disease in order to reduce the risk of future recurrence or to minimize systemic recurrence in the presence of metastatic disease. Tamoxifen is very similar to clomiphene (in structure and actions), both being nonsteroidal compounds structurally related to diethylstilbestrol. Tamoxifen, in binding to the estrogen receptor, competitively inhibits estrogen binding. In vitro, the estrogen binding affinity for its receptor is 100–1000 times greater than that of tamoxifen. Thus, tamoxifen must be present in a concentration 100–1000 times greater than estrogen to maintain inhibition of breast cancer cells. Dose-response studies with tamoxifen have failed to demonstrate an increase in activity with doses larger than the standard, 20 mg daily.²⁰³ In addition, when bound to the estrogen receptor, tamoxifen prevents gene transcription by the TAF-2 pathway. In vitro studies demonstrate that these actions are not cytotoxic, but rather cytostatic (and thus tamoxifen use must be long-term). The mechanism of tamoxifen action is discussed in detail in [Chapter 2](#).

We have available a remarkable worldwide overview of 37,000 women involved in tamoxifen randomized trials.²⁰⁴ Adjuvant treatment with the antiestrogen, tamoxifen, achieves highly significant reductions in recurrence and increases in survival. The beneficial effect of tamoxifen is evident no matter what the age of the patient, in both premenopausal and postmenopausal women, in node positive and node negative disease, and in both estrogen receptor positive and negative tumors (however, the effect of tamoxifen on estrogen receptor negative tumors is small). The impact on recurrence occurs in the first 5 years, but continued impact on survival occurs throughout 10 years. A greater effect is seen with longer treatment (5 years). The 10-year survival difference is even greater than that at 5 years. Adjuvant treatment (which is either tamoxifen, chemotherapy, or ovarian ablation) yields worldwide an extra 100,000 10-year survivors. There is an increased survival at 5 years of approximately 20%, most evident in women over age 50. Response rates in advanced breast cancer are 30–35%, most marked in patients with tumors that are positive for estrogen receptors, reaching 75% in tumors highly positive for estrogen receptors. There is a lower rate (a 47% reduction with 5 years of treatment) of a second primary breast cancer in the contralateral breast in women treated with tamoxifen.

Data from randomized clinical trials document that a treatment duration of 5 years is superior to 2 years.²⁰⁵ However, the results have indicated that there is little reason to extend tamoxifen treatment of breast cancer patients beyond 5 years.^{206,207} Indeed, the data suggested that survival and recurrence rates worsened with longer therapy, probably due to the emergence of tamoxifen-resistant tumors. There are several possible explanations for resistance, and whichever of these are operative, it is believed that a subpopulation resistant to tamoxifen is present from the beginning, and over time grows to be clinically apparent.²⁰⁸

The major disturbing side effect is an increase in hot flushing. In a preliminary report from the prevention trial in England and in the U.S. trial, tamoxifen treatment of postmenopausal women prevented bone loss, but premenopausal women treated with tamoxifen had significant reductions in bone mineral density.^{209,210} Blurred and decreased vision has been reported associated with retinal changes, but it is uncertain whether this is a cause and effect relationship.²¹¹ In a prospective study of 63 patients in Greece, 6.3% developed retinopathy which was reversible except for retinal opacities.²¹² In the 2673 patients in the protocols of the Eastern Cooperative Oncology Group, premenopausal women who received tamoxifen and chemotherapy had significantly more venous and arterial thrombosis than those who received chemotherapy without tamoxifen, and in postmenopausal women, tamoxifen alone was associated with more venous thrombi.²¹³ In summary, the serious side effects of tamoxifen include endometrial cancer (discussed below), venous thrombosis, and cataracts.

Serum protein changes reflect the estrogenic (agonistic) action of tamoxifen. This includes decreases in antithrombin III, cholesterol, and LDL-cholesterol, while HDL-cholesterol and sex hormone-binding globulin (SHBG) levels increase (as do other binding globulins). Because of the significant impact on sex hormone-binding globulin, a marked increase in circulating estrogens has been observed in premenopausal women; however, unbound, free estrogen is actually reduced. For example, in one clinical study of premenopausal women receiving tamoxifen, 20 mg daily, the percent free estradiol decreased from 1.72% to 1.47% after 3 months because of

the increase in SHBG.²¹⁴

The estrogenic activity of tamoxifen, 20 mg daily, is nearly as potent as 2 mg estradiol in lowering FSH levels in postmenopausal women, 26% vs. 34% with estradiol.²¹⁵ The estrogenic actions of tamoxifen include the stimulation of progesterone receptor synthesis, an estrogen-like maintenance of bone and the cardiovascular system, and estrogenic effects on the vaginal mucosa and the endometrium. Indeed, patients with breast cancer who have been treated with tamoxifen have been reported to have less coronary heart disease in some studies, but not all.^{204, 210, 216} Tamoxifen increases the frequency of hepatic carcinoma in rats at very large doses. This is consistent with its estrogenic, agonistic action, but this effect is unlikely to be a clinical problem (and it has not been observed) at doses currently used.²⁰⁴ Tamoxifen causes a decrease in antithrombin III, and there has been a small increase in the incidence of thrombo-embolism observed in tamoxifen-treated patients compared with controls.^{206, 213} However, in the world overview of randomized trials, no significant cardiac or vascular increase in mortality was noted in tamoxifen-treated women.²⁰⁴

Tamoxifen Breast Cancer Prevention Trials

Women at increased risk for breast cancer participated in a breast cancer prevention trial initiated in the U.S. in 1992. The study compared two groups of women, one treated with placebo and one with 20 mg tamoxifen daily for 5 years. Early in 1998 (after about 4 years of follow-up), the study was unblinded because there were 49% fewer cases of invasive breast cancer and 50% fewer cases of noninvasive breast cancer in the tamoxifen-treated arm of the study.²¹⁰ This outcome was not without risk. There was a 2.4-fold increase in postmenopausal endometrial cancer, a 2.8-fold increase in pulmonary embolism, a 1.6-fold increase in venous thrombosis, and a 1.6-fold increase in cataracts. In addition to these side effects, there continues to be concern that, because malignant breast tumors require a relatively long period of time to progress from an abnormal cell to a clinically detectable mass,²¹⁷ the impact of tamoxifen may reflect growth deceleration of a pre-existing tumor. A major argument against an effect on pre-existing tumors is the documentation of persistent protection against recurrent disease over 10 years of follow-up in the overview of tamoxifen adjuvant therapy.²⁰⁴

Because of the early termination of the American prevention trial, the investigators in tamoxifen prevention trials in Italy and the United Kingdom presented preliminary analyses of their results.^{218, 219} Both trials could detect no difference in the frequency of breast cancer between the tamoxifen and placebo arms. A consideration of power calculations indicated that despite the smaller size of these studies it should have been possible to demonstrate an effect comparable to the American trial. A possible explanation is that both the Italian and U.K. trials contained more younger women. This difference could contribute to a lower effect because the impact of tamoxifen in the American trial was confined to estrogen receptor positive cancers in older women. Another possibility, and one that is very worrisome, is that longer durations of treatment as in the European trials could allow the emergence of tamoxifen-resistant, more aggressive tumors (as has been occasionally observed with adjuvant tamoxifen treatment that is longer than 5 years). These European results lend credibility to the argument that estrogen and tamoxifen are exerting promotional (acceleration) and anti-promotional (deceleration) effects on pre-existing tumors, not causing and preventing breast cancer. To answer this, the clinical trials must continue, with long follow-up, especially to document breast cancer mortality in these groups of women. For this reason, the Italian and U.K. investigators both decided to continue their trials. In addition, there is a fourth tamoxifen prevention trial, the International Breast Cancer Intervention Study. In view of the disagreement among the American, Italian, and U.K. trials, the International Study decided to keep their study blinded, and to continue as planned.

These results lead us to recommend tamoxifen prophylaxis (20 mg daily for 5 years) for those women who are diagnosed with ductal carcinoma-in-situ of the breast or who have atypical hyperplasia in a breast biopsy (especially if a positive family history of breast cancer is also present). For others who seek tamoxifen preventive treatment, we advise that the final answers are not in, and that clinical trial results from long-term follow-up will be necessary before fully informed decision making is possible.

Gynecologic Problems With Tamoxifen

Tamoxifen is both an estrogen antagonist and an estrogen agonist. A tissue that is highly sensitive to estrogen, the endometrium, responds to the weak estrogenic action of tamoxifen, which is present in high doses for long durations in women receiving adjuvant treatment for breast cancer. Toremifene has a structure and properties essentially similar to tamoxifen, and we expect the same results, side effects, and problems will be observed when this agent is used in a dose of 60 mg/day to treat breast cancer patients.

The National Surgical Adjuvant Breast and Bowel Project compared the rates of endometrial cancers in tamoxifen and non-tamoxifen treated patients who had breast cancer.²²⁰ The rate of endometrial cancer in the tamoxifen-treated group equaled an increased relative risk of 7.5. Although 88% of the endometrial tumors were stage I, 4 patients died of advanced endometrial cancer. This report from the NSABP finally convinced the breast cancer world that the risk of endometrial cancer is real with tamoxifen treatment. Although the number of deaths from endometrial cancer was small, it was the presence of the 4 deaths that had a major impact. It is worth noting that the incidence of endometrial cancer in the tamoxifen-treated group was estimated to be 6.3 per 1000 patients after 5 years of treatment. This incidence is very similar to what would be expected with unopposed estrogen treatment, a similarity to be expected in that the agonistic estrogenic action of tamoxifen over the long-term should be similar to the relatively low doses of estrogen used for postmenopausal hormone therapy. Similar results have been reported from the Stockholm tamoxifen trial, and an increased rate of postmenopausal endometrial cancer was confirmed in the U.S. Breast Cancer Prevention Trial.^{210, 221} In the world overview of randomized trials, the incidence of endometrial cancer quadrupled with 5 years of tamoxifen treatment.²⁰⁴

The development of endometrial cancer in women receiving tamoxifen should not be so surprising. We know that duration of exposure to estrogen is more important than the dose of estrogen in influencing progression from proliferative endometrium through hyperplasia to cancer. In addition, women being treated with tamoxifen have been reported to develop atypical hyperplasia of the endometrium, endometrial polyps, ovarian cysts, growth of fibroids, adenomyosis, and rapid exacerbation of endometriosis.^{222, 223} In a cohort of postmenopausal women on tamoxifen in the English prevention trial, 16% had atypical hyperplasia of the endometrium at the time of study and 8% had endometrial polyps.²²⁴ In addition, 4 ovarian cysts were detected in the treatment group compared to 2 cysts in the control group. The proper surveillance and management of women being treated with tamoxifen are critical problems.

It is inappropriate to advocate progestational treatment to prevent the endometrial response to tamoxifen. The progestational impact (at the low doses currently used for endometrial protection) on the risk of breast cancer recurrence and the interaction with tamoxifen are not known. Indeed, a relatively high dose of norethindrone (2.5 mg daily for 3 months) was **unable** to exert a protective effect on the endometrium in healthy women participating in the U.K. tamoxifen prevention trial.²²⁵ Periodic endometrial aspiration biopsy, of course, would be sufficient, but this procedure carries with it the potential for a very significant negative effect on patient compliance (with her tamoxifen and with her clinician). It is argued that endometrial assessment should be limited to tamoxifen-treated women who report vaginal bleeding.^{226, 227} However, in the U.K. tamoxifen prevention trial, a greater endometrial response to tamoxifen was observed in those women who developed amenorrhea.²²⁸ To be sure, most tamoxifen-treated women who have developed endometrial cancer have been symptomatic with vaginal bleeding, but not all. Furthermore, some of these women have had advanced, invasive disease at the time of presentation. It makes sense to detect abnormal changes as early as possible. The progestin challenge test (discussed in [Chapter 18](#)) would be a cost-effective method to detect the presence of stimulated endometrium, and a pilot study has documented its use in tamoxifen-treated women.²²⁹ However, until data are available documenting the reliability of this approach, we favor the use of ultrasonographic measurement of endometrial thickness, with saline instillation when the appearance is not totally benign (also discussed in [Chapter 18](#)).²³⁰ Tamoxifen is associated with an ultrasonographic image that is unique, characterized by sonolucent changes that are subendometrial, thus the usefulness of saline instillation.²³¹

It is also logical to expect these patients to be at increased risk for the development and progression of endometriosis. There are case reports of women being treated with tamoxifen, 20 mg daily, who required hysterectomy and oophorectomy for severe endometriosis.^{232, 233} In our view, an annual pelvic examination is not sufficient; every 6 months is best.

The problem of hot flushing should not be underrated. About 25% of women have vasomotor symptoms on tamoxifen, and those that already had flushing have worse flushing.²³⁴ Alternative treatments are available.

We recommend transdermal clonidine, applied with the 100 mg dose once weekly.^{235, 236} Side effects are minimal, and a modest impact can be expected.

Clonidine, bromocriptine, and naloxone given orally are only partially effective for the relief of hot flushes and require high doses with a high rate of side effects. Bellergal (a combination of belladonna alkaloids, ergotamine tartrate, and phenobarbital) treatment is slightly better than a placebo, but it is also a potent sedative.²³⁷ Veralipride, a dopamine antagonist that is active in the hypothalamus, is relatively effective in inhibiting flushing at a dose of 100 mg daily.^{238, 239} Mastodynia and

galactorrhea are the major side effects, and it should be noted that the effect of increased prolactin secretion on the risk of recurrent breast cancer is unknown. Medroxyprogesterone acetate (10–20 mg daily) and megestrol acetate (20 mg bid) are also effective, but concerns regarding exogenous steroids (especially in patients who have had breast cancer) would apply to progestins as well. ^{240, 241} Methyldopa, in doses of 500–1000 mg/day, is approximately twice as effective as a placebo, suggesting a role for adrenoceptors in the hot flush mechanism. ²⁴² Venlafaxine hydrochloride is an antidepressant that inhibits serotonin re-uptake; it effectively reduced hot flush frequency in a dose of 25 mg daily. ²⁴³ Vitamin E, 800 IU daily, is only slightly more effective than placebo. ²⁴⁴

A woman being treated for breast cancer will naturally focus her attention and energy on the cancer itself, especially in the early years of treatment. The same can be said for the specialist who is monitoring the treatment. It falls to the patient's health care manager, her primary clinician, to look at the broader picture. A clinician interacting with patients being treated for breast cancer has an obligation to consider the impact of the patient's treatment on other body systems and functions. Tamoxifen offers the hope of adding many years to a woman's life. Medical intervention by a clinician can help make those years better with good preventive health care.

We recommend the following program for monitoring women during long-term tamoxifen treatment:

All women:	Careful pelvic examination every 6 months to detect the emergence of endometriosis, ovarian cysts, uterine leiomyomata.
Postmenopausal women:	Annual measurement of endometrial thickness by transvaginal ultrasonography. Endometrial biopsy of all women with a two-layer thickness of 5 mm or greater. Saline instillation (sonohysterography) when appearance is not totally benign.
Premenopausal women:	Periodic assessment for ovulation; if ovulatory, no further intervention is necessary; however, contraceptive counseling should not be ignored. If anovulatory, an annual endometrial aspiration biopsy; interpretation of endometrial thickness measurements by ultrasonography is uncertain in premenopausal women.
	Consider the use of the progestin-releasing IUD for both contraception and protection against endometrial change.

An increased risk of endometrial cancer lingers for up to 10 years after discontinuing therapy with estrogen (without the addition of a progestin). ^{245, 246} It is not known whether a similar persistent increased risk is present in the years after tamoxifen treatment. It would be prudent to investigate any unexpected vaginal bleeding in women who have been previously exposed to tamoxifen.

Needle Aspiration

Needle aspiration of breast lumps should be part of the practice of everyone who cares for women. ²⁴⁷ The technique is easy. A small infiltrate of xylocaine is placed in the skin (many clinicians believe that local anesthesia is unnecessary). Holding the lesion between thumb and index fingers with one hand, the other hand passes a 22-gauge needle attached to a 3-finger control syringe into the lesion. Aspiration will reveal the presence of cystic fluid from a cyst. If the mass is solid, the needle should be passed at least 2–4 times (even more if nothing is being obtained) back and forth through the lesion with continuous suction on the syringe. Air is forcibly ejected through the needle on to a cytology slide for smearing and fixing. The usual Pap smear fixative can be used.

The procedure is very cost-effective. When aspiration yields clear or cloudy, green-gray or yellow fluid and the mass disappears, the procedure is both diagnostic and therapeutic. Fluid of any other nature requires cytologic assessment. ²⁴⁸ Failure to obtain material for cytologic evaluation or the persistence of a mass requires biopsy. The mass should not have returned at the follow-up examination 1 month after the aspiration. Locally recurrent cysts should be surgically removed for histologic diagnosis.

Screening Mammography

Mammography is a means of detecting a nonpalpable cancer. Technical advancements have significantly improved the mammographic image and reduced the radiation dose. ²⁴⁹ The doubling time of breast cancer is very variable, but, in general, a tumor doubles in size every 100 days. Thus, it takes a single malignant cell approximately 10 years to grow to a clinically detectable 1 cm mass, but by this time a tumor of 1 cm has already progressed through 30 of the 40 doublings in size which is estimated to be associated with fatal disease. ²¹⁷ Furthermore, the average size at which a tumor is detected (70–75% of tumors are found by patients themselves) has been (prior to mammography) 2.5 cm, a size which has a 50% incidence of lymph node involvement. To decrease the mortality from breast cancer, we must utilize a technique to find the tumors when they are smaller. Mammography is the answer. Studies of breast self-examination have been disappointing in their failure to demonstrate an impact on breast cancer stage of disease and mortality. ²⁵⁰

Mammography is the technique of choice. Thermography has a high rate of false positive findings, and, at best, should be considered experimental. Ultrasound can rarely reveal malignant lesions smaller than 1 cm in size. It is useful, however, to guide the aspiration of lesions. CT scanning has 2 serious limitations. The x-ray dose is large, and the slices are too thick to detect early lesions. Finally, magnetic resonance imaging is not practical because of the expense and the long scan times that are necessary.

Mammography is the only method that detects clustered microcalcifications. These calcifications are less than 1 mm in diameter and are frequently associated with malignant lesions. More than 5 calcifications in a cluster are associated with cancer 25% of the time and require biopsy. Besides microcalcifications, the following mammographic findings usually require surgical evaluation: the appearance of a mass, calcifications associated with a mass, an area of distortion or asymmetrical density, a stellate lesion.

Mammography has a false-negative rate of 5–10%. This means that masses are palpable but not visible. Mammography cannot and should not replace examination by patient and clinician. Cancer commonly presents as a solitary, soli, painless (only 10% of cancers are painful), hard, unilateral, irregular nonmobile mass. A mass requires biopsy regardless of the mammographic picture.

A pattern of dysplasia on the mammogram carries with it an increased risk (2.0–3.5 times normal) of breast cancer. The risk is similar to that seen with the other known risk factors.²⁵¹

The Effectiveness of Mammography

Mammography can reduce breast cancer mortality. In Nijmegen, the breast cancer mortality rate in women 35 and over was reduced by 50% by annual mammographic screening.²⁵² In Utrecht, the relative risk of dying from breast cancer among screened women was reduced by 70%.²⁵³ The first randomized, controlled trials of mammography were begun in Sweden in 1977. Results have demonstrated a 24% reduction in mortality, 29% in women aged 50–69.²⁵⁴ Most impressively, the results in Sweden were obtained with a screening only every 2–3 years and with only a single mediolateral oblique view. Overall, a 30–40% reduction in mortality can be expected with screening mammography of asymptomatic women over age 50.²⁵⁵ A greater impact is to be expected with an increased and regular frequency of use combined with state-of-the-art technology.

About 19% more breast cancers occur in women 40–49 than in women aged 50–59, accounting for approximately 20% of all deaths due to breast cancer.⁷⁷ But, it has been questioned whether mammography screening is effective for women under 50.^{256, 257} The American Breast Cancer Detection Demonstration Project demonstrated that screening was just as effective for women in their 40s as in women over 50.²⁵⁸ This program that was organized by the American Cancer Society and the National Cancer Institute began operating in 1973 in 28 locations throughout the United States, enrolling more than 280,000 women. Despite the fact that this was not an organized research study with a control group, the massive database permits many valuable conclusions. From 1977 to 1982, similar high survival rates (87%) for women in their 40s compared with women in their 50s verify that screening was just as effective in the younger women. A 5-year survival rate for patients under 50 with breast cancers detected by examination was 77% compared to 95% in those patients with breast cancers detected by mammography.²⁵⁹ In a randomized trial in Gothenburg, Sweden, women ages 39–49 undergoing mammographic screening every 18 months had a 45% reduction in breast cancer mortality.²⁶⁰ A meta-analysis of 7 randomized clinical trials concluded that in women aged 40–49 offered mammography screening, there was a 24% reduction in breast cancer mortality.²⁶¹

It takes longer for a significant difference in mortality to appear in 40–49-year-old women compared with women over age 50. There are two explanations. One is that tumors grow faster in younger women, and the other is the greater difficulty in achieving accurate mammography because of the denser, more glandular breasts in younger women compared to the more fatty breasts in older women. Because the breast density changes gradually, rapid tumor growth must be the more critical factor.

Once detected by mammography, the stage of disease and survival expectations are the same comparing women aged 40–49 with women over age 50.²⁶² However, cancers that are detected between screenings have lower survival rates (at all ages). Therefore another reason that it has been difficult to demonstrate an impact of screening in the age group 40–49 is that because of less than annual screening, more of the cancers are detected late (between screenings). This in turn reflects the faster tumor growth in younger women.²⁶³ Because the randomized clinical trials have screened younger women at 2-year or longer intervals, it is not surprising that screening has been less effective for these faster growing tumors. It is logical that women aged 40–49 should have annual screening mammography.^{264, 265}

Younger women without risk factors must understand that approximately 50 out of every 1000 mammograms will require further diagnostic procedures, and the yield will be one invasive cancer and one non-invasive tumor.²⁶⁶ Although false-positive results are more common among younger women, the difference is not so dramatic that the overall effectiveness of screening is impaired.²⁶⁴

There are problems to be anticipated with extensive mammography screening. Small nonpalpable lesions have less than a 5% chance of being malignant, and overall only about 20–30% of biopsy specimens contain carcinoma. That means there will be a large number of biopsies and mammograms performed (including the treatment of clinically irrelevant lesions), which involves costs to the health care system and cost to the individual in terms of stress and anxiety. Nevertheless mammography is the most potent weapon we possess in the battle against breast cancer. Mammography not only lowers mortality, but it also decreases morbidity because less radical surgery is necessary for smaller lesions. Most importantly, the number of unnecessary surgical procedures can be minimized by combining physical examination and mammography with needle aspiration.²⁶⁷ With the so-called triple approach (examination, mammography or possibly ultrasonography in young women, needle aspiration), the failure to detect a malignancy with at least one of the 3 diagnostic tests is very reliable; open biopsy can be avoided.^{268, 269}

It is appropriate to be concerned over the increased cost of annual screening. However, analysis of the increased cost, taking into account the greater efficacy of capturing early tumors comparing annual to biannual screening reveals that the overall benefit is worthwhile, and compares favorably to the cost and benefits of Pap smear screening for cervical cancer.^{270, 271}

Postmenopausal women receiving hormone therapy characteristically develop an increase in mammographic density that is often associated with breast tenderness.^{272, 273} This increase can be focal, multifocal, or diffuse. The increase in density may be greater with continuous, combined estrogen-progestin regimens.²⁷⁴ At the present time, these findings have no prognostic or clinical significance other than making it more difficult to interpret mammograms.²⁷⁵

There is a special problem with elderly women. Old women are less likely to be screened with mammography, probably due to both patient misconceptions and erroneous physician beliefs. The effectiveness of mammography for women over age 75 has not been established; however, decision analysis of available data predicts a major benefit for elderly women as well.²⁷⁶ Older women need to be reminded that risk continues to increase with increasing age.

Every woman should be regarded as at risk. Health care professionals who interact with women have the opportunity to initiate an aggressive program of preventive health care. The major deterrent to patient use of mammography is the absence of a strong clinician recommendation. We urge you to follow these guidelines:

Screening for Breast Cancer

All women should be taught self-examination of the breast by age 20. Because of the changes that occur routinely in response to the hormonal sequence of a normal menstrual cycle, breast examination is most effective during the follicular phase of the cycle and should be performed monthly.

All women over the age of 35 should have an annual breast examination.

Women with a first-degree relative with premenopausal breast cancer should begin annual mammography 5 years before the age of the relative when diagnosed.

Annual mammography should be performed in all women over age 39.

Throughout recorded history, multiple physical and mental conditions have been attributed to the menopause. Although medical writers often wrote colorfully in the past, unfortunately they were also less than accurate, unencumbered by scientific information and data. A good example of the stereotypical, inaccurate thinking promulgated over the years is the following written in 1887:²

The ovaries, after long years of service, have not the ability of retiring in graceful old age, but become irritated, transmit their irritation to the abdominal ganglia, which in turn transmit the irritation to the brain, producing disturbances in the cerebral tissue exhibiting themselves in extreme nervousness or in an outburst of actual insanity.

The belief that behavioral disturbances are related to manifestations of the female reproductive system is an ancient one that has persisted to contemporary times. This belief regarding the menopause is not totally illogical; there is reason to associate the middle years of life with negative experiences. The events that come to mind are impressive: onset of a major illness or disability (and even death) in a spouse, relative, or friend; retirement from employment; financial insecurity; the need to provide care for very old parents and relatives; and separation from children. And thus, it is not surprising that a middle age event, the menopause, shares in this negative outlook.

The scientific study of all aspects of menstruation has been hampered by the overpowering influence of social and cultural beliefs and traditions. Problems arising from life events have often been erroneously attributed to the menopause. But data (especially more reliable community-based longitudinal data) now establish that the increase in most symptoms and problems in middle-aged women reflects social and personal circumstances, not the endocrine events of the menopause.^{3, 4, 5, 6, 7, 8} and ⁹ The variability in menopausal reactions makes the cross-sectional study design particularly unsuitable. Longitudinal studies are now documenting what is normal and the variations around normal.

The Massachusetts Women's Health Study, a large and comprehensive prospective, longitudinal study of middle-aged women, provides a powerful argument that the menopause is not and should not be viewed as a negative experience by the vast majority of women.^{4, 10} The cessation of menses was perceived by these women (as have the women in other longitudinal studies) as having almost no impact on subsequent physical and mental health. This was reflected by women expressing either positive or neutral feelings about menopause. An exception was the group of women who experienced surgical menopause, but here there is good reason to believe that the reasons for the surgical procedure were more important than the cessation of menses.

Changes in menstrual function are not symbols of some ominous "change." There are good physiologic reasons for changing menstrual function, and understanding the physiology will do much to reinforce a healthy, normal attitude. Attitude and expectations about the menopause are very important. Women who have been frequent users of health services and who expect to have difficulty do experience greater symptoms and higher levels of depression.^{5, 9} The symptoms that women report are related to many variables within their lives, and the hormonal change at menopause cannot be held responsible for the common psychosocial and lifestyle problems we all experience. It is time to stress the normalcy of this physiologic event. Menopausal women do not suffer from a disease (specifically a hormone deficiency disease), and postmenopausal hormone therapy should be viewed as specific treatment for symptoms in the short term and preventive pharmacology in the long term.

It can be further argued that physicians have had a biased (negative) point of view, because the majority of women, being healthy and happy, do not seek contact with physicians.^{11, 12} It is important, therefore, that clinicians not only are familiar with the facts relative to the menopause but also have an appropriate attitude and philosophy regarding this period of life. Medical intervention at this point of life should be regarded as an opportunity to provide and reinforce a program of preventive health care. The issues of preventive health care for women are familiar ones. They include family planning, cessation of smoking, control of body weight and alcohol consumption, prevention of cardiovascular disease and osteoporosis, maintenance of mental well-being (including sexuality), cancer screening, and treatment of

urologic problems.

Growth of the Older Population

We are experiencing a relatively new phenomenon: we can expect to become old. We are on the verge of becoming a rectangular society, one of the greatest achievements of the 20th century. This is a society in which nearly all individuals survive to advanced age and then succumb rather abruptly over a narrow age range centering around the age of 85.

In 1000 BC, life expectancy was only 18 years. By 100 BC, the time of Ceasar, it had reached 25 years. In 1900, in the United States, life expectancy still had reached only 49 years. In 2000, the average life expectancy will be 79.7 years for women and 72.9 for men.¹³ Today, once you reach 65, if you are a man you can expect to reach 80.5, if you are a woman, age 84.3. We can anticipate that eventually about two-thirds of the population will survive to 85 or more, and more than 90% will live past age 65—this would be the nearly perfect rectangular society.^{14, 15} Currently, Sweden and Switzerland are closest to this demographic composition.

A good general definition of elderly is 65 and older, although it is not until age 75 that a significant proportion of older people show the characteristic decline and problems. Today the elderly population is the largest contributor to illness and human need in the United States.¹⁶ There are more old people (with their greater needs) than ever before.¹⁷ In 1900, there were approximately 3 million Americans 65 and older (about 4% of the total population). By 2030, the elderly population will reach about 57 million (17% of the total population). Soon population aging will replace population growth as the most important social problem.

Two modern phenomena have influenced the rate of change. The first was the post World War II baby boom (1946–1964) that temporarily postponed the aging of the population, but now is causing a faster aging of the general population. The second major influence has been the modern decrease in old age mortality. Our success in postponing death has increased the upper segment of the demographic contour. By 2050, the current developed nations will be rectangular societies. China, by 2050, will contain more people over age 65 (270 million) than the number of people of all ages currently living in the U.S.

Current World Population Changes¹⁸

	Births	Deaths	Growth
Year	140,773,000	51,315,000	89,458,000
Month	11,731,080	4,276,250	7,454,834
Week	2,707,173	140,589	245,090
Hour	16,070	5,858	10,212
Minute	268	96	170
Second	4.5	1.6	2.8

This is a worldwide development, not limited to affluent societies.¹⁸ The population of the earth will continue to grow until the year 2100 or 2150, when it is expected to stabilize at approximately 11 billion. 95% of this growth will occur in developing countries. The poorest countries today (located in Africa and Asia) will in 2000 account for 87% of the world's population. In most developing countries, the complications associated with pregnancy, abortion, and childbirth are either the first or second most common cause of death, and almost half of all deaths occur in children under age 5. Limiting family size to two children would cut the annual number of maternal deaths by 50% and infant and child mortality also by 50%.¹⁹ Thus, it is appropriate to focus attention on population control; however, even in developing countries this will change. In 1950, only 40% of people 60 and older lived in developing countries. By 2025, more than 70% will live in those countries.

In 1900, older men in the U.S. outnumbered women 102 to 100. In the 1980s, there were only 68 men for every 100 women over the age 65. By age 85, only 40 men are alive for every 100 women. Nearly 90% of white American women can expect to live to age 70. Vital statistics data indicate that this gender difference is similar in both the black and white populations in the U.S.²⁰ Approximately 55% of girls, but only 35% of boys, live long enough to celebrate their 85th birthday.²¹

Men and women reach old age with different prospects for older age, a sex differential that (it can be argued) is due in significant part to the sex hormone-induced differences in the cholesterol-lipoprotein profile and other cardiovascular factors, and thus the greater incidence of atherosclerosis and earlier death in men.²² Therefore, the use of postmenopausal estrogen therapy, with its protective effect on atherosclerosis, may, in fact, exaggerate the sex differential in mortality. From a public health point of view, the greatest impact on the sex differential in mortality would be gained by concentrating on lifestyle changes designed to diminish atherosclerosis in men: low cholesterol diet, no smoking, optimal body weight, and active exercise.

The death rate is higher for men at all ages. Coronary heart disease accounts for 40% of the mortality difference between men and women. Another one-third is from lung cancer, emphysema, cirrhosis, accidents, and suicides. It is interesting to note that in our society the mortality difference between men and women is largely a difference in lifestyle. Smoking, drinking, coronary prone behavior, and accidents account for most of the higher male mortality rate over age 65. It has been estimated that perhaps two-thirds of the difference has been due to cigarettes alone. But we should emphasize that this is due to a greater prevalence of smoking in men. Women whose smoking patterns are similar to those of men have a similar increased risk of morbidity and mortality.²³

The Older U.S. Female Population¹⁷

Age	1990	2000	2010	2020
55–64	10.8 mill. (8.6%)	12.1 mill. (9.0%)	17.1 mill. (12.1%)	19.3 mill. (12.9%)
65–74	10.1 (8.1%)	9.8 (8.1%)	11.0 (7.3%)	15.6 (7.8%)
>75	7.8 (6.2%)	9.3 (6.2%)	9.8 (7.0%)	11.0 (6.9%)
Total	28.7	31.2	37.9	45.9

Perhaps because more women are smoking, drinking, and working, the mortality sex difference has begun to lessen. The U.S. Census Bureau projects that the difference in life expectancy between men and women will increase until the year 2050, and then level off.¹⁷ In 2050, life expectancy for women will be 82 years and for men, 76.7 years.¹³ There will be 33.4 million women 65 and older, compared with 22.1 million men.

In addition to the growing numbers of elderly people, the older population itself is getting older.²⁴ For example, in 1984, the 65–74 age group was over 7 times larger than in 1900, but the 75–84 group was 11 times larger and the 85 and older group was 21 times larger. The most rapid increase is expected between 2010 and 2030 when the baby boom generation hits 65. In the next century, the only age groups in the U.S. expected to experience significant growth will be those past age 55. In this elderly age group, women will outnumber men by 2.6 to 1. By the year 2040, there will be 8 million to 13 million people 85 years of age or older; the estimate varies according to pessimistic to optimistic projections regarding disease prevention and treatment.

Unmarried women will be an increasing proportion of the elderly. By 1983, 50% of American women aged 65–74 were unmarried (partly divorced, but largely widowed), and after age 75, 77%!²⁵ Half of men 85 and older live with their wives, but only 10% of elderly women live with their husbands. Because the unmarried tend to be more disadvantaged, there will be a need for more services for this segment of the elderly population. Older unmarried people are more vulnerable, demonstrating higher mortality rates and lower life satisfaction.

The Rectangularization of Life

The lifespan is the biological limit to life, the maximal obtainable age by a member of a species. The general impression is that human lifespan is increasing. Actually lifespan is fixed, and it is a biological constant for each species.²⁶ In fact, differences in species' lifespans argue in favor of a species-specific genetic basis for longevity. If lifespan were not fixed, it would mean an unlimited increase of our elderly. But a correct analysis of survival reveals that death converges at the same maximal age; what has changed is life expectancy—the number of years of life expected from birth. Life expectancy cannot exceed the lifespan, but it can closely approximate it. Thus the number of old people will eventually hit a fixed limit, but the percentage of a typical life spent in the older years will increase.

Our society has almost eliminated premature death. Diseases of the heart and the circulation, and cancers, are now the leading causes of death. The reason for this is not an increase or an epidemic; it is a result of our success in virtually eliminating infectious diseases. Now the major determinant is chronic disease, affected by genetics, lifestyle, the environment, and aging itself. The major achievement left to be accomplished is in cardiovascular diseases. But even if cancer, diabetes, and all circulatory diseases were totally eliminated, life expectancy would not exceed 90 years.¹⁴

J. F. Fries describes 3 eras in health and disease.²⁷ The first era existed until sometime in the early 1900s, and was characterized by acute infectious diseases. The second era, highlighted by cardiovascular diseases and cancer, is now beginning to fade into the third era, marked by problems of frailty (fading eyesight and hearing, impaired memory and cognitive function, decreased strength and reserve). Much of our medical approach is still based on the first era (find the disease and cure it), and now we have conditions that require a combination of medical, psychological, and social approaches. Our focus has been on age-dependent, fatal chronic diseases. The new challenge is with the nonfatal, age-dependent conditions, such as Alzheimer's disease, osteoarthritis, osteoporosis, obesity, and incontinence. It can be argued that health programs in the future should be evaluated by their impact on years free of disability, rather than on mortality.

The Concept of the Compression of Morbidity

Chronic illnesses are incremental in nature. The best health strategy is to change the slope, the rate at which illness develops, thus postponing the clinical illness, and if it is postponed long enough, effectively preventing it. There has been a profound change in public consciousness toward disease. Disease is increasingly seen as something not necessarily best treated by medication or surgery, but by prevention, or more accurately, by postponement.

Postponing illness is expressed by J.F. Fries as the **compression of morbidity**.^{26, 28} We would live relatively healthy lives and compress our illnesses into a short period of time just before death. Is this change really possible? The mean national body weight has decreased by 5 pounds despite a slight increase in the national average height. There has been a decrease in atherosclerosis in the U.S. Reasons include changes in the use of saturated fat, more effective detection and treatment of hypertension, increased exercise, and decreased smoking.

Smoking initiation has decreased markedly in men but, unfortunately, has remained essentially unchanged in women. In addition, female smokers begin smoking at a younger age. More young women (including teenagers) smoke than young men. It is important to note that smoking appears to have a greater adverse effect on women compared with men.²⁹ Women who smoke only 1 to 4 cigarettes per day have a 2.5-fold increased risk of fatal coronary heart disease.³⁰

Physician smokers have declined from a high of 79% to a small minority.³¹ It is interesting, and amusing, to note that the greatest decrease has been among pulmonary surgeons, not surprising, while the least decrease has been among proctologists. From the mid 1970s to the early 1990s, smoking among physicians in the U.S. declined from 18.8% to 3.3%. Unfortunately, that still amounted to approximately 18,000 physicians who smoke. The numbers are more discouraging among our professional colleagues. By 1991, (from the 1970s), smoking had declined from 31.7% to 18.3% among registered nurses and from 37.1% to only 27.2% among licensed practical nurses.

In the year 2000, approximately 30% of people in the U.S. who have not obtained a high school diploma will be smokers, but less than 10% of those with higher education will be smoking. Currently, approximately 28% of men and 23% of women are smokers.³² Cigarette smoking, therefore, continues to be the single most preventable cause of premature death in the U.S. In addition, the use of chewing tobacco, pipe smoking, and cigars contributes significantly to morbidity and mortality.

Physicians and older patients may be skeptical that quitting smoking after decades of smoking could be beneficial. In a longitudinal study of 2674 people, aged 65–74, the mortality rates for exsmokers were no higher than for nonsmokers.³³ The effects are at least partly reversible within one to five years after quitting. Even older patients who already have coronary artery disease have improved survival if they quit smoking.³⁴ No matter how old you are, if you continue to smoke, you have an increased relative risk of death. But no matter how old you are, if you quit smoking, your risk of death decreases.

Since 1970, the death rate from coronary heart disease has declined approximately 50% in the U.S. Between 1973 and 1987 in the U.S., cardiovascular mortality declined in nearly every age group. In the combined age groups up to 54 years, cardiovascular mortality decreased 42%, and in people 55 to 84 years old, 33%.²⁹ Despite our progress, we must continue to exert preventive efforts on the risk factors associated with cardiovascular disease, especially obesity, hypertension, and lack of physical activity.

The effort to improve the quality of life has an important value to society; it will decrease the average number of years that people are disabled and a liability. Frailty and disability are now the major health and social problems of society. Most significantly, this is a major financial challenge for health care systems and social programs. With evolution toward a rectangular society, the ratio of beneficiaries to taxpayers grows rapidly, jeopardizing the financial support for health and social programs. Compression of morbidity is at least one attractive solution to this problem.

Menopause as an Opportunity

Clinicians who interact with women at the time of the menopause have a wonderful opportunity and, therefore, a significant obligation. Medical intervention at this point of life offers women years of benefit from preventive health care. This represents an opportunity that should be seized.

It is logical to argue that health programs should be directed to the young. It makes sense to create good lifelong health behavior. While not underrating the importance of good health habits among the young, we would argue that the impact of teaching preventive care is more observable and more tangible at middle age. The prospects of limited mortality and the morbidity of chronic diseases are viewed with belief, understanding, and appreciation during these older years. The chance of illness is higher, but the impact of changes in lifestyle is greater.

The Perimenopausal Transition

Definition of the Perimenopausal Transition

There is only one marker, menstrual irregularity, that is used to define and establish what is called the perimenopausal transition. The **menopause** is that point in time when permanent cessation of menstruation occurs following the loss of ovarian activity. Menopause is derived from the Greek words, *men* (month) and *pausis* (cessation). The years prior to menopause that encompass the change from normal ovulatory cycles to cessation of menses are known as the **perimenopausal transitional** years, marked by irregularity of menstrual cycles. **Climacteric** indicates the period of time when a woman passes from the reproductive stage of life through the perimenopausal transition and the menopause to the postmenopausal years. Climacteric is from the Greek word for ladder.

Menstrual cycle length is determined by the rate and quality of follicular growth and development, and it is normal for the cycle to vary in individual women. Our best information comes from two longitudinal studies (with very similar results): the study of Vollman of more than 30,000 cycles recorded by 650 women and the study of Treloar of more than 25,000 woman-years in a little over 2700 women.^{35,36} The observations of Vollman and Treloar documented a normal evolution in length and variation in menstrual cycles.

Menarche is followed by approximately 5–7 years of relatively long cycles at first, and then there is increasing regularity as cycles shorten to reach the usual reproductive age pattern. In the 40s, cycles begin to lengthen again. The highest incidence of anovulatory cycles is under age 20 and over age 40. ^{37,38} At age 25, over 40% of cycles are between 25 and 28 days in length; from 25 to 35, over 60% are between 25 and 28 days. The perfect 28-day cycle is indeed the most common mode, but it totaled only 12.4% of Vollman's cycles. Overall, approximately 15% of reproductive age cycles are 28 days in length. Only 0.5% of women experience a cycle less than 21 days long, and only 0.9% a cycle greater than 35 days. ³⁹ Most women have cycles that last from 24 to 35 days, but at least 20% of women experience irregular cycles. ⁴⁰

When women are in their 40s, anovulation becomes more prevalent, and prior to anovulation, menstrual cycle length increases, beginning 2 to 8 years before menopause. ³⁶ This period of longer cycles uniformly precedes menopause no matter the age when menses cease, whether menopause is early or late. ⁴¹ The duration of the follicular phase is the major determinant of cycle length. ^{42,43} This menstrual cycle change prior to menopause is marked by elevated follicle-stimulating hormone (FSH) levels and decreased levels of inhibin, but normal levels of luteinizing hormone (LH) and slightly elevated levels of estradiol. ^{44,45,46,47 and 48}

Contrary to older belief (based on the report by Sherman, et al, ⁴²), **estradiol levels do not gradually wane in the years before the menopause, but remain in the normal range, although slightly elevated, until 6 months to 1 year before follicular growth and development cease.** The Sherman, et al, data were from a small cross-sectional study of one cycle collected from 8 women, age 46–56. More recent longitudinal studies of women as they pass through the perimenopausal transition reveal that estrogen levels do not begin to decline until less than a year before menopause. ⁴⁸ Indeed, women experiencing the perimenopausal transition actually have higher overall estrogen levels, a response that is logically explained by an increased ovarian follicular response to the increase in FSH secretion during these years. ⁴⁹

As noted, most women experience a 2- to 8-year period of time prior to menopause when anovulation becomes prevalent. ³⁶ During this period of time ovarian follicles undergo an accelerated rate of loss until eventually the supply of follicles is finally depleted. ^{50,51} In a study of human ovaries, the accelerated loss appeared to begin when the total number of follicles reached approximately 25,000, a number reached in normal women at an age of 37–38. ⁵² This loss correlates with a subtle but real increase in FSH and decrease in inhibin. The accelerated loss is probably secondary to the increase in FSH stimulation. These changes, including the increase in FSH, reflect the reduced quality and capability of aging follicles, and their reduced secretion of inhibin, the granulosa cell product that exerts an important negative feedback influence over FSH secretion by the pituitary gland. Both inhibin A and inhibin B may be involved. Luteal phase levels of inhibin A and follicular phase levels of inhibin B decrease with aging, and may antedate the rise in FSH. ^{53,54,627}

The inverse and tight relationship between FSH and inhibin indicates that inhibin is a sensitive marker of ovarian follicular competence and, in turn, that FSH measurement is a clinical assessment of inhibin. Thus, the changes in the later reproductive years (the decline in inhibin allowing a rise in FSH) reflect diminishing follicular reactivity and competence as the ovary ages. ^{45,46} The decrease in inhibin secretion by the ovarian follicles begins early (around age 35), but accelerates after 40 years of age. This is reflected in the decrease in fecundity that occurs with aging (as discussed in [Chapter 26](#)). **Furthermore, the ineffective ability to suppress gonadotropins with postmenopausal hormone therapy is a consequence of the loss of inhibin, and for this reason FSH cannot be used clinically to titer estrogen dosage.**

The perimenopausal years are a time period during which postmenopausal levels of FSH (greater than 20 IU/L) can be seen despite continued menstrual bleeding, while LH levels still remain in the normal range. Occasionally, corpus luteum formation and function occur, and the perimenopausal woman is not safely beyond the risk of an unplanned and unexpected pregnancy until elevated levels of both FSH (>20 IU/L) and LH (>30 IU/L) can be demonstrated. ⁴⁷ However, even under these circumstances, fluctuations can occur, with a period of ovarian failure followed by resumption of ovarian function. ⁴⁶ **Because variability is the rule, it would be wise to recommend the use of contraception until the postmenopausal state is definitely established.** According to the *Guinness Book of World Records*, a woman from Portland, Oregon, holds the modern record for the oldest spontaneous pregnancy, conceiving when 57 years and 120 days old.

In the longitudinal Massachusetts Women's Health Study, women who reported the onset of menstrual irregularity were considered to be in the perimenopausal period of life. ⁵⁵ The median age for the onset of this transition was 47.5 years. Only 10% of women ceased menstruating abruptly with no period of prolonged irregularity. The perimenopausal transition from reproductive to postreproductive status was, for most women, approximately 4 years in duration. In the study by Treolar, the average age for entry into the perimenopausal transition was 45.1, and the age range that included 95% of the women was 39–51. ⁵⁶ The mean duration of the perimenopausal transition was 5.0 years, with a range of 2 to 8 years.

The Perimenopausal Transition ^{36, 55, 56}

Average age of onset — 46

Age of onset for 95% of women — 39 to 51

Average duration — 5 years
Duration for 95% of women — 2 to 8 years

Preventive Health Screening of Healthy Perimenopausal Women

The most important thing a clinician can offer to the perimenopausal woman is the education she needs and desires to make therapeutic choices. This early educational process will help to build a solid relationship with patients, a relationship they will want to continue as they age.

The following recommendations are derived from our own clinical experience:

- Provide guidance and education to facilitate a patient's decision making.
- Provide time and an appropriate location for sensitive and uninterrupted discussions.
- Use educational materials, especially handouts, but also explain them using your own words.
- Involve family members during counseling and educational visits.
- Be accessible. Consider designating a member of your staff as the menopause resource person. Encourage phone calls.
- Be involved in community and hospital educational programs for the public.
- Use an effective, well-trained counselor for patients who need in-depth help in coping with life's trials and tribulations.

Preventive intervention during the perimenopausal years has three major goals. The overall objective is to prolong the period of maximal physical energy and optimal mental and social activity. A specific goal is to detect as early as possible any of the major chronic diseases, including hypertension, heart disease, diabetes mellitus, and cancer, as well as impairments of vision, hearing, and teeth. Finally, the clinician should help perimenopausal women to smoothly traverse the menopausal period of life. Preventive health care and management of the later reproductive years give clinicians an excellent opportunity to function as a woman's primary care provider.

A complete medical history and physical examination should be performed every 5 years, at about age 40, 45, 50, and 55. Annual visits should include a breast and pelvic examination, Pap test, screening for sexually transmitted diseases when appropriate, a TSH assessment in the 40s and every 2 years beginning at age 60, and hemocult testing after age 50. Annual screening mammography should begin at age 40 (discussed in [Chapter 16](#)). At each visit, appropriate testing is scheduled for specific chronic conditions, indicated immunizations are proved, and counseling covers changing nutritional needs, physical activities, injury prevention, occupational, sexual, marital, and parental problems, urinary function, and use of tobacco, alcohol, and drugs.

The Age of Menopause

Designating the average age of menopause has been somewhat difficult. Based on cross-sectional studies, the median age was estimated to be somewhere between 50 and 52.⁵⁷ These studies relied on retrospective memories and the subjective vagaries of the individual being interviewed. Until recently, studies with longitudinal follow-up to observe women and record their experiences as they pass through menopause were hampered by relatively small numbers. The Massachusetts Women's Health Study provides us with data from 2,570 women.⁵⁵

The median age for menopause in the Massachusetts Study was 51.3 years. Only current smoking could be identified as a cause of earlier menopause, a shift of approximately 1.5 years. Those factors that did not affect the age of menopause included the use of oral contraception, socioeconomic status, and marital status. Keep in mind that a median age of menopause means that only half the women have reached menopause at this age. In the classic longitudinal study by Treolar, the **average** age of menopause was 50.7, and the range that included 95% of the women was 44 to 56.⁵⁸ In a survey in the Netherlands, the average age of menopause was 50.2.⁵⁹ About 1% of women will experience menopause before the age of 40.⁶⁰

Clinical impression has suggested that mothers and daughters tend to experience menopause at the same age, and there are two studies indicating that daughters of mothers with an early menopause (before age 46) also have an early menopause.^{61, 62 and 63} There is sufficient evidence to believe that undernourished women and vegetarians experience an earlier menopause.^{61, 64} Because of the contribution of body fat to estrogen production, thinner women experience a slightly earlier menopause.⁶⁵ Consumption of alcohol is associated with a later menopause.⁶² This is consistent with the reports that women who consume alcohol have higher blood and urinary levels of estrogen, and greater bone density.^{66, 67, 68, 69 and 70}

There is no correlation between age of menarche and age of menopause.^{58, 59, 61, 71} In most studies, race, parity, and height have no influence on the age of menopause; however, two cross-sectional studies found later menopause to be associated with increasing parity.^{55, 59, 61, 65} Two studies have found that irregular menses among women in their early 40s predicts an earlier menopause.^{72, 73} A French survey detected no influence of heavy physical work on early menopause (before age 45).⁷⁴ An earlier menopause is associated with living at high altitudes,⁷⁵ There is reason to believe that premature ovarian failure can occur in women who have previously undergone abdominal hysterectomy or endometrial ablation, presumably because ovarian vascular flow has been compromised.^{76, 77} And finally, earlier menopause is associated with growth retardation in late gestation.⁷⁸

Multiple studies have consistently documented that an earlier menopause (an average of 1.5 years earlier) is a consequence of smoking. There is a dose-response relationship with the number of cigarettes smoked and the duration of smoking.^{79, 80} Even former smokers show evidence of an impact.

Unlike the decline in age of menarche that occurred with an improvement in health and living conditions, most historical investigation indicates that the age of menopause has changed little since early Greek times.^{81, 82} Others (a minority) have disagreed, concluding that the age of menopause did undergo a change, starting with an average age of about 40 years in ancient times.⁸³ If there has been a change, however, history indicates it has been minimal. Even in ancient writings, an age of 50 is usually cited as the age of menopause.

Sexuality and Menopause

Sexuality is a lifelong behavior with evolving change and development. It begins with birth (maybe before) and ends with death. The notion that it ends with aging is inherently illogical. The need for closeness, caring, and companionship is lifelong. Old people today live longer, are healthier, have more education and leisure time, and have had their consciousness raised in regard to sexuality.

Younger people, especially physicians, underrate the extent of sexual interest in older people. In a random sample of women aged 50 to 82 in Madison, Wisconsin, nearly one-half of the women reported an ongoing sexual relationship.⁸⁴ In the Duke longitudinal study on aging, 70% of men in the 67 to 77 age group were sexually active, and 80% reported continuing sexual interest, while 50% of all older women were still interested in sex.⁸⁵ In the PEPI trial, 60% of women 55–64 years old were sexually active.⁸⁶

The decline in sexual activity with aging is influenced more by culture and attitudes than by nature and physiology (or hormones). The two most important influences on older sexual interaction are the strength of a relationship and the physical condition of each partner.⁸⁶ The single most significant determinant of sexual activity for older women, therefore, is the unavailability of partners due to divorce and the fact that women are outliving men. Given the availability of a partner, the same general high or low rate of sexual activity can be maintained throughout life.^{5, 87} Longitudinal studies indicate that the level of sexual activity is more stable over time than previously suggested.^{88, 89 and 90} Individuals who are sexually active earlier in life continue to be sexually active into old age.

There are two main sexual changes in the aging woman. There is a reduction in the rate of production and volume of vaginal lubricating fluid, and there is some loss of vaginal elasticity. The dyspareunia associated with postmenopausal urogenital atrophy includes a feeling of dryness and tightness, vaginal irritation and burning with coitus, and postcoital spotting and soreness. Of course, these changes are effectively prevented by estrogen treatment. Less vaginal atrophy is noted in sexually active women than in inactive women; presumably the activity maintains vaginal vasculature and circulation.

Illness and Sex

It is not uncommon to encounter women who have had surgery that affects sexuality. The list includes vulvectomy, coronary bypass surgery, and surgery of the breast. Sexual problems are not limited, however, to surgical procedures and illnesses of the genitalia. Altered self-image can occur with diseases of any site. However, studies have not found hysterectomy to have a detrimental impact on sexuality.^{86, 91}

Sexual counseling, to be effective, must be provided to couples both before and after surgery. It is not unexpected that the surgeon may not be fully capable of providing this counseling. A major contribution from an older woman's primary clinician is to arrange for competent and experienced sexual counseling. Unfortunately, most physicians operate on the principle that if no questions are raised there is no problem. The expert surgeon should be grateful for the help of experts in psychosexual therapy. Seek out the potential for post-treatment sexual morbidity before the treatment. Assess the patient's abilities for coping and her sense of body image. Consider the quality of the patient's relationship, and be sensitive to the absence of a relationship. This entire effort may take some time. The normal state of presurgical anxiety, fear, and denial hampers good communication.

Antihypertensive agents are frequently responsible for male sexual dysfunction, but little information is available regarding female sexual function. However, remember that vaginal lubrication is the female counterpart to the male erection, and, therefore, vaginal dryness is a likely consequence. Adrenergic blocking agents are especially noted to affect libido and potency in men. Similarly, psychotropic drugs of all categories have been associated with inhibition of sexual function. Finally, one should always suspect alcoholism when patients complain of sexual dysfunction.

Hormone Production After Menopause

Shortly after the menopause, one can safely say that there are no remaining ovarian follicles.⁹² Eventually there is a 10–20-fold increase in FSH and approximately a 3-fold increase in LH, reaching a maximal level 1–3 years after menopause, after which there is a gradual, but slight, decline in both gonadotropins.^{93, 94} Elevated levels of both FSH and LH at this time in life are conclusive evidence of ovarian failure. FSH levels are higher than LH because LH is cleared from the blood so much faster (initial half-lives are about 20 minutes for LH and 3–4 hours for FSH), and perhaps because there is no specific negative feedback peptide for LH like inhibin.

The postmenopausal ovary secretes primarily androstenedione and testosterone. After menopause, the circulating level of androstenedione is about one half that seen prior to menopause.⁹⁵ Most of this postmenopausal androstenedione is derived from the adrenal gland, with only a small amount secreted from the ovary, although androstenedione is the principal steroid secreted by the postmenopausal ovary.⁹⁶ Dehydroepiandrosterone (DHEA) and its sulfate (DHEAS), originating in the adrenal gland, decline markedly with aging; in the decade after menopause the circulating levels of DHEA are approximately 70% less and levels of DHEAS are about 74% less than the levels in young adult life.⁹⁷

Testosterone production decreases by approximately 25% after menopause, but the postmenopausal ovary in most women, but not all, secretes more testosterone than the premenopausal ovary. With the disappearance of follicles and estrogen, the elevated gonadotropins drive the remaining stromal tissue in the ovary to a level of increased testosterone secretion. Suppression of gonadotropins with gonadotropin-releasing hormone (GnRH) agonist or antagonist treatment of postmenopausal women results in a significant decrease in circulating levels of testosterone, indicating the gonadotropin-dependent postmenopausal ovarian origin.^{98, 99 and 100} The total amount of testosterone produced after menopause, however, is decreased because the amount of the primary source, peripheral conversion of androstenedione, is reduced. The early postmenopausal circulating level of androstenedione decreases approximately 62% from young adult life.⁹⁷ The menopausal decline in the circulating levels of testosterone is not great, from no change in many women to as much as 15% in others.^{48, 94, 97} Nevertheless, compared with young women, the overall androgen exposure of perimenopausal women to androgens is less.¹⁰¹

Blood Production Rates of Steroids¹⁰²

	Reproductive age	Postmenopausal	Oophorectomized
Androstenedione	2–3 mg/day	0.5–1.5 mg/day	0.4–1.2 mg/day
Dehydroepiandrosterone	6–8	1.5–4.0	1.5–4.0
Dehydroepiandrosterone sulfate	8–16	4–9	4–9
Testosterone	0.2–0.25	0.05–0.18	0.02–0.12
Estrogen	0.350	0.045	0.045

Changes in Circulating Hormone Levels at Menopause^{48, 95, 103}

	Premenopause	Postmenopause
Estradiol	40–400 pg/mL	10–20 pg/mL
Estrone	30–200 pg/mL	30–70 pg/mL
Testosterone	20–80 ng/dL	15–70 ng/dL
Androstenedione	60–300 ng/dL	30–150 ng/dL

The circulating estradiol level after menopause is approximately 10–20 pg/mL, most of which is derived from peripheral conversion of estrone, which in turn is mainly derived from the peripheral conversion of androstenedione.^{95, 103, 104} The circulating level of estrone in postmenopausal women is higher than that of estradiol, approximately 30–70 pg/mL. The average postmenopausal production rate of estrogen is approximately 45 µg/24 hours, almost all, if not all, being estrogen derived from the peripheral conversion of androstenedione. The androgen:estrogen ratio changes drastically after menopause because of the more marked decline in estrogen, and an onset of mild hirsutism is common, reflecting this marked shift in the sex hormone ratio. With increasing age, a decrease can be measured in the circulating levels of dehydroepiandrosterone sulfate (DHEAS) and dehydroepiandrosterone (DHEA), whereas the circulating postmenopausal levels of androstenedione, testosterone, and estrogen remain relatively constant.^{94, 95}

Estrogen production by the ovaries does not continue beyond the menopause; however, estrogen levels in postmenopausal women can be significant, principally due

to the extraglandular conversion of androstenedione and testosterone to estrogen. The clinical impact of this estrogen will vary from one postmenopausal woman to another, depending on the degree of extraglandular production, modified by a variety of factors.

The percent conversion of androstenedione to estrogen correlates with body weight. Increased production of estrogen from androstenedione with increasing body weight is probably due to the ability of fat to aromatize androgens. This fact and a decrease in the levels of sex hormone-binding globulin (which results in increased free estrogen concentrations) contribute to the well known association between obesity and the development of endometrial cancer. Body weight, therefore, has a positive correlation with the circulating levels of estrone and estradiol.⁹⁵ Aromatization of androgens to estrogens is not limited to adipose tissue; however, because almost every tissue tested has this activity.

Eventually, the ovarian stroma is exhausted and, despite huge reactive increments in FSH and LH, no further steroidogenesis of importance results from gonadal activity. The postmenopausal ovary weighs less than 10 g, but it can be visualized by ultrasonography.¹⁰⁵

With increasing age, the adrenal contribution of precursors for estrogen production proves inadequate. In this final stage of estrogen availability, levels are insufficient to sustain secondary sex tissues.

In summary, the symptoms frequently seen and related to decreasing ovarian follicular competence and then estrogen loss in this protracted climacteric are:

1. Disturbances in menstrual pattern, including anovulation and reduced fertility, decreased flow or hypermenorrhea, irregular frequency of menses, and then ultimately, amenorrhea.
2. Vasomotor instability (hot flashes and sweats).
3. Atrophic conditions: atrophy of vaginal epithelium; formation of urethral caruncles; dyspareunia and pruritus due to vulvar, introital, and vaginal atrophy; general skin atrophy; urinary difficulties such as urgency and abacterial urethritis and cystitis.
4. Health problems secondary to long-term deprivation of estrogen: the consequences of osteoporosis and cardiovascular disease.

A precise understanding of the symptom complex the individual patient may display is often difficult to achieve. Some patients will experience severe multiple reactions that may be disabling. Others will show no reactions, or minimal reactions, that go unnoticed until careful medical evaluation.

It is helpful to classify the hormonal problems in 3 categories:

1. Those associated with relative **estrogen excess** such as dysfunctional uterine bleeding, endometrial hyperplasia, and endometrial cancer.
2. Those associated with **estrogen deprivation** such as flushes, atrophic vaginitis, urethritis, and osteoporosis.
3. Those associated with **estrogen-progestin therapy** (Chapter 18).

Problems of Estrogen Excess

Exposure to Unopposed Estrogen

Throughout the perimenopausal period, there is a significant incidence of dysfunctional uterine bleeding. Although the greatest concern provoked by this symptom is endometrial neoplasia, the usual finding is non-neoplastic tissue displaying estrogen effects unopposed by progesterone. This results from anovulation in premenopausal women and from extragonadal endogenous estrogen production or estrogen administration in postmenopausal women.

There are 4 mechanisms that could result in increased endogenous estrogen levels:

1. Increased precursor androgen (functional and nonfunctional endocrine tumors, liver disease, stress).
2. Increased aromatization (obesity, hyperthyroidism, and liver disease).
3. Increased direct secretion of estrogen (ovarian tumors).
4. Decreased levels of SHBG (sex hormone-binding globulin) leading to increased levels of free estrogen.

In all women, whether premenopausal or postmenopausal, whether on or off hormone therapy, specific organic causes (neoplasia, complications of unexpected pregnancy, or bleeding from extrauterine sites) must be ruled out. In addition to careful history and physical examination, dysfunctional uterine bleeding requires evaluation. Transvaginal ultrasonographic measurement of endometrial thickness can be utilized in postmenopausal women to avoid unnecessary biopsies.¹⁰⁶ A total endometrial thickness greater than 4 mm requires biopsy. If the uterus is normal on examination, for reasons of both accuracy and cost-effectiveness, the method of biopsy should be an office aspiration curettage, **NOT** the traditional, more costly and risky, in-hospital dilation and curettage (D and C).

We recommend the use of the plastic endometrial suction device. It is easy to use, requires no cervical dilatation, and is frequently painless. This device is as efficacious as older more painful techniques. Insertion should first be attempted without the use of a tenaculum. In many patients, this is feasible and avoids the sensation of the tenaculum grasping the cervix. Once the suction is applied, the endometrial cavity should be thoroughly curetted in all directions, just as one would with a sharp curette during a D and C. If the cannula fills up with tissue, a second and even a third cannula should be inserted until tissue is no longer obtained. Although most patients report no problems with cramps or pain, the application of suction in some patients stimulates cramping that usually passes within 5–10 minutes. Because cramping occurs in such a small minority of patients, it is not our practice to routinely give an inhibitor of prostaglandin synthesis. For repeat biopsies, in patients known to cramp, it would be helpful to use such an agent at least 20 minutes before the procedure.

Less than 10% of postmenopausal women cannot be adequately evaluated by office biopsy. Most commonly, the reason is the inability to enter the uterine cavity. In such instances, an in-hospital dilatation and curettage (D and C) is in order. **Furthermore, if the uterus is not normal on pelvic examination, the office endometrial biopsy must yield to an in-hospital D and C with hysteroscopy in order to achieve accuracy of diagnosis.**

If vulva, vagina, and cervix appear normal on inspection, perimenopausal bleeding can be assumed to be intrauterine in origin. Confirmation requires the absence of abnormal cytology on the Pap smear. The principal symptom of endometrial cancer is abnormal vaginal bleeding, but carcinoma will be encountered in patients with bleeding in only about 1–2% of postmenopausal endometrial biopsies.^{107, 108} Normal endometrium is found over half the time, polyps in approximately 3%, endometrial hyperplasia about 15% of the time, and atrophic endometrium in the rest of patients with postmenopausal bleeding. Postmenopausal bleeding should always be taken seriously. Approximately 10% of patients who have benign findings at the initial evaluation will subsequently develop significant pathology within 2 years.¹⁰⁸ **The**

persistence of abnormal bleeding demands repeated evaluation.

Additional procedures include the following:

Colposcopy and cervical biopsy for abnormal cytology or obvious lesions.

Endocervical assessment by curettage for abnormal cytology (the endocervix must always be kept in mind as a source for abnormal cytology).

Hysteroqram, hysteroscopy, or ultrasonography with the uterine instillation of saline if bleeding persists to determine the presence of endometrial polyps or submucosal fibroids.

Keep in mind that the pathologic reading, “tissue insufficient for diagnosis,” when a patient is on estrogen-progestin treatment, often represents atrophic, decidualized endometrium that yields little to the exploring curet. The clinician must be confident in his or her technique, knowing that a full investigation of the intrauterine cavity has been accomplished, then *as long as the patient does not persist in bleeding*, this reading can be interpreted as comforting and benign, the absence of pathology.

In the absence of organic disease, appropriate management of uterine bleeding is dependent on the age of the woman and endometrial tissue findings. In the perimenopausal woman with dysfunctional uterine bleeding associated with proliferative or hyperplastic endometrium (uncomplicated by atypia or dysplastic constituents), periodic oral progestin therapy is mandatory, such as 5–10 mg medroxyprogesterone acetate given daily for at least the first 10 days of each month. If hyperplasia is present, follow-up aspiration curettage after 3–4 months is required, and if progestin is ineffective and histological regression is not observed, formal curettage is an essential preliminary to alternate therapeutic surgical choices. Because hyperplasia with atypia carries with it a risk of cancer (even invasive), hysterectomy is the treatment of choice.

When monthly progestin therapy reverses hyperplastic changes (which it does in 95–98% of cases) and controls irregular bleeding, treatment should be continued until withdrawal bleeding ceases. This is a reliable sign (in effect, a bioassay) indicating the onset of estrogen deprivation and the need for the addition of estrogen. If vasomotor disturbances begin before the cessation of menstrual bleeding, the combined estrogen-progestin program can be initiated as needed to control the flushes.

If contraception is required, the healthy, nonsmoking patient should seriously consider the use of oral contraception. The anovulatory woman cannot be guaranteed that spontaneous ovulation and pregnancy will not occur. The use of a low-dose oral contraceptive will at the same time provide contraception and prophylaxis against irregular, heavy anovulatory bleeding and the risk of endometrial hyperplasia and neoplasia.

Clinicians have been made so wary of providing oral contraceptives to older women that a traditional postmenopausal hormone regimen is often utilized to treat a woman with the kind of irregular cycles usually experienced in the perimenopausal years. This addition of exogenous estrogen without an a contraceptive dose of progestin when a woman is not amenorrheic or experiencing menopausal symptoms is inappropriate and even risky (exposing the endometrium to excessively high levels of estrogen). And most importantly, a postmenopausal hormonal regimen does not inhibit ovulation and provide contraception.¹⁰⁹ The appropriate response is to regulate anovulatory cycles with monthly progestational treatment along with an appropriate contraceptive method or to utilize low-dose oral contraception (see [Chapter 15](#)). The oral contraceptive that contains 20 µg estrogen provides effective contraception, improves menstrual cycle regularity, diminishes bleeding, and relieves menopausal symptoms.¹¹⁰

A common clinical dilemma is when to change from oral contraception to postmenopausal hormone therapy. It is important to change because even with the lowest estrogen dose oral contraceptive available, the estrogen dose is four-fold greater than the standard postmenopausal dose, and with increasing age, the dose-related risks with estrogen become significant. One approach to establish the onset of the postmenopausal years is to measure the FSH level, beginning at age 50, on an annual basis, being careful to obtain the blood sample on day 6 or 7 of the pill-free week (when steroid levels have declined sufficiently to allow FSH to rise). Friday afternoon works well for patients who start new packages on Sunday. When FSH is greater than 20 IU/L, it is time to change to a postmenopausal hormone program. Because of the variability in FSH levels experienced by women around the menopause, this method is not always accurate.¹¹¹ But there is no harm in retesting after another year or two on low-dose oral contraceptives. Some clinicians are comfortable allowing patients to enter their mid-50s on low-dose oral contraception, and then empirically switching to a postmenopausal hormone regimen.

In postmenopausal women, one must view any adnexal mass as cancer until proven otherwise. Surgical intervention is usually necessary, and appropriate consultation must be obtained not only for the surgical procedure but also for suitable preoperative evaluation and preparation. Nonpalpable, asymptomatic ovarian cysts are commonly detected by ultrasonography. Cysts that are less than 5 cm in diameter and without septations or solid components have a very low potential for malignant disease and may be managed with serial ultrasound surveillance (at 3 months, 6 months, 12 months and then annually).¹¹² Surgery is recommended for symptomatic cases, if growth occurs, if internal echoes are obtained, if fluid develops in the pelvis, or if there is a family history of breast or ovarian cancer.

The Impact of Postmenopausal Estrogen Deprivation

The menopause should serve to remind patients and clinicians that this is a time for education. Certainly preventive health care education is important throughout life, but at the time of the menopause, a review of the major health issues can be especially rewarding. Besides the general issues of good health, attention is now being focused (because of their relationship to postmenopausal hormone therapy) on cardiovascular disease and osteoporosis.

During the menopausal years, some women will experience severe multiple symptoms, whereas others will show no reactions or minimal reactions that can go unnoticed. The differences in menopausal reactions in symptoms across different cultures is poorly documented, and indeed, it is difficult to do so. Individual reporting is so conditioned by sociocultural factors that it is hard to determine what is due to biological versus cultural variability.^{113, 114} For example, there is no word to describe a hot flush in Japanese, Chinese, and Mayan.¹¹⁵ Nevertheless, there is reason to believe that the nature and prevalence of menopausal symptoms are common to most women, and that variations among cultures and within cultures reflect not physiology, but differences in attitudes, societies, and individual perceptions.^{116, 117, 118} and ¹¹⁹

Vasomotor Symptoms

The vasomotor flush is viewed as the hallmark of the female climacteric, experienced to some degree by most postmenopausal women. The term “hot flush” is descriptive of a sudden onset of reddening of the skin over the head, neck, and chest, accompanied by a feeling of intense body heat and concluded by sometimes profuse perspiration. The duration varies from a few seconds to several minutes and, rarely, for an hour. The frequency may be rare to recurrent every few minutes. Flushes are more frequent and severe at night (when a woman is often awakened from sleep) or during times of stress. In a cool environment, hot flushes are fewer, less intense, and shorter in duration compared with a warm environment.¹²⁰

In the longitudinal follow-up of a large number of women, fully 10% of the women experienced hot flushes before menopause, while in other studies as many as 15–25% of premenopausal women reported hot flushes.^{9, 55, 121, 122} The frequency has been reported to be even higher in premenopausal women diagnosed with premenstrual syndrome.¹²³ In the Massachusetts Women's Health Study, the incidence of hot flushes increased from 10% during the premenopausal period to about 50% just after cessation of menses.⁵⁵ By approximately 4 years after menopause, the rate of hot flushes declined to 20%. In a community-based Australian survey, 6% of premenopausal women, 26% of perimenopausal women, and 59% of postmenopausal women reported hot flushing.¹²⁴

Although the flush can occur in the premenopause, it is a major feature of postmenopause, lasting in most women for 1–2 years but, in some (as many as 25%) for longer than 5 years. In cross-sectional surveys, up to 40% of premenopausal women and 85% of menopausal women report vasomotor complaints.¹²² In the U.S., there is no difference in the prevalence of vasomotor complaints in surveys of black and white women.^{125, 126} In a massive review of hot flushes, it was concluded that exact estimates on prevalence are hampered by inconsistencies and differences in methodologies, cultures, and definitions.¹²⁷

The physiology of the hot flush is still not understood, but it apparently originates in the hypothalamus and is brought about by a decline in estrogen. However, not all hot flushes are due to estrogen deficiency. Flushes and sweating can be secondary to diseases, including pheochromocytoma, carcinoid, leukemias, pancreatic tumors, and thyroid abnormalities.¹²⁸ Unfortunately, the hot flush is a relatively common psychosomatic symptom, and women often are unnecessarily treated with estrogen. **When the clinical situation is not clear and obvious, estrogen deficiency as the cause of hot flushes should be documented by elevated levels of**

FSH.

The Hot Flush

Premenopausal	10–25% of women
Postmenopausal: No flushes	15–25%
Daily flushing	15–20%
Duration	1–2 years average 5 plus years: 25%
Other causes:	
Psychosomatic	
Stress	
Thyroid disease	
Pheochromocytoma	
Carcinoid	
Leukemia	
Cancer	

The correlation between the onset of flushes and estrogen reduction is clinically supported by the effectiveness of estrogen therapy and the absence of flushes in hypoestrogen states, such as gonadal dysgenesis. Only after estrogen is administered and withdrawn do hypogonadal women experience the hot flush. Although the clinical impression that premenopausal surgical castrates suffer more severe vasomotor reactions is widely held, this is not borne out in objective study. ¹²⁹

Although the hot flush is the most common problem of the postmenopause, it presents no inherent health hazard. The flush is accompanied by a discrete and reliable pattern of physiologic changes. ¹³⁰ The flush coincides with a surge of LH (not FSH) and is preceded by a subjective prodromal awareness that a flush is beginning. This aura is followed by measurable increased heat over the entire body surface. The body surface experiences an increase in temperature, accompanied by changes in skin conductance, and followed by a fall in core temperature—all of which can be objectively measured. In short, the flush is not a release of accumulated body heat but is a sudden inappropriate excitation of heat release mechanisms. Its relationship to the LH surge and temperature change within the brain is not understood. The observation that flushes occur after hypophysectomy indicates that the mechanism is not dependent on or due directly to LH release. In other words, the same hypothalamic event that causes flushes also stimulates gonadotropin-releasing hormone (GnRH) secretion and elevates LH. This is probably secondary to hypothalamic changes in neurotransmitters that increase neuronal and autonomic activity. ¹³¹

Premenopausal women experiencing hot flushes should be screened for thyroid disease and other illnesses. A comprehensive review of all possible causes is available. ¹³² Clinicians should be sensitive to the possibility of an underlying emotional problem. Looking beyond the presenting symptoms into the patient's life will be an important service to the patient and her family that eventually will be appreciated. This is far more difficult than simply prescribing estrogen, but confronting problems is the only way of reaching some resolution. Prescribing estrogen inappropriately (in the presence of normal levels of gonadotropins) only temporarily postpones by a placebo response dealing with the underlying issues.

A striking and consistent finding in most studies dealing with menopause and hormonal therapy is a marked placebo response in a variety of symptoms, including flushing. In an English randomized, placebo-controlled study of women being treated with estrogen implants and requesting repeat implants, there was no difference in outcome in terms of psychological and physical symptoms comparing the women who received an active implant to those receiving a placebo. ¹³³

A significant clinical problem encountered in our referral practice is the following scenario: a woman will occasionally undergo an apparent beneficial response to estrogen, only to have the response wear off in several months. This leads to a sequence of periodic visits to the clinician and ever-increasing doses of estrogen. When a patient reaches a point of requiring large doses of estrogen, a careful inquiry must be undertaken to search for a basic psychoneurotic or psychosocial problem. To help persuade a patient that her symptoms are not due to low levels of estrogen, we find it very helpful and convincing to measure the patient's blood level of estradiol and share the result with her.

Atrophic Changes

With extremely low estrogen production in the late postmenopausal age, or many years after castration, atrophy of vaginal mucosal surfaces takes place, accompanied by vaginitis, pruritus, dyspareunia, and stenosis. Genitourinary atrophy leads to a variety of symptoms that affect the ease and quality of living. Urethritis with dysuria, urgency incontinence, and urinary frequency are further results of mucosal thinning, in this instance, of the urethra and bladder. Recurrent urinary tract infections are effectively prevented by postmenopausal intravaginal estrogen treatment. ¹³⁴ Vaginal relaxation with cystocele, rectocele, and uterine prolapse, and vulvar dystrophies are not a consequence of estrogen deprivation.

Although it is argued that genuine stress incontinence will not be affected by treatment with estrogen, others contend that estrogen treatment improves or cures stress incontinence in over 50% of patients due to a direct effect on the urethral mucosa. ^{135, 136} Most cases of urinary incontinence in elderly women are a mixed problem with a significant component of urge incontinence that definitely can be improved by estrogen therapy.

Dyspareunia seldom brings older women to our offices. A basic reluctance to discuss sexual behavior still permeates our society, especially among older patients and physicians. Gentle questioning may lead to estrogen treatment of atrophy and enhancement of sexual enjoyment. Objective measurements have demonstrated that vaginal factors that influence the enjoyment of sexual intercourse can be maintained by appropriate doses of estrogen. ¹³⁷ Both patient and clinician should be aware that a significant response can be expected by one month, but it takes a long time to fully restore the genitourinary tract (6–12 months), and clinicians and patients should not be discouraged by an apparent lack of immediate response. Furthermore, sexual activity by itself supports the circulatory response of the vaginal tissues and enhances the therapeutic effects of estrogen. Therefore sexually active older women will have less atrophy of the vagina even without estrogen.

A decline in skin collagen content and skin thickness that occurs with aging can be considerably avoided by postmenopausal estrogen therapy. ^{138, 139, 140 and 141} The effect of estrogen on collagen is evident in both bone and skin; bone mass and collagen decline in parallel after menopause and estrogen treatment reduces collagen turnover and improves collagen quality. ^{142, 143} Although it is uncertain whether estrogen treatment can affect physical appearance, at least one study demonstrated not only an increase in facial skin thickness, but an improvement in wrinkles with topical estrogen. ¹⁴⁴ More impressively, data from the U.S. First National Health and Nutrition Examination Survey indicated that estrogen use was associated with a lower prevalence of skin wrinkling and dry skin. ¹⁴⁵ However, smoking is a major risk factor for facial skin wrinkling, and hormone therapy cannot diminish this impact of smoking. ¹⁴⁶

One of the features of aging in men and women is a steady reduction in muscular strength. Many factors affect this decline, including height, weight, and level of physical activity. However, women currently using estrogen have been reported to demonstrate a lesser decline in muscular strength, although at least one study could detect no impact of estrogen. ^{147, 148 and 149} This is an important issue because of the potential protective consequences against fractures, as well as a benefit due to the ability to maintain vigorous physical exercise.

Psychophysiologic Effects

The view that menopause has a deleterious effect on mental health is not supported in the psychiatric literature, or in surveys of the general population. ^{121, 122, 150, 151} The concept of a specific psychiatric disorder (involutional melancholia) has been abandoned. Indeed, depression is less common, not more common, among middle-aged women, and the menopause cannot be linked to psychological distress. ^{3, 4, 5, 6, 7, 8 and 9, 152} The longitudinal study of premenopausal women indicates that hysterectomy with or without oophorectomy is not associated with a negative psychological impact among middle-aged women. ¹⁵³ And longitudinal data from the Massachusetts Women's Health Study document that menopause is not associated with an increased risk of depression. ¹⁵⁴ Although women are more likely to experience depression than men, this sex difference begins in early adolescence not at menopause. ¹⁵⁵

The U.S. National Health Examination Follow-up Study includes both longitudinal and cross-sectional assessments of a nationally representative sample of women. This study has found no evidence linking either natural or surgical menopause to psychologic distress.¹⁵⁶ Indeed, the only longitudinal change was a slight decline in the prevalence of depression as women aged through the menopausal transition. Results in this study were the same in estrogen users and non-users.

A negative view of mental health at the time of the menopause is not justified; many of the problems reported at the menopause are due to the vicissitudes of life.^{157, 158} Thus, there are problems encountered in the early postmenopause that are seen frequently, but their causal relation with estrogen is unlikely. These problems include fatigue, nervousness, headaches, insomnia, depression, irritability, joint and muscle pain, dizziness, and palpitations. Indeed, men and women at this stage of life both express a multitude of complaints, which do not reveal a gender difference that could be explained by a hormonal cause.¹⁵⁹

Attempts to study the effects of estrogen on these problems have been hampered by the subjectivity of the complaints (high placebo responses) and the “domino effect” of what reduction of hot flushes does to the frequency of the symptoms. Using a double-blind crossover prospective study format, Campbell and Whitehead concluded many years ago that many symptomatic “improvements” ascribed to estrogen therapy result from relief of hot flushes—a “domino” effect.¹⁶⁰

A study of 2001 Australian women aged 45–55 focused on the utilization of the health care system by women in the perimenopausal period of life.¹¹ Users of the health care system in this age group were frequent previous users of health care, less healthy, and had more psychosomatic symptoms and vasomotor reactions. These women were more likely to have had a significant previous adverse health history, including a past history of premenstrual complaints. This study emphasized that perimenopausal women who seek health care help are different from those who do not seek help, and they often embrace hormone therapy in the hope it will solve their problems. Similar findings have been reported in a cohort of British women.¹⁶¹ It is this population that is seen most often by clinicians, producing biased opinions regarding the menopause among physicians. We must be careful not to generalize to the entire female population the behavior experienced by this relatively small group of women. Most importantly, perimenopausal women who present to clinicians often end up being treated with estrogen inappropriately and unnecessarily. Nevertheless, it is well-established that a woman's quality of life is disrupted by vasomotor symptoms, and estrogen therapy provides impressive improvement.^{162, 163} Patients are grateful to be the recipients of this “domino” effect.

Emotional stability during the perimenopausal period can be disrupted by poor sleep patterns. Hot flushing does have an adverse impact on the quality of sleep.¹⁶⁴ Estrogen therapy improves the quality of sleep, decreasing the time to onset of sleep and increasing the rapid eye movement (REM) sleep time.^{162, 165, 166} Perhaps flushing may be insufficient to awaken a woman but sufficient to affect the quality of sleep, thereby diminishing the ability to handle the next day's problems and stresses. An improvement in insomnia with estrogen treatment can even be documented in postmenopausal women who are reportedly asymptomatic.¹⁶⁶

Thus, the overall “quality of life” reported by women can be improved by better sleep and alleviation of hot flushing. However, it is still uncertain whether estrogen treatment has an additional direct pharmacologic antidepressant effect or whether the mood response is an indirect benefit of relief from physical symptoms and, consequently, improved sleep. Utilizing various assessment tools for measuring depression, improvements with estrogen treatment have been recorded in oophorectomized women.^{167, 168} In the large prospective cohort study of the Rancho Bernardo retirement community, no benefit could be detected in measures of depression in current users of postmenopausal estrogen compared with untreated women.¹⁶⁹ Indeed, treated women had higher depressive symptom scores, presumably reflecting treatment selection bias; symptomatic and depressed women seek hormone therapy. Nevertheless, estrogen therapy is reported to have a more powerful impact on women's well-being beyond the relief of symptoms such as hot flushes.¹⁷⁰ In elderly depressed women, improvements in response to fluoxetine were enhanced by the addition of estrogen therapy.¹⁷¹

Cognition and Alzheimer's Disease

Depending on the method of assessment, evidence for beneficial effects of estrogen on cognition can be found in the literature, especially in verbal memory.^{172, 173} However, the effects in healthy women are not impressive, and perhaps of little clinical value. A short-term study failed to document an objective improvement in memory, although a slight improvement in mood was recorded.¹⁷⁴ Another short-term (3 months) randomized, double-blind study could detect no improvement in cognitive performance compared with placebo treatment.¹⁷⁵ On the other hand, estrogen treatment of women immediately after bilateral oophorectomy was associated with improvement in certain, but not all, specific tests of memory, and healthy postmenopausal women taking estrogen scored higher on tests of immediate and delayed recall.^{176, 177} In a case-control study of women aged 55–93 years, estrogen users had better recall of proper names, but no improvement in word recall.¹⁷⁸ Women in the Baltimore Longitudinal Study of Aging who were using estrogen performed better in a test of short-term visual memory.¹⁷⁹ In a New York City cohort of women, the use of estrogen was associated with better performance in tests of cognition, and better performance in verbal memory.¹⁸⁰ Perhaps a lack of agreement is due to the variability in test vehicles and the specific aspects of memory function studied. Furthermore, there is impressive individual variability, and when differences have been observed they have not been large, and perhaps of little clinical importance. In addition, any beneficial effects may be attenuated by progestational agents.¹⁷³ Fatigue, irritability, headache, and depression are not thought to be estrogen-related phenomena.

Tests of cognitive function in the prospective cohort study of the Rancho Bernardo retirement community failed to support a positive impact of postmenopausal estrogen on mental function in old age.¹⁸¹ The Rancho Bernardo study has the attribute of being large in size (800 women), which also allowed for testing of duration of use (there was no benefit that resulted from long duration of use). There were too few patients in the Rancho Bernardo cohort with dementia to assess the impact of estrogen on Alzheimer's disease.

Up to 3 times as many women as men develop Alzheimer's disease. Estrogen is capable of protecting central nervous system function by means of multiple mechanisms. For example, estrogen protects against neuronal cytotoxicity induced by oxidation; estrogen reduces the serum concentration of amyloid P component (the glycoprotein found in Alzheimer's neurofibrillary tangles); and estrogen increases synapses and neuronal growth, especially dendritic spine density.^{182, 183 and 184} Progestational agents do not exert similar actions.

Important early findings have indicated that Alzheimer's disease and related dementia occurred less frequently (perhaps as much as 60% less) in estrogen users, and the effect was greater with increasing dose and duration of use.^{185, 186} In the Baltimore Longitudinal Study of Aging (a prospective cohort), the risk of Alzheimer's disease was 54% reduced, in a cohort in New York City, the risk was reduced 60%, and in the Italian Longitudinal Study of Aging, the risk was 72% reduced in estrogen users.^{187, 188 and 189} Furthermore, the administration of estrogen to patients with Alzheimer's disease has improved cognitive performance.¹⁹⁰ The presence of estrogen therapy also enhances the beneficial response to tacrine in women with Alzheimer's disease.¹⁹¹ If this effect of estrogen can be verified in the ongoing clinical trials, the potential impact on this dreadful condition that is more prevalent in women cannot be underrated. This would be another argument in favor of long-term treatment.

Cardiovascular Disease

Diseases of the heart are the leading cause of death for women in the United States, followed by malignant neoplasms, cerebrovascular disease, and motor vehicle accidents. Since 1984, the number of cardiovascular disease deaths for women has exceeded those for men.³² About 20,000 women under age 65 die of myocardial infarction each year in the U.S. The death rate for coronary heart disease in women is approximately 3 times greater than the rates for breast cancer and lung cancer. Female survivors of a first myocardial infarction face the prospects of a second myocardial infarction in 31%, a stroke in 18%, and sudden death in 6%.

Most cardiovascular disease results from atherosclerosis in major vessels. The risk factors are the same for men and women: high blood pressure, smoking, diabetes mellitus, and obesity. However, when controlling for these risk factors, men have a risk of developing coronary heart disease over 3.5 times that of women. Even taking into consideration the changing lifestyle of women (e.g., employment outside the home), women still maintain their advantage in terms of risk for coronary heart disease. With increasing age, this advantage is gradually lost, and cardiovascular disease becomes the leading cause of death for both older women and older men.

Cardiovascular disease, especially atherosclerosis, is a consequence of multiple metabolic changes that interact with each other.

1. Adverse changes in the circulating lipid-lipoprotein profile.
2. Oxidation of LDL, producing a modified LDL that is chemotactic for circulating monocytes, that inhibits macrophage motility (thus trapping macrophages in the intima), and that causes cell injury and death in the endothelium.
3. Endothelial injury and dysfunction affecting nitric oxide and prostacyclin production.
4. Macrophage migration and functions, influenced by growth factors and cytokines.
5. Proliferation and migration of smooth muscle cells, also influenced by growth factors and cytokines; these cells become the dominant cell type and the source of the connective tissue matrix in the atherosclerotic lesion, the fibrous plaque.

6. Vasoconstriction and thrombotic events.
7. Remodeling of coronary arteries. An artery is able to respond to a developing atherosclerotic plaque by increasing its overall diameter in an attempt to maintain flow.¹⁹² The mechanism of this adaptive remodeling is not known, but the extent of this process must affect the risk of occlusion and infarction.

The fatty streak in arterial vessels is the precursor to clinically significant lesions. The fatty streak lesion, therefore, antedates the fibrous plaque, developing under the endothelial surface and dominated by fat-laden macrophages (the foam cells). The process is initiated by the aggregation and adherence of circulating monocytes to a site on the arterial endothelium. When the monocytes penetrate through the endothelium and enter the intima, they become loaded with lipids and converted to the foam cells. Modification of LDL, especially oxidation, is crucial in this conversion of monocytes to foam cells. The initial step, adherence of monocytes to endothelium, can be induced by elevated cholesterol and LDL-cholesterol in the circulation.

During the reproductive years, women are “protected” from coronary heart disease. For this reason, women lag behind men in the incidence of coronary heart disease by 10 years, and for myocardial infarction and sudden death, women have had a 20-year advantage. The reasons for this are complex, but a significant contribution to this protection can be assigned to the higher high-density lipoprotein (HDL) levels in younger women, an effect of estrogen. Throughout adulthood, the blood HDL-cholesterol level is about 10 mg/dL higher in women, and this difference continues through the postmenopausal years. Total and low-density (LDL)-cholesterol levels are lower in premenopausal women than in men, although the levels gradually increase with aging and after menopause they rise rapidly.^{193, 194, 195 and 196} After menopause the risk of coronary heart disease doubles for women as the atherogenic lipids about age 60 reach levels greater than those in men. These changes can be favorably reduced by dietary changes.^{197, 198} Of course, these lipid changes at menopause (whether natural or surgical) can be reversed with estrogen treatment.¹⁹⁹ At all ages, however, HDL-cholesterol values in women are 10 mg/dL higher than in men.

Prospective studies have documented the strong association between total cholesterol and coronary heart disease in women; however, coronary heart disease risk appears at higher total cholesterol levels for women than for men.^{200, 201} Women with total cholesterol concentrations greater than 265 mg/dL have rates of coronary heart disease 3 times that of women with low levels. Even in elderly women, a high total cholesterol remains a significant predictor of heart disease; but the strength of the association between the cholesterol level and cardiovascular disease decreases with aging, and by age 80 the cost and benefits may not justify cholesterol intervention.²⁰² This is the reason for ceasing lipoprotein screening after age 75 in patients with normal lipids. However, this decision should be individualized, taking

into account the vigor and health of the patient.

The strongest predictor of coronary heart disease in women is a low HDL-cholesterol, [200](#), [201](#), [203](#). The average HDL-cholesterol in women is approximately 55–60 mg/dL. A decrease in HDL-cholesterol of 10 mg/dL increases coronary heart disease risk by 40–50%. In women (and men) who have normal total cholesterol and LDL-cholesterol levels, but low HDL-cholesterol levels, treatment with lovastatin reduced the risk of an acute major coronary event by approximately 37%. [204](#) Women with very high HDL-cholesterol levels (over 55–60 mg/dL) have virtually no increased risk of heart disease even in the presence of elevated concentrations of total cholesterol. ***It is appropriate to be concerned when HDL-cholesterol levels are less than 50 mg/dL.***

The Optimal Cholesterol/Lipoprotein Profile

Total cholesterol—Less than 200 mg/dL

HDL-cholesterol—Greater than 50 mg/dL

LDL-cholesterol—Less than 130 mg/dL

Triglycerides —Less than 250 mg/dL

In some studies, elevated LDL-cholesterol has been identified as a predictor of coronary heart disease in women, but in others it has not. [205](#), [206](#) It should be emphasized that modest elevations in blood pressure markedly increase the risk associated with an elevated LDL-cholesterol or a low HDL-cholesterol.

Triglycerides are also an important risk factor for coronary heart disease in women; however, an increased rate of cardiovascular disease is observed only when increased triglyceride levels are present in association with low HDL-cholesterol levels, [206](#), [207](#). If the triglyceride level is greater than 400 mg/dL and the HDL-cholesterol is less than 50 mg/dL, the risk of heart disease is substantially increased. Patients with an elevated triglyceride level and a positive family history for heart disease most likely have an autosomal dominant disorder classified as familial combined hyperlipidemia. This disorder accounts for most myocardial infarctions in women less than 40 years old. Triglyceride levels of 200–400 mg/dL are considered borderline elevated. Triglyceride levels can be elevated because of obesity, smoking, and lack of exercise. Weight loss alone can return elevated triglyceride levels to normal.

The proportion of HDL-cholesterol in the total cholesterol decreases with age in women and results in an age-related increase in the ratio of total cholesterol to HDL-cholesterol, from 3.4 at ages 25–34 years to 4.7 at ages 75–89 years. When the ratio exceeds 7.5, women have the same coronary heart disease risk as men. The optimal ratio is about 3.5, and risk increases significantly above 5.0. ***For ease of remembering, consider anything below 4.0 as good and any ratio above 4.0 as unhealthy.*** However, attention should not be totally focused on this ratio; the LDL-cholesterol and triglyceride levels cannot be ignored, and the entire lipid profile should be assessed.

Heart Disease Risk Based on Cholesterol/HDL Ratio

Lowest risk —Less than 2.5

Below average risk—2.5–3.7

Average risk —3.8–5.6

High risk —5.7–8.3

Dangerous —Greater than 8.3

An important contribution to the gender difference in cardiovascular disease prevalence and age of onset is the favorable effect of estrogen on important endothelial events. Vasodilatory and antithrombotic activities can be attributed to endothelial production of nitric oxide and prostacyclin, a process favorably influenced by estrogen. Hypercholesterolemia adversely affects this important endothelial process, and estrogen protects this important endothelial function in the presence of hypercholesterolemia. [208](#) Estrogen inhibits the oxidation of LDL, and also protects against the toxic effects of oxidized LDL on the endothelium.

Observational studies and clinical trials indicate that the major determinants of blood lipid levels are the same for both sexes. A diet high in saturated fatty acids and dietary cholesterol unfavorably increases blood lipids. Excess caloric intake and obesity decrease HDL-cholesterol and increase total cholesterol, LDL-cholesterol, and triglycerides. Smoking decreases HDL-cholesterol (and also produces lower estrogen levels and an earlier menopause). Genetic defects of receptor-mediated cholesterol uptake account for only a small percentage of hyperlipidemia in men and women. There is also evidence that men and women who had impaired fetal growth have increased levels of cholesterol and LDL-cholesterol in middle age. [209](#) The speculation is that impaired liver growth in utero produces a permanent adverse change in cholesterol and lipoprotein metabolism. Reduced fetal growth also leads to insulin resistance and lower HDL-cholesterol levels, most severe in those who become obese. [210](#)

Another newly appreciated factor is the connection between hormones and fat. Adiposity of the trunk is a risk factor for coronary heart disease in women and is associated with a relatively androgenic hormonal state, hypertension, and disorders of lipid and carbohydrate metabolism. [211](#) Central fat distribution in women is positively correlated with increases in total cholesterol, triglycerides, and LDL and negatively correlated with HDL. [212](#) The atherogenic lipid profile associated with abdominal adiposity is at least partly mediated through an interplay with insulin and estrogen. [213](#) It is worth noting that there is a strong correlation between the magnitude of the worsening in cardiovascular risk factors (lipid and lipoprotein changes, blood pressure, and insulin levels) and the amount of weight gained during the menopausal transition. [214](#) Attention to weight gain during middle age is one of the most important components of good preventive health care. However, weight gain at menopause is not an effect of hormonal changes, but it reflects diet, exercise, and aging. [214](#)

In the last 30 years, stroke mortality has declined by 60% and mortality from coronary heart disease by more than 50% in the U.S. [215](#) Improvements in medical and surgical care can account for some of this decline, but 60–70% of the improvement is due to preventive measures. Excellent data from epidemiologic studies and clinical trials demonstrate a decline in stroke and heart disease morbidity and mortality from smoking cessation, blood pressure reduction, and lowering of cholesterol. [216](#), [217](#) It is now recognized that there is a strong and growing scientific basis for preventive medicine and health promotion efforts in clinical practice.

We now have another opportunity. Postmenopausal hormone therapy deserves consideration as a legitimate component of preventive health care for older women. One can argue convincingly that protection against cardiovascular disease is the major benefit of postmenopausal estrogen treatment, and the magnitude of this benefit is considerable. There is a sound rationale for this protection in the link between cardiovascular disease and the sex hormones.

The Evidence for Protection Against Cardiovascular Disease by Estrogen

A review of case-control studies in the literature finds overwhelming support for about a 50% reduced risk of coronary heart disease in estrogen users. [218](#), [219](#), [220](#), [221](#), [222](#), [223](#), [224](#), [225](#), [226](#), [227](#), [228](#), [229](#), [230](#) and [231](#) A population-based case-control study in Rochester, Minnesota, concluded that if all eligible women utilized estrogen, myocardial

infarctions could be reduced as much as 45%, an impact comparable with the elimination of smoking or the prevention of hypertension. ²³¹

One important and large cross-sectional study (1444 cases and 744 controls) compared postmenopausal women undergoing coronary arteriography and therefore utilized an objective end point for coronary disease. ²²⁶ The relative risk of coronary disease was decreased 56% in estrogen users after adjustment for age, cigarette smoking, diabetes, cholesterol, and hypertension. Even women over age 70 demonstrated a 44% reduction in risk. In three other studies of women undergoing angiography, a comparison of coronary artery occlusion in users and nonusers of estrogen indicated a significant protective effect of postmenopausal estrogen. ^{227 228} and ²²⁹

In cohort studies, only two produced conflicting data. ^{232 233 234 235 236 237 238 239 240 241 242 243} and ²⁴⁴ The Walnut Creek Study, one initially with conflicting data, had, in its first report, only 26 women with myocardial infarctions, and only 9 were estrogen users. ²³⁵ An update of the Walnut Creek data documented a 50% reduction in death from diseases of the circulatory system when adjusted for all other factors. ²⁴⁵

The Framingham Heart Study presented data in 1978, and in 1985, which argued that there was a 50% *increased* risk for cardiovascular disease among estrogen users, although there was no difference in fatality rates between users and nonusers. ^{233 236} Because of the respect the Framingham Heart Study carries, its impact was significant. Subsequent re-analysis of the Framingham data (eliminating angina as a consideration) by the authors of the study reversed their conclusion. ²⁴⁶ The early reports from the Framingham Heart Study, therefore, stand in lonely opposition to overwhelming evidence that appropriately low doses of estrogen protect postmenopausal women against cardiovascular disease.

In the Nurses' Health Study with 16 years of follow-up, the age-adjusted relative risk of coronary disease in current users of estrogen alone was 40% reduced, and with estrogen and progestin, 61% reduced. ²⁴³ No association between use and stroke was observed, but there were relatively few strokes in this cohort. Adjustments for diet, use of vitamins, use of aspirin, and physical activity did not change the conclusions. The beneficial impact was observed to diminish beginning 3 years after discontinuation. It was suggested that higher doses might be harmful because there was an apparent increase in the risk of coronary disease among women taking more than 0.625 mg conjugated estrogens per day. Current postmenopausal hormone users in the Nurses' Health Study have had a 37% reduced risk of mortality, due largely to protection against coronary heart disease, an effect that was still present after adjusting for dietary factors, alcohol intake, vitamin or aspirin use, and exercise. ²⁴⁴

The Lipid Research Clinics Follow-up Study (a prospective 8.5-year follow-up of 2270 women) demonstrated a 63% reduction in the relative risk of fatal cardiovascular disease in current estrogen users, including a protective effect in current and exsmokers. ²³⁷ The National Health and Nutrition Examination Survey Epidemiologic Follow-up Study is a longitudinal study of a cohort derived from the first National Health and Nutrition Examination Survey (NHANES I) conducted from 1971 to 1975. ²⁴⁰ The use of estrogen significantly reduced (40% to 60%) the risk of cardiovascular disease regardless of the age of menopause. Long-term estrogen users (10–25 years) were identified in the Kaiser Permanente Medical Care Program in California and found to have a 46% reduced risk of all-cause mortality, largely due to reductions in cardiovascular disease. ²⁴⁷ Women who used estrogen for more than 15 years had a 30% greater reduction in the risk for mortality than short-term users.

Electron beam tomography (also called ultrafast computed tomography) can assess the presence of coronary artery disease by quantifying the amount of calcium in the coronary arteries, a measure that is known to correlate with the degree of disease and the risk of coronary events. Studies using this technique have demonstrated a lower prevalence of coronary artery calcium in women under age 60, a prevalence comparable to men (of any age) in women older than 60, and less calcium (and therefore less coronary artery disease) in women using postmenopausal hormone therapy compared with nonusers. ²⁴⁸

An important question has been raised, asking whether estrogen treatment is a marker for variables (such as better diet and better health care) that place postmenopausal estrogen users in a low risk group for cardiovascular disease (the “healthy user” effect). And indeed, women who choose to use hormone therapy have been reported to have a better cardiovascular risk profile than nonusers. ²⁴⁹ This question has been addressed by the Lipid Research Clinics study, the Leisure World Study, and the Nurses' Health Study. ^{237 250 251} These epidemiologists concluded that their evidence strongly indicates that in women receiving estrogen treatment who have the same risk factors for cardiovascular disease as those not receiving treatment the same beneficial effect of estrogen is present. A cohort follow-up study in Southeastern New England documented similar levels of total cholesterol, HDL-cholesterol, body mass index, and blood pressure in estrogen users and non-users, indicating that selection of significantly more healthy women for estrogen use cannot fully explain the beneficial effect of estrogen on the risk of cardiovascular disease. ²⁵² In a comparison of health variables among users and non-users in south Australia, there was no evidence to support the presence of a “healthy user” effect. ²⁵³ This issue will not be settled definitively until data are available from the ongoing long-term randomized clinical trials of postmenopausal hormone therapy.

Stroke

The incidence of stroke in women aged 45–64 years (1–2 per 1000 per year) has changed little in the past few decades; however, mortality rates have decreased. ²⁵⁴ In contrast to the uniform results from observational studies of the association between postmenopausal hormone therapy and coronary heart disease, epidemiologic data over the last 20 years regarding estrogen use and stroke have not been consistent. The many studies have indicated either no effect of postmenopausal hormone therapy on the risk of stroke or a reduction in risk associated with estrogen or estrogen-progestin use. ^{234 235 237 243 255 256 257 258 259 260 261} and ²⁶²

In a large Danish case-control study, no impact could be detected of either estrogen or combined estrogen and progestin on the risk of non-fatal stroke, both thromboembolic and hemorrhagic. ²⁶¹ A case-control study from Seattle found about a 50% reduced risk of subarachnoid hemorrhage with the use of postmenopausal hormone therapy, and the effect was even greater among smokers. ²⁶⁰ Positive relationships with duration and recency of use argued in favor of a causal association. In the prospective study of the Leisure World cohort, estrogen therapy was associated with a 46% overall reduction in the risk of death from stroke, with a 79% reduction in recent users. ²⁵⁵ This protection was present in both women with and without hypertension and in both smokers and nonsmokers. This level of protection was similar to that observed in this same Leisure World population for estrogen protection against deaths due to myocardial infarction. ²³⁹ The failure to observe protection against stroke in the Nurses' Health Study cohort is in striking contrast to the Leisure World cohort. ²⁴³ Indeed, in the Nurses' Health Study cohort, there was a slight increase (not statistically significant) in risk for thromboembolic stroke in current estrogen users. The population-based cohort study in Uppsala, Sweden, documented a 30% reduced incidence of stroke in postmenopausal users of estrogen, and, importantly, women prescribed an estrogen-progestin combination, containing a significant dose of the potent androgenic agent levonorgestrel, also experienced a reduced incidence of stroke. ²⁵⁹ A reduced risk for mortality from stroke in this Swedish study was confined to intracerebral hemorrhage. ²⁶³

Within this confusing mixture of results, there is one consistent observation. The cohort studies (with a sufficient number of cases) that have assessed the impact of hormone use on the risk of death from stroke have all indicated a beneficial impact. For example, the National Health and Nutrition Examination Survey (NHANES) recruited a very large cohort of women in 1971–1975 for epidemiologic analysis. The follow-up longitudinal study of this cohort yielded a U.S. national sample of 1910 white postmenopausal women. Postmenopausal hormone use in this cohort provided a 31% reduction in stroke incidence and a strongly significant 63% reduction in stroke mortality. ²⁵⁸ These relative risks were present even after adjusting for age, hypertension, diabetes, body weight, smoking, socioeconomic status, and previous cardiovascular disease. This study specifically addressed the criticism that one should expect less disease in estrogen users because they are healthier. After adjusting for physical activity as a marker of general health status, the risk estimates remained identical. By virtue of the size of the cohort and the magnitude of the hormone effect, the results of this study provide impressive evidence of the beneficial impact of postmenopausal estrogen on the risk of dying from a stroke.

The epidemiologic evaluation of the association between postmenopausal hormone therapy and stroke is consistent with the possibility that hormone use decreases the severity of strokes, and, thus, reduces the incidence of fatal strokes.

Hypertension

Hypertension is both a risk factor for cardiovascular mortality and a common problem in older people. It is important, therefore, to know that no relationship has been established between hypertension and the doses of estrogen used for postmenopausal therapy. Studies have either shown no effect or a small, but statistically significant, decrease in blood pressure due to estrogen treatment. ^{264 265 266 267} and ²⁶⁸ This has been the case in both normotensive and hypertensive women. ^{269 270} and ²⁷¹ The addition of a progestin does not affect this response. ^{272 273} Discontinuing hormone therapy in women with hypertension does not result in a decrease in blood pressure (an expected response if the treatment were raising blood pressure), and in some patients discontinuation is followed by an increase in blood pressure. ²⁷⁴

The acute administration of estrogen to women with hypertension is followed by decreases in blood pressure, pulse rate, and circulating levels of norepinephrine. ²⁷⁵

The very rare cases of increased blood pressure due to oral estrogen therapy truly represent idiosyncratic reactions. Because of the protective impact of appropriate estrogen treatment on the risk of cardiovascular disease, it can be argued that a woman with controlled hypertension is in need of that specific benefit of estrogen. Indeed, in the Nurses' Health Study, hypertensive women who used postmenopausal hormone therapy did have a reduced risk of coronary heart disease. ²⁴³ Blood pressure should be assessed every 6 months in hypertensive women being treated with postmenopausal hormones, and if the blood pressure is labile, every 3 months.

Mechanisms for Estrogen's Protection Against Cardiovascular Disease

A Favorable Impact on Lipids and Lipoproteins

The most important lipid effects of postmenopausal estrogen treatment are the reduction in LDL-cholesterol and the increase in HDL-cholesterol. Although it is now recognized that this is not the sole mechanism for estrogen's beneficial impact on cardiovascular disease, the lipid effects still play a substantial role. ²⁷⁶

Estrogen increases triglyceride levels and increases LDL catabolism as well as lipoprotein receptor numbers and activity, resulting in decreasing LDL levels. ^{277, 278} and ²⁷⁹ The increase in HDL levels, particularly due to the HDL₂ subfraction, is to an important degree the consequence of the inhibition of hepatic lipase activity, which converts HDL₂ to HDL₃. Postmenopausal estrogen therapy with or without added progestin also produces a beneficial reduction in the circulating levels of lipoprotein(a). ²⁸⁰

LDL particle size gets smaller (potentially a more atherogenic adverse effect) with estrogen treatment, a change that is associated with an increase in the triglyceride content of LDL; however, it is not certain to what degree this change is related to dose nor is the clinical significance understood. ²⁸¹ The addition of a progestin does not affect this response. ^{194, 272, 273} Furthermore, although small LDL is more atherogenic because it is more easily oxidized, this change in LDL particle size may be compensated by the antioxidant activity of estrogen, which protects against atherosclerosis by inhibiting lipoprotein oxidation. ²⁸² Indeed, in the monkey, a smaller, more dense LDL is produced in response to estrogen, and this smaller LDL is less atherogenic. ²⁸³ In addition, the increase in triglycerides is associated with an increase in a form (buoyant) of very low density lipoprotein (VLDL), a form that is more rapidly transported and thus less likely to be atherogenic. ²⁸⁴ Therefore, estrogen induces a change in LDL toward a smaller more dense particle, but it is in a form with a more rapid turnover in the circulation, allowing less time for oxidation and acquisition of cholesterol.

The changes in circulating apolipoprotein levels mirror those of the lipoproteins: apolipoprotein B (the principal surface protein of LDL) levels diminish in response to estrogen, and apolipoprotein A-I (the principal apolipoprotein of HDL) increases. The HDL and triglyceride increases induced by estrogen treatment are attenuated if progestins are added in sufficient doses. ^{272, 285, 286} Both estrogen and exercise favorably affect the lipid and lipoprotein profile; however, in a comparison of exercise and estrogen treatment, combining estrogen and exercise did not produce a synergistic outcome. ²⁸⁷ On the other hand, the concomitant administration of estrogen and an HMG-CoA reductase inhibitor (pravastatin) produced a more favorable change in the lipid profile in hypercholesterolemic women than either treatment alone. ²⁸⁸

The degree to which estrogen-induced lipid changes contribute to the overall protection against cardiovascular disease exerted by estrogen is uncertain. One analysis suggested that 25% of the estrogen effect could be attributed to lipid changes. ²³⁷ Certainly the lipid story is not as important as we once thought it was; nevertheless, it should not be underrated. One study concluded that estrogen-induced lipid changes could reduce the risk of coronary artery disease by about 50% in women who have abnormal lipids. ²⁸¹

Direct Antiatherosclerotic Effects

Important studies in monkeys support the protective action of estrogen against atherosclerosis, emphasizing mechanisms independent of the cholesterol-lipoprotein profile. Oral administration of a combination of estrogen and a high dose of progestin to monkeys fed a high-cholesterol diet decreased the extent of coronary atherosclerosis despite a reduction in HDL-cholesterol levels. ^{289, 290} and ²⁹¹ In somewhat similar experiments, estrogen treatment markedly prevented arterial lesion development in rabbits, and this effect was not reduced by adding progestin to the treatment regimen. ^{292, 293, 294} and ²⁹⁵ In this same rabbit model, raloxifene also inhibited the development of atherosclerosis, but not as effectively as estrogen. ²⁹⁶ These findings of a direct effect against atherosclerosis suggest that women with already favorable cholesterol profiles would benefit through this additional action. And, in considering the impact of progestational agents, lowering of HDL is not necessarily atherogenic if accompanied by an increased estrogen impact.

The monkey studies have been extended to a postmenopausal model (ovariectomized monkeys). Compared with no hormone treatment, treatment with either estrogen alone or estrogen with progesterone in a sequential manner significantly reduced atherosclerosis, once again independently of the circulating lipid and lipoprotein profile. ^{297, 298} A direct inhibition of LDL accumulation and an increase in LDL metabolism in arterial vessels could be demonstrated in these monkeys being fed a highly atherogenic diet. ²⁹⁹ However, the daily administration of medroxyprogesterone acetate in this monkey model prevented the beneficial effect of conjugated estrogen on coronary artery atherosclerosis. ³⁰⁰

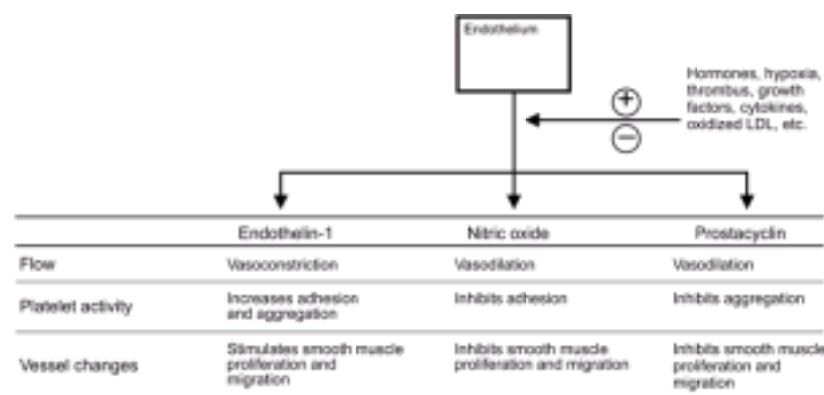

In postmenopausal women, the prevalence of atherosclerosis is reduced using either estrogen alone or combined estrogen-progestin therapy as documented in the coronary arteries by CT scanning and in the carotid arteries by ultrasonography. ^{248, 301, 302}

Thus, estrogen exerts a protective effect directly on the arterial wall independent of its effects on circulating lipoproteins. The presence of sex steroid receptors in arterial endothelium and smooth muscle lends support for the importance of this direct action; however, the mechanisms involved remain unknown. ³⁰³ One important mechanism may be coronary artery remodeling. Atherosclerosis is associated with a compensatory change in coronary artery size that increases the magnitude of the lumen (a process called remodeling). It is important to note that the addition of a progestin did not attenuate the beneficial effect of estrogen on coronary remodeling in monkeys. ²⁹⁸ Involvement of estrogen and estrogen receptors is supported by the observation that atherosclerotic coronary arteries in premenopausal women demonstrate diminished expression of estrogen receptors compared with normal premenopausal arteries. ³⁰⁴

Endothelium-Dependent Vasodilatation and Antiplatelet Aggregation

Endothelium modulates the degree of contraction and function of the surrounding smooth muscle, primarily by the release of endothelium-derived relaxing and contracting factors (EDRFs and EDCFs). In hypertension and other cardiovascular diseases, the release of EDRFs (which is probably one factor, nitric oxide) is blunted, and the release of EDCFs (the most important being endothelin-1) is augmented. The endothelins are a family of peptides that act in a paracrine fashion on smooth muscle cells. Endothelin-1 appears to be exclusively synthesized by endothelial cells. Endothelin-induced vasoconstriction is a consequence of a direct action on vascular smooth muscle cells, an action that is reversed by nitric oxide. Impaired release of nitric oxide, therefore, enhances endothelin action. Hypertension and atherosclerosis are believed to be influenced by the balance among these factors. Women have lower circulating levels of endothelin, and the levels are even lower during pregnancy and decrease in response to oral and transdermal estrogen treatment. ^{305, 306}

Nitric oxide (and estrogen) also inhibits the adhesion and aggregation of platelets in a synergistic manner with prostacyclin (also a potent vasodilator derived from the endothelium). ^{307, 308} These local actions are a likely site for sex steroid involvement; the vasodilating and antiplatelet action of estrogen, especially in the coronary arteries, is a consequence of endothelial responses. In addition, postmenopausal women experience greater stress-induced neuroendocrine and blood pressure responses that are ameliorated by estrogen treatment. ^{309, 310} However, the addition of medroxyprogesterone acetate (10 mg for 10 days) attenuated the beneficial effects of estrogen on measures of cardiovascular reactivity. ³¹¹

Increased blood flow due to vasodilatation and decreased peripheral resistance can be observed to occur rapidly following the administration of estrogen. This response can be produced by both transdermal and oral administration.^{312,313} The synthesis and secretion of nitric oxide (the potent endothelial vasodilating product) can be directly stimulated by estrogen in in vitro experimental preparations of coronary arteries.³¹⁴ In both normal postmenopausal women and women with hypertension, hypercholesterolemia, diabetes mellitus, or coronary artery disease, the intra-arterial infusion of physiologic amounts of estradiol into the forearm potentiates endothelium-dependent vasodilatation, and there is a dose-response effect with enhanced responses limited to the production of high blood levels of estradiol.^{315,316} Nevertheless, comparing brachial artery responses in women who are long-term hormone users (with or without progestin) with non-users, improved endothelium-dependent vasodilatation could be observed with standard doses.³¹⁷ In a careful, randomized study, the addition of norethindrone acetate did not reduce the beneficial effect of estrogen on peripheral artery blood flow.³¹⁸ However, not all studies agree; a Danish assessment of brachial artery responses demonstrated no difference between postmenopausal women on long-term combined estrogen-progestin therapy compared with postmenopausal women receiving no treatment.³¹⁹

The synthesis of nitric oxide is involved in the regulation of vascular (and gastrointestinal) tone, and in neuronal activity. A family of isozymes (nitric oxide synthases) catalyze the oxidation of L-arginine to nitric oxide and citrulline. The action of nitric oxide synthase in the endothelium is calcium dependent, and its synthesis is mediated specifically by estrogen.³²⁰ In animal experiments, the endothelial basal release of nitric oxide is greater in females, a gender difference that is mediated by estrogen.^{314,321} In women treated with postmenopausal estrogen and either cyproterone acetate or medroxyprogesterone acetate, circulating nitric oxide (as reflected in nitrite-nitrate levels) is increased, a consequence of estrogen-induced nitric oxide production in the endothelium.^{322,323} In contrast, long-term treatment with estradiol and norethindrone acetate was not associated with changes in nitric oxide, endothelin-1, prostacyclin, or thromboxane A₂.³²⁴

Acetylcholine induces vasoconstriction in coronary arteries; however, the direct administration of estradiol in physiologic doses into the coronary arteries of postmenopausal women with and without coronary heart disease converts acetylcholine-induced vasoconstriction into vasodilatation with increased flow.³²⁵ This favorable vasomotor response to acetylcholine can also be demonstrated in acute experiments with the transdermal administration of estradiol (achieving blood levels of 67–89 pg/mL).³²⁶ This same estrogen-associated response is observed in women with coronary atherosclerosis comparing estrogen users to non-users.³²⁷ This is an endothelium-dependent response, mediated to a significant degree by an increase in nitric oxide.³²⁸ The administration of standard doses of estrogen to women with coronary artery disease reduces the degree of ischemia and delays the onset of signs of myocardial ischemia on electrocardiograms, and increases exercise tolerance.^{329,330 and 331} In normal women, the standard oral 0.625 mg dose of conjugated estrogens had no effect on hemodynamic responses to treadmill exercise.³³² In the monkey, the vasodilatory response to acetylcholine requires a blood level of estradiol higher than 60 pg/mL.³³³

Endothelium-Independent Vasodilatation

Estrogen causes relaxation in coronary arteries that are denuded of epithelium.³³⁴ This response is not prevented by the presence of inhibitors of nitric oxide synthase or prostaglandin synthase. Thus this vasodilatation is achieved through a mechanism independent of the vascular endothelium, perhaps acting on calcium-mediated events.³³⁵ The vasodilatation produced by sodium nitroprusside is endothelium-independent. In normal postmenopausal women and postmenopausal women with risk factors for atherosclerosis (hypertension, hypercholesterolemia, diabetes mellitus, coronary artery disease), the administration of physiologic levels of estradiol increases forearm vasodilatation induced by sodium nitroprusside.³¹⁵

Inotropic Actions on the Heart and Large Blood Vessels

Estrogen treatment increases left ventricular diastolic filling and stroke volume.^{336,337 and 338} This effect is probably a direct inotropic action of estrogen that delays the age-related change in compliance that impairs cardiac relaxation.³³⁹ In a 3-month study, medroxyprogesterone acetate (5 mg daily for 10 days each month) did not attenuate the increase in left ventricular output (systolic flow velocity) observed with estrogen treatment.³⁴⁰ On the other hand, others have detected attenuation of estrogen's beneficial effects on compliance (stiffness) associated with combined estrogen-progestin treatment,^{339,341} and others have not been able to demonstrate an effect of short-term oral estrogen or long-term transdermal estrogen treatment on cardiac structure and function.^{342,343} The reasons for these differences are not apparent.

Improvement of Glucose Metabolism

An age-related decline in the basal metabolic rate begins at menopause, associated with an increase in body fat, especially central (android) body fat.^{344,345} Insulin resistance and circulating insulin levels increase in women after menopause, and impaired glucose tolerance predicts an increased risk of coronary heart disease.^{346,347} Estrogen (with or without progestin) prevents the tendency to increase central body fat with aging.^{348,349,350 and 351} This would inhibit the interaction among abdominal adiposity, hormones, insulin resistance, hyperinsulinemia, blood pressure, and an atherogenic lipid profile. Hyperinsulinemia also has a direct atherogenic effect on blood vessels, perhaps secondary to insulin propeptides. In addition to its vasoconstrictive properties, endothelin-1 exerts a mitogenic effect and, therefore, contributes to the atherosclerotic process. Insulin directly stimulates the secretion of endothelin-1 in endothelial cells, and the circulating levels of endothelin-1 are correlated with insulin levels.³⁵²

Postmenopausal women being treated with oral estrogen have lower fasting insulin levels and a lesser insulin response to glucose, indicating another mechanism for the protection against cardiovascular disease.^{353,354,355 and 356} However, not all studies have observed these favorable changes.³⁵⁷ There is an important dose-response relationship; 0.625 mg conjugated estrogens improved insulin sensitivity, 1.25 mg did not.³⁵⁸ The addition of a progestational agent can attenuate this beneficial response to oral estrogen, but the clinical impact and variation with dose are unknown.^{358,359} In a 1-year randomized trial comparing unopposed conjugated estrogens to the usual sequential and continuous regimens of conjugated estrogens and medroxyprogesterone acetate, no differences in the treatment groups were observed in the favorable decreases in fasting insulin levels.³⁵⁵ Nonoral administration of estrogen has little effect on insulin metabolism, unless a dose is administered that is equivalent to 1.25 mg conjugated estrogens.^{354,359} Because a lower oral dose produces a beneficial impact, this suggests that the hepatic first-pass effect is important in this response.

Consistent with this salutary impact of estrogen, the Nurses' Health Study has documented a 20% decreased risk of noninsulin-dependent diabetes mellitus in current users of estrogen.³⁶⁰ However, in the Rancho Bernardo cohort, no statistically significant difference could be detected comparing hormone users and never users.³⁶¹ There was a trend for the lowest incidence of diabetes among those who had received estrogen treatment throughout the period of follow-up, and the highest incidence was among never users, but the investigators believed this reflected the better health status of hormone users. Observational studies examining the incidence of diabetes mellitus are hampered by the biases of "healthy users" and preferential prescribing to women perceived to be at reduced risk of diabetes. Hopefully, the long-term randomized trials will provide reliable information regarding this potential benefit of hormone therapy.

A strong argument can be made that postmenopausal women with diabetes mellitus can benefit from the cardioprotective actions of estrogen. In addition, as noted above, estrogen may improve the metabolic changes associated with diabetes. Indeed, in double-blind, cross-over, placebo-controlled studies of postmenopausal women with noninsulin-dependent diabetes mellitus, estrogen treatment improved all glucose metabolic parameters (including insulin resistance), the lipoprotein profile, and measurements of androgenicity.^{362,363} These changes would reduce the risk of cardiovascular disease; however, long-term studies are yet to be available.

Inhibition of Lipoprotein Oxidation

The oxidation of LDL particles is a step (perhaps the initial step) in the formation of atherosclerosis, and smoking is associated with a high level of lipoprotein oxidation. In animal experiments the administration of large amounts of antioxidants inhibits the formation of atherosclerosis and causes the regression of existing lesions. Vitamin E and beta-carotene (the prohormone of vitamin A) are antioxidants. Studies indicate that the risk of myocardial infarction in smokers is higher in men and women with the lowest carotene levels, and supplementary intake of vitamin E decreases the risk of coronary heart disease.^{364, 365 and 366} The Nurses' Health Study reported a decreased risk of coronary heart disease in women with high carotene levels.³⁶⁶ Thus, treatment with antioxidants may reduce the risk of cardiovascular disease and the risk of complications in those who already have cardiovascular disease.

Estrogen is an antioxidant. Estradiol directly inhibits LDL oxidation in response to copper, and decreases the overall formation of lipid oxides.^{282, 367} Importantly, this antioxidant action of estradiol is associated with physiologic blood levels.³⁶⁸ In addition, estrogen may regenerate circulating antioxidants (tocopherols and beta-carotene) and preserve these antioxidants within LDL particles. This antioxidant action of estrogen preserves endothelial-dependent vasodilator function by preventing the deleterious effect that oxidized LDL has on endothelial production of vasoactive agents.³⁶⁹ There is evidence in the monkey in a short-term study that progesterone partially attenuates the inhibition of LDL oxidation by estradiol.³⁷⁰ However, in an assessment of peroxide formation by platelets, women treated with both estrogen and medroxyprogesterone acetate in a sequential regimen had greater antioxidant activity compared with the days on estrogen alone.³⁷¹ And in a 1-year study, the presence of levonorgestrel did not attenuate the antioxidant activity of estradiol.³⁷²

A Favorable Impact on Fibrinolysis

Menopause is followed by increases in factor VII, fibrinogen, and plasminogen activator inhibitor-1 (PAI-1).^{373, 374} These changes produce a relatively hypercoagulable state and are associated with an increased risk of cardiovascular events. Postmenopausal women treated with estrogen have lower fibrinogen and plasminogen levels.

Reduced levels of fibrinogen, factor VII, and plasminogen activator inhibitor-1 (PAI-1) have been observed in premenopausal women compared with postmenopausal women, and oral estrogen alone or combined with a progestin prevents the usual increase in these clotting factors associated with menopause.^{357, 375, 376 and 377} This would be consistent with increased fibrinolytic activity, another possible cardioprotective mechanism probably mediated, at least partially, by nitric oxide and prostacyclin. Platelet aggregation is also reduced by postmenopausal estrogen treatment, and this response is slightly attenuated by medroxyprogesterone acetate.³⁰⁷ However, in a randomized 1-year trial, the addition of medroxyprogesterone acetate, either sequentially or continuously, produced a more favorable change in coagulation factors compared with unopposed estrogen.³⁷⁸

The transdermal and oral routes of administration of estrogen (combined with medroxyprogesterone acetate) have puzzling differences in the reported effects on most hemostatic risk factors, such as factor VII, fibrinogen, PAI-1, and antithrombin III. In at least one study, however, antithrombin III levels were reduced by oral estrogen, but not transdermal administration; however the values remained within the normal range.³⁷⁹ In regards to PAI-1, studies with transdermal estrogen have provided us with conflicting data; for example, favorable changes in PAI-1 levels as well as no effect.^{380, 381} However, in a crossover study designed to compare 100 µg transdermal estradiol with 0.625 mg oral conjugated estrogens (both combined with 2.5 mg medroxyprogesterone acetate daily), only the oral estrogen had a favorable reduction in PAI-1 levels.³⁸¹ Appropriate doses of hormone therapy have been reported to not have an adverse impact on clotting factors.^{376, 382, 383} However, one study found slightly increased clotting activation with transdermal administration of estradiol, but no change with oral conjugated estrogens.³⁸⁴ Fibrinopeptide A is an indicator of thrombin generation, and in 3-month studies, no significant alteration was produced by 0.625 mg conjugated estrogens in one and an increase in another.^{385, 386} The clotting story is difficult to unravel. Perhaps one contributor to the uncertainty is a possible difference between short-term and long-term effects.^{379, 382, 385}

Coagulation and Fibrinolysis Factors

Coagulation Factors:

Factors that favor clotting when increased

Fibrinogen
Factors VII, VIII, X

Factors that favor clotting when decreased

Antithrombin III
Protein C
Protein S

Fibrinolysis Factors:

Factors that favor clotting when increased

Plasminogen
Plasminogen activator inhibitor-1 (PAI-1)

Factors that favor clotting when decreased

Antiplasmin

Overall, estrogen treatment is associated with favorable changes consistent with an increase in fibrinolysis. The favorable changes in the clotting system may contribute to estrogen's protection of the cardiovascular system by inhibiting arterial thrombosis. How can there be a beneficial effect on arterial thrombosis when there is an increased risk of venous thrombosis (discussed in [Chapter 18](#))? Why is there a difference between venous and arterial clotting? The venous system has low flow with a state of high fibrinogen and low platelets, in contrast to the high-flow state of the arterial system with low fibrinogen and high platelets. Thus, it is understandable why these two different systems can respond in different ways. Decreases in antithrombin III and protein S associated with estrogen treatment, a hypercoagulable change, may have a greater impact on the venous system.³⁸⁶

It is important to recognize the importance of the dose-response relationship between estrogen and the risk of arterial thrombosis. We learned from our experience with high-dose oral contraceptives that high doses of estrogen cause arterial thrombosis. Low doses of estrogen may even protect against arterial thrombosis. Thus, we refer to this important dose effect as a **"narrow therapeutic window."** (also discussed in [Chapter 18](#)) Doses of estrogen greater than those that protect against cardiovascular disease and osteoporosis (equivalent to 0.625 mg conjugated estrogens) should be avoided. At least 3 studies have found that estrogen doses greater than 0.625 mg conjugated estrogens are less beneficial in terms of coronary heart disease and mortality; however, the numbers of patients on the higher doses were relatively small, and these conclusions did not achieve statistical significance.^{247, 250, 251}

Inhibition of Vascular Smooth Muscle Growth and Migration — Intimal Thickening

Hypertension and atherosclerosis are associated with increased proliferation of vascular smooth muscle cells. This growth of smooth muscle cells is also characterized by migration into the intima. Arterial intimal thickening is an early indicator of atherosclerosis. The proliferation and migration of human aortic smooth muscle cells in response to growth factors are inhibited by estradiol, and importantly, this inhibition is not prevented by the presence of progestins.^{387, 388} Nitric oxide, which is regulated by estrogen, also inhibits smooth muscle proliferation and migration.³⁸⁹ This smooth muscle response occurs following vascular injury, and this injury-induced reaction is inhibited by estradiol even in a mouse model deficient in the estrogen receptor-alpha, suggesting that the estrogen receptor-beta is an

important component of blood vessel cells.³⁹⁰ Only ER-b, and not ER-a, is expressed in endothelial cells obtained from umbilical veins.³⁹¹

Imaging studies have documented a reduction in intimal thickening in postmenopausal women who are estrogen users compared with nonusers, and this beneficial effect is not compromised by the addition of a progestational agent to the treatment regimen.^{341, 392, 393} Thus, postmenopausal hormonal therapy can bring about a reduction in atherosclerosis, and this effect is comparable with that produced by a lipid-lowering drug.^{392, 394}

Protection of Endothelial Cells

Endothelial cells can respond to injury by initiating the clotting process or by atherosclerosis. Animals studies indicate that estrogen accelerates healing and recovery of the endothelium in response to injury.³⁹⁵ This is correlated with inhibition of intimal thickening and recovery of important functions such as nitric oxide production. In vitro studies of human endothelial cells demonstrate that estrogen can inhibit cytokine-induced apoptosis.³⁹⁶ In the rat, medroxyprogesterone acetate blocked the estrogen-induced healing response after carotid artery injuries.³⁹⁷

Inhibition of Macrophage Foam Cell Formation

A feature of atherosclerotic plaque formation is monocytic infiltration into the arterial wall and the formation of macrophage foam cells. In a non-antioxidant activity, estrogen inhibits macrophage foam cell accumulation in atherosclerotic lesions.³⁹⁸

Reduction of Angiotensin-Converting Enzyme (ACE) and Renin Levels

Although oral estrogen, but not transdermal estrogen, increases angiotensinogen levels, ACE and renin levels are decreased (with or without progestin) by both routes of administration.^{399, 400}

Reduction of P-Selectin Levels

P-selectin is an adhesion glycoprotein that recruits leukocytes to the endothelium and plays a role in attaching platelets to endothelium. It is stored in and mobilized from platelets. Increased P-selectin expression has been demonstrated in atherosclerotic endothelial cells, and premenopausal women have lower circulating levels compared with men. Estrogen treatment lowers circulating levels of P-selectin, a change that should contribute to protection against atherosclerosis.⁴⁰¹

Reduction of Homocysteine Levels

Increased circulating levels of homocysteine are correlated with increased risks of atherosclerosis and thrombosis. Homocysteine levels increase after menopause, and these levels are significantly lowered by estrogen or estrogen-progestin treatment.⁴⁰²

H3>Summary — Estrogen and the Cardiovascular System

The possible beneficial actions of estrogens on cardiovascular disease include all of the following. A study in mice lacking the estrogen receptor-alpha suggests that some (perhaps many or all) of these actions are mediated by the estrogen receptor-beta or by nongenomic actions of estrogen.³⁹⁰ ER-a and ER-b are both prevalent in coronary and aortic smooth muscle cells from monkeys.⁴⁰³ Only ER-b is expressed in umbilical vein endothelial cells.³⁹¹

1. A favorable impact on the circulating lipid and lipoprotein profile, especially a decrease in total cholesterol and LDL-cholesterol and an increase in HDL-cholesterol.
2. A direct antiatherosclerotic effect in arteries.
3. Augmentation of vasodilating and antiplatelet aggregation factors, specifically nitric oxide and prostacyclin (endothelium-dependent mechanisms).
4. Vasodilatation by means of endothelium-independent mechanisms.
5. Direct inotropic actions on the heart and large blood vessels.
6. Improvement of peripheral glucose metabolism with a subsequent decrease in circulating insulin levels.
7. Antioxidant activity.
8. Favorable impact on fibrinolysis, at least partially mediated by endothelial nitric oxide and prostacyclin synthesis.
9. Inhibition of vascular smooth muscle growth and migration — intimal thickening.
10. Protection of endothelial cells from injury.
11. Inhibition of macrophage foam cell formation.
12. Reduced levels of angiotensin-converting enzyme and renin.
13. Reduction of P-selectin levels.
14. Reduction of homocysteine levels.

Cardiovascular Disease and Progestins

Because the public health benefit of estrogen therapy on cardiovascular disease is of such enormous impact, it is vital that we know whether the addition of progestin attenuates estrogen's effects on the cardiovascular system. Conclusions regarding the impact of progestational agents on cardiovascular disease are very much influenced by dose and duration of administration of the progestational agent involved. While short-term studies suggest a negative impact of progestin (i.e., subtracting from the beneficial effect of estrogen), long-term studies indicate that this short-term effect disappears.

In sequential regimens, a review of the literature on this issue suggests a dose-response relationship.^{404, 405, 406, 407, 408, 409, 410, 411} and ⁴¹² A decrease in HDL-cholesterol has been noted with 10-day monthly treatment with norethindrone (5 mg), megestrol acetate (5 mg), levonorgestrel (250 µg), and even medroxyprogesterone acetate (10 mg). No significant change was noted with micronized progesterone (200 mg). The lack of an effect noted with micronized progesterone was observed with a dose (200 mg daily) that yields a normal luteal phase blood level of progesterone. A similar "physiologic" dose of synthetic progestins may be free of an adverse impact on HDL-cholesterol. Barrett-Connor and colleagues have been studying the adult residents of Rancho Bernardo, California. The women using both estrogen and progestin demonstrated the same favorable impact on cardiovascular risk factors as estrogen-only users compared with the nonusers.⁴¹³ On the other hand, a well-designed study indicated that although the sequential estrogen plus progestin program had a favorable impact on lipids and the lipoprotein profile, the impact (as measured one year later) was less than that achieved by estrogen alone.⁴¹⁴

Studies with the combination of an estrogen and a low dose of a progestational agent administered continuously (every day without a break) are documenting a favorable impact on total cholesterol and LDL, with attenuation of the estrogen-induced increase in HDL. The various formulations include estradiol and levonorgestrel,⁴¹⁵ estradiol and 1 mg norethindrone acetate,⁴¹⁶ estradiol and dydrogesterone,⁴¹⁷ estradiol valerate and levonorgestrel or cyproterone acetate,⁴¹⁸ ethinyl estradiol and 0.5–1.0 mg norethindrone acetate,^{286, 419} and 0.625 conjugated estrogen and 2.5–5.0 mg medroxyprogesterone acetate.⁴²⁰ Christiansen has documented the maintenance of a favorable lipid profile over a period of 5 years of treatment with continuous, combined estradiol and 1 mg norethindrone acetate.⁴¹⁶

A large, prospective, 1-year randomized clinical trial compared sequential and combined regimens of conjugated estrogens and medroxyprogesterone acetate with unopposed estrogen.³⁵⁵ Although the increase in HDL-cholesterol, HDL₂, and apolipoprotein A-I levels was greater with unopposed estrogen, there was still a significant increase with combined estrogen-progestin treatment. Importantly, the decrease in total cholesterol, LDL-cholesterol, apolipoprotein B, and Lp(a) was equivalent, comparing unopposed estrogen with either sequential or daily, combined estrogen-progestin. Fasting glucose and insulin levels were improved in all treatment groups. Similar results have been observed in a 2-year randomized trial with 2 mg estradiol and 1 mg norethindrone acetate.⁴²¹ A prospective case-control study indicated that the decrease in Lp(a) achieved by estrogen is attenuated by the addition of a progestin.⁴²² In a large cross-sectional study of 4958 postmenopausal women, a favorable impact on the lipoprotein profile and fasting insulin levels was observed in users of unopposed estrogen and combined estrogen-progestin compared with nonusers.²⁸⁵ In Spain, 8 months of uninterrupted treatment with a daily dose of 2.5 mg medroxyprogesterone acetate in a combined estrogen-progestin program produced a favorable effect on the lipoprotein profile not substantially different from that achieved with estrogen alone.⁴²³ Nevertheless, the bulk of evidence indicates that the addition of a progestin attenuates, but does not eliminate, the favorable increase in HDL achieved with estrogen treatment,

whereas the beneficial decreases in total cholesterol, LDL, lipoprotein(a), and the apolipoproteins are maintained. ⁴²⁴

Studies in women of arterial vascular resistance by Doppler ultrasound flow patterns have indicated no detrimental effects of exogenous progesterone or medroxyprogesterone acetate to the beneficial decrease in resistance (and increase in blood flow) produced by estrogen administration. ^{425, 426}

The Postmenopausal Estrogen/Progestin Interventions (PEPI) Trial

PEPI was a randomized, double-blind, placebo-controlled, 3-year trial of 875 postmenopausal women conducted in 7 clinical centers in the U.S. ^{272, 427} The participants were randomly assigned to the following treatment groups:

1. Placebo.
2. Estrogen alone, 0.625 mg conjugated estrogens daily.
3. Sequential estrogen and progestin, 0.625 mg conjugated estrogens daily and 10 mg medroxyprogesterone acetate days 1–12.
4. Sequential estrogen and progesterone, 0.625 mg conjugated estrogens daily and 200 mg micronized progesterone days 1–12.
5. Continuous combination estrogen and progestin, 0.625 mg conjugated estrogens and 2.5 mg medroxyprogesterone acetate daily.

The statistical analysis indicated that an increase in HDL-cholesterol levels was greater with unopposed estrogen (mean increase 5.6 mg/dL) and with sequential estrogen and micronized progesterone (mean increase 4.1 mg/dL), than in women receiving estrogen and medroxyprogesterone. However, as in the trials reviewed above, ^{355, 421} the decrease in LDL-cholesterol was essentially the same in all treatment groups, and significantly improved compared with the placebo group. There were no significant differences in systolic blood pressure, although all groups gradually increased systolic blood pressure with aging. There were no differences in diastolic blood pressure, and no changes with aging. The placebo group demonstrated the well-recognized increase in fibrinogen (a risk factor for cardiovascular disease) that occurs after menopause. All treatments prevented this increase in fibrinogen.

All treatment groups exerted a modestly favorable effect on fasting insulin and glucose levels, and the effect was greater in individuals with elevated fasting insulin concentrations. ⁴²⁸ These changes are consistent with a beneficial impact on insulin resistance, and most notably, the addition of a progestational agent, either medroxyprogesterone acetate or micronized progesterone, did not alter the responses.

The PEPI trial demonstrated a favorable impact on cardiovascular risk factors in women taking estrogen as well as combinations of estrogen and progestins. A major question is whether it is justified to interpret the results as indicating that a combination of estrogen plus micronized progesterone is clinically better because of the HDL-cholesterol responses. Studies have indicated that in women there is a 2–3% decrease in heart disease with a 1 mg increase in HDL-cholesterol. If this is accurate, then potentially the difference between estrogen and micronized progesterone compared with estrogen plus medroxyprogesterone acetate (a 3 mg HDL-cholesterol difference) would amount to a 9% difference in the risk of heart disease. However, the story is not that simple. Many of the beneficial actions of estrogen in terms of cardiovascular disease are dynamic effects on blood flow, atherosclerosis, the clotting system, and insulin levels. Given this complicated and multifactorial impact, the small difference in HDL-cholesterol is reduced in importance. It is worth emphasizing that the PEPI trial revealed the same beneficial effects in all treatment groups on LDL-cholesterol, fibrinogen, insulin levels, and glucose levels. In a Finnish ultrasonographic study, women receiving estradiol valerate and levonorgestrel had as great a reduction in large artery atherosclerotic plaques as those women on unopposed estrogen, despite a similar attenuation in HDL-cholesterol levels as observed in the PEPI trial. ⁴²⁹

One of the important contributions of PEPI is to provide a good response to the criticism that the reason estrogen users have less cardiovascular disease is because clinicians give estrogen to healthier women. The results of this randomized trial demonstrate that estrogen has a greater impact compared with a placebo group, thus the design compensated for this criticism.

Clinical Events — Epidemiologic Data

The various mechanisms by which estrogen protects the cardiovascular system can be viewed as “surrogate end points,” parameters by which the risk of cardiovascular disease can be assessed. A summary of the responses of these surrogate end points to the addition of progestational agents in estrogen regimens indicates a mixed story. This less than clear picture, we would argue, makes it impossible to determine with surrogate end points the overall effect of progestins on actual clinical events; e.g., myocardial infarctions. We must turn to epidemiologic data regarding actual clinical events, and here the data (just now emerging because estrogen and progestin use is relatively recent) are reassuring.

Progestin Effects on Estrogen Actions

ATTENUATION

1. **Increase in HDL and triglyceride levels.**
2. **Measure of acute reactivity; e.g., acute vasodilatation.**
3. **Cardiac inotropic activity; compliance responses.**
4. **Effect of estrogen on coronary atherosclerosis in the monkey.**

NO ATTENUATION

1. **Decrease in cholesterol and LDL.**
2. **Increase in fibrinolysis.**
3. **Inhibition of atherosclerosis (intimal thickening and remodeling).**
4. **Antioxidant activity.**
5. **Reduction in angiotensin converting enzyme (ACE) activity.**

UNCERTAIN

1. **Reduction in hyperinsulinemia.**
2. **Favorable changes in P-selectin.**
3. **Protection of endothelial cells.**
4. **Inhibition of macrophage foam cell formation.**

A report from the ongoing cohort study from Uppsala, Sweden, provided information from the follow-up of approximately 23,000 women who were prescribed hormone therapy. ⁴³⁰ Overall, there was a 30% reduction in myocardial infarction in women prescribed estradiol valerate or conjugated estrogens. What is especially noteworthy was a 50% reduced risk of myocardial infarction in women exposed to a sequential estrogen-progestin regimen consisting of 2 mg estradiol valerate and 10 days each month of levonorgestrel (250 µg). Treatment with this combined estrogen-progestin product was also associated with a 40% reduced risk of stroke. ²⁵⁹

In an updated assessment of the Uppsala cohort, reduced mortality rates were documented for ischemic heart disease and intracerebral hemorrhage. ²⁶³ Once again, an even greater reduction in the risk of mortality from these conditions was observed in those women taking an estrogen-progestin combination.

In a case-control study from Seattle, unopposed estrogen and sequential estrogen and progestin were associated with a 28% reduction in the risk of myocardial infarction, and the reduction increased with increasing duration of treatment in the current users. ⁴³¹ There certainly was no evidence of attenuation secondary to the addition of a progestin. A retrospective cohort study by this same Seattle group determined prognosis in women surviving a myocardial infarction and detected a 36% reduced risk of re-infarction in current estrogen users, with a similar result in the one-third of their women on hormone therapy taking both estrogen and a progestin. ⁴³²

In a comparison of postmenopausal women in Finland receiving unopposed estrogen or a sequential regimen of estradiol valerate and levonorgestrel (250 µg for 10

days), both treatment groups had an equal reduction in ultrasonographically observed atherosclerotic plaques in the aorta and in the carotid and iliac arteries. ⁴²⁹

Carotid arterial wall thickening and the prevalence of carotid stenosis can be assessed by ultrasonography. In a study unique because it consisted of women who were 65-years old and older, the same beneficial decreases in carotid atherosclerosis could be documented in users of estrogen alone compared with women who were current users of estrogen and progestin. ³⁰² In this study of elderly long-term users of postmenopausal hormone therapy, the HDL-cholesterol levels were similar in the two groups of women. This raises the possibility that the attenuation of estrogen-induced increases in HDL-cholesterol attributed to progestin treatment may disappear with very long-term use of combined therapy.

As epidemiologic studies gather growing numbers of women on estrogen and progestin, there is consistent reporting of an even greater beneficial impact with combined estrogen and progestin than with estrogen alone. In the Nurses' Health Study report on mortality, the relative risk of death for current users of estrogen-progestin was 54% reduced compared with a 31% reduction with unopposed estrogen. ²⁴⁴ In the 16-year follow-up report of the Nurses' Health Study, the risk of coronary heart disease was reduced 40% in estrogen users and 61% in users of estrogen and progestin. ²⁴³ An explanation for this difference is not readily apparent.

The Heart and Estrogen/Progestin Replacement Study (HERS)

The HERS trial was a randomized, double-blind, placebo-controlled clinical trial to determine whether daily treatment with 0.625 mg conjugated estrogens and 2.5 mg medroxyprogesterone acetate would reduce coronary heart disease events in women with pre-existing coronary disease. ⁴³³ 2763 women (average age 66.7 years) were enrolled in 20 U.S. clinical centers and randomized to treatment and placebo beginning in February, 1993, and ending in July, 1998. Overall, there were 172 myocardial infarctions and coronary deaths in the hormone group and 176 in the placebo group, obviously no difference. However, over time, differences were recorded:

	Treated	Placebo	Relative Hazard (Risk) & Confidence Interval
Year 1	57 cases	38 cases	1.52 (1.01–2.29)
Year 2	47 cases	48 cases	1.00 (0.67–1.49)
Year 3	35 cases	41 cases	0.87 (0.55–1.37)
Year 4	33 cases	49 cases	0.67 (0.43–1.04)

Thus, there was an increase in events in the first year (mostly in the first 4 months), and after two years of treatment, the appearance of a beneficial impact (although the annual relative risks did not achieve statistical significance, the test for the trend was significant). The authors attribute the increasing beneficial impact noted with increasing duration of treatment to a favorable effect on lipids, a 11% decrease in LDL-cholesterol and an 10% increase in HDL-cholesterol after one year, compared with the levels in the placebo group.

The results of the HERS trial were surprising in view of the overwhelming evidence from observational studies that postmenopausal hormone therapy prevents coronary heart disease. The authors offered two possible explanations for the difference between the HERS trial and previous observational studies. First, they pointed out the common and favorite criticism of the observational studies: selection bias, specifically that healthier women choose to use postmenopausal hormone therapy and therefore develop less coronary heart disease. This issue was addressed earlier in this chapter, noting that several studies have adjusted for this factor and a favorable impact of hormone therapy on coronary heart disease was still present. ^{237, 250, 251 and 252}

The authors further emphasized that the HERS trial consisted of older women with significant coronary heart disease, whereas observational studies have focused on primary prevention in younger and healthier women. However, there are observational studies that examined the impact of hormone therapy in women with pre-existing disease, and reported a beneficial effect. ^{237, 250, 432, 434, 435 and 436} In the Leisure World study, estrogen users with previous myocardial infarctions, strokes, or hypertension had a 50% reduction in risk for death from a subsequent stroke or myocardial infarction. ²⁵⁰ In the Lipids Research Clinics study, the cardiovascular mortality in women with previous cardiovascular disease was reduced 85%. And most impressively, in women with severe coronary disease (documented by arteriography), estrogen users had a 97% survival rate at 5 years compared with a significantly different 81% rate in nonusers. ⁴³⁴ Estrogen therapy reduces the rate of restenosis in women who have undergone either coronary angioplasty or percutaneous atherectomy. ⁴³⁷ In women who have undergone coronary artery bypass surgery, the 10-year survival rate in estrogen users was 81.4% compared with 65.1% in nonusers. ⁴³⁵ In women who have been treated with estrogen after coronary angioplasty, case-control analysis indicated that the treated women had a better survival rate and experienced fewer subsequent myocardial infarctions. ⁴³⁶

The HERS trial is also in disagreement with recent reports that estrogen treatment could produce a regression in atherosclerosis. Imaging studies have documented a reduction in intimal thickening in postmenopausal women who are estrogen users compared with nonusers, and this beneficial effect was not compromised by the addition of a progestational agent to the treatment regimen. ^{341, 392} Thus, postmenopausal hormonal therapy has been reported to bring about a reduction in atherosclerosis, and this effect is comparable to that produced by a lipid-lowering drug. ^{392, 394}

The size of the HERS trial was determined by power calculations based upon specific assumptions. A comparison of the pre-trial assumptions with the actual outcomes reveals important differences:

	Assumption	Actual
Clinical event rate in the placebo group	5% /year	3.3% /year
Drop-out rate	5% in year 1	18% in year 1
Conversion of placebo to treatment rate	1% /year	1.7% /year
Average follow-up	4.75 years	4.1 years
Recruitment	Paced	Late

These differences between the assumptions and the actual events raise the important question whether the trial achieved sufficient statistical power to provide confident conclusions. The authors indicated that this concern was "partially" compensated by an 18% increase in recruitment. But, here too, there was a problem. The reason why the average follow-up was less than expected is that most of the women were enrolled toward the end of the recruitment period. This seriously affected the accuracy of the impact of duration of treatment, an apparent beneficial effect in the HERS trial. Indeed, the late recruitment into HERS would have minimized this effect, and the apparent benefit in years 4 and 5 did not reach statistical significance (although a test for trend was significant). The apparent increasing protection with increasing duration of use is consistent with the preventive effect exerted by hormone therapy in the many observational studies. This is also important information for women who begin hormonal treatment at menopause and are contemplating long-term therapy.

The increase in events recorded in the first year is difficult to understand. The most attractive explanation is to attribute, as the authors did, the increase to prothrombotic effects of estrogen. However, there is a host of evidence that indicates that postmenopausal hormone therapy (with and without progestin) affects clotting factors in a pattern that favors fibrinolysis, an effect that should protect against thrombosis (reviewed earlier in this chapter). It may be that older women with atherosclerosis respond differently than younger, healthier women. In other words, increasing age and disease may change a woman's thrombotic sensitivity to estrogen, perhaps because of the presence of unstable atherosclerotic plaques.

The most disturbing thought about the HERS trial is that the results reflect the impact of the continuous presence of medroxyprogesterone acetate. The clotting factor studies fail to find a detrimental effect of medroxyprogesterone acetate. However, there is reason to believe that the continuous presence of medroxyprogesterone acetate could attenuate and even block the favorable effects of estrogen on atherosclerosis and vasomotor function. There is evidence in the monkey that medroxyprogesterone antagonises the favorable impact of conjugated estrogens on both the process of atherosclerosis and vasodilatation, but progesterone did not interfere with the ability of estrogen to inhibit atherosclerosis. ^{297, 300, 438, 439} Could attenuation of these estrogen effects make women with coronary heart disease more sensitive to any thrombogenic or ischemic effect of estrogen? In a study of mechanisms involved in the regression of atherosclerosis, conjugated estrogens did exert

favorable activity (aortic connective tissue remodeling in response to lipid lowering) in the monkey, but medroxyprogesterone acetate prevented this action. ⁴⁴⁰

Do the HERS results indicate a difference between sequential and daily, continuous regimens of estrogen-progestin treatment? The observational data have consistently failed to find any evidence that the addition of a progestational agent to estrogen therapy produced an attenuating impact on protection against clinical coronary events. ^{243, 244, 263, 430, 431 and 432} However, this evidence is virtually all derived from experience with sequential regimens because the use of the daily, continuous methods is too recent for epidemiologic study. In our view, the HERS results combined with the experimental data derived from monkeys do raise concern. There are other treatment options, and products with new combinations are around the corner. At this point in time, treatment decisions must be informed clinical judgements, one of the reasons patients turn to their clinicians for assistance, an enduring and rewarding feature of the practice of medicine. All of the available evidence must be included in this decision making, not just the results of the HERS trial, and this evidence must be balanced with individual patient needs.

Protection Against Cardiovascular Disease Is the Major Benefit of Hormone Therapy

The uniformity and consistency of the literature on the effect of postmenopausal hormone therapy on the risk of cardiovascular disease are very impressive. All the population-based case-control studies and (with the re-analysis of the Framingham Heart Study) all of the prospective studies conclude that postmenopausal use of estrogens protects against cardiovascular disease. Sophisticated assessment and analysis (using the methods of information synthesis and meta-analysis) indicate that the effect of estrogen on heart disease is not controversial or ambiguous, but there clearly exists a protective benefit. ^{441, 442} We have such uniformity and consistency among the epidemiologic studies that the argument is very convincing. There remains, therefore, the important question of the nature and degree of impact due to the addition of progestational agents.

Epidemiologic evidence is accumulating to indicate that a progestational dose that protects the endometrium avoids significant attenuation of estrogen's cardiovascular benefits. These epidemiologic data, however, reflect largely sequential regimens, and soon, we anticipate the appearance of data derived from women using daily, continuous combined methods. Ultimately, the best information will be derived from large, randomized trials, specifically the ongoing Women's Health Initiative in the U.S. (to be completed in 2008) and the WISDOM trial (Women's International Study of Long-Duration Oestrogen use after Menopause) in the U.K. (to be completed in 2011).

In view of the impressive association between estrogen and cardiovascular health in women, it is not illogical to ask whether a little estrogen therapy would be good for men. The normal levels of estrogen in men are important. The experimental suppression of normal physiologic levels of estradiol in young men leads to a significant decrease in apoprotein A-I and HDL-cholesterol, particularly the HDL₂ subfraction. ⁴⁴³ A case report detailed a man with an inability to respond to estrogen because of disruptions in the estrogen receptor gene; this man had osteoporosis, hyperinsulinemia, and low levels of HDL-cholesterol. ⁴⁴⁴ The long-term administration of estrogen in relatively high doses to male to female transsexuals is associated with improvements in vascular function mediated by many of the mechanisms reviewed in this chapter. ⁴⁴⁵

The acute administration of estradiol into the coronary arteries of men, however, did not produce the vasodilatation and increased flow in response to acetylcholine that have been observed in women studied in a similar fashion. ⁴⁴⁶ The failure of this acute response may reflect the presence of androgens; e.g., androgen depletion of estrogen receptors. Given the major impact of cardiovascular disease in men, it makes sense that pharmacologic long-term treatment with a small dose of estrogen might have an impressive beneficial impact. Perhaps the administration of phytoestrogens to men will be an acceptable preventive health care approach.

Osteoporosis

Bone is a very active organ. A continuous process, called bone remodeling, involves constant resorption (osteoclastic activity) and bone formation (osteoblastic activity). Both osteoblasts and osteoclasts are derived from bone marrow progenitors, osteoblasts from mesenchymal stem cells and osteoclasts from hematopoietic white cell lineage. Cytokines are involved in this development process, a process regulated by the sex steroids.

The amount of bone at any point of time reflects the balance of the osteoblastic and osteoclastic forces, influenced by a multitude of stimulating and inhibiting agents. Aging and a loss of estrogen both lead to excessive osteoclastic activity. A decrease in calcium intake and/or absorption lowers the serum level of ionized calcium. This stimulates parathyroid hormone (PTH) secretion to mobilize calcium from bone by direct stimulation of osteoclastic activity. Increased PTH also stimulates the production of vitamin D to increase intestinal calcium absorption. Calcium increases and PTH levels return to normal. A deficiency in estrogen is associated with a greater responsiveness of bone to PTH. Thus, for any given level of PTH there is more calcium removed from bone, raising serum calcium which, in turn, lowers PTH and decreases vitamin D and intestinal absorption of calcium.

Osteoporosis, the most prevalent bone problem in the elderly, is decreased bone mass with a normal ratio of mineral to matrix, leading to an increase in fractures. **Osteopenia** is sometimes used to indicate low bone mass, whereas osteoporosis is reserved for low bone mass with fractures. Osteoporosis is a major global public health problem, and it is epidemic in the United States, presently affecting more than 20 million individuals. ⁴⁴⁷ The increase in osteoporotic fractures in the developed world is partly due to an increase in the elderly population, but not totally. A comparison of bone densities in proximal femur bones in specimens from a period of over 200 years suggested that women lose more bone today, perhaps due to less physical activity and less parity. ⁴⁴⁸ Other contributing factors include a dietary decrease in calcium and an earlier and greater loss of bone because of the impact of smoking. Our Stone Age predecessors consumed a diet high in calcium, mostly from vegetable sources. ⁴⁴⁹ However, the impact of the tremendous increase in the elderly population throughout the world cannot be underrated. Because of this demographic change, the number of hip fractures occurring in the world each year will increase approximately 6-fold from 1990 to 2050, and the proportion occurring in Europe and North America will fall from 50% to 25% as the numbers of old people in developing countries increase. ⁴⁵⁰

Pathophysiology

Osteoporosis is characterized by microarchitectural deterioration of bone tissue, leading to enhanced bone fragility and a consequent increase in the risk of fractures even with little or no trauma. The skeleton consists of two bone types. Cortical bone (the bone of the peripheral skeleton) is responsible for 80% of total bone, while trabecular bone (the bone of the axial skeleton—the spinal column, the pelvis, and the proximal femur) constitutes a honeycomb structure filled with red marrow and fat, providing greater surface area per unit volume.

The subsequent risk of fracture from osteoporosis will depend on bone mass at the time of menopause and the rate of bone loss following menopause. ⁴⁵¹ Although the peak bone mass is influenced by heredity and endocrine factors, it is now recognized that there exists only a relatively narrow window of opportunity for acquiring bone mass. Almost all of the bone mass in the hip and the vertebral bodies will be accumulated in young women by late adolescence (age 18), and the years immediately following menarche (11–14) are especially important. ^{452, 453} After adolescence, there continues to be only a slight gain in total skeletal mass that ceases around age 30, and in many individuals a decline in bone mass in the hip and spine begins after age 18. ^{453, 454} After age 30 in most people, there is a slow decline in bone mass density, approximately 0.7% per year. The importance of a normal diet and a normal hormonal environment during adolescence cannot be overrated.

The onset of spinal bone loss begins in the 20s, but the overall change is small until menopause. Bone density in the femur peaks in the mid to late 20s and begins to decrease around age 30. In general, trabecular bone resorption and formation occur four to eight times as fast as cortical bone. Beyond age 30, trabecular resorption begins to exceed formation by about 0.7% per year. This adverse relationship accelerates after menopause and up to 5% of trabecular bone and 1–1.5% of total bone mass loss will occur per year after menopause. This accelerated loss will continue for 10–15 years, after which bone loss is considerably diminished but continues as the aging-related loss. For the first 20 years following cessation of menses, menopause-related bone loss results in a 50% reduction in trabecular bone and a 30% reduction in cortical bone. ^{455, 456}

When estrogen levels decline, bone remodeling increases. Each remodeling unit is initiated by osteoclast excavation followed by osteoblast refilling. Estrogen exerts a tonic suppression of remodeling and maintains a balance between osteoclastic and osteoblastic activity; in the absence of estrogen, osteoclastic activity predominates, resulting in bone resorption. The precise mechanism of action for sex steroid protection of bones remains unknown; however a growing body of knowledge indicates complex interactions at the molecular level. ⁴⁵⁷ Increased efficiency of calcium absorption (probably secondary to estrogen-induced enhancement of the availability of vitamin D (1,25-dihydroxycholecalciferol) and a direct role for the estrogen receptors in the osteoblasts are likely important factors. Many estrogen-dependent growth factors and cytokines are involved in bone remodeling. ⁴⁵⁸ Estrogen modulates the production of bone resorbing cytokines such as interleukin-1 and -6, bone stimulating factors such as insulin-like growth factors I and II, and transforming growth factor- β . Estrogen increases vitamin D receptors in

osteoblasts, and this may be a method by which estrogen modulates vitamin D activity in bone.⁴⁵⁹ There is little evidence that estrogen affects bone by altering the circulating calcitropic hormones.⁴⁶⁰ Thus, the actions of estrogen are primarily direct effects on bone and important effects on vitamin D metabolism, and renal and intestinal handling of calcium.

Estrogen is a critical hormone in both males and females. Males with mutations in the estrogen receptor alpha or who have aromatase deficiencies grow slowly and have markedly reduced bone densities.^{444, 461} Analysis of the decline in testosterone and estrogen circulating levels with aging indicates that the amount of bioavailable estrogen circulating in the blood is the most consistent predictor of bone density in men and women.⁴⁶² And most impressively, a man with an aromatase deficiency, treated with estrogen, demonstrated that both androgens and estrogens are necessary in order for males to reach optimal bone mass.⁴⁶³

The process is slower in blacks, and bone mass, adjusted for body size, is greater in black women. It is believed that racial differences in bone density are established in childhood and early adolescence.^{464, 465} The reasons for this are not entirely clear; it is not simply a difference in estrogen metabolism.⁴⁶⁶

In general, bone mass is increased in black and obese women and decreased in white, Asian, thin, and sedentary women. Despite the greater bone mass (and lower fracture rates) in blacks, the impact of osteoporotic fractures in black women is still considerable. Black women are subject to similar risk factors for osteoporosis (thinness, high alcohol consumption), and, most importantly,

postmenopausal estrogen therapy is associated with protection.⁴⁶⁷ Japanese women demonstrate the same amount and pattern of bone loss after menopause as white women.⁴⁶⁸

Although estrogen plays a principal role in regulating bone density, a genetic susceptibility is important. A study of the premenopausal daughters of women with osteoporosis revealed a reduction in bone mass, suggesting a genetic influence as well as the sharing of a lifestyle that produces a relatively low peak bone mass.⁴⁶⁹ Studies of twins and mother-daughter pairs indicate that up to 70% of the variation in bone density is determined by heredity.⁴⁷⁰

Variations in the gene that encodes the vitamin D receptor are prevalent in postmenopausal women with decreased bone densities.⁴⁷¹ The absence of vitamin D receptor gene allelic polymorphisms has been reported in older women who neither lose significant bone nor respond to calcium supplementation.⁴⁷² In addition, low bone density is associated with specific alleles of COL1A1, one of the two genes that encode the two polypeptides of collagen.⁴⁷³ This opens the way to develop genetic markers to identify individuals at increased risk for osteoporosis, and, ultimately, to develop genetic therapy.

The change in trabecular bone in postmenopausal women is largely attributed to estrogen deficiency; 75% or more of the bone loss that occurs in women during the first 15 years after menopause is attributable to estrogen deficiency rather than to aging itself.^{474, 475} Vertebral bone is especially vulnerable, beginning to decline as early as 20 years of age.⁴⁷⁶ Vertebral bone mass can be found to be significantly decreased in perimenopausal and early postmenopausal women who have rising FSH and decreasing estrogen levels, while bone loss from the radius is not found until at least a year out from the menopause.⁴⁷⁷ This early loss of axial skeleton bone suggests that the hypoestrogenic postmenopausal state is not the only cause of vertebral osteoporosis.⁴⁷⁸ One obvious suspect is a decline in dietary intake of calcium in the premenopausal years, nevertheless menopause and the loss of estrogen remain as the major contributors to bone loss. The risk of fracture, therefore, depends upon 2 factors: the bone mass achieved at maturity and the subsequent rate of bone loss. A high rate of bone loss after menopause (the “fast loser”) is highly predictive of an increased risk of fracture. The combination of a low bone mass and fast losing is additive, and thus, these individuals are at the highest risk of fracture. Fast losing probably reflects lower endogenous estrogen levels. The bone density, which is the threshold for vertebral fractures, is only slightly below the lower limit of normal for premenopausal women.⁴⁷⁹

Bone Loss During the Perimenopausal Transition

Should a clinician be concerned about bone loss and consider interventions during the perimenopausal years? Some studies have concluded that calcium supplementation of perimenopausal women retards metacarpal and lumbar bone loss.^{480, 481} However, the amount of perimenopausal bone loss is small unless estrogen levels are below normal.^{482, 483 and 484} Healthy women (exercisers and non-exercisers) who are anovulatory or who have inadequate luteal phase function (and thus are exposed to less progesterone) do not have an increase in bone loss.^{485, 486} Interventions and treatments to prevent future osteoporosis are not necessary in women who have adequate estrogen levels and who are eating normally.

Signs and Symptoms

The osteoporotic disabilities sustained by the castrate or postmenopausal woman include back pain, decreased height and mobility, and fractures of the vertebral

body, humerus, upper femur, distal forearm, and ribs. Back pain is a major clinical symptom of vertebral compression fractures. The pain with a fracture is acute, and then it subsides over 2–3 months, but lingers as chronic low back pain due to increasing lumbar lordosis. The pain will subside within 6 months unless multiple fractures produce a picture of constant pain.

Epidemiologic studies have revealed the following:⁴⁸⁷

1. **Spinal (vertebral) compression fracture.** Symptomatic spinal osteoporosis, causing pain, loss of height, postural deformities (the kyphotic Dowager's hump) with consequent pulmonary, gastrointestinal, and bladder dysfunction, is 5 times more common in white women than men. Approximately 50% of women over 65 years of age have spinal compression fractures; about two-thirds are clinically unrecognized. Each complete compression fracture causes the loss of approximately 1 cm in height. The average non-treated postmenopausal white woman can expect to shrink 2.5 inches (6.4 cm). The most common sites for vertebral fractures are the 12th thoracic and the first 3 lumbar vertebrae. These physical changes also have a negative impact on body image and self esteem.
2. **Colles' fracture.** There is a 10-fold increase in distal forearm fractures in white women as they progress from age 35 to 60 years. A white woman has approximately a 15% lifetime risk of a forearm fracture. Colles' fractures are the most common fractures among white women until age 75, when hip fractures become more common.
3. **Head of femur fracture.** The incidence of hip fractures increases with age in white women, rising from 0.3/1000 to 20/1000 from 45 to 85 years. Eighty percent of all hip fractures are associated with osteoporosis. White women have approximately a 16% lifetime risk of having a hip fracture. This fracture carries an increased risk of morbidity and mortality. Between 15–20% of patients with hip fracture die due to the fracture or its complications (surgical, embolic, cardiopulmonary) within 3 months, and Beals found that only half of hip fracture victims in Portland, Oregon, survived for 1 year.⁴⁸⁸ However, most of this increase in mortality is due to underlying conditions and prevention of these fractures would have only a minor impact on longevity.⁴⁸⁹ Nevertheless, the survivors are frequently severely disabled and may become permanent invalids. Hip fractures alone occur in more than 300,000 women per year in the U.S. with a mortality of 40,000 annually and an associated cost of billions of dollars.
4. **Tooth Loss.** Oral alveolar bone loss (which can lead to loss of teeth) is strongly correlated with osteoporosis, and the salutary effect of estrogen on skeletal bone mass is also manifested on oral bone.⁴⁹⁰ Even in women without osteoporosis, there is a correlation between spinal bone density and number of teeth.⁴⁹¹ Tooth loss is also correlated with the use of cigarettes, a recognized contributor to bone loss.

Diagnostic Tests

Patients with osteoporosis should be screened for other conditions that lead to osteoporosis:

1. Serum parathyroid hormone, calcium, phosphorus, and alkaline phosphatase: for primary hyperparathyroidism.
2. Renal function tests: for secondary hyperparathyroidism with chronic renal failure.
3. Blood count and smear, sedimentation rate, protein electrophoresis: for multiple myeloma, leukemia, or lymphoma.
4. Thyroid function tests: for hyperthyroidism and excessive thyroid hormone treatment.
5. Careful history and, when indicated, appropriate laboratory studies to rule out hypercortisolism, alcohol abuse, and metastatic cancer.

The presence of osteomalacia, to be suspected in all elderly patients with osteoporosis, can be detected by measuring the serum calcium, phosphorous, alkaline phosphatase, and the 1,25-dihydroxyvitamin D levels. These are all normal in patients with osteoporosis.

The effect of excess thyroid hormone on bone is not entirely clear. Although it is recognized that excess thyroxine treatment can cause bone loss, retrospective studies of thyroid function and bone mass have not produced uniform conclusions.⁴⁹² In the Study of Osteoporotic Fractures, women with a previous history of hyperthyroidism had an increased risk of subsequent hip fractures, and women taking thyroid hormone also had an increased risk of fracture (which did not reach statistical significance).⁴⁹³ However, in a prospective assessment of TSH levels in the Study of Osteoporotic Fractures, no association could be detected between low TSH and bone loss.⁴⁹⁴ Perhaps abnormal thyroid levels affect bone quality rather than quantity, and until accurate fracture data become available with this issue, it is prudent to maintain TSH levels within the normal range.

Specific Causes of Bone Disease

Drugs	Heparin, anticonvulsants, high intake of alcohol
Chronic disease	Renal and hepatic
Endocrine diseases	Excess glucocorticoids Hyperthyroidism Estrogen deficiency Hyperparathyroidism
Nutritional	Calcium, phosphorous, vitamin D deficiencies

Measuring Bone Density

There is a 50–100% increase in fracture risk for each standard deviation decline in bone mass (approximately 0.1 g/cm bone mass).⁴⁹⁵ Measurement of lower bone mass in the hip is even more predictive; a one standard deviation is associated with nearly a 3-fold increase in risk of fracture.⁴⁹⁶ Although low bone density reliably predicts the risk of fracture, increases in bone density in response to treatment do not demonstrate a direct correlation with a reduction in fractures. Therefore, a few percentage point differences achieved by various treatments have little clinical meaning.

The impressive correlation between fracture risk and low bone density has raised the question whether it is of value to screen for osteoporosis. Keep in mind that because the rate of bone loss after menopause contributes equally to the risk of fracture as the total bone mass present at the time of the menopause, a normal bone density measurement at the time of menopause does not mean that the patient will not be at risk of fracture later in life. A relatively young woman with a low bone mass could be targeted for appropriate intervention; however, it is not cost-effective to attempt to screen all postmenopausal women with an expensive method, and attention is now returning to the methods of single photon and single-energy x-ray absorptiometry because measurement of bone loss at the heel and radius accurately assess future fracture risk.⁴⁹⁷

Bone density measurements are certainly useful when an individual woman requires the information in order to make an informed decision regarding hormone therapy. Indeed, a decision to use hormone therapy and better maintenance of a hormone program are correlated with patients' knowledge of their bone density measurements.^{498, 499} Because smokers have lower estrogen levels on estrogen therapy, it is worthwhile to document the impact of treatment on bone density in order to consider whether dosage is adequate. Patients who have received long-term corticosteroid, thyroxine, anticonvulsant, or heparin treatment deserve bone mass assessment.

There is a percentage of postmenopausal women on hormone therapy (from 5% to 15%, depending upon compliance) who continue to lose bone.^{500, 501} Consideration should be given to an occasional measurement of bone density as an effective method of assessment and to motivate compliance.

Summary of Reasons to Measure Bone Mass

1. To help patients to make decisions regarding hormone therapy.
2. To assess response to therapy in selected patients, e.g., smokers, and women with eating disorders.
3. To assess bone mass in patients being treated long-term with glucocorticoids, thyroid hormone, anticonvulsants, or heparin.
4. To confirm the diagnosis and assess the severity of osteoporosis to aid in treatment decisions, and to monitor efficacy of therapy.
5. To assess bone mass in postmenopausal women who present with fractures, who have one or more risk factors for osteoporosis, or who are over age 65.

Standard x-rays do not provide an early assessment of fracture risk; 30–40% of bone must be lost before radiographic changes become apparent. Photon absorptiometry measures the transmission of photons through bone. Single-photon absorptiometry uses an ¹²⁵I source of energy or, more recently, miniature x-ray

tubes. These methods measure bone density in the radius and the calcaneus and are relatively inexpensive. These measurements correlate with vertebral bone density and predict the risk of future fracture.⁴⁹⁷ Dual-energy absorptiometry employs photons from two energy sources. Dual-energy x-ray absorptiometry (DEXA) provides good precision for all sites of osteoporotic fractures, and the radiation dose is much less than for a standard chest x-ray. Whole body scans by DEXA can measure total body calcium, lean body mass, and fat mass. Quantitative computed tomography for bone density measurements can be performed on most commercial computed tomography (CT) systems; however, radiation exposure is higher than with DEXA, and measurements of the femur are not available, although very accurate measurements of the spine are possible.

For high precision, the best information is provided by the DEXA technique (together with sophisticated software to give a precision of 1%), measuring the three sites of greatest interest, the radius, the hip, and the spine.⁵⁰² Better accuracy is gained by 3-site assessments because there can be differences among the sites. In other words, a normal value at one site does not preclude a low bone density at another site. Serial measurements are usually at least one year apart. For practical clinical use (and for screening), measurement of the bone density at the radius or calcaneus is sufficient and cost-effective. It is anticipated that ultrasonography will prove to be a low-cost effective method for bone mass assessment.⁵⁰³ Ultrasonographic measurements of the calcaneus have been reported to be as accurate as femoral neck measurements by DEXA in predicting the risk of hip fractures.^{504, 505} Ultrasonometry of the calcaneus can also predict spine and femur fracture risk.

T Score —Standard deviations between patient and average peak young adult bone mass. The more negative, the greater the risk of fracture.

Z Score —Standard deviations between patient and average bone mass for same age and weight. A Z score lower than —2.0 (2.5% of normal population of same age) requires diagnostic evaluation for causes other than postmenopausal bone loss.

Definitions Based on Bone Mineral Density

Normal	0 to -1 S.D. from the reference standard (84% of the population)
Osteopenia	-1 to -2.5 S.D.
Osteoporosis	below -2.5 S.D.

Biochemical Markers of Bone Turnover

There are many serum and urinary biochemical markers of bone turnover. Markers of bone formation include serum levels of osteocalcin, total and bone alkaline phosphatase, and procollagen peptide. Bone resorption is indicated by changes in urinary calcium, hydroxyproline, pyridinoline and deoxypyridinoline cross-links of collagen, telopeptides of collagen, and serum cross-linked telopeptides.

The urinary tests use a second morning voided urine specimen, and the immunoassays measure hydroxyproline, pyridinoline, deoxypyridinoline, the collagen cross-linked N-telopeptides, or the collagen cross-linked C-telopeptides.⁵⁰⁷ Because of individual variability, marker measurements correlate poorly with bone mineral density; however, changes in these markers quickly indicate responses to estrogen therapy.⁵⁰⁸ Therefore, efficacy of therapy (any of the anti-resorptive treatments) can be judged by comparing a baseline value with a single follow-up measurement after 1–3 months of treatment. A lesser decrease in the urinary cross-linked peptides indicates a less than optimal bone response, identifying patients for further evaluation and specific added treatment.^{509, 510} How reliable, practical, and cost-effective this approach is for routine clinical use is yet to be determined.

Treatment

Estrogen therapy will stabilize the process of osteoporosis or prevent it from occurring. Besides inhibiting osteoclastic resorption activity, estrogen increases intestinal calcium absorption, increases 1,25-dihydroxyvitamin D (the active form of Vitamin D), increases renal conservation of calcium, and supports the survival of osteoblasts. With estrogen therapy one can expect a 50–60% decrease in fractures of the arm and hip,^{511, 512, 513 and 514} and when estrogen is supplemented with calcium, an 80% reduction in vertebral compression fractures can be observed.⁵¹⁵ This reduction is seen primarily in patients who have taken estrogen for more than 5 years.^{241, 516} **Protection against fractures wanes with age, and long-term estrogen use is necessary to maximally reduce the risk of fracture after age 75.**

Because most osteoporotic fractures occur late in life, women and clinicians must understand that the short-term use of estrogen immediately after menopause cannot be expected to protect against fractures in the 7th and 8th decades of life. Some long-term protection is achieved with 7–10 years of estrogen therapy after menopause, but the impact is minimal after age 75.⁵¹⁷ In a prospective cohort study of women 65 years of age and older, in the women who had stopped using estrogen, and in those who were over 75 and had stopped using estrogen even if they had used estrogen for more than 10 years, there was no substantial effect on the risk for fractures.⁵¹⁸ The effective impact of estrogen requires initiation within 5 years of menopause and for current use to extend into the elderly years. The protective effect of estrogen rapidly dissipates after treatment is stopped because estrogen withdrawal is followed by rapid bone loss. In the 3- to 5-year period following loss of estrogen, whether after menopause or after cessation of estrogen therapy, there is an accelerated loss of bone.^{519, 520 and 521} In a Swedish case-control study, most of the beneficial effect of hormone therapy was lost 5 years after discontinuing treatment.⁵¹⁴ Maximal protection against osteoporotic fractures, therefore, requires lifelong therapy, and even some long-term protection requires 10 or more years of treatment.⁵²² Standard doses of estrogen administered transdermally (50 µg) appear to protect against fractures as well as standard oral doses.⁵¹⁴

For many years, it was believed that estrogen therapy would either prevent or slow bone loss, but not produce a gain in bone density. Modern studies indicate that this is not the case. For example, in the PEPI trial, at the end of 3 years, the women receiving hormone treatment had experienced about a 5% gain in bone mineral density in the spine and 2% in the hip compared with approximately a 2% loss in the placebo group.⁵⁰¹ How long does this gain in bone continue? In a 10-year follow-up study of women receiving estrogen-progestin therapy, the spinal bone density steadily increased, reaching a level 13% over baseline after 10 years of treatment.⁵²³ It is still unknown whether a continuing increase over many years provides additional fracture protection.

The positive impact of hormone therapy on bone has been demonstrated to take place even in women over age 65.^{241, 516, 517 and 518, 524, 525} This is a strong argument in favor of treating very old women who have never been on estrogen. Estrogen use between the ages of 65 and 74 has been documented to protect against fractures.⁵¹³

Studies have demonstrated that a dose of 0.625 mg of conjugated estrogens is necessary to preserve bone density.⁵²⁶ The conventional wisdom has stated that an estradiol blood level of 40–60 pg/mL is required to protect against bone loss.^{527, 528} We now know that any amount of estrogen can have an impact, although it is very likely that some degree of protection is lost when doses are less than the equivalent of 0.625 mg conjugated estrogens.

The rate of bone loss and the incidence of hip and vertebral fracture is inversely related to the circulating estrogen levels in older women.^{529, 530} Estradiol levels as low as 10 pg/mL have a beneficial impact on bone density and fracture rates compared with values below 5 pg/mL. **Thus, any increment in estrogen, even within the usual postmenopausal range, will exert protective effects.** This explains how a positive effect on bone was observed even with the utilization of the vaginal ring that delivers a very small amount of estradiol with minimal systemic absorption.⁵³¹

A lower dose of 0.3 mg daily of conjugated estrogens or 0.5 mg estradiol prevented loss of vertebral trabecular bone when combined with calcium supplementation (to achieve a total intake of 1500 mg daily).^{532, 533 and 534} In a small study without calcium supplementation, the daily administration of 0.3 mg conjugated estrogens and 2.5 mg medroxyprogesterone acetate produced a slight increase in lumbar bone density with a lesser effect on the hip.⁵³⁵ A study of women randomized to treatment either with continuous transdermal delivery of estradiol 50 µg daily or oral estrogen demonstrated that both equally prevented postmenopausal bone loss.⁵³⁶ Major concerns with lower doses include the possibilities that there will be a significant percentage of non-responders and some cardiovascular benefit will be sacrificed. Nevertheless, a lower dose of estrogen may be more acceptable (fewer side effects) in elderly women. Patients electing to be treated with lower doses should have follow-up assessments for response with measurements of either bone density or urinary biochemical markers. After 6 months to one year, we urge patients on lower doses to move up to a standard regimen.

While progestational agents are considered antiestrogenic, they have been reported to act independently, in a manner similar to estrogen, to reduce bone resorption.⁵³⁷ When added to estrogen, progestins can lead to an apparent synergistic increase in bone formation associated with a positive balance of calcium.^{538, 539}

[540](#) and [541](#) On the other hand, good studies have failed to find a greater impact on bone, comparing estrogen alone to estrogen plus a progestin. [518](#) However, the synergistic result of combining estrogen with a progestin is probably determined by the type of progestin, being limited to members of the 19-nortestosterone (norethindrone) family. [286](#) This could reflect an increase in free estrogen levels because of a reduction in sex hormone-binding globulin. Careful studies indicate that the addition of medroxyprogesterone provides an additional effect on bone only in women with established, significant osteoporosis. [541](#), [542](#) and [543](#)

In the PEPI trial, at the end of 3 years, there was little difference comparing treatment with estrogen only to the groups receiving combinations of estrogen and medroxyprogesterone acetate or micronized progesterone. [501](#) Thus, the daily, continuous combination of estrogen-progestin is equally efficacious in maintaining bone density as the standard sequential regimens, although at least one study has indicated a greater response in the lumbar spine with continuous treatment. [544](#), [545](#), and [546](#)

The addition of testosterone to an estrogen therapy program has been reported to provide no additional beneficial impact on bone or on relief from hot flashes. [547](#), [548](#) Others have demonstrated a greater increase in bone density with an estrogen-androgen combination compared with estrogen alone, although the blood estrogen levels achieved were higher than those associated with standard postmenopausal hormone therapy. [549](#)

Follow-up Assessment of Hormone-Treated Women

Not all women will maintain or gain bone density on postmenopausal hormone therapy; in one study, 12% of treated women lost bone despite apparently good compliance. [500](#) In the PEPI 3-year clinical trial, where compliance rates were probably maximal, 4% of treated women lost bone in the spine and 6% in the hip. [501](#)

It is worthwhile to measure the bone density in treated women when they are in their late 60s. The reason why some women fail to respond is unknown. It is further unknown whether these patients will respond to added treatment, such as calcitonin or a bisphosphonate, but it is worth special evaluation, treatment, and surveillance.

Selective Estrogen Agonists/Antagonists (Selective Estrogen Receptor Modulators)

A greater understanding of the estrogen receptor mechanism ([Chapter 2](#)) allows us to understand how mixed estrogen agonists-antagonists can have selective actions on specific target tissues. New agents are being developed in an effort to isolate desired actions from unwanted side effects. Raloxifene exerts no proliferative effect on the endometrium but produces favorable responses in bone and lipids. [550](#), [551](#) The changes in bone remodeling produced by raloxifene are consistent with an estrogen agonist effect. [552](#)

Estrogen selective agonists/antagonists (tamoxifen and raloxifene) have been reported to reduce the incidence of breast cancer within 2–3 years of treatment. [553](#), [554](#) Short-term clinical trial data indicate that raloxifene has a positive impact on bone density, favorable effects on LDL-cholesterol, fibrinogen, and lipoprotein(a), but no effects on HDL-cholesterol and PAI-1, and raloxifene increases hot flushing. [555](#), [556](#) Long-term clinical trial data will be necessary to determine the ultimate impact on clinical events, specifically fractures, coronary heart disease, stress incontinence, and cognition. The MORE study (**M**ultiple **O**utcomes of **R**aloxifene **E**valuation) is a worldwide clinical trial of raloxifene in osteoporotic women. After 2 years, raloxifene treatment was associated with a 44% reduction in vertebral fractures. [557](#) In a 2-year randomized trial in monkeys, raloxifene exerted no protection against coronary artery atherosclerosis despite changes in circulating lipids similar to those achieved in women. [558](#) However, a combination of actions (antioxidant activity, some beneficial effects on lipids, a reduction in homocysteine levels) makes it likely there will be some favorable impact on the cardiovascular system. [556](#), [559](#), [560](#) RUTH (**R**aloxifene **U**se for **T**he **H**eart) is both a primary and secondary coronary heart disease prevention trial, started in 1998, that should provide data by 2003. In our view, raloxifene is an option for prevention of osteoporosis, especially for patients reluctant to use hormone therapy, but not a substitute for estrogen.

Calcium Supplementation

There has been considerable confusion over whether calcium supplementation by itself can offer protection against postmenopausal osteoporosis. This is partly due to the fact that calcium studies have been performed in women who were in the very early postmenopausal years, in the midst of the rapid loss of calcium associated with estrogen deficiency, and this estrogen effect overwhelmed any responses to calcium. Studies that involve women beyond this early stage of the postmenopausal period definitely indicate a positive impact of calcium supplementation. [561](#), [562](#) and [563](#)

Calcium absorption decreases with age because of a decrease in biologically active vitamin D and becomes significantly impaired after menopause. A positive calcium balance is mandatory to achieve adequate prevention against osteoporosis. Calcium supplementation (1000 mg per day) reduces bone loss and decreases fractures, especially in individuals with low daily intakes. [564](#) However, estrogen acts to improve calcium absorption (by increasing the levels of 1,25-dihydroxyvitamin D) and makes it possible to utilize effective supplemental calcium in lower doses. In order to remain in zero calcium balance, women on estrogen therapy require a total of 1000 mg elemental calcium per day. [564](#), [565](#) and [566](#) Because the average woman receives about 500 mg of calcium in her diet, the minimal daily supplement equals an additional 500 mg. Women not on estrogen require a daily supplement of at least 1000 mg calcium.

Even with the commonly used therapeutic doses of calcium, nearly 40% of postmenopausal women will have inefficient absorption. [567](#) Estrogen improves calcium absorption and allows the utilization of supplemental calcium in effective doses without the side effects associated with higher doses (constipation and flatulence) that diminish compliance. We must emphasize that although calcium supplementation is important, it cannot provide the same degree of protection against osteoporosis as that achieved by hormonal therapy. [568](#), [569](#) Nevertheless, the beneficial impact of estrogen on bone is reduced in the absence of calcium supplementation. [533](#)

Improved calcium intake in adolescents results in significant increases in bone density and skeletal mass, providing protection against osteoporosis later in life. [570](#), [571](#) Calcium supplementation is far more important during adolescence than in the reproductive years when bone formation is minimal. Under age 25, during the years of bone accumulation, the daily calcium intake should be 1500 mg. [564](#) This amount, 1500 mg/day, is also recommended during pregnancy and lactation. Most calcium comes from dairy products; relying on other foods is not easy because it requires a high intake volume of other foods to provide the same amount of calcium in normal daily servings of dairy products.

Calcium Content of Foods

Yogurt (one cup)	415 mg
Yogurt with fruit (one cup)	345 mg
Juice fortified with calcium (one cup)	300 mg
Milk (one cup)	300 mg plus 100 IU Vitamin D

Ice cream (one cup)	175 mg
Cottage cheese (1 cup)	140 mg
Romano cheese (1 ounce)	300 mg
Parmesan cheese (1 ounce)	335 mg
Cheddar cheese (1 ounce)	205 mg
Swiss cheese (1 ounce)	270 mg
Mozarella cheese (1 ounce)	207 mg
Broccoli, cooked (one cup)	80 mg
Beans, cooked (one cup)	80 mg

There are dozens of calcium supplements on the market, containing calcium carbonate, calcium lactate, calcium phosphate, or calcium gluconate. ⁵⁷² Calcium carbonate tablets are the cheapest and contain the most elemental calcium (40%). Calcium lactate tablets contain 13% calcium, and calcium gluconate only 9%. The calcium carbonate antacids are excellent, inexpensive sources. One should be aware that aluminum-containing antacids such as Maalox, Mylanta, Gelusil, and Riopan can inhibit gastrointestinal absorption of calcium. Bone meal and dolomite as sources of calcium should be avoided because they can be contaminated with lead. Calcium citrate does not require gastric acid for absorption and is the best choice for older patients with reduced gastric acid production. **Calcium supplementation is most efficient when single doses do not exceed 500 mg and when taken with a meal.** Excess calcium supplementation (especially not with meals) is associated with a slight increase in risk for kidney stones. ⁵⁷³

Vitamin D

Osteoporosis related to aging is due significantly to age-related changes in vitamin D and calcium metabolism. There is an age-related decrease in the ability of the skin and the kidney to synthesize the active form of vitamin D (1,25-dihydroxycholecalciferol, also known as 1,25-dihydroxyvitamin D), and there is a decrease in the ability of the intestine to absorb dietary vitamin D. Exposure of the skin to ultraviolet rays in sunlight stimulates the formation of cholecalciferol (vitamin D₃). Commercial vitamin preparations contain ergocalciferol (vitamin D₂ or calciferol). Vitamin D-fortified milk contains cholecalciferol. Cholecalciferol and ergocalciferol are converted in the liver to calcifediol, which is converted in the kidneys to calcitriol (1,25-dihydroxyvitamin D).

It is now recommended that individuals over age 70 should add 800 units of vitamin D to calcium supplementation. A large randomized trial in Finland documented a reduced rate of fractures in elderly women receiving supplementation of vitamin D₂ (by an annual intramuscular injection), and in France, supplementation of calcium and vitamin D₃ reduced the number of hip fractures by 43%. ^{568, 574} In postmenopausal women with osteoporosis, treatment with calcitriol (vitamin D) produced a 3-fold reduction in vertebral fractures. ⁵⁷⁵ And finally, supplementation with 400 IU vitamin D₃ in women age 70 and older restored the markers of vitamin D and calcium metabolism to that observed in young adults, and the bone mineral density at the femoral neck increased. ⁵⁷⁶

Because adequate and active vitamin D depends upon cutaneous generation mediated by sun exposure, women who live in cloudy areas during the winter months are relatively vitamin D deficient and lose bone. ⁵⁷⁷ In far northern and southern areas, the winter sunlight is inadequate to stimulate dermal activation. Vitamin D supplementation is recommended for these women as well but only during the winter and at a lower level, 400 units daily (usually available in over-the-counter multivitamins or in combination with calcium). High doses cause hypercalciuria with a risk of stone formation. If uncertain regarding vitamin D supplementation, the serum level of 1,25-dihydroxyvitamin D can be measured; a level below 15 ng/L is abnormal. ⁵⁷⁸

The impact of vitamin D supplementation may be less in younger, early postmenopausal women. In a 2.5-year randomized clinical trial in Finland, supplementation with 300 IU vitamin D₃ did little by itself and added nothing to the beneficial effect of estrogen on bone density. ⁵⁷⁹ The benefit of vitamin D supplementation is clear in older women, and the lack of side effects with low doses encourages us to recommend vitamin D supplementation as part of the overall program for osteoporosis prevention in younger women.

Bisphosphonates

Bisphosphonates are effective in preventing bone loss by inhibiting bone resorption. The bisphosphonates bind to bone mineral where they remain for many years, making bone less susceptible to osteoclastic action. The most promising of these agents are etidronate, alendronate, clodronate, pamidronate, tiludronate, and risedronate. ^{580, 581} The first generation of bisphosphonates (etidronate) also inhibited bone mineralization, and therefore intermittent therapy was necessary. The second generation of bisphosphonates allows bone formation to occur while inhibiting bone resorption and makes it possible to use continuous therapy rather than intermittent therapy.

In women with osteoporosis, alendronate (10 mg daily) administration reduced the risk of subsequent non-vertebral fractures by at least 30% (and probably 50%) and vertebral fractures by 90% in the first 3 years of treatment. ^{582, 583} In normal postmenopausal women, alendronate increased bone density in both the spine and the hip, and the 5 mg dose (the preferred dose for preventive treatment) was more effective than 2.5 mg. ^{584, 585} The increase in bone density with the 5 mg dose is slightly less than that observed with estrogen-progestin therapy. ⁵⁸⁴ It is unlikely that a difference of a few percentage points in bone density gain has an impact on the number of fractures ultimately experienced. Alendronate must be taken on an empty stomach with a full glass of water at least 30 minutes before any other food or liquid intake in order to achieve adequate absorption. A failure to remain upright for at least 30 minutes and until after the first food intake of the day after ingesting alendronate can result in esophageal injuries, such as esophagitis, esophageal ulcers, and esophageal erosions with bleeding. ⁵⁸⁶ Risedronate, 5 mg daily, is as effective as alendronate for the prevention of bone loss and may be better tolerated. ⁵⁸⁷

Etidronate given in a cyclic fashion (e.g., 400 mg daily for 2 weeks followed by a 12-week drug-free interval during which calcium supplementation is administered) prevents bone loss and reduces the vertebral fracture rate. ^{588, 589} In many countries, etidronate is the drug of choice for the treatment of osteoporosis. Although no comparison studies are available, it is probable that the bisphosphonates are comparable in efficacy and safety.

Bisphosphonates are an effective addition to osteoporotic prevention because they are well tolerated if taken correctly. However, unlike estrogens, bisphosphonates are unidimensional, having no effect on cardiovascular disease, hot flashes, or the atrophic changes seen in menopause. A combination of bisphosphonates and estrogen has an additive effect on bone; with alendronate and hormone therapy, there was about a 2% greater gain in bone density in the spine after 2 years of treatment. ⁵⁹⁰ It is not believed that this addition of several percentage points in bone mineral density will provide a worthwhile gain in fracture protection. Unlike, estrogen, accelerated bone loss does not occur after discontinuation of alendronate therapy. ⁵⁹¹ For this reason, long-term treatment may not be necessary.

Calcitonin

Calcitonin regulates plasma calcium by inhibiting bone resorption and can be used in patients for whom hormone therapy is contraindicated. Given by subcutaneous injection in a dose of 100 IU daily to women early after menopause it has the same effectiveness as estrogen in conserving bone density. ⁵⁹² Studies with intranasal delivery of salmon calcitonin (200 IU daily) indicate it can be similarly effective. ⁵⁹³ Calcitonin treatment should be combined with vitamin D and calcium supplementation. The disadvantages are the high cost and the potential for immunologic reactions to non-human calcitonin. Human calcitonin is available, but recombinant salmon calcitonin is more potent. An oral preparation will soon be available.

Fluoride

The addition of fluoride, a potent stimulator of bone formation, offers significant protection against osteoporosis. The clinical response depends on the formulation and dose. Slow-release sodium fluoride (25 mg bid given 12 of every 14 months) combined with calcium supplementation reduces the vertebral fracture rate with essentially no side effects. ⁵⁹⁴ Treatments recommended for no longer than 4 years to avoid the toxic accumulation of fluoride in bone. ⁵⁹⁵ Thus, this treatment is reserved for patients with established postmenopausal osteoporosis.

Tibolone

Tibolone is a steroid, related to the 19-nortestosterone family, that is effective for the treatment of bone and hot flashes in a dose of 2.5 mg per day.^{596,597} A lower dose of 1.25 mg daily also provides bone protection, but it is less effective and there is more vaginal bleeding. Tibolone is metabolized into 3 steroid isomers with varying estrogenic, progestogenic, and androgenic properties. The metabolites differ in their activities and dominance according to the target tissue. Thus, tibolone provides estrogenic effects on bone and hot flushing, but it induces atrophy of the endometrium.⁵⁹⁸ Its beneficial impact on bone (2.5 mg dose) is comparable to standard hormonal therapy.⁵⁹⁹ In the endometrium, tibolone is converted locally (by endometrial 3 beta-hydroxysteroid dehydrogenase/isomerase) to its D₄ progestational isomer, explaining its nonproliferative effect on the endometrium.⁶⁰⁰ Tibolone has an estrogenic effect on the vagina, and women report improvements in the symptoms of vaginal dryness and dyspareunia, and an increase in sexual enjoyment and libido.⁶⁰¹

Although a short-term reduction in HDL-cholesterol is an undesirable consequence; the long-term impact has not been well studied.⁶⁰² In a 2-year study, the unfavorable effect on lipoproteins was accompanied by beneficial changes in coagulation factors consistent with enhanced fibrinolysis and unchanged coagulation.⁶⁰³ Overall, it is possible that some favorable activity on the cardiovascular system is maintained. A major advantage of tibolone (2.5 mg daily) is its low (10–20%) incidence of bleeding. Because tibolone inhibits breast cell proliferation in vitro, it is possible that future studies will indicate that tibolone offers some protection against breast cancer. Tibolone also has a beneficial impact in short-term studies on insulin resistance in normal women and in women with noninsulin-dependent diabetes mellitus.^{604,605}

Thiazides

Older women are often treated with thiazides for hypertension. Thiazides reduce the urinary loss of calcium, induce a positive calcium balance, and treatment is associated with a higher bone density. It is useful to know that estrogen and thiazides are additive; a significantly higher bone density is achieved with combined use.⁶⁰⁶

Growth Hormone

Human growth hormone administration stimulates bone remodeling, but does not produce a significant increase in bone density.⁶⁰⁷ The extreme expense and the high incidence of unpleasant side effects further make this option unattractive.

Lifestyle Modifications

Lifestyle can have a beneficial effect on bone density. Physical activity (weight-bearing), as little as 30 minutes a day for 3 days a week, will increase the mineral content of bone in older women.⁶⁰⁸ To be effective, exercise must exert a load on bone, especially the spine.⁶⁰⁹ Ordinary walking will not suffice.⁶¹⁰ Even brisk walking achieves a significant increase in bone density only in the calcaneus, the site subjected to stress with walking.⁶¹¹ However, brisk walking may slow the rate of bone loss in the hip.⁶¹² In other words, weight lifting is better for the spine than is ordinary walking, although running probably helps hip bone mass. The activities that are beneficial are running, weight training, aerobics, stair climbing, and sports other than swimming. The effect of weight-bearing exercise on bone density is additive when combined with hormone therapy.⁶¹³ Although ordinary walking has little impact on bone density, it is still reasonable to expect walking to have an overall beneficial effect on the risk of fracture. Walking improves the cardiovascular status of patients and reduces body mass. These changes plus the exercise itself will improve balance and decrease the risk of falling. For these reasons, walking, even after adjusting for bone density, is associated with a reduced risk of hip fracture.⁴⁹³

The impact of exercise on bone is significantly less than that achieved by hormone therapy.⁵⁶⁷ Women require the full combination of pharmacologic therapy, calcium supplementation, and exercise in order to minimize the risk of fractures. For each of these, the beneficial impact lasts only as long as the therapy is continued.

Adverse habits, such as cigarette smoking or excessive alcohol consumption, are associated with an increased risk of osteoporosis. The magnitude of bone loss associated with cigarette smoking is consistent with a 40–45% increase in the risk of hip fracture.⁶¹⁴ Women who smoke also enter menopause earlier, and lose bone at a greater rate in the first years of the postmenopausal period.⁶¹⁵ Studies have indicated that estrogen is associated with lesser protection against fractures in smokers; however, this may be correctable by titrating the blood level of estrogen with the dose administered. The lower blood levels of estrogen in smokers have been correlated with an earlier menopause and a reduced bone density, and, therefore, the standard dose of estrogen may not totally counteract the predisposition of smoking toward osteoporosis.⁶¹⁶ The titration of estrogen dosage with circulating blood estradiol levels in smokers makes clinical sense, allowing the use of higher hormonal doses to maintain bone density. Monitoring of bone response with bone density measurements or urinary markers would further aid in achieving maximal effects of therapy.

Clinicians should always remember that exposure to excessive thyroid and glucocorticoid hormones is associated with osteoporosis and an increased rate of fractures. The bone loss associated with glucocorticoid treatment is significantly prevented by estrogen/progestin therapy,^{617,618} and excessive thyroid effects can be avoided by annually monitoring treatment dosage with TSH levels. Specific treatment should also be offered to patients using anticonvulsants.

A high coffee intake has been reported to be associated with an increased risk of osteoporosis.⁶¹⁹ However, this increase in risk is dependent upon dietary calcium intake. In women who drank at least one glass of milk (300 mg calcium) per day throughout most of their lives, increasing caffeinated coffee intake was not associated with a lower bone density.⁶²⁰ Repeatedly, we see the importance of teaching children and adolescents the merit of an adequate calcium intake; drinking nonfat milk throughout life is good for you. An adequate calcium intake compensates for “calcium robbers,” such as caffeine and soft drinks. A British study concluded that an increase of only 300 mL of milk per day in adolescents increases bone density without an increase in weight or body fat.⁶²¹

Remember that not all fractures are solely due to osteoporosis. Drug side effects, impaired vision, neurological dysfunction, and muscular conditions all put patients at risk because more than 90% of fractures occur following a fall.⁴⁶⁷ Interventions that reduce the odds of falling and enhance the ability to withstand the impact of a fall are important.⁶²² This includes patient education regarding hazards in the home, monitoring drug use, adequate nutrition, and a good exercise program. In addition, there is evidence that estrogen with or without added progestin improves muscle strength and balance.^{147,148 and 149,623,624} On the other hand, some studies have not been able to document an increase in muscle strength or improvements in balance.^{613,625} Furthermore, the increase in muscle mass and strength in response to weight-bearing exercise was the same when hormone users were compared with non-users.⁶²⁶

Conclusion

The menopause is a physiologic event that brings clinicians and patients together, providing the opportunity to enroll patients in health maintenance. The failure to respond appropriately (by either clinician or patient) easily leads to a loss of the patient from a practice, but equally, if not more, importantly, is the probability that the loss of a patient from a practice means that another woman has lost her involvement in a preventive health care program. Contrary to popular opinion, the menopause

is not a signal of impending decline, but, rather, a wonderful phenomenon that can signal the start of something positive, a good health program. Postmenopausal hormone therapy is an option that should be considered by virtually all women as a legitimate part of their preventive health program.

Postmenopausal hormone therapy had its beginning in the effort to alleviate specific symptoms associated with the decline in estrogen production at menopause. There is little question that women who suffer from hot flashes or atrophy of reproductive tract tissues can be relieved of their problems by the use of estrogens. However, in the last decade, the focus of postmenopausal hormone therapy has changed from short-term treatment to the preventive health care benefits associated with long-term treatment. It is almost certain that the long-term disabilities of osteoporosis can be largely prevented by therapy with estrogen and progestin. It is increasingly accepted that appropriate doses of estrogen have a beneficial impact on the risk of cardiovascular disease. The long-term impacts on urinary incontinence and cognition remain to be documented, but there is reason to believe there will be benefits in these areas.

We suggest treatment with estrogen for all women disturbed by the symptoms of hormone deprivation and advocate hormonal prophylaxis against osteoporosis and cardiovascular disease. The decision to use or not to use estrogen belongs to the patient, and it should be based on the information available in this book. The recommendation that hormone therapy be given for the shortest period of time appears to be shortsighted in view of the impressive evidence that sustained therapy has a profound impact on osteoporosis and cardiovascular disease, and that there are more beneficial than potentially harmful effects.

The evidence supporting many of the benefits with postmenopausal hormone therapy is reviewed in the previous chapter (Chapter 17, [Menopause and the Perimenopausal Transition](#)) where the effects of hormonal treatment are considered in conjunction with the impact of postmenopausal estrogen deprivation. In this chapter, we will review the clinical aspects of postmenopausal hormone therapy and our methods of patient management.

History^{1, 2 and 3}

Charles Edouard Brown-Sequard, practicing in London, reported in 1889, that he was rejuvenated by the self-administration of testicular extracts, and he suggested that ovarian extracts would have the same effect in women. Efforts to do so around the turn of the century were largely unsuccessful, but in 1897, ovarian extract was reported to be effective for hot flushing.⁴ The first American attempt to treat menopausal symptoms is attributed to E.L. Sevringhaus and J. Evans of Madison, Wisconsin, who, in 1929, administered a derivative from the amniotic fluid of cattle.^{2, 5} In the 1930s, the ovarian hormones were isolated, and the “estrin” products and the synthetic estrogens, stilbestrol and ethinyl estradiol, were administered to menopausal women.

Allen and Doisy were the first to isolate the estrogenic ovarian hormone. Edgar Allen was born in Colorado, educated at Brown University, and served in France during World War I. In 1933, Allen became the chairman of the Department of Anatomy at Yale University. He died of a heart attack, on patrol off Long Island, for the U.S. Coast Guard, in February 1943.

Edward Doisy was born in Illinois and educated at the University of Illinois and Harvard. During World War I, he was assigned to the Rockefeller Institute in New York City, and then to the Walter Reed Hospital in Washington. Doisy was the first chairman of biochemistry at the St. Louis University School of Medicine. He received the

Nobel Prize in Medicine, along with Henrik Dam, in 1943, for his isolation and synthesis of vitamin K. He died in 1986 at the age of 92.

In 1919, Edgar Allen and Edward Doisy, being discharged from the army after World War I, joined the faculty at the Washington University School of Medicine in St. Louis. They became friends playing on a faculty baseball team, and planned their first experiments driving to work together. In 1922, Allen moved to the University of Missouri to be Professor of Anatomy (and Dean in 1930), and Doisy to St. Louis University, but they continued their collaboration. Doisy prepared ovarian extracts and mailed them to Allen for experiments. In 1923 and 1924, Allen and Doisy reported the isolation from pig ovaries and the administration (to animals) of "an ovarian hormone."

In 1926, A.S. Parkes and C.W. Bellerby coined the basic word estrin to designate the hormone (or hormones) that induces estrus in animals. The terminology was extended to include estrone, estradiol, and estriol, although significant amounts of pure estradiol were not isolated until 1936. Doisy and his students (Veler and Thayer) in St. Louis isolated estrone in crystalline form from the urine of pregnant women in 1929. In 1932, at the first meeting of the International Conference on the Standardization of Sex Hormones in London, the pioneering chemists were bemoaning the problem of scarcity, limiting supplies to milligram amounts, when a relatively unknown biochemist, Girard, offered 20 grams of crystalline substance, derived by the use of a new reagent to treat mare's urine.

George W. Corner, at the University of Rochester, invited Willard Myron Allen, an organic chemist but now a medical student at the time in the 1920s, to join him in the study of the corpus luteum. Within 2 years, they had a pure extract, but it was not until 1934 that a crystalline progestin was isolated almost simultaneously in several countries. It took the corpora lutea of 50,000 pigs to yield a few milligrams. At the Second International Conference on Standardization of Sex Hormones in London, Corner and Allen proposed the name progestin. Others proposed luteosterone, and at a cocktail party, the various biochemists agreed to call the chemical progesterone.

Corner was born in Baltimore, graduated from the Johns Hopkins medical school, and completed an internship in gynecology under Howard Kelley. He joined the Department of Anatomy at the University of California, and in 1923 at the age of 34, he became the first professor of anatomy in the new medical school of the University of Rochester. In 1940, Corner became the Director of the Carnegie Laboratory of Embryology in Baltimore. He died in 1981.

Allen was born in Macedon, New York, educated at Hobart College and Brown University, finally receiving his medical degree from the University of Rochester in 1932. He completed a residency in obstetrics and gynecology and served on the faculty in Rochester until he became chairman of obstetrics and gynecology at the Washington University School of Medicine in 1940. He died in 1993.

In the 1930s, the Ayerst Company was extracting estrogens from the urine of pregnant women. Limited by the problems of supply, low activity, plus bad taste and odor, Gordon A. Grant, head of biochemistry for Ayerst, suggested in 1939 that they use urine from horses. The process produced sodium salts from the sulfate esters of the various estrogens, yielding a water-soluble conjugate. Premarin (conjugated estrogens) was **approved in Canada in 1941 and in the U.S. in 1942** for the treatment of symptoms associated with menopause.⁶ The tablets were and are still designated as variations of 1.25 mg, based on the equivalent amounts of Premarin and estrone (1.25 mg) that could produce the same effect in the Allen—Doisy bioassay (amount required to produce an increase in rat uterine weight). It was not until 1972 that the first quantitative analysis of Premarin was performed, based on gas chromatography.

Composition of Conjugated Estrogens (Premarin)

Sodium estrone sulfate	49.3%
Sodium equilin sulfate	22.4%
Sodium 17a-dihydroequilin sulfate	13.8%
Sodium 17a-estradiol sulfate	4.5%
Sodium D8,9-dehydroestrone sulfate	3.5%
Sodium equilenin sulfate	2.2%
Sodium 17b-dihydroequilin sulfate	1.7%
Sodium 17a-dihydroequilenin sulfate	1.2%
Sodium 17b-estradiol sulfate	0.9%
Sodium 17b-dihydroequilenin sulfate	0.5%

Estrogens and progestins used for postmenopausal hormone therapy are among the most commonly prescribed medications in the U.S. Currently, 46% of women who have experienced a natural menopause and 71% of women who have had bilateral oophorectomy report having used postmenopausal hormone therapy.⁷ The average duration of use in the U.S. as of 1992 was 6.6 years, but only 20% of users had maintained treatment for at least 5 years.

Selection of Patients for Treatment

Women Under Age 40 (Castrates and Women With Gonadal Dysgenesis)

In these women, the duration of estrogen deprivation is prolonged, and in women after surgical menopause the loss of estrogen is acute. The cyclic use of estrogen is recommended for short-term reduction of vasomotor symptoms and for long-term prophylaxis against cardiovascular disease, osteoporosis, and target organ atrophy. In some young patients, the equivalent of 0.625 mg conjugated estrogens is insufficient to allow menstrual bleeding. Because women of this age ordinarily are exposed to estrogen levels that stimulate endometrial growth and withdrawal bleeding, and for psychological reasons, a higher dose should be considered, if necessary, to maintain withdrawal bleeding until the menopausal time of life. However, in our experience, the doses equivalent to 0.625 mg conjugated estrogens almost always suffice. A standard sequential program is utilized. In those patients castrated because of endometriosis, recurrence of endometriosis has very rarely been a problem with estrogen therapy, but because endometrial cancer has been reported to occur in remaining endometriosis exposed to unopposed estrogen, an estrogen and progestin combination is strongly recommended.

The Perimenopausal Transition Years

After exclusion of other gynecologic causes, dysfunctional uterine bleeding is treated by progestin or oral contraceptive therapy and, if necessary, biopsy surveillance. Vasomotor reactions appearing in women despite the presence of menstrual bleeding should receive careful evaluation. Abnormal thyroid function should be ruled out. If a follicle-stimulating hormone (FSH) level is not greater than 20 IU/L, serious consideration should be directed toward psychosocial reasons for the flushing response.

The risk of fracture from osteoporosis will depend on bone mass at the time of menopause and the rate of bone loss following menopause.⁸ Although the peak bone mass is influenced by heredity and endocrine factors, it is now recognized that there exists only a relatively narrow window of opportunity for acquiring bone mass. Almost all of the bone mass in the hip and the vertebral bodies will be accumulated in young women by late adolescence (age 18), and the years immediately following menarche (11–14) are especially important.^{9,10} After adolescence, there continues to be only a slight gain in total skeletal mass that ceases around age 30, and in many individuals a decline in bone mass in the hip and spine begins after age 18.^{10,11} After age 30 in most people, there is a slow decline in bone mass density, about 0.7% per year. The importance of a normal diet and a normal hormonal environment during adolescence cannot be overrated.

Meaningful perimenopausal bone loss that is secondary to a decrease in estrogen is limited to those women with fluctuating hormonal and menstrual function, irregular bursts of follicular function alternating with no ovarian response to gonadotropins, so that these women are exposed to low estrogen over significant periods of time. The bone loss that begins in the 20s is due to a mechanism that is independent of hormones, and longitudinal studies have documented that trivial amounts of bone are lost prior to menopause in women with adequate estrogen levels.

The Early Postmenopause

The long-term postmenopausal use of hormone therapy depends heavily on a woman's own informed assessment, a process that should occur at this point in life. An

understanding of hormone therapy is an important component in any preventive health program directed toward the postmenopausal years. As a result of immediate responses in early climacteric symptoms, the patient enters the postmenopausal period of life more confident of herself emotionally, sexually, and physically. In our view, this establishes or cements good patient-clinician interchange and relations. The follow-up of the patient on effective estrogen-progestin therapy is more secure and certain. The practitioner offering estrogen-progestin treatment has a better and more reliable opportunity to act as primary clinician for these aging women. All monitoring of health systems will be improved as a result of this single involvement.

The Late Postmenopause

Atrophic conditions can be effectively treated with local or oral therapy in low maintenance doses. If there is no apparent basis for osteoporosis other than aging and ovarian failure, estrogen-progestin therapy and calcium plus vitamin D supplementation are advisable even for very old women. Further loss of bone can be halted and the risk of fractures reduced. In these older women, an assessment of progress can be obtained by measuring bone density. The impact of initiating hormone therapy in elderly women on the risk of cardiovascular disease has not been ascertained. However, it makes sense that elderly women would benefit from estrogen's dynamic protective mechanisms with an impact on stress incontinence, and probably, on the risk of Alzheimer's disease, as well.

Hormonal Agents and Routes of Administration

The dose of estrogen that is maximally effective in maintaining the axial and peripheral bone mass is equivalent to 0.625 mg conjugated estrogens.^{12,13} The relative potencies of commercially available estrogens become of great importance when prescribing estrogen, and the clinician should be familiar with the potencies in the [Table](#).

Relative Estrogen Potencies^{14, 15, 16, 17 and 18}

Estrogen	FSH levels	Liver proteins	Bone density
Conjugated estrogens	1.0 mg	0.625 mg	0.625 mg
Micronized estradiol	1.0 mg	1.0 mg	1.0 mg
Estropipate (piperazine estrogen sulfate)	1.0 mg	1.25 mg	1.25 mg
Ethinyl estradiol	5.0 µg	2–10 µg	5.0 µg
Estradiol valerate	—	—	1.0 mg
Esterified estrogens	—	—	0.625 mg
Transdermal estradiol	—	—	50 µg

The 17a-ethinyl group of ethinyl estradiol (by resisting metabolism) appears to enhance hepatic effects, for no matter by which route it is administered, liver function is affected.¹⁷ The same is true for conjugated equine estrogens. Contrary to the case with estradiol, the liver appears to preferentially extract ethinyl estradiol and conjugated equine estrogens no matter what the route of administration. Thus, the route of administration appears to influence the metabolic responses only in the case of specific estrogens, most notably estradiol.

At least two studies have been unable to demonstrate prevention of bone loss with the administration of 2 mg estriol daily.^{19,20} A major factor in the potency differences among the various estrogens (estradiol, estrone, estriol) is the length of time the estrogen-receptor complex occupies the nucleus. The higher rate of dissociation with the weak estrogen (estriol) can be compensated for by continuous application to allow prolonged nuclear binding and activity. Estriol has only 20–30% affinity for the estrogen receptor compared to estradiol; therefore, it is rapidly cleared from a cell. But if the effective concentration is kept equivalent to that of estradiol, it can produce a similar biologic response.²¹ In pregnancy, where the concentration of estriol is very great, it can be an important hormone, not just a metabolite. Thus, higher estriol levels are not necessarily protective. Because estriol protects the rat against breast tumors induced by various chemical carcinogens,²² it has been hypothesized that a higher estriol level protects against the more potent effects of estrone and estradiol. Indeed, antagonism of estradiol occurs only within a very narrow range of the ratio of estradiol to estriol, a range rarely encountered either physiologically or pharmacologically.²³ Below this range, estradiol is unimpeded, above this range estriol itself exerts estrogenic activity.

Esterified estrogens are synthetically prepared from plant precursors and are composed mostly of sodium estrone sulfate with a 6–15% component of sodium equilin sulfate. Estradiol valerate is rapidly hydrolyzed to estradiol, and, therefore, the pharmacology and effects are comparable at similar dosages.²⁴

Transdermal Administration

The patches first used for transdermal estrogen administration contained an alcohol reservoir; the estrogen was released through a semipermeable membrane attached to the skin with an adhesive. The current generation of patches has the hormones dissolved and distributed throughout the adhesive matrix. In a study of women who had previously discontinued patches because of skin irritation (contact dermatitis), skin reactions were less common with the newer matrix patches.²⁵ In addition, the matrix patches are better tolerated in tropical environments.²⁶ The patches are designated according to the amount of estrogen delivered per day: 50 µg and 100 µg.

The effect of steroids on lipids and lipoproteins is determined by the type of steroid, the dose, and the route of administration. An obstacle to the use of transdermal hormone therapy has been the scarcity of data indicating a beneficial impact on the lipoprotein profile. There has been concern that delivery of estrogen through the skin yields a blood level that might be too low to provide protection against cardiovascular disease, especially because after peak concentrations in the first day after application, there is a progressive decrease that can be relatively rapid. Furthermore, there is marked variation in levels among individuals and within the same individual.

The concentration of estrogen in the portal system after oral administration is 4–5 times higher than that in the periphery.²⁷ Furthermore, the estradiol:estrone ratio differs in the portal system. Thus, the first-pass effect is either significant for the lipoprotein effects, or it is important only in the short term. For example, short-term studies (6 weeks) could document increased catabolism of LDL and increased production of apoprotein A-I with oral estrogen, but no effect with transdermal estrogen.^{28,29} And a 2-year study in Los Angeles with a transdermal dose (100 µg) detected no significant change in HDL-cholesterol levels.³⁰ However, English data indicate that the transdermal administration of 50 µg estradiol twice a week is as effective as 0.625 mg oral conjugated estrogens, when combined with a progestin in sequential regimens, on bone density and lipids over a duration of 3 years.³¹ Of note, 12% of the women on either the transdermal or oral regimen lost bone from the femoral neck, despite documented adequate compliance. The transdermal administration of 100 µg estradiol combined with a progestin will not only increase bone density, but also reduce the fracture rate in older women who already have significant osteoporosis.³² However, standard doses of estrogen administered transdermally (50 µg) appear to protect against fractures as well as standard oral doses.³³

Until data are available documenting the degree of impact of the various routes of administration on actual clinical events (especially cardiovascular disease), the prudent clinical decision is to select the method (an oral program) that has epidemiologic support.

Estradiol Implants

Estradiol pellets are available in doses of 25, 50, and 75 mg for subcutaneous administration twice yearly. The 25 mg pellet provides blood levels in the range of 40–60 pg/mL, levels that are comparable with those obtained with standard oral doses.³⁴ However, the effect is cumulative, and after several years the blood levels are 2–3 times higher. Significant blood levels of estradiol will persist for up to 2 years after the last insertion. Progestational treatment is necessary, and because of the higher blood levels, a minimal duration of 14 days each month is advised. We believe that the estradiol pellets confer no advantages over the usual treatment regimens. We further recommend that women receiving pellets be monitored with blood estradiol levels, and levels greater than 200 pg/mL (and preferably, 100 pg/mL) should be avoided.

Percutaneous Estrogen

Estradiol delivery can be accomplished by the application of a gel to the skin, usually over the upper arms and shoulders or the abdomen and thighs. The preparation produces blood levels of estradiol of approximately 95–125 pg/mL, levels that are both higher and more variable than the standard oral regimens. ^{35, 36} As with pellets, we recommend that blood estradiol levels be monitored and maintained at a level below 100–200 pg/mL.

The Narrow Therapeutic Indow

There are reasons to believe that the dose of estrogen administered is important in achieving maximal cardiovascular benefits. Hemodynamic responses to estrogen vary according to blood estrogen levels. Relatively normal levels are associated with better left ventricular contraction and performance. ^{37, 38} and ³⁹ Very high estradiol levels achieved with large doses of estrogen produce the opposite effects, a decrease in left ventricular size and aortic blood flow. ⁴⁰ The beneficial effect of postmenopausal estrogen in preventing the hyperinsulinemia associated with aging is present with a dose of 0.625 mg conjugated estrogens, but lost with a dose of 1.25 mg. ⁴¹ The effect of estrogen on arterial thrombosis is dose related; we know from our experience with oral contraceptives that high doses of estrogen cause myocardial infarctions and strokes. At least 3 studies have found that estrogen doses greater than 0.625 mg conjugated estrogens are less beneficial in terms of coronary heart disease and mortality; although the numbers of patients on the higher doses were relatively small, and these conclusions did not achieve statistical significance. ^{42, 43} and ⁴⁴ For these reasons, we believe it is important to avoid excessive dosage. We find it helpful to measure the blood level of estradiol in patients who demand ever-increasing doses of estrogen. **Sharing the results of the measurement and the concern regarding high doses helps patients accept the recommendation to keep the blood level of estradiol below 200 pg/mL, and, preferably, below 100 pg/mL.**

Is there a dose of estrogen below which the beneficial effects begin to be lost? This is a difficult question to answer because so few women in epidemiologic studies have taken less than the standard doses. In a 2-year study, the lipid effects associated with 0.3 mg esterified estrogen were not significantly different from the placebo group. ⁴⁵ In the monkey, the cardiovascular beneficial responses begin to diminish below a circulating blood estradiol level of 60 pg/mL. ⁴⁶ Therefore, it is likely that some reduction in cardiovascular benefit occurs with less than standard estrogen doses.

Studies have demonstrated that a dose of 0.625 mg of conjugated estrogens is necessary to preserve bone density. ¹² The conventional wisdom has stated that an estradiol blood level of 40–60 pg/mL is required to protect against bone loss. ^{47, 48} We now know that any amount of estrogen can have an impact, although it is very likely that some degree of protection is lost when doses are less than the equivalent of 0.625 mg conjugated estrogens.

The rate of bone loss and the incidence of hip and vertebral fracture is inversely related to the circulating estrogen levels in older women. ^{49, 50} Estradiol levels as low as 10 pg/mL have a beneficial impact on bone density and fracture rates compared with values below 5 pg/mL. **Thus, any increment in estrogen, even within the usual postmenopausal range, will exert protective effects.** This explains how a positive effect on bone was observed even with the utilization of the vaginal ring that delivers a very small amount of estradiol with minimal systemic absorption. ⁵¹

A lower dose of 0.3 mg daily of conjugated estrogens or 0.5 mg estradiol prevented loss of vertebral trabecular bone when combined with calcium supplementation (to achieve a total intake of 1500 mg daily). ^{45, 52, 53} In a small study without calcium supplementation, the daily administration of 0.3 mg conjugated estrogens and 2.5 mg medroxyprogesterone acetate produced a slight increase in lumbar bone density with a lesser effect on the hip. ⁵⁴ A study of women randomized to treatment either with continuous transdermal delivery of estradiol 50 µg daily or oral estrogen demonstrated that both equally prevented postmenopausal bone loss. ⁵⁵ Major concerns with lower doses include the possibility that there will be a significant percentage of non-responders, and some cardiovascular benefit will be sacrificed. Nevertheless, a lower dose of estrogen may be more acceptable (fewer side effects) in elderly women. Patients electing to be treated with lower doses should have follow-up assessments for bone response with measurements of either bone density or urinary biochemical markers. After 6 months to one year, we urge patients on lower doses to move up to a standard regimen.

Monitoring Estrogen Dosage With Estradiol Blood Levels

Monitoring the estradiol blood level in postmenopausal women receiving hormone therapy is not as straightforward as it would seem. There are two primary difficulties. First, the clinical assays available differ considerably in their technique and quality (laboratory and antibody variations). Second, the various commercial products represent a diverse collection of estrogenic compounds, ranging from estradiol to unique equine estrogens. Although the body interconverts various estrogens into estrone and estradiol, is this process relatively consistent within and between individuals? For example, a highly specific assay for estradiol will detect very low levels of estradiol in women receiving 0.625 mg conjugated equine estrogens; nevertheless, most clinical assays will report a level of 40–100 pg/mL in these women. We find measurement of blood estradiol levels very useful in selected patients, such as the patient who requests ever-increasing doses of estrogen for the treatment of symptoms, which in the presence of very high blood levels of estradiol, can be confidently diagnosed as psychosomatic. What each clinician must do is learn what blood level of estradiol as performed by the local laboratory is associated with the standard doses of hormone therapy (0.625 mg conjugated estrogens, 1 mg estradiol, 50 µg transdermal estradiol). In our laboratory this range is 40–100 pg/mL estradiol. **Remember that because FSH is regulated by a factor other than estrogen (i.e., inhibin), FSH levels cannot be used to monitor estrogen dosage.** Postmenopausal hormone therapy will produce only a 10–20% decrease in FSH and LH, and there is great individual variability in the responses. ⁵⁶

Sequential and Continuous Regimens

The most common sequential method in the U.S. involves oral estrogen administration with 0.625 mg conjugated estrogens or the equivalent doses of a variety of available products. A daily dose of 5 mg medroxyprogesterone acetate (MPA) is added for 14 days of every month. One-year randomized trial data indicate that the 5 mg dose protects the endometrium as well as the 10 mg dose. ⁵⁷ Unfortunately, progestin withdrawal bleeding occurs in 80–90% of women on a sequential regimen. ^{58, 59} and ⁶⁰ The sequential regimen can also cause adverse symptoms related to the dose of progestin such as breast tenderness, bloating, fluid retention, and depression. Switching from medroxyprogesterone acetate to norethindrone often relieves these complaints.

The Sequential Program for Oral Postmenopausal Hormone Therapy

Daily estrogen:	0.625 mg conjugated estrogens, or 1.25 mg estropiate, or 1.0 mg micronized estradiol or equivalent doses of other estrogens.
Monthly progestin:	0.7 mg norethindrone, or 200 mg micronized progesterone, or 5 mg medroxyprogesterone acetate, or equivalent doses of other progestins given daily for 2 weeks every month.

Combined with daily calcium supplementation (500 mg with a meal), and vitamin D (400 IU in winter months and 800 IU for women over age 70).

In the sequential regimen, the amount of norethindrone equivalent to 10 mg medroxyprogesterone acetate is 1.0 mg. ⁶¹ Norethindrone is available in a dose of 0.35 mg in the progestin-only minipill oral contraceptive. In a 3-year randomized trial, 200 mg micronized progesterone given daily for 12 days each month effectively protected the endometrium against hyperplasia. ⁶⁰ The lowest effective dose of micronized progesterone and the proper dose for continuous daily administration are not established; however, a short-term (6 months) study indicated 100 mg/day was effective. ⁶² Micronized progesterone is absorbed irregularly, metabolized rapidly, and peaks in blood levels of progesterone and active metabolites are associated with sedation and other disturbing CNS reactions.

The continuous combined method of treatment evolved to improve patient continuance in the presence of bleeding and other symptoms. The continuous activity of progestin allows the use of lower doses that by virtue of a daily availability inhibit endometrial growth. This approach involves the continuous daily use of the following estrogen-progestin combinations:

The Continuous Combination Program for Oral Postmenopausal Hormone Therapy

Daily estrogen:	0.625 mg conjugated estrogens, or 1.25 mg estropipate, or 1.0 mg micronized estradiol, or equivalent doses of other estrogens.
Daily progestin:	0.35 mg norethindrone, or 100 mg micronized progesterone, or 2.5 mg medroxyprogesterone acetate, or equivalent doses of other progestins.

Combined with daily calcium supplementation (500 mg with a meal), and vitamin D (400 IU in winter months and 800 IU for women over age 70).

Continuance with hormone therapy programs is notoriously poor.^{63,64} The two most common reasons why women discontinue or do not start hormone treatment are fear of cancer and vaginal bleeding.⁶⁵ The current data on breast cancer are reassuring, and the addition of a progestational agent has effectively prevented endometrial cancer. But the persistence of bleeding with the traditional sequential regimen continues to be a barrier to good continuance. To go from 80–90% withdrawal bleeding to 80% no bleeding represents a major accomplishment, and thus, the continuous approach has a significant advantage.

Managing Bleeding During Postmenopausal Hormone Therapy

With sequential therapy, approximately 80–90% of women experience monthly withdrawal bleeding. With continuous, combined estrogen-progestin therapy, one can expect 40–60% of patients to experience breakthrough bleeding during the first 6 months of treatment; however, this percentage decreases to 10–20% after one year.^{55,60,66} Although this percentage of amenorrhea with continuous, combined therapy is a gratifying accomplishment, the number of women who experience breakthrough bleeding is considerable, and it is a difficult management problem. Indeed, the single most aggravating and worrisome problem with daily, continuous therapy is this breakthrough bleeding.

Why call it breakthrough bleeding? The bleeding experienced by women on continuous, combined therapy is similar to that seen with oral contraceptives: breakthrough bleeding. It originates from an endometrium dominated by progestational influence; hence the endometrium is usually atrophic and yields little, if anything, to the exploring biopsy instrument. Breakthrough bleeding is probably due to a progestational effect on vascular strength and integrity, producing a fragility that is prone to breakdown and bleeding. It is helpful to explain to patients that this bleeding represents tissue breakdown as the endometrium adjusts to its new hormonal stimulation. From our experience with oral contraceptives, we have learned to be comfortable with this type of bleeding. We have learned, that for most patients, the incidence of breakthrough bleeding with oral contraceptives is greatest in the first few months of treatment, and usually disappears in the majority of women. Indeed, this is the same pattern exhibited by postmenopausal women on continuous, combined therapy, and, therefore, the most effective management strategy is patient education and support.

There is no effective method supported by clinical studies, or a large experience, of drug alteration or substitution to manage this breakthrough bleeding. The breakthrough bleeding rate is only slightly better with a higher dose of progestin (5.0 mg medroxyprogesterone acetate) than with the lower dose (2.5 mg).^{55,66} Therefore, there is not a strong reason to use the higher dose, thus minimizing side effects. The best approach is to gain time, because most patients will cease bleeding. This means good educational preparation of the patient beforehand and frequent telephone contact to allay anxiety and encourage persistence.

Options for Persistent Bleeding

- Sequential therapy
- Vaginal hysterectomy
- Endometrial ablation
- The progestin IUD

There is a hard core of patients (10–20% at the end of one year) who continue to bleed. The closer a patient is to having been bleeding (either to her premenopausal state or to having been on a sequential method with withdrawal bleeding), the more likely that patient will experience breakthrough bleeding. Some clinicians, therefore, prefer to start patients near the menopause on the sequential method and convert to the continuous method some years later. We prefer to start with the continuous method because those women who achieve amenorrhea are highly appreciative. For the patients who persist in having breakthrough bleeding, it is better to return to the sequential program in order to have expected and orderly withdrawal bleeding instead of the irregularity of breakthrough bleeding.

Some patients may choose to undergo endometrial ablation in order to overcome the problem of breakthrough bleeding. But remember that concern still exists regarding the potential for isolated, residual endometrium to progress to carcinoma without recognition. Another option deserving of consideration is the progestin intrauterine device (IUD). The local release of progestin is effective in suppressing endometrial response and preventing bleeding, but the progesterone-releasing IUD must be replaced every 18 months. The levonorgestrel-releasing IUD can be left in place for 10 years, a decided advantage.^{67,68} Finally, for some patients, vaginal hysterectomy will prove to be an acceptable alternative.

Indications for Pretreatment Biopsy

- Characteristics associated with a high risk of pathology
- Previous unopposed estrogen therapy

Indications for Endometrial Biopsy During Treatment

- Clinician anxiety
- Patient anxiety
- Treatment with unopposed estrogen
- Endometrial thickness greater than 4 mm
- Past history of unopposed estrogen therapy

It is not essential to routinely perform endometrial biopsies prior to treatment. Endometrial abnormalities in asymptomatic postmenopausal women are very rare.^{66,69,70} A reasonable economic moderation would be to limit pretreatment biopsies (using the plastic endometrial suction device in the office) to patients at higher risk for endometrial changes: those women with conditions associated with chronic estrogen exposure (obesity, dysfunctional uterine bleeding, anovulation and infertility, hirsutism, high alcohol intake, hepatic disease, metabolic problems such as diabetes mellitus and hypothyroidism) and those women in whom irregular bleeding occurs while on estrogen-progestin therapy. In the absence of abnormal bleeding, a certain amount of trust in the protective effects of the progestin is justified, and routine, periodic biopsies are not necessary. **However, women who elect to be treated with unopposed estrogen require endometrial surveillance at least once a year.**

It is appropriate to perform an endometrial aspiration biopsy when the patient's anxiety over the possibility of pathology requires this response. It is also appropriate to perform a biopsy when the clinician is concerned; with increasing experience with this method, it takes more and more to be concerned. If bleeding persists for 6 months, consider an office hysteroscopy; an impressive number of polyps and intrauterine fibroids will be discovered.

Abnormal endometrium is more frequently encountered in patients on combination estrogen-progestin when the patients have previously been treated for a period of time with unopposed estrogen. Breakthrough bleeding or unscheduled bleeding in these patients requires endometrial surveillance because an increased risk for endometrial cancer persists beyond the period of exposure to unopposed estrogen, and it is unknown how effective the subsequent protective exposure to a progestin will be.^{71,72 and 73} It is prudent to assess the endometrium in these patients prior to changing from unopposed to combined therapy. Clinicians should

maintain a highly anxious state of mind with patients who have been treated previously with unopposed estrogen.

A combined estrogen-progestin program will not totally prevent endometrial cancer.⁷² Vigilance on the part of the clinician, however, will detect endometrial cancer at an early stage, a stage that can be treated with excellent results.

It is common for women on a sequential regimen to begin bleeding while in the midst of progestin administration. The timing of withdrawal bleeding in women on a sequential estrogen-progestin program has been suggested as a screening method for biopsy decision making. In women taking a variety of progestins for 12 days each month, bleeding on or before day 10 after the addition of the progestin was associated with proliferative endometrium. Bleeding beginning on day 11 or later was associated with secretory endometrium, presumably indicating less need for biopsy.⁷⁴ But does this correlate with the risk of hyperplasia and cancer? According to a study of 413 postmenopausal women, the day of bleeding did **NOT** predict endometrial safety.⁷⁵ Late regular withdrawal bleeding on a sequential program does not give 100% assurance that there is no hyperplasia and perhaps endometrial cancer. This uncertainty with the sequential program is another reason to turn to the daily, combined method where irregular bleeding and sonographic measurement of increased endometrial thickness provide us with good indications for endometrial biopsy.

If a patient has recurrent bleeding despite repeated medical therapy, submucous myomas or endometrial polyps must be suspected. Thorough curettage can miss such pathology, and further diagnostic study can be helpful. Either hysterosalpingography with slow instillation of dye and careful fluoroscopic examination or ultrasonography with instillation of saline into the uterine cavity or hysteroscopy may reveal a myoma or polyp. Hysteroscopy can also direct a more accurate biopsy of the endometrium.

Measurement of Endometrial Thickness by Transvaginal Ultrasonography

The thickness of the postmenopausal endometrium as measured by transvaginal ultrasonography in postmenopausal women correlates with the presence or absence of pathology. However, the severity of pathologic change does not correlate with the measured thickness.⁷⁶ Endometrial thickness (the two layers of the anterior and posterior walls in the longitudinal axis) under 5 mm is reassuring and allows conservative management.^{77, 78} Endometrial thickness greater than 4 mm requires biopsy; it is estimated that 50–75% of bleeding patients on hormone therapy and evaluated by ultrasonography will require biopsy.^{76, 79} An endometrial thickness less than 5 mm in women receiving hormone therapy, either a sequential regimen or a daily combination of estrogen-progestin, is reassuring.^{78, 80, 81} Because endometrial thickness by ultrasonography in patients on a sequential regimen can be affected by day in the treatment cycle, ultrasonography assessment should be obtained toward the end of the progestin phase or at the beginning of the cycle.⁸² When a thick endometrium is associated with atrophic endometrium on biopsy, polyps are often present. Greater accuracy can be gained by the instillation of saline into the uterine cavity during ultrasonography.⁸³ Doppler velocimetry does not improve the accuracy of discriminating between normal and abnormal endometrium.⁸⁴ ***A clinician should not be satisfied with “normal” findings on ultrasonography if a patient has persistent bleeding. The pursuit of abnormal bleeding despite “normal” findings should reduce missed cases of pathology to nearly zero.***⁸⁵ ***In this circumstance, hysteroscopy is recommended.***

The Progestin Challenge Test

The administration of a progestational agent (e.g., 10 mg medroxyprogesterone acetate for 2 weeks) was developed by R. Don Gambrell Jr. as a means of detecting the presence of estrogen-dependent endometrium in postmenopausal women.⁸⁶ A withdrawal bleed would indicate that an endometrial response has occurred to the progestin, a response that requires previous endometrial stimulation by estrogen, and indicates the need for endometrial assessment. In other words, the lack of a withdrawal bleed is reassuring for clinician and patient. Concern with this clinical maneuver has focused on whether there are false-negative and false-positive responses. Several studies are now available that support the efficacy and validity of this method.^{87, 88 and 89} The published data indicate that most, but perhaps not all, women with endometrial proliferation, hyperplasia, and even cancer will respond with a withdrawal bleed after a progestin challenge, and ultrasonography measurement of endometrial thickness will be greater than 4 mm.⁹⁰ The problem is that the studies thus far do not consist of very large numbers, and there is a lingering question whether a patient with abnormal endometrium will always bleed in response to progestin treatment and withdrawal.

Progestational Side Effects

Many women do not tolerate treatment with progestational hormones. Typical side effects include breast tenderness, bloating, and depression. These reactions are significant detrimental factors with continuance. However, appropriately designed, placebo-controlled studies fail to document adverse physical or psychological effects with short-term treatment utilizing medroxyprogesterone acetate, except for breast discomfort.^{91, 92, 416} This suggests that progestin side effects other than mastalgia are related to duration of treatment or that only studies with large numbers of subjects will detect the small percentage of women who have problems (and both explanations are probably true).

Can the progestational agent be administered less frequently? We are secure in our position, supported by clinical data, that a monthly estrogen-progestin sequential or a daily combination program effectively prevents endometrial hyperplasia. Experience with other regimens is very limited. The administration of medroxyprogesterone acetate every 3 months was associated in one study with longer, heavier menses and unscheduled bleeding, and a 1.5% incidence of hyperplasia at one year, while in another study, overall bleeding was less, but the incidence of hyperplasia was approximately 4%.^{93, 94} In yet another study, there was no endometrial hyperplasia encountered by 143 women who completed two years of treatment; however, the progestin administered every 3 months was of high dosage, 20 mg medroxyprogesterone acetate daily for 14 days.⁹⁵ Most impressively, the Scandinavian LongCycle Study, a clinical trial scheduled to last 5 years, was canceled after 3 years because of a 12% incidence of endometrial hyperplasia and 4 cases of endometrial cancer.⁹⁶ Therefore, if a patient chooses this regimen, more intensive endometrial monitoring is required. In our view, an annual endometrial biopsy is strongly recommended. Indeed, any program that differs from the standard regimen is untested by clinical studies of sufficient length and patient numbers and, therefore, requires periodic surveillance of the endometrium.

Some patients are very sensitive to medroxyprogesterone acetate. In our experience, these patients are often relieved of their symptoms by switching to norethindrone. In a sequential regimen, the dose of norethindrone is 0.7 mg (available in the progestin-only, minipill oral contraceptive; each pill contains 0.35 mg norethindrone). In the continuous, combined regimen, the dose of norethindrone is 0.35 mg daily.

Progesterone can be administered in a vaginal gel that allows the delivery of very low doses that can effectively protect the endometrium with low systemic levels because of a first-pass effect on the uterus.⁹⁷ The administration of 90 mg every 2 days produces secretory changes in the endometrium.⁹⁸ An application of the 4% commercial preparation twice weekly protects the endometrium and is associated with amenorrhea in most patients. In a sequential regimen, the one applicator of the 4% preparation should be applied daily for at least 10 days each month. No long-term studies are available documenting endometrial safety and metabolic effects.

The only transdermal progestins being used are norethindrone and levonorgestrel.

Progestins Available Worldwide

	Estimated Comparable Doses
21-Carbon derivatives:	
Medroxyprogesterone acetate	5.0 mg
Megestrol acetate	5.0 mg
Cyproterone acetate	1.0 mg
Dydrogesterone	10.0 mg
Chlormadinone acetate	

Medrogestone	
Demegestone	
Promegestone	
Trimegestonel	
Nomegestrol acetate	
19-Nortestosterone Family:	
Norethindrone	0.7 mg
Norethindrone acetate	1.0 mg
Levonorgestrel	0.75 mg
Desogestrel	0.15 mg
Nomegestrol	
Norethynodrel	
Lynestrenol	
Ethinodiol diacetate	
Gestodene	
Norgestimate	
Dienogest	

The Progestin Intrauterine Device

The contraceptive levonorgestrel-releasing intrauterine device (IUD) has been reconfigured in a smaller model releasing as little as 5 µg of levonorgestrel per 24 hours.^{68, 95, 100} The intrauterine presence of the progestin effectively protects the endometrium against hyperplasia and cancer. The local site of action provides endometrial protection and escapes systemic progestin side effects; for example, estrogen's favorable lipid effects are not attenuated.¹⁰¹ As with the oral continuous, combined regimens, there is irregular breakthrough bleeding in the first 6 months, and after one year, approximately 60–70% of the women are amenorrheic. The levonorgestrel device has the advantage of a 10-year duration of use. The progesterone-releasing device is larger, must be replaced every 18 months, and there have been few studies in postmenopausal women.

Should Progestins Be Administered to Hysterectomized Women?

There are some special conditions that warrant the use of a combined estrogen-progestin regimen in hysterectomized women.

1. **Because adenocarcinoma has been reported in patients with pelvic endometriosis being treated with unopposed estrogen,**^{102, 103, 104 and 105} **the combined estrogen-progestin program is strongly advised in patients with a past history of endometriosis.** In addition, we have encountered a case of hydronephrosis secondary to ureteral obstruction caused by endometriosis (with atypia) in a woman on unopposed estrogen for years after hysterectomy and bilateral salpingo-oophorectomy for endometriosis.
2. Patients who have had procedures that have the potential to leave residual endometrium (e.g., a supracervical hysterectomy) should be treated with an estrogen-progestin combination. Responsive endometrium may be sequestered in patients who have undergone endometrial ablation,^{106, 107} and combined estrogen-progestin treatment is recommended for these women.
3. It has been reported that patients who have had Stage I or Stage II adenocarcinoma of the endometrium can take estrogen without fear of recurrence,^{108, 109, 110 and 111} but the combination of estrogen-progestin is recommended in view of the potential protective action of the progestational agent. Treatment can be initiated immediately postoperatively.
4. The combined estrogen-progestin approach makes sense for patients previously treated for endometrioid tumors of the ovary.¹¹²
5. There is evidence that the combination of estrogen and progestin has a greater positive impact on bone density than estrogen alone. Thus, in hysterectomized women at high risk for osteoporosis, the combined estrogen-progestin program may offer an important potential advantage. However, this synergistic effect is influenced by the type of progestin, and a greater bone response is probably limited to the 19-nortestosterone (norethindrone) family.¹¹³ Careful studies indicate that the addition of medroxyprogesterone provides an additional effect on bone only in women with established, significant osteoporosis.^{114, 115 and 116}
6. In women with elevated triglyceride levels, the addition of a progestin, especially a 19-nortestosterone progestin, may attenuate a further estrogen-induced increase in triglycerides.

The Addition of Androgens

After menopause, the circulating level of androstenedione is about one half that seen prior to menopause.¹¹⁷ Most of this postmenopausal androstenedione is derived from the adrenal gland, with only a small amount secreted from the ovary. Testosterone levels do not fall appreciably, and in most women, the postmenopausal ovary, for a few years, actually secretes more testosterone than the premenopausal ovary. The remaining active stromal tissue in the ovary is stimulated by the elevated gonadotropins to this level of increased testosterone secretion. The total amount of testosterone produced, however, is slightly decreased because the primary source, the peripheral conversion of androstenedione, is reduced. Because of this decrease, some argue that androgen treatment is indicated in the postmenopausal period.

The potential benefits of androgen treatment include improvement in psychological well-being and an increase in sexually motivated behavior. These effects, however, have been reported with the administration of relatively large doses of androgen.¹¹⁸ In a well-designed, placebo-controlled study, lower doses of androgen (but still very pharmacologic—5 mg methyltestosterone) contributed little to actual sexual behavior, although an increase in sexual fantasies and masturbation could be documented.¹¹⁹

Any benefit must be balanced by the unwanted effects, in particular, virilization (acne, alopecia, and hirsutism), and a negative impact on the cholesterol-lipoprotein profile. In a short-term study comparing a product with estrogen and a relatively low oral dose of testosterone (1.25 mg methyltestosterone) to estrogen alone, a negative impact on the lipid profile was apparent within 3 months.¹²⁰ Over a 2-year period, the administration of estrogen (1.25 mg) combined with 2.5 mg methyltestosterone produced a significant overall adverse impact on the cholesterol-lipoprotein profile.¹²¹ In addition, 30% of the patients experienced acne, and 36% developed facial hirsutism. A lower dose of this combination (0.625 mg esterified estrogens and 1.25 mg methyltestosterone) also significantly lowers HDL-cholesterol.¹²² The adverse impact on the lipid profile is less (and may even be avoided) by the parenteral administration of testosterone.¹²³ Of course, the clinical effects of these metabolic changes are not known.

It should also be remembered that androgens do not protect the endometrium, and the addition of a progestin is still necessary. It is uncertain (and unstudied) how much aromatization of the administered testosterone increases the estrogen impact and whether this might increase the risk of endometrial and/or breast cancer. The addition of androgen does not reduce the amount of breakthrough bleeding women experience with a continuous combination regimen.¹²⁴ Adding testosterone to an

estrogen therapy program has been reported to provide no additional beneficial impact on bone or on relief from hot flashes. ^{121, 125} On the other hand, others have demonstrated a greater increase in bone density with an estrogen-androgen combination compared with estrogen alone, although the blood levels achieved were higher than those associated with standard postmenopausal hormone therapy. ¹²³ A greater effect on bone associated with androgen treatment may be indirect, reflecting higher free estrogen levels because of a reduction in sex hormone-binding globulin and/or androgen-induced changes in muscle mass.

There is no doubt that pharmacologic amounts of androgen can increase libido, but these same doses produce unwanted effects. ¹²⁶ In addition, patients on high doses of androgens often are somewhat addicted to this therapy. Small amounts of androgen supplementation can be provided in situations where the patient and clinician are convinced a depressed libido cannot be explained by psychosocial circumstances. In these cases, the lipid profile should be carefully monitored. Any positive clinical response may well be a placebo effect. After some months or a few years, conversion to a standard program without androgen is recommended.

Selective Estrogen Agonists/Antagonists (Selective Estrogen Receptor Modulators)

A greater understanding of the estrogen receptor mechanism ([Chapter 2](#)) allows us to understand how mixed estrogen agonists/antagonists can have selective actions on specific target tissues. New agents are being developed in an effort to isolate desired actions from unwanted side effects. Indeed, in time we can expect to see new agents with progressively better agonist/antagonist profiles, yielding increasingly user friendly drugs.

Raloxifene exerts no proliferative effect on the endometrium but produces favorable responses in bone and lipids. ^{127, 128} Early results (2–3 years of treatment) indicate that women receiving raloxifene have a reduction in the incidence of estrogen receptor-positive breast cancer. ¹²⁹ However, because malignant breast tumors require a relatively long period of time to progress from an abnormal cell to a clinically detectable mass, ¹³⁰ the impact of a specific drug treatment may reflect growth acceleration (as discussed with estrogen therapy) or deceleration of a pre-existing tumor, *not causation or prevention*.

Short-term clinical trial data indicate that raloxifene has a positive impact on bone density, favorable effects on LDL-cholesterol, fibrinogen, and lipoprotein(a), but no effects on HDL-cholesterol and PAI-1, and raloxifene increases hot flushing. ^{131, 132} Long-term clinical trial data will be necessary to determine the ultimate impact on clinical events, specifically fractures, coronary heart disease, stress incontinence, endometrial cancer, and cognition. The MORE study (**M**ultiple **O**utcomes of **R**aloxifene **E**valuation) is a worldwide clinical trial of raloxifene in osteoporotic women. After 2 years, raloxifene treatment was associated with a 44% reduction in vertebral fractures. ¹³³

In a 2-year randomized trial in monkeys, raloxifene exerted no protection against coronary artery atherosclerosis despite changes in circulating lipids similar to those achieved in women. ¹³⁴ In a rabbit model, raloxifene did inhibit aortic atherosclerosis, but not as effectively as estrogen treatment. ¹³⁵ However, a combination of actions (antioxidant activity, some beneficial effects on lipids, a reduction in homocysteine levels) makes it likely there will be some favorable impact on the cardiovascular system. ^{132, 136, 137} RUTH (**R**aloxifene **U**se for **T**he **H**eart) is both a primary and secondary coronary heart disease international prevention trial, started in 1998, that should provide data by 2003–05.

At the present time, in our view, raloxifene is an option for prevention of osteoporosis, especially for patients reluctant to use hormone therapy, but not a substitute for estrogen. Remember that women can develop hot flushing on raloxifene, and a 3-fold increase in leg cramping is a problem that is thus far unique for raloxifene.

Does Hormone Therapy Cause Fibroid Tumors to Grow?

Uterine leiomyomas are monoclonal tumors that retain sensitivity to both estrogen and progestin ([Chapter 4](#)); and, therefore, it is appropriate to be concerned over whether leiomyomata will grow in response to postmenopausal hormone therapy. As assessed by vaginal ultrasonography, the number and size of uterine leiomyomas increased in women being treated with an intramuscular depot form of estrogen-progestin therapy. ¹³⁸ However, the hormonal dose in this study was relatively high, certainly higher than standard regimens. At the end of one year, women with small asymptomatic fibroids administered a daily combination of 0.625 mg conjugated estrogens and 2.5 mg medroxyprogesterone acetate had no sonographic evidence of growth in contrast to an increase in size observed with transdermal estradiol (50 µg) and 5 mg medroxyprogesterone acetate daily (a response that may reflect the effect of a higher progestin dose). ¹³⁹ In follow-up studies with standard doses of estrogen-progestin or tibolone, ultrasonography has detected no changes in uterine or myoma volumes. ^{140, 141} Clinical experience indicates that fibroid tumors of the uterus almost always are not stimulated to grow by the usual postmenopausal doses of estrogen and progestin. Nevertheless, pelvic examination surveillance is a wise course. For example, a vulvar leiomyoma with growth stimulated by estrogen-progestin treatment has been reported. ¹⁴² A case-control study could find no statistically significant increase in the risk of uterine sarcomas associated with estrogen therapy. ¹⁴³

Estrogen Therapy and Sleep Apnea

The low prevalence of sleep apnea in premenopausal women and the increased frequency after menopause suggest a hormonal link. In a careful study, however, postmenopausal hormone therapy had no significant effect on sleep disordered breathing in women with more than mild obstructive sleep apnea. ¹⁴⁴ The slight rise in basal body temperature induced by a progestational agent may be sufficient to disrupt the quality of sleep in some women, a problem that may be more noticeable with a sequential regimen and with nighttime administration.

Estrogen Therapy and Rheumatic Diseases

No clear conclusion is apparent from the studies of estrogen's effect on rheumatic diseases, especially rheumatoid arthritis. Studies have indicated that exogenous estrogen, either oral contraceptives or postmenopausal therapy, protects against the onset of rheumatoid arthritis, while other studies find no effect. ^{145, 146 and 147} These studies have been hampered by small numbers, a problem that will not be overcome unless postmenopausal hormone therapy becomes more widespread. In a randomized, placebo-controlled, clinical trial, maintenance of standard serum estradiol levels was associated with improvements in some measurements of disease activity in patients with rheumatoid arthritis. ¹⁴⁸ There has been no evidence that postmenopausal hormone therapy aggravates rheumatoid arthritis or causes a flare in disease activity.

In the Nurses' Health Study, the use of postmenopausal estrogen was associated with approximately a twofold increase in systemic lupus erythematosus, an observation based on 30 cases in past and current users of estrogen. ¹⁴⁹ If this epidemiologic association is true, the absolute risk is very small, and, importantly, postmenopausal women with systemic lupus erythematosus may derive substantial benefit from the cardiovascular actions of estrogen. In a follow-up of 60 postmenopausal women with stable systemic lupus erythematosus, no adverse effects of hormone therapy could be detected. ¹⁵⁰ Furthermore, patients with systemic lupus erythematosus treated with glucocorticoids are at greater risk for osteoporosis. ¹⁵¹ Nevertheless, there is a concern that exogenous estrogen will increase flares and stimulate thrombosis in patients with systemic lupus erythematosus because of their hypercoagulable state. Postmenopausal hormone therapy can be considered in patients with stable or inactive disease, without renal involvement and high antiphospholipid antibodies. SELINA (Safety of Estrogen in Lupus Erythematosus National Assessment) is an ongoing randomized, controlled clinical trial of hormone therapy and lupus erythematosus in postmenopausal women, as well as oral contraceptive therapy in premenopausal women.

Bone loss associated with glucocorticoid therapy can be avoided with the usual postmenopausal hormone regimens. ^{152, 153} These patients are also excellent candidates for bisphosphonate treatment, another effective option that prevents glucocorticoid-induced bone loss. ^{154, 155} In addition, calcium and vitamin D supplementation has been demonstrated to prevent bone loss associated with low-dose glucocorticoid treatment. ¹⁵⁶

Estrogen Therapy and Osteoarthritis

Osteoarthritis is the most common form of arthritis in older people, and its prevalence increases rapidly in women after menopause. Osteoporosis protects against arthritis, ¹⁵⁷ and, therefore, the impact of estrogen therapy on osteoarthritis is a logical concern. Increasing severity of osteoarthritis of the knee has been reported to be associated with increasing bone density and the current use of postmenopausal hormone therapy in middle-aged women. ¹⁵⁸ However, a cross-sectional study concluded that current users of estrogen had a reduced prevalence of osteoarthritis of the hip, and there was protection against the severity of osteoarthritis, with a greater effect with longer duration of use. ¹⁵⁹ Because there are no known treatments that modify the course of arthritis, this potential benefit of postmenopausal hormone therapy deserves study by a randomized clinical trial.

Estrogen Therapy and Asthma

In some women, changes in asthma activity have been noted to correlate with phases of the menstrual cycle. The impact of postmenopausal hormone therapy on asthma activity has not been well investigated, but there is an indication that estrogen has an adverse effect. A worsening in spirometry assessment could be detected in asthmatics after estrogen therapy; however, the difference was judged to be subclinical, and the patients did not report any changes in their perceptions of symptoms.¹⁶⁰ In a prospective assessment of a cohort of women, the use of postmenopausal hormone therapy (estrogen with or without progestin) was associated with a 50% increase in the risk of developing adult-onset asthma, and the risk was greater with long-term use and with higher doses of estrogen.¹⁶¹ Because hormonal changes may precipitate asthmatic activity (e.g., catamenial asthma), attention should be directed to the symptomatic pattern and consideration given to the daily, continuous, combined regimen.

Asthma is another condition treated with glucocorticoids and associated with glucocorticoid-induced bone loss.¹⁶² Prevention with hormone therapy or bisphosphonate treatment should be considered.

Estrogen Therapy and the Oral Cavity

Oral complaints are common among postmenopausal women. The administration of estrogen provides significant relief from oral discomfort, burning, bad taste, and dryness.¹⁶³ Estrogen therapy is also associated with a reduction in gingival inflammation and bleeding.¹⁶⁴ These changes may reflect epithelial responses to estrogen by the oral mucosa, in a manner similar to that of the vaginal mucosa. Oral alveolar bone loss (which can lead to loss of teeth) is strongly correlated with osteoporosis, and the salutary effect of estrogen on skeletal bone mass should also be manifested on oral bone.^{165, 166} In the Leisure World Cohort, tooth loss and edentia were significantly reduced in estrogen users compared with nonusers (with a reduced need for dentures), and this beneficial effect was greater with increasing duration of estrogen use.¹⁶⁷ Approximately a 25% reduced risk of tooth loss in current users of estrogen has been observed in the Nurses' Health Study.¹⁶⁸

Professional singers have used hormone therapy to prevent what they view as unwanted voice changes associated with menopause.¹⁶⁹ In a 1-year study, objective voice analyses documented a more androgenic change in voice in the early postmenopausal years with a lesser change associated with estrogen treatment, slightly attenuated by the addition of a progestin.¹⁷⁰

Estrogen Therapy and Vision

There is some evidence that estrogen therapy improves visual acuity (or lessens the decrease occurring during the early postmenopausal years), perhaps due to a beneficial effect on lacrimal fluid.¹⁷¹ An increased prevalence of keratoconjunctivitis sicca (dry eyes) in menopausal and postmenopausal women is recognized by ophthalmologists, and estrogen therapy offers the potential for symptomatic relief.¹⁷² There is further evidence that postmenopausal estrogen therapy has an effect that protects against lens opacities.^{173, 174 and 175} Estrogen-progestin treatment also lowers intraocular pressure in postmenopausal women with normal eyes or glaucoma.^{176, 177}

Estrogen Therapy and Age-Related Hearing Loss

Demineralization of the cochlear capsule occurs with aging and with metabolic bone diseases, such as cochlear otosclerosis. This demineralization is associated with neural hearing loss. Postmenopausal women (age 60–85 years) who have lower than average femoral neck bone mass have an increased risk of having a hearing loss.¹⁷⁸ This association between femoral neck bone mass and age-related hearing loss suggests that prevention of bone loss with estrogen therapy might also prevent to some degree age-related hearing loss. It is possible that this potential action of estrogen could be exerted on the cochlear capsule.

Should Very Old Women Be Started on Hormone Therapy?

The positive impact of hormone therapy on bone has been demonstrated to take place even in women over age 65.^{179, 180} This is a strong argument in favor of treating very old women who have never been on estrogen. Estrogen treatment that is not begun until after age 60 can with long-term use achieve bone densities nearly comparable with those in women taking estrogen from menopause, and estrogen use between the ages of 65 and 74 has been documented to protect against hip fractures.^{181, 182} Whether estrogen's cardiovascular protection has anything significant to contribute in the elderly has not been addressed. It makes clinical sense, however, that some positive contribution can be expected. Adding a pharmacologic regimen to an old woman's daily life is not a trivial consideration. This judgment requires the conclusion that a relatively youthful and vigorous elderly woman has something to gain from the treatment. Patients with osteoporosis and/or unfavorable lipoprotein profiles would certainly qualify.

If postmenopausal hormone therapy is demonstrated to have a beneficial effect on the risk and severity of Alzheimer's disease, this would become a powerful reason to recommend treatment for very old women.

Older women who have been deficient in estrogen for many years often experience side effects when standard doses of estrogen are initiated. Breast tenderness can be especially disturbing. It is usually better to start older women with lower doses. This can utilize the oral products at half the usual doses (0.3 mg conjugated estrogens or 0.5 mg estradiol) or a transdermal product that delivers relatively low amounts of estrogen. After 6 months, an increase to standard doses is recommended to maximize the bone, cardiovascular, and central nervous system benefits.

How Long Should Postmenopausal Hormone Therapy Be Continued?

The answer to this question is relatively straightforward. A woman should continue her postmenopausal hormone regimen as long as she wants the benefits. Although some estrogen effects will be long-lasting, the full impact is rapidly lost after discontinuation. For example, in the Nurses' Health Study, reduced risk of mortality (largely cardiovascular) was lost by the 5th year after discontinuing treatment.¹⁸³

Can the Diet Produce Variations in Systemic Estrogen Levels?

Oral estrogens have an extensive first-pass metabolism, both in the gastrointestinal tract and the liver. This metabolism consists chiefly of sulfation and hydroxylation. The cytochrome P450 system catalyzes the hydroxylation of estrogen, and antioxidants can inhibit this action. Flavanoids (e.g., naringenin and quercetin) are present in high concentrations in fruits and vegetables, and grapefruit juice inhibits estrogen metabolism, producing an increase in bioavailability that is consistent with an inhibition of hydroxylation.^{184, 185} This raises the possibility that dietary interactions with food products could produce a clinical impact. It is well recognized that there is great variability within individuals and between individuals in the pharmacokinetics of exogenously administered estrogen. It is possible that this variability partially reflects the dietary habits of individuals and not intrinsic metabolism. Because of this possibility, it seems prudent to recommend that patients take oral postmenopausal hormone therapy before they go to bed at night. This may minimize any effect of diet on blood levels of steroids.

An effect of alcohol ingestion by premenopausal women was not demonstrated on circulating levels of estrone, estradiol, dehydroepiandrosterone sulfate (DHEAS), or sex hormone-binding globulin in a cross-sectional study that depended on a questionnaire to assess alcohol intake.¹⁸⁶ However, when alcohol is administered under experimental conditions, circulating estrogen concentrations are raised to high levels.^{187, 188} And in a prospective cohort study of premenopausal women in Italy, higher estradiol levels were correlated with an increased alcohol intake over a 1-year period of time.¹⁸⁹

Alternative Treatments for Hot Flashes

When patients with hot flushing cannot take estrogen, we recommend transdermal clonidine, applied with the 100 µg dose once weekly.^{190, 191} Side effects are minimal, and a modest impact can be expected.

Clonidine, bromocriptine, and naloxone given orally are only partially effective for the relief of hot flushes and require high doses with a high rate of side effects.

Bellergal (a combination of belladonna alkaloids, ergotamine tartrate, and phenobarbital) treatment is slightly better than a placebo, but it is also a potent sedative.¹⁹² Veralipride, a dopamine antagonist that is active in the hypothalamus, is relatively effective in inhibiting flushing at a dose of 100 mg daily.^{193, 194} Mastodynia and galactorrhea are the major side effects. Medroxyprogesterone acetate (10–20 mg daily) and megestrol acetate (20 mg bid) are also effective, but concerns regarding exogenous steroids (especially in patients who have had breast cancer) would apply to progestins as well.^{195, 196} Methyldopa, in doses of 500–1000 mg/day, is approximately twice as effective as a placebo, suggesting a role for adrenoreceptors in the hot flush mechanism.¹⁹⁷ Venlafaxine hydrochloride is an antidepressant that inhibits serotonin re-uptake; it effectively reduced hot flush frequency in a dose of 25 mg daily.¹⁹⁸ Vitamin E, 800 IU daily, is only slightly more effective than placebo.¹⁹⁹

Tibolone

Tibolone is a steroid, related to the 19-nortestosterone family, that is effective for the treatment of bone and hot flushes in a dose of 2.5 mg per day.^{200, 201} Tibolone is metabolized into 3 steroid isomers with varying estrogenic, progestogenic, and androgenic properties. The metabolites differ in their activities and dominance according to the target tissue. Thus, tibolone provides estrogenic effects on bone and hot flushing, but it induces atrophy of the endometrium.²⁰² Its

beneficial impact on bone (2.5 mg dose) is comparable with standard hormonal therapy.²⁰³ A lower dose of 1.25 mg daily also provides bone protection, but it is less effective and there is more vaginal bleeding. In the endometrium, tibolone is converted locally (by endometrial 3 β-hydroxysteroid dehydrogenase/isomerase) to its Δ^4 progestational isomer; hence, tibolone exerts a progestational effect on the endometrium.²⁰⁴ Tibolone has an estrogenic effect on the vagina, and women report improvements in the symptoms of vaginal dryness and dyspareunia, and an increase in sexual enjoyment and libido.²⁰⁵

Although a short-term reduction in HDL-cholesterol is an undesirable consequence with tibolone treatment; the long-term impact on the risk of cardiovascular disease is unknown.²⁰⁶ In a 2-year study, the unfavorable effect on lipoproteins was accompanied by beneficial changes in coagulation factors consistent with enhanced fibrinolysis and unchanged coagulation.²⁰⁷ Overall, it is possible that some favorable activity on the cardiovascular system is maintained. A major advantage of tibolone (2.5 mg daily) is its low (10–20%) incidence of bleeding. Because tibolone inhibits breast cell proliferation in vitro, it is possible that future studies will indicate that tibolone offers some protection against breast cancer. Tibolone also has a beneficial impact in short-term studies on insulin resistance in normal women and in women with noninsulin-dependent diabetes mellitus.^{208, 209}

“Natural” Therapies

Patients should be questioned regarding the use of “natural” therapies. Some of the herbs that contain estrogen-like compounds include ginseng, agnus castus, red sage, black cohosh, and beth root. The dosage and purity of herbal preparations are unknown, and most importantly, there are no substantial studies documenting either harmful or beneficial effects.^{210, 211} Herbs are often contaminated with heavy metals. A rigorous evaluation of one popular herb, dong quai, could detect no effects on vaginal maturation or menopausal symptoms, especially hot flushing.²¹² In our view, the use of products without scientific study should be discouraged. We believe it is appropriate to inform a patient that when she uses preparations lacking in data regarding safety and efficacy, she is experimenting with her own body. Of course, every patient has the right to do so, but we have the obligation to provide this admonishment.

Phytoestrogens

Phytoestrogens are classified into 3 groups: isoflavones, coumestans, and lignans.^{213, 214} They are present in many plants, especially legumes, and bind to the estrogen receptor. Soybeans, a rich source of phytoestrogens, contain isoflavones, the most common form of phytoestrogens, mainly genistein and daidzein, and a little glycitein. These phytoestrogens are characterized by mixed estrogenic and antiestrogenic actions, depending on the target tissue. Variations in activity may also be due to the fact that the soy phytoestrogens have a greater affinity for the estrogen receptor-beta compared with estrogen receptor-alpha.²¹⁵ Estradiol and soy protein produce comparable metabolic changes in the monkey, including favorable lipid changes, improved carbohydrate metabolism, and a decrease in central, android abdominal fat.²¹⁶ Human clinical trials have resulted in inconsistent lipid effects.²¹⁴ The soybean phytoestrogens do not maintain bone density in the monkey, but do have favorable effects on atherosclerosis and vasomotor responses, although the effect on atherosclerosis is not as robust as that of estrogen.^{217, 218, 219, 220} and ²²¹ Also in the monkey, these phytoestrogens do not stimulate proliferation of breast and endometrial cells.²²²

The daily intake of dietary soy reduces the number of hot flushes in postmenopausal women, although there is significant variability in response, and efficacy appears to be less than that of estrogen.²²³ In women, soy consumption produces a reduction in the circulating levels of estradiol, and it is suggested that the replacement of potent estradiol with target specific phytoestrogens may be beneficial.²²⁴ In the parts of the world where soy intake is high, there is a lower incidence of breast, endometrial, and prostate cancers.²²⁵ For example, a case-control study concluded that there was a 54% reduced risk of endometrial cancer, and another case-control study indicated a reduction in the risk of breast cancer, in women with a high consumption of soy and other legumes.^{226, 227} It is by no means certain, however, that there is a direct effect of soy intake.²²⁸ Indeed, a study of the impact of administered soy protein on breast secretions in premenopausal and postmenopausal women revealed increased breast secretions with the appearance of hyperplastic epithelial cells.²²⁹ It will require appropriate clinical trials to determine how phytoestrogens compare to estrogens, and the efficacy, safety, and correct dosage (studies thus far recommend a daily intake of 60 g soy protein). In addition, the intake of sufficient soy to produce a clinical response is not easy, handicapped by gastrointestinal symptoms, a major alteration in diet or the use of an unpalatable supplement, and great variability in plant contents and products (due to processing). In addition, individuals demonstrate great variability in absorption and metabolism. A user-friendly preparation needs to be developed that minimizes individual variability in response.

Ipriflavone is a synthetic product with a structure that is very similar to the naturally occurring isoflavones. It prevents postmenopausal bone loss with no major side effect problems.^{230, 231} Larger clinical trials are required to determine the variability in response.

Dehydroepiandrosterone (DHEA)

Adrenal androgen production decreases dramatically with aging. The mechanism is not known, but it is not due to the loss of estrogen at menopause, nor can it be reversed with estrogen treatment.²³² The impressive decline (75–85%) in circulating levels of DHEA that occur with aging (greater in men than in women) has stimulated a search for a beneficial impact of DHEA supplementation. Animal studies (in animals that do not even synthesize DHEA) have suggested that DHEA administration enhances the immune system and protects against many conditions associated with aging. Preliminary human studies have indicated significant increases (even at the usual 50 mg/day dose) in testosterone and dihydrotestosterone levels in women (by peripheral conversion in a variety of tissues).²³³ Short-term studies of even small doses (25 mg/day) indicate that DHEA administration produces an adverse effect on the lipid profile.²³⁴ What is the impact of a long-term increase in androgens? It is prudent to await the outcome of clinical trials before advocating DHEA supplementation.

Miscellaneous Considerations

A striking and consistent finding in most studies dealing with menopause and hormonal therapy is a marked placebo response in a variety of symptoms, including flushing. A significant clinical problem encountered in our referral practice is the following scenario: a woman will occasionally undergo an apparent beneficial

response to estrogen, only to have the response wear off in several months. This leads to a sequence of periodic visits to the clinician and ever-increasing doses of estrogen therapy. When a patient reaches a point of requiring large doses of estrogen, a careful inquiry must be undertaken to search for a basic psychoneurotic or psychosocial problem.

Assessing vaginal cytology is not useful. The vaginal mucosa is too sensitive to estrogen to allow dose-response titering.

High-dose calcium supplementation can unmask asymptomatic hyperparathyroidism. Women receiving calcium supplementation in excess of 500 mg daily should have their blood levels of calcium and phosphorous measured yearly for the first 2 years. If normal, no further surveillance is necessary.

Assessment of the cholesterol-lipoprotein profile should follow the guidelines for general preventive care, with one exception. No further measurements are required in women on postmenopausal hormone therapy, neither before nor during treatment. The one exception is the patient with previous evidence of elevated triglycerides. After 2–4 weeks of hormone treatment, the triglyceride level should be measured to make sure the patient is not the rare individual who responds to estrogen with excessively high triglyceride levels.

The Problems of Estrogen-Progestin Therapy

Metabolic

Patients with high-risk factors need special attention when estrogen therapy is being considered. Metabolic contraindications to estrogen therapy include: chronically impaired liver function, acute vascular thrombosis (with or without emboli), and neurophthalmologic vascular disease. Estrogens may have adverse effects on some patients with seizure disorders, familial hyperlipidemias (very high triglycerides), and migraine headaches.

Pancreatitis and severe hypertriglyceridemia can be precipitated by the administration of oral estrogen to women with elevated triglyceride levels.²³⁵ In women with triglyceride levels between 250 mg/dL and 750 mg/dL, estrogen should be provided with great caution, and a nonoral route of administration is preferred. **The triglyceride response is rapid, and a repeat level should be obtained in 2–4 weeks. If increased, hormone therapy must be discontinued. A level greater than 750 mg/dL represents an absolute contraindication to estrogen treatment.** Although triglyceride levels in the normal range were not affected by progestins in the PEPI trial (see Chapter 17), an exaggerated triglyceride response to estrogen might be attenuated by a progestin, especially a progestin of the 19-nortestosterone family, and, therefore, the daily, combination method of treatment should be considered for women with elevated triglycerides.

Although physiologic and epidemiologic evidence indicates that estrogen use increases the risk of gallbladder disease, the overall impact is not great. The Nurses' Health Study indicated that oral estrogen therapy may carry a 1.5–2.0-fold increased risk of gallbladder disease.²³⁶ The risk of cholecystectomy appeared to increase with dose and duration of use and to persist for 5 or more years after stopping treatment. Others have also reported increased risks of cholecystectomy in past and current users of estrogen.^{237, 238} In the HERS clinical trial, the relative risk of gallbladder disease was 1.38; however, this did not achieve statistical significance.²³⁹ At least two case-control studies concluded that estrogen use is not a risk factor for gallstone disease in postmenopausal women, although the statistical power was limited by small numbers.^{240, 241} A cross-sectional study of gallstone disease could detect no association with postmenopausal hormone treatment.²⁴²

The routine, periodic use of blood chemistries is not cost-effective, and careful monitoring for the appearance of the symptoms and signs of biliary tract disease will suffice. It is not certain that this potential problem is limited to oral therapy. Non-oral routes of estrogen administration have been reported to both increase and not increase biliary cholesterol saturation (a lithogenic response).^{243, 244}

Weight Gain

The gain in weight that many middle-aged individuals experience is the result of lifestyle, specifically, the balance of dietary intake and exercise. Weight gain in women at menopause is not due to the hormonal changes associated with menopause.²⁴⁵ Likewise, postmenopausal hormone therapy cannot be blamed for weight gain. The large Rancho Bernardo prospective cohort study and the randomized PEPI clinical trial documented that hormone therapy with or without progestin does not cause an increase in body weight.^{246, 247} In fact, in the PEPI trial, the hormone-treated groups actually gained less weight than the placebo group.

Estrogen (with or without progestin) prevents the tendency to increase central body fat with aging.^{248, 249, 250 and 251} This would inhibit the interaction among abdominal adiposity, hormones, insulin resistance, hyperinsulinemia, blood pressure, and an atherogenic lipid profile.

Venous Thrombosis

It is well recognized that pharmacologic doses of estrogen (oral contraceptives) are associated with an increased risk of venous thrombosis. The impact of the lower doses administered to postmenopausal women has been more difficult to ascertain. Older case-control studies failed to find a link between postmenopausal doses of estrogen and venous thrombosis.^{252, 253} However, these studies excluded cases with pre-existing risk factors for thrombosis. A well-designed case-control study of older women unselected for other thrombotic risk factors indicated that postmenopausal doses of estrogen did not increase the risk of venous thrombosis.²⁵⁴ Others have also failed to find an increase in venous thromboembolism associated with postmenopausal hormone therapy.²⁵⁵

The conventional wisdom that the low postmenopausal doses of estrogen do not increase the risk of venous thrombosis was challenged more recently by 4 case-control studies and one cohort study. These studies were larger, but still were limited to 20–40 cases on hormone therapy. In the Nurses' Health Study cohort, the risk of pulmonary embolism was increased 2-fold in the current hormone users.²⁵⁶ The case-control studies found a 2.1- to 3.6-fold increased risk of deep vein thrombosis in current but not past hormone users.^{257, 258, 259 and 260} The case numbers were too small to enable a reliable analysis of a dose-response effect or the effect of transdermal use. The studies all indicated that the increased risk was confined to early use, and that the risk lowers to a non-significant level after one year. There was no indication that the addition of a progestin changed the risk.

The overall impact of postmenopausal hormone therapy on the clotting cascade is compatible with a favorable effect due to changes consistent with an increase in fibrinolysis.^{261, 262, 263 and 264} However, the favorable impact may be confined to arterial thrombosis. Furthermore, it is always more prudent to make clinical judgments based on epidemiologic event data rather than laboratory tests. However, epidemiologic study of venous thrombosis (deep vein thrombosis and pulmonary embolism) is difficult because of the low incidence of the complication and the problem of diagnostic bias (a clinician is more suspicious of the diagnosis because of the use of estrogen).

The clinching argument on this issue, in our view, is the observation of an increased risk of venous thrombosis in both the HERS secondary prevention study of daily estrogen-progestin therapy for women who already have coronary heart disease and the data obtained with raloxifene.^{129, 239} HERS (the Heart and Estrogen-Progestin Replacement Study) recorded a 2.89 relative risk of venous thromboembolism comparable with that reported in the observational studies. The increased risks in these instances were observed in randomized clinical trials, and it is difficult, if not impossible, to not accept these results.

What is the final message for clinicians and patients? First, it should be emphasized that the risk appears to apply only to new starters; women who have been on hormone therapy can be reassured that there is no evidence of an increased risk of venous thrombosis after the initial one year of treatment. The actual risk is very low because of the low frequency of this event. If the relative risk is increased 3-fold, this would increase the incidence of venous thromboembolism by about two cases per 10,000 women per year of hormone use. Furthermore, venous thrombosis carries with it a very low risk of mortality, around 1%, and most of the fatal cases have followed venous thrombosis associated with trauma, surgery, or a major illness.

If a patient has a close family history (parent or sibling) or a previous episode of idiopathic thromboembolism, an evaluation to search for an underlying abnormality in the coagulation system is warranted. The following measurements are recommended, and abnormal results require consultation with a hematologist regarding prognosis and prophylactic treatment. The list of laboratory tests is long, and because this is a dynamic and changing field, the best advice is to consult with a hematologist. When a diagnosis of a congenital condition is made, screening should be offered to other family members.

Hypercoaguable Conditions

Antithrombin III
Protein C deficiency
Protein S deficiency
Factor V Leiden mutation
Prothrombin gene mutation
Antiphospholipid syndrome

Thrombophilia Screening

deficiency Antithrombin III
Protein C
Protein S
Activated protein C resistance ratio
Activated partial thromboplastin time
Hexagonal activated partial thromboplastin time
Anticardiolipin antibodies
Lupus anticoagulant
Fibrinogen
Prothrombin G mutation (DNA test)
Thrombin Time
Homocysteine level
Complete blood count

A DNA-based test can be used to verify the presence of the factor V Leiden mutation. Other risk factors for thromboembolism that should be considered by clinicians include an acquired predisposition, such as the presence of lupus anticoagulant or malignancy, and immobility or trauma. Varicose veins are not a risk factor unless they are very extensive, and unlike arterial thrombosis, smoking either has no effect or at best is a weak risk factor for venous thromboembolism.

If a patient has a congenital predisposition for venous thrombosis or if she is considered to be at high risk for venous thromboembolism, the clinician and patient can consider the combination of hormone therapy and chronic anticoagulation, in consultation with a hematologist.

There are no studies of venous thromboembolism following surgical procedures in postmenopausal hormone users. ***It now seems sensible to recommend appropriate prophylactic anticoagulant treatment in hormone users anticipating immobility with hospitalization, especially if other risk factors are present. Some patients may elect to discontinue hormone treatment 4 weeks prior to major surgery (if extended immobility is to be expected), but this is an empiric, individual decision. Hormone therapy can be resumed when the patient is ambulatory.***

Endometrial Neoplasia

There are two different types of endometrial cancer. The more uncommon form (perhaps 20%) develops rapidly, usually in older women, with a histologic pattern more characteristic of serous carcinomas, in a background of atrophic endometrium. Endometrioid carcinoma develops slowly from a precursor lesion in response to estrogen stimulation. This type is less aggressive, better differentiated, and responds to progestational treatment.

Estrogen normally promotes mitotic growth of the endometrium. Abnormal progression of growth through simple hyperplasia, complex hyperplasia, atypia, and early carcinoma has been associated with unopposed estrogen activity, administered either continuously or in cyclic fashion. Only one year of treatment with unopposed estrogen (0.625 mg conjugated estrogens or the equivalent) will produce a 20% incidence of hyperplasia, largely simple hyperplasia; in the 3-year PEPI trial, 30% of the women on unopposed estrogen developed adenomatous or atypical hyperplasia.^{57, 60, 265} Some 10% of women with complex hyperplasia progress to frank cancer, and complex hyperplasia is observed to antedate adenocarcinoma in 25–30% of cases. If atypia is present, 20–25% of cases will progress to carcinoma within a year.²⁶⁶

Approximately 40 case-control and cohort studies have estimated that the risk of endometrial cancer in women on estrogen therapy (unopposed by a progestational agent) is increased by a factor of somewhere from 2 to 10 times the normal incidence of 1 per 1000 postmenopausal women per year.^{267, 268} The risk increases with the dose of estrogen and with the duration of exposure (reaching a 10-fold increase with 10–15 years of use, and perhaps an incidence of 1 in 10 with very long-term use), lingers for up to 10 years after estrogen is discontinued, and the risk of cancer that has already spread beyond the uterus is increased 3-fold in women who have used estrogen a year or longer.^{269, 270} Although most endometrial cancer associated with estrogen use is of low grade and stage, and associated with better survival (probably because of earlier detection), the overall risk of invasive cancer and death is increased. The risk of endometrial hyperplasia and cancer is not reduced by the administration of unopposed estrogen in a cyclic fashion (a period of time each month without treatment).^{267, 271}

A short-term study (2 years) has indicated that one-half the usual standard dose of estrogen (in this case, 0.3 mg esterified estrogens) was not associated with an increased incidence of endometrial hyperplasia compared with a placebo group.²⁷² But we have learned that long-term exposure to low levels of estrogen can induce abnormal endometrial growth, and in our view, lower dose estrogen therapy requires either endometrial assessment annually or the addition of a progestin to the treatment regimen. This is supported by a case-control study from Washington that contained 18 cases and 9 controls who had exclusively used only 0.3 mg/day of unopposed conjugated estrogens.²⁷³ The use of this half-dose estrogen was associated with an overall 5-fold increased risk of endometrial cancer, reaching a relative risk of 9.2 in current users for more than 8 years' duration. Although limited by small numbers, the conclusion is logical and consistent with our understanding of the importance of duration of exposure to any increased level of endometrial estrogen stimulation.

It is now apparent that this risk can be reduced by the addition of a progestational agent to the program.²⁶⁵ Although estrogen promotes the growth of endometrium, progestins inhibit that growth. This countereffect is accomplished by progestin reduction in cellular receptors for estrogen, and by induction of target cell enzymes that convert estradiol to an excreted metabolite, estrone sulfate. As a result, the number of estrogen receptor complexes that are retained in the endometrial nuclei are decreased in number, as is the overall intracellular availability of the powerful estradiol. In addition, progestational agents suppress estrogen-mediated transcription of oncogenes.

Reports of the clinical impact of adding progestin in sequence with estrogen include both the reversal of hyperplasia and a diminished incidence of endometrial cancer.^{274, 275, 276, 277 and 278} The protective action of progestational agents operates via a mechanism that requires time in order to reach its maximal effect. For that reason, the duration of exposure to the progestin each month is critical. While one standard method incorporated the addition of a progestational agent for the last 10 days of estrogen exposure, most have argued in favor of 12 or 14 days. Studies indicate that the minimal requirement is a monthly exposure of at least 10 days' duration.^{71, 279, 280} About 2–3% of women per year develop endometrial hyperplasia when the progestin is administered for less than 10 days monthly.

Important unanswered questions are what will be the actual incidence of endometrial cancer in long-term users of postmenopausal hormone therapy and will there be differences among the various regimens and routes of administration. A case-control study from Seattle reported that the use of combined estrogen-progestin (essentially all sequential and oral) for 5 or more years was associated with an increased relative risk of endometrial cancer, even with 10–21 days of added progestin per month.⁷³ However, the increased risk was confined to those women who had been previously exposed to unopposed estrogen treatment; remember, after discontinuing unopposed estrogen treatment, the risk of endometrial cancer lingers for up to 10 years, even if a subsequent regimen includes a progestin. In the Swedish prospective cohort in Uppsala, a reduced risk of mortality due to endometrial cancer was observed in women receiving an estrogen-progestin combination; however, there were only 2 deaths, precluding statistical significance.²⁸¹ A case-control study from Los Angeles found no increased risk of endometrial cancer with the continuous combined estrogen-progestin regimen or when at least 10 days of progestin were provided in a sequential regimen.²⁸⁰

An attractive idea is that protection against endometrial cancer requires shedding of the endometrium. However, we know that at least one-third and up to one-half of the functioning endometrium is not lost during withdrawal bleeding, and it has not been established that endometrial shedding is essential to protect against cancer.²⁸² It is just as logical to believe that prevention of growth and development of atrophic endometrium are protective. There is good reason to believe that both the sequential regimens (with appropriate dose and duration of progestin administration) and the continuous combined regimens offer protection against endometrial cancer. The degree of protection and comparable performance will ultimately be determined by the long-term randomized clinical trials currently ongoing.

The lowest daily dose of progestin that protects the endometrium has not been established. Currently, the sequential program utilizes 5 or 10 mg medroxyprogesterone acetate and the combined daily method uses 2.5 mg. The dose of norethindrone that is comparable with 2.5 mg medroxyprogesterone acetate is 0.25 mg.⁶¹ Although lower doses of progestational agents are effective in achieving target tissue responses (such as reducing the nuclear concentration of estrogen receptors), the long-term impact on endometrial histology has not yet been firmly established. The question of dose is an issue of major importance, especially in terms of the cardiovascular system and compliance because of progestin-induced side effects.

Although the protective effect of progestin is considerable and predictable, it is unwise to expect all patients on estrogen-progestin therapy to never develop endometrial cancer. Appropriate monitoring of patients cannot be disregarded. Although routine assessments are not cost-effective, interventions directed by clinical responses are prudent and necessary.

Ovarian Cancer

A prospective cohort study concluded that the risk of fatal ovarian cancer is increased with long-term estrogen use.²⁸³ There was no significant increase in the relative risk of fatal ovarian cancer with ever use of postmenopausal estrogen, and the link with long-term use achieved statistical significance only with the 18 cases using estrogen for 11 or more years. By no means is it certain if this association is real. There have been 12 case-control studies of ovarian cancer risk factors, and the pooled analysis of this literature could find no consistent evidence for an association between ovarian cancer and estrogen therapy.²⁸⁴ A meta-analysis concluded that there is a 14% increased risk of ovarian carcinoma among ever users of hormone therapy, and that there is a 27% increase in risk with more than 10 years of long-term use.²⁸⁵ We are not impressed by this small increase in a meta-analysis of case-control studies, subject to multiple potential biases. Among the 6 studies included in the analysis of duration of use, only one reported a statistically significant increase in risk with 10 or more years of hormone therapy.

Individual studies have been hampered by relatively small numbers, but the lack of a uniform and consistent association argues against a major impact of postmenopausal estrogen treatment on the risk of ovarian cancer. In a more recent and relatively large case-control study, no indication could be found for an association between postmenopausal hormone therapy and the risk of epithelial ovarian cancer, even with long-term treatment.²⁸⁶ Another case-control study reported a slightly increased risk, but it was not statistically significant.²⁸⁷ In a retrospective analysis, no detrimental impact could be detected on prognosis after surgery for ovarian cancer in patients who received postmenopausal hormone therapy after diagnosis.²⁸⁸

Cervical Cancer

The association between postmenopausal hormone therapy and cancer of the uterine cervix has not been extensively studied. Evidence from one cohort study and one case-control study indicates that the postmenopausal use of estrogen does not increase the risk of cervical cancer.^{289, 290} Indeed, these studies observed protection against cervical cancer in the estrogen users, but this may reflect detection bias (more examinations and Pap smears in estrogen users). In a follow-up report of 120 women treated for Stage I and II cervical cancer, no adverse effects of hormone therapy on survival or recurrence were observed.²⁹¹

Colorectal Cancer

Most, but not all, cohort and case-control studies have reported a significantly reduced risk of colorectal cancer incidence and mortality in users of postmenopausal estrogen.^{292, 293, 294, 295 and 296} The effect is greatest in current users and most studies have not indicated an increased effect with increasing duration of use; for example, the Nurses' Health Study (which found a 35% reduced risk in current users) could not demonstrate an added benefit with longer duration of current use.²⁹⁷ A reduction in fatal colon cancer has been documented in current users.²⁹⁴ There also appears to be a reduced risk of polyps, especially large polyps, among current and recent hormone users.

One can only speculate regarding the mechanism of this benefit. The estrogen-induced change in the bile (a decrease in bile acids with an increase in cholesterol saturation) favors gallstone formation, but may reduce promotion (by bile acids) of colonic cancer. Other possible mechanisms include a direct suppressive effect on mucosal cell growth and an effect on beneficial mucosal secretions. This potential benefit deserves greater attention; colorectal cancer ranks third in women, both in incidence and mortality, more prevalent than cancers of the uterus or ovary.²⁹⁸

Malignant Melanoma

The possibility of a relationship between exogenous hormones and cutaneous malignant melanoma has been the subject of many observational studies. Accurate evaluation utilizing the Royal College of General Practitioners and Oxford Family Planning Association prospective cohorts and accounting for exposure to sunlight did not indicate a significant difference in the risk of melanoma comparing users of oral contraceptives to nonusers.^{299, 300} Results with the use of postmenopausal estrogen therapy have not indicated a major impact. A slightly increased risk with long-term use of estrogen was noted in one case-control study (a conclusion based on 10–20 cases and not achieving statistical significance), whereas another case-control study could find no association with postmenopausal estrogen treatment.^{301, 302} Others have reported slight increases in the risk of malignant melanoma associated with the use of exogenous estrogen, but all failed to reach statistical significance.^{289, 303, 304} In an analysis of cancer incidence in a Swedish cohort of women prescribed postmenopausal hormone therapy, no increase in malignant melanoma was observed.³⁰⁵

Breast Cancer

The possibility that estrogen use increases the risk of breast cancer must be intensively scrutinized. The American epidemiologic data on the scope of human female breast cancer are astonishing: 1 of every 8 women will develop breast cancer in her lifetime (assuming an 85-year life expectancy). In America, breast cancer is the leading type of cancer in women (29.7%) and now second to lung cancer as the leading cause of cancer death in women (16.1%), about 10 times the number of deaths from endometrial cancer.²⁹⁸

Sufficient evidence exists to indicate the possibility of a slightly increased risk of breast cancer associated with long durations (5 or more years) of postmenopausal estrogen use. However, the epidemiologic data on this relationship are by no means consistent and uniform. A review of the epidemiologic studies on postmenopausal hormone therapy and the risk of breast cancer fails to provide definitive evidence regarding this issue. Nevertheless, we believe that patients must consider this possibility in their informed decision making.

Early studies on estrogen use and breast cancer indicated higher risks in special subcategories, such as women with benign breast disease, long duration of use, or natural versus surgical menopause.^{306, 307, 308, 309, 310, 311, 312, 313, 314 and 315} These studies were all limited by a lack of control groups or by relatively small numbers. The CASH (Cancer and Sex Hormone Study of the Centers for Disease Control and Prevention) did not detect an overall increased risk of breast cancer with postmenopausal estrogen use nor a relationship with duration of use up to 20 years or longer,³¹⁶ An absence of an effect was evident in all of the following: parity, age at first pregnancy, early or late menopause, menopause by hysterectomy or oophorectomy, family history of breast cancer, presence of benign breast disease, use for many years (20 years or longer), and use of high doses.

A well-publicized study from Uppsala, Sweden, concluded that estrogen use was associated with a slight increase in the risk of breast cancer (relative risk 1.1), and that there was a relationship with duration of use; the relative risk reaching 1.7 after 9 years (although this conclusion did not reach statistical significance).^{317, 318} Another conclusion of this study was the indication of increased risk with combined treatment with estrogen-progestin. This conclusion also was not statistically significant, based on only 10 women with breast cancer, and the confidence interval (CI) was impressively wide: 0.9–22.4. In a later report based on an additional 4 years of data, the overall risk of breast cancer associated with the use of the estrogen-progestin sequential product was 0.9 (CI: 0.7–1.1); in those women with 7 to 11 years of follow-up, the relative risk was increased to 1.6 (CI: 1.1–2.1).³¹⁹ However, the statistical power of this study continues to be limited, and there is no control group; the relative risk was calculated by using the expected breast cancer incidence in the general population. In a nested case-control study within this Swedish cohort of women, these investigators again reported a moderately increased risk of breast cancer with more than 10 years of postmenopausal hormone therapy.³²⁰

A Danish case-control study used questionnaires to obtain information on cases and controls and also indicated a slightly increased risk of breast cancer associated with postmenopausal hormone therapy.³²¹ Interestingly, this report indicated an increased risk only with sequential estrogen and progestin and not with the daily administration of combined estrogen and progestin (however, these conclusions were very limited by the small numbers involved). This study contains statistical problems similar to the Uppsala study (e.g., the relative risk associated with estrogen-progestin use was 1.41, but the confidence interval included 1.0 and was not statistically significant).

The latest reports from the Nurses' Health Study represent 16 years of follow-up (1976–1992).^{322, 323} During that period, 1935 cases of breast cancer were identified among more than 69,000 postmenopausal women. The analysis revealed that women who had used estrogen in the past (even for 10 or more years) were not at increased risk of breast cancer. However, the relative risk for current users was 1.46 (CI 1.22–1.74) for 5–9 years of use, and 1.46 (CI 1.20–1.76) for 10 or more years

of use.

By virtue of the large numbers in the Nurses' Health Study and the careful analyses by the investigators, reports from this study must be given great credibility. The 16-year follow-up report is disturbing with its finding of an increased risk in current users. Because estrogen users may be examined more frequently, detection bias is a major concern. It is noteworthy that current users had a 14% higher prevalence of mammography compared with never users. Current users were different from never users (history of benign breast disease, birth only once or twice, menarche at age 13 or less, body mass index of 21–23). Another important consideration is the need to adjust for alcohol consumption, an accepted risk factor for breast cancer. In the Iowa Women's Health Study, an increased risk of breast cancer was observed only in those postmenopausal women who consumed one drink or more of alcohol daily.³²⁴ The concern is that alcohol consumption raises estrogen levels in hormone users to very high concentrations.^{187, 188 and 189} Although each of these factors standing alone would not explain the observed outcome in the Nurses' Health Study, what is the additive effect of all factors? Thus, the finding of an increased relative risk in long-term current users is not definitive and not free of all confounding variables. The size of the statistical risk is not outside the range of influence by biases.

Based on 359 deaths due to breast cancer, the risk of dying of breast cancer in the Nurses' Health Study was 0.80 (CI 0.60–1.07) for past users, 0.99 (CI 0.66–1.48) for current users with less than 5 years of use, and 1.45 (CI 1.01–2.09) with 5 or more years of use. These mortality data raise a question of “prevalence bias,” also called by statisticians as interdependence between the probabilities of disease incidence in a population (an issue of competing risks).³²⁵ Is it possible that the protection against cardiovascular disease is so great with long durations of estrogen use that the long-term current users develop a problem that is prevalent with aging, breast cancer. The never users, deprived of the cardiovascular benefit of estrogen, may develop cardiovascular disease before living long enough to experience breast cancer.

A case-control study from Australia, which attempted to control for secular trends in estrogen use, type of menopause, and duration of estrogen use, concluded that there was no evidence for an association between estrogen use and the risk of breast cancer in postmenopausal women.³²⁶

There is a very helpful study that specifically addressed the relationship between the use of estrogen and benign breast disease.³²⁷ This study is impressive because it is based on 10,366 consecutive breast biopsy specimens with follow-up information on 4227 biopsy specimens in 3303 women (a mean duration of follow-up of 17 years). Analysis indicated that the use of estrogen was associated with a reduced risk of developing breast cancer. Most importantly, in patients with atypical hyperplasia in their biopsies, the use of estrogen did not increase and even lowered the risk of breast cancer. Although the protective effect probably indicates detection/surveillance bias, certainly this is strong evidence that estrogen use does not increase the risk of breast cancer in women with surgically proven benign breast disease, even with atypia.

In a study of 1686 cases and 2077 controls in the eastern U.S., the relative risk for current users was a nonsignificant 1.1 (CI, 0.7–1.6), for a duration of use of 15 or more years, the relative risk was 0.9 (CI, 0.4–1.9).³²⁸ As in the eastern U.S., a study from Toronto found no evidence for an increased risk in either current or recent users or in users for up to 15 years.³²⁹ A case-control study from Washington found no increased risk of breast cancer with past or long-term current use of estrogen alone or with estrogen-progestin.³³⁰ These large case-control studies failed to support the conclusion of the Nurses' Health Study that current users are associated with an increased risk, even with long durations of use. On the other hand, other studies (of smaller size and limited statistical power) have found an increased risk of breast cancer in current users and long-term users.^{331, 332} A prospective study from the National Cancer Institute could document only an increase in the risk of *in situ* breast cancer (not invasive disease), possibly reflecting surveillance bias in women taking either estrogen alone or a combination of estrogen and progestin.³³³

The Iowa Women's Health Study, like the Nurses' Health Study, is prospectively following a cohort of women (selected in 1985). After 6 years of follow-up, a statistically significant increase in the risk of breast cancer could not be detected in ever users or current users of hormone therapy.³³⁴ A report through 8 years of follow-up focused on whether postmenopausal hormone therapy increased the risks for breast cancer and mortality in women with a family history of breast cancer.³³⁵ Even in women with a positive family history of breast cancer who were current users of hormone therapy for more than 5 years, there was no significant increase in the rate of breast cancer. A very large case-control study found no increased risk of breast cancer associated with the ever use of estrogen alone or estrogen and progestin combinations, and when long-term use for 15 years or more was examined, again no increase in risk was detected.³³⁶

Meta-Analyses. Meta-analysis is an increasingly popular statistical method in which many studies are combined and undergo rigorous analysis. The term “meta-analysis” was coined in 1976 to indicate the re-analysis of data to answer new questions.³³⁷ The method was first used in social science, and then in the late 1980s, in medicine. Simply put, the purpose of a meta-analysis is to gain the statistical power that is lacking in individual studies.

An Australian meta-analysis of 23 studies of estrogen use and breast cancer concluded “unequivocally” that estrogen use did not alter the risk of breast cancer.³³⁸ In the meta-analysis by Dupont and Page (Nashville, Tennessee), the authors concluded that “considerable and consistent” evidence exists that a daily dose of 0.625 mg conjugated estrogens taken for several years does not appreciably increase the risk of breast cancer.³³⁹ They found no evidence of an association between the duration of treatment and the risk of breast cancer at this dosage. On the other hand, the data suggested that a daily dose of 1.25 mg conjugated estrogens and higher may increase the risk of breast cancer. This analysis failed to reveal an increased risk in patients with a history of benign breast disease.

A third meta-analysis was from the CDC.³⁴⁰ This meta-analysis was conducted by using what the authors called a “dose-response curve” for duration of use. The curve for each study analyzed was calculated by plotting breast cancer risk against duration of estrogen use. The combined dose-response slope represented the average change in risk associated with estrogen use over time. The analysis concluded that duration of estrogen use was associated with an increased risk of breast cancer, regardless of whether menopause was natural or surgical. No increase in risk was noted in the first 5 years of use, but after 15 years of use, the risk was increased by 30%. The effect was present irrespective of other risk factors, such as parity or history of benign breast disease. The effect of estrogen therapy on risk of breast cancer was enhanced in women with a positive family history of breast cancer.

A fourth meta-analysis, from Spain, concluded that estrogen is associated with a very small, but statistically significant, increased relative risk of breast cancer and that the increased risk is higher among current users.³⁴¹ Confining their analysis to a dose of 0.625 mg conjugated estrogens; however, the Spanish epidemiologists could not detect a statistically significant increased risk. Indeed, this meta-analysis concluded that an estrogen dose of 0.625 mg conjugated estrogens is safe.

A fifth meta-analysis from the epidemiologists associated with the Nurses' Health Study concluded (based on 25 case-control and 6 cohort studies) that there is no increased risk of breast cancer in ever users of estrogen.³⁴² Current use was associated with an increased risk (which was lost 2 years after using estrogen), and there was a slight increase with more than 10 years of use (but there was no linear trend with increasing duration of use). This observation in long-term users could be influenced by an increased proportion of current users in this group, and the increased risk in current users could be a consequence of detection bias. The statistical power of this meta-analysis was in the ever use category, giving strength to its negative conclusion. This meta-analysis could not detect a link between risk of breast cancer and dosage. Nevertheless, we continue to be concerned with a possible effect of higher doses. The Australia, Nashville, and Spain meta-analyses indicated an increased risk with a daily dose of conjugated estrogens greater than 0.625 mg (or its equivalent).

The Nashville, CDC, and Nurses' Health analyses did not find an enhanced risk in women with a history of benign breast disease. In contrast to the CDC report, the Australia and Nurses' Health analyses found no link between positive family history and estrogen use. The Nashville and Spain investigators did not consider family history.

In a major overview and assessment (yet another meta-analysis) of the world's literature on postmenopausal hormone therapy, commissioned by the American College of Physicians, the authors concluded that long-term use of estrogen was associated with a relative risk of breast cancer of 1.25 (CI, 1.04–1.51).³⁴³ This conclusion, in our view, was not appropriately critical and represents a judgment that extends beyond the statistical power available from the many heterogeneous studies. The heterogeneity of the many studies is an important issue: different drugs, different doses, different methods of diagnosis, different comparison and control groups. The Spanish meta-analysis is the only one to raise the question: perhaps the heterogeneity is too great to allow an accurate meta-analysis of this literature.

A Re-analysis of the World's Literature. A team of epidemiologists invited all investigators who had previously studied the association of postmenopausal hormone use and the risk of breast cancer (51 studies) to submit their original data for a collaborative combined re-analysis, an undertaking more rigorous than a standard meta-analysis. This analysis reached the following conclusions:³⁴⁴

- Ever users of postmenopausal hormones had an overall increased relative risk of breast cancer of 1.14
- Current users for 5 or more years had a relative risk of 1.35 (CI = 1.21–1.49), and the risk increased with increasing duration of use.
- Current and recent users had evidence of having only localized disease (no metastatic disease) and ever users had less metastatic disease.

- There was no effect of a family history of breast cancer.
- There was no increase in relative risk in past users.
- The increase in relative risk in current and recent users was greatest in women with lower body weights.

The most compelling reason to believe that long-term use of postmenopausal estrogen increases the risk of breast cancer is the inherent biologic plausibility. Factors known to increase a woman's exposure to estrogen are known to increase the risk of breast cancer; e.g., age of menarche and age of menopause. Indeed, in this report, the authors made a point of demonstrating that the quantitative effect of their conclusion is similar to extending the age of menopause. According to their calculations, current and recent hormone use was associated with a 2.3% increase in breast cancer risk per year and the effect of the age of menopause was equivalent to a 2.8% increase in risk per year of delay. Many clinicians are attracted by the logic in this comparison; however, the steady exposure to postmenopausal estrogen is not exactly the same as extended exposure to cyclic ovarian function.

A strong indication that the conclusion of the re-analysis is subject to bias is the finding that current and recent hormone users had evidence only of localized disease. This is consistent with detection/surveillance bias and hormone acceleration of tumors already present and thus detection at an early, less aggressive stage.

The Influence of Detection/Surveillance Bias and Accelerated Tumor Growth — An Answer to the Paradox of Increased Risk and Decreased Mortality. It is relevant to note that many of the studies that have examined the mortality rates of women who were taking estrogen at the time of breast cancer diagnosis have documented improved survival rates.^{305, 345, 346} This undoubtedly reflects earlier diagnosis in users because the greater survival rate in current users is associated with a lower frequency of late-stage disease.^{183, 347, 348 and 349} There is also evidence to suggest that estrogen users develop better differentiated tumors, and that detection/surveillance bias is not the only explanation for better survival.^{349, 350} This implies that hormone treatment accelerates the growth of a malignant locus already in place, and it presents clinically at a less virulent and aggressive stage. This conclusion is consistent with the fact that virtually all the studies find that any increase in risk disappears within 5 years of discontinuing hormone therapy.

Increased utilization of mammography by hormone users is a well recognized phenomenon.³⁵¹ Indeed, when corrected for use of mammography, an apparent increase in breast cancer in long-term estrogen users in a retrospective cohort study lost its statistical significance.³⁵² A greater frequency of mammography and breast examinations among hormone users introduces detection/surveillance bias into all observational studies.

If the conclusion of the re-analysis of the world's literature were correct, it would mean that there would be a detectable increase in deaths from breast cancer due to hormone use. However, studies have indicated a *decreased* risk of breast cancer mortality in postmenopausal hormone users. For example, the American Cancer Society 9-year prospective follow-up documented a 16% reduced risk of fatal breast cancer in estrogen users.³⁴⁶ The mortality data support the contention that accelerated growth of a pre-existing tumor and detection/surveillance bias are influencing the results of observational studies.

Estrogen agonists/antagonists (tamoxifen and raloxifene) have been reported to reduce the incidence of breast cancer within 2–3 years of treatment.^{129, 353} Given the length of time it takes for a malignancy to become clinically detectable (approximately 10 years to grow to a 1 cm mass),¹³⁰ how is it possible to demonstrate hormonal effects within several years? Do tamoxifen and raloxifene prevent breast cancer and does estrogen increase the risk of breast cancer—or are we only changing the time (age) of diagnosis? Instead of causation/prevention, are we observing acceleration/deceleration of pre-existing tumors?

Causation	and OR and	Prevention
Acceleration		Deceleration
Hormone therapy		Tamoxifen (Chapter 16)
Oral contraceptives (Chapter 22)		Raloxifene
Pregnancy (Chapter 16)		
Return to baseline after therapy		

Why Is There No Definitive Answer Despite Approximately 50 Observational Studies? Misinterpretation of epidemiologic data should not be attributed to epidemiologic methods, but to their interpreters. When the impact of an association is large, it is relatively easy to demonstrate uniformity and consistency of results with case-control and cohort studies (observational studies). This can be appreciated in the impressive data indicating protection against cardiovascular disease by the use of postmenopausal estrogen. In the case of postmenopausal hormone therapy and the risk of breast cancer, we have neither the comfortable position produced by uniformity and consistency among observational studies nor the results of a randomized clinical trial. The lack of a definitive answer can be attributed to the following:

1. Observational studies lack the ability to overcome recognized and unrecognized biases, unless the studied effect is large. A large effect yields uniformity and consistency of results with case-control and cohort studies (good examples are the benefits of a reduction in the risks of endometrial and ovarian cancer with the use of oral contraception). Therefore, any impact of postmenopausal hormone therapy on the risk of breast cancer is unlikely to be great; otherwise, the observational studies would have achieved uniformity and consistency of results.
2. Most of the available data are derived from a time when hormone dosages and schedules (higher doses and shorter durations) were different compared with current methods—the problem of heterogeneity. In addition to different doses and durations of exposure, heterogeneity is the result of different study designs, different sources for controls, different geographic locations, different populations, and different drugs.
3. The method of meta-analysis was developed to combine the results of small, randomized trials.³³⁷ Rapidly (perhaps too rapidly), the method has been extended to observational studies, especially when the results of the individual studies are contradictory. Combining the results of contradictory studies, rather than the results of small (randomized) studies, is precisely when meta-analysis is weakest. Statistical analysis is not an appropriate method to address contradictory results. And even when the technique of meta-analysis is restricted to small randomized trials, because of various subjective and objective problems, the outcomes of subsequent large randomized, controlled trials were not predicted accurately 35% of the time by the previous meta-analyses.³⁵⁴ The method of meta-analysis is not infallible and does not always yield the truth.

The method of meta-analysis has not overcome the problem of achieving sufficient statistical power. The conclusions of meta-analyses of observational studies are not free of selection bias, detection bias, and the problem of a positive result emerging just by chance when multiple subgroup analyses are performed. Meta-analysis is further limited, not only when the database is subject to biases as is the case with observational studies, but also when there is heterogeneity among the studies (different drugs, doses, durations of exposures, and populations). A meta-analysis can make the problem of bias worse by magnifying the significance level of erroneous results; a meta-analysis does not correct for design flaws in individual studies.

Therefore, our uncertainty will not be resolved by more case-control studies, more cohort studies, or more meta-analyses. Only a properly performed randomized clinical trial will provide us with definitive information.

Where Does That Leave Clinicians and Patients? The lack of agreement, uniformity, and consistency in approximately 50 case-control and cohort studies indicates that the use of postmenopausal hormone therapy cannot be associated with a major impact on the risk of breast cancer, otherwise there would be agreement among the studies. It is helpful to compare this situation with 3 other conditions: the protection against ovarian cancer by oral contraceptives, the protection against coronary heart disease by postmenopausal estrogen use, and the increase in lung cancer due to cigarette smoking. Clinicians believe each of these 3 epidemiologic associations despite the lack of a single randomized clinical trial because all of the studies say the same thing, an impressive agreement and uniformity among observational studies. The results with postmenopausal hormone therapy and the risk of breast cancer indicate either a small impact of estrogen use or the effect of biases that can only be eliminated by large, randomized trials, specifically the ongoing Women's Health Initiative in the U.S. (to be completed in 2008) and the WISDOM trial (Women's International Study of Long-Duration Oestrogen use after Menopause) in the U.K. (to be completed in 2011).

If estrogen use were associated with an increased risk of breast cancer, wouldn't one expect to see an impact on mortality? In the mortality report from the Leisure World follow-up study in California, the risk of breast cancer mortality in hormone users was 19% reduced, and a similar reduction in fatal breast cancer has been documented in the Nurses' Health Study and in the American Cancer Society cohort.^{43, 183, 346} This lower relative risk probably is influenced by detection/surveillance bias and by the presence of better differentiated tumors in estrogen users, but certainly there is no evidence that women using estrogen for a long time are dying of

breast cancer at a greater rate.

Doses of estrogen known to protect against osteoporosis and cardiovascular disease (0.625 mg conjugated estrogens and 1.0 mg estradiol) are, at the present time, not known to be associated with any clear-cut increased risk of breast cancer. However, because of the concern raised by some studies and reviews that there is a slightly increased risk of breast cancer associated with long-term use of postmenopausal estrogen, this issue requires discussion during the clinician-patient dialogue regarding postmenopausal hormone therapy.

The comfort found in large numbers with epidemiologic research is lost to us when we must make clinical decisions with individual patients. If we wish to minimize the uncertainty from imprecise measurements, we will adopt an appropriate strategy. If we wish to emphasize the possibility or probability of an outcome, we will adopt another. In our view, it is appropriate to emphasize the benefits of postmenopausal hormone therapy, point out the continuing concern regarding the relationship between estrogen use and breast cancer (particularly long-term use), and to **emphasize the absence of definitive evidence linking such therapy to an increased risk of breast cancer.**

The Risk of Breast Cancer and Estrogen-Progestin Therapy. The addition of a progestational agent to postmenopausal estrogen therapy is now accepted as a standard part of the treatment program. The obvious reason for this combined estrogen-progestin approach is the need to prevent the increased risk of endometrial cancer associated with exposure to unopposed estrogen. Even though this endometrial cancer is not frequently encountered and survival rates are excellent with early disease, the fear of this cancer is a major force in patient continuance, and, therefore, the combined approach is warranted. Clinicians and patients have rapidly turned to the method of a daily combination of estrogen and a progestin, in order to overcome bleeding which is the second major continuance problem.

Only two reports have claimed that the addition of a progestational agent protects against breast cancer. [355](#), [356](#) The first was limited by bias in treatment selection (the breast cancer risk factor profiles were not matched in the treated and untreated groups). The second (the Nachtigall study), although it has been the only randomized, placebo-controlled trial, was hampered by small numbers.

At the present time, the available epidemiologic evidence on the impact of combined estrogen-progestin treatment indicates that neither a protective nor a detrimental effect has yet to be convincingly demonstrated; recent studies find that the addition of a progestin does not change the findings with estrogen alone. [323](#), [330](#), [331](#), [332](#) and [333](#) Balancing the information available involving all of the health issues affected by hormone therapy, a combined estrogen-progestin program in appropriate doses continues to offer significant benefits for postmenopausal women. As time goes on, more studies and greater duration of use should provide us with better answers to many of our questions. By virtue of the magnitude of the postmenopausal female population, these questions deserve continuing biologic and epidemiologic research from both the public health and individual points of view.

SUMMARY: Postmenopausal Hormone Therapy and Breast Cancer

- **Some epidemiologic case-control and cohort studies conclude that long-term (5 or more years) of current use of postmenopausal hormone therapy is associated with a slight increase in the risk of breast cancer, a risk that is less than that associated with postmenopausal obesity or daily alcohol consumption. This conclusion might be due to confounding biases, particularly detection/surveillance bias, and accelerated growth of a pre-existing malignancy.**
- **Many observational studies have failed to develop evidence that long-term postmenopausal hormone therapy increases the risk of breast cancer.**
- **All epidemiologic studies fail to find an increased risk of breast cancer associated with short-term (less than 5 years) use or past use of postmenopausal hormone therapy.**
- **The epidemiologic data agree that the addition of a progestin to the treatment regimen neither increases nor decreases the risk observed in individual studies.**
- **The epidemiologic data indicate that a positive family history of breast cancer should not be a contraindication to the use of postmenopausal hormone therapy.**
- **Women who develop breast cancer while using postmenopausal hormone therapy have a reduced risk of dying from breast cancer. This is because of two factors: (1). Increased surveillance and early detection; and (2). Acceleration of pre-existing tumor growth so that tumors appear at a less virulent and aggressive stage.**

Contraindications to Postmenopausal Hormone Therapy

Endometrial Cancer, Endometrioid Tumors, and Endometriosis

Gynecologic oncologists have reported that patients who have had Stage I and Stage II adenocarcinoma of the endometrium can take estrogen without fear of an increased risk of recurrence or a decrease in disease-free interval. [108](#), [109](#), [110](#) and [111](#) Nothing is known about the risk in patients with more advanced disease. If a high-risk tumor is estrogen and progesterone receptor negative, it seems reasonable to allow immediate hormone therapy. Because the latent period with endometrial cancer is relatively short, a period of time (5 years) without evidence of recurrence would increase the likelihood of safety on an estrogen program. We recommend that hormone therapy be avoided in patients with high-risk tumors that are receptor-positive until 5 years have elapsed. The combination of estrogen-progestin is recommended in view of the potential protective action of the progestational agent. A similar approach makes sense for patients previously treated for endometrioid tumors of the ovary. In view of the fact that adenocarcinoma has been reported in patients with pelvic endometriosis and on unopposed estrogen, the combined estrogen-progestin program is advised in patients with a past history of endometriosis. [102](#), [103](#) and [104](#)

Should a Woman Who Has Had Breast Cancer Use Postmenopausal Hormones?

The increasing incidence of breast cancer, together with earlier detection and treatment, is producing a growing pool of patients for whom the question of estrogen treatment is important and at the same time difficult. The problem is easy to articulate: we have no data. There are absolutely no published clinical trials of sufficient size and scope in which the impact of estrogen treatment has been documented when given to women with previously treated breast cancer.

Because there is good reason to believe that breast cancer is hormonally influenced, it is not hard to understand the breast surgeon or medical oncologist who believes that estrogen treatment is foolish and dangerous. Yet, that position is just as unencumbered by data as the position of the clinician who believes that appropriate patients stand to benefit more from estrogen compared with the unknown risk of breast cancer recurrence.

The single most useful prognostic information in women with operable breast cancer has been the histologic status of the axillary lymph nodes. At 10 years, only 25% of patients with positive nodes are free of disease compared with 75% of patients with negative nodes. If more than 3 nodes are involved, the 10-year survival rate drops to 13%. Because of this recognition for the importance of the axillary nodes, the traditional approach to breast cancer (the Halsted surgical approach) was based on the concept that breast cancer is a disease of stepwise progression. There has been an important change in concept. Breast cancer is now viewed as a systemic disease, with spread to local and distant sites at the same time. Breast cancer is best viewed as occultly metastatic (microscopically disseminated) at the time of presentation. Dissemination of tumor cells has occurred by the time of surgery in many patients, and it is concern over the possible response of these cells that fires the debate over this question: should women who have had breast cancer take postmenopausal hormones?

There are two opposing hypotheses that link breast cancer to a hormonal influence: one assigns the critical role to estrogen; the other, to progesterone.

Is Estrogen the Important Influence? When one reviews the various factors associated with breast cancer, many of the factors support a role for increased exposure to estrogen, specifically the importance of age of menarche, age of menopause, obesity, the effect of pregnancy, and added to this list is the therapeutic effect of an antiestrogen, tamoxifen.

Stanley Korenman, therefore, suggested that the endocrine environment does not cause the disease but influences the susceptibility to carcinogens—the so-called estrogen window hypothesis. [357](#), [358](#) The two periods of life when the estrogen window is open (this means long periods of unopposed estrogen) are after menarche before ovulation is established and the perimenopausal years. Estrogen shows a significant increase at about Tanner stage 2, ages 8 to 10. Because ovulation occurs on the average 1.5 years after menarche, this window can last 4 to 5 years. It is well recognized that anovulation is common in the perimenopausal years because of the lesser capabilities of the remaining ovarian follicles. Korenman argued that the open window (estrogen exposure) influences the risk of breast cancer and that the window is closed by exposure to progesterone after ovulation and during pregnancy. This argument is supported by observational studies indicating that anovulatory

and infertile women (exposed to less progesterone) have an increased risk of breast cancer later in life. ^{359, 360 and 361} However, the statistical power of these studies was limited by small numbers (all fewer than 15 cases), and others have failed to find a link between anovulation and the risk of breast cancer. ^{362, 363 and 364} In summary, factors that would be associated with an increased risk of breast cancer are those that would prolong the duration of the open window: obesity, infertility due to anovulation, delayed pregnancy, early menarche, late menopause.

Is Progesterone the Important Influence? Some argue that progesterone is the key to influencing the risk of breast cancer because mitotic activity in the breast reaches its peak during the progesterone-dominant luteal phase of the menstrual cycle. ^{365, 366 and 367} An earlier age of menarche is sometimes used to buttress the progesterone hypothesis because earlier menarche means an earlier onset of ovulatory cycles. The interaction of estrogen and progesterone on target tissue has been studied mostly in the endometrium, where estrogen clearly stimulates cell growth and progesterone inhibits this estrogen effect. However, there is evidence that progesterone exerts an effect on breast epithelial proliferation similar to its effect on the endometrium. ^{368, 369, 370 and 371} With human breast cancer cells, progestins inhibit growth and stimulate differentiation. ³⁷²

Which Hypothesis Is Correct? The hormonal sensitivity of breast cancer appears to be unquestionable, but whether estrogen or progesterone plays a key role is not certain. And perhaps, it is a unique exposure to a combination of factors that is pivotal. Both the estrogen hypothesis and the progesterone hypothesis continue to fuel the debate over these issues. There are specific areas in our clinical experience, however, which are relevant to this consideration.

Pregnancy and Breast Cancer. At one point in time, it was believed that pregnancy (and its impressive levels of estrogens and progesterone) had an adverse impact on the prognosis of breast cancer diagnosed during the pregnancy. It is now believed that there is no difference in survival when pregnant women with breast cancer are matched to nonpregnant women by age and stage of disease, and termination of pregnancy is not associated with improved survival. ^{373, 374} Pregnant women do have a 2.5-fold higher risk of metastatic disease, but the reason is later diagnosis because the breast changes associated with pregnancy make diagnosis difficult. As with other premenopausal patients, most breast cancers in pregnant women are receptor-negative tumors. ³⁷⁴ Thus, it can be argued that the intense hormonal stimulation of pregnancy (both estrogen and progesterone) has no adverse impact on the course of breast cancer. However, studies do indicate an impact of pregnancy on the risk of subsequent breast cancer. A very large case-control study concluded that pregnancy transiently increases the risk (perhaps for up to 3 years) after a woman's first childbirth, and this is followed by a lifetime reduction in risk. ³⁷⁵ And some have found that a concurrent or recent pregnancy (3–4 years previously) adversely affects survival (even after adjustment for size of tumor and number of nodes). ³⁷⁶ It is argued that breast cells which have already begun malignant transformation are adversely affected (acceleration of growth) by the hormones of pregnancy, whereas normal stem cells become more resistant because of a pregnancy.

Breast Cancer and Subsequent Pregnancy. As with breast cancer diagnosed in already pregnant women, subsequent pregnancy, after diagnosis and treatment, has had no negative impact on prognosis. ³⁷⁷ This, too, would argue against an impact of hormonal stimulation on the risk of recurrent or new disease. But all studies on this subject are retrospective and limited by small numbers. The apparent lack of an adverse impact could be because it is the healthier patients who get pregnant. ³⁷⁸ However, after adjustments for factors that could produce a selection bias, an adverse effect of pregnancy on outcome after breast cancer treatment was still not apparent. ³⁷⁹

Oral Contraception and the Risk of Breast Cancer. The experience with oral contraceptives over the last 30 years has provided neither definitive evidence that exogenous estrogen and progestin increase the risk of premenopausal breast cancer, nor evidence that exposure to these exogenous hormones offers major protection against breast cancer ([Chapter 22](#)). The lack of a major detrimental effect is an effective argument against a major link between breast cancer and exogenous hormone treatment.

Depo-Provera and the Risk of Breast Cancer. Medroxyprogesterone acetate, in large continuous doses, produced breast tumors in beagle dogs. This is an effect unique to the dog (perhaps because in dogs progestins stimulate growth hormone secretion, known to be a mammatrophic agent in dogs) and has not appeared in other animals or in women after years of use. A very large, hospital-based case-control World Health Organization study conducted over 9 years in 3 developing countries has indicated that exposure to Depo-Provera very slightly increased the risk of breast cancer in the first 4 years of use, but there was no evidence for an increase in risk with increased duration of use. ³⁸⁰ The number of cases in the recent use group was not large, and the confidence intervals reflected this. For example, the relative risk for recent users (based on a total of 19 cases) was 1.21, but the confidence interval included 1.0 and, thus, was not statistically significant.

Two earlier population-based case-control studies indicated a possible association between breast cancer and Depo-Provera. One, from Costa Rica, was based on only 19 cases. ³⁸¹ The other, from New Zealand, did not find an increased relative risk in ever users but did find an indication of increased risk shortly after initiating use in early age (less than age 25). ³⁸² A pooled analysis of the WHO and New Zealand data indicated that the highest risk was in women who had received a single injection. ³⁸³

Certainly the risk, if real, is very slight, and it is equally possible that the suggestions of increased risk have not been free of confounding variables. The results can be interpreted to suggest that the growth of already existing tumors is accelerated. *It is appropriate to emphasize that these studies did not find evidence for an overall increased risk of breast cancer, and the risk did not increase with duration of use.* Thus, experience with exposure to a pure progestational agent does not support the argument that progestational influence will increase the risk of breast cancer; however, this experience reflects the use of very pharmacologic doses of this progestin.

Postmenopausal Hormone Therapy and the Risk of Recurrent Breast Cancer

The argument that postmenopausal hormone therapy should not be given to women who have had breast cancer is a reasonable one. It is based on the recognition of a large body of evidence that indicates that breast cancer is a hormone-responsive tumor. The overriding fear of many clinicians (and patients) is that metastatic cells are present (perhaps being controlled by various host defense factors) that will be susceptible to stimulation by exogenous hormones. ³⁸⁴ However, many women who have had breast cancer are aware of the benefits of postmenopausal hormone treatment (especially protection against cardiovascular disease and osteoporosis) and are asking clinicians to help make this risk-benefit decision. In addition, some women suffer from such severe hot flushing and vaginal dryness that they are willing to consider hormonal treatment. Indeed, estrogen deficiency symptoms are the most common complaints associated with the treatment of breast cancer. ³⁸⁵ Because of the current lack of epidemiologic data, both sides of this debate are strongly influenced by theoretical considerations and clinical experiences, which, unfortunately, often become an obstacle to the patient's own informed choice.

There are reassuring reports that breast cancer survivors using hormone therapy do not experience an obvious increase in recurrent disease. There is a small series in which a combination of 0.625 conjugated estrogens and 0.15 mg norgestrel was given continuously for a short period of time (a maximum of 6 months) to women who had been previously treated for breast cancer. ³⁸⁶ Over the next two years, no patients developed recurrence. Another small series (25 and then 77 women with breast cancer ranging from in situ to stage III disease) received estrogen-progestin therapy for 24 to 82 months; the recurrence rate was not greater than that expected. ^{387, 388} From this group of patients, 41 breast cancer survivors receiving hormone therapy had the same outcomes when compared with 82 women selected from a cancer registry and not taking hormones. ³⁸⁹ In a report from Australia, 152 women with a history of breast cancer who were given a combination of estrogen and progestin had lower mortality and recurrence rates; however, the dose of progestin was very high (which in itself can be therapeutic) and treatment was not randomized. ³⁹⁰ In a follow-up of 49 women treated with estrogen after treatment for localized breast cancer, only one patient developed recurrent disease. ³⁹¹ And in another series of 114 women, hormone treatment of disease-free patients was associated with a low rate of recurrence. ³⁹² These patients had both positive and negative nodes and estrogen receptor status. ***Although it is reassuring that the results conform to an incidence of recurrent disease no greater than expected, the outcomes may reflect biases in clinician and patient decision making that can only be overcome with a proper long-term, randomized clinical trial.***

A clinical U.S. trial is currently under way, providing estrogen to randomized women who have been treated for stage I or II breast cancer, who have been disease-free for at least 2 years from estrogen receptor negative disease or 10 years if the estrogen receptor status is unknown. ³⁹³ Other randomized trials of hormone therapy after breast cancer treatment are underway in Europe; for example, the HABITS study in Sweden.

Because of better treatment and earlier diagnosis, 50–75% of women diagnosed with breast cancer are now cured. ³⁹⁴ Of 100 patients with breast cancer, about 60 will be cured by mastectomy or breast-conserving surgery with radiotherapy and would receive no benefit from adjuvant treatment. Is this group safe for hormone therapy? Of the remaining 40, some will live longer (an average of 2–3 years) because of adjuvant treatment, but only a few. Is the unknown risk with exogenous hormone treatment worth it in this group? Although intuitively it seems that the risk:benefit ratio would be more favorable in the presence of negative nodes, negative receptors, and small tumors, are negative estrogen and progesterone receptor assessments sufficient to conclude that the cancer is not sensitive to hormones? And if the

patient is in the high-cure category, does it make any difference what the receptor status is? Receptor status is not absolute; it is always a relative measure. The answers to all of these questions are not known.

Patients and clinicians have to incorporate all of the above considerations into this medical decision. But when all is said and done, patients have to take an unknown risk if they want the benefits of hormone treatment, and clinicians have to take an unknown medical-legal risk. Some patients will choose to take hormones, judging the benefits to be worth the unknown risk. Physicians should support patients in this decision. Other patients will prefer to avoid any unknown risks. These patients, too, deserve support in their decision. Until data are available from appropriate clinical trials, there is no right or wrong decision.

Women With Cardiovascular Disease

Is the woman with a previous history of a cardiovascular event, such as a myocardial infarction or stroke, the very woman who needs the protection of estrogen against cardiovascular disease? There is evidence to support this contention. In the Leisure World study, estrogen users with previous myocardial infarctions, strokes, or hypertension had a 50% reduction in risk for death from a subsequent stroke or myocardial infarction.⁴³ In the Lipids Research Clinics study, the cardiovascular mortality in women with previous cardiovascular disease was reduced 85%. And most impressively, in women with severe coronary disease (documented by arteriography), estrogen users had a 97% survival rate at 5 years compared with a significantly different 81% rate in nonusers.³⁹⁵ In women with mild to moderate disease, there was no difference at 5 years, but at 10 years, estrogen users had a 96% survival rate compared with 85% in nonusers.

Estrogen therapy reduces the rate of restenosis in women who have undergone either coronary angioplasty or percutaneous atherectomy.³⁹⁶ In women who have undergone coronary artery bypass surgery, the 10-year survival rate in estrogen users was 81.4% compared with 65.1% in nonusers.³⁹⁷ In women who have been treated with estrogen after coronary angioplasty, case-control analysis indicated that the treated women had a better survival rate and experienced fewer subsequent myocardial infarctions.³⁹⁸ The number of patients on estrogen-progestin was too small in this study for analysis. A retrospective cohort study in Seattle determined prognosis in women surviving a myocardial infarction and detected a 36% reduced risk of re-infarction in current estrogen users, although small numbers prevented the achievement of statistical significance.³⁹⁹ These studies all indicate reduced risks for adverse clinical events and support the use of postmenopausal hormone therapy in women with coronary heart disease. Furthermore, hormone therapy can improve the state of atherosclerosis; i.e., produce a regression in disease.

Imaging studies have documented a reduction in intimal thickening in postmenopausal women who are estrogen users compared with nonusers, and this beneficial effect is not compromised by the addition of a progestational agent to the treatment regimen.^{400, 401} Thus, postmenopausal hormonal therapy can bring about a reduction in atherosclerosis, and this effect is comparable with that produced by a lipid-lowering drug.^{400, 402}

The results of the Heart and Estrogen/progestin Replacement Study (HERS), discussed in detail in [Chapter 17](#), are contrary to the many observations reviewed above.²³⁹ However, the inconsistencies with previous biologic studies, concerns regarding the statistical power of HERS, and the disagreement with an impressively large number of observational studies mean that the HERS results are not definitive. Decision making will be easier as the results of more clinical trials become available. Until then, in our opinion, estrogen treatment with the appropriate, standard dose is indicated and safe for patients with cardiovascular disease. We should emphasize, however, that excellent preventive results are obtained with the usual armamentarium of drugs employed by cardiologists for the treatment of coronary heart disease.

In a short-term, randomized, crossover clinical trial, combined conjugated estrogens and medroxyprogesterone acetate raised HDL-cholesterol equally well as simvastatin in women with hypercholesterolemia.⁴⁰³ Simvastatin achieved a greater reduction in LDL-cholesterol and no effect on lipoprotein(a) and triglyceride levels, while hormone therapy produced a decrease in lipoprotein(a) and an increase in triglycerides. The hormonal effects were even greater in women who had abnormal lipids or atherosclerosis. Thus, both treatments produce beneficial effects, and it is not known whether the differences are clinically important.

The dose of estrogen is very important because it is becoming increasingly apparent that the beneficial cardiovascular effects of estrogen are restricted to a relatively narrow therapeutic window; the benefits may be reduced at doses of estrogen greater than that equivalent to 0.625 mg conjugated estrogens. The HERS results combined with experimental data derived from monkeys (see [Chapter 17](#)) make it reasonable to use other progestins than medroxyprogesterone acetate in women with coronary heart disease.

Women With Diabetes Mellitus

A strong argument can be made that postmenopausal women with diabetes mellitus can benefit from the cardioprotective actions of estrogen. In addition, estrogen may improve the metabolic changes associated with diabetes. Indeed, in prospective studies of postmenopausal women with noninsulin-dependent diabetes mellitus, estrogen treatment improved all glucose metabolic parameters, including insulin resistance, the lipoprotein profile, and measurements of androgenicity.^{404, 405} These changes should reduce the risk of cardiovascular disease; however, long-term studies are yet to be available. Tibolone also has a beneficial impact in short-term studies on insulin resistance in normal women and in women with noninsulin-dependent diabetes mellitus.^{208, 209}

Women With Liver Disease

Osteoporosis is a major consequence of chronic liver disease. Although other bone-preserving agents can be utilized, none provides the multisystem benefits associated with estrogen therapy. In an evaluation of liver chemistries in a group of patients with primary biliary cirrhosis, standard hormone therapy doses produced no adverse changes over a period of one year.⁴⁰⁶ We recommend measurement of liver chemistries after one month of treatment, and every 6 months, with continuing hormone therapy in the absence of deterioration.

The Vaginal Administration of Estrogen

Many clinicians believe that estrogen administered intravaginally is not absorbed, and systemic effects can be avoided. However, estrogen is absorbed very readily from a vagina with immature, atrophic mucosa.⁴⁰⁷ Indeed the initial absorption is rapid, and relatively high circulating levels of estrogen are easily reached. As the vaginal mucosa cornifies, absorption decreases.⁴⁰⁸ This decline takes approximately 3–4 months, after which lesser, but still significant absorption takes place. European studies have demonstrated that vaginal maturation can be achieved with a vaginal ring (which is left in place for 3 months) having incredibly small doses of estrogen, with a low-level of systemic absorption.^{409, 410} This is an acceptable method to relieve atrophic vaginal symptoms in women with contraindications to estrogen treatment.

Other Conditions

Close surveillance is indicated for some patients with seizure disorders, familial hyperlipidemias (elevated triglycerides), and migraine headaches. Patients with migraine headaches often improve if a daily, continuous method of treatment is used, eliminating a cyclic change in hormone levels that can serve to trigger headaches.

Conditions that do not represent contraindications include controlled hypertension, diabetes mellitus, smoking, and varicose veins. The belief that estrogen is potentially harmful with each of these clinical situations is derived from old studies of high-dose oral contraceptives. Estrogen appropriate doses is acceptable in the presence of these conditions.

No other cancers (besides those mentioned above) are known to be adversely affected by hormone therapy. Postmenopausal hormone therapy can be administered to all patients with cervical, ovarian, or vulvar malignancies.

Unusual anecdotal reports include the following:

1. Provocation of chorea by estrogen therapy in a woman with a history of Sydenham's chorea.⁴¹¹
2. Exacerbation of pulmonary leiomyomatosis by estrogen therapy.⁴¹²
3. Psychiatric symptoms in response to estrogen in patients with acute intermittent porphyria.⁴¹³
4. Idiosyncratic ocular symptoms associated with estrogen.⁴¹⁴

Conclusion

We hope we have convinced you that the menopause is a normal life event, not a disease, and that long-term postmenopausal hormone therapy is pharmacologic treatment to obtain preventive health care benefits. We have learned this from the women who revealed what they believe and what they know in the longitudinal studies of the last decade. It only makes sense that trying to convince a woman she has a disease, when she does not believe it, will have a negative impact on the clinician—patient relationship. In addition, we believe our approach yields more willful and stronger decision making that ultimately produces better continuation rates with treatment. Postmenopausal hormone therapy is an option that should be offered to most women as they consider their paths for successful aging, but the attitude and beliefs of the clinician have a major influence on the decisions made by patients. As beneficial as the impact of hormonal therapy may be, we must also emphasize the large improvement in health to be gained by lifestyle changes in smoking cessation, regular exercise, and control of body weight.

Because approximately one-third of American adults are obese, the unrewarding fight against obesity is all too common, not only with our patients but also with ourselves.¹ About 25% of U.S. women are overweight, and an additional 25% are obese.² Unfortunately, for over 100 years the incidence of obesity has been increasing in the United States and Europe, a reflection of an affluent society with an increasingly sedentary life combined with high caloric foods.^{1,3,4} This change in lifestyle has produced an increasing prevalence of obesity that is similar in adults and children.⁵

The lack of success in treating obesity is not due to an unawareness of the implications of obesity; there is a clear-cut, well recognized relationship between mortality and weight.^{6,7} The death rate from diabetes mellitus, for example, is approximately 4 times higher among obese diabetics than among those who control their weight. The death rate from appendicitis is double, presumably from anesthetic and surgical complications. Even the rate of accidents is higher, perhaps because fat people are awkward or because their view of the ground or floor is obstructed. The Nurses' Health Study estimates that 23% of all deaths in nonsmoking middle-aged women are attributable to being overweight.⁷

The incidence of hypertension, heart disease, noninsulin-dependent diabetes mellitus, gout, gallbladder disease, colorectal cancer, endometrial cancer, postmenopausal breast cancer, and osteoarthritis is elevated in overweight people.⁸ Being overweight in adolescence is even a more powerful predictor of cardiovascular adverse health effects than being overweight as an adult.⁹

When the personal and social problems encountered by obese people are also considered, it is no wonder that a clinician without a weight problem cannot comprehend why fat individuals remain overweight. The frequency with which a practitioner encounters the obese patient whose weight does not decrease despite a sworn adherence to a limited-calorie diet makes one question if there is something physiologically different about this patient. Is the problem due to lack of discipline and cheating on a diet, or does it also involve a pathophysiologic factor? Is the physiology of obese people unusual, or are they simply gluttons? **Modern studies of obesity strongly indicate that this is a multifactorial problem, and that lack of willpower and laziness are not the simple answers.**

Definition of Obesity

Obesity is an excess storage of triglycerides in adipose cells. There is a difference between obesity and overweight.¹⁰ Obesity is an excess of body fat. Overweight is a body weight in excess of some standard or ideal weight. The ideal weight for any adult is believed to correspond to his or her ideal weight from age 20 to 30. The following formulas give ideal weight in pounds:

Women: $100 + (4 \times (\text{height in inches} - 60))$
Men: $120 + (4 \times (\text{height in inches} - 60))$

At a weight close to ideal weight, individuals may be overweight, but not overfat. This is especially true of individuals engaged in regular exercise. An estimate of body fat, therefore, is more meaningful than a measurement of height and weight.

The most accurate method of determining body fat is to determine the density of the body by underwater measurement (hydrodensitometry). It certainly is not practical to measure density by submerging individuals in water in our offices; therefore, skinfold measurements with calipers have become popular as an index of body fat, or expensive imaging techniques can be utilized. These latter methods are not necessary for clinical practice. It is far simpler to utilize the body mass index nomogram, a method that has been found to correspond closely to densitometry measurements.¹¹

The body mass index (the Quetelet index) is the ratio of weight divided by the height squared (in metric units):

$$\text{BMI} = \text{kilograms/meters}^2$$

To use the nomogram for body mass index (BMI), read the central scale by aligning a straightedge between height and body weight. Over the last 30 years, the mean body mass index has increased in the U.S., and now averages 26.3.¹ A body mass index of 27 or more warrants treatment.¹² A body mass index of about 30 is roughly equivalent to 30% excess body weight, the point at which excess mortality begins (approximately 10–12% of people in the U.S. have a body mass index of 30 or greater). Above age 40, the risk from obesity itself is comparable to that associated with major health problems such as hypertension and heavy smoking. A “good” BMI for most people is in the range of 20 to 24. Mortality is minimal although still increased at a body mass index of approximately 22 and lowest in middle-aged women with a body mass index below 19.⁷

Overweight: BMI = 25–29.9
Obesity: BMI = 30 and higher

A person is obese when the amount of adipose tissue is sufficiently high (20% or more over ideal weight) to detrimentally alter biochemical and physiological functions and to shorten life expectancy. Obesity is associated with four major risk factors for atherosclerosis: hypertension, diabetes, hypercholesterolemia, and hypertriglyceridemia. Overweight individuals have a higher prevalence of hypertension at every age, and the risk of developing hypertension is related to the amount of weight gain after age 25.¹³ The two in combination (hypertension and obesity) increase the risk of heart disease, cerebrovascular disease, and death. The Nurses' Health Study has documented a continuing correlation between the body mass index and cardiovascular disease, diabetes, and cancer.^{7, 14, 15} In other words, even a modest gain in adult weight, even in a range not considered to be overweight, increases the risk of cardiovascular and metabolic diseases. However, at any given BMI level, the presence of an increase in abdominal fat, metabolic risk factors, or a strong family history of diabetes, hypertension, and heart disease increases the risk to good health.

It is well documented that women have a greater prevalence of obesity compared with men. One reason may be the fact that women have a lower metabolic rate than men, even when adjusted for differences in body composition and level of activity.¹⁶ Another reason that more women gain weight with age is the postmenopausal loss of the increase in metabolic rate that is associated with the luteal phase of the menstrual cycle.¹⁷ The difference between men and women is even greater in older age.

Unfortunately, the basal metabolic rate decreases with age.^{18, 19} After age 18, the resting metabolic rate declines about 2% per decade. The age-related decline in basal metabolic rate is not observed in women who continue to be involved in a regular endurance exercise program.²⁰ A 30-year-old individual will inevitably gain weight if there is no change in caloric intake or exercise level over the years. The middle-age spread is both a biologic and a psychosociologic phenomenon. It is, therefore, important for both our patients and ourselves to understand adipose tissue and the problem of obesity.

Physiology of Adipose Tissue

Adipose tissue serves three general functions:

1. Adipose tissue is a storehouse of energy.
2. Fat serves as a cushion from trauma.
3. Adipose tissue plays a role in the regulation of body heat.

Each cell of adipose tissue can be regarded as a package of triglyceride, the most concentrated form of stored energy. There are 8 calories per gram of triglyceride compared to 1 calorie per gram of glycogen. The total store of tissue and fluid carbohydrate in adults (about 300 calories) is inadequate to meet between-meal demands. The storage of energy in fat tissue allows us to do other things besides eating. Our energy balance, therefore, is essentially equivalent to our fat balance. Thus, obesity is a consequence of the fat imbalance inherent in high caloric diets.

The mechanism for mobilizing energy from fat involves various enzymes and neurohormonal agents. Following ingestion of fat and its breakdown by gastric and pancreatic lipases, absorption of long-chain triglycerides and free fatty acids takes place in the small bowel. Chylomicrons (microscopic particles of fat) transferred through lymph channels into the systemic venous circulation are normally removed by hepatic parenchymal cells where a new lipoprotein is released into the circulation. When this lipoprotein is exposed to adipose tissue, lipolysis takes place through the action of lipoprotein lipase, an enzyme derived from the fat cells themselves. The fatty acids that are released then enter the fat cells where they are reesterified with glycerophosphate into triglycerides. Because alcohol diverts fat from oxidation to storage, body weight is directly correlated with the level of alcohol consumption.²¹

Glucose serves three important functions:

1. Glucose supplies carbon atoms in the form of acetyl coenzyme A (acetyl CoA).
2. Glucose provides hydrogen for reductive steps.
3. Glucose is the main source of glycerophosphate.

The production and availability of glycerophosphate (required for reesterification of fatty acids and their storage as triglycerides) are considered rate limiting in lipogenesis, and this process depends on the presence of glucose.

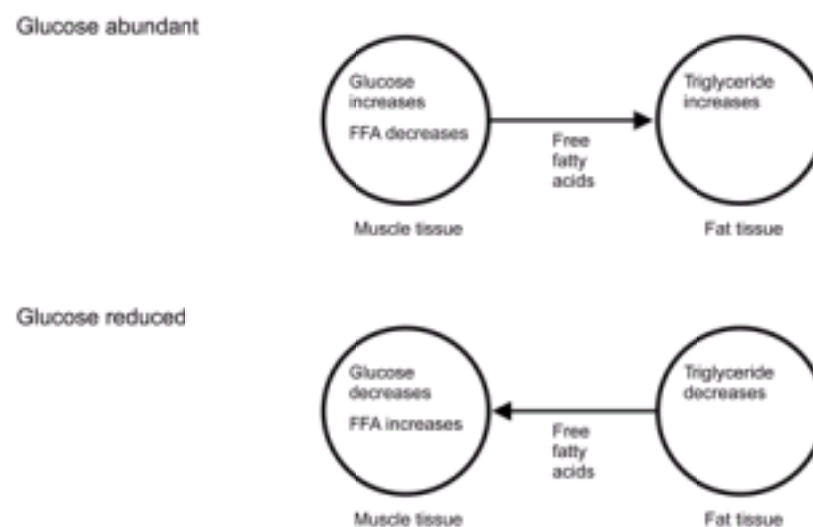

After esterification, subsequent lipolysis results in the release of fatty acids and glycerol. In the cycle of lipolysis and reesterification, energy is freed as heat. A low

variable level of lipolysis takes place continuously; its basic function is to provide body heat.

The chief metabolic products produced from fat are the circulating free fatty acids. Their availability is controlled by adipose tissue cells. When carbohydrate is in short supply, a flood of free fatty acids can be released. The free fatty acids in the peripheral circulation are almost wholly derived from endogenous triglycerides that undergo rapid hydrolysis to yield free fatty acid and glycerol. The glycerol is returned to the liver for resynthesis of glycogen.

Free fatty acid release from adipose tissue is stimulated by physical exercise, fasting, exposure to cold, nervous tension, and anxiety. The release of fatty acids by lipolysis varies from one anatomic site to another. Omental, mesenteric, and subcutaneous fat is more labile and easily mobilized than fat from other sources. Areas from which energy is not easily mobilized are retrobulbar and perirenal fat where the tissue serves a structural function. Adipose tissue lipase is sensitive to stimulation by both epinephrine and norepinephrine. Other hormones that activate lipase are ACTH, thyroid-stimulating hormone (TSH), growth hormone, thyroxine (T_4), 3,5,3 ϕ -triiodothyronine (T_3), cortisol, glucagon, as well as vasopressin and human placental lactogen (HPL).

Lipase enzyme activity is inhibited by insulin, which appears to be alone as the major physiologic antagonist to the array of stimulating agents. When both glucose and insulin are abundant, transport of glucose into fat cells is high, and glycerophosphate production increases to esterify fatty acids.

The carbohydrate and fat composition of the fuel supply is constantly changing, depending on stresses and demands. Because the central nervous system and some other tissues can utilize only glucose for energy, a homeostatic mechanism for conserving carbohydrate is essential. When glucose is abundant and easily available, it is utilized in adipose tissue for producing glycerophosphate to immobilize fatty acids as triglycerides. The circulating level of free fatty acids in muscle will, therefore, be low, and glucose will be used by all of the tissues.

When carbohydrate is scarce, the amount of glucose reaching the fat cells declines, and glycerophosphate production is reduced. The fat cell releases fatty acids, and their circulating levels rise to a point where glycolysis is inhibited. Thus, carbohydrate is spared in those tissues capable of using lipid substrates. If the rise of fatty acids is great enough, the liver is flooded with acetyl CoA. This is converted into ketone bodies, and clinical ketosis results.

In the simplest terms, when a person eats, glucose is available, insulin is secreted, and fat is stored. In starvation, the glucose level falls, insulin secretion decreases, and fat is mobilized.

If only single large meals are consumed, the body learns to convert carbohydrate to fat very quickly. Epidemiologic studies with schoolchildren demonstrate a positive correlation between fewer meals and a greater tendency toward obesity.¹⁷ The person who does not eat all day and then stocks up at night is perhaps doing the worst possible thing.

Clinical Obesity

Leptin and the Ob Gene (the Lep Gene in Humans)

The hypothalamic location of the appetite center was established in 1940 by the demonstration that bilateral lesions of the ventromedial nucleus produce experimental obesity in rats. Such lesions lead to hyperphagia and decreased physical activity. Interestingly, this pattern is similar to that seen in human beings — the pressure to eat is reinforced by the desire to be physically inactive. The ventromedial nucleus was thought to represent an integrating center for appetite and hunger information. Destruction of the ventromedial nucleus was believed to result in a loss of satiety signals, leading to hyperphagia. Overeating and obesity, however, are not due to ventromedial nucleus damage but rather to destruction of the nearby ventral noradrenergic bundle.²² Hypothalamic noradrenergic terminals are derived from long fibers ascending from hindbrain cell bodies. Lesions of the ventromedial nucleus produced by radiofrequency current fail to cause obesity. These lesions lead to overeating and obesity only when they extend beyond the ventromedial nucleus. Selective destruction of the ventral noradrenergic bundle results in hyperphagia. A sudden onset of hyperphagia can be due to a hypothalamic lesion. Possible causes include tumors, trauma, inflammatory processes, and aneurysms.

Signals arriving at these CNS centers originate in peripheral tissues. Opiates, substance P, and cholecystokinin play a role in mediating taste, the gatekeeper for feeding, while peptides released from the stomach and intestine act as satiety signals.²³ Neuropeptides that inhibit appetite include corticotropin-releasing hormone (CRH), neurotensin, and cyclo(HisPro), a peptide derived by proteolysis of thyrotropin-releasing hormone.²⁴ Although recent attention has focused on leptin and the ob gene, keep in mind that the control of food intake and energy expenditure is very complex, and no agent or system functions in isolation.

The word leptin is derived from the Greek word, "leptos," which means thin. **Leptin is a 167-amino acid peptide secreted in adipose tissue, that circulates in the blood bound to a family of proteins, and acts on the central nervous system neurons that regulate eating behavior and energy balance.** Rat studies in the 1950s suggested the existence of a hormone in adipose tissue that regulated body weight through an interaction with the hypothalamus.^{25,26} But it was not until 1994 that the ob gene was identified, the gene responsible for obesity in the mouse.²⁷ In the human, this gene is known as the Lep gene.

There are 4 recessive gene mutations known in mice, and one dominant (Ay/Ay).²⁸ Fat/fat mice are obese and remain insulin sensitive; the mutation decreases carboxypeptidase E, an enzyme that is involved in the conversion of prohormones to hormones; e.g., proinsulin to insulin. The biology of tub is yet unknown.

Genetic Rodent Models of Obesity

Single Gene Mutations	Gene Product	Rodent Chromosome	Human Chromosome
Mice: ob/ob	Leptin	6	7
db/db	Leptin receptor	4	1
fat/fat	Carboxypeptidase E	8	11
tub/tub	Phosphodiesterase	7	4
Ay/Ay	Agouti protein	2	20
Rats: fa/fa	Leptin receptor	5	1

Ob/ob and db/db mice were described over 30 years ago. The ob/ob mutation arose spontaneously in the Jackson Laboratory mouse colony in 1949. The ob/ob mouse is homozygous for a mutation of the ob gene on chromosome 6, and the db/db mouse, discovered in 1966, is homozygous for a mutation of the db gene on

chromosome 4.^{28, 29} These mice have been the subject of over 1000 publications. The product of the *ob* gene is leptin, and in the human, the *Lep* gene is located on chromosome 7q31.3. *Db* is the *diabetes* gene, and this is the locus of the mouse leptin receptor gene. Thus, the *ob/ob* mouse is obese because it does not produce leptin, and the *db* mouse is obese because it cannot respond to leptin; its leptin levels are very high (the mutation alters the leptin receptor).

The Leptin Receptor

The leptin receptor belongs to the cytokine receptor family.²⁸ There are two major forms, a short form and a long form, OB-R_S and OB-R_L. The extracellular domain is very large with 816 amino acids. The intracellular domain of the short form contains 34 amino acids, and in the long form, about 303 amino acids. The short form has many variations, whereas the long form is the likely signaling receptor. The only place that the long form is expressed in greater amounts than the short forms is in the hypothalamus, in the arcuate, ventromedial, paraventricular, and dorsomedial nuclei.^{30, 31}

High levels of the short form leptin receptors in the choroid plexus suggest a transport role for the short form from blood into the cerebrospinal fluid to diffuse into the brain.³² However, a separate transport mechanism has also been demonstrated for leptin.³³

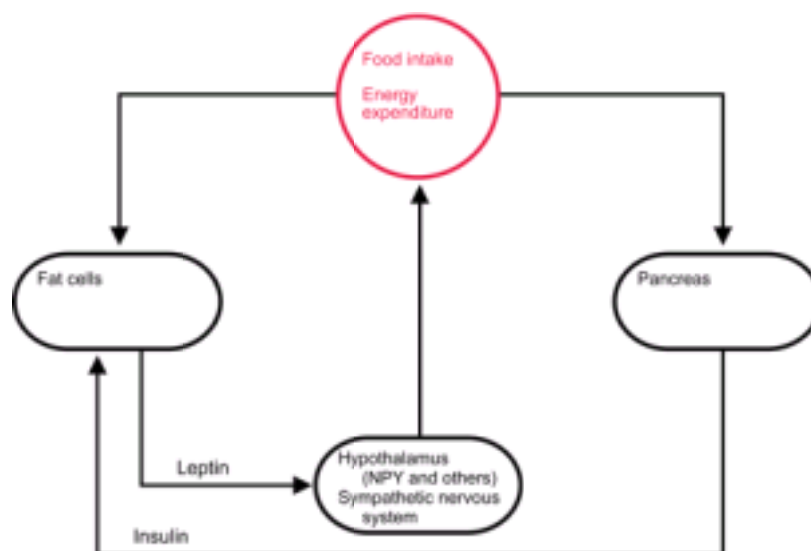

The class I cytokine receptor family (to which the long form belongs) acts by proteins that phosphorylate the receptor after binding and STAT proteins that are activated after phosphorylation, and then translocate to the nucleus and stimulate gene transcription. The long-form receptor works through STAT proteins, but gene knockouts specific for STAT proteins are not obese, indicating the presence of other pathways. These signaling mechanisms are the subjects of intense molecular biology studies.

The *db* gene encodes the leptin receptor. The *db* mutation converts the long form to the short form. The *db/db* mouse has a single G for T nucleotide substitution within the C terminal untranslated end of the short intracellular domain of the *ob* receptor. This results in a new splice site that creates an abnormal exon inserted into the mRNA that encodes the long intracellular domain of the *ob* receptor. As a result, the long-form mRNA in *db/db* mice encodes a protein with most of the intracellular domain truncated to be similar to the short form of the *ob* receptor. The *fa/fa* mutation is a glutamine for proline substitution in the extracellular domain, and in contrast to the *db/db* mouse, the *fa/fa* rat will respond to leptin, but only if it is delivered into the brain.³⁴

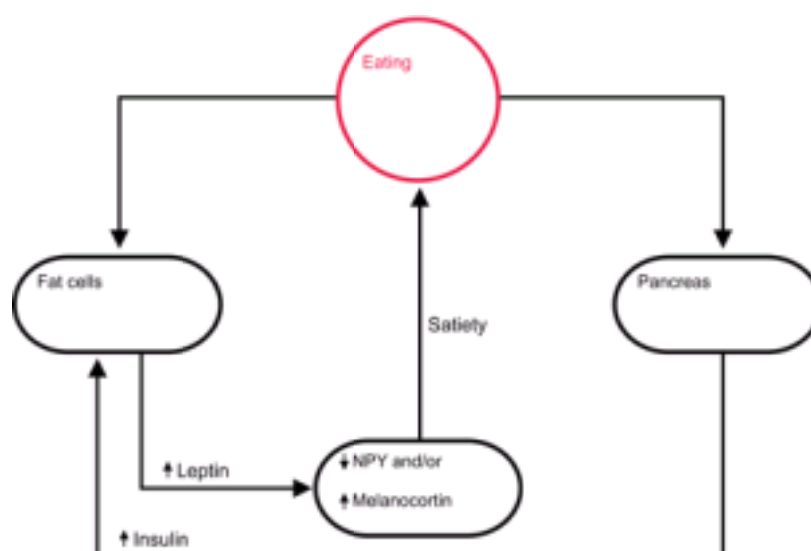

The Physiologic Feedback Loop

Energy expenditure is composed of the basal metabolic rate, diet and temperature-induced heat production, and the energy necessary for physical activity. Leptin induces weight loss in mice due to decreased appetite and food consumption and an increase in heat production and activity.³⁵ Leptin placed in the lateral ventricle of the rodent brain causes this weight loss, associated with a decrease in the hypothalamic peptide, neuropeptide Y (NPY) expression and secretion. NPY is a 36-amino acid polypeptide that is a potent stimulator of eating when injected directly into the rodent brain.³⁶ NPY has a tyrosine at both ends, hence the use of Y to stand for tyrosine. NPY stimulates food intake, decreases heat production, and increases insulin and cortisol secretion.

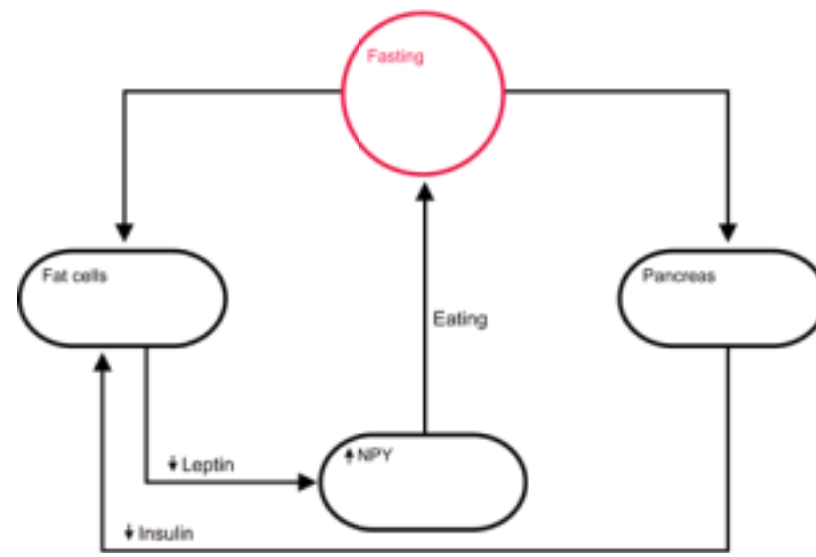

In rodents, insulin increases the expression of the *ob* gene, but there is controversy in humans.³⁵ In humans, there is no surge of leptin after meals, and the acute administration of insulin does not stimulate an increase in leptin levels. However, an increase in *ob* gene expression occurs in humans with chronic insulin stimulation, a situation that would be similar to overeating.³⁷ In addition, at least one study has found an acute increase in leptin levels following the induction of hyperinsulinemia (but only in women, not in men).³⁸ It is likely that insulin is at least one regulator of the *ob* gene and its secretion of leptin. Thus, this is a physiologic feedback loop to maintain weight and energy.

The *Ay/Ay* rodent becomes fat late in life. The *Agouti* gene encodes a protein produced by hair follicles. This protein binds to a melanocortin receptor in melanocytes in the skin, thus preventing melanocyte-stimulating hormone action. *Agouti* rats have high levels of this protein and have yellow instead of black fur. Melanocortins have been demonstrated in the hypothalamus, produced in the arcuate nucleus. Melanocortins binding to the brain receptor influence appetite.^{39, 40} Knockout mice for the melanocortin receptor become obese, and these mice have high NPY expression. *Ay/Ay* rodents make an excess of *Agouti* protein, blocking melanocortin action. Thus, too little melanocortin could be another pathway for obesity. The importance of this pathway is evident in the report of mutations within the proopiomelanocortin (POMC) gene characterized by deficiencies in both melanocyte-stimulating hormone (MSH) and adrenocorticotrophin (ACTH), yielding individuals with obesity, adrenal insufficiency, and red hair pigmentation.⁴¹

Fasting and exercise decrease leptin secretion and increase NPY gene expression in the arcuate nucleus, followed by release of NPY by neuronal projections into the paraventricular nucleus. The neurons that respond to NPY originate in the arcuate nucleus and project into the paraventricular and dorsomedial nuclei. The arcuate nucleus lies outside the blood-brain barrier (there is no blood-brain barrier in the medial basal hypothalamus) and can be reached by leptin in the circulation. The

NPY neurons stimulate feeding and inhibit heat production by inhibiting sympathetic nervous activity. In ob/ob mice with no leptin, NPY levels are high in the hypothalamus, and leptin treatment lowers NPY and restores everything to normal.³⁰

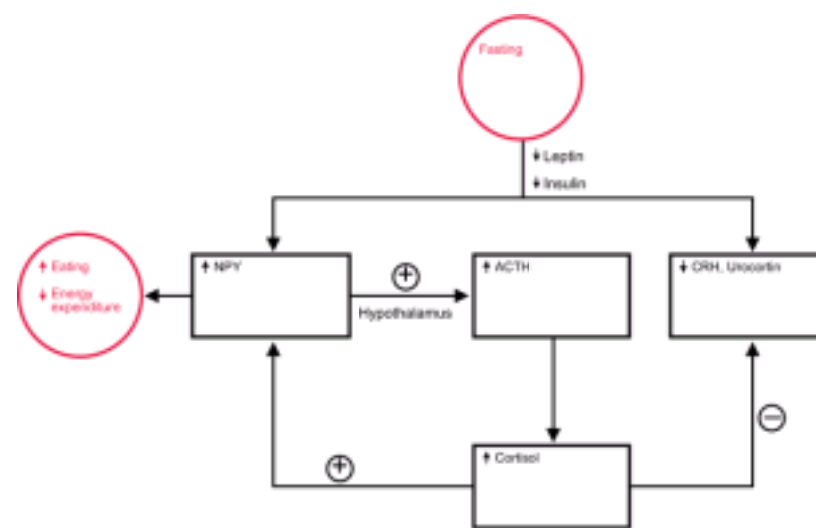

In rodents, caloric restriction increases the expression of NPY in the arcuate nucleus and the release of NPY in the paraventricular nucleus. Leptin and insulin decrease during fasting, allowing an increase in the expression of the NPY gene. Because an increase in metabolism is unwanted during fasting, CRH decreases; however, there is an increase in cortisol that is a consequence of an NPY-induced hypothalamic signal, not yet identified. Fasting decreases leptin more than expected by the decrease in fat content, indicating the presence of other control mechanisms.⁴²

In normal mice, leptin decreases NPY.⁴³ In most animal models, the NPY content in the hypothalamus is high with obesity, and brain infusions of NPY cause obesity and increased ob gene expression.⁴⁴ Knockout mice deficient in NPY maintain normal weight and respond to leptin, indicating that NPY is part of a redundant system, not an absolute requirement.⁴⁵

In the human, the ob gene, known as the Lep gene, does not appear to be acutely regulated.⁴⁶ Feeding increases leptin levels, but slowly, correlating with insulin levels.^{37, 47} Insulin provides negative feedback to the brain in a manner similar to leptin, including an effect on NPY.³⁶ The hyperphagia of diabetes mellitus reflects a deficiency in this insulin action. In fa/fa rats (obese because of a mutation in the leptin receptor), insulin does not affect neuropeptide Y expression, indicating that the inhibition of NPY exerted by insulin is mediated through the leptin-signaling system.⁴⁸

CRH inhibits food intake and increases energy expenditure; thus, it is expected that weight loss would decrease CRH. In addition, leptin stimulates CRH gene expression, and therefore, lower leptin levels with fasting should lower CRH levels.⁴⁸ And indeed, CRH secretion is not increased after acute weight loss; however, it is well recognized that cortisol secretion is increased with stress and exercise. This may be due to a hypothalamic effect of NPY on ACTH secretion by the pituitary.⁴⁸ The specific food and energy response associated with CRH may also be mediated by urocortin, a CRH-related peptide.⁴⁹ Urocortin is very potent in reducing food intake, perhaps activating the energy system without activating the overall CRH mechanism. These relationships are further confused by evidence that glucocorticoids stimulate leptin synthesis and secretion in humans.⁵⁰

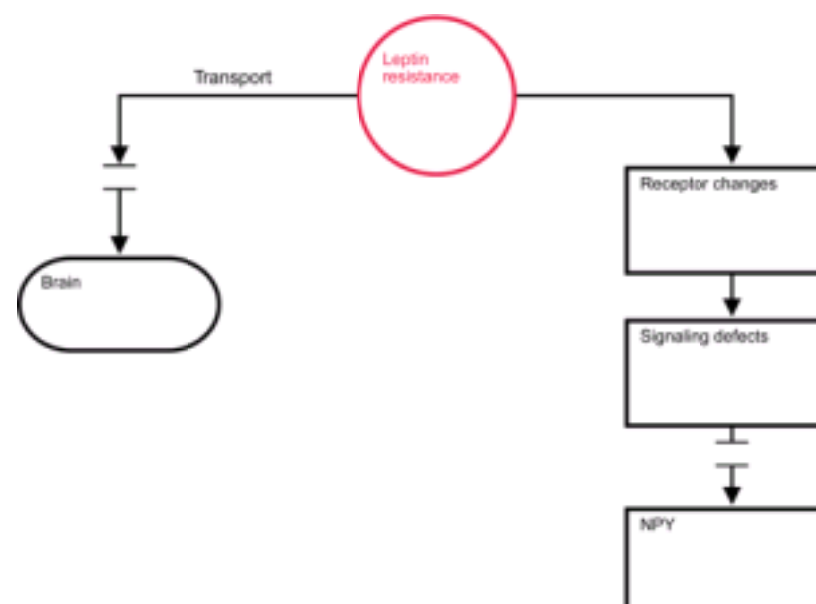

Leptin in Obese People

Most studies have indicated that nearly all obese individuals have elevated leptin levels, probably due to an increase in Lep gene expression and partly due to greater production because of larger fat cells.^{51, 52 and 53} The greater weight of these individuals represents the leptin level at which stability is achieved, when leptin resistance is overcome. In lean individuals, leptin levels are similar in men and women, but in women, as weight increases, leptin increases 3 times more rapidly than in men.³⁸ Higher levels in women suggest a greater resistance to leptin, correlating with a greater prevalence of obesity in women.⁵⁴

The incidence of obesity in black women is almost twice that of white women.⁵⁵ Obese postmenopausal black women have 20% lower leptin levels than white women.⁵⁶ These lower leptin levels correlate with a lower resting metabolic rate in the black women. The lower levels may indicate a greater sensitivity to the leptin mechanism in black women.

In obese individuals, fat cells produce leptin normally and a prevalent genetic failure has not been identified. **Thus it is hypothesized that obesity is due to resistance to leptin.**⁵⁷ This may be due to a transport problem of leptin into the brain, as indicated by the finding that leptin level differences between obese and lean individuals are greater in blood than in cerebrospinal fluid.^{58, 59} At least in the mouse, this resistance is present only in the periphery in that leptin administered in the brain still works.⁶⁰

Only a small percentage of humans are expected to have mutations in the leptin receptor and be refractory to leptin agonist treatment.⁶¹ Diet-induced obesity in mice responds to leptin treatment, and it is expected that the majority of overweight humans would also. However, in genetically normal animals, leptin treatment does not

always reduce weight by reducing food intake.⁶² A crucial question is what happens within physiologic range changes in leptin.

In obese individuals, the majority of leptin is unbound and presumably active, consistent with the resistance hypothesis.⁶³ In lean individuals, the majority of circulating leptin is bound. Another important subject for research is the regulation of leptin binding to proteins in the circulation.

Why Is Weight Loss So Hard To Maintain?

The average adult eats nearly 1 million calories per year.²⁵ When life was tougher, leptin served the purpose of meeting the threat of starvation. During periods of food availability, individuals with leptin defects could consume large amounts and store excess fat. Today, with no shortage of food, these individuals who survived during food shortages in the past now become obese, and succumb to the complications of obesity. But the most vexing problem is that 90% to 95% of people who lose weight subsequently regain it.⁶⁴

Weight loss in obese and lean people produces the same response, decreased leptin and insulin. The obese person tends to regain weight because the lower leptin started from a different set point and is now lower than what the body views as required to be stable in terms of the amount of fat. When energy expenditure, food intake, and body weight are in balance, leptin is at a level consistent with a set point determined by this balance. With weight loss and loss of fat, leptin decreases, causing an increase in appetite and a decrease in energy. This is great when you lose weight with an illness, but not good for an overweight person trying to lose weight. Whenever a perturbation occurs, leptin levels change to restore the original status quo, making it difficult for overweight people to maintain weight loss. Thus, there is hope for leptin agonist treatment of these individuals.

Circulating levels of leptin are correlated with the percent body fat.⁵¹ In other words increased body fat increases the expression of the Lep gene in fat cells. The amount of leptin in the circulation, therefore, is a measure of the amount of adipose tissue in the body. For this reason, neither baseline levels nor initial changes in leptin predict whether weight loss can be maintained.⁶⁵

A *reduction* of 10% in body weight is associated with a 53% reduction in serum leptin.⁵¹ This would stimulate an effort to regain the weight. The key question is what happens if an individual can successfully maintain the lower weight. In a longitudinal study of obese people, when weight loss was maintained, leptin levels remained low.⁶⁶

Therefore, whenever a perturbation occurs, leptin levels change to restore the original status quo. Thus, these acute responses work against attempts to lose weight. A change in energy intake causes a change in leptin levels.⁴⁸ The body then changes appetite and energy expenditure to conform to the new leptin level. A 10% *increase* in body weight is associated with a 300% increase in serum leptin.⁶⁷ The basic purpose is to conserve energy during periods of fasting and to avoid obesity during periods of excess. When caloric intake is reduced, the basal metabolic rate is reduced in a regulatory compensatory adaptation that makes maintenance of weight loss difficult.

Congenital Leptin Deficiency

The Lep gene (ob gene in mice) has been sequenced from hundreds of obese individuals and mutations have been rare, and mutations in the leptin receptor have also not been detected in obese people.^{57, 68}

The first definitive demonstration of a congenital leptin deficiency in humans was reported in two severely obese Pakistani children who were cousins.⁶⁹ Despite their mass of fat, their serum leptin levels were very low, and the molecular biology study of a fat biopsy revealed a homozygous deletion of a single guanine in the leptin gene. This mutation results in the introduction of 14 aberrant amino acids into the leptin peptide followed by a premature truncation. All four parents were heterozygotes. These children had normal birth weights, but immediately began gaining excessive weight with marked increases in appetites. In contrast to ob/ob mice, they did not have elevated cortisol levels; however they were hyperinsulinemic. Three obese members of a Turkish family have been reported with an amino acid substitution that impairs intracellular transport of leptin.⁷⁰ It is noteworthy that these individuals also displayed suppression of gonadal function.

An obese individual has been reported with a mutation in prohormone convertase (an enzyme that participates in the conversion of prohormones into hormones as does the carboxypeptidase E enzyme deficient in the fat/fat mouse).⁷¹ However, a single gene mutation responsible for obesity will probably be discovered only in individuals such as these with extremely severe obesity. Nevertheless, linkages to obesity have been described to regions near the leptin gene or the leptin receptor gene, perhaps indicating differences in regulatory elements of these genes.⁷²

It is expected that only a small percentage of obese humans will have mutations in the leptin receptor or the Lep gene.

Leptin and Reproduction

Several observations support a role for leptin in reproductive physiology.

1. Leptin administration accelerates the onset of puberty in rodents.⁷³
2. Leptin levels increase at puberty in boys.⁷⁴
3. Low leptin levels are present in athletes and in patients with anorexia and delayed puberty.⁷⁵
4. The ob/ob mouse undergoes normal sexual development, but remains prepubertal and never ovulates, but fertility is restored with leptin administration.⁷³

Leptin levels are greater in females than in males, and in premenopausal women compared with postmenopausal women.⁶¹ In girls, leptin levels are higher and decrease with increasing Tanner stages of puberty.⁷⁶ Thus with puberty, there is increasing sensitivity to leptin. Or in another way to look at this relationship, decreasing leptin during puberty may allow greater food intake for growth by lowering the satiety signal.

The effect of leptin on reproduction can be viewed as an additional role in maintaining responses to stress. Weight loss is known to be associated with an increased adrenal response and a decrease in thyroid function; these endocrine changes, along with suppression of the estrous cycle, occur in fasted mice and are reversed by treatment with leptin.⁷⁷

The puzzle is why CRH is elevated in stress amenorrhea (especially that associated with weight loss) in contrast to fasting in normal and obese individuals. One possibility is that the decrease in leptin and increase in NPY associated with stress-related weight loss is the expected response, but it is inadequate to suppress the stress-induced increase in CRH. The blunted patterns in amenorrheic athletes support this. The increase in CRH and resulting hypercortisolism further increase metabolism and weight loss.

Athletes with cyclic menses demonstrate a normal diurnal rhythm in leptin levels. However, amenorrheic athletes do not have a diurnal pattern.⁷⁸ Both cycling athletes and amenorrheic athletes have low leptin levels (3-fold reduction) that correlate with reduced body fat, but the levels are further lowered by hypoinsulinemia and hypercortisolemia. In addition, amenorrheic athletes have a blunted leptin response to the increase in insulin following meals.

In postmenopausal women, leptin levels decrease with endurance training, and hormone therapy has no effect.⁷⁹ This indicates that the gender difference (higher levels in women) is due to a difference in fat content, not a hormonal difference.

Because of the tight connection between insulin and leptin levels in mice, and the now well recognized prevalence of hyperinsulinemia in women with polycystic ovaries, it makes sense to examine leptin levels in these women.

Although an initial study reported increased leptin levels in women with polycystic ovaries, the study has been criticized for not adjusting for body weight.⁸⁰ At least 3 studies, controlling for weight, detected no differences in leptin levels comparing women with and without polycystic ovaries.^{81, 82, 83} In women with polycystic ovaries, the relationship between leptin and body weight is maintained. Thus, in contrast to the rodent model, hyperinsulinemia and insulin resistance do not affect leptin levels

in these women.

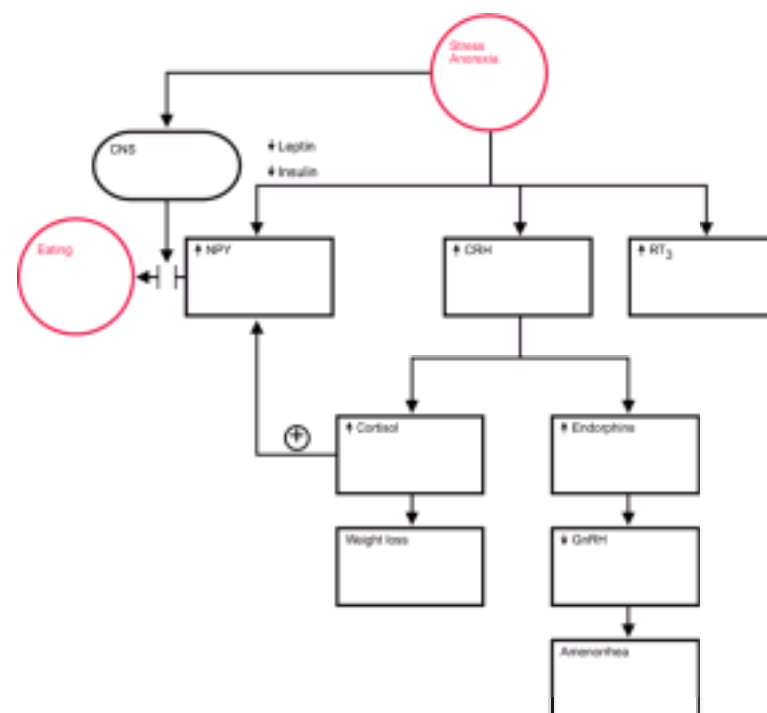

However, a role for leptin in the changes associated with polycystic ovaries should not yet be discounted. There may be subtle differences that have biologic consequences. At least one study demonstrated a correlation between leptin levels and 24-hour insulin levels in women with polycystic ovaries.⁸¹ Furthermore, the drug that lowers insulin resistance, troglitazone, inhibits transcription of the Lep gene and may be especially suited for obese women with polycystic ovaries.⁸⁴

Is it possible that leptin has a target tissue role in reproduction? An isoform of leptin has been identified in the ovary, and leptin exerts specific actions on steroidogenesis as studied in vitro.^{85,86} Leptin inhibits the synergistic action of insulin-like growth factor-I (IGF-I) on FSH-stimulated estradiol production (but not progesterone) in rat granulosa cells, and also inhibits FSH stimulation of IGF-I production. In addition, leptin is expressed in human granulosa and cumulus cells, and is present in mature human oocytes and follicular fluid; thus, leptin appears to be secreted by the ovarian follicle.⁸⁷ A rise in maternal serum leptin levels after the administration of human chorionic gonadotropin and before ovum retrieval was correlated with a higher pregnancy rate.⁸⁷ Leptin, therefore, probably is involved in a multitude of important metabolic and developmental functions.

The leptin story has restored credibility to the critical weight hypothesis originally proposed by Rose Frisch in the 1970s.⁸⁸ The critical weight hypothesis states that the onset and regularity of menstrual function necessitate maintaining weight above a critical level, and, therefore, above a critical amount of body fat. It has always been a mystery how total body fat could talk with the brain. A mystery no longer! Fat talks to the brain via leptin, and the leptin system affects reproduction.

There is a difference, however, between ordinary weight loss and stress-induced (e.g., exercise or psychologic problems such as anorexia) weight loss. In ordinary weight loss, corticotropin-releasing hormone (CRH) secretion is reduced, and the hypercortisolism is believed to be mediated through NPY signals in the hypothalamus. In stress-induced weight loss, CRH secretion is increased.

CRH directly inhibits hypothalamic GnRH secretion, probably by augmenting endogenous opioid secretion. Women with hypothalamic amenorrhea (including exercisers and women with eating disorders) demonstrate hypercortisolism (due to increased CRH and ACTH, perhaps augmented by NPY stimulation of ACTH secretion), suggesting that this is the pathway by which stress interrupts reproductive function.⁸⁹ In regards to reproduction, the final pathway is suppression of GnRH, a response to multiple inputs indicating the availability of metabolic fuel. The clinical presentation (inadequate luteal phase, anovulation, amenorrhea) will depend on the degree of GnRH suppression.

A unifying hypothesis focuses on energy balance.⁹⁰ When available energy is excessively diverted, as in exercise, or when insufficient, as with eating disorders, reproduction is suspended in order to support essential metabolism for survival. Thus reproduction may not be directly affected by the level of body fat, rather body fat is a marker of the metabolic energy state, and the extremely low leptin levels in anorexic patients are an appropriate attempt to restore appetite, an attempt that fails to overcome the stress-induced increase in CRH and its consequences. This is consistent with the finding that NPY stimulates GnRH secretion and amplifies gonadotropin response to GnRH in the rodent.⁹¹ From a teleological point of view, there is sense to these relationships; the responses that assist the body to withstand stress also inhibit menstrual function because a stressful period is not the ideal time for reproduction.

Leptin Summary

Because of the high levels of leptin present in overweight people, the purpose of leptin function may be limited to an effect at low levels. A low circulating level of leptin may serve as a signal that fat stores are not sufficient for growth and reproduction. Thus low levels would ordinarily stimulate hyperphagia, reduce energy expenditure, and suppress gonadotropin secretion and reproduction. The high levels of leptin and the apparent resistance to leptin action associated with excess body weight and fat would then reflect not resistance, but a lack of physiologic effect.

Although the leptin mechanism offers the potential for new treatments for obesity, it is not around the corner. Leptin, a polypeptide, cannot be administered orally, and in view of high levels in overweight people, another method must be found to attack the lack of effect or the apparent resistance to leptin. Thus far, it appears that genetic defects in the Lep gene are uncommon; nevertheless, for affected individuals, a leptin agonist may be therapeutic. Even if this complex system yields new treatments, it is unlikely that we will be able to ignore eating appropriately and exercising adequately.

Inherited Aspects of Obesity

Fat cells develop from connective tissue early in fetal life. An important question is whether new fat cells are produced by metaplasia in the adult, or whether an individual achieves a total complement during a certain period of life. In other words, is excess fat stored by increasing the size of the fat cell, or by increasing the number of cells? The possibility arises that there is an inherited increase in the total number of fat cells, which just wait to be packed full of storage fat. Furthermore, the total number of fat cells may depend on an infant's nutritional state during the neonatal period and perhaps in utero as well.

Studies of fat obtained at surgery indicate that the mean fat cell volume is increased 3-fold in obese people, but an increase in the number of fat cells is seen only in the grossly obese. When patients diet, the fat cells decrease in size but not in number. Hypercellular obesity may be a more difficult problem to overcome, because an individual may be saddled with a permanent increase in fat cells.

Some researchers think that, at some period in a person's life, a fixed number of fat cells is obtained. Adolescence, infancy, and intrauterine life seem particularly critical.^{92,93} This premise is not solidly established, because there is no certain way to identify an empty fat cell, and potential fat cells cannot be recognized. Nevertheless, a hyperplastic type of obesity (more fat cells) may be associated with childhood and have a poor prognosis; a hypertrophic type (enlarged fat cells) that is responsive to dieting may occur in adults.

There certainly appears to be a genetic component. The weights of adopted children in Denmark correlated with the body weights of their biologic parents but not with their adoptive parents.⁹⁴ This would suggest that the genetic influence is even more important in childhood than environmental factors. Other work suggests that the familial occurrence of obesity can be attributed in part to a genetically related reduced rate of energy expenditure.⁹⁵ In studies of identical and fraternal twins reared apart, approximately 70% of the variance in the body mass index could be assigned to genetic influences and the remaining 30% to environmental effects.⁹⁶ After the age of 3, obesity in childhood predicts obesity in adulthood, and parental obesity doubles the risk of adult obesity in both obese and nonobese children.⁹⁷

Some argue that each individual has a set point, a level regulated by a signal between the fat cells and the brain (the leptin system). According to this argument,

previously obese people who have successfully lost weight have to maintain themselves in a state of starvation (at least as far as their fat cells are concerned).

Genetics and biochemistry are against many obese people. It is best to recognize that an obese individual who has suffered with the problem lifelong does have a disorder, a disorder which is not well understood. However, for each individual, the extent to which the genetic predisposition is expressed depends on environmental influences. The prevalence of obesity is inversely related to the level of physical activity and education and directly related to parity.⁹⁸ Thus, socioeconomic and behavioral factors are important determinants of body weight, and surely each individual will reflect varying impacts of genetics and environment.

Endocrine Changes

The most important endocrine change in obesity is elevation of the basal blood insulin level. The circulating insulin level is proportional to the volume of body fat. Increases in body fat change the body's secretion and sensitivity to insulin, appropriately so because insulin acts to reduce food intake by inhibiting the expression of neuropeptide Y as well as affecting other agents that influence appetite.⁴⁸ The effect on neuropeptide Y is believed to be mediated via the leptin signaling system.

Overweight individuals are characterized by insulin resistance. The key factors that affect insulin resistance are the amount of fat tissue in the body, the caloric intake per day, the amount of carbohydrates in the diet, and the amount of daily exercise. At least one mechanism for the increased resistance to insulin observed with increasing weight is down-regulation of insulin receptors brought about by the increase in insulin secretion. The increase in insulin resistance affects the metabolism of carbohydrate, fat, and protein. Circulating levels of free fatty acids increase as a result of inadequate insulin suppression of the fat cell. Insulin resistance results in decreased catabolism of triglycerides, yielding a decrease in HDL-cholesterol and an increase in LDL-cholesterol. This, of course, is a major mechanism for the development of atherosclerosis. Hyperinsulinemia is also directly associated with hypertension. The hyperinsulinemia associated with obesity is reversible with weight loss.

The simplest way to assess insulin resistance is to measure the ratio of fasting glucose to fasting insulin. A ratio lower than 4.5 is characteristic of insulin resistance.⁹⁹ This method has limitations, the most notable being the variation due to assay precision and pulsatile secretion of insulin. It is more reliable to measure the insulin response to 1 g/kg glucose; the maximal response should not be greater than 150 μ U/mL. However, if a patient is obese, one can assume the patient is insulin-resistant.

Genetics plays a greater role in the development of maturity onset diabetes than juvenile onset.¹⁰⁰ It is impossible to predict exactly who eventually will develop diabetes because the tendency is recessive, and it will not develop in every generation in a family. But weight is a good tip-off. As weight increases, the frequency of occurrence of diabetes increases. Both gestational diabetes and insulin-dependent diabetes are more common in overweight pregnant patients.

Contrary to popular misconception, hypothyroidism does not cause obesity. Weight gain due to hypothyroidism is confined to the fluid accumulation of myxedema. There is no place, therefore, for thyroid hormone administration in the treatment of obesity when the patient is euthyroid.

Obese people are relatively unable to excrete both salt and water, especially while dieting. During dieting, this seems to be mediated by increased output of aldosterone and vasopressin. Because water produced from fat outweighs the fat, people on diets often show little initial weight loss. The early use of a diuretic may encourage a patient to persist with dieting.

The basic question is whether metabolic changes observed in obesity represent adaptive responses to a markedly enlarged fat organ or whether they are representative of a metabolic or hormonal defect. The former is true. These changes are secondary responses; they are totally reversible with weight loss. Four-year follow-up in a group of patients who did not regain their weight after dieting revealed persistently normal insulin and glucose responses; patients who regained their weight showed further deterioration in these metabolic factors.¹⁰¹

Anatomic Obesity

Gynoid obesity (the pear shape) refers to fat distribution in the lower body (femoral and gluteal regions), whereas android obesity (the apple shape) refers to central body distribution. Gynoid fat is more resistant to catecholamines and more sensitive to insulin than abdominal fat; thus, extraction and storage of fatty acids easily occur, and fat is accumulated more readily in the thighs and buttocks. This fat is associated with minimal fatty acid flux, and, therefore, the negative consequences of fatty acid metabolism are less. Gynoid fat is principally stored fat. The clinical meaning of all this is that women with gynoid obesity are less likely than women with android obesity to develop diabetes mellitus and coronary heart disease.¹⁰²

During pregnancy, lipoprotein lipase activity increases in gynoid fat, further promoting fat storage and explaining the tendency for women to gain thigh and hip weight during pregnancy. Also, because this fat is more resistant to mobilization, it is harder to get rid of. This difficulty is related to the adrenergic receptor concentration in the fat cells, the regulation of which remains a mystery.

Android obesity refers to fat located in the abdominal wall and visceral-mesenteric locations. This fat is more sensitive to catecholamines and less sensitive to insulin and, thus, more active metabolically. It more easily delivers triglyceride to other tissues to meet energy requirements. This fat distribution is associated with hyperinsulinemia, impaired glucose tolerance, diabetes mellitus, an increase in androgen production rates, decreased levels of sex hormone-binding globulin, and increased levels of free testosterone and estradiol.^{103, 104} In addition, women with central obesity have decreased cortisol levels, a finding that would be consistent with increased leptin levels.^{105, 106} These metabolic changes improve with weight loss.¹⁰⁶

It is central body obesity that is associated with cardiovascular risk factors, including hypertension and adverse cholesterol-lipoprotein profiles.¹⁰⁷ The waist:hip ratio is a variable strongly and inversely associated with the level of HDL₂, the fraction of HDL-cholesterol most consistently linked with protection from cardiovascular disease.¹⁰⁸ The adverse impact of excess weight in adolescence can be explained by the fact that deposition of fat in adolescence is largely central in location.^{9, 109} Weight loss in women with lower body obesity is mainly cosmetic, whereas loss of central body weight is more important for general health in that an improvement in cardiovascular risk is associated with loss of central body fat. At any given level of body mass index (BMI), an increase in central, android fat increases the risk of cardiovascular disease.

It is somewhat surprising that leptin expression and circulating levels are not influenced by android, central obesity.^{110, 111} This indicates that leptin is regulated only by subcutaneous fat.

The waist:hip ratio is a means of estimating the degree of upper to lower body obesity; the ratio accurately predicts the amount of intra-abdominal fat (which is greater with android obesity).^{112, 113} However, studies have demonstrated that the more easily determined circumference of the waist is a better predictor of central, android abdominal fat.^{114, 115} **A waist circumference greater than 100 cm (about 40 inches) in men and 90 cm (about 35 inches) in women is predictive of abnormal endocrinologic and metabolic function and is associated with an increased risk of cardiovascular disease.**¹¹⁴

Management of Obesity

In addition to not smoking cigarettes, weight reduction is the most important health measure available for reducing the risk of cardiovascular disease.¹¹⁶ After adjusting for age and smoking, the Nurses' Health Study documented a 3-fold increase in risk for coronary disease among women with a body mass index of 29 or greater.¹¹⁷ Even women who are mildly or moderately overweight have a substantial increase in coronary risk. In the Nurses' Health Study, 40% of coronary events could be attributed to excessive body weight, and in the heaviest women, 70%. But most importantly, weight loss is followed by a decrease in mortality from all causes, and, especially, a decrease in cardiovascular and cancer mortality.¹¹⁸

For most patients, after a routine evaluation to rule out pathology such as diabetes mellitus, the clinician is left with the frustrating task of prescribing a diet. But it is not enough to just prescribe a diet or prescribe an anorectic drug. An effective weight loss program requires commitment from both patient and clinician.

Clinician and patient should agree on the goal of a diet program. Although the clinician may want the patient to reach ideal weight, the patient may be satisfied with less. Motivation is improved when the goals meet both personal and medical objectives. It is realistic to lose 4–5 pounds in the first month and 20–30 pounds in 4–5 months. To achieve a respectable rate of weight loss, intake must be 500–1000 calories below energy expenditure.¹¹⁹ But as weight is lost, energy requirements

decrease; therefore unless energy intake decreases, the rate of weight loss will slow. Clinicians and patients need to establish reasonable goals, and only modest changes in diet and activity are necessary.

Despite various fads and diet books, the best diet continues to be a limitation of calories to between 900 and 1200 calories per day, the actual amount depending on what the individual patient will accept and pursue. When energy intake is less than this, it is very difficult to obtain the recommended levels of vitamins and minerals. A daily vitamin and mineral supplement should be used with very low calorie diets. There is no evidence supporting the contention that changing the relative proportions of carbohydrates, protein, and fat without reducing overall caloric intake will produce effective weight loss. ¹²⁰

Ideal Diet:

Carbohydrates	—50%
Protein	—15–20%
Fat	—<30%

The discouraging aspect is that to lose a pound of fat, the equivalent to a 3500-calorie intake must be expended. Dieting has to be slow and steady to be effective. Successful programs include behavior modification, frequent visits to the clinician, and involvement of family members. Behavior modification starts with daily recording of activity and behavior related to food intake, followed by the elimination of inappropriate cues (other than hunger) that lead to eating.

Careful studies (performed in hospitalized subjects on metabolic wards) have indicated that the carbohydrate and fat composition of the diet has no effect on the rate of weight loss.¹²¹ Restriction of calories remains the important principle, recognizing that reduction in fat intake is the most effective method of weight loss. Substituting one of the liquid formulas for meals has been successful in many individuals. Unbalanced formulations, however, have the same side effects as seen with total starvation (carbohydrate-deprived regimens). Adequate carbohydrate is necessary for utilization of amino acids. In addition, electrolyte problems have been encountered, and there is an initial diuretic phase that can lead to postural hypotension.

The protein-sparing modified fast is a ketogenic regimen providing approximately 800 calories per day. Unsupplemented liquid protein diets have been associated with deaths due to cardiac arrhythmias. The low-calorie diets that use protein and carbohydrate supplemented with minerals and vitamins as the sole source of nutrition are safer but should be used only for severe obesity and under medical supervision. ¹²² These diets are still potentially dangerous. The other disadvantage to the semistarvation diet is that short-term success does not guarantee long-term weight maintenance. It is reported that at best only one-fourth to one-third of individuals who lose weight by a semistarvation ketogenic regimen plus behavior modification therapy will have significant long-term weight reduction. ¹²³ On the other hand, for that one-fourth to one-third, this represents a major accomplishment and is worth doing. Unfortunately, repeated dieting and recidivism have a negative impact. With each episode, the body learns to become more efficient, so that with each diet, weight comes off more slowly and is regained more rapidly.

It is not unusual to encounter patients who claim to be unable to lose weight despite following a diet with less than 1200 calories per day. In a study of such patients, it was discovered that underreporting of actual food intake and overreporting of physical activity are both common. ¹²⁴ While it may not be true for all patients, certainly some individuals do eat more than they think and exercise less than they report to their clinicians. This is not a deliberate conscious attempt to deceive the clinician. These patients truly believe their resistance to weight loss is genetic and not due to their own personal behavior. They are astonished and distressed to learn the results of accurate recording of dietary intake and physical exercise. The use of a dietitian to record a typical week's worth of eating and exercise is worthwhile. This kind of knowledge proves to be a powerful lever in providing the motivation to make the changes in lifestyle that can yield loss of weight.

As an index of the general lack of success with diets, a summary of 10 studies (approximately 1200 patients) revealed that only 30% lose 20 pounds or more, and only 4% lose 40 pounds or more.¹²⁵ Although most efforts yield short-term success, maintenance of weight loss is uncommon. Commercial organizations are no more successful than physician-directed programs or nonprofit self-help groups. ^{126, 127} Approximately 90% to 95% of people who lose weight subsequently regain it. ⁶⁴ Thus, it is obvious why gimmicks abound in this area of patient management. A more reasonable attitude is to emphasize how much can be gained with only a little weight loss. A weight loss of 5–10% of body weight will produce beneficial effects on the risks of cardiovascular disease and diabetes mellitus. ^{128, 129}

Unfortunately, smoking cessation is associated with an increase in being overweight. ¹³⁰ And, of course, the link between smoking and weight control is exploited by the tobacco industry in its advertising. This should only increase the importance of our efforts to keep young people from starting smoking and to educate middle-aged people regarding the dangers of smoking.

Anorectics are useful as short-term therapy to control hunger, especially at the beginning of a diet and at a plateau or relapse stage. Compared with amphetamines (which modulate both dopaminergic and noradrenergic neurotransmission), there is far less abuse associated with the catecholamine congeners that affect only noradrenergic neurotransmission. Fenfluramine and dexfenfluramine have no effects on either dopaminergic or noradrenergic neurotransmission, but they increase serotonin release and partially inhibit serotonin reuptake, thus depleting serotonin in the CNS by making it more available for metabolism. However, circulating levels of serotonin become elevated. All of these agents act on the central nervous system to depress appetite.

Because of CNS and cardiovascular side effects (e.g., insomnia, nervousness, euphoria, hypertension, and tachycardia) and the lack of long-term data, the noradrenergic agents should be reserved for short-term use for individuals who wish to lose a small amount of weight. Noradrenergic agents should not be used in individuals with cardiovascular disease. Dexfenfluramine is the d-enantiomer of fenfluramine, the active component of the racemic mixture of d,l-fenfluramine. It was reasoned that lower doses of a noradrenergic agent and a serotonergic agent, when combined, would yield better results, and this proved to be true, but only in a small number of patients.¹³¹ The combination of phentermine and fenfluramine became popular, although weight is promptly regained when treatment is stopped. The popularity of the serotonergic agents received a setback with reports of increased risks due to high circulating levels of serotonin (even with short-term therapy) of the rare but life-threatening conditions, primary pulmonary hypertension and cardiac valvular disease, either with the combination or with either agent (including dexfenfluramine) alone, and these products were withdrawn from the U.S. market. ^{132, 133 and 134} Symptoms associated with pulmonary hypertension include the onset of dyspnea, changes in exercise tolerance, angina, syncope, and lower extremity edema. Patients who develop valvular disease are usually symptomatic with dyspnea and evidence of congestive heart failure. Minor side effects of serotonergic drugs include diarrhea, polyuria, dry mouth, sleep disturbance, and somnolence. Patients who have used fenfluramine or dexfenfluramine should be examined, and those who have a heart murmur or who used the drugs for long durations or at high doses should be studied with echocardiography. ¹³⁵

Weight Loss Drugs

Noradrenergic Agents (affecting the catecholaminergic system):

Diethylpropion 25 mg before meals; 75 mg in morning in slow release form

Phentermine 8 mg before meals; 15 or 37.5 mg in morning

Phendimetrazine 35 mg before meals; 105 mg slow release form daily

Mazindol 1–3 mg 1–3 times daily

Serotonergic Agents:

Fenfluramine 20–40 mg before meals; 60 mg daily in slow release form

Dexfenfluramine 15 mg before meals

Noradrenergic and Serotonergic Agent:

Sibutramine 10–15 mg daily

Lipase Inhibitor:

Orlistat 120 mg tid

Sibutramine (10 or 15 mg daily) blocks the neuronal uptake of both norepinephrine and serotonin, and is an effective appetite suppressant with mild side effects (dry mouth, constipation, and insomnia), but it can increase blood pressure. ¹³⁶ Orlistat (120 mg tid with meals) inhibits pancreatic lipase and increases fecal fat loss. ^{137, 138} Orlistat is associated with annoying gastrointestinal side effects (increased defecation of oily stools). There is some loss of the fat soluble vitamins, and a vitamin supplement should be taken at bedtime.

Because weight is regained after discontinuing drug treatment, long-term therapy has been championed. However, very little information is available regarding the

long-term use of appetite-suppressing drugs. Although the serotonergic agents produce neurotoxicity in animal brains, it is uncertain whether long-term depletion of brain serotonin has adverse neuropsychological effects (e.g., on mood and memory).¹³⁹ Short-term studies indicate only a modest efficacy with variable responses.⁶⁴ Most of the weight loss occurs in the first 6 months and is limited to 5–10 kg (11–22 lbs). Nevertheless, long-term treatment may enable some individuals to sustain weight loss and to more effectively make beneficial changes in diet and lifestyle. It is recommended that treatment with appetite-suppressing drugs should be limited to individuals who have failed to lose weight with conventional methods and who demonstrate significant comorbidities, such as android obesity, coronary heart disease, insulin resistance, and hypertension.⁶⁴ **Attainment of a normal body weight is unlikely with drug treatment; however, a 5% to 10% weight loss will have an important beneficial impact on risk factors for disease.**⁶⁴

Over-the-counter products contain phenylpropanolamine as the active ingredient. This drug is a sympathomimetic derived from ephedrine and can act synergistically with caffeine to produce amphetamine-like reactions. **It should be noted that phenylpropanolamine taken in combination with a dopamine agonist (e.g. bromocriptine) or a monoamine oxidase inhibitor can precipitate a hypertensive crisis.** Appetite-suppressing drugs of all kinds are contraindicated in patients taking monoamine oxidase inhibitors and patients with glaucoma.

Surgical treatment and starvation should be reserved for patients who are morbidly obese. Both methods involve many potential problems and require close monitoring.

Controlled studies have not demonstrated the effectiveness of thyroid preparations or human chorionic gonadotropin.¹⁴⁰ Indeed, adding thyroid hormone increases the loss of lean body mass rather than fat tissue. It is clear that adjunctive drug measures are not successful unless the patient is also motivated either to limit caloric intake or to increase the exercise level in what will be a lifelong battle.

A regular pattern of physical exercise reduces the risk of myocardial infarction in all people.¹⁴¹ Both weight loss and increased physical activity, through an unknown mechanism, lower the level of low density lipoprotein (LDL), and increase the level of high density lipoprotein (HDL).¹⁴² A further benefit of strenuous or prolonged exercise is an inhibition of appetite that lasts many hours and that is associated with an increase in the resting metabolic rate for 2–48 hours. There is one study, however, that indicates a rebound increase in appetite 1–2 days after exercise.¹⁴³ The optimal program includes, therefore, a *daily* period of exercise. A combination of diet and exercise is better than either alone, and those who exercise are more successful in maintaining weight loss.^{127, 144, 145} The best time for exercise is before meals or about 2 hours after eating. It is probably wise to take a day off at least once a week to give muscles and joints a rest.

Unfortunately one cannot burn up significant calories quickly; it takes 18 minutes of running to compensate for the average hamburger.¹⁴⁶

Activity	Calories per Hour
Sleeping	90
Office work	240
Walking	240
Golf	300
Housework	300
Bicycling	360
Swimming	360
Tennis	480
Bowling	510
Running slowly	750 (ca. 120/mile)
Cross country skiing	840
Running fast	960 (ca. 160/mile)

Most frustrating is the problem of some patients who limit caloric intake yet do not lose weight. In fact, as the weights of certain patients increase, the number of calories required to remain in equilibrium decreases, due to a combination of reduced activity and a change in metabolism, now known to be appropriate consequences of changes in leptin levels. The Vermont study demonstrated that the normal person with induced obesity requires 2700 calories to remain in equilibrium; spontaneously obese patients require only about 1300 calories.¹⁴⁷ Others argue that virtually everyone can lose weight on a diet of 1000 calories per day in that the maintenance requirement for a sedentary adult is about 1.5 times the resting metabolic rate (about 1000–1500 calories per day).¹⁴⁸ Nevertheless, an individual who has been overweight requires about 15% fewer calories to maintain weight than an individual who has never been obese.¹⁴⁹ The clinician must be careful to avoid a condemning or punitive attitude and understand that it is possible to significantly restrict caloric intake and not lose weight.

Patients appear doomed to frustration and despair unless the clinician can motivate them to increase physical activity. In all individuals, dieting is more effective when combined with physical exercise, but this is especially true in chronically obese patients. In other words, the lifestyle of an obese person must be changed to overcome the desire to be inactive (walk instead of riding). Only by significantly increasing caloric expenditure will the input-output equilibrium be disturbed.

The obese person feels trapped. Obesity leads to characteristic behavioral manifestations, including passive personality, frequent periods of depression, decreased self-respect, and a sense of being hopelessly overwhelmed by problems. But just as the endocrine and metabolic changes are secondary to obesity, many of the psychosocial attributes surrounding obesity are also secondary.¹⁵⁰

Maintenance of a newly gained lower weight requires constant preventive attention. Motivation to change and emotional support during the change are important. They can be provided by friends, relatives, clinicians, or self-help organizations. If the vicious circle of failed diets, resignation to fate, guilt, and shame can be broken, a more effective, happier person will emerge.

Thomas Wharton, in 1656, gave the thyroid gland its modern name (meaning oblong shield) because he believed the function of the thyroid was to fill vacant spaces and contribute to the shape and beauty of the neck, especially in women.¹ For unknown reasons, thyroid disease is more common in women than in men. Because most thyroid disease is autoimmune in nature, an increased susceptibility to autoimmune diseases, perhaps secondary to the female endocrine environment, is a likely contributing factor.

The clinical objective is to detect and treat thyroid disease before the symptoms and signs are significant and intense. Subtle thyroid disease is easily diagnosed by the sensitive laboratory assessments now available. Therefore, the key to early diagnosis is to maintain a high index of suspicion and to readily screen for the presence of abnormal thyroid function.

Normal Thyroid Physiology

Thyroid hormone synthesis depends in large part on an adequate supply of iodine in the diet. In the small intestine, iodine is absorbed as iodide that is then transported to the thyroid gland. Plasma iodide enters the thyroid under the influence of thyroid-stimulating hormone (TSH), the anterior pituitary thyrotropin hormone. Within the thyroid gland, iodide is oxidized to elemental iodine, which is then bound to tyrosine. Monoiodotyrosine and diiodotyrosine combine to form thyroxine (T_4) and triiodothyronine (T_3). These iodinated compounds are part of the thyroglobulin molecule, the colloid that serves as a storage depot for thyroid hormone. TSH induces a proteolytic process that results in the release of iodothyronines into the bloodstream as thyroid hormone.

Removal of one iodine from the phenolic ring of T_4 yields T_3 , while removal of an iodine from the nonphenolic ring yields reverse T_3 (RT_3) which is biologically inactive. In a normal adult, about one third of the T_4 secreted each day is converted in peripheral tissues, largely liver and kidney, to T_3 , and about 40% is converted to the inactive, reverse T_3 . About 80% of the T_3 generated is derived outside the thyroid gland, chiefly in the liver and kidney. T_3 is 3–5 times more potent than T_4 , and virtually all the biologic activity of T_4 can be attributed to the T_3 generated from it. Although T_4 is secreted at 20 times the rate of T_3 , it is T_3 that is responsible for most if not all the thyroid action in the body. T_3 is more potent than T_4 because the nuclear thyroid receptor has a ten-fold greater affinity for T_3 than T_4 . While T_4 may have some intrinsic activity of its own, it serves mainly as a prohormone of T_3 . It is hard to think of a body process or function that doesn't require thyroid hormone for its normal operation, not only metabolism but also development, steroidogenesis, and most specific tissue activities.

Carbohydrate calories appear to be the primary determinant of T_3 levels in adults. A reciprocal relationship exists between T_3 and RT_3 . Low T_3 and elevated RT_3 are seen in a variety of illnesses such as febrile diseases, burn injuries, malnutrition, and anorexia nervosa. The metabolic rate is determined to a large degree by the relative production of T_3 and RT_3 . During periods of stress, when a decrease in metabolic rate would conserve energy, the body produces more RT_3 and less T_3 , and metabolism slows. Upon recovery, this process reverses, and metabolic rate increases.

Circulating thyroid hormones are present in the circulation mainly bound to proteins. Approximately 70% of thyroid hormones are bound to thyroxine-binding globulin (TBG), which, therefore, is the major determining factor in the total thyroid hormone concentration in the circulation. The remaining 30% is bound to thyroxine-binding prealbumin and albumin. The binding proteins have a greater affinity for T_4 and thus allow T_3 to have greater entry into cells. TBG is synthesized in the liver, and this synthesis is increased by estrogens.

The nuclear receptor for thyroid hormone is a member of the super family that includes the steroid hormone receptors ([Chapter 2](#)).² The thyroid hormone receptor exists in several forms, the products of 2 genes located on different chromosomes. The a receptor is on chromosome 17, and the b receptor is on chromosome 3. The nuclear T_3 receptor is truly ubiquitous, indicating the widespread actions of thyroid hormone throughout the body. Mutations in the gene for the thyroid receptor lead to the synthesis of a receptor that actually antagonizes normal receptors, a syndrome of thyroid resistance characterized by elevated thyroid hormone levels. TSH is elevated as well because of the impairment in thyroid hormone action.

The thyroid axis is stimulated by the hypothalamic factor, thyrotropin-releasing hormone (TRH) and inhibited by somatostatin and dopamine. Thyroid hormones regulate TSH by suppressing TRH secretion, but primarily affecting the pituitary sensitivity to TRH (by reducing the number of TRH receptors). Pituitary secretion of TSH is very sensitive to changes in the circulating levels of thyroid hormone; a slight change in the circulating level of T_4 will produce a many-fold greater response in TSH. TSH-secreting cells are regulated by T_4 , but only after the T_4 is converted to T_3 in the pituitary cells. Although modulation of thyroid hormone occurs at the pituitary level, this function is permitted by the hypothalamic releasing hormone, TRH. Although some tissues depend mainly on the blood T_3 for their intracellular T_3 ,

the brain and the pituitary depend on their own intracellular conversion of T_4 . The measurement of T_4 and TSH, therefore, provides the most accurate assessment of thyroid function.

The TSH response to TRH is influenced mainly by the thyroid hormone concentration in the circulation; however, lesser effects are associated with dopamine agonists (inhibition), glucocorticoids (inhibition), and dopamine antagonists (stimulation). Estrogen increases the TRH receptor content of the pituitary; hence, the TSH response to TRH is greater in women than in men, and greater in women taking combined oral contraceptives.

TRH also stimulates prolactin secretion by the pituitary. The smallest doses of TRH that are capable of producing an increase in TSH, also increase prolactin levels, indicating a physiologic role for TRH in the control of prolactin secretion. However, except in hypothyroidism, normal physiologic changes as well as abnormal prolactin secretion can be understood in terms of dopaminergic inhibitory control, and TRH need not be considered.

Functional Changes With Aging

Thyroxine metabolism and clearance decrease in older people, and thyroxine secretion decreases in compensation to maintain normal serum thyroxine concentrations.³ With aging, conversion of T_4 to T_3 decreases, and TSH levels increase. The TSH response to TRH is normal in older women. TBG concentrations decrease slightly in postmenopausal women but not enough to alter measurements in serum.

Thyroid Function Tests

Free Thyroxine (FT_4)

Assays that measure free T_4 are usually displacement assays using an antibody to T_4 . The result is not affected by changes in TBG and binding. The free T_4 level has a different range of normal values from laboratory to laboratory.

Total Thyroxine (TT_4)

The total thyroxine, both the bound portion to TBG and the free unbound portion, is measured by displacement assays, and in the absence of hormone therapy or other illnesses, estimates the thyroxine concentration in the blood. However, the free T_4 is unaffected by factors that influence TBG and is preferred.

Free Thyroxine Index (FTI or T_7)

The free thyroxine index is calculated from the TT_4 and the T_3 resin uptake measurements. This test too has been replaced by the free T_4 assay.

Total T_3 and Reverse T_3

Both of these thyronines can be measured by sensitive immunoassays. However, in most clinical circumstances they add little to what is learned by the free T_4 and TSH measurements. The clinical situations where measurement will be useful will be discussed under the specific diseases and indicated on the algorithm.

Thyroid-Stimulating Hormone (TSH)

TSH is measured by highly sensitive assays utilizing monoclonal antibodies, usually in a technique that uses two antibodies, one directed at the α -subunit and one directed at the β -subunit of TSH. The normal levels vary from laboratory to laboratory, but the sensitive TSH assay can detect concentrations as low as 0.01 μ U/L. TSH is a very sensitive indicator of thyroid hormone action at the tissue level because it is dependent upon the pituitary exposure to T_4 . In the absence of hypothalamic or pituitary disease, the sensitive TSH assays will provide the best indication of excess or deficient thyroxine; slight changes in T_4 are reflected in a many-fold greater response in TSH. Nearly all women with elevated TSH levels have hypothyroidism. Transient changes in TSH can be caused by systemic illnesses, major psychiatric disturbances, and pharmacologic treatment with glucocorticoid agents or dopamine.

Radioactive Iodine Uptake

Because the thyroid gland is the only tissue that utilizes iodine, radioisotopes of iodine can be used as a measure of thyroid gland activity and to localize activity within the gland.

The Laboratory Evaluation. The algorithm represents a cost-effective and accurate clinical strategy.⁴ For screening purposes, or when there is a relatively low clinical suspicion of thyroid disease, the initial step is to measure the TSH by a sensitive assay. A normal TSH essentially excludes hypothyroidism or hyperthyroidism. A high TSH requires the measurement of free T_4 to confirm the diagnosis of hypothyroidism.

If the initial TSH is low, especially less than 0.08 μ U/mL, then measurement of a high T_4 will confirm the diagnosis of hyperthyroidism. If the T_4 is normal, the T_3 level is measured, since some patients with hyperthyroidism will have predominantly T_3 toxicosis. If the T_3 is normal, it implies that thyroxine secretion is autonomous from TSH, and this is called subclinical hyperthyroidism. Some of these patients will eventually have increased T_4 or T_3 levels with true hyperthyroidism.

Hypothyroidism

In most cases of hypothyroidism, a specific cause is not apparent. It is believed that the hypothyroidism is usually secondary to an autoimmune reaction, and when goiter formation is present, it is called Hashimoto's thyroiditis.⁵ Unless abnormal thyroid function can be documented by specific laboratory assessment, empiric treatment with thyroid hormone is not indicated, and it is especially worth emphasizing that thyroid hormone treatment does not help infertility in euthyroid women. It is uncertain whether hypothyroidism can be a cause of recurrent miscarriages, but an assessment of thyroid function is worthwhile in these patients.

Hypothyroidism increases with aging and is more common in women.⁶ Up to 45% of thyroid glands from women over age 60 show evidence of thyroiditis.⁷ The incidence of antithyroglobulin antibodies is 7.4% in women over age 75 years, while 16.9% of women age 60 and 17.4% of women over age 75 have elevated TSH levels. In women admitted to geriatric wards, 2–4% have clinically apparent hypothyroidism. **Therefore, hypothyroidism is frequent enough to warrant consideration in most older women, justifying screening even in asymptomatic older women. We recommend that older women be screened with the highly sensitive TSH assay every 5 years beginning at age 35, then every 2 years beginning at age 60, or with the appearance of any symptoms suggesting hypothyroidism.**⁸

Menstrual irregularities and bleeding problems are common in hypothyroid women. Amenorrhea can be a consequence of hypothyroidism, either with TRH-induced increases in prolactin or with normal prolactin levels. Other clinical manifestations of hypothyroidism include constipation, cold intolerance, psychomotor retardation, carpal tunnel syndrome, and decreased exercise tolerance. However, patients often appear asymptomatic. Close evaluation can reveal mental slowness, decreased energy, fatigue, poor memory, somnolence, slow speech, a low-pitched voice, water retention, periorbital edema, delayed reflexes, or a low body temperature and bradycardia. Hypothyroidism can cause hypertension, cognitive abnormalities, pericardial effusion, asymmetric septal myocardial hypertrophy, myopathy, neuropathy, ataxia, anemia, elevated cholesterol and LDL-cholesterol, or hyponatremia. Myxedematous infiltration can produce enlarged, cystic ovaries.⁹ The increase in cholesterol is due to impaired LDL-cholesterol clearance secondary to a decrease in cell membrane LDL receptors. The mechanism for this LDL effect is attributed to a thyroid response element in the LDL receptor gene.¹⁰

Serum enzymes may be elevated because of decreased clearance, including creatine phosphokinase (CPK), aspartate aminotransferase (AST,SGOT), alanine aminotransferase (ALT, SGPT), lactic dehydrogenase (LDH), and alkaline phosphatase, triggering a fruitless search for other organ disease. It is worth screening for hypothyroidism in any women with abnormal menses or with complaints of fatigue and depression. In addition, patients should be screened who have elevated levels of cholesterol and LDL-cholesterol.

Diagnosis of Hypothyroidism

With primary thyroid failure, the circulating thyroid hormone levels fall, stimulating the pituitary to increase TSH output. Elevated TSH and low T_4 confirm the diagnosis. Hypothyroidism can occur due to pituitary failure in which case the TSH will be inappropriately low for the T_4 . The most common cause will be autoimmune thyroid disease (elevated titers of antithyroid antibodies) in areas with normal iodine intake. However, making an etiologic diagnosis in women adds little to the clinical management.

Subclinical Hypothyroidism

In early hypothyroidism, with undetectable symptoms or signs, a compensated state can be detected by an elevated TSH (usually 5–20 $\mu\text{U/L}$) and normal T_4 (called subclinical hypothyroidism). Many of these patients (but not all) will eventually become clinically hypothyroid with low T_4 concentrations. A good reason to treat subclinical hypothyroidism is to avoid the development of a goiter. Furthermore, some patients in retrospect (after treatment) recognize improved physical and mental well-being. Patients with subclinical hypothyroidism have alterations in energy metabolism in skeletal muscle.¹¹ An improvement in impaired cognitive function and emotional behavior has been documented with thyroxine treatment of subclinical hypothyroidism.¹² In those patients who are asymptomatic, it is worth measuring antithyroid antibodies. A positive test identifies those who are likely to become clinically hypothyroid, at a rate of approximately 20% per year. With only very slight elevations of TSH (less than 10 $\mu\text{U/L}$), it is reasonable not to treat and to check thyroid function every 6 months to detect further deterioration. Patients with an abnormal cholesterol-lipoprotein profile can show improvement with thyroxine treatment, usually within one month of therapy.¹³

Treatment of Hypothyroidism

Initial therapy is straightforward with synthetic thyroxine, T_4 , given daily. Mixtures of T_4 and T_3 , such as desiccated thyroid, provide T_3 in excess of normal thyroid secretion. It is better to provide T_4 and allow the peripheral conversion process to provide the T_3 .^{14, 15} "Natural" thyroid preparations are not better, and in fact are potentially detrimental. Patients taking biological preparations should be switched to synthetic thyroxine. Because of a risk of coronary heart disease in older women, the initial dose should be 25–50 μg per day for 4 weeks, at which time the dose is increased by 25 μg daily every 4 weeks according to the clinical and biochemical assessment. Usually the dose required will be close to 1.5 $\mu\text{g/lb}$ body weight, but it may be less in very old women.¹⁶ The average final dose required in the elderly is approximately 70% of that in younger patients. **Patients who have been on thyroid hormone for a long time may have their medication discontinued. Recovery of the hypothalamic-pituitary axis usually requires 6–8 weeks at which time the TSH and free T_4 levels can be measured.**

Evaluation of Therapy

When the patient appears clinically euthyroid, evaluation of TSH levels will provide the most accurate assessment of the adequacy of thyroid hormone replacement. A patient being treated with thyroid hormone should be evaluated once every year with the sensitive TSH assay. Thyroid hormone requirements tend to decrease with age. If the sensitive TSH assay is low, then the free T_4 should be measured to help adjust the thyroxine dose.¹⁷ **The full response of TSH to changes in T_4 is relatively slow; a minimum of 6–8 weeks is necessary between changes in dosage and assessment of TSH.**

Hyperthyroidism

The two primary causes of hyperthyroidism are Graves' disease (toxic diffuse goiter) and Plummer's disease (toxic nodular goiter).¹⁸ Plummer's disease is usually encountered in postmenopausal women who have had a long history of goiter. Twenty percent of hyperthyroid patients are over 60, and 25% of older women with hyperthyroidism present with an apathetic or atypical syndrome.

Graves' disease is characterized by the triad of hyperthyroidism, exophthalmos, and pretibial myxedema and is believed to be caused by autoantibodies that have TSH properties and, therefore, bind to and activate the TSH receptor. Menstrual changes associated with hyperthyroidism are unpredictable, ranging from amenorrhea to oligomenorrhea to normal cycles (hence, the amenorrhea in a thyrotoxic woman can be due to pregnancy).

The classic symptoms of thyrotoxicosis are nervousness, heat intolerance, weight loss, sweating, palpitations, and diarrhea. These symptoms are associated with typical findings on physical examination: proptosis, lid lag, tachycardia, tremor, warm and moist skin, and goiter. Women in the reproductive years usually present with the classic picture. In postmenopausal women, symptoms are often concentrated in a single organ system, especially the cardiovascular or central nervous system. Goiter is absent in 40%. Sinus tachycardia occurs in less than half, but atrial fibrillation occurs in 40% and is resistant to cardioversion or spontaneous reversion to sinus rhythm. In old women, there is often a coexistent disease, such as an infection or coronary heart disease that dominates the clinical picture.

The triad of weight loss, constipation, and loss of appetite, suggesting gastrointestinal malignancy, occurs in about 15% of older patients with hyperthyroidism. Ophthalmopathy is rare in older patients. Hyperthyroidism in older women is sometimes described as "apathetic hyperthyroidism" because the clinical manifestations are different. The clinician should consider the diagnosis in older patients with "failure to thrive," in patients who are progressively deteriorating for unexplained

reasons, and in patients with heart disease, unexplained weight loss, and mental or psychologic changes.

Psychologic changes are not unusual in hyperthyroid women. Women who complain of emotional lability and nervousness should be screened for hyperthyroidism.

Diagnosis of Hyperthyroidism

The diagnosis of hyperthyroidism requires laboratory testing. A suppressed TSH with a high T_4 or a high T_3 confirms the diagnosis. Hyperthyroidism caused by high levels of T_3 is more common in older women. Most patients should have a radioactive iodine thyroid uptake and scan after laboratory confirmation of the diagnosis. If the uptake is suppressed then drug therapy is indicated. The scan will indicate whether the patient has a diffuse toxic goiter, a solitary hot nodule, or a hot nodule in a multinodular gland. Toxic multinodular goiters occur more frequently in the elderly. TSH hypersecretion as a cause of hyperthyroidism is extremely rare; the combination of a normal or elevated TSH and elevated thyroid hormone will be the clue to this possibility.

Subclinical Hyperthyroidism

By definition, patients with subclinical hyperthyroidism have normal T_4 and T_3 levels, but subnormal concentrations of TSH. TSH levels can be suppressed to 0.1–0.5 $\mu\text{U/L}$ by general illnesses and drugs such as glucocorticoids, dopamine, and anticonvulsants; however, this suppression does not extend below 0.1 $\mu\text{U/L}$. Values below 0.1 $\mu\text{U/L}$ are regarded as nondetectable, and patients with overt hyperthyroidism usually have undetectable TSH. Subclinical hyperthyroidism is half as common in older people as subclinical hypothyroidism (excluding the most common cause, treatment with excessive doses of thyroxine). Keep in mind that the dose of thyroxine required to treat hypothyroidism declines with age (because of the decrease in metabolic clearance with age); all patients being treated with thyroid hormone should have their TSH levels assessed every year. Atrial fibrillation is a common cardiovascular problem associated with subclinical hyperthyroidism.¹⁹ If subclinical hyperthyroidism persists, it should be treated, especially in postmenopausal women, because of the cardiac complications and the loss of bone associated with excess thyroid hormone. TSH levels that are low but not undetectable (0.1–5.0 $\mu\text{U/L}$) need not be treated, but TSH measurement is warranted every 6 months. Progression to overt hyperthyroidism is uncommon.

Treatment of Hyperthyroidism

There are multiple objectives of therapy: control of thyroid hormone effects on peripheral tissues by pharmacologic blockade of beta-adrenergic receptors, inhibition of thyroid gland secretion and release of thyroid hormone, and specific treatment of nonthyroidal systemic illnesses which can exacerbate hyperthyroidism or be adversely affected by hyperthyroidism.²⁰ Antithyroid drugs are usually administered first to achieve euthyroidism, then definitive therapy is accomplished by radioactive iodine treatment. Of course, it is important to make sure a woman is not pregnant before treatment with radioactive iodine, and pregnancy should be postponed for several months after treatment. Monitoring treatment response requires a full 8-week interval for stabilization of the hypothalamic-pituitary-thyroid system.

Antithyroid Drugs

The drug of choice in most circumstances will be methimazole because it has fewer adverse effects. The drug inhibits organification of iodide and decreases production of T_4 and T_3 . The oral dose is 10–20 mg daily. The onset of effect takes 2–4 weeks. Remember that the half-life of thyroxine is about one week, and the gland usually has large stores of T_4 . Maximal effect occurs at 4–8 weeks. The dose can be titrated down once the disease is controlled to a maintenance dose of 5–10 mg daily. The major side effects are rash, gastrointestinal symptoms, and agranulocytosis (an idiosyncratic reaction). Propranolol and other beta-blockers are effective in rapidly controlling the effects of thyroid hormone on peripheral tissues. The dose is usually 20–40 mg, every 12 hours, orally, and the dose is titrated to maintain a heart rate of about 100 beats/minute. The drug may cause bronchospasm, worsening congestive heart failure, fatigue, and depression. Rarely inorganic iodine will be needed to block release of hormone from the gland. Lugol's solution, 2 drops in water daily, is sufficient. The onset of effect is 1–2 days, with maximal effect in 3–7 days. There may be an escape from protection in 2–6 weeks, and the drug can cause rash, fever, and parotitis. Iodine precludes radioiodine administration for several months.

After the symptoms are controlled, and the patient is euthyroid, a dose of radioactive iodine can be selected, the thiouracil withheld temporarily, and definitive therapy accomplished. Patients with solitary nodules will be treated in the same fashion. Some patients with hot nodules in multinodular glands will require surgery because of the size of the gland and because the hyperthyroidism tends to recur in new nodules after the ablation of the original hot nodule. This can result in repetitive treatments with substantial doses of radioactive iodine, and surgery may be preferable. All patients definitively treated for hyperthyroidism must be monitored for the onset of hypothyroidism.

Osteoporosis and Excessive Thyroxine

Because postmenopausal women are at increased risk for osteoporosis, and frequently develop hyperthyroidism or receive levothyroxine treatment for hypothyroidism, the clinician needs to understand how thyroid hormone affects bones.²¹ Thyroid hormone excess alters bone integrity via direct effects on bone and gut absorption and indirectly through the effects of vitamin D, calcitonin, and parathyroid hormone.

Thyroid hormone increases bone mineral resorption. In addition, total and ionized calcium increase in hyperthyroid women, leading to increases in serum phosphorous, alkaline phosphatase, and bone Gla protein (osteocalcin), a marker of bone turnover. Parathyroid hormone decreases in response to the increased serum calcium, and this results in decreased hydroxylation of vitamin D. Intestinal calcium and phosphate absorption decrease, while urinary hydroxyproline and calcium excretion increase. The net effect is increased bone resorption and a subsequent decrease in bone density — osteoporosis.²²

These effects become more clinically important in prolonged exposure to excessive thyroid hormone.²³ Women who have had hyperthyroidism experience postmenopausal fractures earlier than usual.²⁴

The major concern is that mild chronic excess thyroid hormone replacement, especially in postmenopausal women, might increase the risk of osteoporosis, and indeed this subsequently was documented.²⁵ Bone density has been found to be reduced (9%) in premenopausal women receiving enough thyroxine to suppress TSH for 10 years or more.²⁶ A meta-analysis of the literature on this subject concluded that premenopausal women treated for long durations did not suffer a clinically significant loss of bone (probably because of the protective presence of estrogen); however, postmenopausal women lose an excess of bone if thyroid treatment results in TSH levels below the normal range.²⁷

Thus, exposure to excessive thyroxine must be added to the risk factors for osteoporosis. It makes sense to monitor patients (both premenopausal women and especially postmenopausal women) receiving thyroxine with the sensitive TSH assay to ensure that levothyroxine doses are “physiologic.” Some patients who require TSH suppressive doses of thyroxine, such as patients with nodules, goiters, and cancer, must be considered at increased risk of osteoporosis. It would be wise to assess bone density in women on long-term thyroid treatment and in women receiving high-dose thyroxine suppression of TSH. The use of hormone therapy, exercise programs, and possibly biphosphate treatment must be seriously considered for these patients. In a cross-sectional study of elderly women, the bone loss associated with long-term thyroid treatment was avoided in those women also taking estrogen.²⁸

Thyroid Nodules

The major concern with thyroid nodules is the potential for thyroid cancer.²⁹ Single nodules are 4 times more common in women, and carcinoma of the thyroid is nearly 3 times more common in women than in men. The incidence rises steadily from the age of 55. Mortality from thyroid cancer occurs predominantly in the middle-aged and the elderly. There are 4 major types of primary thyroid carcinoma: papillary, follicular, anaplastic, and medullary. In solitary nodules that are “cold” (those that do not take up radioactive iodine or pertechnetate on thyroid scan), 12% prove to be malignant. This also means that the majority are benign. Surgical excision of nodules can result in vocal cord paralysis, hypoparathyroidism, and other complications. Therefore, the goal is to select patients for curative surgery who have the greatest likelihood of having cancer in the nodule.

Epidemiologic and Clinical Data

The major risk factors for thyroid cancer are family history of this disease and a history of irradiation to head or neck. In those who have received thyroid irradiation, about one-third will have thyroid abnormalities, and about one-third of those with abnormalities will have thyroid cancer (about 10% overall). The carcinogenic risk has been estimated to be 1% per 100 rads in 20 years. A rapidly growing nodule, a hard nodule, the presence of palpable regional lymph nodes, or vocal cord paralysis greatly increase the probability of thyroid cancer.

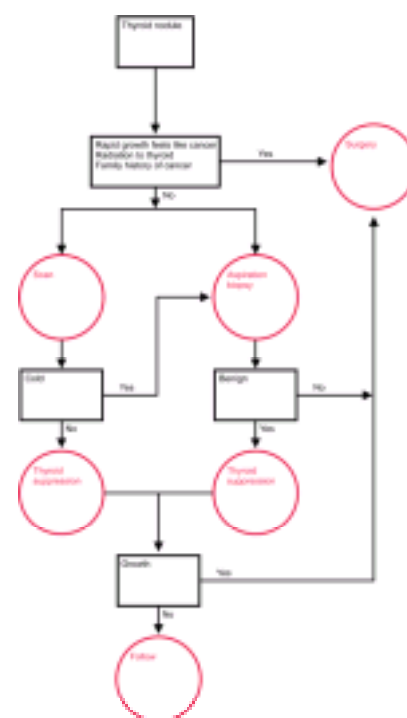

Thyroid nodules in multinodular thyroid glands, not previously exposed to thyroid irradiation, have no greater risk of thyroid carcinoma than normal glands. Therefore, predominant thyroid nodules in multinodular glands should be followed and, if a nodule grows, then biopsy or surgery should be considered.

Diagnostic Strategy

In patients with a thyroid nodule, laboratory assessment of thyroid function is essential. When abnormal thyroid function is present, the nodule is almost always benign. Detection of a thyroid nodule is followed by clinical characterization of the nodule, examination of the lymph nodes, and inquiry regarding rapid growth, family history, and history of thyroid irradiation. In the presence of any of these findings, surgery is recommended for excision of the nodule. If none of these is present, proceed directly to fine needle aspiration biopsy or thyroid scan.

If a scan is chosen, hot nodules are evaluated independently. Cold nodules require a surgical diagnosis. If the patient prefers, one can treat with suppressive doses of levothyroxine and evaluate over time. Unfortunately, many of these thyroid nodules do not regress with thyroid treatment, but it is very reassuring if they do. Growth or lack of disappearance with thyroid suppression is an indication for fine needle aspiration biopsy. Thyroid ultrasound can be utilized to more accurately establish size for comparison over time.

Although accounting for only 5% of thyroid cancers, medullary carcinoma is associated with early spread and poor survival rates. Medullary carcinoma of the thyroid is unique in having the serum calcitonin as a very sensitive and specific tumor marker. Measuring the serum calcitonin is recommended for older patients with solitary nodules in order to achieve earlier diagnosis of medullary carcinoma. ³⁰

Fine-Needle Aspiration

Fine-needle aspiration biopsy has a 83% sensitivity and 92% specificity in diagnosing thyroid malignancy. ³¹ When “indeterminate” by biopsy, about one-third prove to be malignant at thyroidectomy. If the fine-needle aspiration biopsy reveals suspicious cells or is indeterminate, a subtotal thyroidectomy should be performed for diagnosis and treatment. If the aspiration biopsy is benign some would repeat the biopsy in one year to avoid false negatives. Most would provide thyroid hormone suppressive therapy (aiming for a TSH level below 0.1 $\mu\text{U/L}$) for one year with close observation for growth of the nodule. ³² Growth or lack of disappearance indicates the need for biopsy or surgery. If the nodule shrinks during suppression, after one year a choice is made between no treatment or maintenance of the TSH level at the lower end of normal. In some cases, especially in older women, nodules can be followed with no therapy and little risk. If the nodule increases in size, suppressive therapy is recommended. One of the reasons many are treated with levothyroxine is because of the known growth-promoting effects of TSH in carcinoma of the thyroid and the hope that TSH suppression will inhibit the growth of early carcinoma.

The method for fine-needle aspiration biopsy requires no anesthetic. Using sterile technique and a 23-gauge needle on a 10 mL syringe, the nodule is fixed with two fingers of one hand and the needle entered. Aspiration is performed with the syringe while several passes are made through a vertical distance of about 2 mm in the nodule. Suction is stopped when biopsy material becomes visible in the hub of the needle. The contents of the needle should be expelled onto a slide and fixed for pathology. Gentle pressure is applied over the nodule for 10 minutes. Occasionally, a patient will have some bleeding into the nodule or surrounding tissues, but it is usually self-limiting.

The Thyroid Gland and Pregnancy

In response to the metabolic demands of pregnancy, there is an increase in the basal metabolic rate (which is mainly due to fetal metabolism), iodine uptake, and the size of the thyroid gland caused by hyperplasia and increased vascularity. ³³ However, a pregnant woman is euthyroid with normal levels of TSH, free T_4 , and free T_3 ; thyroid nodules and goiter require evaluation. During pregnancy, iodide clearance by the kidney increases. For this reason (plus the iodide losses to the fetus), the prevalence of goiter is increased in areas of iodine deficiency. ³⁴ This is not a problem in the U.S., and any goiter should be regarded as pathologic. In many parts of the world, iodine is not sufficiently available in the environment, and pregnancy increases the risk of iodine deficiency.

The increase in thyroid activity in pregnancy is compensated by an marked increase in the circulating levels of TBG in response to estrogen; therefore, a new

equilibrium is reached with an increase in the bound portion of the thyroid hormone. The mechanism for the estrogen effect on TBG is an increase in hepatic synthesis and an increase in glycosylation of the TBG molecule that leads to decreased clearance.

The increase in thyroid activity is attributed to the thyrotropic substances secreted by the placenta: a chorionic thyrotropin and the thyrotropic activity in human chorionic gonadotropin (HCG).³⁵ It has been calculated that HCG contains approximately 1/4000th of the thyrotropic activity of human TSH. In conditions with very elevated HCG levels, the thyrotropic activity can be sufficient to produce hyperthyroidism, and this can even be encountered in normal pregnancy.³⁶

TBG levels reach a peak (twice nonpregnant levels) at about 15 weeks, which is maintained throughout the rest of pregnancy.³⁷ T_4 undergoes a similar change, but T_3 increases more markedly. Because of the increase in TBG, free T_4 and T_3 levels actually decrease, although they remain within the normal range.³⁸ There is an inverse relationship between maternal circulation levels of TSH and HCG.³⁷ TSH reaches a nadir at the same time that HCG reaches a peak at 10 weeks of pregnancy. TSH levels then increase as HCG levels drop to their stable levels throughout the rest of pregnancy. These changes support a role for HCG stimulation of the maternal thyroid gland during early pregnancy.^{37,39,40} It is well recognized that patients who have conditions associated with very high levels of HCG (trophoblastic disease, HCG-secreting cancers) can develop hyperthyroidism. The thyroid-stimulating activity of HCG is explained by the molecular homology between HCG and TSH, and between their receptors.

In normal pregnancies, placental transfer of TSH, T_4 , and T_3 is severely limited in both directions. Indeed, the placenta is essentially impermeable to these substances no matter whether the fetus is euthyroid or hypothyroid. Slight transfer of T_4 and T_3 can occur, however, when maternal levels are very high or when fetal levels are substantially lower than the maternal levels.

The majority of patients with hyperemesis gravidarum have laboratory values consistent with hyperthyroidism, and the severity of the hyperemesis correlates with the degree of hyperthyroidism.^{41,42} These patients have higher levels of HCG, and the transient hyperthyroidism and severity of the hyperemesis may be mediated by the thyrotropic and steroidogenic activity of the HCG. These clinical manifestations in normal pregnancies may be linked to a specific subpopulation of HCG molecules with greater thyrotropic bioactivity (because highly purified, standard HCG has only trivial TSH-like activity).⁴³ Specifically, HCG with reduced sialic acid content is increased in pregnant patients with hyperemesis and hyperthyroidism.⁴⁴

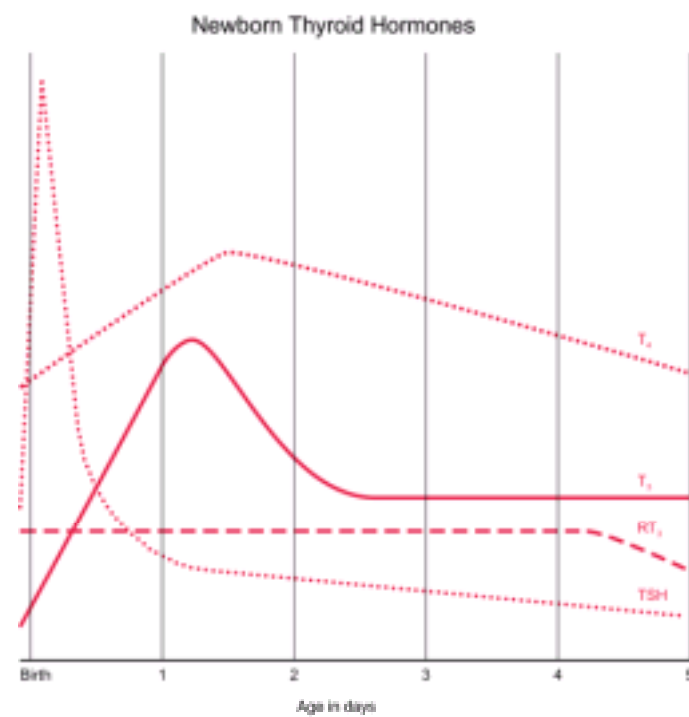

Thyroid Physiology in the Fetus and the Neonate

The human fetal thyroid gland develops the capacity to concentrate iodine and synthesize hormone between 8 and 10 weeks of gestation, the same time that the pituitary begins to synthesize TSH.^{45,46} Some thyroid development and hormone synthesis are possible in the absence of the pituitary gland, but optimal function requires TSH. By 12–14 weeks, development of the pituitary-thyroid system is complete. Function is minimal, however, until an abrupt increase in fetal TSH occurs at 20 weeks. As with gonadotropin and other pituitary hormone secretion, this thyroid function correlates with the maturation of the hypothalamus and the development of the pituitary portal vascular system, which makes releasing hormone available to the pituitary gland.

Fetal TSH increases and reaches a plateau at 28 weeks and remains at relatively high levels to term. The free T_4 concentration increases progressively. At term, fetal T_4 levels exceed maternal levels. Thus, a state of fetal thyroidal hyperactivity exists near term.

The major thyroid hormone secreted by the fetus is T_4 . However, total T_3 and free T_3 levels are low throughout gestation, and levels of RT_3 are elevated, paralleling the rise in T_4 . Like T_3 , this compound is derived predominantly from conversion of T_4 in peripheral tissues. The increased production of T_4 in fetal life is compensated by rapid conversion to the inactive RT_3 , allowing the fetus to conserve its fuel resources.

With delivery, the newborn moves from a state of relative T_3 deficiency to a state of T_3 thyrotoxicosis. Shortly after birth serum TSH concentrations increase rapidly to a peak at 30 minutes of age. They fall to baseline values by 48–72 hours. In response to this increase in TSH, total T_4 and free T_4 increase to peak values by 24–48 hours of age. T_3 levels increase even more, peaking by 24 hours of age. By 3–4 weeks, the thyrotoxicosis has disappeared.

The postnatal surge in TSH is accompanied by a prolactin surge, suggesting that both are increased in response to TRH. The TRH surge is thought to be a response to rapid neonatal cooling. A puzzle is the fact that the early increase in T_3 is independent of TSH and is tied in some way to cutting of the umbilical cord. Delaying cord cutting delays the increase in T_3 , but TSH levels still reach their peak at 30 minutes. In some way cord cutting augments peripheral (largely liver) conversion of T_4 to T_3 . The later increases in T_3 and T_4 (after 2 hours) are due to increased thyroid gland activity. These thyroid changes after birth probably represent defense mechanisms against the sudden entry into the cold world. The high RT_3 levels during pregnancy continue during the first 3–5 days of life, and then fall gradually to normal levels by 2 weeks.

Summary of Fetal and Newborn Thyroid Changes

1. TSH and T_4 appear in the fetus at 10–13 weeks. Levels are low until an abrupt rise at 20 weeks.
2. T_4 rises rapidly and exceeds maternal values at term.
3. T_3 levels rise, but concentrations are relatively low, similar to hypothyroid adults.
4. RT_3 levels exceed normal adult levels.
5. The fetal pattern of low T_3 and high RT_3 is similar to that seen with calorie malnutrition.
6. After delivery, TSH peaks at 30 minutes of age, followed by a T_3 peak at 24 hours and a T_4 peak at 24–48 hours. The T_3 increase is independent of the TSH change.
7. High RT_3 levels persist for 3–5 days after delivery, then reach normal values by 2 weeks.

Newborn Screening for Hypothyroidism

The incidence of neonatal hypothyroidism is about one in 4000 live births, and newborn screening programs exist in most of the world. The problem is that congenital hypothyroidism is not clinically apparent at birth. Fortunately, infants with congenital hypothyroidism have low T_4 and high TSH concentrations easily detected in blood, and early treatment before 3 months of age is usually associated with normal mental development.⁴⁷ Less than normal development can be a consequence of a delay in treatment or extremely low thyroid hormone production in the fetus.

There is a familial tendency for hypothyroidism, and if the diagnosis is made in the antepartum period, intra-amniotic injections of thyroxine can raise fetal levels of thyroid hormone.⁴⁸ Ultrasonographic examination of patients with polyhydramnios should include a search for a fetal goiter. In addition, the fetus should be monitored for goiter formation in women treated with antithyroid drugs for hyperthyroidism during pregnancy. Amniotic fluid iodothyronines and TSH reflect fetal plasma levels, and abnormal values may allow prenatal diagnosis of fetal hypothyroidism by amniocentesis.^{48,49} However, fetal cord blood sampling is advocated for accurate diagnosis.⁵⁰ Treatment of fetal hypothyroidism is important because there is a concern that prenatal hypothyroidism can affect some aspects of development; e.g., the full function of physical skills. Although transfer of thyroid hormone from mother to fetus is limited, even a small amount provides protection, especially to the brain, for a fetus with hypothyroidism.

Hyperthyroidism in Pregnancy

Untreated thyrotoxicosis in pregnancy is associated with a higher risk of preeclampsia, heart failure, intrauterine growth retardation, and stillbirth.⁵¹ Heart failure is a consequence of the demands of pregnancy superimposed upon the hyperdynamic cardiovascular state induced by the increased thyroid hormone.⁵²

The most common cause of thyrotoxicosis in pregnancy is Graves' disease. However, the clinician should always keep in mind that trophoblastic disease can cause hyperthyroidism due to the TSH property inherent in human chorionic gonadotropin. The maternal changes with pregnancy can make diagnosis difficult. Tachycardia upon awakening from sleep and a failure to gain weight should make a clinician suspicious. Hyperemesis gravidarum is a common presentation of hyperthyroidism in pregnancy. Laboratory assessment is unaffected by pregnancy and should follow our algorithm.

The choice of treatment is between surgery and antithyroid drugs. However prior to surgery, the thyroid gland has to be controlled with medical therapy. Most women can be successfully treated with thioamide drugs.⁵¹ Propylthiouracil and methimazole are equally safe and effective for pregnant women; however, propylthiouracil is preferred in breastfeeding patients because it is less concentrated in breast milk.⁵³

The aim of treatment should be to maintain mild hyperthyroidism in the mother to avoid thyroid dysfunction in the fetus. Treatment of maternal hyperthyroidism with propylthiouracil, even with moderate doses of 100–200 mg daily, suppresses T_4 and increases TSH levels in newborns.⁵⁴ The infants are clinically euthyroid, however, and their laboratory measurements are normal by the 4th to 5th day of life. In addition, follow-up assessment has indicated unimpaired intellectual development in children whose mothers received propylthiouracil during pregnancy.⁵⁵ Nevertheless, pregnant women with thyrotoxicosis should be treated with as low a dose of antithyroid drugs as possible. With proper antithyroid drug treatment, very few, if any, deleterious effects are experienced by mother, fetus, or neonate.⁵⁶ Although small amounts of antithyroid drugs are transmitted in breast milk, the amount has no impact on neonatal thyroid function, and breastfeeding should be encouraged. Poor control of maternal hyperthyroidism is associated with increased risks of preeclampsia and low-birth-weight infants.⁵⁷

Maternal TSH-like autoantibodies can cross the placenta and cause fetal thyrotoxicosis and demise. Some have advocated fetal cord blood sampling in women with Graves' disease who are euthyroid but who have positive titers of TSH-like antibodies to assess the fetal thyroid status.⁵⁸ The fetus can be treated by treating the mother. Neonates have to be observed closely until antithyroid drugs are cleared (a few days) and the true thyroid state can be assessed.

Thyroid Storm

This life-threatening augmentation of thyrotoxicosis is usually precipitated by stress such as labor, cesarean section, or infection. Stress should be limited as much as possible in patients with uncontrolled thyrotoxicosis.

Hypothyroidism in Pregnancy

Serious hypothyroidism is rarely encountered during pregnancy. Patients with this degree of illness probably do not get pregnant. Patients with mild hypothyroidism probably never have a laboratory assessment for thyroid function during pregnancy and go undetected. Preeclampsia, intrauterine growth retardation, and fetal distress are more frequent in women with significant hypothyroidism.^{59, 60 and 61} There is also reason to believe that patients with hypothyroidism have an increased rate of spontaneous abortion.⁶² The mechanism may be impaired ability of important organs such as the endometrium and the corpus luteum. Women being treated for hypothyroidism require an increase (20–50%) in thyroxine during pregnancy.^{63, 64} **TSH should be monitored monthly in the first trimester and again in the postpartum period, and dosage should be adjusted to keep the TSH level in the normal range.**

Postpartum Thyroiditis

Autoimmune thyroid disease is suppressed to some degree by the immunologic changes of pregnancy. Thus, there is a relatively high incidence of postpartum thyroiditis (5–10%), usually 3–6 months after delivery, manifested by either hyperthyroidism or hypothyroidism, although commonly transient hyperthyroidism is followed by hypothyroidism.⁶⁵ This condition is due to a destructive thyroiditis associated with thyroid microsomal autoantibodies.⁶⁶ Women at high risk for postpartum thyroiditis are those with a personal or family history of autoimmune disease, and those with a previous postpartum episode. Women with insulin-requiring diabetes mellitus are at particularly high risk.⁶⁷

Most importantly, the symptoms in these women are often attributed to anxiety or depression, and the obstetrician must have a high index of suspicion for hypothyroidism. The symptoms usually last 1–3 months, and almost all women return to normal thyroid function. Postpartum thyroiditis tends to recur with subsequent pregnancies, and eventually hypothyroidism remains.⁶⁸ The symptoms of hyperthyroidism in this condition are not responsive to antithyroid medication, and patients are usually not treated or given beta-adrenergic blocking agents (e.g., propranolol in a dose sufficient to reduce the resting pulse to less than 100 per minute). Because spontaneous remission is common, patients who are treated with hypothyroidism should be reassessed one year after gradual withdrawal of thyroxine. Patients who return to normal should undergo periodic laboratory surveillance of their thyroid status.

As societies become more affluent, fertility decreases. This decrease is in response to the use of contraception and abortion. During her reproductive lifespan, the average Kung woman, a member of an African tribe of hunter-gatherers, experienced 15 years of lactational amenorrhea, 4 years of pregnancy, and only 48 menstrual cycles.¹ In contrast, a modern urban woman will experience 420 menstrual cycles. Contemporary women undergo earlier menarche and start having sexual intercourse earlier in their lives than in the past. Even though breastfeeding has increased in recent years, its duration is relatively brief, and its contribution to contraception in the developed world is trivial. Therefore, it is more difficult today to limit the size of a family unless some method of contraception is utilized.

More young women (under age 25) in the United States become pregnant than do their contemporaries in other Western countries.^{2,3} The teenage pregnancy rates in 5 northern European countries and Canada range from 13 to 53% of the U.S. rate. The differences disappear almost completely after age 25. This is largely because American men and women after age 25 utilize surgical sterilization at a great rate.

It is not true that young American women want to have these higher pregnancy rates. About 78% of all pregnancies among American teenagers are unintended.⁴ American teenagers abort nearly half of their pregnancies, and this proportion is similar to that seen in other countries.⁴ American women age 20–34 have the highest proportion of pregnancies aborted compared with other countries, indicating an unappreciated, but real, problem of unintended pregnancy existing beyond the teenage years. A decrease in unintended pregnancies (about 16%) and the abortion rate in the U.S. in the 1990s is due to better use of contraception; however, the rates are still relatively high. About half of all pregnancies in the U.S. are estimated to be unplanned, and more than half of these are aborted.⁴

Delaying marriage prolongs the period in which women are exposed to the risk of unintended pregnancy. This, however, cannot be documented as a major reason for the large differential between young adults in Europe and the U.S. The available evidence also indicates that a difference in sexual activity is not an important explanation. The major difference between American women and European women is that American women under age 25 are less likely to use any form of contraception.² Significantly the use of oral contraceptives (the main choice of younger women) is lower in the U.S. than in other countries.

Why are Americans different? The cultures in areas such as the United Kingdom and the Scandinavian countries are certainly very similar with similar rates of sexual experience. A major difference must be attributed to the availability of contraception. In the rest of the world, contraceptive services can be obtained from more accessible resources and relatively inexpensively. Major problems are the enormous diversity of people and the unequal distribution of income in the U.S. These factors influence the ability of our society to effectively provide education regarding sex and contraception and to effectively make contraception services available.

Contraception is not new, but its widespread development and application are new. The era of modern contraception dates from 1960 when oral contraception was first approved by the U.S. Food and Drug Administration, and intrauterine devices were re-introduced. For the first time, contraception did not have to be a part of the act of coitus. However, national family planning services and research were not funded by the U.S. Congress until 1970, and the last U.S. law prohibiting contraception was not reversed until 1973.

Efficacy of Contraception

A clinician's anecdotal experience with contraceptive methods is truly insufficient to provide the accurate information necessary for patient counseling. The clinician must be aware of the definitions and measurements used in assessing contraceptive efficacy and must draw on the talents of appropriate experts in this area to summarize the accurate and comparative failure rates for the various methods of contraception. The publications by Trussell et al., summarized below, accomplish these purposes and are highly recommended.^{5, 6 and 7}

Definition and Measurement

Contraceptive efficacy is generally assessed by measuring the number of unplanned pregnancies that occur during a specified period of exposure and use of a contraceptive method. The two methods that have been used to measure contraceptive efficacy are the Pearl index and life-table analysis.

The Pearl Index

The Pearl index is defined as the number of failures per 100 woman-years of exposure. The denominator is the total months or cycles of exposure from the onset of a method until completion of the study, an unintended pregnancy, or discontinuation of the method. The quotient is multiplied by 1200 if the denominator consists of months or by 1300 if the denominator consists of cycles.

With most methods of contraception, failure rates decline with duration of use. The Pearl index is usually based on a lengthy exposure (usually one year) and, therefore, fails to accurately compare methods at various durations of exposure. This limitation is overcome by using the method of life-table analysis.

Life-Table Analysis

Life-table analysis calculates a failure rate for each month of use. A cumulative failure rate can then compare methods for any specific length of exposure. Women who leave a study for any reason other than unintended pregnancy are removed from the analysis, contributing their exposure until the time of the exit.

Failure Rates During the First Year of Use, United States⁷

Method	Percent of Women with Pregnancy Lowest Expected	Typical
No method	85.0%	85.0%
Combination Pill	0.1	3.0
Progestin only	0.5	3.0
IUDs		

IUDs		
Progesterone IUD	1.5	2.0
Levonorgestrel IUD	0.6	0.8
Copper T 380A	0.1	0.1
Norplant	0.05	0.05
Female sterilization	0.05	0.05
Male sterilization	0.1	0.15
Depo-Provera	0.3	0.3
Spermicides	6.0	26.0
Periodic abstinence		25.0
Calendar	9.0	
Ovulation method	3.0	
Symptothermal	2.0	
Post-ovulation	1.0	
Withdrawal	4.0	19.0
Cervical cap		
Parous women	26.0	40.0
Nulliparous women	9.0	20.0
Sponge		
Parous women	9.0	28.0
Nulliparous women	6.0	18.0
Diaphragm and spermicides	6.0	20.0
Condom		
Male	3.0	14.0
Female	5.0	21.0

Contraceptive failures do occur and for many reasons. Thus, “method effectiveness” and “use effectiveness” have been used to designate efficacy with correct and incorrect use of a method. It is less confusing to simply compare the very best performance (the lowest expected failure rate) with the usual experience (typical failure rates) as noted in the table of failure rates during the first year of use. The lowest expected failure rates are determined in clinical trials, where the combination of highly motivated subjects and frequent support from the study personnel yields the best results. It should be noted that slightly more than half of the unintended pregnancies in the U.S. are due to contraceptive failures. ⁴

Contraceptive Use in the United States

The National Survey of Family Growth is conducted by the National Center for Health Statistics of the Centers for Disease Control and Prevention. Data are available from 1972, 1976, 1982, 1988 and 1995. ^{8, 9, 10, and 11} The samples are very large, and, therefore, the estimates are very accurate.

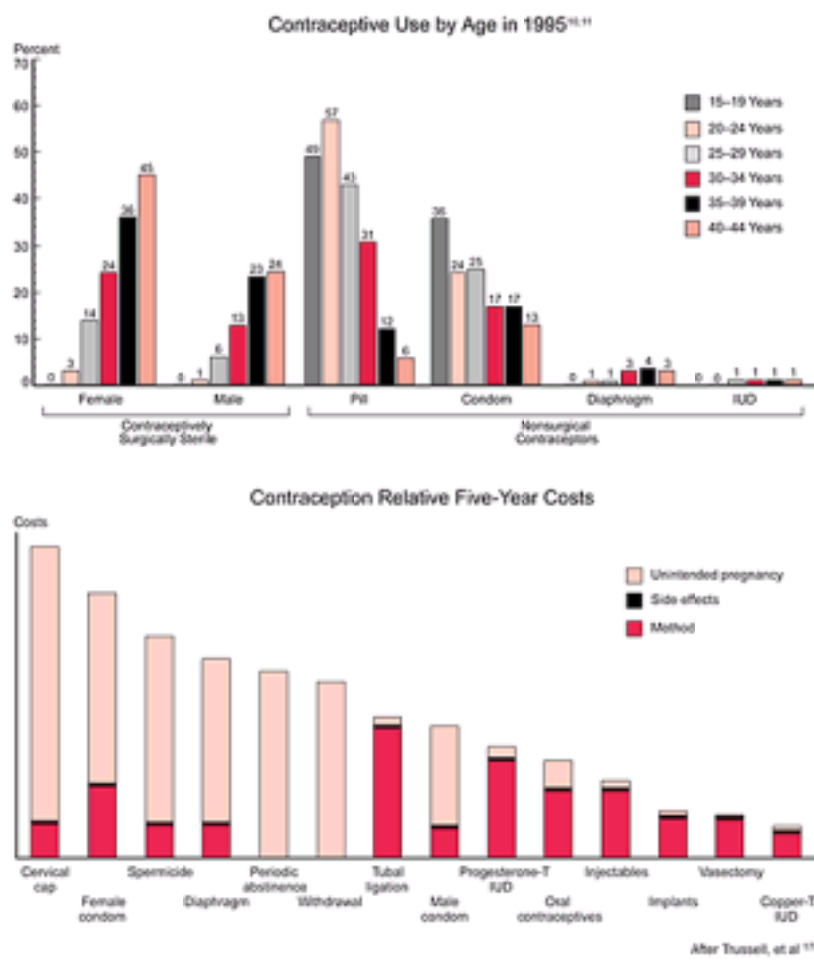

The percent of married couples using sterilization as a method of contraception more than doubled from 1972 to 1988, and has remained stable since then. The use of oral contraception reached a high in 1992, and then decreased in 1995, especially among Hispanic and black Americans. Approximately 10.7 million American women used oral contraceptives in 1988, and 10.4 million in 1995. Among never married women, oral contraception has been the leading method of birth control, but from 1988 to 1995, oral contraceptive use decreased in women younger than 25 and rose among women aged 30–44. A part of the decrease in oral contraceptive use is due to the new availability and use of implant (about 0.5 million women in 1995) and injectable methods (about 1.0 million women in 1995). However, the greater impact is due to an increase in condom use, especially by never married and formerly married women, women younger than 25, black women, and Hispanic women; indeed, the recent increase in overall contraceptive use is due to the increase in condom use which rose from 5.1 million women aged 15–44 in 1988 (15%) to 7.9 million in 1995 (20%). This increase occurred in all race and ethnic groups. These changes reflect the concern regarding sexually transmitted diseases, including human immunodeficiency (HIV). About one-third of condom users in 1995 were using more than one method, especially younger and never married women!

In 1982, 56% of U.S. women, 15–44 years of age, were using contraception, and this increased in 1995 to 64% (about 39 million women). In 1995, contraceptive sterilization (male and female) was utilized by 38% (15 million) of these women (the next leading method was oral contraception, 27%) The number of reproductive age women using the intrauterine device (IUD) decreased by two-thirds from 1982 to 1988, and further decreased in 1995, from 7.1% to 2% to 0.8%, respectively. IUD use is concentrated in the U.S. in married women over age 35. In 1982 more than 2 million women used the IUD and a similar number used the diaphragm, but in 1995 only 0.3 million women used the IUD and 0.7 million women (1.9%) used the diaphragm. The decrease in IUD use since 1982 has been especially marked in Hispanic and black women.

The oral contraceptive is the most popular method among teenagers. However, studies have repeatedly documented that the use of the implant and injectable methods is associated with lower discontinuation rates and a lower rate of repeat pregnancies following delivery. ^{12,13} This warrants a renewed effort to extend the use of these methods.

In 1995, 95% of those who were at risk of getting pregnant were using some method of contraception, whereas 36% of women of reproductive age were not using a method of contraception for the following reasons:

- 11%—no sexual experience,
- 9% —pregnant or trying to get pregnant,
- 6% —not sexually active,
- 5% —sterilized for medical reasons,
- 5% —at risk for an unintended pregnancy (this percentage steadily decreased over the last decade).

U.S. couples have made up for the lack of contraceptive choices by greater reliance on voluntary sterilization. Between 1973 and 1982, oral contraception and sterilization changed places as the most popular contraceptive method among women over the age of 30. Approximately one-half of American couples choose sterilization within 15 to 20 years of their last wanted birth. During the years of maximal fertility, oral contraceptives are the most common method peaking at age 20–24. The use of condoms is the second most widely used method of reversible contraception, rising from about 9% in the mid 1980s to approximately 20% of couples in 1995.¹¹

The pattern of contraceptive use in Canada in 1995 was similar to that of the U.S., with a slightly higher percentage of oral contraceptive use (38.2% of women 15–44 years of age) and a slightly lower utilization of sterilization (32.5%).¹⁴ Canada, too, has seen an increase in condom use and a decrease in use of the IUD. In France, 36.3% of reproductive aged women used oral contraceptives (in 1994), and although IUD use has slightly decreased (only among younger women), French women use the IUD at a rate that is more than 16-fold greater compared with North American women.¹⁵ Most French women use oral contraceptives when young, and then turn to the IUD in their older years (only 4.1% of French women relied on sterilization in 1994 — male sterilization is virtually nonexistent).

The Impact of the Worldwide Use of Contraception

The world population is expected to stabilize at between 11 and 12 billion around 2150, with a fertility rate of 2.1 children per woman. ¹⁶ Approximately 95% of the growth will occur in developing countries, so that by 2100, 13% of the population will live in developed countries, a decrease from the current 25%. ¹⁷

WORLD POPULATION

- 1 billion —achieved in 1800–1850
- 2 billion —achieved in 1930
- 3 billion —achieved in 1960
- 4 billion —achieved in 1976
- 5 billion —achieved in 1987
- 9 billion —in 2025
- 11.5 billion —in 2150

Throughout the world, 45% of married women of reproductive age practice contraception. However, there is significant variation from area to area; e.g., 69% in east

Throughout the world, 45% of married women of reproductive age practice contraception. However, there is significant variation from area to area; e.g., 69% in east Asia but only 11% in Africa. Female sterilization and the IUD are most popular in developing countries, whereas oral contraceptives and condoms are most popular in developed countries. Less than 15% of women of reproductive age in the world are using oral contraceptives, and more than half live in the U.S., Brazil, France, and Germany.

The 76% of the world's population living in developing countries account for:

- 85% of all births,
- 95% of all infant and childhood deaths,
- 99% of all maternal deaths.

The problem in the developing world is self-evident. The ability to regulate fertility has a significant impact on infant, child, and maternal mortality and morbidity. A pregnant woman has a 200 times greater chance of dying living in a developing country than in a developed country. The health risks associated with pregnancy and childbirth in the developing world are far greater than risks secondary to the use of modern contraception. ¹⁹

In recent years, there has been an appropriate shift from a narrow focus on contraception to a broader view that encompasses the impact of poverty, emphasizes overall well-being and the rights of individuals, endorses gender equality, and examines the interactions among these issues. ²⁰ It is not enough to simply limit fertility; contraception is only one component of reproductive health.

The Impact of Use and Non-use

Inadequate access to contraception is associated with a high induced abortion rate. Effective contraceptive use largely, although not totally, replaces the resort to abortion. ²¹ The combination of restrictive abortion laws and the lack of safe abortion services continues to make unsafe abortion a major cause of morbidity and mortality throughout the world. Both safe and unsafe abortions can be minimized by maximizing contraceptive services. However, the need for safe abortion services will persist. Contraceptive failures account for about half of the 1.33 million annual induced abortions in the U.S.

In the U.S. in the late 1980s, \$1 spent on public funding for family planning saved an average of \$4.40 spent on medical, welfare, and nutritional services. ²² States with higher family planning expenditures have fewer induced abortions, low-birthweight newborns, and premature births. ²³ The investment in family planning leads to short-term reductions in expenditures on maternal and child health services and after 5 years, a reduction in costs for education budgets. Cutting back on publicly funded family planning services impacts largely on poor women, increasing the number of unintended births and abortions. In California, in the 1980s, there was an average of \$7.70 saved for every \$1 spent to provide contraceptive services. ²⁴

There is a gap between the low levels of unintentional pregnancy that can be achieved and the actual levels being obtained, most of which are in couples using reversible contraception. A major thrust, in addition to providing services, must include education and counseling of couples about effective contraception.

STDs and Contraception

The interaction between clinician and patient for the purpose of contraception provides an opportunity to control sexually transmitted diseases (STDs). The World Health Organization estimates that in the year 2000, over 13 million women will be infected with the human immunodeficiency virus (HIV). ²⁵ The modification of unsafe sexual practices reduces the risk of unplanned pregnancy and the risk of infections of the reproductive tract. A patient visit for contraception is an excellent time for STD screening; if an infection is symptomatic, it should be diagnosed and treated during the same visit in which contraception is requested. A positive history for STDs should trigger both screening for asymptomatic infections and counseling for safer sexual practices. Attention should be given to the contraceptive methods that have the greatest influence on the risk of STDs.

The Future

From 1970 to 1986, the number of births in women over 30 quadrupled; since 1990, the fertility rate among women over 30 has remained relatively stable. ²⁶ As more and more couples defer pregnancy until later in life, the use of sterilization under age 35 will decline, and the need for reversible contraception will increase. Between 1988 and 1995, oral contraceptive use decreased in women younger than 25 and increased in women aged 30–44. ¹¹ These numbers changed because clinicians and patients have come to understand and accept that low-dose oral contraception is safe for healthy, nonsmoking older women.

The need for reversible contraception in women over the age of 30 is growing, not diminishing. The highest number of births in the U.S. occurred between 1947 and 1965 — the post-World War II baby boom (a demographic phenomenon shared by all parts of the developed world). The entire cohort of women born in this period will not reach their 45th birthday until around 2010. For approximately a 20-year period, therefore, there will be an unprecedented number of women in the later childbearing years. The number of women aged 35–49 increased 61% between 1982 and 1995. The proportion of births accounted for by this group of women will increase by about 72%, from 5% in 1982 to 8.6% in 2000. ²⁷ This group of women is not only increasing in number, but it is changing its fertility pattern.

The deferment of marriage is a significant change in our society. In 1960, 28% of women aged 20–24 were single; in 1985, 58.5%. In 1960, 10% of women aged 25–29 were single; in 1985, 26%. But only 16% of the decline in the total fertility rate is accounted for by the increase in the average age at first marriage. Eighty-three percent of the decline in total fertility rate is accounted for by changes in marital fertility rates. In other words postponement of pregnancy in marriage is the more significant change. ²⁸ This combination of increasing numbers, deferment of marriage, and postponement of pregnancy in marriage is responsible for the fact that we will be seeing more and more older women who will need reversible contraception. In short, there will continue to be longer duration of use in younger women and greater use in older women, a pattern that began in 1990.

Change in U.S. Female Demographics 1985–2000²⁷

Age	1985	1990	1995	2000	% Change 1985–2000
15–24	19.5 mill.	17.4 mill.	16.7 mill.	17.7 mill.	-9.2%
25–29	10.9	10.6	9.3	8.6	-21.1
30–34	10.0	11.0	10.8	9.4	-6.0
35–44	16.2	19.1	21.1	21.9	+35.2
Total	56.6	58.1	57.9	57.6	+1.8
15–44					

One solution to the problem of a restricted number of contraceptive choices for American women is to develop new methods. There are many obstacles to the development of new methods, including the attitudes of the American public (besides America's traditionally conservative, religion-oriented views toward sex and family, polarization is produced by responses evoked by specific issues such as sterilization and induced abortion), the funding available for research, the time and cost required to meet federal regulations, and the problems of product liability. ²⁹ However, experts in the field remain optimistic, citing the many needs and opportunities for improvements and new developments. ³⁰

Fortunately, clinicians and patients have recognized that low-dose oral contraception is very safe for healthy, nonsmoking older women. Between 1988 and 1995, the use of oral contraceptives doubled among women aged 35–39, and increased 6-fold in women over age 40. ¹¹ However, as the above statistics indicate, its use is still not sufficient to meet the need. Besides fulfilling a need, this population of women has a series of benefits to be derived from oral contraception that tilt the risk:benefit ratio to the positive side ([Chapter 22](#)).

The growing need for reversible contraception would also be served by increased utilization of the IUD. The decline in IUD use in the U.S. is in direct contrast to the experience in the rest of the world, a complicated response to publicity and litigation. An increased risk of pelvic infection with contemporary IUDs in use is limited to the act of insertion and the transportation of pathogens to the upper genital tract. This risk is effectively minimized by careful screening with preinsertion cultures and

not sufficient to meet the need. Besides fulfilling a need, this population of women has a series of benefits to be derived from oral contraception that tilt the risk-benefit ratio to the positive side ([Chapter 22](#)).

The growing need for reversible contraception would also be served by increased utilization of the IUD. The decline in IUD use in the U.S. is in direct contrast to the experience in the rest of the world, a complicated response to publicity and litigation. An increased risk of pelvic infection with contemporary IUDs in use is limited to the act of insertion and the transportation of pathogens to the upper genital tract. This risk is effectively minimized by careful screening with preinsertion cultures and the use of good technique. A return to IUD use by American couples is both warranted and desirable.

A major problem in the U.S. is the prevalence of misconceptions. More than half of women, even well-educated women, are not accurately aware of the efficacy or the benefits and side effects associated with contraception. ^{31, 32} Unfortunately, a significant percentage of women still do not know that there are many health benefits with the use of oral contraception. Misconceptions regarding contraception have, in many instances, achieved the stature of myths. Myths are an obstacle to good utilization and can only be dispelled by accurate and effective educational efforts.

Contraceptive advice is a component of good preventive health care. The clinician's approach is a key. This is an era of informed choice by the patient. Patients deserve to know the facts and need help in dealing with the state of the art and the uncertainty. But there is no doubt that patients, especially young patients, are influenced in their choice by their clinicians' advice and attitude. Although the role of a clinician is to provide the education necessary for the patient to make proper choices, one should not lose sight of the powerful influence exerted by the clinician in the choices ultimately made. In the 1970s, we approached the patient with great emphasis on risk. At the turn of the century, the approach should be different, highlighting the benefits and the greater safety of appropriate contraception.

If one attempts to sum the impact of the benefits of contraception on public health, as some have done with models focusing on hospital admissions, there is no doubt that the benefits outweigh the risks. The impact can be measured in terms of both morbidity and mortality. But the impact on public health is of little concern during the clinician-patient interchange in the medical office. Here personal risk is paramount, and compliance with effective contraception requires accurate information presented in a positive, effective fashion.

Sterilization

Contraceptive methods today are very safe and effective, however, we remain decades away from a perfect method of contraception for either women or men. Because reversible contraceptive methods are not perfect, more than a third of American couples use sterilization instead, and sterilization is now the predominant method of contraception in the world. ³³

Over the past 20 years, nearly one million Americans each year have undergone a sterilization operation, and recently, more women than men. By 1995, 38% of reproductive aged women relied on contraceptive sterilization: 27% had tubal occlusion (11 million women), and 11% depended on their partners' vasectomies (4 million men). ¹¹ This same trend has occurred in Great Britain, where by age 40, over 20% of men and women have had a sterilization procedure. ³⁴ In Spain and Italy, sterilization rates are very low, but the use of oral contraceptives and the IUD is very high. ³⁵

History

James Blundell proposed in 1823, in lectures at Guy's Hospital in London, that tubectomy ought to be performed at cesarean section to avoid the need for repeat sections. ³⁶ He also proposed a technique for sterilization, which he later described so precisely that he must actually have performed the operation, although he never wrote about it. The first report was published in 1881 by Samuel Lungren of Toledo, Ohio, who ligated the tubes at the time of cesarean section, as Blundell had suggested 58 years earlier. ³⁷ The Madlener procedure was devised in Germany in 1910 and reported in 1919. Because of many failures, the Madlener technique was supplanted in the U.S. by the method of Ralph Pomeroy, a prominent physician in Brooklyn, New York. This method, still popular today, was not described to the medical profession by Pomeroy's associates until 1929, 4 years after Pomeroy's death. Frederick Irving of the Harvard Medical School described his technique in 1924, and the Uchida method was not reported until 1946.

Few sterilizations were performed until the 1930s when "family planning" was first suggested as an indication for surgical sterilization by Baird in Aberdeen. He required women to be over 40 and to have had 8 or more children. Mathematical formulas of this kind persisted through the 1960s. In 1965, Sir Dugald Baird delivered a remarkable lecture, entitled "The Fifth Freedom," calling attention to the need to alleviate the fear of unwanted pregnancies, and the important role of sterilization. ³⁸ By the end of the 1960s, sterilization was a popular procedure.

Laparoscopic methods were introduced in the early 1970s. The annual number of vasectomies began to decline, and the number of tubal occlusion operations increased rapidly. By 1973, more sterilization operations were performed for women than for men. This is accurately attributed to dramatic decreases in costs, hospital time, and pain due to the introduction of laparoscopy and minilaparotomy methods. The use of laparoscopy for tubal occlusion increased from only 0.6% of sterilizations in 1970 to more than 35% by 1975. ³⁹ Since 1975, minilaparotomy, a technique popular in the less developed world, has been increasingly performed in the U.S. These methods have allowed women to undergo sterilization operations at times other than immediately after childbirth or during major surgery.

Laparoscopy and minilaparotomy have led to a profound change in the convenience and cost of sterilization operations for women. In 1970, the average woman

Laparoscopy and minilaparotomy have led to a profound change in the convenience and cost of sterilization operations for women. In 1970, the average woman stayed in the hospital 6.5 days for a tubal sterilization. By 1975, this had declined to 3 days, and today, women rarely remain in the hospital overnight. The shorter length of stay achieved from 1970 to 1975 represented a savings of more than \$200 million yearly in health care costs and a tremendous increase in convenience for women eager to return to work and their families.⁴⁰ Unlike some advances in technology, laparoscopy and minilaparotomy sterilization are technical innovations that have resulted in large savings in medical care costs.

The great majority of sterilization procedures are accomplished in hospitals by physicians in private practice, but a rapidly increasing proportion is performed outside of hospitals in ambulatory surgical settings, including physicians' offices. In either hospital or outpatient settings, female sterilization is a very safe operation. Deaths specifically attributed to sterilization now account for a fatality rate of only 1.5 per 100,000 procedures, a mortality rate that is lower than that for childbearing (about 10 per 100,000 births in the U.S.).⁴¹ When the risk of pregnancy from contraceptive method failure is taken into account, sterilization is the safest of all contraceptive methods.

Vasectomy has long been more popular in the U.S. than anywhere else in the world, but why don't more men use it? One explanation is that women have chosen laparoscopic sterilization in increasing numbers. Another is that men have been frightened by reports, often from animal data, of associations with autoimmune diseases, atherosclerosis, and most recently, prostatic cancer. Large epidemiologic studies have failed to confirm any definite adverse consequences.⁴² When patients consider sterilization, we can assure them that vasectomy has not been demonstrated to have any harmful effects on men's health.⁴³ In addition, vasectomy is less expensive than tubal sterilization, morbidity is less, and mortality is essentially zero.

Efficacy of Sterilization

Laparoscopic and minilaparotomy sterilizations are not only convenient, they are almost as effective at preventing pregnancy as were the older, more complex operations. Vasectomy is also highly effective once the supply of remaining sperm in the vas deferens is exhausted. After 6 weeks or 15 ejaculations, essentially all men are sterile.

Failure Rates During the First Year, United States⁶

Method	Percent of Women with Pregnancy Lowest Expected	Typical
Female sterilization	0.2%	0.4%
Male sterilization	0.1%	0.15%

Besides the specific operation used, the skill of the operator and characteristics of the patient make important contributions to the efficacy of female sterilization. Up to 50% of failures are due to technical errors. The methods using complicated equipment, such as spring-loaded clips and silastic rings, fail for technical reasons more commonly than do simpler procedures such as the Pomeroy tubal ligation.⁴⁴ Minilaparotomy failures, therefore, occur much less frequently from technical errors.

It is hardly surprising that more complicated techniques of tubal occlusion have higher technical failure rates. What is surprising is the finding that characteristics of the patient influence the likelihood of failure even when technical problems are controlled for in analytical adjustments. In a careful study of this issue, two patient characteristics, age and lactation, demonstrated a significant impact.⁴⁵ Patients younger than 35 years were 1.7 times more likely to become pregnant, and women who were not breastfeeding following sterilization were 5 times more likely to become pregnant. These findings probably reflect the greater fecundity of younger women and the contraceptive contribution of lactation.

Significant numbers of pregnancies after tubal occlusion are present before the procedure. For this reason, some clinicians routinely perform a uterine evacuation or curettage prior to tubal occlusion. It seems more reasonable (and cost-effective) to exclude pregnancy by careful history taking, physical examination, and an appropriate pregnancy test prior to the sterilization procedure.⁴⁶

Because method, operator, and patient characteristics all influence sterilization failures, it is difficult to predict which individual will experience a pregnancy after undergoing a tubal occlusion. Therefore, during the course of counseling, all patients should be made aware of the possibility of failure as well as the intent to cause permanent, irreversible sterility. It is important to avoid giving patients the impression that the tubal occlusion procedure is foolproof or guaranteed. Individual clinicians must be cautious judging their own success in accomplishing sterilization because failure is infrequent and many patients who become pregnant after sterilization never reveal the failure to the original surgeon.

Ectopic pregnancies can occur following tubal occlusion, and the incidence is much higher with some types of tubal occlusion.^{47, 48 and 49} Bipolar tubal coagulation is more likely to result in ectopic pregnancy than is mechanical occlusion.^{44, 50} The probable explanation is that microscopic fistulae in the coagulated segment connecting to the peritoneal cavity permit sperm to reach the ovum. Ectopic pregnancies following tubal ligation are more likely to occur 2 or more years after sterilization, rather than immediately after. In the first year after sterilization, about 6% of pregnancies will be ectopic, but the majority of pregnancies that occur 2–3 years after occlusion will be ectopic.⁵¹ Overall, however, the risk of an ectopic pregnancy in sterilized women is lower than if they had not been sterilized. Nevertheless, approximately one-third of the pregnancies that occur after tubal sterilization are ectopic.⁵²

Vaginal procedures have higher failure rates than laparoscopy or minilaparotomy, but the principal disadvantage is a higher rate of infection. Intraoperative infection is a rare complication of minilaparotomy or laparoscopic techniques, but in vaginal procedures, abscess formation approaches 1%.⁵³ This risk can be reduced by the use of prophylactic antibiotics administered intraoperatively, but open laparoscopy is usually easier and safer than vaginal sterilization even in obese women.

Sterilization and Ovarian Cancer — A Benefit of Sterilization

Evidence from the Nurses' Health Study indicated that tubal sterilization was associated with a 67% reduced risk of ovarian cancer.⁵⁴ In the prospective mortality study, conducted by the American Cancer Society, women who had undergone tubal sterilization experienced about a 30% reduction in the risk of fatal ovarian cancer.⁵⁵ In addition, case-control data have consistently supported this finding.^{56, 57 and 58} The mechanism for such an effect is not clear, but this information is worth sharing with patients.

Female Sterilization Techniques

study, conducted by the American Cancer Society, women who had undergone tubal sterilization experienced about a 30% reduction in the risk of fatal ovarian cancer.⁵⁵ In addition, case-control data have consistently supported this finding.^{56, 57 and 58} The mechanism for such an effect is not clear, but this information is worth sharing with patients.

Female Sterilization Techniques

Because laparoscopy permits direct visualization and manipulation of the abdominal and pelvic organs with minimal abdominal disruption, it offers many advantages. Hospitalization is not required; most patients return home within a few hours, and the majority return to full activity within 24 hours. Discomfort is minimal, the incision scars are barely visible, and sexual activity need not be restricted. In addition, the surgeon has an opportunity to inspect the pelvic and abdominal organs for abnormalities. The disadvantages of laparoscopic sterilization include the cost, the expensive, fragile equipment, the special training required, and the risks of inadvertent bowel or vessel injury.

Laparoscopic sterilization can be achieved with any of these methods:

1. Occlusion and partial resection by unipolar electrocautery.
2. Occlusion and transection by unipolar electrocautery.
3. Occlusion by bipolar electrocoagulation.
4. Occlusion by mechanical means (clips or silastic rings).

All of these methods can use an operating laparoscope alone, or the diagnostic laparoscope with operating instruments passed through a second trocar, or both the operating laparoscope and secondary puncture equipment. All can be used with the "open" laparoscopic technique in which the laparoscopic instrument is placed into the abdominal cavity under direct vision to avoid the risk of bowel or blood vessel puncture on blind entry. Patient acceptance and recovery are approximately the same with all methods.

It is now apparent that the long-term failure rates for all methods are higher than previous estimates; overall, 1.85% of sterilized women experience a failure within 10 years.⁵⁹ As much as one-third of these failures are ectopic pregnancies.⁵² The higher failure rates with silastic rings, clips, and bipolar coagulation reflect the greater degree of skill required for these methods. The methods with a greater percentage of failures occurring many years after the procedure are unipolar coagulation, bipolar coagulation, and the silastic ring. Because of the effect of declining fecundity with increasing age, younger sterilized women are more likely to have a failure, including ectopic pregnancy, compared with older women. For these reasons, women seeking sterilization should consider the use of the copper IUD or implants, reversible methods that offer very low failure rates.

Female Tubal Sterilization Methods, 10-Year Cumulative Failure Rates⁵⁹

Unipolar coagulation	0.75%
Postpartum tubal excision	0.75
Silastic (Falope or Yoon) ring	1.77
Interval tubal exclusion	2.01
Bipolar coagulation	2.48
Hulka-Clemens clip	3.65

Tubal Occlusion by Electrosurgical Methods

If electrons from an electrosurgical generator are concentrated in one location, heat within the tissue increases sharply and desiccates the tissue until resistance is so high that no more current can pass. Unipolar methods of sterilization create a dense area of current under the grasping forceps of the unipolar electrode. In order to complete the circuit, however, these electrons must spread through the body and be returned to the generator via a return electrode (the ground plate) that has a broad surface to minimize the density of the current to avoid burns as the electrons leave the body. "Unipolar" refers to the method that requires the patient ground plate.

With the unipolar method, if tissue resistance is high and the electrical pressure (voltage) relatively low, current may cease to flow or may search out alternate pathways with lower resistance. When the voltage is increased, the electrons have more "push" to find another pathway, therefore, the surgeon must use the lowest possible voltage necessary to completely coagulate. The return electrode (the ground plate) must be in good contact with the patient.

Unipolar electrocautery can create a unique electrical "capacitance" problem when an operating laparoscope is used with unipolar forceps. A capacitor is any device that can hold an electric charge, and can exist wherever an insulated material separates two conductors that have different potentials. This property of capacitance explains some of the inadvertent bowel burns that have occurred with laparoscopic sterilization.⁶⁰ The operating laparoscope is a hollow metal tube surrounding an active electrode, the forceps used to grasp and coagulate the tubes. When current passes through the active electrode, the laparoscope itself becomes a capacitor. Up to 70% of the current passed through the active electrode can be induced into the laparoscope. Should bowel or other structures touch a laparoscope, which is insulated from the abdominal incision (for example, by a fiberglass cannula), the stored electrons will be discharged at high density directly into the vital organ. This potential hazard is eliminated by using a metal trocar sleeve rather than a nonconductive sleeve-like fiberglass. Because there is little pressure behind the electrons from a low-voltage generator, not enough heat is generated to burn the skin as the capacitance current leaks out into the patient's body through the sleeve. Even if the active electrode comes in direct contact with the laparoscope, as when a two-incision technique is used, the current will leak harmlessly through the metal trocar sleeve. The risk of inadvertent coagulation of bowel or other organs cannot be completely eliminated because all body surfaces offer a path back to the ground plate.

The unipolar electrocautery technique is straightforward. The isthmic portion of the fallopian tube is grasped and elevated away from the surrounding structures, and the electrical energy applied until the tissue blanches, swells, and then collapses. The tube is then grasped, moving toward the uterus, recoagulated, and the steps repeated until 2–3 cm of tube have been coagulated. Some surgeons advise against cornual coagulation for fear it may increase the risk of ectopic pregnancy due to fistula formation.

The coagulation and transection technique is performed in a similar fashion with the same instruments. In order to transect the tube, however, an instrument designed to cut tissue must be utilized. The transection of tissue increases the risk of possible bleeding and does not, by itself, reduce the failure rate over coagulation alone. The specimens obtained by this method are usually coagulated beyond microscopic recognition, and therefore will not provide pathological evidence of successful sterilization.

The bipolar method of sterilization eliminates the ground plate required for unipolar electrocautery and uses a specially designed forceps. One jaw of the forceps is the active electrode, and the other jaw is the ground electrode. Current density is great at the point of forceps contact with tissue, and the use of a low-voltage, high-frequency current prevents the spread of electrons. By eliminating the return electrode, the chance of an aberrant pathway through bowel or other structures is greatly reduced. There is, however, a disadvantage with this technique. Because electron spread is decreased, more applications of the grasping forceps are necessary to coagulate the same length of tube than with unipolar coagulation. As desiccation occurs at the point of high current density, tissue resistance increases, and the coagulated area eventually provides resistance to flow of the low-voltage current. Should the resistance increase beyond the voltage's capability to push electrons through the tissue, incomplete coagulation of the endosalpinx can result.⁶¹ In addition, the desiccated tissue can adhere to the bipolar forceps, making it difficult to remove from the surface of the tube.

The bipolar method can be used with either a single-incision operating laparoscope or with dual incision instruments. The forceps are, however, more delicate than unipolar equipment and must be kept meticulously clean. Damage to the instruments can alter the ability to coagulate, and inadequate or incomplete electrocoagulation is the main cause of failure.

Bipolar cautery is safer than unipolar cautery with regard to burns of abdominal organs, but most studies indicate higher failure rates. Although the bipolar forceps will not burn tissues that are not actually grasped, care must be taken to avoid coagulating structures adherent to the tubes. For example, the ureter can be damaged when the tube is adherent to the pelvic side wall.

Tubal Occlusion With Clips and Rings

Female sterilization by mechanical occlusion eliminates the safety concerns with electrocautery. However, mechanical devices are subject to flaws in material, defects in manufacturing, and errors in design, all of which can alter efficacy. Three mechanical devices have been widely used and have low failure rates with long-term follow-up: the Hulka-Clemens (spring) clip, the Filshie Clip, and the silastic (Falope or Yoon) ring. Each of the three requires an understanding of its mechanical

Tubal Occlusion With Clips and Rings

Female sterilization by mechanical occlusion eliminates the safety concerns with electrosurgery. However, mechanical devices are subject to flaws in material, defects in manufacturing, and errors in design, all of which can alter efficacy. Three mechanical devices have been widely used and have low failure rates with long-term follow-up: the Hulka-Clemens (spring) clip, the Filshie Clip, and the silastic (Falope or Yoon) ring. Each of the three requires an understanding of its mechanical function, a working knowledge of the intricate applicator necessary to apply the device, meticulous attention to maintenance of the applicators, and skillful tubal placement. These devices are less effective when used immediately postpartum on dilated tubes.

Hulka-Clemens Spring Clip. The spring clip consists of two plastic jaws made of Lexan, hinged by a small metal pin 2 mm from one end. Each jaw has teeth on the opposed surface, and a stainless steel spring is pushed over the jaws to hold them closed over the tube. A special laparoscope for one incision application is most commonly used, although the spring clip can also be used in a two-incision procedure. The spring clip should be applied at a 90 degree angle to include some mesosalpinx at the proximal isthmus of a stretched fallopian tube. The spring clip destroys 3 mm of tube and has one-year pregnancy rates of 2 per 1000 women, but the highest 10-year cumulative failure rate. [44](#), [59](#)

Complications unique to spring clip sterilization result from mechanical difficulties. Should the clip be dislodged or dropped into the abdomen during the procedure, it should be retrieved. Usually, it can be removed laparoscopically, but sometimes laparotomy is necessary. Should incomplete occlusion or incorrect alignment of the clip occur, a second clip can be applied without hazard. This clip offers a good chance for reanastomosis, better than electrosurgical methods that destroy more tube.

Filshie Clip. The Filshie clip is made of titanium lined with silicone rubber. The hinged clip is locked over the tube using a special applicator through a second incision or operating laparoscope. The rubber lining of the clip expands on compression to keep the tube blocked. Only 4 mm of the tube is destroyed. Failure rates one year after the procedure with the newest model approximate 1 per 1000 women. [46](#) Because the Filshie clip is longer, it is reported to occlude dilated tubes more readily than does the spring clip. Both the spring clip and the Filshie clip provide good chances for tubal reanastomosis.

Silastic (Falope or Yoon) Ring. This nonreactive silastic rubber band has an elastic memory of 100% if stretched to no more than 6 mm for a brief time (a few minutes at most). A special applicator, 6 mm in diameter, can be placed through a second cannula or through a standard offset operating laparoscope. The applicator is designed to grasp a knuckle of tube and release the silastic band onto a 2.5 cm loop of tube. The avascular loop of tube can be resected with biopsy forceps to provide a pathology specimen, but this is rarely performed (it does not increase efficacy). Ten to 15% of patients experience severe postoperative pelvic cramping from the tight bands (which can be alleviated by the application of a local anesthetic to the tube before or after banding).

The ring applicator consists of two concentric cylinders. Within the inner cylinder is a forceps for grasping, elevating, and retracting a segment of the tube. The silastic ring is stretched around the exposed end of the inner cylinder by means of a special ring loader and ring guide. The outer cylinder moves the ring from the inner cylinder on to the tube, a loop of which is held within the inner cylinder by the forceps.

As with application of clips, the ring should be placed at the junction of the proximal and middle third of each fallopian tube. Once the tube is grasped, it is gently withdrawn into the inner cylinder by slowly squeezing the pistol-like handle of the applicator. A final strong pull is needed to slide the ring from the inner applicator

The ring applicator consists of two concentric cylinders. Within the inner cylinder is a forceps for grasping, elevating, and retracting a segment of the tube. The silastic ring is stretched around the exposed end of the inner cylinder by means of a special ring loader and ring guide. As with application of clips, the ring should be placed at the junction of the proximal and middle third of each fallopian tube. Once the tube is grasped, it is gently withdrawn into the inner cylinder by slowly squeezing the pistol-like handle of the applicator. A final strong pull is needed to slide the ring from the inner applicator cylinder onto the loop of tube. Necrosis occurs promptly and a 2–3 cm segment of the tube is destroyed. Failure rates are about 1% after two years, and the 10-year cumulative rate is only better with unipolar coagulation and postpartum tubal excision. ⁵⁹

Mesosalpingeal bleeding is the most common complication of silastic ring application. It usually occurs when the forceps grabs not only the tube but also a vascular fold of mesosalpinx. The mesosalpinx can also be torn on the edge of the stainless steel cylinder as the tube is drawn into the applicator. If bleeding is noted, application of the silastic band often controls it. If the placement of additional bands or electrocoagulation fails to stop bleeding, laparotomy may be required.

Silastic rings are occasionally placed on structures other than the tube. If this mistake is recognized, the band can usually be removed from the round ligament or mesosalpingeal folds by grasping the band with the tongs of the applicator and applying gradual, increasing traction. If a gentle attempt fails, removal is not necessary. If rings are inadvertently discharged into the peritoneal cavity, they can safely be left behind.

Patients should be prepared for the use of electrosurgical instruments in case bands or clips cannot be applied (because of adhesions or bleeding).

Minilaparotomy

Tubal ligation, accomplished through a small suprapubic incision, “minilaparotomy,” is the most frequent method of interval female sterilization around the world. In the U.S. and most of the developed world, laparoscopy is more popular, but minilaparotomy is gaining in favor because of its safety, simplicity, and adaptability to ambulatory surgical settings (particularly when local anesthesia is used). ^{62, 63}

The fallopian tubes can be occluded through the minilaparotomy incision with bands or clips, but a simple Pomeroy tubal ligation is the method most commonly used. Patient characteristics, such as obesity, previous pelvic infection, or previous surgery, are the principal determinants of complications. ⁶⁴

Minilaparotomy is accomplished through an incision that usually measures 3–5 cm in length. Tubal ligation through a suprapubic incision can be accomplished for obese patients, but the incision will necessarily exceed the usual length. Forceful retraction increases the pain associated with the procedure and the time of recovery. For these reasons, we believe that minilaparotomy for ambulatory tubal occlusion should be limited to patients who are not obese (usually less than 150–160 pounds, 70 kg).

Patients who are likely to have adhesions from previous surgery or pelvic infection will probably have a shorter operating and recovery time (and less pain) with open laparoscopic tubal occlusion. In addition, the wide view provided by the laparoscope will make possible a precise description of the pelvic abnormalities that may be useful should the patient develop chronic pelvic pain or recurrent infection.

Tubal occlusion is difficult to accomplish through a minilaparotomy if the uterus is immobile. Laparoscopic tubal occlusion, on the other hand, does not require extreme uterine elevation or rotation and is a better choice for a patient with a uterus fixed in position.

The Vaginal Approach

Although vaginal techniques are still used for tubal sterilization, high rates of infection and occasional pelvic abscesses following these operations have caused most clinicians to abandon them. ⁶⁵ An apparent advantage in obese patients is sometimes deceptive because omental fat can block access to the fallopian tubes. Open laparoscopy is usually easier and safer in obese women.

Counseling for Sterilization

All patients undergoing a surgical procedure for permanent contraception should be aware of the nature of the operation, its alternatives, efficacy, safety, and complications. The operation can be described using drawings or pelvic models, as well as films, slides, or video tapes. The description of the operation should emphasize its similarities to and differences from laparoscopy and pelvic surgery, especially hysterectomy or ovariectomy which may be confused with simple tubal ligation. Women who undergo tubal sterilization by any method are 4–5-fold more likely to have a hysterectomy; no biologic explanation is apparent, and this may reflect patient attitudes toward surgical procedures. ⁶⁵ Alternatives, including vasectomy, oral contraception, long-acting hormone methods, barrier methods, and IUDs, should be reviewed. It should be emphasized to the patient that tubal ligation is not intended to be reversible, that it cannot be guaranteed to prevent intrauterine or ectopic pregnancy, and that failures can occur long after the sterilization procedure. Informed consent is best obtained at a time when a patient is not distracted or distraught; e.g., not immediately before or after an induced abortion.

Sexuality

There is no detrimental effect on sexuality specifically due to sterilization procedures. ⁶⁶ Indeed, sexual life is usually positively affected. Many couples are less inhibited and more spontaneous in lovemaking when they don't have to worry about an unwanted pregnancy.

Menstrual Function

The effects of tubal sterilization on menstrual function are less clear, and, therefore, more difficult to explain. The first well-controlled studies of this issue demonstrated no change in menstrual patterns, volume, or pain. ^{67, 68} Subsequently these same authors reported an increase in dysmenorrhea and changes in menstrual bleeding. ^{69 and 70} However, these authors failed to agree in their findings (a change found by one group was not confirmed by the other). Adding to the confusion, the incidence of hysterectomy for bleeding disorders in women after tubal sterilization was reported to be increased by some, ⁷¹ but not by others. ⁷² In a large cohort of women in a group health plan, hospitalization for menstrual disorders was significantly increased; however, the authors believed this reflected bias by patient and physician preference for surgical treatment. ⁷³ In the U.S. prospective long-term follow-up study of sterilization, the increased risk of hysterectomy after sterilization was concentrated in women who were treated for gynecologic disorders before tubal sterilization. ⁶⁵ These discordant reports do not make patient counseling about the long-term effects of tubal sterilization an easy task.

It is possible that extensive electrocoagulation of the fallopian tubes can change ovarian steroid production. Perhaps this is why menstrual changes were detected with longer (4 years) follow-up, while no changes have been noted with the use of rings or clips. ^{73, 74 and 75} However, attempts to relate poststerilization menstrual changes with extent of tissue destruction fail to find a correlation, and an increase in hospitalization for menstrual disorders after unipolar cautery cannot be documented. ^{73, 75} Still another long-term follow-up study (3–4.5 years) failed to document any significant changes in menstrual cycles. ⁷⁶ This inconsistency can reflect differences in sterilization techniques, as well as the fact that a surgical solution is more likely to be chosen if continuing fertility is no longer an issue.

More studies with careful attention to the type of tubal occlusion procedure will be necessary. The best answer for now is that some women experience menstrual changes, but most do not.

Reversibility

An important objective of counseling is to help couples make the right decision about an irreversible decision to become sterile. The active participation of both partners is a critical factor. ⁷⁷ Not all couples are pleased following sterilization; in one series, 2% of U.S. women expressed regret one year later and 2.7% after two years. ⁷⁸ At the two-year mark, the main factors associated with regret were age less than 30 and sterilization at the convenient time of a cesarean section. In Europe where tubal sterilization is less common, the most important risk factor for regret was an unstable marriage. ⁷⁹ A change in marital status is undoubtedly an important reason for a desire to reverse sterilization. ⁸⁰

Young women in unstable relationships need special attention in counseling, and both partners should participate in the counseling. Furthermore, for many couples tubal occlusion at the time of cesarean section or immediately after a difficult labor and delivery is not the best time for the procedure. It is important to know that sterilized women have not been observed to develop psychological problems at a greater than expected rate. ^{81, 82}

Microsurgery for tubal anastomosis is associated with excellent results if only a small segment of the tube has been damaged. Pregnancy rates correlate with the

Young women in unstable relationships need special attention in counseling, and both partners should participate in the counseling. Furthermore, for many couples tubal occlusion at the time of cesarean section or immediately after a difficult labor and delivery is not the best time for the procedure. It is important to know that sterilized women have not been observed to develop psychological problems at a greater than expected rate. ^{81, 82}

Microsurgery for tubal anastomosis is associated with excellent results if only a small segment of the tube has been damaged. Pregnancy rates correlate with the length of remaining tube, a length of 4 cm or more is optimal. Thus, the pregnancy rates are lowest with electrocoagulation, and reach 70–80% with clips, rings, and surgical methods such as the Pomeroy. ^{83, 84} About 2 per 1000 sterilized women will eventually undergo tubal anastomosis. ⁸⁰

Male Sterilization: Vasectomy

Vasectomy is safer, easier, less expensive, and has a lower failure rate than female sterilization. ⁸⁵ The operation is almost always performed under local anesthesia, usually by a urologist in a private office. ⁸⁶ Surgeons who do more than 10 operations yearly have lower complication rates. ⁸⁷

Hematomas and infection occur rarely, and are easily treated with heat, scrotal support, and antibiotics. Most men will develop sperm antibodies following vasectomy, but no long-term sequelae have been observed, including no increased risk of cardiovascular disease. ^{43, 88} Adverse psychological and sexual effects have not been reported. Since the other constituents of semen are made downstream from the testes, men do not notice a decreased volume or velocity of ejaculate.

Prostate cancer is the most frequent cancer among men, with a lifetime risk of 1 in 11 in the United States. An increased risk of prostate cancer after vasectomy has been reported in several cohort and case-control studies. ^{89, 90, 91} and ⁹² However, there is disagreement because other studies could not support an association between prostate or testicular cancer risk and vasectomy. ^{93, 94, 95} and ⁹⁶ In a very large mixed racial/ethnic (black and white; Chinese-Americans and Japanese-Americans) case-control study of prostate cancer, no statistically significant increase in risk could be identified after vasectomy, including no effect of age at vasectomy or years since vasectomy. ⁹⁷ Reviews of 6 cohort studies and 5 case-control studies concluded that there is no increased risk of cancer of the testis following vasectomy, and consideration of the studies examining the possible association between prostate cancer and vasectomy (6 cohort and 7 case-control studies), found the evidence to be equivocal and weak. ^{98, 99} A meta-analysis of the literature concluded there is no increased risk of prostate cancer in men who have undergone vasectomy. ¹⁰⁰ Observational studies cannot totally avoid potential biases, and the disagreement in regards to prostate cancer is consistent with either no effect or an effect too small to escape confounding biases. It is worth noting that the countries with the highest vasectomy rates (China and India) do not have the highest rates of prostate cancer. Screening for prostate cancer should be no different in men who have had a vasectomy.

Vasectomy reversal is associated with pregnancy rates as high as 70–80%. ¹⁰¹ The prospect for pregnancy diminishes with time elapsed from vasectomy, decreasing significantly to 30% after 10 years; the best results are achieved when reversal is performed within 3 years after vasectomy. ¹⁰²

Induced Abortion

Contraception is more effective and convenient than ever, but our modern methods are far from perfect. Even the most conscientious couples can experience contraceptive failure. In the past, failure of contraception meant another, sometimes unwanted, birth or recourse to dangerous, secret abortion. The most ancient medical texts indicate that abortion has been practiced for thousands of years. Induced abortion did not become illegal until the 19th century, as a result of changes in the teachings of the Catholic Church (life begins at fertilization), and in the U.S., the efforts of the American Medical Association to have greater regulation of the practice of medicine.

In the 1950s, vacuum aspiration led to much safer abortion, and beginning in Asia, induced abortion was gradually legalized in the developed countries of the world. This trend reached the U.S. from Western Europe in the late 1960s when California, New York, and other states rewrote their abortion laws. The U.S. Supreme Court followed the lead of these states in 1973 in the “Roe versus Wade” decision that limited the circumstances under which “the right of privacy” could be restricted by local abortion laws. By 1980, legal abortion became the most common surgical procedure performed in the U.S.

The number of abortions performed in the United States has been decreasing since a peak was reached in 1990, totaling 1.33 million in 1993 and 1.21 million in 1995. ^{103, 104} and ¹⁰⁵ This is partly because the number of pregnancies in the U.S. has been decreasing and the proportion of reproductive age women under age 30 is also decreasing. ¹⁰⁶ About one-third of pregnancies not ending in miscarriage or stillbirth are terminated by abortion. The proportion of abortions performed in hospitals has steadily declined, reaching 7% in 1992. The proportion handled by specialized abortion clinics has increased, while the percentage of abortions performed by physicians in their own offices has remained low, about 3–5% of all abortions. More than 50% of abortions are obtained by women younger than 25 (about 20% under the age of 20), with the rate peaking at ages 18–19, and about 80% are unmarried. ^{103, 105, 107}

A concern in the U.S. is the fact that the decline in the annual number of induced abortions has been greater than the decline in the annual number of births. ¹⁰⁵ Possible explanations include a reduction in unintended pregnancies (better contraception) and a greater willingness to experience a pregnancy; however, another possibility is reduced access to abortion services.

American teenagers are especially dependent on abortion compared with their European counterparts who are better educated about sex and use contraception more often and more effectively. In 1993, 20% of women who obtained legal abortions were adolescents. ¹⁰⁴ In addition, from ages 20–34, American women have the highest proportion of pregnancies aborted compared with other countries, indicating an unappreciated, but real problem, of unintended pregnancy occurring beyond the teenage years. The lack of perfect contraception and imperfect use of contraception will keep abortion with us.

Public health authorities have demonstrated that the legalization of abortion reduced maternal morbidity and mortality more than any single development since the advent of antibiotics to treat puerperal infections and blood banking to treat hemorrhage. The number of American women reported as dying from abortion declined from nearly 300 deaths in 1961, to only 6 in 1985 and 11 in 1991, or about *0.8 deaths for every 100,000 legal abortions*. ¹⁰⁸ For comparison, in 1990, the maternal death rate for childbirth in the U.S. was 10 per 100,000 births, and for ectopic pregnancy, approximately 50 per 100,000 cases. ^{108, 109, 110}

The most important determinants of abortion mortality are duration of gestation and type of anesthesia: later abortions and general anesthesia are more hazardous. ^{111, 112} and ¹¹³ As with mortality, morbidity rates vary primarily with duration of pregnancy, but other factors are important as well, including type of operation, age of patient, type of anesthesia, operator's skill, and method of cervical dilatation. More experienced surgeons and younger, healthier women are less likely to have complications.

Major and minor complications in a series of 170,000 first-trimester abortion patients were as follows: ¹¹⁴

Major Complications (Hospitalization Required)

Retained tissue	—27.7 per 100,000 induced abortions
Sepsis	—21.2
Uterine perforation	—9.4
Hemorrhage	—7.1
Inability to complete	—3.5
Intrauterine plus tubal pregnancy	—2.4

Minor Complications (Managed in Clinic or Office)

Mild infection	—462.0 per 100,000 induced abortions
Reaspiration same day	—180.8
Reaspiration later	—167.8
Cervical stenosis	—16.5
Cervical tear	—10.6
Underestimated gestation	—6.5
Convulsive seizure	—4.0

The possibility that abortion can result in longer-term complications has been examined in over 150 studies. ¹¹⁵ There is no evidence for any adverse consequences of vacuum aspiration abortion for subsequent fertility, ^{116, 117} pregnancies, ^{118, 119} or increased risk for ectopic pregnancy. ^{120, 121} It is not yet clear if second-trimester abortions or several first-trimester abortions can affect the outcome of later pregnancies. However, multiple induced abortions do not increase the risk of a subsequent ectopic pregnancy. ¹²² The long-term effects of second-trimester abortion may depend on the method used. ¹²³ A French study disagrees with these conclusions, finding a slightly increased risk of ectopic pregnancy in women with a prior induced abortion and no previous ectopic pregnancy. ¹²⁴

The possibility that abortion can result in longer-term complications has been examined in over 150 studies. There is no evidence for any adverse consequences of vacuum aspiration abortion for subsequent fertility, ^{116, 117} pregnancies, ^{118, 119} or increased risk for ectopic pregnancy. ^{120, 121} It is not yet clear if second-trimester abortions or several first-trimester abortions can affect the outcome of later pregnancies. However, multiple induced abortions do not increase the risk of a subsequent ectopic pregnancy. ¹²² The long-term effects of second-trimester abortion may depend on the method used. ¹²³ A French study disagrees with these conclusions, finding a slightly increased risk of ectopic pregnancy in women with a prior induced abortion and no previous ectopic pregnancy. ¹²⁴

The psychological sequelae of elective abortion have been studied and debated. The unequivocal evidence indicates that depression is less frequent among women postabortion compared with postpartum, that women denied abortion experience resentment for years, and that the children born after abortion is denied have social, occupational, and interpersonal difficulties lasting into early adulthood. ¹²⁵

Conflicting results have been reported in over 20 studies examining the risk of breast cancer associated with the number of abortions (especially induced abortions) experienced by individual patients. ^{126, 127} Concern for an adverse effect has been based on the theoretical suggestion that a full-term pregnancy protects against breast cancer by invoking complete differentiation of breast cells, but abortion increases the risk by allowing breast cell proliferation in the first-trimester of pregnancy, but not allowing the full differentiation that occurs in later pregnancy. In these studies there has been a major problem of recall bias; women who develop breast cancer are more likely to truthfully reveal their history of induced abortion than healthy women. In studies that avoided recall bias (e.g., by deriving data from national registries instead of personal interviews), the risk of breast cancer was identical in women with and without induced abortions. ^{128, 129}

Safe abortion is still unavailable to many women in parts of Asia, Africa, and Latin America. ¹³⁰ Therefore many women resort to clandestine, unsafe abortions, accounting for about 20% of the world's maternal mortality. These deaths are preventable. Family planning services that provide effective contraceptive choices as well as access to safe abortion early in pregnancy are essential in order for societies to achieve desired fertility rates and a healthy female population.

Preoperative Care of Abortion Patients

Approximately 90% of the 1.2 million induced abortions performed in the U.S. yearly are performed during the first-trimester of pregnancy. ^{103, 131} During the first-trimester, abortion morbidity and mortality rates are less than one tenth those of abortions performed in the later midtrimester. ¹⁰⁸ The vast majority of these operations occur in free-standing abortion clinics, although in recent years, physicians have performed larger numbers in their offices where women are less subject to the harassment that has plagued clinics. ¹⁰³ The safety of outpatient abortion under local anesthesia is well established.

The care of the patient who has decided to terminate a pregnancy begins with the diagnosis of intrauterine pregnancy and an accurate estimate of gestational age. Failure to accomplish this is the most common source of abortion complications and subsequent litigation. Tests for pregnancy, including vaginal ultrasound, should be used when accuracy is difficult.

Nearly all women who want to terminate a pregnancy in the first-trimester are good candidates for an outpatient procedure under local anesthesia. Possible exceptions include patients with severe cardiorespiratory disease, severe anemias or coagulopathies, mental disorders severe enough to preclude cooperation, and excessive concern about operative pain that is not alleviated by reassurance.

Abortions should not be undertaken for women who have known uterine anomalies or leiomyomata or who have previously had difficult first-trimester abortion procedures, unless ultrasonography is immediately available and the surgeon is experienced in its intraoperative use. Previous cesarean section or other pelvic surgery is not a contraindication to outpatient first-trimester abortion.

Counseling Abortion Patients

Counseling has played a critical role in the development of efficient and acceptable abortion services. ¹³² Whether abortion is accomplished in a clinic, a physician's office, or a surgical center, the functions of a counselor must be fulfilled to ensure quality patient care. These include help with decision making, provision of information about the procedure, obtaining informed consent, provision of emotional support for the patient and her family before, during, and after the operation, and providing information about contraception. ¹³³ Referral opportunities should be provided for prenatal care or adoption for women who choose to carry an unplanned pregnancy to term. These responsibilities can be performed by a physician, nurse, psychologist, social worker, or a trained lay person. An informed consent document should unequivocally state the possibilities of common adverse outcomes, such as incomplete abortion, infection, uterine perforation, the need for laparotomy, ectopic pregnancy, and failed abortion. The counselor should document that all preoperative responsibilities have been discharged.

Methods for First-Trimester Abortions

The most widely used technique for first-trimester abortions is vacuum curettage (99% of legal induced abortions in 1995). ¹⁰⁵ The procedure is performed using local anesthesia (a paracervical block). Cervical dilatation is accomplished with tapered Pratt dilators. Some surgeons recommend the preoperative insertion of cervical tents. These are osmotic dilators of dried seaweed or synthetic hydrophilic substances that are left in place from a few hours (synthetic) to overnight (seaweed). ¹³⁴ Mifepristone (RU486), the progesterone antagonist, produces preoperative cervical dilatation equally effectively, and the ease of its single oral dosage makes it a more attractive choice. After the procedure, the patient is observed for 1–2 hours before returning home.

Aspiration abortion is safe and effective, but it is not available everywhere, and some women find it difficult to undergo a surgical procedure or to go to a clinic where they may be subject to loss of privacy or harassment. Nonsurgical methods might make abortion available to more women and improve the circumstances under which pregnancies are terminated. Two such methods have undergone clinical testing. The progesterone antagonist mifepristone (RU486) and the antimetabolite methotrexate have both been demonstrated to induce abortion early in pregnancy when combined with a prostaglandin.

France and China were the first countries to approve the marketing of the medical abortifacient mifepristone (now available in Great Britain and Sweden as well), a synthetic relative of the progestational agents in oral contraceptives. Mifepristone acts primarily, but not totally, as an antiprogesterone agent.

Both progesterone and mifepristone form hormone-responsive element-receptor complexes that are similar, but the mifepristone complex has a slightly different conformational change (in the hormone-binding domain) that prevents full gene activation. The agonistic activity of this progesterone antagonist is due to its ability to activate certain, but not all, of the transcription activation functions on the progesterone receptor. The dimethyl (dimethylaminophenyl) side chain at carbon 11 is the principal factor in its antiprogesterone action. There are three major characteristics of its action that are important: a long half-life, high affinity for the progesterone receptor, and active metabolites.

A single 600 mg oral dose of mifepristone is followed a day later by the administration of a prostaglandin analogue. Several analogues have been used, but the most widely available and best tolerated is misoprostol, 800 mg administered vaginally. ¹³⁵ The combination allows a reduction in dosage of both agents. When administered in the first 8 weeks of pregnancy, this medical termination carries success and complication rates similar to that achieved with vacuum curettage. ¹³⁶ Misoprostol is a stable, orally active synthetic analogue of prostaglandin E₁, available commercially for the treatment of peptic ulcer. Combined with mifepristone, it provides an effective, simple, inexpensive, completely oral or vaginal method. ^{137, 138} In the large U.S. trial of 600 mg mifepristone followed by 400 mg misoprostol orally, there was a 1% failure rate under 7 weeks of pregnancy and 9% from 8 weeks to 9 weeks. ¹³⁹ Based on worldwide experience, the regimen with the least side effects and cost, but equally good efficacy, is a combination of a lower dose of oral mifepristone (200 mg), 36–48 hrs later by the vaginal administration of 800 mg misoprostol. ¹⁴⁰

It is likely that abortion with mifepristone is the result of multiple actions. Although mifepristone does not induce labor, it does open and soften the cervix (this may be an action secondary to endogenous prostaglandins). Its major action is its blockade of progesterone receptors in the endometrium. This leads to a disruption of the embryo and the production of prostaglandins. The disruption of the embryo and perhaps a direct action on the trophoblast lead to a decrease in human chorionic gonadotropin (HCG) and a withdrawal of support from the corpus luteum. The success rate is dependent on the length of pregnancy — the more dependent the pregnancy is on progesterone from the corpus luteum, the more likely the progesterone antagonist, mifepristone, will result in abortion. The combined mifepristone-prostaglandin analogue method is usually restricted to pregnancies that are not beyond 9 weeks gestation. However, a regimen using a higher dose of misoprostol (administered vaginally) achieved a 95% complete abortion rate in women at 9–13 weeks' gestation. ¹⁴¹ Other progesterone antagonists have been developed, but only mifepristone has undergone extensive abortion trials. It seems unlikely that mifepristone could have serious adverse effects, and there have been none reported.

Mifepristone is most noted for its abortifacient activity and the political controversy surrounding it. However, the combination of its agonistic and antagonistic actions can be exploited for many uses, including contraception, therapy of endometriosis, induction of labor, treatment of Cushing's syndrome, and, potentially, treatment of various cancers.

Mifepristone is most noted for its abortifacient activity and the political controversy surrounding it. However, the combination of its agonistic and antagonistic actions can be exploited for many uses, including contraception, therapy of endometriosis, induction of labor, treatment of Cushing's syndrome, and, potentially, treatment of various cancers.

Lack of progesterone antagonists in the U.S. prompted use of methotrexate as an abortifacient in the same dose used to treat ectopic pregnancy, 50 mg intramuscularly per square meter of body surface area.¹⁴² Later, a single 75 mg intramuscular dose was demonstrated to be as effective.¹⁴³ Methotrexate has also been administered orally, in doses of 25 or 50 mg.¹⁴⁴ As with mifepristone, a prostaglandin is added to promote expulsion of the uterine contents, and again vaginal misoprostol is the most useful analogue. The first trials demonstrated that if the prostaglandin (800 mg misoprostol vaginally) was given a week after the injection of methotrexate, this method could be almost as effective as mifepristone.¹⁴⁵ Like mifepristone, efficacy diminishes with advancing gestation beyond 7 weeks (since the last menstrual period).^{146, 147 and 148} Because methotrexate takes longer to act than mifepristone, the prostaglandin is used a week after the initial treatment, and is repeated a day later if expulsion has not occurred. Methotrexate is easily available and inexpensive. It has been used in low doses to treat psoriasis and rheumatoid arthritis, as well as ectopic pregnancy, without adverse effects. It is, however, a known teratogen that can be deadly in high doses, and its use as an abortifacient results in prolonged bleeding and a prolonged time to abortion (up to a month in some cases). Mifepristone is preferred by clinicians who have experience with both methods. There are no direct comparison studies of methotrexate and mifepristone.

Another new approach uses the combination of tamoxifen and misoprostol. The administration of tamoxifen (20 mg daily for 4 days) followed by misoprostol (800 mg vaginally, with a second dose if necessary 24 hours later) was associated with a 92% rate of complete abortion in 100 women with pregnancies less than 9 weeks gestational age.¹⁴⁹

The use of prostaglandin alone has also been pursued.¹⁵⁰ Relatively high success rates have been reported with multiple dosing,¹⁵¹ but the most effective regimen and the best method of administration remain to be determined. The administration of 800 mg misoprostol daily for 3 days has been reported to be very effective late in the first-trimester (10–12 weeks).¹⁵²

One word of caution regarding misoprostol, the synthetic prostaglandin E₁ analogue; it is now recognized that infants born to pregnant women exposed to misoprostol have an increased risk of abnormal vascular development resulting in Möbius's syndrome (congenital facial paralysis with or without limb defects) and defects such as equinovarus and arthrogryposis.^{153, 154} Although the risk is low, this possibility must be considered in decision making when the various methods for first-trimester abortion are considered.

Careful prospective follow-up assessments can detect no health differences in women who have medical abortions compared with women who have abortions by vacuum aspiration.¹⁵⁵

Complications of Abortions

Postoperative complications of elective abortions are classified as either immediate or delayed. Uterine perforation and uterine atony are examples of immediate complications. Delayed complications can occur several hours to several weeks after the operation. These usually present according to the major complaint: bleeding, pain, and continuing symptoms of pregnancy.

Bleeding

By far the most common cause of unusually heavy postabortal bleeding is retained products of conception. Rates in large series vary from 0.2 to 0.6%.¹¹⁴ Patients with retained products of conception occasionally present several weeks after an abortion, but most report excessive bleeding within one week. Severe pain or pelvic tenderness suggests that infection is also present. Treatment is prompt aspiration of the uterus with the largest cannula that will pass the cervix.

Infection

Infection is sometimes marked by uterine bleeding; although without retained products of conception, the volume of blood loss is usually modest. Fever and uterine tenderness are the most common signs of postabortal endometritis, occurring in about 0.5% of cases.¹¹⁴ Some studies indicate that prophylactic antibiotics reduce the risk of postabortal infection.^{156, 158} Most clinicians agree that women at risk of pelvic infection benefit from the use of prophylactic antibiotics prior to induced abortion; others state that women who have not had a previous delivery should receive prophylaxis, while still others believe that all abortion patients would benefit from prophylactic antibiotics.^{158, 159} A meta-analysis of antibiotics at the time of induced abortion unequivocally concluded that prophylactic antibiotics should be routinely used without exceptions.¹⁶⁰ Because both gonorrhea and chlamydia, as well as other organisms, can cause postabortal infections, a tetracycline seems the best drug for prophylaxis. Doxycycline, 100 mg an hour before the abortion and 200 mg 30 minutes afterward, is the most convenient and comprehensive regimen.¹⁶¹ Tetracycline, 500 mg once before and once after the operation, is also acceptable. Metronidazole, 400 mg an hour before and 4–8 hours afterward, has been tested and is effective treatment for patients with bacterial vaginosis detected at the time of abortion.^{162, 163}

Patients who present with uterine tenderness, fever, and bleeding require uterine aspiration as well as antibiotic treatment. Patients who have fevers above 38°C (101°F) and signs of peritoneal inflammation, as well as uterine tenderness, require hospitalization and intravenous antibiotics active against anaerobes, gonorrhea, and chlamydia. Outpatient treatment with doxycycline, 100 mg bid for 14 days, should be reserved for patients whose signs and symptoms are confined to the uterus.

Dysfunctional Uterine Bleeding Following Abortion

Women may present with uterine bleeding but without signs or symptoms of retained products of conception or infection. When these two diagnoses have been ruled out by absence of fever, a closed cervix, and a nontender uterus, the bleeding itself can be treated hormonally. Curettage is rarely necessary unless bleeding is excessive.

Ectopic Pregnancy

Failure to diagnose ectopic pregnancy at the time of induced abortion can cause a patient to return with complaints of persistent bleeding with or without pelvic pain. Careful examination of the uterine aspirate for villi at the time of abortion should make a missed ectopic pregnancy an unusual cause of delayed bleeding. If, however, a patient presents with this possibility, quantitative measurement of chorionic gonadotropin and vaginal ultrasonography should be used for accurate diagnosis and management.

Cervical Stenosis

Patients who experience amenorrhea or hypomenorrhea and cyclic uterine pain after first-trimester abortion may have stenosis of the internal os. This condition occurs in about 0.02% of cases and is more common among women whose abortions are performed in the early first-trimester with a minimum of cervical dilatation and a small diameter, flexible plastic cannula. Possibly, the tip of this type of cannula abrades the internal os, and the minimal dilatation allows the abraded areas to heal in contact. The condition is easily treated with cervical dilatation with Pratt dilators under paracervical block.

Other Late Complications

Amenorrhea, usually without pain, can also be caused by Asherman's syndrome, destruction and scarification of the endometrium. This condition is very rare and usually follows endometrial infection. This problem is best diagnosed and treated at hysteroscopy.

Sensitization of Rh-negative women should be prevented. Approximately 4% of these women become sensitized following an induced abortion (the later the abortion the higher the proportion). Subsequent hemolytic disease of the newborn can be prevented by administering 50 mg Rh immunoglobulin to all Rh-negative, Du-negative women undergoing early abortion. The standard dose is administered for second-trimester abortion.

Abortion in the Second-Trimester

Second-trimester abortions can be accomplished surgically or medically. The surgical procedure is termed dilatation and evacuation (D & E). Several approaches have been used for the medical termination of pregnancy. These include the vaginal, intramuscular, or intra-amniotic administration of prostaglandins and the intra-amniotic injection of hypertonic saline or urea. The D & E procedure is safer and less expensive than the medical methods and is better tolerated (and thus

Abortion in the Second-Trimester

Second-trimester abortions can be accomplished surgically or medically. The surgical procedure is termed dilatation and evacuation (D & E). Several approaches have been used for the medical termination of pregnancy. These include the vaginal, intramuscular, or intra-amniotic administration of prostaglandins and the intra-amniotic injection of hypertonic saline or urea. The D & E procedure is safer and less expensive than the medical methods and is better tolerated (and thus preferred) by patients.^{164, 165, 166}

In 1994, only 4% of induced abortions occurred at 16–20 weeks of gestation and 1% at 21 weeks or later.¹³¹ In 1994, 94% of second-trimester abortions were performed by D & E.

The training, experience, and skills of the surgeon are the primary factors that limit the gestational age at which abortion can be safely performed. Advanced gestational age by itself incurs increased risks for all types of complications. These are multiplied when the duration of pregnancy is discovered, after beginning uterine evacuation, to be beyond the experience and skill of the surgeon or capacity of the equipment. Uterine perforation, infection, bleeding, amniotic fluid embolism, and anesthetic reactions are increased as gestational age increases.¹⁶⁴

When errors in estimating gestational age require the surgeon to use unfamiliar instruments or techniques that are not frequently practiced, the increased duration of the procedure can cause problems. Efforts to sedate or relieve pain by administering additional drugs increase the risk of toxic reactions or overdosage. If a change from local to general anesthesia is undertaken, the patient is at much greater risk of anesthetic complications. Finally, if complications caused by advanced gestational age necessitate transfer of the patient to physicians who are not familiar with uterine evacuation techniques, the patient may undergo unnecessarily extensive surgery, such as hysterectomy, with all the risks inherent in emergency procedures.

Preoperative cervical dilatation with osmotic dilators makes first-trimester abortion safer and easier and is essential for second-trimester abortion. Local anesthesia instead of general anesthesia also makes abortion safer.^{167, 168} Some patients are not good candidates for surgical procedures of any kind under local anesthesia, and others may have special reasons to prefer that an abortion be performed under general anesthesia. Patient requests should be seriously considered, but the clinician also has a responsibility to inform the patient of the risks and benefits of local versus general anesthesia.

In the United Kingdom, prostaglandin analogues are favored for a noninvasive method of second-trimester abortion. A combination of the progesterone antagonist, mifepristone, (a single oral 200 mg dose of mifepristone administered 36 hours before prostaglandin treatment) and an E prostaglandin analogue (misoprostol) administered orally or vaginally is highly effective, and the combination allows a lesser dose of both agents, which results in fewer side effects.¹⁶⁹ In addition, this combination does not require the use of cervical laminaria for dilatation.

Contraception is commonly viewed as a modern event, a recent development in human history. On the contrary, efforts to limit reproduction predate our ability to write about it. It is only oral contraception with synthetic sex steroids that is recent.

History^{1, 2 and 3}

It wasn't until the early 1900s, that inhibition of ovulation was observed to be linked to pregnancy and the corpus luteum. Ludwig Haberlandt, professor of physiology at the University of Innsbruck, Austria, was the first to demonstrate that ovarian extracts given orally could prevent fertility (in mice). In the 1920s, Haberlandt and a Viennese gynecologist, Otfried Otto Fellner, were administering steroid extracts to a variety of animals and reporting the inhibition of fertility. By 1931, Haberlandt was proposing the administration of hormones for birth control. An extract was produced, named Infecundin, ready to be used, but Haberlandt's early death in 1932, at age 47, brought an end to this effort. Fellner disappeared after the annexation of Austria to Hitler's Germany.

The concept was announced by Haberlandt, but steroid chemistry wasn't ready. The extraction and isolation of a few milligrams of the sex steroids required starting points measured in gallons of urine or thousands of pounds of organs. Edward Doisy processed 80,000 sow ovaries to produce 12 mg of estradiol.

Russell Marker

The supply problem was solved by an eccentric chemist, Russell E. Marker, who completed his thesis, but not his course work, for his Ph.D. Marker, born in 1902 near Hagerstown, Maryland, received his Bachelor's degree in organic chemistry and his Master's degree in colloidal chemistry from the University of Maryland. After leaving the University of Maryland, Marker worked with the Ethyl Gasoline Corporation, and in 1926, developed the process of octane rating, based on the discovery that knocking in gasoline was due to hydrocarbons with an uneven number of carbons.

From 1927 to 1935, Marker worked at the Rockefeller Institute, publishing a total of 32 papers on configuration and optical rotation as a method of identifying compounds. He became interested in solving the problem of producing abundant and cheap amounts of progesterone, but he was told to continue with his work in optical technology. In 1935, he moved to Pennsylvania State University at a reduced salary, but with the freedom to pursue any field of research. At that time, it required the ovaries from 2500 pregnant pigs to produce 1 mg of progesterone. In 1939, Marker devised the method (called the Marker degradation) to convert a sapogenin molecule into a progestin. Marker became convinced that the solution to the problem of obtaining large quantities of steroid hormones was to find plants (in the family that includes the lily, the agave, and the yam) that contained sufficient amounts of diosgenin, a plant steroid (a sapogenin) that could be used as a starting point for steroid hormone production. This conviction was strengthened with his discovery that a species of *Trillium*, known locally as Beth's root, was collected in North Carolina and used in the preparation of Lydia Pinkham's Compound, popular at the time to relieve menstrual troubles. The active ingredient in Beth's root was diosgenin, but the rhizome was too small to provide sufficient amounts for commercial production. Marker's search for an appropriate plant took him to California, Arizona, and Texas.

On a visit to Texas A & M University, Marker found a picture of a large dioscorea (*Dioscorea mexicana*) in a book that he just happened to pick up and browse through while spending the night at the home of a retired botanist. After returning to Pennsylvania, he decided to go to Veracruz, Mexico (it took 3 days by train), to search for this dioscorea. He made several attempts in 1941 and early 1942, but was frustrated first by the lack of a plant-collecting permit from the Mexican government and then by his failure to find the plant. He remembered that the book with the picture reported that this dioscorea was known locally as "cabeza de negro," black tubers that grew near Orizaba and Cordoba. Marker took a bus to Cordoba, and near Orizaba, an Indian who owned a small store brought him two plants. Each tuber was 9–12 inches high and consisted of white material like a turnip, used by local Mexicans as a poison to catch fish.

Marker managed to get one bag of tubers back to Pennsylvania State University and isolated diosgenin. Unable to obtain support from the pharmaceutical industry, Marker used his life savings, and in 1942, he returned to Veracruz, collected the roots of the Mexican yam, and prepared a syrup from the roots. Back in Pennsylvania with his 5-gallon cans of syrup, Marker worked out the degradation of diosgenin to progesterone. One 5-gallon can yielded 3 kg of progesterone. United States pharmaceutical companies still refused to back Marker, and even the University refused, despite Marker's urging, to patent the process.

In 1943, Marker resigned from Pennsylvania State University and went to Mexico where he collected the roots of *Dioscorea mexicana*, 10 tons worth! Looking through the yellow pages in a Mexico City telephone directory, Marker found a company called Laboratorios Hormona, owned by a lawyer, Emeric Somlo, and a physician, Frederick Lehman. Marker arranged a meeting, and the three agreed to form a Mexican company to produce hormones. In an old pottery shed in Mexico City (the laboratories of Laboratorios Hormona), in two months, he prepared several pounds of progesterone (worth \$300,000) with the help of four young women who had little education and spoke no English (Marker did not speak Spanish). The two partners and Marker formed a company in 1944 that they called Syntex (from *synthesis* and *Mexico*). In 1944, Marker produced over 30 kg of progesterone. The price of progesterone fell from \$200 to \$50 a gram.

During this time, Marker received expenses, but he was not given his share of the profits or the 40% share of stock due to him. Failing to reach a settlement, Marker left Syntex after only one year and started a new company in Texcoco, called Botanica-Mex. He changed to *Dioscorea barbasco*, which gave a greater yield of diosgenin, and the price of progesterone dropped to \$10 a gram, and later to \$5. This company was allegedly harassed (legally and physically) by Syntex, and in 1946, sold, eventually reaching ownership by Organon of Holland, which still uses it.

In 1949, Marker retired to Pennsylvania to devote the rest of his life to making replicas of antique works in silver, a successful business that allowed him, in the 1980s, to endow scientific lectureships at both Pennsylvania State University and the University of Maryland. However, he took his know-how with him. Fortunately for Syntex, he had published a scientific description of his process, and there still was no patent on his discoveries. Syntex recruited George Rosenkranz, a Hungarian immigrant living in Cuba, to reinstitute the commercial manufacture of progesterone (and testosterone) from Mexican yams, a task that took him (with the help of the women left behind by Marker) 2 years.

In 1970, the Mexican government recognized Marker and awarded him the Order of the Aztec Eagle; he declined. In 1984, Pennsylvania State University established the annual Marker Lectures in Science, and in 1987, the Russell and Mildred Marker Professorship of Natural Product Chemistry. In 1987, Marker was granted an honorary Doctorate in Science from the University of Maryland, the degree he failed to receive in 1926. At the age of 92, Russell Earl Marker died in Wernersville, Pennsylvania, in 1995, from complications after a broken hip.

Carl Djerassi⁴

The Djerassi family lived in Bulgaria for hundreds of years after escaping Spain during the Inquisition. Carl Djerassi, the son of a Bulgarian physician, was born in Vienna (as was his physician mother). Djerassi, at the age of 16, and his mother emigrated to the United States in 1939. A Jewish refugee aid organization placed Djerassi with a family in Newark, New Jersey. With a scholarship to Tarkio College in Tarkio, Missouri, he was exposed to middle America, where he earned his way giving talks to church groups about Bulgaria and Europe. His education was further supported by another scholarship from Kenyon College in Ohio, where he pursued chemistry. After a year working for CIBA, Djerassi received his graduate degree from the University of Wisconsin. Returning to CIBA and being somewhat unhappy, he responded to an invitation to visit Syntex. Rosenkranz proposed that Djerassi head a research group to concentrate on the synthesis of cortisone.

In 1949, it was discovered that cortisone relieved arthritis, and the race was on to develop an easy and cheap method to synthesize cortisone. Carl Djerassi, at age 26, joined Syntex to work on this synthesis using the Mexican yam plant steroid diosgenin as the starting point. This was quickly achieved (in 1951), but soon after, an even better method of cortisone production using microbiologic fermentation was discovered at Upjohn. This latter method used progesterone as the starting point, and, therefore, Syntex found itself as the key supplier to other companies for this important process, at the rate of 10 tons of progesterone per year and a price of 48 cents per gram.

Djerassi and other Syntex chemists then turned their attention to the sex steroids. They discovered that the removal of the 19-carbon from yam-derived progesterone increased the progestational activity of the molecule. Ethisterone had been available for a dozen years, and the Syntex chemists reasoned that removal of the 19-carbon would increase the progestational potency of this orally active compound. In 1951, norethindrone was synthesized; the patent for this drug is the first patent for a drug listed in the National Inventor's Hall of Fame in Akron, Ohio. A closely related compound, norethynodrel, was actually the first orally active progestational agent to receive a patent, assigned to Frank Colton, a chemist at G.D. Searle & Company.

Gregory Pincus

Gregory Goodwin (Goody) Pincus was born in 1903 in New Jersey, the son of Russian Jewish immigrants who lived on a farm colony founded by a German-Jewish philanthropic organization. Pincus was the oldest of 6 children and grew up in a home of intellectual curiosity and energy, but even his family regarded him as a

genius.

Pincus graduated from Cornell and went to Harvard to study genetics, joining Hudson Hoagland and B.F. Skinner as graduate students of W.J. Crozier in physiology, receiving degrees in 1927. Crozier's hero was Jacques Loeb who discovered artificial parthenogenesis working with sea urchin eggs. Most importantly, Loeb was a strong believer in applying science to improve human life. Thus, Crozier, influenced by Loeb, taught Pincus, Hoagland, and Skinner (respectively, in reproductive biology, neurophysiology, and psychology) to apply science to human problems. This was to be the cornerstone of Pincus's own philosophy.

Hoagland, after a short stay at Harvard, spent a year in Cambridge, England, and then moved to Clark University in Worcester, Massachusetts, to be the chair of biology at the age of 31. Pincus went to England and Germany, and returned to Harvard as an assistant professor of physiology.

Pincus performed pioneering studies of meiotic maturation in mammalian oocytes, in both rabbit and human oocytes. In 1934, Pincus reported the achievement of in vitro fertilization of rabbit eggs, earning him a headline in the New York Times that alluded to Haldane and Huxley. An article in *Colliers* depicted him as an evil scientist. By 1936, Harvard had cited Pincus's work as one of the university's outstanding scientific achievements of all time, but Harvard denied him tenure in 1937.

At Clark University, Hudson Hoagland was in constant conflict with the president of the university, Wallace W. Atwood, the senior author of a widely used textbook on geography. In 1931, the Department of Biology consisted of one faculty member and his graduate student, and their chair, Hudson Hoagland. Hoagland, upset and angry over Harvard's refusal to grant tenure to his friend (suspecting that this was because of anti-Semitism), invited Pincus to join him.

Hoagland secured funds for Pincus from philanthropists in New York City, enough for a laboratory and an assistant. This success impressed the two men, especially Hoagland, planting the idea that it would be possible to support research with private money.

Min-Chueh Chang received his Ph.D. degree from Harvard on an infamous day, December 7, 1941, and thus he was forced to remain in this country. He was drawn to Pincus because of Pincus's book, *The Eggs of Mammals*, published in 1936, a book that had a major impact on biologists at that time. The successful recruitment of M-C Chang by Hoagland and Pincus was to pay great dividends.

Soon Hoagland had put together a group of outstanding scientists, but because of his on-going antagonism with President Atwood, the group was denied faculty status. Working in a converted barn, they were totally supported by private funds. By 1943, 12 of Clark's 60 faculty were in the Department of Biology.

Frustrated by the politics of academia, Hoagland and Pincus (who both enjoyed stepping outside of convention) had a vision of a private research center devoted to their philosophy of applied science. Indeed, the establishment of the Worcester Foundation for Experimental Biology, in 1944, can be attributed directly to Hoagland and Pincus, their friendship for each other, their confidence, enthusiasm, ambition, and drive. It was their spirit that turned many members of Worcester society into financial supporters of biologic science. Hoagland and Pincus accomplished what they set out to do. They created and sustained a vibrant, productive scientific institution in which it was a pleasure to work.

Although named the Worcester Foundation for Experimental Biology, the Foundation was located in the summer of 1945 across Lake Quinsigamond in a house on an estate in Shrewsbury. The Board of Trustees was chaired by Harlow Shapley, a distinguished astronomer, vice-chaired by Rabbi Levi Olan, and included 3 Nobel laureates and a group of Worcester businessmen.

From 1945 to the death of Pincus in 1967, the staff grew from 12 to 350 (scientists and support people), 36 of whom were independently funded and 45 were postdoctoral fellows. The annual budget grew from \$100,000 to \$4.5 million. One hundred acres of adjoining land were acquired, and the campus grew to 11 buildings. In its first 25 years, approximately 3000 scientific papers were published.

But in those early years, Pincus was the animal keeper, Mrs. Hoagland the bookkeeper, M-C Chang was the night watchman, and Hoagland mowed the lawn. During the years of World War II, Pincus and Hoagland combined their interests in hormones and neurophysiology to focus on stress and fatigue in industry and the military.

The initial discoveries that led to an oral contraceptive can be attributed to M-C Chang (also the first to describe the capacitation process of sperm). In 1951, he confirmed the work of Makepeace (in 1937) demonstrating that progesterone could inhibit ovulation in rabbits. When norethindrone and norethynodrel became available, Chang found them to be virtually 100% effective in inhibiting ovulation when administered orally to rabbits.

Katherine Dexter McCormick was a very rich woman; in 1904, she married Stanley McCormick, the son of Cyrus McCormick, the founder of International Harvester. She was also intelligent, the second woman to graduate from the Massachusetts Institute of Technology, socially conscious, and a generous contributor to family planning efforts. McCormick's husband suffered from schizophrenia, and she established the Neuroendocrine Research Foundation at Harvard to study schizophrenia. This brought her together with Hoagland who told her of the work being done by Chang and Pincus.

Pincus attributed his interest in contraception to his growing appreciation for the world's population problem, and to a 1951 visit with Margaret Sanger, at that time president of the Planned Parenthood Federation of America. At that visit, Sanger expressed hope that a method of contraception could be derived from the laboratory work being done by Pincus and Chang.

In 1952, Margaret Sanger brought Pincus and Katherine McCormick together. During this meeting, Pincus formulated his thoughts derived from his mammalian research. He envisioned a progestational agent in pill form as a contraceptive, acting like progesterone in pregnancy. Sanger and McCormick provided a research grant for further animal research. By the time of her death, McCormick had contributed more than \$2 million to the Worcester Foundation, and left another \$1 million in her will. In his book, *The Control of Fertility*, published in 1965, Pincus wrote: "This book is dedicated to Mrs. Stanley McCormick because of her steadfast faith in scientific inquiry and her unswerving encouragement of human dignity."⁵

It was Pincus who made the decision to involve a physician because he knew human experiments would be necessary. John Rock, chief of gynecology and obstetrics at Harvard, met Pincus at a scientific conference and discovered their mutual interest in reproductive physiology. Rock and his colleagues pursued Pincus's work. Using oocytes from oophorectomies, they reported in vitro fertilization in 1944, probably the first demonstration of fertilization of human oocytes in vitro. Rock was interested in the work with progestational agents, not for contraception however, but because he hoped the female sex steroids could be used to overcome infertility.

Sanger and McCormick needed some convincing that Rock's Catholicism would not be a handicap, but they were eventually won over because of his stature. Rock was a physician who literally transformed his personal values in response to his recognition of the problems secondary to uncontrolled reproduction. With the help of Luigi Mastroianni, the first administration of synthetic progestins to women was to Rock's patients in 1954. Of the first 50 patients to receive 10–40 mg of synthetic progestin (a dose extrapolated from the animal data) for 20 days each month, all failed to ovulate during treatment (causing Pincus to begin referring to the medication as "the pill"), and 7 of the 50 became pregnant after discontinuing the medication (pleasing Rock who all along was motivated to treat infertility).

Pincus and Chang decided to announce their findings at the International Planned Parenthood meeting in Tokyo, in the fall of 1955. Rock refused to join in this effort, believing that Pincus and Chang were moving too fast. Despite this disagreement (which apparently was spirited and strong), it was done, and the Tokyo presentation generated worldwide publicity.

In 1956, with Celso-Ramon Garcia and Edris Rice-Wray, working in Puerto Rico, the first human trial was performed. The initial progestin products were contaminated with about 1% mestranol. In the amounts being used, this added up to 50–500 µg of mestranol, a sufficient amount of estrogen to inhibit ovulation by itself. When efforts to provide a more pure progestin lowered the estrogen content and yielded breakthrough bleeding, it was decided to retain the estrogen for cycle control, thus establishing the principle of the combined estrogen-progestin oral contraceptive. Early clinical trials were conducted by J.W. Goldzieher in San Antonio and E.T. Tyler in Los Angeles.

Pincus, a longtime consultant to Searle, picked the Searle compound for extended use, and with great effort, convinced Searle that the commercial potential of an oral contraceptive warranted the risk of possible negative public reaction. Pincus also convinced Rock, and together they pushed the U.S. Food and Drug Administration for acceptance of oral contraception. In 1957, Enovid was approved for the treatment of miscarriages and menstrual disorders, and in 1960, for contraception. Neither Pincus nor the Worcester Foundation got rich on the pill; alas, there was no royalty agreement.

The Pill did bring Pincus fame and travel. There is no doubt that he was very much aware of the accomplishment and its implications. As he traveled and lectured in 1957, he said: "How a few precious facts obscurely come to in the laboratory may resonate into the lives of men everywhere, bring order to disorder, hope to the hopeless, life to the dying. That this is the magic and mystery of our time is sometimes grasped and often missed, but to expound it is inevitable."⁵

Pincus was the perfect person to bring oral contraception into the public world, at a time when contraception was a private, suppressed subject. Difficult projects require people like Pincus. A scientific entrepreneur, he could plow through distractions. He could be hard and aggressive with his staff. He could remain focused. He hated to lose, even in meaningless games with his children. Yet he combined a gracious, charming manner with his competitive hardness. He was filled with the kind of self-confidence that permits an individual to forge ahead, to translate vision into reality. Pincus died in 1967 (as did Katherine McCormick at the age of 92), of aplastic anemia that some have argued was caused by his long-term exposure to solvents and chemicals. Rock died in 1984, at the age of 94, and Chang, in 1991, was buried at the age of 82, in Shrewsbury, near his laboratory and close to the grave of Pincus.

Pincus wrote his book, *The Control of Fertility*, in 1964–65, only because "a break came in the apparent dam to publication on reproductive physiology and particularly its subdivisions concerned with reproductive behavior, conception, and contraception."⁵

"We have conferred and lectured in many countries of the world, seen at first hand the research needs and possibilities in almost every European, Asiatic, Central, and South American country. We have faced the hard fact of overpopulation in country after country, learned of the bleak demographic future, assessed the prospects for the practice of efficient fertility control. This has been a saddening and a heartening experience; saddening because of the sight of continuing poverty and misery, heartening because of the dedicated colleagues and workers seeking to overcome the handicap of excess fertility and to promote healthy reproductive function. Among these we have made many friends, found devoted students."⁵

Syntex, a wholesale drug supplier, was without marketing experience or organization. By the time Syntex had secured arrangements with Ortho for a sales outlet, Searle marketed Enovid in 1960 (150 µg mestranol and 9.85 mg norethynodrel). Ortho-Novum, using norethindrone from Syntex, appeared in 1962. Wyeth Laboratories introduced norgestrel in 1968, the same year in which the first reliable prospective studies were initiated. It was not until the late 1970s that a dose-response relationship between problems and the amount of steroids in the pill was appreciated. As a result, health care providers and patients, over the years, have been confronted by a bewildering array of different products and formulations. The solution to this clinical dilemma is relatively straightforward: the theme of this chapter, use the lowest doses that provide effective contraception.

Pharmacology of Steroid Contraception

The Estrogen Component of Combination Oral Contraceptives

Estradiol is the most potent natural estrogen and is the major estrogen secreted by the ovaries. The major obstacle to the use of sex steroids for contraception was inactivity of the compounds when given orally. A major breakthrough occurred in 1938 when it was discovered that the addition of an ethinyl group at the 17 position made estradiol orally active. Ethinyl estradiol is a very potent oral estrogen and is one of the two forms of estrogen in every oral contraceptive. The other estrogen is the 3-methyl ether of ethinyl estradiol, mestranol.

Mestranol and ethinyl estradiol are different from natural estradiol and must be regarded as pharmacologic drugs. Animal studies have suggested that mestranol is weaker than ethinyl estradiol, because mestranol must first be converted to ethinyl estradiol in the body. Indeed, mestranol will not bind to the cellular estrogen receptor. Therefore, unconjugated ethinyl estradiol is the active estrogen in the blood for both mestranol and ethinyl estradiol. In the human body, differences in potency between ethinyl estradiol and mestranol do not appear to be significant, certainly not as great as indicated by assays in rodents. This is now a minor point because all of the low-dose oral contraceptives contain ethinyl estradiol.

The metabolism of ethinyl estradiol (particularly as reflected in blood levels) varies significantly from individual to individual, and from one population to another.⁶ There is even a range of variability at different sampling times within the same individual. Therefore, it is not surprising that the same dose can cause side effects in one individual and none in another.

The estrogen content (dosage) of the pill is of major clinical importance. Thrombosis is one of the most serious side effects of the pill, playing a key role in the increased risk of death (in the past with high doses) from a variety of circulatory problems. This side effect is related to estrogen, and it is dose related. Therefore, the dose of estrogen is a critical issue in selecting an oral contraceptive.

The Progestin Component of Combination Oral Contraceptives

The discovery of ethinyl substitution and oral potency led (at the end of the 1930s) to the preparation of ethisterone, an orally active derivative of testosterone. In 1951, it was demonstrated that removal of the 19-carbon from ethisterone to form norethindrone did not destroy the oral activity, and most importantly, it changed the major hormonal effect from that of an androgen to that of a progestational agent. Accordingly, the progestational derivatives of testosterone were designated as 19-nortestosterones (denoting the missing 19-carbon). The androgenic properties of these compounds, however, were not totally eliminated, and minimal anabolic and androgenic potential remains within the structure.

The "impurity" of 19-nortestosterone, i.e., androgenic as well as progestational effects, was further complicated in the past by a belief that they were metabolized within the body to estrogenic compounds. This question was restudied, and it was argued that the previous evidence for metabolism to estrogenic compounds was due to an artifact in the laboratory analysis. More recent studies indicate that norethindrone can be converted to ethinyl estradiol; however, the rate of this conversion is so low that insignificant amounts of ethinyl estradiol can be found in the circulation or urine following the administration of the commonly used doses of norethindrone.⁷ Any estrogenic activity, therefore, would have to be due to a direct effect. In animal and human studies, however, only norethindrone, norethynodrel, and ethynodiol diacetate have estrogen activity, and it is very slight due to weak binding to the estrogen receptor.⁸ Clinically, androgenic and estrogenic activities of the progestin component are, therefore, insignificant due to the low dosage in the current oral contraceptives. As with the estrogen component, serious side effects

have been related to the high doses of progestins used in old formulations, not the particular progestin, and routine use of oral contraceptives should now be limited to the low-dose products.

The norethindrone family contains the following 19-nortestosterone progestins: norethindrone, norethynodrel, norethindrone acetate, ethynodiol diacetate, lynestrenol, norgestrel, norgestimate, desogestrel, and gestodene.

Most of the progestins closely related to norethindrone are converted to the parent compound. Thus the activity of norethynodrel, norethindrone acetate, ethynodiol diacetate, and lynestrenol is due to rapid conversion to norethindrone.

Norgestrel is a racemic equal mixture of the dextrorotatory enantiomer and the levorotatory enantiomer. These enantiomers are mirror images of each other and rotate the plane of polarized light in opposite directions. The dextrorotatory form is known as d-norgestrel, and the levorotatory form is l-norgestrel (known as levonorgestrel). Levonorgestrel is the active isomer of norgestrel.

Desogestrel undergoes two metabolic steps before the progestational activity is expressed in its active metabolite, 3-keto-desogestrel. This metabolite differs from levonorgestrel only by a methylene group in the 11 position. Gestodene differs from levonorgestrel by the presence of a double bond between carbons 15 and 16; thus, it is D-15 gestodene. It is metabolized into many derivatives with progestational activity, but not levonorgestrel. Several metabolites contribute to the activity of norgestimate, including 17-deacetylated norgestimate, 3-keto norgestimate, and levonorgestrel. Although norgestimate is a “new” progestin, epidemiologists have included it in the oral contraceptive second generation family because its activity is believed to be largely due to levonorgestrel and levonorgestrel metabolites, although this may not be totally accurate.^{9, 10}

Definitions Used in Epidemiologic Studies

Low-Dose Oral Contraceptives — Products containing less than 50 µg ethinyl estradiol

First Generation Oral Contraceptives — Products containing 50 µg or more of ethinyl estradiol

Second Generation Oral Contraceptives — Products containing levonorgestrel, norgestimate, and other members of the norethindrone family and 30 or 35 µg ethinyl estradiol

Third Generation Oral Contraceptives — Products containing desogestrel or gestodene with 20 or 30 µg ethinyl estradiol

A second group of progestins became available for use when it was discovered that acetylation of the 17-hydroxy group of 17-hydroxyprogesterone produced an orally active but weak progestin. An addition at the 6 position is necessary to give sufficient progestational strength for human use, probably by inhibiting metabolism.

Derivatives of progesterone with substituents at the 17 and 6 positions include the widely used medroxyprogesterone acetate.

Potency

For many years, clinicians, scientists, medical writers, and even the pharmaceutical industry have attempted to assign potency values to the various progestational components of oral contraceptives. An accurate assessment, however, has been difficult to achieve for many reasons. Progestins act on numerous target organs (e.g., the uterus, the mammary glands, and the liver), and potency varies depending upon the target organ and end point being studied. In the past, animal assays, such as the Clauberg test (endometrial change in the rabbit) and the rat ventral prostate assay, were used to determine progestin potency. Although these were considered acceptable methods at the time, a better understanding of steroid hormone action and metabolism, and a recognition that animal and human responses differ, have led to greater reliance on data collected from human studies.

Historically, this has been a confusing issue because publications and experts used potency ranking to provide clinical advice. There is absolutely no need for confusion. Oral contraceptive progestin potency is no longer a consideration when it comes to prescribing oral contraception, because the potency of the various progestins has been accounted for by appropriate adjustments of dose. In other words, the biologic effect (in this case the clinical effect) of the various progestational components in current low-dose oral contraceptives is approximately the same. The potency of a drug does not determine its efficacy or safety, only the amount of a drug required to achieve an effect.

Clinical advice based on potency ranking is an artificial exercise that has not stood the test of time. There is no clinical evidence that a particular progestin is better or worse in terms of particular side effects or clinical responses. Thus oral contraceptives should be judged by their clinical characteristics: efficacy, side effects, risks, and benefits. Our progress in lowering the doses of the steroids contained in oral contraceptives has yielded products with little serious differences. Potency is no longer an important clinical issue.

New Progestins

Probably the greatest influence on the effort that yielded the new progestins was the belief throughout the 1980s that androgenic metabolic effects were important, especially in terms of cardiovascular disease. Cardiovascular side effects are now known to be due to a dose-related stimulation of thrombosis by estrogen. In the search to find compounds that minimize androgenic effects, however, the pharmaceutical companies succeeded.

The new progestins include desogestrel, gestodene, and norgestimate, and even newer progestins are in development.¹¹ In regard to cycle control (breakthrough bleeding and amenorrhea), the new formulations are comparable with previous low-dose products. All progestins derived from 19-nortestosterone have the potential to decrease glucose tolerance and increase insulin resistance. The impact on carbohydrate metabolism of the previous low-dose formulations was very minimal, and the impact of the new progestins is negligible. Most changes are not statistically significant, and when they are, they are so subtle as to be of no clinical significance. The decreased androgenicity of the progestins in the new products is reflected in increased sex hormone-binding globulin and decreased free testosterone concentrations to a greater degree than the older oral contraceptives. This difference may be of greater clinical value in the treatment of acne and hirsutism, but appropriate comparative clinical studies to document a better response have not been performed.

The new progestins, because of their reduced androgenicity, predictably do not adversely affect the cholesterol-lipoprotein profile. Indeed, the estrogen-progestin balance of combined oral contraceptives containing one of the new progestins may even promote favorable lipid changes. Thus, the new formulations have the potential to offer protection against cardiovascular disease, an important consideration as we enter an era of women using oral contraceptives for longer durations and later in life. But one must be cautious regarding the clinical significance of subtle changes, and it will be difficult to accumulate data with these rare events.

New Formulations

The multiphasic preparation alters the dosage of both the estrogen and progestin components periodically throughout the pill-taking schedule. The aim of these new formulations is to alter steroid levels in an effort to achieve lesser metabolic effects and minimize the occurrence of breakthrough bleeding and amenorrhea, while maintaining efficacy. We are probably at or very near the lowest dose levels that can be achieved without sacrificing efficacy. Metabolic studies with the multiphasic preparations indicate no differences or slight improvements over the metabolic effects of low-dose monophasic products.

Mechanism of Action

The combination pill, consisting of estrogen and progestin components, is given daily for 3 of every 4 weeks. The combination pill prevents ovulation by inhibiting gonadotropin secretion via an effect on both pituitary and hypothalamic centers. The progestational agent in the pill primarily suppresses luteinizing hormone (LH) secretion (and thus prevents ovulation), while the estrogenic agent suppresses follicle-stimulating hormone (FSH) secretion (and thus prevents the selection and emergence of a dominant follicle). Therefore, the estrogenic component significantly contributes to the contraceptive efficacy. However, even if follicular growth and development were not sufficiently inhibited, the progestational component would prevent the surge-like release of LH necessary for ovulation.

The estrogen in the pill serves two other purposes. It provides stability to the endometrium so that irregular shedding and unwanted breakthrough bleeding can be minimized; and the presence of estrogen is required to potentiate the action of the progestational agents. The latter function of estrogen has allowed reduction of the progestational dose in the pill. The mechanism for this action is probably estrogen's effect in increasing the concentration of intracellular progestational receptors. Therefore, a minimal pharmacologic level of estrogen is necessary to maintain the efficacy of the combination pill.

Because the effect of a progestational agent will always take precedence over estrogen (unless the dose of estrogen is increased many, many-fold), the endometrium, cervical mucus, and perhaps tubal function reflect progestational stimulation. The progestin in the combination pill produces an endometrium that is not receptive to ovum implantation, a decidualized bed with exhausted and atrophied glands. The cervical mucus becomes thick and impervious to sperm transport. It is possible that progestational influences on secretion and peristalsis within the fallopian tubes provide additional contraceptive effects. Even if there is some ovarian follicular activity (especially with the lowest dose products), these actions serve to ensure good contraceptive efficacy.¹²

Efficacy

In view of the multiple actions of oral contraceptives, it is hard to understand how the omission of a pill or two can result in a pregnancy. Indeed, careful review of failures suggests that pregnancies usually occur because initiation of the next cycle is delayed allowing escape from ovarian suppression. Strict adherence to 7 pill-free days is critical in order to obtain reliable, effective contraception. For this reason, the 28-day pill package, incorporating 7 pills that do not contain steroids, is a very useful aid to ensure adherence to the necessary schedule. The most prevalent problems that can be identified associated with apparent oral contraceptive failures are vomiting and diarrhea.^{13 14} **Even if no pills have been missed, patients should be instructed to use a backup method for at least 7 days after an episode of gastroenteritis.**

The contraceptive effectiveness of the new progestin oral contraceptives, multiphasic formulations, and lowest estrogen dose products are unequivocally comparable with older low-dose (less than 50 µg estrogen) and higher dose monophasic combination birth control pills.¹² While carefully monitored studies with motivated subjects achieve an annual failure rate of 0.1%, typical usage is associated with a 3.0% failure rate during the first year of use.¹⁵ Efficacy decreases slightly when the estrogen component is removed, and only a small dose of the progestin is administered (the progestin-only minipills).

Failure Rates During the First Year of Use, United States¹⁶

Method	Percent of Women with Pregnancy Lowest Expected	Typical
No method	85.0%	85.0%
Combination Pill	0.1	3.0
Progestin only	0.5	3.0
IUDs	1.5	2.0
Progesterone IUD		

Levonorgestrel IUD	0.6	0.8
Copper T 380A	0.1	0.1
Norplant	0.05	0.05
Female sterilization	0.05	0.05
Male sterilization	0.1	0.15
Depo-Provera	0.3	0.3
Spermicides	6.0	26.0
Periodic abstinence Calendar	9.0	25.0
Ovulation method	3.0	
Symptothermal	2.0	
Post-ovulation	1.0	
Withdrawal	4.0	19.0
Cervical cap Parous women	26.0	40.0
Nulliparous women	9.0	20.0
Sponge Parous women	9.0	28.0
Nulliparous women	6.0	18.0
Diaphragm and spermicides	6.0	20.0
Condom Male	3.0	14.0
Female	5.0	21.0

Metabolic Effects of Oral Contraception

Cardiovascular Disease

In October, 1995, the United Kingdom Committee on Safety of Medicines sent a letter to all U.K. physicians and pharmacists stating that women taking oral contraceptives containing desogestrel or gestodene should be urged to complete their current cycle and to continue a formulation with these progestins only if prepared to accept an increased risk of venous thromboembolism. The Committee on Safety of Medicines took this action because of observational studies that indicated a two-fold increase in the risk of venous thromboembolism when desogestrel- and gestodene-containing contraceptives were compared with products with other progestins (mostly levonorgestrel). This action and the studies on which it was based immediately became controversial. The controversy went beyond the validity of the epidemiologic data. The publicity surrounding these events reverberated throughout Europe, leading to an immediate overall decrease in oral contraceptive use, an increase in unwanted pregnancies, and an increase in induced abortions. [17](#), [18](#)

The controversy involving new progestin oral contraceptives that began in late 1995, continued through 1996, and began to reach resolution in 1997. The fundamental question is whether oral contraceptives containing desogestrel and gestodene have a different risk of thrombosis compared with oral contraceptives containing older progestins. Thrombosis can be divided into two major categories, venous thromboembolism and arterial thrombosis. Venous thromboembolism includes both deep vein thrombosis and pulmonary embolism. Arterial thrombosis includes acute myocardial infarction and stroke.

The Coagulation System

The goal of the clotting mechanism is to produce thrombin, which converts fibrinogen to a fibrin clot. Thrombin is generated from prothrombin by factor Xa in the presence of factor V, calcium, and phospholipids. The vitamin K-dependent factors include factors VII, IX, and X, as well as prothrombin. Antithrombin III is one of the body's natural anticoagulants, an irreversible inhibitor of thrombin and factors IXa, Xa, and XIa. Protein C and protein S are two other major inhibitors of coagulation and are also vitamin K-dependent. Protein C, and its helper, Protein S, inhibit clotting at the level of factors V and VIII. Tissue plasminogen activator (t-PA) is produced by endothelial cells and released when a clot forms. Both t-PA and plasminogen bind to the fibrin clot. The t-PA converts the plasminogen to plasmin which lyses the clot by degrading the fibrin. Deficiencies of antithrombin III, protein C, and protein S are inherited in an autosomal dominant pattern, accounting for 10–15% of familial thrombosis. A mutation in the prothrombin gene and the factor V Leiden mutation are the most common inherited causes of venous thromboembolism. [19](#)

An inherited resistance to activated protein C has been identified as the basis for about 50% of cases of familial venous thrombosis, due in almost all cases to a gene alteration recognized as the factor V Leiden mutation. [20](#), [21](#) The factor V Leiden mutation is found in approximately 30% of individuals who develop venous thromboembolism. [22](#) Activated protein C inhibits coagulation by degrading factors V and VIII. One of the 3 cleavage sites in factor V is the precise site of a mutation (known as the factor V Leiden mutation) that substitutes glutamine instead of arginine at this site (adenine for guanine at nucleotide 1691 in the gene). [22](#) This mutation makes factor V resistant to degradation (and activation in fibrinolysis). The entire clotting cascade is then resistant to the actions of the protein C system.

Coagulation and Fibrinolysis Factors

Coagulation Factors:

Factors that favor clotting when increased

Fibrinogen
Factors VII, VIII, X

Factors that favor clotting when decreased

Antithrombin III
Protein C
Protein S

Fibrinolysis Factors:

Factors that favor clotting when increased

Plasminogen
Plasminogen activator inhibitor-1 (PAI-1)

Factors that favor clotting when decreased

Antiplasmin

Heterozygotes for the factor V Leiden mutation have an 8-fold increased risk of venous thrombosis, and homozygotes, an 80-fold increased risk, and this risk appears

to be further enhanced by oral contraceptive use. The highest prevalence (3–4% of the general population) of factor V Leiden is found in Europeans, and its occurrence in populations not of European descent is very rare, perhaps explaining the low frequency of thromboembolic disease in Africa, Asia, and in native Americans.²³ The mutation is believed to have arisen in a single ancestor approximately 21,000 to 34,000 years ago.²⁴ It has been suggested that this was a useful adaptation in heterozygotes in response to life-threatening bleeding, such as with childbirth.

The next most common inherited disorder (after the factor V Leiden mutation) is a mutation, a guanine to adenine change, in the gene encoding prothrombin.^{19, 25} The prevalence of this abnormality in the white population is estimated to range from 0.7% to 4%.²⁶

The administration of pharmacologic amounts of estrogen as in high-dose oral contraceptives causes an increase in the production of clotting factors such as factor V, factor VIII, factor X, and fibrinogen.²⁷ Some studies of the blood coagulation system have concluded that both monophasic and multiphasic low-dose oral contraceptives have no significant clinical impact on the coagulation system. Slight increases in thrombin formation are offset by increased fibrinolytic activity.^{28, 29} Other studies of formulations containing 30 and 35 µg of ethinyl estradiol indicate an increase in clotting factors associated with an increase in platelet activity.³⁰ However, these changes are essentially all within normal ranges and their clinical significance is unknown. Smoking produces a shift to hypercoagulability.³¹ A 20 µg estrogen formulation has been reported to have no effect on clotting parameters, even in smokers.^{31, 32} One study comparing a 20 µg product with a 30 µg product found similar mild pro-coagulant and fibrinolytic activity, although there was a trend toward increased fibrinolytic activity with the lower dose.³³

There is no evidence of an increase in risk of cardiovascular disease among past users of oral contraception.^{34, 35 and 36} In the Nurses' Health Study and the Royal College of General Practitioners' Study, long-term past use of oral contraceptives was not associated with an increase in overall mortality.^{37, 393} Part of the concern for a possible lingering effect of oral contraceptive use was based on a presumed adverse impact on the atherosclerotic process, which would then be added to the effect of aging and, thus, would be manifested later in life. Instead, the findings have been consistent with the contention that cardiovascular disease due to oral contraception is secondary to acute effects, specifically estrogen-induced thrombosis, a dose-related event.

Venous Thromboembolism — The Conventional Wisdom

Older epidemiologic evaluations of oral contraceptives and vascular disease indicated that venous thrombosis was an effect of estrogen, limited to current users, with a disappearance of the risk by 3 months after discontinuation.^{38, 39} Thromboembolic disease was believed to be a consequence of the pharmacologic administration of estrogen, and the level of risk was believed to be related to the estrogen dose.^{40, 41 and 42} Smoking was documented to produce an additive increase in the risk of arterial thrombosis,^{43, 44 and 45} but had no effect on the risk of venous thromboembolism.^{46, 47}

Is there still a risk of venous thromboembolism with the current low-dose (less than 50 µg ethinyl estradiol) formulations of oral contraceptives? In the first years of oral contraception, the available products, containing 80 and 100 µg ethinyl estradiol (an extremely high dose), were associated with a 6-fold increased risk of venous thrombosis.⁴⁸ Because of the increased risks for venous thrombosis, myocardial infarction, and stroke, lower dose formulations (less than 50 µg estrogen) came to dominate the market, and clinicians became more careful in their screening of patients and prescribing of oral contraception. Two forces, therefore, were at work simultaneously to bring greater safety to women utilizing oral contraception: (1). the use of lower dose formulations, and (2). the avoidance of oral contraception by high-risk patients. Because of these two forces, the Puget Sound study in the United States documented a reduction in venous thrombosis risk to 2-fold.⁴⁹ The new studies also reflect the importance of these two forces, but they still indicate an increased risk.

The Hierarchy of Epidemiologic Studies

I. Clinical Reports

A case report: An anecdotal report that serves to bring attention to a possible problem or condition.

A case series: A collection of similar cases that suggests more than a chance or coincidental occurrence.

II. Observational Studies (Non-experimental Studies: Observation Without Intervention)

Cross-sectional studies: A description of a group of individuals at one point in time.

Advantages: A reliable method to estimate prevalence, quick and inexpensive.

Disadvantages: Cannot assess changes over time and very susceptible to sampling error (the group is not representative of the actual population of interest).

Example: The Health and Nutritional Examination Survey

Case-control studies: A retrospective comparison of a group of individuals with a condition or problem compared with a carefully selected control group. Subjects are selected according to specific inclusion and exclusion criteria. The exposure history of those with disease and those with no disease is collected and compared.

Advantages: Relatively quick and inexpensive because of small sample sizes.

Disadvantages: Subject to biases and errors.

Example: WHO Collaborative Study of Cardiovascular Disease and Steroid Hormone Contraception

Cohort studies: A prospective follow-up over a long period of time of a large group of individuals. Also referred to as longitudinal or follow-up studies. Exposure information is collected from all subjects who are disease-free, and subjects are followed over time to determine who develops disease.

Advantages: A relatively accurate estimation because of large numbers, can evaluate changes over time, avoids recall bias.

Disadvantages: Expensive, lengthy in time, and subject to biases (particularly surveillance bias).

Example: The Nurses' Health Study

III. Randomized Controlled Trials

A true clinical experiment in which an intervention is compared with a standard treatment, no treatment, or a placebo, with allocation to treatment by chance. More than one comparison can be made within a study.

Advantages: Provides scientific, epidemiologic proof.

Disadvantages: Very expensive and time-consuming. Only a limited number of hypotheses can be evaluated in any one study.

Example: The Women's Health Initiative

Possible Confounders and Biases of Importance

Confounders: Factors associated with the disease and the exposure, such as age, body weight, smoking, family history, duration of oral contraceptive use, preferential prescribing, healthy user effect.

Biases: Errors due to study design.

Detection or Surveillance Bias: Systematic errors in methods of ascertainment, diagnosis, or verification of cases. Not everyone in the study population has equal access to or utilization of medical interventions and diagnostic tests.

Publication Bias: Negative (null) studies and studies that confirm old results tend not to be published. An important source of bias in meta-analysis.

Reporting or Recall Bias: Inaccurate memory and dishonesty introduce errors.

Selection Bias: Differences in characteristics between those selected for study and those who are not, such as preferential prescribing, family history, preferential referral of patients, healthy user effect. For case-control studies, the source of the controls is important. Hospital-based controls are less likely to be representative of the general population than population-based controls. It is best to choose controls by random selection, but this is not always possible. Selection bias in a cohort study can result in differences between exposed and unexposed groups.

Information or observer bias: A flaw in measuring exposure or outcome that produces different results between comparison groups. Nonresponse or patients lost to follow-up can produce differences in cohort studies.

A Guide to Epidemiologic Terms Commonly Used

Relative Risk:

The ratio of the risk among those exposed to the risk among the unexposed or the ratio of the cumulative incidence rate in the exposed and the unexposed. Also called risk ratio.

Odds Ratio:

The odds ratio is the measure of association calculated in case-control studies when the prevalence of disease events is low; the estimate and interpretation are similar to relative risk.

Confidence Interval (CI):

The range of relative risk that would include 95% of the subjects being studied; the range of relative risks within which the true magnitude of effect lies, given the study data, with a certain degree of assurance. To be statistically significant, a reduced relative risk (a beneficial effect) requires the larger number (the right hand number) to be less than 1.0. An increased relative risk (an adverse effect), to be statistically significant, requires the smaller number (the left hand number) to be greater than 1.0. The tighter (more narrow) the range, the more precise the conclusion. The wider the CI, the more imprecise the conclusion, usually because of small numbers of study subjects.

Attributable risk:

The difference in actual incidence between exposed and unexposed groups, providing a realistic estimate of the change in incidence in a given population. A modest increase in relative risk will produce only a small number of cases when clinical events are rare, such as venous thromboembolism and arterial thrombosis in young women.

Venous Thromboembolism — The Controversial Studies

The World Health Organization (WHO) Collaborative Study of Cardiovascular Disease and Steroid Hormone Contraception was a hospital-based, case-control study with subjects collected from 21 centers in 17 countries in Africa, Asia, Europe, and Latin America.⁵⁰ As part of this study, the risk of *idiopathic* venous thromboembolism associated with a formulation containing 30 µg ethinyl estradiol and levonorgestrel (doses ranging from 125 µg to 250 µg) was compared with the risk with preparations containing 20 or 30 µg ethinyl estradiol and either desogestrel or gestodene (data from 10 centers in 9 countries).⁵¹ There were only 9 cases and 3 controls using combined oral contraceptives with other progestins, precluding precise analysis. The users of the levonorgestrel formulation had an increased odds ratio (an estimation of relative risk used in case-control studies) of 3.5 compared with nonusers. Current users of a desogestrel product had an increased risk of 9.1 compared with nonusers, and with gestodene, the odds ratio was also 9.1. Thus, the increased risk for desogestrel and gestodene was 2.6 times that of levonorgestrel, when adjusted for body weight and height. Also of note, the increased risk for the desogestrel formulation containing 20 µg ethinyl estradiol was 38.2, a number that is obviously not reliable because it was based upon only 8 cases and 1 control; the confidence interval (CI) of 4.5–325 reflected this imprecision. Overall, these increased risks were lower than those estimated by earlier case-control studies of higher dose oral contraceptives.

The second case-control study (from an international team of epidemiologists and called **the Transnational Study on Oral Contraceptives and the Health of Young Women**) analyzed 471 cases of deep vein thrombosis and/or venous thromboembolism from the United Kingdom and Germany.⁵² Second generation oral contraceptives were defined as products containing 35 µg or less of ethinyl estradiol and a progestin other than desogestrel or gestodene. Comparing users of second generation products to nonusers, the odds ratio was 3.2 (CI = 2.3–4.3). Comparing users of desogestrel and gestodene products to users of second generation oral contraceptives, the risk of venous thromboembolism was 1.5-fold greater.

The third study was from Boston University, but the data were derived from **the General Practice Research Database**, a computerized system involving the general practitioners in the U.K.⁵³ Using this cohort, the authors calculated the death rate from pulmonary embolism, stroke, and acute myocardial infarction in the users of levonorgestrel, desogestrel, and gestodene low-dose oral contraceptives. Over a 3-year period, they collected a total of 15 unexpected idiopathic cardiovascular deaths in users of these products, a *nonsignificant change*, and no difference in the risk comparing desogestrel and gestodene with levonorgestrel. The risk estimates for venous thromboembolism (adjusted for smoking and body size) were about 2 times greater for desogestrel and for gestodene, compared with levonorgestrel uses. There were only 4 cases and 9 controls using the 20 µg ethinyl estradiol and desogestrel product, and although the risk was similar to that associated with the 30 µg ethinyl estradiol and desogestrel product, this is too small a number for analysis.

Similar results were reported when women with deep vein thrombosis in the **Leiden Thrombophilia Study** in the Netherlands were re-analyzed for their use of oral contraceptives.⁵⁴ As expected, the risk of deep vein thrombosis was markedly higher in women who were carriers of the factor V Leiden mutation and in women with a family history of thrombosis.

Smoking, well recognized as a risk factor for arterial thrombosis, did not affect the risk estimates in these studies. This is not a new observation; older studies of venous thromboembolism also failed to identify smoking as a risk factor.^{46, 47}

Venous Thromboembolism — Subsequent Studies

The publication of the 4 reports in late 1995 and early 1996 was followed by a flood of letters to editors, as well as reviews and editorials, highlighting confounding and bias problems in these studies.^{55, 56 and 57} Some prominent figures were convinced the reports of increased risks with desogestrel and gestodene were real;^{58, 59}

others were skeptical, pointing out possible confounding biases. Subsequently, re-analysis and new studies revealed confounders and biases in the initial studies. Thus, a consistent picture gradually emerged with consideration of proper analysis of the generated data, and the adjustment for confounding biases not initially apparent.

In Denmark, Lidegaard and colleagues performed a hospital-based, case-control study of women with confirmed diagnoses of venous thromboembolism in 1994 and 1995 (in Denmark, all women with this diagnosis are hospitalized, and therefore, very few, if any, cases were missed).⁶⁰ A 2-fold increased risk of venous thromboembolism was found in current users of oral contraceptives, regardless of estrogen doses ranging from 20 to 50 µg. The increased risk was concentrated in the first year of use. *Because there were more short-term users of the new progestins and more long-term users of the older progestins, adjustment for duration of use resulted in no significant differences between the different types of progestins.* Those factors associated with an increased risk of thromboembolism included coagulation disorders, treated hypertension during pregnancy, family history of venous thromboembolism, and an increasing body mass index. Notably, conditions not associated with an increased risk of venous thromboembolism included smoking, migraine, diabetes, hyperlipidemia, parity, or age at first birth. There was still insufficient strength in this study to establish the absence or presence of a dose-response relationship comparing the 20 µg estrogen dose to higher doses.

A case-control study using 83 cases of venous thromboembolism derived from the computer records of general practices in the U.K. concluded that the increased risk associated with oral contraceptives was the same for all types, and that the pattern of risk with specific oral contraceptives suggested confounding because of “preferential prescribing” (defined below).⁶¹ *In this study, matching cases and controls by exact year of birth eliminated differences between different types of oral contraceptives.* A similar analysis based on 42 cases from a German database again found no difference between new progestin and older progestin oral contraceptives.⁶² Thus, in these two studies, more precise adjustments for age eliminated a confounding bias.

A re-analysis of the Transnational Case-Control Study considered the duration and patterns of oral contraceptive use.⁶³ This re-analysis focused on first-time users of second and third generation oral contraceptives. *Statistical analysis with adjustment for duration of use in 105 cases who were first-time users could find no differences between second and third generation products.*

Evaluation of the Studies

An immediate problem with the initial studies was how to reconcile the results with the conventional wisdom that thrombosis is an estrogen dose-related complication. Furthermore, progestational agents, and desogestrel and gestodene in particular, have no significant impact on clotting parameters.¹¹ Therefore, there was inherent biologic implausibility surrounding the new studies.

The initial reports resurrected the claim by Kuhl in 1988 and 1989 that gestodene could cause more thrombosis because it affected ethinyl estradiol metabolism, resulting in higher estrogen levels.^{64, 65} Other laboratories, however, could not replicate Kuhl's findings.^{66, 67}

Former users discontinue oral contraceptives for a variety of reasons, and often are switched to what clinicians perceive to be “safer” products (*“preferential prescribing”*).^{68, 69} and ⁷⁰ Individuals who do well with a product tend to remain with that product. Thus, at any one point in time, individuals on an older product will be relatively healthy and free of side effects (*“healthy user effect”*). This is also called *attrition of susceptibles* because higher risk individuals with problems are gradually eliminated from the group.⁵⁶ *Comparing users of older and newer products, therefore, can involve disparate cohorts of individuals.*

Because desogestrel- and gestodene-containing products were marketed as less androgenic and therefore “better” (a marketing claim not substantiated by epidemiologic studies), clinicians chose to provide these products to higher risk patients and older women.^{68, 69} In addition, clinicians switched patients perceived to be at greater risk for thrombosis from older oral contraceptives to the newer formulations with desogestrel and gestodene. Furthermore, these products were prescribed more often to young women who were starting oral contraception for the first time (these young women will not have experienced the test of pregnancy or previous oral contraceptive use to help identify those who have a congenital predisposition to venous thrombosis). These changing practice patterns exert different effects over the lifetime of a product, and analytical adjustments are extremely difficult. The Transnational Group believed it accomplished an appropriate adjustment by focusing on first-time users and duration of use.⁶³ It is also unlikely that the “healthy user effect” will be dominant in first-time users. And, of course, this analysis found no differences between second and third generation oral contraceptives.

The challenge for a clinician is to make a decision: is an observational study with statistically significant results clinically (biologically) real? This controversy illustrates how difficult this can be. When faced with results from observational studies, clinicians want to see uniformity, consistency, agreement—all arguing in favor of a real clinical effect. Examples are the protective effect of oral contraceptives on the risk of ovarian cancer, and the benefits of postmenopausal estrogen therapy on cardiovascular disease. The initial studies were impressive in their agreement. All indicated increased relative risks associated with desogestrel and gestodene compared with levonorgestrel. Nevertheless, all of the early studies, somewhat similar in design, were influenced by the same unrecognized biases. *Persistent errors will produce consistent conclusions.*

The apparent differences associated with the new progestins, it is now apparent, were due to the marketing and preferential prescribing of new products, which influenced the characteristics of the patients for whom the new products were prescribed. Most impressive and important is the fact that there is no evidence of an increase in mortality due to venous thromboembolism since the introduction of new progestin oral contraceptives.^{53, 71}

Venous Thromboembolism and the Factor V Leiden Mutation

The new studies indicate that a risk of idiopathic venous thrombosis persists with low-dose oral contraceptives, at a level of approximately 3–4-fold greater than the normal, general incidence.^{51, 52,}

⁵³ and ^{54, 72} However, an inherited resistance to activated protein C, the factor V Leiden mutation, may account for a significant portion of the patients who experience venous thrombosis while taking oral contraceptives.

Relative Risk and Actual Incidence of Venous Thromboembolism^{73, 74}

Population	Relative Risk	Incidence per 100,000 per year
Young women—general population	1	4–5
Pregnant women	12	48–60
High-dose oral contraceptives	6–10	24–50
Low-dose oral contraceptives	3–4	12–20
Leiden mutation carrier	6–8	24–40
Leiden carrier and oral contraceptives	30	120–150
Leiden mutation—homozygous	80	320–400

An inherited resistance to activated protein C, the factor V Leiden mutation, is the most common inherited coagulation problem, transmitted in an autosomal dominant fashion.^{20, 75} Heterozygotes have a 6- to 8-fold increased risk of venous thromboembolism, and homozygotes an 80-fold increased risk. Oral contraceptive users who have this mutation have been reported to have a 30-fold increased risk of venous thrombosis.^{76, 77} There is no known association between the factor V Leiden mutation and arterial thrombosis.⁷⁸

Should screening for the factor V Leiden mutation (or for other inherited clotting disorders) be routine prior to prescribing contraceptives? The carrier frequencies of the Leiden mutation in the American population (the percentages are similar in men and women) are as follows:⁷⁴

Caucasian Americans	5.27%
---------------------	-------

Hispanic Americans	2.21%
Native Americans	1.25%
Black Americans	1.23%
Asian Americans	0.45%

These estimates are consistent with the European assessments, indicating that this is a trait carried in people of European origin. In the United States, of the approximately 10 million women currently using oral contraceptives, about 450,000 are likely to carry the factor V Leiden mutation. However, because the incidence rate of venous thromboembolism is so low (4–5 per 100,000 young women per year),^{73,74} the number of women required to be screened to prevent one death is prohibitively large. The prevalence of all deficiencies is only about 0.5% in the asymptomatic population, and only one-third of patients at risk are detected by the present tests.⁷⁹

Furthermore, because only a small number of women even with the Leiden mutation (less than 1 in 1000) have a clinical event, the finding of a positive screening test, especially considering the high rate of false positive tests, would be a barrier to the use of oral contraceptives, and a subsequent increase in unwanted pregnancies (which has an even greater risk of venous thromboembolism) would likely follow. **Most experts believe that screening for inherited disorders should be pursued only in women with a previous episode of venous thromboembolism or a close positive family history (parent or sibling) of venous thrombosis.**

This aspect of the oral contraceptive venous thromboembolism controversy received a transfusion of energy with the publication of a report from the Netherlands, utilizing a laboratory test for resistance to activated protein C to compare differences in oral contraceptive non-users, users of second generation oral contraceptives, and users of third generation oral contraceptives.⁸⁰ Women who used any oral contraceptive had a decreased sensitivity to activated protein C compared with nonusers, and women who used third generation oral contraceptives were even less sensitive, and less than users of second generation products. This was presented as an explanation for the epidemiologic data indicating greater risks of venous thromboembolism associated with desogestrel and gestodene, and an editorial in the April 19, 1997, issue of *Lancet* concluded that this report was the “nail in the coffin” confirming the epidemiologic evidence.⁵⁹

Subsequent epidemiologic reports not only removed the nails from the coffin, but returned the coffin to its maker. A closer look at the report from the Netherlands finds considerable overlap in the results among all the groups tested, and many of the oral contraceptive users had results comparable with the nonusers. It is always prudent to avoid making clinically meaningful conclusions from acquired changes in a single laboratory test (especially when the clinical meaning of a laboratory test is uncertain). Furthermore, the results could not be corroborated by another laboratory.⁸¹

Arterial Thrombosis

Because the incidence of cerebral thrombotic attacks (thrombotic strokes and transient ischemic attacks) among young women is higher than venous thromboembolism and myocardial infarction, and death and disability are more likely, stroke is the most important possible side effect. A very low incidence of stroke in young women carries with it little increase in absolute risk. However, because the incidence of cerebral thrombotic attacks is higher in women over age 40, we should do our best, as the following paragraphs will indicate, to make sure oral contraceptive users over age 40 are in good health and without significant risk factors for cardiovascular disease (especially hypertension, migraine with aura, diabetes mellitus, and smoking).

It has been difficult to establish arterial thrombosis dose-response relationships with estrogen because these events are so rare. Nevertheless, the estrogen dose is important for the risk of myocardial infarction and thrombotic strokes.^{82,83} Thus, a rationale for advocating low-dose estrogen oral contraceptives continues to be valid. It is acknowledged that the apparent higher risk of venous thromboembolism associated with 20 µg products in the WHO and Transnational studies reflects small numbers as well as preferential prescribing and healthy user effects.

Arterial Thrombosis — Myocardial Infarction

A population-based, case-control study analyzed 187 cases of myocardial infarction in users of low-dose oral contraceptives in the Kaiser Permanente Medical Care Program.⁸⁴ *There was no statistically significant increase in the odds ratio for myocardial infarction in current oral contraceptive users compared with past or never users.*

In the Transnational case-control study of myocardial infarctions collected from 16 centers in Austria, France, Germany, Switzerland, and the United Kingdom, the results were as follows:^{85,86}

	Cases	Controls	Odds Ratio	Confidence Interval
Any OC use	57	156	2.35	1.42–3.89
50 µg estrogen OCs	14	22	4.32	1.59–11.74
Old progestin OCs	28	71	2.96	1.54–5.66
New progestin OCs	7	49	0.82	0.29–2.31

These data were interpreted as indicating no *increased* risk of myocardial infarction associated with oral contraceptives containing desogestrel or gestodene. However, the *reduced* risk with the new progestin oral contraceptives was also emphasized (the comparison of third generation products to second generation products yielded a reduced risk that was statistically significant), suggesting a possible saving of deaths from myocardial infarction with desogestrel and gestodene. The problem is that the small actual incidence makes it difficult to acquire sufficient numbers. The conclusion was based on only 7 cases and 49 controls using third generation oral contraceptives and 28 cases and 71 controls using second generation products, and, in our view, the power is too limited to make any conclusion regarding the new progestin oral contraceptives. This is a good example of a conclusion that may be statistically significant, but clinically not real.

The Transnational study found that cigarette smoking carried a higher risk for myocardial infarction than oral contraceptives, and *that nonsmoking users of oral contraceptives had no evidence of an increased risk.*⁸⁵ In addition, there was an indication that patient screening is important in minimizing the impact of hypertension on the risk of myocardial infarction.

In the WHO multicenter study, there were 368 cases of acute myocardial infarction.⁸⁷ Factors associated with an increased risk of myocardial infarction included smoking, a history of hypertension (including hypertension in pregnancy), diabetes, rheumatic heart disease, abnormal blood lipids, and a family history of stroke or myocardial infarction. Duration of use and past use of oral contraceptives did not affect risk. Although there was about a 5-fold overall increased odds ratio of myocardial infarction in current users of oral contraceptives, essentially all cases occurred in women with cardiovascular risk factors. There was no apparent effect of increasing age on risk; however, there were only 12 cases among oral contraceptive users less than 35 years old. There was no apparent relationship with estrogen dose, and there was no apparent influence of type or dose of progestin. However, the rare occurrence of this condition produced such small numbers that there was insufficient statistical power to accurately assess the effects of progestin type, and estrogen and progestin doses. *The conclusion of this study was that the risk of myocardial infarction in women who use oral contraceptives is increased only in smokers.*

*In a Danish case-control study of acute myocardial infarction in young women, a statistically significant increase in risk was noted only in current users of 50 µg ethinyl estradiol.*⁸³ There was a progressive increase in risk with the number of cigarettes smoked, (accounting for 80% of the acute myocardial infarctions in young women), increasing body mass index, treated hypertension, treated hypertension in pregnancy, diabetes mellitus, hyperlipidemia, frequent migraine, and family history of myocardial infarction. However, only family history of myocardial infarction and smoking affected the risk associated with oral contraceptives; no influence on oral contraceptive risk was apparent with diabetes, hypertension, and heart disease. No differences could be demonstrated according to type of progestin.

Overall incidence ⁸⁸	5 per 100,000 per year
Women less than age 35	
Nonsmokers	4 per 100,000 per year
Nonsmokers and OCs	4 per 100,000 per year
Smokers	8 per 100,000 per year
Smokers and OCs	43 per 100,000 per year
Women 35-years-old and older	
Nonsmokers	10 per 100,000 per year
Nonsmokers and OCs	40 per 100,000 per year
Smokers	88 per 100,000 per year
Smokers and OCs	485 per 100,000 per year

Note: The above incidences are estimates based on oral contraceptive use paired with cardiovascular risk factors prevalent in the general population. Effective screening would produce smaller numbers. The increased risks in the smokers and OC groups reflect the impact of undetected cardiovascular risk factors, especially hypertension.

Arterial Thrombosis — Stroke

Older case-control and cohort studies indicated an increased risk of cerebral thrombosis among current users of high-dose oral contraceptives.^{88, 90 and 91} However, thrombotic stroke did not appear to be increased in healthy, nonsmoking women with the use of oral contraceptives containing less than 50 µg ethinyl estradiol.^{90, 91} A case-control study of all 794 women in Denmark who suffered a cerebral thromboembolic attack during 1985–1989 concluded that there was an almost two-fold increased relative risk associated with oral contraceptives containing 30–40 µg estrogen, and the risk was significantly influenced by both smoking and the dose of estrogen in additive (not synergistic) fashion.⁴⁵ A case-control analysis of data collected by the Royal College of General Practitioners' Oral Contraception Study concluded that current users were at increased risk of stroke (with a persisting effect in former users); however, this outcome was limited mainly to smokers and to formulations with 50 µg or more of estrogen.⁹¹

A population-based, case-control study of 408 strokes from the California Kaiser Permanente Medical Care Program found no increase in risk for either ischemic stroke or hemorrhagic stroke.⁹² The identifiable risk factors for ischemic stroke were smoking, hypertension, diabetes, elevated body weight, and low socioeconomic status. The risk factors for hemorrhagic stroke were the same plus greater body mass and heavy use of alcohol. *Current users of low-dose oral contraceptives did not have an increased risk of ischemic or hemorrhagic stroke compared with former users and with never users.* There was no evidence for an adverse effect of increasing age or for smoking (for hemorrhagic stroke, there was a suggestion of a positive interaction between current oral contraceptive use and smoking, but the numbers were small, and the result was not statistically significant).

The Transnational study also analyzed their data for ischemic stroke in a case-control study of 220 ischemic strokes in the United Kingdom, Germany, France, Switzerland, and Austria.⁹³ Overall, there was a 3-fold increase in the risk of ischemic stroke associated with the use of oral contraceptives, with higher risks observed in smokers (more than 10 cigarettes per day), in women with hypertension, and in users of higher dose estrogen products. No differences were observed comparing second and third generation progestins. A case-control study from the state of Washington concluded that there is no increased risk of stroke in current users of low-dose oral contraceptives.⁹⁴

The World Health Organization data on stroke come from the same collaborative study that yielded the publications on venous thromboembolism. The results with stroke were published as two separate reports, one on ischemic stroke and the other on hemorrhagic stroke.^{95, 96}

This hospital-based, case-control study from 21 centers in 17 countries accumulated 697 cases of ischemic stroke, 141 from Europe and 556 from developing countries.⁹⁵ The overall odds ratio for ischemic stroke indicated about a 3-fold increased risk. In Europe, however, the risk was statistically significant only for higher-dose products, and **NOT** statistically significant for products with less than 50 µg ethinyl estradiol. In developing countries, there was no difference in risk with low-dose and higher dose oral contraceptives. This is believed to be due to the strong influence of hypertension. In Europe, it was uncommon for women with a history of hypertension to be using oral contraceptives; however, this was not the case in developing countries. Duration of use and type of progestin had no impact, and past users did not have an increased risk, but smoking 10 or more cigarettes daily exerted a synergistic effect with oral contraceptives, increasing the risk of ischemic stroke, approximating the effect of hypertension and oral contraceptives. The risk was greater in women 35 years and older; however, this, too, was believed to be due to an effect of hypertension. *Thus, the conclusion of this study was that the risk of ischemic stroke is extremely low, concentrated in those who use higher dose products, smoke, or have hypertension.*

In the WHO study on hemorrhagic stroke, there were 1068 cases.⁹⁶ Current use of oral contraceptives was associated with a slightly increased risk of hemorrhagic stroke only in developing countries, not in Europe. This again probably reflects the presence of hypertension, because the greatest increased risk (about 10- to 15-fold) was identified in current users of oral contraceptives who had a history of hypertension. Current cigarette smoking also increased the risk in oral contraceptive users, but not as dramatically as hypertension. For hemorrhagic stroke, the dose of estrogen had no effect on risk, and neither did duration of use or type of progestin. *This study concluded that the risk of hemorrhagic stroke due to oral contraceptives is increased only slightly in older women, probably occurring only in women with risk factors such as hypertension.*

A second Danish case-control study included thrombotic strokes and transitory cerebral ischemic attacks analyzed together as cerebral thromboembolic attacks.⁸² In this study, the 219 cases during 1994 and 1995 included 146 cases of cerebral infarction and 73 cases of transient ischemic attacks. Only users of 2nd generation oral contraceptives (levonorgestrel, norgestrel, and norgestimate) had a statistically significant increased risk (about 2.5-fold). There was a dose-response relationship with estrogen in the dose ranges of 20, 30–40, and 50 µg ethinyl estradiol, although the number of 20 µg users (5 cases, 22 controls) was not sufficient to establish a lower risk at this lower dose. This analysis claimed a reduced risk associated with desogestrel and gestodene; however, the odds ratio did not achieve statistical significance. Risk was increased with smoking, treated hypertension, diabetes, heart diseases, frequent migraine, a family history of myocardial infarction, but not duration of use, or family history of venous thromboembolism.

Incidence of Stroke in Reproductive Age Women^{88, 92, 95, 96}

Incidence of ischemic stroke	5 per 100,000 per year
	1–3 per 100,000 per year in women under age 35
	10 per 100,000 per year in women over age 35
Incidence of hemorrhagic stroke	6 per 100,000 per year
Excess cases per year due to OCs, including smokers and hypertensives	2 per 100,000 per year in low-dose OC users
	1 per 100,000 per year in low-dose OC users under age 35
	8 per 100,000 per year in high-dose OC users

Arterial Thrombosis — Current Assessment

There has been no evidence with respectable statistical power that the new progestins have an appreciable difference in risk for arterial disease, an event that is

already **NOT** increased with low-dose older type progestin oral contraceptives. It is possible that as these studies continue and acquire greater statistical power, a difference will emerge, but even if this is the case, the difference will be minor and likely unmeasurable. Conclusions based on a limited number of cases are premature, and a critical attitude toward arterial thrombosis is appropriate just as such an approach finally revealed explanations for the initial findings with venous thrombosis.

Most importantly, the new studies fail to find any substantial risk of ischemic or hemorrhagic stroke with low-dose oral contraceptives in healthy, young women. The WHO study did find evidence for an adverse impact of smoking in women under age 35; the Kaiser study did not. This difference is explained by the confounding effect of hypertension, the major risk factor identified. In the WHO study, a history of hypertension was based on whether a patient reported ever having had high blood pressure (other than in pregnancy) and not validated by medical records. In the Kaiser study, women were classified as having hypertension if they reported using antihypertensive medication (less than 5% of oral contraceptive users had treated hypertension, and there were no users of higher dose products). In the WHO study, the effect of using oral contraceptives in the presence of a high-risk factor is apparent in the different odds ratios when European women who received good screening from clinicians were compared with women in developing countries who received little screening; therefore, more women with cardiovascular risk factors in developing countries were using oral contraceptives.

Over the years, there has been recurring discussion over whether to provide oral contraceptives over the counter on a non-prescription basis. The data in the WHO report make an impressive argument against such a move. The increased risk of myocardial infarction was most evident in developing countries where 70% of the cases received their oral contraceptives from a non-clinical source. Deprived of screening, women with risk factors in developing countries were exposed to greater risk.

Oral contraceptives containing less than 50 µg ethinyl estradiol do not increase the risk of myocardial infarction or stroke in healthy, nonsmoking women, regardless of age. The effect of smoking in women under age 35 is, as we have long recognized, not detectable in the absence of hypertension. After age 35, the subtle presence of hypertension makes analysis difficult, but the Kaiser study indicates that increasing age and smoking by themselves have little impact on the risk of stroke in low-dose oral contraceptive users. The screening of patients in the Kaiser program was excellent, resulting in few women with hypertension using oral contraceptives. **The new studies indicate that hypertension should be a major concern, especially in regards to the risk of stroke**. Certainly, women with uncontrolled hypertension should not use oral contraceptives. Generally, family planning experts have believed that well-treated hypertension should not be a contraindication for oral contraceptive use. The new data do not help us with this problem because it is impossible to accurately categorize hypertensive patients in the studies into groups representing successful and unsuccessful treatment. Nevertheless, the outstanding safety of low estrogen dose oral contraceptives in these studies supports the continued use of low-dose oral contraceptives in treated and well-controlled hypertensive women.

Smoking

Smoking continues to be a difficult problem, not only for patient management, but for analysis of data as well. In large U.S. surveys in 1982 and 1988, the decline in the prevalence of smoking was similar in users and nonusers of oral contraception; however, 24.3% of 35- to 45-year-old women who used oral contraceptives were smokers!⁹⁷ In this group of smoking, oral contraceptive-using women, 85.3% smoked 15 or more cigarettes per day (heavy smoking). Despite the widespread teaching and publicity that smoking is a contraindication to oral contraceptive use over the age of 35, more older women who use oral contraceptives smoke and smoke heavily, compared with young women. This strongly implies that older smokers are less than honest with clinicians when requesting oral contraception, and this further raises serious concern over how well this confounding variable can be controlled in case-control and cohort studies. **A former smoker must have stopped smoking for at least 12 consecutive months to be regarded as a nonsmoker. Women who have nicotine in their bloodstream obtained from patches or gum should be regarded as smokers.**

Lipoproteins and Oral Contraception

The balance of estrogen and progestin potency in a given oral contraceptive formulation can potentially influence cardiovascular risk by its overall effect on lipoprotein levels. Oral contraceptives with relatively high doses of progestins (doses not used in today's low-dose formulations) do produce unfavorable lipoprotein changes.⁹⁸ The levonorgestrel triphasic exerts no significant changes on HDL-cholesterol, LDL-cholesterol, apoprotein B, and no change or an increase in apoprotein A, while the levonorgestrel monophasic combination (with a higher dose of levonorgestrel) has a tendency to increase LDL-cholesterol and apoprotein B, and to decrease HDL-cholesterol and apoprotein A. The monophasic desogestrel and desogestrel pills have a favorable effect on the lipoprotein profile, while the triphasic norgestimate and gestodene pills produce beneficial alterations in the LDL:HDL and apoprotein B:apoprotein A ratios.^{99, 100, 101 and 102} Like the triphasic levonorgestrel pills, norethindrone multiphasic pills have no significant impact on the lipoprotein profile over 6–12 months.¹⁰³ *In summary, studies of low-dose formulations indicate that the adverse effects of progestins are limited to the fixed-dose combination with a dose of levonorgestrel that exceeds that in the multiphasic formulation.*

An important study in monkeys indicated a protective action of estrogen against atherosclerosis, but by a mechanism independent of the cholesterol-lipoprotein profile. Oral administration of a combination of estrogen and progestin to monkeys fed a high-cholesterol, atherogenic diet decreased the extent of coronary atherosclerosis despite a reduction in HDL-cholesterol levels.^{104, 105 and 106} In somewhat similar experiments, estrogen treatment markedly prevented arterial lesion development in rabbits.^{107, 108 and 109} In considering the impact of progestational agents, lowering of HDL is not necessarily atherogenic if accompanied by a significant estrogen impact. These animal studies help explain why older, higher dose combinations, which had an adverse impact on the lipoprotein profile did not increase subsequent cardiovascular disease.^{34, 37} The estrogen component provided protection through a direct effect on vessel walls, especially favorably influencing vasomotor and platelet factors such as nitric oxide and prostacyclin.

This conclusion is reinforced by angiographic and autopsy studies. Young women with myocardial infarctions who have used oral contraceptives have less diffuse atherosclerosis than nonusers.^{110, 111} Indeed, a case-control study indicated that the risk of myocardial infarction in patients taking older, high-dose levonorgestrel-containing formulations is the same as that experienced with pills containing other progestins.³⁴

In the past decade, we have been subjected to considerable marketing hype about the importance of the impact of oral contraceptives on the cholesterol-lipoprotein profile. If indeed certain oral contraceptives had a negative impact on the lipoprotein profile, one would expect to find evidence of atherosclerosis as a cause of an increase in subsequent cardiovascular disease. There is no such evidence. Thus, the mechanism of the cardiovascular complications is undoubtedly a short-term acute mechanism—thrombosis (an estrogen-related effect).

Hypertension

Oral contraceptive-induced hypertension was observed in approximately 5% of users of higher dose pills. More recent evidence indicates that small increases in blood pressure can be observed even with 30 mg estrogen, monophasic pills, including those containing the new progestins. However, an increased incidence of clinically significant hypertension has not been reported.^{112, 113, 114 and 115} The lack of clinical hypertension in most studies may be due to the rarity of its occurrence. The Nurses' Health Study observed an increased risk of clinical hypertension in current users of low-dose oral contraceptives, providing an incidence of 41.5 cases per 10,000 women per year.¹¹⁶ Therefore, an annual assessment of blood pressure is still an important element of clinical surveillance, even when low-dose oral contraceptives are used. Postmenopausal women in the Rancho Bernardo Study who had previously used oral contraceptives (probably high-dose products) had slightly higher (2–4 mm Hg) diastolic blood pressures.¹¹⁷ Because past users do not demonstrate differences in incidence or risk factors for cardiovascular disease, it is unlikely this blood pressure difference has an important clinical effect.

Variables such as previous toxemia of pregnancy or previous renal disease do not predict whether a woman will develop hypertension on oral contraception.¹¹⁸ Likewise, women who have developed hypertension on oral contraception are not more predisposed to develop toxemia of pregnancy.

The mechanism for an effect on blood pressure is thought to involve the renin-angiotensin system. The most consistent finding is a marked increase in plasma angiotensinogen, the renin substrate, up to 8 times normal values (on higher dose pills). In nearly all women, excessive vasoconstriction is prevented by a compensatory decrease in plasma renin concentration. If hypertension does develop, the renin-angiotensinogen changes take 3–6 months to disappear after stopping combined oral contraception.

One must also consider the effects of oral contraceptives in patients with preexisting hypertension or cardiac disease. In our view, with medical control of the blood pressure and close follow-up (at least every 3 months), the patient and her clinician may choose low-dose oral contraception. Close follow-up is also indicated in women with a history of preexisting renal disease or a strong family history of hypertension or cardiovascular disease. It seems prudent to suggest that patients with

marginal cardiac reserve should utilize other means of contraception. Significant increases in cardiac output and plasma volume have been recorded with oral contraceptive use (higher dose pills), probably a result of fluid retention.

Cardiovascular Disease — Summary

The outpouring of epidemiologic data in the last few years allows the construction of a clinical formulation that is evidence-based. The following conclusions are consistent with the recent reports.

SUMMARY: Oral Contraceptives and Thrombosis

- Pharmacologic estrogen increases the production of clotting factors.
- Progestins have no significant impact on clotting factors.
- Past users of oral contraceptives do not have an increased incidence of cardiovascular disease.
- All low-dose oral contraceptives, regardless of progestin type, have an increased risk of venous thromboembolism. The actual risk of venous thrombosis with low-dose oral contraceptives is lower in the new studies compared with previous reports. Some have argued that this is due to preferential prescribing and the healthy user effect. However, it is also logical that the lower risk reflects better screening of patients and lower estrogen doses.
- Smoking has no effect on the risk of venous thrombosis.
- Smoking and estrogen have an additive effect on the risk of arterial thrombosis. Why is there a difference between venous and arterial clotting? The venous system has low flow with a state of high fibrinogen and low platelets, in contrast to the high-flow state of the arterial system with low fibrinogen and high platelets. Thus, it is understandable why these two different systems can respond in different ways.
- Hypertension is a very important additive risk factor for stroke in oral contraceptive users.
- Low-dose oral contraceptives (less than 50 µg ethinyl estradiol) do not increase the risk of myocardial infarction or stroke in healthy, nonsmoking women, regardless of age.
- Almost all myocardial infarctions and strokes in oral contraceptive users occur in users of high-dose products, or users with cardiovascular risk factors over the age of 35.
- Arterial thrombosis (myocardial infarction and stroke) has a dose-response relationship with the dose of estrogen, but there are insufficient data to determine whether there is a difference in risk with products that contain 20, 30 or 35 µg ethinyl estradiol.

The recent studies reinforce the belief that the risks of arterial and venous thrombosis are a consequence of the estrogen component of combination oral contraceptives. Current evidence does not support an advantage or disadvantage for any particular formulation, except for the greater safety associated with any product containing less than 50 µg ethinyl estradiol. Although it is logical to expect the greatest safety with the lowest dose of estrogen, the rare occurrence of arterial and venous thrombosis in healthy women makes it unlikely that there will be any measurable differences in the attributable incidence of clinical events with all low-dose products.

The new studies emphasize the importance of good patient screening. The occurrence of arterial thrombosis is essentially limited to older women who smoke or have cardiovascular risk factors, especially hypertension. The impact of good screening is evident in the repeated failure to detect an increase in mortality due to myocardial infarction or stroke in several studies.^{53, 88} Although the risk of venous thromboembolism is slightly increased, the actual incidence is still relatively rare, and the mortality rate is about 1% (probably less with oral contraceptives, because most deaths from thromboembolism are associated with trauma, surgery, or a major illness). The minimal risk of venous thrombosis associated with oral contraceptive use does not justify the cost of routine screening for coagulation deficiencies. Nevertheless, the importance of this issue is illustrated by the increased risk of a very rare event, cerebral sinus thrombosis, in women who have an inherited predisposition for clotting and use oral contraceptives.^{19, 119}

If a patient has a close family history (parent or sibling) or a previous episode of idiopathic thromboembolism, an evaluation to search for an underlying abnormality in the coagulation system is warranted.⁷⁷ The following measurements are recommended, and abnormal results require consultation with a hematologist regarding prognosis and prophylactic treatment. The list of laboratory tests is long, and because this is a dynamic and changing field, the best advice is to consult with a hematologist. If a diagnosis of a congenital deficiency is made, screening should be offered to other family members.

Hypercoagulable Conditions

Antithrombin III deficiency
Protein C deficiency
Protein S deficiency
Factor V Leiden mutation
Prothrombin gene mutation
Antiphospholipid syndrome

Thrombophilia Screening

Antithrombin III
Protein C
Protein S
Activated protein C resistance ratio
Activated partial thromboplastin time
Hexagonal activated partial thromboplastin time
Anticardiolipin antibodies
Lupus anticoagulant
Fibrinogen
Prothrombin G mutation (DNA test)
Thrombin Time
Homocysteine level
Complete blood count

Combination oral contraception is contraindicated in women who have a history of idiopathic venous thromboembolism, and also in women who have a close family history (parent or sibling) of idiopathic venous thromboembolism. These women will have a higher incidence of congenital deficiencies in important clotting measurements, especially antithrombin III, protein C, protein S, and resistance to activated protein C.¹²⁰ Such a patient who screens negatively for an inherited clotting deficiency might still consider the use of oral contraceptives, but this would be a difficult decision with unknown risks for both patient and clinician, and it seems more prudent to consider other contraceptive options. Other risk factors for thromboembolism that should be considered by clinicians include an acquired predisposition such as the presence of lupus anticoagulant or malignancy, and immobility or trauma. Varicose veins are not a risk factor unless they are very extensive.⁴⁸

The conclusion once again is that low-dose oral contraceptives are very safe for healthy, young women. By effectively screening for the presence of smoking and cardiovascular risk factors, especially hypertension, in older women, we can limit, if not eliminate, any increased risk for arterial disease associated with low-dose oral contraceptives. And it is very important to emphasize that there is no increased risk of cardiovascular events associated with duration (long-term) use.

Carbohydrate Metabolism

With the older high-dose oral contraceptives, an impaired glucose tolerance test was present in many women. In these women, plasma levels of insulin as well as the blood sugar were elevated. Generally, the effect of oral contraception is to produce an increase in peripheral resistance to insulin action. Most women can meet this challenge by increasing insulin secretion, and there is no change in the glucose tolerance test, although 1-hour values may be slightly elevated.

Insulin sensitivity is affected mainly by the progestin component of the pill.¹²¹ The derangement of carbohydrate metabolism may also be affected by estrogen influences on lipid metabolism, hepatic enzymes, and elevation of unbound cortisol. The glucose intolerance is dose-related, and once again effects are less with the low-dose formulations. **Insulin and glucose changes with low-dose monophasic and multiphasic oral contraceptives are so minimal, that it is now believed they are of no clinical significance.**^{115, 122, 123 and 124} This includes long-term evaluation with hemoglobin A1c.

The observed changes in studies of oral contraception and carbohydrate metabolism are in the nondiabetic range. In order to measure differences, investigators have resorted to analysis by measuring the area under the curve for glucose and insulin responses during glucose tolerance tests. A highly regarded cross-sectional study utilizing this technique reported that even lower dose formulations have detectable effects on insulin resistance.¹²¹ The reason this is important is that it is now

recognized that hyperinsulinemia due to insulin resistance is a contributor to cardiovascular disease. However, there are several critical questions that remain unanswered. Can the results from a cross-sectional study be duplicated in a study of sufficient size with patients serving as their own controls? Is a statistically significant hyperinsulinemia, detected in a study, clinically meaningful?

Because long-term, follow-up studies of large populations have failed to detect any increase in the incidence of diabetes mellitus or impaired glucose tolerance (even in past and current users of high-dose pills),^{117, 125, 126} the concern now appropriately focuses on the slight impairment as a potential risk for cardiovascular disease. If slight hyperinsulinemia were meaningful, wouldn't you expect to see evidence of an increase in cardiovascular disease in past users who took oral contraceptives when doses were higher? As we have emphasized before, there is no such evidence. The data strongly indicate that the changes in lipids and carbohydrate metabolism that have been measured are not clinically meaningful.

It can be stated definitively that oral contraceptive use does not produce an increase in diabetes mellitus.^{125, 126, 127 and 128} The hyperglycemia associated with oral contraception is not deleterious and is completely reversible. Even women who have risk factors for diabetes in their history are not affected. In women with recent gestational diabetes, no significant impact on glucose tolerance could be demonstrated over 6–13 months comparing the use of low-dose monophasic and multiphasic oral contraceptives with a control group, and no increase in the risk of overt diabetes mellitus could be detected with long-term follow-up.^{129, 130} A high percentage of women with previous gestational diabetes develop overt diabetes and associated vascular complications. Until overt diabetes develops, it is appropriate for these patients to use low-dose oral contraception.

In clinical practice, it may, at times, be necessary to prescribe oral contraception for the overt diabetic. No effect on insulin requirement is expected with low-dose pills.¹³¹ According to the older epidemiologic data, the use of oral contraceptives increases the risk of thrombosis in women with insulin-dependent diabetes mellitus; therefore, women with diabetes have been encouraged to use other forms of contraception. However, this effect in women under age 35 who are otherwise healthy is probably very minimal with low-dose oral contraception, and reliable protection against pregnancy is a benefit for these patients that outweighs the small risk. A case-control study could find no evidence that oral contraceptive use by young women with insulin-dependent diabetes mellitus increased the development of retinopathy or nephropathy.¹³² In a 1-year study of women with insulin-dependent diabetes mellitus who were using a low-dose oral contraceptive, no deterioration could be documented in lipoprotein or hemostatic biochemical markers for cardiovascular risk.¹³³

The Liver

The liver is affected in more ways and with more regularity and intensity by the sex steroids than any other extragenital organ. Estrogen influences the synthesis of hepatic DNA and RNA, hepatic cell enzymes, serum enzymes formed in the liver, and plasma proteins. Estrogenic hormones also affect hepatic lipid and lipoprotein formation, the intermediary metabolism of carbohydrates, and intracellular enzyme activity. Nevertheless, an extensive analysis of the prospective cohorts of women in the Royal College of General Practitioners' Oral Contraception Study and the Oxford-Family Planning Association Contraceptive Study could detect no evidence of an increased incidence or risk of serious liver disease among oral contraceptive users.¹³⁴

The active transport of biliary components is impaired by estrogens as well as some progestins. The mechanism is unclear, but cholestatic jaundice and pruritus were occasional complications of higher dose oral contraception, and are similar to the recurrent jaundice of pregnancy, i.e., benign and reversible. The incidence with lower dose oral contraception is unknown, but it must be a very rare occurrence.

The only absolute hepatic contraindication to oral contraceptive use is acute or chronic cholestatic liver disease. Cirrhosis and previous hepatitis are not aggravated. Once recovered from the acute phase of liver disease, a woman can use oral contraception.

Data from the Royal College of General Practitioners' prospective study indicated that an increase in the incidence of gallstones occurred in the first years of oral contraceptive use, apparently due to an acceleration of gallbladder disease in women already susceptible.¹³⁵ In other words, the overall risk of gallbladder disease was not increased, but in the first years of use, disease was activated or accelerated in women who were vulnerable because of asymptomatic disease or a tendency toward gallbladder disease. The mechanism appears to be induced alterations in the composition of gallbladder bile, specifically a rise in cholesterol saturation that is presumably an estrogen effect.¹³⁶ The Nurses' Health Study reported no significant increase in the risk of symptomatic gallstones among ever-users, but slightly elevated risks among current and long-term users.¹³⁷ Although oral contraceptive use has been linked to an increased risk of gallbladder disease, the epidemiologic evidence has been inconsistent. Indeed an Italian case-control study and a report from the Oxford Family Planning Association cohort found no increase in the risk of gallbladder disease in association with oral contraceptive use and no interaction with increasing age or body weight.^{138, 139} Keep in mind that even though some studies found a statistically significant modest increase in the relative risk of gallbladder disease, even if the effect were real, it is of little clinical importance because the actual incidence of this problem is very low.

Other Metabolic Effects

Nausea, breast discomfort, and weight gain continue to be disturbing effects, but their incidence is significantly less with low-dose oral contraception. Fortunately, these effects are most intense in the first few months of use and, in most cases, gradually disappear. Weight gain usually responds to dietary restriction, but for some patients, the weight gain is an anabolic response to the sex steroids, and discontinuation of oral contraception is the only way that weight loss can be achieved. This must be rare with low-dose oral contraception because data in published studies fail to indicate a difference in body weight between users and nonusers.^{140, 141}

There is no association between oral contraception and peptic ulcer disease or inflammatory bowel disease.^{142, 143} Oral contraception is not recommended for patients with problems of gastrointestinal malabsorption because of the possibility of contraceptive failure.

Chloasma, a patchy increase in facial pigment, was, at one time, found to occur in approximately 5% of oral contraceptive users. It is now a rare problem due to the decrease in estrogen dose. Unfortunately, once chloasma appears, it fades only gradually following discontinuation of the pill and may never disappear completely. Skin-blanching medications may be useful.

Hematologic effects include an increased sedimentation rate, increased total iron-binding capacity due to the increase in globulins, and a decrease in prothrombin time. The continuous use of oral contraceptives may prevent the appearance of symptoms in porphyria precipitated by menses. Changes in vitamin metabolism have been noted: a small nonharmful increase in vitamin A and decreases in blood levels of pyridoxine (B₆) and the other B vitamins, folic acid, and ascorbic acid. Despite these changes, routine vitamin supplements are not necessary for women eating adequate, normal diets.

Mental depression is very rarely associated with oral contraceptives. In studies with higher dose oral contraceptives, the effect was due to estrogen interference with the synthesis of tryptophan that could be reversed with pyridoxine treatment. It seems wiser, however, to discontinue oral contraception if depression is encountered. Though infrequent, a reduction in libido is occasionally a problem and may be a cause for seeking an alternative method of contraception.

Adverse androgenic voice changes were occasionally encountered with the use of the first very high-dose oral contraceptives. Vocal virilization can be a serious and devastating problem for some women, especially when vocal performance is important. Careful study of women on low-dose oral contraceptives indicates that this is no longer a side effect of concern.¹⁴⁴

The Risk of Cancer

Endometrial Cancer

The use of oral contraception protects against endometrial cancer. Use for at least 12 months reduces the risk of developing endometrial cancer by **50%**, with the greatest protective effect gained by use for more than 3 years.^{145, 146 and 147} This protection persists for 20 or more years after discontinuation (the actual length of duration of protection is unknown) and is greatest in women at highest risk: nulliparous and low parity women.¹⁴⁸ This protection is equally protective for all 3 major histologic subtypes of endometrial cancer: adenocarcinoma, adenoacanthoma, and adenosquamous cancers. Finally, protection is seen with all monophasic formulations of oral contraceptives, including pills with less than 50 µg estrogen.¹⁴⁵ There are no data as yet with multiphasic preparations or the new progestin

formulations, but because these products are still dominated by their progestational component, there is every reason to believe that they will be protective.

Ovarian Cancer

Protection against ovarian cancer, the most lethal of female reproductive tract cancers, is one of the most important benefits of oral contraception. Because this cancer is detected late and prognosis is poor, the impact of this protection is very significant. Indeed, a decline in mortality from ovarian cancer has been observed in several countries since the early 1970s, perhaps an effect of oral contraceptive use.¹⁴⁹ The risk of developing epithelial ovarian cancer of all histologic subtypes in users of oral contraception is reduced by **40%** compared with that of nonusers.^{147, 150, 151 and 152} This protective effect increases with duration of use and continues for at least 10–15 years after stopping the medication. This protection is seen in women who use oral contraception for as little as 3 to 6 months (although at least 3 years of use are required for a notable impact), reaches an 80% reduction in risk with more than 10 years of use, and is a benefit associated with all monophasic formulations, including the low-dose products.¹⁵³ The protective effect of oral contraceptives is especially observed in women at high risk of ovarian cancer (nulliparous women and women with a positive family history).¹⁵⁴ Continuous use of oral contraception for 10 years by women with a positive family history for ovarian cancer can reduce the risk of epithelial ovarian cancer to a level equal to or less than that experienced by women with a negative family history.¹⁵⁴ Again, the multiphasic and new progestin products have not been in use long enough to yield any data on this issue, but because ovulation is effectively inhibited by these formulations, protection against ovarian cancer should be exerted. The same magnitude of protection has been observed in a case-control study of women with *BRCA1* or *BRCA2* mutations.¹⁵⁵

Cancer of the Cervix

Studies have indicated that the risk for dysplasia and carcinoma in situ of the uterine cervix increases with the use of oral contraception for more than one year.^{156, 157, 158, 159 and 160} Invasive cervical cancer may be increased after 5 years of use, reaching a two-fold increase after 10 years. It is well recognized, however, that the number of partners a woman has had and age at first coitus are the most important risk factors for cervical neoplasia. Other confounding factors include exposure to human papillomavirus, the use of barrier contraception (protective), and smoking. These are difficult factors to control, and, therefore, the conclusions regarding cervical cancer are not definitive. An excellent study from the Centers for Disease Control and Prevention (CDC) concluded there is no increased risk of invasive cervical cancer in users of oral contraception, and an apparent increased risk of carcinoma in situ is due to enhanced detection of disease (because oral contraceptive users have more frequent Pap smears).¹⁵⁹ In the World Health Organization Study of Neoplasia and Steroid Contraceptives, a Pap smear screening bias was identified, nevertheless the evidence still suggested an increased risk of cervical carcinoma in situ with long-term oral contraceptive use.¹⁶⁰

A case-control study of patients in Panama, Costa Rica, Colombia, and Mexico concluded that there was a significantly increased risk for invasive adenocarcinoma.¹⁶¹ Similar results were obtained in a case-control study in Los Angeles and in the World Health Organization Collaborative Study.^{162, 163} In Los Angeles, the relative risk of adenocarcinoma of the cervix increased from 2.1 with ever use to 4.4 with 12 or more years of oral contraceptive use.¹⁶² Because the incidence of adenocarcinoma of the cervix (10% of all cervical cancers) has increased in young women over the last 20 years, there is concern that this increase reflects the use of oral contraception.¹⁶⁴ Oral contraceptives increase cervical ectopia, but whether this increases the risk of cervical adenocarcinoma is unclear.

This concern obviously is an important reason for annual Pap smear surveillance. Fortunately, steroid contraception does not mask abnormal cervical changes, and the necessity for prescription renewals offers the opportunity for improved screening for cervical disease. It is reasonable to perform Pap smears every 6 months in women using oral contraception for 5 or more years who are also at higher risk because of their sexual behavior (multiple partners, history of sexually transmitted diseases). Oral contraceptive use is appropriate for women with a history of cervical intraepithelial neoplasia (CIN), including those who have been surgically treated.

Liver Adenomas

Hepatocellular adenomas can be produced by steroids of both the estrogen and androgen families. Actually, there are several different lesions, peliosis, focal nodular hyperplasia, and adenomas. Peliosis is characterized by dilated vascular spaces without endothelial lining, and may occur in the absence of adenomatous changes. The adenomas are not malignant; their significance lies in the potential for hemorrhage. The most common presentation is acute right upper quadrant or epigastric pain. The tumors may be asymptomatic, or they may present suddenly with hemoperitoneum. There is some evidence that the tumors and focal nodular hyperplasia regress when oral contraception is stopped.^{165, 166} Epidemiologic data have not supported the contention that mestranol increased the risk more than ethinyl estradiol.

The risk appears to be related to duration of oral contraceptive use and to the steroid dose in the pills. This is reinforced by the rarity of the condition ever since low-dose oral contraception became available. The ongoing prospective studies have accumulated many woman-years of use and have not identified an increased incidence of such tumors.¹³⁴ In our view it is not even worth mentioning during the informed consent (choice) process.

No reliable screening test or procedure is currently available. Routine liver function tests are normal. Computed tomography (CT) scanning or magnetic resonance imaging (MRI) is the best means of diagnosis; angiography and ultrasonography are not reliable. Palpation of the liver should be part of the periodic evaluation in oral contraceptive users. If an enlarged liver is found, oral contraception should be stopped, and regression should be evaluated and followed by imaging.

Liver Cancer

Oral contraception has been linked to the development of hepatocellular carcinoma.^{167, 168} However, the very small number of cases, and, thus, the limited statistical power, requires great caution in interpretation. The largest study on this question, the WHO Collaborative Study of Neoplasia and Steroid Contraceptives, found no association between oral contraception and liver cancer.¹⁶⁹ Even case-control analysis of oral contraceptives containing cyproterone acetate (known to be toxic to the liver in high doses) could detect no evidence of an increased risk of liver cancer.¹⁷⁰ In the United States, Japan, Sweden, England, and Wales, the death rates from liver cancer have not changed over the last 3 decades despite introduction and use of oral contraception.^{171, 172}

Breast Cancer

Because of its prevalence and its long latent phase, concern over the relationship between oral contraception and breast cancer continues to be an issue in the minds of both patients and clinicians. Unfortunately, the issue is not totally resolved and probably will not be until another decade passes, allowing data to emerge from the modern era of lower dose oral contraception.

Worth emphasizing is the protective effect of higher dose oral contraception on benign breast disease, an effect that became apparent after 2 years of use.¹⁷³ After 2 years there was a progressive reduction (about 40%) in the incidence of fibrocystic disease of the breast. Women who used oral contraception were one-fourth as likely to develop benign breast disease as nonusers, but this protection was limited to current and recent users. It is still uncertain whether this same protection is provided by the lower dose products. A French case-control study indicated a reduction of nonproliferative benign breast disease associated with low-dose oral contraceptives used before a first full-term pregnancy, but no effect on proliferative disease or with use after a pregnancy.¹⁷⁴

The Royal College of General Practitioners,¹⁷⁵ Oxford Family Planning Association,^{176, 177} and Walnut Creek¹⁷⁸ cohort studies (and more recently, the Nurses' Health Study)¹⁷⁹ indicated no significant differences in breast cancer rates between users and nonusers. However, patients were enrolled in these studies at a time when oral contraception was used primarily by married couples spacing out their children. Beginning in the 1980s, oral contraception was primarily being used by women early in life, for longer durations, and to delay an initial pregnancy (remember, a full-term pregnancy early in life protects against breast cancer).

Over the last decade, case-control studies have focused on the use of oral contraception early in life, for long duration, and to delay a first, full-term pregnancy. Because the cohort of women who have used oral contraception in this fashion is just now beginning to reach the ages of postmenopausal breast cancer, the studies have had to focus on the risk of breast cancer diagnosed before age 45 (only 13% of all breast cancer). The results of these studies have not been clear-cut. Some studies have indicated an overall increased relative risk of early, premenopausal breast cancer,^{180, 181, 182, 183, 184, 185, 186 and 187} while others indicated no increase in overall risk.^{188, 189 and 190} The most impressive finding indicates a link in most studies,^{191, 192, 193, 194, 195 and 196} but not all,^{197, 198, 199, 200 and 201} of early breast cancer before age 40 with women who used oral contraception for long durations of time.

A collaborative group composed of an enormous number of epidemiologists and cancer investigators from around the world re-analyzed data from 54 studies in 26

countries, a total of 53,297 women with breast cancer and 100,239 without breast cancer, in order to assess the relationship between the risk of breast cancer and the use of oral contraceptives.²⁰² Oral contraceptives were grouped into 3 categories: low, medium, and high dose (which correlated with <50µg, 50 µg, and >50 µg of estrogen). At the time of diagnosis, 9% of the women with breast cancer were under age 35, 25% were 35–44, 33% were 45–54, and 33% were age 55 and older. A similar percentage of women with breast cancer (41%) and women without breast cancer (40%) had used combined oral contraceptives at some time in their lives. Overall, the relative risk (RR) of breast cancer in ever users of oral contraceptives was very slightly elevated and statistically significant: RR = 1.07; CI = 1.03–1.10.

The relative risk analyzed by duration of use was barely elevated and not statistically significant (even when long-term use, virtually continuous, was analyzed). Women who had begun use as teenagers had about a 20% statistically significant increased relative risk. In other words, recent users who began use before age 20 had a higher relative risk compared with recent users who began at later ages. The evidence was strong for a relationship with time since last use, an elevated risk being significant for current users and in women who had stopped use 1–4 years before (recent use). No influence on this risk was observed with the following: a family history of breast cancer, age of menarche, country of origin, ethnic groups, body weight, alcohol use, years of education, and the design of the study. There was no variation according to specific type of estrogen or progestin in the various products. Importantly, there was no statistically significant effect of low, medium, or high dose preparations. Ten or more years after stopping use, there was no increased risk of breast cancer. Indeed, the risk of metastatic disease compared with localized tumors was reduced: Relative Risk = 0.88; CI = 0.81–0.95.

Oral Contraceptives and the Risk of Breast Cancer Re-analysis of the World's Data²⁰²

Current users	RR = 1.24, 95% CI 1.15–1.33
1–4 years after stopping	RR = 1.16, 95% CI 1.08–1.23
5–9 years after stopping	RR = 1.07, 95% CI 1.02–1.13

Data were limited for progestin-only methods. The re-analysis indicated that the results were similar to those with combined oral contraceptives, but a close look at the numbers reveals that not one relative risk reached statistical significance.

Overall, this massive statistical exercise yielded good news. No major adverse impact of oral contraceptives emerged. ***Even though the data indicated that young women who begin use before age 20 have higher relative risks of breast cancer during current use and in the 5 years after stopping, this is a time period when breast cancer is very rare; and, thus, there would be little impact on the actual number of breast cancers.*** The difference between localized disease and metastatic disease was statistically greater and should be observable. Thus many years after stopping oral contraceptive use, the main effect may be protection against metastatic disease. Breast cancer is more common in older years, and 10 or more years after stopping, the risk was not increased.

What other explanation could account for an increased risk associated only with current or recent use, no increase with duration of use, and a return to normal 10 years after exposure? The slightly increased risk could be influenced by detection/surveillance bias (more interaction with the health care system by oral contraceptive users). It is also possible that this situation is analogous to that of pregnancy. Recent studies indicate that pregnancy transiently increases the risk of breast cancer (for a period of several years) after a woman's first childbirth, and this is followed by a lifetime reduction in risk.²⁰³ And some have found that a concurrent or recent pregnancy adversely affects survival.^{204, 205} It is argued that breast cells that have already begun malignant transformation are adversely affected by the hormones of pregnancy, while normal stem cells become more resistant because of a pregnancy. It is possible that early and recent use of oral contraceptives also accelerates the growth of a pre-existing malignancy, explaining the limitation of the finding to current and recent use and the increase in localized disease. With the accumulation of greater numbers of older women previously exposed to oral contraceptives, a protective effect may become evident. In a case-control study of women in Toronto, Canada, age 40–69 years, those women who had used oral contraceptives for 5 or more years, 15 or more years previously, had a 50% reduced risk of breast cancer.²⁰⁶

Conclusion

Adding up the benefits of oral contraception, the possible slight increase in risk of breast cancer is far outweighed by positive effects on our public health. But the impact on public health is of little concern during the private clinician—patient interchange in the office. Here personal risk receives highest priority; fear of cancer is a motivating force, and compliance with effective contraception requires accurate information. For these reasons, we provide the following summary of our assessment of the impact of oral contraceptives on the risk of breast cancer.

SUMMARY: Oral Contraceptives and the Risk of Breast Cancer

- **Current and recent use of oral contraceptives may be associated with about a 20% increased risk of early premenopausal breast cancer, essentially limited to localized disease and a very small increase in the actual number of cases (so small, there would be no major impact on incidence figures). This finding may be due to detection/surveillance bias and accelerated growth of already present malignancies, a situation similar to the effects of pregnancy and postmenopausal hormone therapy on the risk of breast cancer (as reviewed in Chapter 18). Further comfort can be derived from the fact that the increase in breast cancer in American women was greater in older women from 1973 to 1994, those who did not have the opportunity to use oral contraception.²⁰⁷ In women under 50 years of age, there was only a slight increase during this same time period.**
- **Previous oral contraceptive use may be associated with a reduced risk of metastatic breast cancer later in life, and possibly with a reduced risk of postmenopausal breast cancer.**
- **Oral contraceptive use does not further increase the risk of breast cancer in women with positive family histories of breast cancer or in women with proven benign breast disease.**
- **The clinician should not fail to take every opportunity to direct attention to all factors that affect breast cancer. Breastfeeding and control of alcohol intake are good examples, and are also components of preventive health care. Especially important is this added motivation to encourage breastfeeding. The protective effect of breastfeeding is exerted (although it is probably a small one; see Chapter 16) on premenopausal breast cancer, the cancer of concern to younger women using oral contraception.**

Other Cancers

The Walnut Creek study suggested that melanoma was linked to oral contraception; however, the major risk factor for melanoma is exposure to sunlight. More recent and accurate evaluation utilizing both the Royal College General Practitioners and Oxford Family Planning Association prospective cohorts and accounting for exposure to sunlight did not indicate a significant difference in the risk of melanoma comparing users to nonusers.^{208, 209} There is no evidence linking oral contraceptive use to kidney cancer, gallbladder cancer, or pituitary tumors.²¹⁰ Long-term oral contraceptive use may slightly increase the risk of molar pregnancy, but there is no convincing evidence of a cause-and-effect association.²¹¹ Although previous studies have not been in agreement, the Nurses' Health Study reports about a 40% reduced risk of colorectal cancer associated with 8 years of previous use of oral contraceptives (most likely higher dose products).²¹²

Endocrine Effects

Adrenal Gland

Estrogen increases the cortisol-binding globulin (CBG). It had been thought that the increase in plasma cortisol while on oral contraception was due to increased binding by this globulin and not an increase in free active cortisol. Now it is apparent that free and active cortisol levels are also elevated. Estrogen decreases the ability of the liver to metabolize cortisol, and in addition, progesterone and related compounds can displace cortisol from transcortin, and thus contribute to the elevation of unbound cortisol. The effects of these elevated levels over prolonged periods of time are unknown, but no obvious impact has become apparent. To put this into perspective, the increase is not as great as that which occurs in pregnancy, and, in fact, it is within the normal range for nonpregnant women.

The adrenal gland responds to adrenocorticotropic hormone (ACTH) normally in women on oral contraceptives; therefore, there is no suppression of the adrenal gland itself. Initial studies indicated that the response to metyrapone (an 11b-hydroxylase blocker) was abnormal, suggesting that the pituitary was suppressed. However, estrogen accelerates the conjugation of metyrapone by the liver; and, therefore, the drug has less effect, thus explaining the subnormal responses initially

reported. The pituitary-adrenal reaction to stress is normal in women on oral contraceptive pills.

Thyroid

Estrogen increases the synthesis and circulating levels of thyroxine-binding globulin. Prior to the introduction of new methods for measuring free thyroxine levels, evaluation of thyroid function was a problem. Measurement of TSH (thyroid-stimulating hormone) and the free thyroxine level in a woman on oral contraception provide an accurate assessment of a patient's thyroid state. Oral contraception affects the total thyroxine level in the blood as well as the amount of binding globulin, but the free thyroxine level is unchanged.

Oral Contraception and Reproduction

The impact of oral contraceptives on the reproductive system is less than initially thought. Early studies that indicated adverse effects have not stood the test of time and the scrutiny of multiple, careful studies. There are two major areas that deserve review: (1). Inadvertent use of oral contraceptives during the cycle of conception and during early pregnancy, and (2). Reproduction after discontinuing oral contraception.

Inadvertent Use During the Cycle of Conception and During Early Pregnancy

One of the reasons, if not the major reason, why a lack of withdrawal bleeding while using oral contraceptives is such a problem is the anxiety produced in both patient and clinician. The patient is anxious because of the uncertainty regarding pregnancy, and the clinician is anxious because of the concerns stemming from the retrospective studies that indicated an increased risk of congenital malformations among the offspring of women who were pregnant and using oral contraception.

Organogenesis does not occur in the first 2 embryonic weeks (first 4 weeks since last menstrual period); however, teratogenic effects are possible between the third and eighth embryonic weeks (5 to 10 weeks since LMP).

Initial positive reports linking the use of contraceptive steroids to congenital malformations have not been substantiated. Many suspect a strong component of recall bias in the few positive studies due to a tendency of patients with malformed infants to recall details better than those with normal children. Other confounding problems have included a failure to consider the reasons for the administration of hormones (e.g., bleeding in an already abnormal pregnancy), and a failure to delineate the exact timing of the treatment (e.g., treatment was sometimes confined to a period of time during which the heart could not have been affected).

An association with cardiac anomalies was first claimed in the 1970s.^{213, 214} This link received considerable support with a report from the U.S. Collaborative Perinatal Project; however, subsequent analysis of these data uncovered several methodologic shortcomings.²¹⁵ Simpson, in a very thorough and critical review in 1990, concluded that there was no reliable evidence implicating sex steroids as cardiac teratogens.²¹⁶ In fact, in his review, Simpson found no relationship between oral contraception and the following problems: hypospadias, limb reduction anomalies, neural tube defects, and mutagenic effects which would be responsible for chromosomally abnormal fetuses. Even virilization is not a practical consideration because the doses required (e.g., 20–40 mg norethindrone per day) are in excess of anything currently used. These conclusions reflect use of combined oral contraceptives as well as progestins alone.

In the past there was a concern regarding the VACTERL complex. VACTERL refers to a complex of vertebral, anal, cardiac, tracheoesophageal, renal, and limb anomalies. While case-control studies indicated a relationship with oral contraception, prospective studies have failed to observe any connection between sex steroids and the VACTERL complex.²¹⁷ A meta-analysis of 26 prospective studies of the risk of birth defects with oral contraceptive ingestion during pregnancy concluded that there was no increase in risk for major malformations, congenital heart defects, or limb reduction defects.²¹⁸

Women who become pregnant while taking oral contraceptives or women who inadvertently take birth control pills early in pregnancy should be advised that the risk of a significant congenital anomaly is no greater than the general rate of 2–3%. This recommendation can be extended to those pregnant woman who have been exposed to a progestational agent such as medroxyprogesterone acetate or 17-hydroxyprogesterone caproate.^{219, 220}

Reproduction After Discontinuing Oral Contraception

Fertility

The early reports from the British prospective studies indicated that former users of oral contraception had a delay in achieving pregnancy. In the Oxford Family Planning Association study, former use had an effect on fertility for up to 42 months in nulligravida women and for up to 30 months in multigravida women.²²¹ Presumably, the delay is due to lingering suppression of the hypothalamic-pituitary reproductive system.

A later analysis of the Oxford data indicated that the delay was concentrated in women age 30–34 who have never given birth.²²² At 48 months, 82% of these women had given birth compared with 89% of users of other contraceptive methods, not a big difference. No effect was observed in women younger than 30 or in women who had previously given birth. Childless women age 25–29 experienced some delay in return to fertility, but by 48 months, 91% had given birth compared with 92% in users of other methods. It should be noted that after 72 months the proportions of women who remained undelivered were the same in both groups of women.

This delay has been observed in the United States as well. In the Boston area, the interval from cessation of contraception to conception was 13 months or greater for 24.8% of prior oral contraceptive users compared with 10.6% for former users of all other methods (12.4% for intrauterine device (IUD) users, 8.5% for diaphragm uses, and 11.9% for other methods).²²³ Oral contraceptive users had a lower monthly percentage of conceptions for the first 3 months, and somewhat lower percentage from 4 to 10 months. It took 24 months for 90% of previous oral contraceptive users to become pregnant, 14 months for IUD users, and 10 months for diaphragm users. Similar findings in Connecticut indicate that this delay lasts at least a year, and the effect is greater with higher dose preparations.²²⁴ Despite this delay, there is no evidence that infertility is increased by the use of oral contraception. In fact, in young women, previous oral contraceptive use is associated with a lower risk of primary infertility.²²⁵

Spontaneous Miscarriage

There is no increase in the incidence of spontaneous miscarriage in pregnancies after the cessation of oral contraception. Indeed, the rate of spontaneous miscarriages and stillbirths is slightly less in former pill users, about 1% less for spontaneous miscarriages and 0.3% less for stillbirths.²²⁶ A protective effect of previous oral contraceptive use against spontaneous miscarriage has been observed to be more apparent in women who become pregnant after age 30.²²⁷

Pregnancy Outcome

There is no evidence that oral contraceptives cause changes in individual germ cells that would yield an abnormal child at a later time.²¹⁶ There is no increase in the number of abnormal children born to former oral contraceptive users, and there is no change in the sex ratio (a sign of sex-linked recessive mutations).^{226, 228} These observations are not altered when analyzed for duration of use. Initial observations that women who had previously used oral contraception had an increase in chromosomally abnormal fetuses have not been confirmed. Furthermore, as noted above, there is no increase in the miscarriage rate after discontinuation, something one would expect if oral contraceptives induce chromosomal abnormalities because these are the principal cause of spontaneous miscarriage.

In a 3-year follow-up of children whose mothers used oral contraceptives prior to conception, no differences could be detected in weight, anemia, intelligence, or development.²²⁹ Former pill users have no increased risks for the following: perinatal morbidity or mortality, prematurity, and low birth weight.^{230, 231} Dizygous twinning has been observed to be nearly two-fold (1.6% versus 1.0%) increased in women who conceive soon after cessation of oral contraception.²²⁶ This effect was greater with longer duration of use.

The only reason (and it is a good one) to recommend that women defer attempts to conceive for a month or two after stopping the pill is to improve the accuracy of gestational dating by allowing accurate identification of the last menstrual period.

Breastfeeding

Oral contraception has been demonstrated to diminish the quantity and quality of lactation in postpartum women. Also of concern is the potential hazard of transfer of contraceptive steroids to the infant (a significant amount of the progestational component is transferred into breast milk);²³² however, no adverse effects have thus far been identified. Women who use oral contraception have a lower incidence of breastfeeding after the 6th postpartum month, regardless of whether oral contraception is started at the first, second, or third postpartum month.^{233, 234 and 235}

In adequately nourished breastfeeding women, no impairment of infant growth can be detected; presumably, compensation is achieved either through supplementary feedings or increased suckling.²³⁶ In an 8-year follow-up study of children breastfed by mothers using oral contraceptives, no effect could be detected on diseases, intelligence, or psychological behavior.²³⁷ This study also found that mothers on birth control pills lactated a significantly shorter period of time than controls, a mean of 3.7 months versus 4.6 months in controls.

Because the above considerations indicate that oral contraception shortens the duration of breastfeeding, it is worthwhile to consider the contraceptive effectiveness of lactation. The contraceptive effectiveness of lactation, i.e., the length of the interval between births, depends on the level of nutrition of the mother (if low, the longer the contraceptive interval), the intensity of suckling, and the extent to which supplemental food is added to the infant diet. If suckling intensity and/or frequency is diminished, contraceptive effect is reduced. Only amenorrheic women who exclusively breastfeed (full breastfeeding) at regular intervals, including nighttime, during the first 6 months have the contraceptive protection equivalent to that provided by oral contraception (98% efficacy); with menstruation or after 6 months, the chance of ovulation increases.^{238, 239} With full or nearly full breastfeeding, approximately 70% of women remain amenorrheic through 6 months and only 37% through one year; nevertheless with exclusive breastfeeding, the contraceptive efficacy at one year is high, at 92%.²³⁹ Fully breastfeeding women commonly have some vaginal bleeding or spotting in the first 8 postpartum weeks, but this bleeding is not due to ovulation.²⁴⁰

Supplemental feeding increases the chance of ovulation (and pregnancy) even in amenorrheic women.²⁴¹ Total protection is achieved by the exclusively breastfeeding woman for a duration of only 10 weeks.²⁴⁰ Half of women studied who are not fully breastfeeding ovulate before the 6th week, the time of the traditional postpartum visit; a visit during the 3rd postpartum week is strongly recommended for contraceptive counseling.

It is apparent that although lactation provides a contraceptive effect, it is variable and not reliable for every woman. Furthermore, because frequent suckling is required to maintain full milk production, women who use oral contraception and also breastfeed less frequently (e.g., because they work outside their home) have two reasons for decreased milk volume. This combination can make it especially difficult to continue nursing.

Initiation of Oral Contraception in the Postpartum Period

The individual woman is in need of contraception early in the postpartum period. In a careful study of 22 postpartum, nonbreastfeeding women, the mean time from delivery to the first menses was 45 ± 10.1 days, and no woman ovulated before 25 days after delivery.²⁴² A high proportion of the first cycles (81.8%) and the subsequent cycles (37%) were not normal; however, this is certainly not predictable in individual women. Others have documented a mean delay of 7 weeks before resumption of ovulation, but half of the women studied ovulated before the 6th week, the time of the traditional postpartum visit. *The obstetrical tradition of scheduling the postpartum visit at 6 weeks should be changed. A 3-week visit would be more productive in avoiding postpartum surprises.*

The Rule of 3's:

In the presence of FULL breastfeeding, a contraceptive method should be used beginning in the 3rd postpartum month.

With PARTIAL breastfeeding or NO breastfeeding, a contraceptive method should begin during the 3rd postpartum week.

After the termination of a pregnancy of less than 12 weeks, oral contraception can be started immediately. After a pregnancy of 12 or more weeks, oral contraception has traditionally been started 2 weeks after delivery to avoid an increased risk of thrombosis during the initial postpartum period. We believe that oral contraception can be started immediately after a second-trimester abortion or premature delivery.

Because of the concerns regarding the impact of oral contraceptives on breastfeeding, a useful alternative is to combine the contraceptive effect of lactation with the progestin-only minipill. This low dose of progestin has no negative impact on breast milk, and some studies document an increase in milk quantity and nutritional quality.²⁴³ Highly effective (near total) protection can be achieved with the combination of lactation and the minipill. Because of the slight positive impact on lactation, the minipill can be started soon after delivery, but at least a 3-day postpartum delay is recommended to allow the decline in pregnancy levels of estrogen and progesterone and the establishment of lactation.²⁴⁴ In addition, use of the progestin-only minipill has been reported to be associated with a 3-fold increased risk of diabetes mellitus in lactating women with recent gestational diabetes.¹³⁰ This special group of women should consider other methods of contraception.

Other Considerations

Prolactin-Secreting Adenomas

Because estrogen is known to stimulate prolactin secretion and to cause hypertrophy of the pituitary lactotrophs, it is appropriate to be concerned over a possible relationship between oral contraception and prolactin-secreting adenomas. Case-control studies have uniformly concluded that no such relationship exists.^{245, 246} Data from both the Royal College of General Practitioners and the Oxford Family Planning Association studies indicated no increase in the incidence of pituitary adenomas.^{210, 247} Previous use of oral contraceptives is not related to the size of prolactinomas at presentation and diagnosis.^{247, 248} Oral contraception can be prescribed to patients with pituitary microadenomas without fear of subsequent tumor growth.^{249, 250} **We have routinely prescribed oral contraception to patients with pituitary microadenomas and have never observed evidence of tumor growth.**

Postpill Amenorrhea

The approximate incidence of "postpill amenorrhea" is 0.7–0.8%, which is equal to the incidence of spontaneous secondary amenorrhea,^{231, 251, 252} and there is no evidence to support the idea that oral contraception causes secondary amenorrhea. If a cause-and-effect relationship exists between oral contraception and subsequent amenorrhea, one would expect the incidence of infertility to be increased after a given population discontinues use of oral contraception. In those women who discontinue oral contraception in order to get pregnant, 50% conceive by 3 months, and after 2 years, a maximum of 15% of nulliparous women and 7% of parous women fail to conceive.²³¹ rates comparable with those quoted for the prevalence of spontaneous infertility. Attempts to document a cause-and-effect relationship between oral contraceptive use and secondary amenorrhea have failed.²⁵³ Although patients with this problem come more quickly to our attention because of previous oral contraceptive use and follow-up, there is no cause-and-effect relationship. Women who have not resumed menstrual function within 12 months should be evaluated as any other patient with secondary amenorrhea.

Use During Puberty

Should oral contraception be advised for a young woman with irregular menses and oligoovulation or anovulation? The fear of subsequent infertility should not be a deterrent to providing appropriate contraception. Women who have irregular menstrual periods are more likely to develop secondary amenorrhea whether they use oral contraception or not. The possibility of subsequent secondary amenorrhea is less of a risk and a less urgent problem for a young woman than leaving her unprotected. The need for contraception takes precedence

There is no evidence that the use of oral contraceptives in the pubertal, sexually active girl impairs growth and development of the reproductive system.²²⁵ Again, the most important concern is and should be the prevention of an unwanted pregnancy. For most teenagers, oral contraception, dispensed in the 28-day package for better compliance, is the contraceptive method of choice.

Infections and Oral Contraception

Viral STDs

The viral STDs include human immunodeficiency virus (HIV), human papillomavirus (HPV), herpes simplex virus (HSV), and hepatitis B (HBV). At the present time, no known associations exist between oral contraception and the viral STDs. Of course, significant prevention includes barrier methods of contraception. Thus far, most studies have found no association between oral contraceptive use and HIV seropositivity, and some have indicated a protective effect. ^{254, 255 and 256} **For women not in a stable, monogamous relationship, a dual approach is recommended, combining the contraceptive efficacy and protection against PID offered by oral contraception with the use of a barrier method (and spermicide) for prevention of viral STDs.**

Bacterial STDs

Sexually transmitted diseases (STDs) are one of the most common public health problems in the United States. It was estimated in 1995, that 7.6% of reproductive age U.S. women reported having been treated for pelvic inflammatory disease (PID). ²⁵⁷ This upper genital tract infection is usually a consequence of STDs. The best estimate of subsequent tubal infertility is derived from an excellent Swedish report; approximately 12% after one episode of PID, 23% after 2 episodes, and 54% after 3 episodes. ²⁵⁸ Because pelvic infection is the single greatest threat to the reproductive future of a young woman, the now recognized protection offered by oral contraception against pelvic inflammatory disease is highly important. ^{259, 260 and 261} **The risk of hospitalization for PID is reduced by approximately 50–60%, but at least 12 months of use are necessary, and the protection is limited to current users.** ^{259, 262} Furthermore, if a patient does get a pelvic infection, the severity of the salpingitis found at laparoscopy is decreased. ^{263, 264} The mechanism of this protection remains unknown. Speculation includes thickening of the cervical mucus to prevent movement of pathogens and bacteria-laden sperm into the uterus and tubes, and decreased menstrual bleeding, reducing movement of pathogens into the tubes as well as a reduction in “culture medium.”

The argument has been made that this protection is limited to gonococcal disease, and chlamydial infections may even be enhanced. Fifteen of 17 published studies by 1985 reported a positive association of oral contraceptives with lower genital tract chlamydial cervicitis. ²⁶⁵ Because lower genital tract infections caused by chlamydia are on the rise (now the most prevalent bacterial STD in the U.S.) and the rate of hospitalization for PID is also increased, it is worthwhile for both patients and clinicians to be alert for symptoms of cervicitis or salpingitis in women on oral contraception who are at high risk of sexually transmitted disease (multiple sexual partners, a history of STD, or cervical discharge). The mechanism for the association between chlamydial cervicitis and oral contraceptives may be the well recognized extension of the columnar epithelium from the endocervix out over the cervix (ectopia) that occurs with oral contraceptive use. ²⁶⁶

Despite this potential relationship between oral contraception and chlamydial infections, it should be emphasized that there is no evidence for an impact of oral contraceptives increasing the incidence of tubal infertility. ²⁶⁷ In fact, a case-control study indicated that oral contraceptive users with chlamydia infection are protected against symptomatic PID. ²⁶⁸ A case-control study has suggested that oral contraceptive users are more likely to harbor unrecognized endometritis, and that this would explain the discrepancy between the observed rates between lower and upper tract infection. ²⁶⁹ However, this would not explain the lack of an association between oral contraceptive use and tubal infertility. Thus, the influence of oral contraception on the upper reproductive tract may be different than on the lower tract. These observations on fertility are derived mostly, if not totally, from women using oral contraceptives containing 50 µg of estrogen. The continued progestin dominance of the lower dose formulations, however, should produce the same protective impact, and evidence indicates that this is so. ²⁶²

Other Infections

In the British prospective studies of high-dose oral contraceptives, urinary tract infections were increased in users of oral contraception by 20%, and a correlation was noted with estrogen dose. An increased incidence of cervicitis was also reported, an effect related to the progestin dose. The incidence of cervicitis increased with the length of time the pill was used, from no higher after 6 months to 3 times higher by the 6th year of use. A significant increase in a variety of viral diseases, e.g., chickenpox, was observed, suggesting steroid effects on the immune system. The prevalence of these effects with low-dose oral contraception is unknown.

Oral contraception appears to protect against bacterial vaginosis and infections with *Trichomonas*. ^{270, 271} Evidence is lacking to convincingly implicate oral contraception with vaginal infections with *Candida* species; ²⁷⁰ however, clinical experience is sometimes impressive when recurrence and cure repeatedly follow use and discontinuation of oral contraception.

Patient Management

Absolute Contraindications to the Use of Oral Contraception

1. Thrombophlebitis, thromboembolic disorders (including a close family history, parent or sibling, suggestive of an inherited susceptibility for venous thrombosis), cerebral vascular disease, coronary occlusion, or a past history of these conditions, or conditions predisposing to these problems.
2. Markedly impaired liver function. Steroid hormones are contraindicated in patients with hepatitis until liver function tests return to normal.
3. Known or suspected breast cancer.
4. Undiagnosed abnormal vaginal bleeding.
5. Known or suspected pregnancy.
6. Smokers over the age of 35.

Relative Contraindications Requiring Clinical Judgment and Informed Consent

1. **Migraine headaches.** In retrospective studies of low-dose pills, it is not clear whether migraine headaches are associated with an increased risk of stroke. Some women report an improvement in their headaches, and in our view, a trial of the lowest dose oral contraceptives is warranted. Oral contraceptives should be avoided in women who have migraine with complex or prolonged aura, or if additional stroke factors are present (older age, smoking, hypertension). ²⁷²
2. **Hypertension.** A woman under 35 who is otherwise healthy and whose blood pressure is well controlled by medication can elect to use oral contraception. We recommend the use of the lowest estrogen dose products.
3. **Uterine leiomyoma.** This is not a contraindication with low-dose oral contraceptives. There is evidence that the risk of leiomyomas was decreased by 31% in women who used higher dose oral contraception for 10 years. ²⁷³ However, case-control studies with lower dose oral contraceptives have found neither a decrease nor an increase in risk, although the Nurses' Health Study reported a slightly increased risk when oral contraceptives were first used in early teenage years. ^{274, 275 and 276} The administration of low-dose oral contraceptives to women with leiomyomata does not stimulate fibroid growth, and is associated with a reduction in menstrual bleeding. ²⁷⁷
4. **Gestational diabetes.** Low-dose formulations do not produce a diabetic glucose tolerance response in women with previous gestational diabetes, and there is no evidence that combined oral contraceptives increase the incidence of overt diabetes mellitus. ^{129, 130} We believe that women with previous gestational diabetes can use oral contraception with annual assessment of the fasting glucose level.
5. **Elective surgery.** The recommendation that oral contraception should be discontinued 4 weeks before elective major surgery to avoid an increased risk of postoperative thrombosis is based on data derived from high-dose pills. If possible, it is safer to follow this recommendation when a period of immobilization is to be expected. It is prudent to maintain contraception right up to the performance of a sterilization procedure, and this short, outpatient operation carries very minimal risk.
6. **Epilepsy.** Oral contraceptives do not exacerbate epilepsy, and in some women, improvement in seizure control has occurred. ²⁷⁸ Antiepileptic drugs, however, may decrease the effectiveness of oral contraception.
7. **Obstructive jaundice in pregnancy.** Not all patients with this history will develop jaundice on oral contraception, especially with the low-dose formulations.
8. **Sickle cell disease or sickle C disease.** Patients with sickle cell trait can use oral contraception. The risk of thrombosis in women with sickle cell disease or sickle C diseases is theoretical (and medicolegal). We believe effective protection against pregnancy in these patients warrants the use of low-dose oral contraception.
9. **Diabetes mellitus.** Effective prevention of pregnancy outweighs the small risk of complicating vascular disease in diabetic women who are under age 35 and otherwise healthy.

10. **Gallbladder disease.** Oral contraceptives do not cause gallstones, but may accelerate the emergence of symptoms when gallstones are already present.

Clinical Decisions

Surveillance

In view of the increased safety of low-dose preparations for healthy young women with no risk factors, such patients need be seen only every 12 months for exclusion of problems by history, measurement of the blood pressure, urinalysis, breast examination, palpation of the liver, and pelvic examination with Pap smear. Women with risk factors should be seen every 6 months by appropriately trained personnel for screening of problems by history and blood pressure measurement. Breast and pelvic examinations are necessary only yearly. It is worth emphasizing that better continuation is achieved by reassessing new users within 1–2 months. It is at this time that subtle fears and unvoiced concerns need to be confronted and resolved.

Oral contraception is safer than most people think it is, and the low-dose preparations are extremely safe. Health care providers should make a significant effort to get this message to our patients (and our colleagues). We must make sure our patients receive adequate counseling, either from ourselves or our professional staff. The major reason why patients discontinue oral contraception is fear of side effects.²⁷⁹ Let's take time to put the risks into proper perspective, and to emphasize the benefits as well as the risks.

Laboratory surveillance should be used only when indicated. Routine biochemical measurements fail to yield sufficient information to warrant the expense. Assessing the cholesterol-lipoprotein profile and carbohydrate metabolism should follow the same guidelines applied to all patients, users and nonusers of contraception. The following is a useful guide as to who should be monitored with blood screening tests for glucose, lipids, and lipoproteins:

- Young women, at least once.
- Women 35 years or older.
- Women with a strong family history of heart disease, diabetes mellitus, or hypertension.
- Women with gestational diabetes mellitus.
- Women with xanthomatosis.
- Obese women.
- Diabetic women.

Choice of Pill

The therapeutic principle remains: utilize the formulations that give effective contraception and the greatest margin of safety. You and your patients are urged to choose a low-dose preparation containing less than 50 µg of estrogen, combined with low doses of new or old progestins. Current data support the view that there is greater safety with preparations containing less than 50 µg of estrogen. The arguments in this chapter indicate that all patients should begin oral contraception with low-dose products, and that patients on higher dose oral contraception should be changed to the low-dose preparations. Stepping down to a lower dose can be accomplished immediately with no adverse reactions such as increased bleeding or failure of contraception.

The multiphasic preparations do have a reduced progestin dosage compared with some of the existing monophasic products; however, based on currently available information there is little difference between the low-dose monophasics and the multiphasics.

The pharmacologic effects in animals of various formulations have been used as a basis for therapeutic recommendations in selecting the optimal oral contraceptive pill. *These recommendations (tailor-making the pill to the patient) have not been supported by appropriately controlled clinical trials. All too often this leads to the prescribing of a pill of excessive dosage with its attendant increased risk of serious side effects.* It is worth repeating our earlier comments on potency. Oral contraceptive potency (specifically progestin potency) is no longer a consideration when it comes to prescribing birth control pills. The potency of the various progestins has been accounted for by appropriate adjustments of dose. Clinical advice based on potency is an artificial exercise that has not stood the test of time. The biologic effect of the various progestational components in current low-dose oral contraceptives is approximately the same. Our progress in lowering the doses of the steroids contained in oral contraceptives has yielded products with little serious differences.

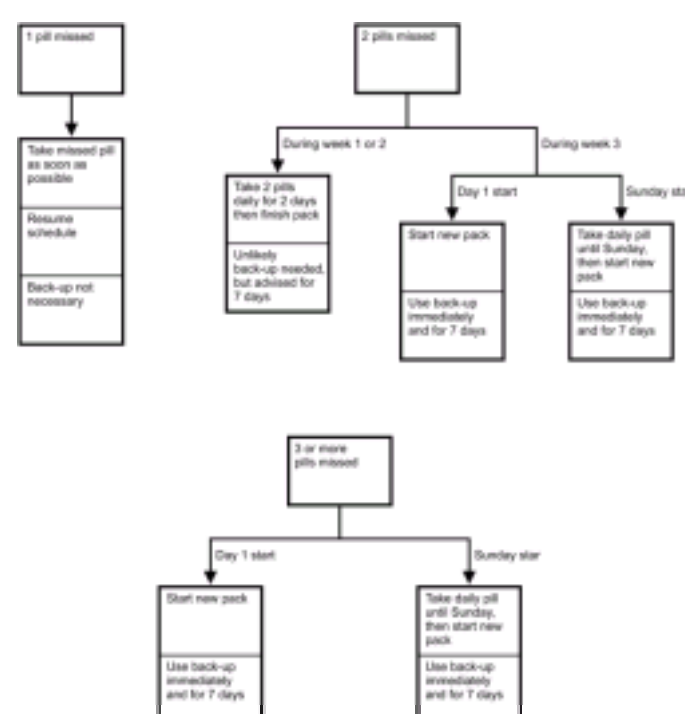

Pill Taking

Effective contraception is present during the first cycle of pill use, provided the pills are started no later than the 5th day of the cycle, and no pills are missed. Thus, starting oral contraception on the first day of menses ensures immediate protection. In the United States, most clinicians and patients prefer the Sunday start packages, beginning on the first Sunday following menstruation. This can be easier to remember, and it usually avoids menstrual bleeding on weekends. It is probable, but not totally certain, that even if a dominant follicle should emerge in occasional patients after a Sunday start, an LH surge and ovulation would still be prevented.²⁸⁰ Some clinicians prefer to advise patients to use added protection in the first week of use.

Occasionally patients would like to postpone a menstrual period; e.g., for a wedding, holiday, or vacation. This can be easily achieved by omitting the 7-day hormone-free interval. Simply start a new package of pills the next day after finishing the series of 21 pills in the previous package. Remember, when using a 28-pill package, the patient would start a new package after using the 21 active pills.

There is no rationale for recommending a pill-free interval "to rest." The serious side effects are not eliminated by pill-free intervals. This practice all too often results in unwanted pregnancies.

How important is it to take the oral contraceptive at the same time every day? Although not well studied, there is reason to believe precise pill taking minimizes breakthrough bleeding. In addition, compliance is improved by a fixed schedule that is habit-forming.

What To Do When Pills Are Missed

Irregular pill taking is a common occurrence. Using an electronic monitoring device to measure compliance, it was apparent that consistency of pill taking is even worse than what patients report; only 33% of women were documented to have missed no pills in cycle 1, and by cycle 3, about one-third of the women missed 3 or more pills with many episodes of consecutive days of missed pills.²⁸¹ These data indicate that women become less careful over time, emphasizing the importance of

repeatedly reviewing with patients what to do when pills are missed.

If a woman misses 1 pill, she should take that pill as soon as she remembers and take the next pill as usual. No backup is needed.

If she misses 2 pills in the first two weeks, she should take two pills on each of the next two days; it is unlikely that a back-up method is needed, but the official consensus is to recommend backup for the next 7 days.

If 2 pills are missed in the third week, or if more than 2 active pills are missed at any time, another form of contraception should be used as backup immediately and for 7 days; if a Sunday starter, keep taking a pill every day until Sunday, and on Sunday start a new package; if a non-Sunday starter, start a new package the same day.

Studies have questioned whether missing pills has an impact on contraception. One study demonstrated that skipping 4 consecutive pills at varying times in the cycle did not result in ovulation.²⁸⁰ Studies in which women deliberately lengthen their pill-free interval up to 11 days have failed to show signs of ovulation.^{282, 283} So far there is no evidence that moving to lower doses has had an impact on the margin of error. The studies have involved small numbers of women and given the large individual variation, it still is possible that some women might be at risk with a small increase in the pill-free interval. However, the progestational effects on endometrium and cervical mucus serve to ensure good contraceptive efficacy.¹² We may well prove that current recommendations are too conservative, and that a woman's chance of getting pregnant with missing pills is nearly zero. Nevertheless, this conservative advice is the safest message to convey.

The most prevalent problems that can be identified associated with apparent oral contraceptive failures are vomiting and diarrhea.^{13, 14} ***Even if no pills have been missed, patients should be instructed to use a backup method for at least 7 days after an episode of gastroenteritis.***

Clinical Problems

Breakthrough Bleeding

A major continuation problem is breakthrough bleeding. Breakthrough bleeding gives rise to fears and concerns; it is aggravating, and even embarrassing. Therefore, on starting oral contraception, patients need to be fully informed about breakthrough bleeding.

There are two characteristic breakthrough bleeding problems: irregular bleeding in the first few months after starting oral contraception, and unexpected bleeding after many months of use. Effort should be made to manage the bleeding problem in a way that allows the patient to remain on low-dose oral contraception. ***There is no evidence that the onset of bleeding is associated with decreased efficacy, no matter what oral contraceptive formulation is used, even the lowest dose products.*** Indeed, in a careful study, breakthrough bleeding did not correlate with changes in the blood levels of the contraceptive steroids.²⁸⁴

The most frequently encountered breakthrough bleeding occurs in the first few months of use. The incidence is greatest in the first 3 months, ranging from 10–30% in the first month to less than 10% in the third. Breakthrough bleeding rates are higher with the lowest dose oral contraceptives, but not dramatically.²⁸⁵ However, breakthrough bleeding is further increased in women who smoke and use formulations with 20 µg ethinyl estradiol.²⁸⁶ Breakthrough bleeding is best managed by encouragement and reassurance. This bleeding usually disappears by the third cycle in the majority of women. If necessary, even this early pattern of breakthrough bleeding can be treated as outlined below. It is helpful to explain to the patient that this bleeding represents tissue breakdown as the endometrium adjusts from its usual thick state to the relatively thin state allowed by the hormones in oral contraceptives.

Breakthrough bleeding that occurs after many months of oral contraceptive use is a consequence of the progestin-induced decidualization. This endometrium and blood vessels within the endometrium tend to be fragile and prone to breakdown and asynchronous bleeding.

There are two recognized factors (both preventable) that are associated with a greater incidence of breakthrough bleeding. Consistency of use and smoking increase spotting and bleeding, but inconsistency of pill taking is more important and has a greater effect in later cycles, whereas smoking exerts a general effect from beginning to later cycles.²⁸⁷ Reinforcement of consistent pill taking can help minimize breakthrough bleeding. Cervical infection can be another cause of breakthrough bleeding; the prevalence of cervical chlamydial infections is higher among oral contraceptive users who report breakthrough bleeding.²⁸⁸

If bleeding occurs just before the end of the pill cycle, it can be managed by having the patient stop the pills, wait 7 days and start a new cycle. If breakthrough bleeding is prolonged or if it is aggravating for the patient, regardless of the point in the pill cycle, control of the bleeding can be achieved with a short course of exogenous estrogen. Conjugated estrogen, 1.25 mg, or estradiol, 2 mg, is administered daily for 7 days when the bleeding is present, no matter where the patient is in her pill cycle. The patient continues to adhere to the schedule of pill taking. Usually, one course of estrogen solves the problem, and recurrence of bleeding is unusual (but if it does recur, another 7-day course of estrogen is effective).

Responding to irregular bleeding by having the patient take 2 or 3 pills is not effective. The progestin component of the pill will always dominate; hence, doubling the number of pills will also double the progestational impact and its decidualizing, atrophic effect on the endometrium and its destabilizing effect on endometrial blood vessels. The addition of extra estrogen while keeping the progestin dose unchanged is logical and effective. This allows the patient to remain on the low-dose formulation with its advantage of greater safety. Breakthrough bleeding, in our view, is not sufficient reason to expose patients to the increased risks associated with higher dose oral contraceptives. Any bleeding that is not handled by this routine requires investigation for the presence of pathology.

There is no evidence that any oral contraceptive formulations that are approximately equivalent in estrogen and progestin dosage are significantly different in the rates of breakthrough bleeding. Clinicians often become impressed that switching to another product effectively stops the breakthrough bleeding. It is more likely that the passage of time is the responsible factor, and bleeding would have stopped regardless of switching and regardless of product.

Amenorrhea

With low-dose pills, the estrogen content is not sufficient in some women to stimulate endometrial growth. The progestational effect dominates to such a degree that a shallow atrophic endometrium is produced, lacking sufficient tissue to yield withdrawal bleeding. It should be emphasized that permanent atrophy of the endometrium does not occur, and resumption of normal ovarian function will restore endometrial growth and development. Indeed, there is no harmful, permanent consequence of amenorrhea while on oral contraception.

The major problem with amenorrhea while on oral contraception is the anxiety produced in both patient and clinician because the lack of bleeding may be a sign of pregnancy. The patient is anxious because of the uncertainty regarding pregnancy, and the clinician is anxious because of the medicolegal concerns stemming from the old studies which indicated an increased risk of congenital abnormalities among the offspring of women who inadvertently used oral contraception in early pregnancy. We reviewed this problem earlier, and emphatically stated that there is no association between oral contraception and an increased risk of congenital malformation, and there is no increased risk of having abnormal children.

The incidence of amenorrhea in the first year of use with low-dose oral contraception is less than 2%. This incidence increases with duration, reaching perhaps 5% after several years of use. It is important to alert patients upon starting oral contraception that diminished bleeding and possibly no bleeding may ensue.

Amenorrhea is a difficult management problem. A pregnancy test will allow reliable assessment for the presence of pregnancy even at this early stage. However, routine, repeated use of such testing is expensive and annoying, and may lead to discontinuation of oral contraception. ***A simple test for pregnancy is to assess the basal body temperature during the END of the pill-free week; a basal body temperature less than 98 degrees (36.6°C) is not consistent with pregnancy, and oral contraception can be continued.***

Many women are reassured with an understanding of why there is no bleeding and are able to continue on the pill despite the amenorrhea. Some women cannot reconcile themselves to a lack of bleeding, and this is an indication for trying other formulations (a practice unsupported by any clinical trials, and, therefore, the expectations are uncertain). But again, this problem does not warrant exposing patients to the greater risks of major side effects associated with higher dose products.

Some clinicians have observed that the addition of extra estrogen for 1 month (1.25 mg conjugated estrogens or 2 mg estradiol daily throughout the 21 days while taking the oral contraceptive) will rejuvenate the endometrium, and withdrawal bleeding will resume, persisting for many months.

Weight Gain

The complaint of weight gain is frequently cited as a major problem with compliance. Yet, studies of the low-dose preparations fail to demonstrate a significant weight gain with oral contraception, and no major differences among the various products. ^{140, 141, 289} This is obviously a problem of perception. The clinician has to carefully reinforce the lack of association between low-dose oral contraceptives and weight gain and focus the patient on the real culprit: diet and level of exercise. Most women gain a moderate amount of weight as they age, whether they take oral contraceptives or not.

Acne

Low-dose oral contraceptives improve acne regardless of which product is used. ^{122, 290, 291 and 292} The low progestin doses (including levonorgestrel formulations) currently used are insufficient to stimulate an androgenic response.

Ovarian Cysts

Anecdotal reports suggested that functional ovarian cysts are encountered more frequently and suppress less easily with multiphasic formulations. This observation failed to withstand careful scrutiny. ²⁹³ Functional ovarian cysts occurred less frequently in women on higher dose oral contraception. ²⁹⁴ This protection is reduced with the current lower dose products to the point where little effect can be measured. ^{295, 296, 297 and 298} Thus, the risk of such cysts is not eliminated; and, therefore, clinicians can encounter such cysts in patients taking any of the oral contraceptive formulations.

Drugs That Affect Efficacy

There are many anecdotal reports of patients who conceived on oral contraceptives while taking antibiotics. There is little evidence, however, that antibiotics such as ampicillin, metronidazole, quinolone, and tetracycline, which reduce the bacterial flora of the gastrointestinal tract, affect oral contraceptive efficacy. Studies indicate that while antibiotics can alter the excretion of contraceptive steroids, plasma levels are unchanged, and there is no evidence of ovulation. ^{299, 300} A review of a large number of patients derived from dermatology practices failed to find an increased rate of pregnancy in women on oral contraceptives and being treated with antibiotics (tetracyclines, penicillins, cephalosporins). ³⁰¹

There is good reason to believe that drugs, which stimulate the liver's metabolic capacity, can affect oral contraceptive efficacy. On the other hand, a search of a large database failed to discover any evidence that lower dose oral contraceptives are more likely to fail or to have more drug interaction problems when other drugs are used. ³⁰²

To be cautious, patients on medications that affect liver metabolism should choose an alternative contraceptive. These drugs are as follows:

- Rifampin
- Phenobarbital
- Phenytoin (Dilantin)
- Primidone (Mysoline)
- Carbamazepine (Tegretol)
- Possibly* ethosuximide, griseofulvin, and troglitazone.

Other Drug Interactions

Although not extensively documented, there is reason to believe that oral contraceptives potentiate the action of diazepam (Valium), chlorthalidone (Librium), tricyclic antidepressants, and theophylline. ³⁰³ Thus, lower doses of these agents may be effective in oral contraceptive users. Because of an influence on clearance rates, oral contraceptive users may require larger doses of acetaminophen and aspirin. ³⁰⁴

Migraine Headaches

True migraine headaches are more common in women, while tension headaches occur equally in men and women. There have been no well done studies to determine the impact of oral contraception on migraine headaches. Patients may report that their headaches are worse or better.

Studies with high-dose pills indicated that migraine headaches were linked to a risk of stroke. More recent studies reflecting the use of low-dose formulations yield mixed results. One failed to find a further increase in stroke in patients with migraine who use oral contraception, another concluded that the use of oral contraception by migraineurs was associated with a 4-fold increase of the already increased risk of ischemic stroke. ^{305, 306} Because 20–30% of women experience migraine headaches, one would expect the study populations in the most recent studies of thrombosis to have included substantial numbers of migraineurs. An adverse effect of low-dose oral contraceptives on stroke risk in migraineurs should have manifested itself in the data. The lack of an increased risk of stroke in these studies is reassuring.

Because of the seriousness of this potential complication, the onset of visual symptoms or severe headaches requires a response. If the patient is at a higher dose, a move to a low-dose formulation may relieve the headaches. Switching to a different brand is worthwhile, if only to evoke a placebo response. True vascular headaches (classic migraine with aura) are an indication to avoid or discontinue oral contraception. Oral contraceptives should be avoided in women who have migraine with complex or prolonged aura, or if additional stroke factors are present (older age, smoking, hypertension). ²⁷²

Clues To Severe Vascular Headaches:

- Headaches that last a long time.
- Dizziness, nausea, or vomiting with headaches.
- Scotomata or blurred vision.
- Episodes of blindness.
- Unilateral, unremitting headaches.
- Headaches that continue despite medication.

In some women, a relationship exists between their fluctuating hormone levels during a menstrual cycle and migraine headaches, with the onset of headaches characteristically coinciding with menses. We have had personal success (anecdotal to be sure) alleviating headaches by eliminating the menstrual cycle, either with the use of *daily* oral contraceptives or the daily administration of a progestational agent (such as 10 mg medroxyprogesterone acetate) or the use of depot-medroxyprogesterone acetate. Some women with migraine headaches have extremely gratifying responses. Women who experience an exacerbation of their headaches with oral contraception should consider one of the progestin-only methods.

Summary: Oral Contraceptive Use and Medical Problems

Gestational Diabetes. There is no contraindication to combined oral contraceptive use following gestational diabetes. ^{129, 130} There is a concern with breastfeeding women using the progestin-only minipill (discussed later in this chapter).

Diabetes Mellitus. Oral contraception can be used by diabetic women less than 35 years old who do not smoke and are otherwise healthy (especially an absence of diabetic vascular complications). A case-control study could find no evidence that oral contraceptive use by young women with insulin-dependent diabetes mellitus

increased the development of retinopathy or nephropathy.¹³² In a one-year study of women with insulin-dependent diabetes mellitus who were using a low-dose oral contraceptive, no deterioration could be documented in lipoprotein or hemostatic biochemical markers for cardiovascular risk.¹³³

Hypertension. Low-dose oral contraception can be used in women less than age 35 years old with hypertension well controlled by medication, and who are otherwise healthy and do not smoke. We recommend the lowest estrogen dose formulations.

Pregnancy-Induced Hypertension. Women with pregnancy-induced hypertension can use oral contraception as soon as the blood pressure is normal in the postpartum period.

Hemorrhagic Disorders. Women with hemorrhagic disorders and women taking anticoagulants can use oral contraception. Inhibition of ovulation can avoid the real problem of a hemorrhagic corpus luteum in these patients. A reduction in menstrual blood loss is another benefit of importance.

Gallbladder Disease. Oral contraception use may precipitate a symptomatic attack in women known to have stones or a positive history for gallbladder disease and, therefore, should either be used very cautiously or not at all.

Obesity. An obese woman who is otherwise healthy can use low-dose oral contraception.

Hepatic Disease. Oral contraception can be utilized when liver function tests return to normal. Follow-up liver function tests should be obtained after 2–3 months of use.

Seizure Disorders. There is no impact of oral contraceptives on pattern or frequency of seizures. The concern is that anticonvulsant-induced hepatic enzyme activity can increase the risk of contraceptive failure. Some clinicians advocate the use of higher dose (50 mg estrogen) products; however, no studies have been performed to demonstrate that this higher dose is necessary.

Mitral Valve Prolapse. Oral contraception use is limited to nonsmoking patients who are asymptomatic (no clinical evidence of regurgitation). There is a small subset of patients with mitral valve prolapse who are at increased risk of thromboembolism. Patients with atrial fibrillation, migraine headaches, or clotting factor abnormalities should consider progestin-only methods or the IUD (prophylactic antibiotics should cover IUD insertion if mitral regurgitation is present).

Systemic Lupus Erythematosus. Oral contraceptive use can exacerbate systemic lupus erythematosus, and the vascular disease associated with lupus, when present, represents a contraindication to estrogen-containing oral contraceptives.³⁰⁷ The progestin-only methods are a good choice. However, in patients with stable or inactive disease, without renal involvement and high antiphospholipid antibodies, low-dose oral contraception can be considered.³⁰⁸ SELENA (Safety of Estrogen in Lupus Erythematosus National Assessment) is an on-going randomized, controlled clinical trial of oral contraceptive therapy in premenopausal women with systemic lupus erythematosus (as well as postmenopausal hormone therapy).

Migraine Headaches. Low-dose oral contraception (the lowest estrogen dose formulation) can be tried with careful surveillance in women with common migraine headaches. Daily administration can prevent menstrual migraine headaches. Oral contraception is best avoided in women with classic migraine headaches associated with neurologic symptoms.

Sickle Cell Disease. Patients with sickle cell trait can use oral contraception. The risk of thrombosis in women with sickle cell disease or sickle C diseases is theoretical (and medicolegal). We believe effective protection against pregnancy in these patients warrants the use of low-dose oral contraception. In the only long-term (10 years) follow-up report of women with sickle cell disease and using oral contraceptives, no apparent adverse effects were observed (at a time when higher dose products were prevalent).³⁰⁹ Keep in mind that depot-medroxyprogesterone acetate used for contraception is associated with inhibition of sickling and improvement in anemia in patients with sickle cell disease.³¹⁰

Benign Breast Disease. Benign breast disease is not a contraindication for oral contraception; with 2 years of use, the condition may improve.

Congenital Heart Disease or Valvular Heart Disease. Oral contraception is contraindicated only if there is marginal cardiac reserve or a condition that predisposes to thrombosis.

Hyperlipidemia. Because low-dose oral contraceptives have negligible impact on the lipoprotein profile, hyperlipidemia is not an absolute contraindication, with the exception of very high levels of triglycerides (which can be made worse by estrogen). If vascular disease is already present, oral contraception should be avoided. If other risk factors are present, especially smoking, oral contraception is not recommended. Dyslipidemic patients who begin oral contraception should have their lipoprotein profiles monitored monthly for a few visits to ensure no adverse impact. If the lipid abnormality cannot be held in control, an alternative method of contraception should be used.³¹¹ Oral contraceptives containing desogestrel, noregestimate, or gestodene can increase HDL levels, but it is not known if this change is clinically significant.

Depression. Low-dose oral contraceptives have minimal, if any, impact on mood.

Smoking. Oral contraception is absolutely contraindicated in smokers over the age of 35. In patients 35 years old and younger, heavy smoking (15 or more cigarettes per day) is a relative contraindication. The relative risk of cardiovascular events is increased for women of all ages who smoke and use oral contraceptives; however, because the actual incidence of cardiovascular events is so low at a young age, the real risk is very low for young women, although it increases with age. An ex-smoker (for at least one year) should be regarded as a nonsmoker. Risk is only linked to active smoking. Is there room for judgment? Given the right circumstances, low-dose oral contraceptives might be appropriate for a light smoker or the user of a nicotine patch. A 20 µg estrogen formulation may be a better choice for smoking women, regardless of age (because this dose of estrogen has no impact on clotting factors and platelet activation).^{31, 32}

Pituitary Prolactin-Secreting Adenomas. Low-dose oral contraception can be used in the presence of microadenomas.

Infectious Mononucleosis. Oral contraception can be used as long as liver function tests are normal.

Ulcerative Colitis. There is no association between oral contraception and ulcerative colitis. Women with this problem can use oral contraceptives.¹⁴³ Oral contraceptives are absorbed mainly in the small bowel.

An Alternative Route of Administration

Occasionally, a situation may be encountered when an alternative to oral administration of contraceptive pills is required. For example, patients receiving chemotherapy can either have significant nausea and vomiting, or mucositis, both of which would prevent oral drug administration. The low-dose oral contraceptives can be administered vaginally. Initially, it was claimed that two pills must be placed high in the vagina daily in order to produce contraceptive steroid blood levels comparable with the oral administration of one pill.³¹² However, a large clinical trial has demonstrated typical contraceptive efficacy with one pill administered vaginally per day.³¹³

Athletes and Oral Contraception

Because athletes are often amenorrheic and hypoestrogenic, oral contraceptives provide not only confidence against the risk of an unwanted pregnancy, but also estrogen support against bone loss. This is a situation where bone density measurements are worthwhile. A low bone density can help motivate an athlete to take hormone therapy, and a subsequent bone density measurement that reveals a failure of response to estrogen can indicate the presence of a hidden eating disorder.

Competing athletes are often concerned that oral contraceptives could reduce exercise performance. A rationale for the concern can be traced to the physiologic increase in ventilation during pregnancy, mediated by progesterone. Thus, progestin enhancement of ventilatory response could consume energy otherwise available for athletic performance. Indeed, reports have generated conflicting data as measured by laboratory testing. However, experimental studies that simulate athletic

events can find no adverse effects on oxygen uptake or respiratory rate.³¹⁴ One study documented decreased soreness, both perceived and with palpation, after exercise in women using oral contraceptives.³¹⁵ Oral contraceptive use has no effect on prevalence or severity of low back pain, a common problem among female athletes.³¹⁶

Oral contraceptives have a lot to offer with no serious drawbacks for athletes. In athletes who wish to avoid menstrual bleeding, oral contraceptives can be administered on a daily basis, with no breaks, preventing withdrawal bleeding.

The Noncontraceptive Benefits of Oral Contraception

The noncontraceptive benefits of low-dose oral contraception can be grouped into two main categories: benefits that incidentally accrue when oral contraception is specifically utilized for contraceptive purposes and benefits that result from the use of oral contraceptives to treat problems and disorders.

The noncontraceptive incidental benefits can be listed as follows:

Effective Contraception.

- less need for induced abortion.
- less need for surgical sterilization.

Less Endometrial Cancer.

Less Ovarian Cancer.

Fewer Ectopic Pregnancies.

More Regular Menses.

- less flow.
- less dysmenorrhea.
- less anemia.

Less Salpingitis.

Probably Less Endometriosis.

Possibly Less Benign Breast Disease.

Possibly Less Rheumatoid Arthritis.

Possibly Protection against Atherosclerosis.

Possibly Increased Bone Density.

Possibly Fewer Fibroids.

Possibly Fewer Ovarian Cysts.

Many of these benefits have been previously discussed. Protection against pelvic inflammatory disease is especially noteworthy and a major contribution to not only preservation of fertility but to lower health care costs. Also important is the prevention of ectopic pregnancies. Ectopic pregnancies have increased in incidence (partly due to an increase in STDs) and represent a major cost for our society and a threat to both fertility and life for individual patients.

Of course, prevention of benign and malignant neoplasia is an outstanding feature of oral contraception. High-dose oral contraceptive use decreased the incidence of benign breast disease diagnosed clinically as well as fibrocystic disease and fibroadenomas diagnosed by biopsy; hopefully, the same impact will become evident with current lower dose formulations. A 40% reduction in ovarian cancer and a 50% reduction in endometrial cancer represent substantial protection. Studies with higher dose formulations documented in long-term users a 31% reduction in uterine leiomyomata and, in current users, a 78% reduction in corpus luteum cysts and a 49% reduction in functional ovarian cysts.²⁹⁴ The impact of low-dose preparations on these problems remains to be accurately measured and may be less.

Case-control studies with low-dose oral contraceptives have found no impact on the risk of uterine fibroids, neither increased nor decreased.^{274, 275} Epidemiologic studies have indicated that a progressive decline in the incidence of ovarian cysts is proportional to the steroid doses in oral contraceptives.^{295, 296} Current low-dose monophasic and multiphasic formulations provide no protection against functional ovarian cysts.^{295, 296, 297 and 298} This apparent weaker protection afforded by the current low-dose formulations makes it very likely that clinicians will encounter such cysts in their patients on oral contraceptives.

The low-dose contraceptives are as effective as higher dose preparations in reducing menstrual flow and the prevalence and severity of dysmenorrhea.^{317, 318} The use of oral contraception is associated with a lower incidence of endometriosis, although the protective effect is probably limited to current or recent use.^{319, 320 and 321} These benefits involving two common gynecologic problems have an important, positive impact on compliance.

An Austrian study concluded that osteoporosis occurs later and is less frequent in women who have used long-term oral contraception.³²² Cross-sectional studies of postmenopausal women indicate that prior use of oral contraception is associated with higher levels of bone density and that the degree of protection is related to duration of exposure.^{323, 324} However, other studies reflecting modern use of low-dose products indicate little impact of oral contraceptive use on bone.^{325, 326 and 327} These measurements of bone density are not as important as the clinical outcome: fractures. The available evidence suggests that any favorable effects on bone density are not clinically important. In the Royal College of General Practitioners Study, the overall risk of fractures in ever users of oral contraceptives was actually slightly increased.³²⁸ Similar results have been observed in the Oxford Family Planning Association Study.³²⁹ It is likely that the increased risk reflects lifestyle effects among oral contraceptive users, but thus far, there is no evidence of a protective effect against fractures. However, previous oral contraceptive users are just now becoming elderly and reaching the age of greatest fracture prevalence. Future studies of postmenopausal women may eventually reveal a beneficial effect on osteoporotic fractures.

The literature on rheumatoid arthritis has been controversial, with studies in Europe finding evidence of protection and studies in North America failing to demonstrate such an effect. An excellent Danish case-control study was designed to answer criticisms of shortcomings in the previous literature.³³⁰ Ever use of oral contraception reduced the relative risk of rheumatoid arthritis by 60%, and the strongest protection was present in women with a positive family history. One meta-analysis concluded that the evidence consistently indicated a protective effect, but that rather than preventing the development of rheumatoid arthritis, oral contraception may modify the course of disease, inhibiting the progression from mild to severe disease; whereas a later meta-analysis concluded there was no evidence of a protective effect.^{331, 332}

Oral contraceptives are frequently utilized to manage the following problems and disorders:

Definitely Beneficial:

- dysfunctional uterine bleeding.
- dysmenorrhea.
- mittelschmerz.
- endometriosis prophylaxis.
- acne and hirsutism.
- hormone therapy for hypothalamic amenorrhea.
- prevention of menstrual porphyria.
- control of bleeding (dyscrasias, anovulation).

Possibly Beneficial:

- functional ovarian cysts.

-premenstrual syndrome.

Oral contraceptives have been a cornerstone for the treatment of anovulatory, dysfunctional uterine bleeding. For patients who need effective contraception, oral contraceptives are a good choice to provide hormone therapy for amenorrheic patients, as well as to treat dysmenorrhea. Oral contraceptives are also a good choice to provide prophylaxis against the recurrence of endometriosis in a woman who has already undergone more vigorous treatment with surgery or the GnRH analogues. To protect against endometriosis, oral contraceptives should be taken daily, with no break and no withdrawal bleeding.

The low-dose oral contraceptives are effective in treating acne and hirsutism. Suppression of free testosterone levels is comparable with that achieved with higher dosage.^{290, 333} The beneficial clinical effect is the same with low-dose preparations containing levonorgestrel, previously recognized to cause acne at high dosage.^{290, 334} Formulations with desogestrel, gestodene, and norgestimate are associated with greater increases in sex hormone-binding globulin and significant decreases in free testosterone levels. Comparison studies with oral contraceptives containing these progestins can detect no differences in effects on various androgen measurements among the various products.³³⁵ Theoretically, these products would be more effective in the treatment of acne and hirsutism; however, this is yet to be documented by clinical studies. It is likely that all low-dose formulations, through the combined effects of an increase in sex hormone-binding globulin and a decrease in testosterone production, produce an overall similar clinical response, especially over time (a year or more).

Oral contraceptives have long been used to speed the resolution of ovarian cysts, but the efficacy of this treatment has not been established. Randomized trials have been performed with women who develop ovarian cysts after induction of ovulation.^{336, 337} No advantage for the contraceptive treatment could be demonstrated. The cysts resolved completely and equally fast in both treated and non-treated groups. Of course, these were functional cysts secondary to ovulation induction, and this experience may not apply to spontaneously appearing cysts. Two short-term (5 and 6 weeks) randomized studies could document no greater effect of oral contraceptive treatment on resolution of spontaneous ovarian cysts when compared with expectant management.^{338, 339} Clinical experience (untested by studies) leads us to believe that oral contraception does provide protection in women against the recurrent formation of ovarian cysts.

Continuation: Failure or Success?

Despite the fact that oral contraception is highly effective, hundreds of thousands of unintended pregnancies (close to 1 million) occur each year in the United States because of the failure of oral contraception. Worldwide, literally millions of unintended pregnancies result from poor compliance. In general, unmarried, poor, and minority women are more likely to have failures, reaching rates of 10–20%.^{340, 341} Overall, the failure rate with actual use ranges from 3 to 6%. This difference between the theoretical efficacy and actual use reflects compliance and noncompliance. Noncompliance includes a wide variety of behavior: failure to fill the initial prescription, failure to continue on the medication, and incorrectly taking oral contraception. Compliance (continuation) is an area in which personal behavior, biology, and pharmacology come together. Oral contraceptive continuation reflects the interaction of these influences. Unfortunately, women who discontinue oral contraception often utilize a less effective method or, worse, fail to substitute another method.

There are 3 major factors that affect continuation:

1. The experience of side effects, such as breakthrough bleeding and amenorrhea, and perceived experience of “minor” problems, such as headaches, nausea, breast tenderness, and weight gain. Multiple side effects dramatically and progressively increase the likelihood of discontinuation.^{342, 343} Because these complaints respond well even to placebo treatment,³⁴⁴ it is reasonable to expect a favorable response to sensitive and attentive counseling.
2. Fears and concerns regarding cancer, cardiovascular disease, and the impact of oral contraception on future fertility.
3. Nonmedical issues, such as inadequate instructions on pill taking, complicated pill packaging, and difficulties arising from the patient package insert.

The information in this chapter is the foundation for good continuation, but the clinician must go beyond the presentation of information and develop an effective means of communicating that information. We recommend the following approach to the clinician—patient encounter as one way to improve continuation with oral contraception.

1. Explain how oral contraception works.
2. Review briefly the risks and benefits of oral contraception, but be careful to put the risks in proper perspective, and to emphasize the safety and noncontraceptive benefits of low-dose oral contraceptives.
3. Show and demonstrate to the patient the package of pills she will use.
4. Explain how to take the pills:
 - When to start.
 - The importance of developing a daily routine to avoid missing pills.
 - What to do if pills are missed (Identify a backup method).
5. Review the side effects that can affect continuation: amenorrhea, breakthrough bleeding, headaches, weight gain, nausea, etc., and what to do if one or more occurs.
6. Explain the warning signs of potential problems: abdominal or chest pain, trouble breathing, severe headaches, visual problems, leg pain or swelling.
7. Ask the patient to be sure to call if another clinician prescribes other medications.
8. Ask the patient to repeat critical information to make sure she understands what has been said. Ask if the patient has any questions.
9. Schedule a return appointment in 1–2 months to review understanding and address fears and concerns; a visit at 3 months is too late because most questions and side effects occur early.³⁴³ Inconsistent use of oral contraceptives is more common in women who are new starters.³⁴¹
10. Make sure a line of communication is open to clinician or office personnel. Ask the patient to call for any problem or concern before she stops taking the oral contraceptives.

The Progestin-Only Minipill

The minipill contains a small dose of a progestational agent and must be taken daily, in a continuous fashion.^{345, 346} There is no evidence for any difference in clinical behavior among the available minipill products.

Minipills available worldwide:

1. Micronor, Nor-QD, Noriday, Norod ----- 0.350 mg norethindrone.
2. Microval, Noregeston, Microlut ----- 0.030 mg norgestrel.
3. Ovrette, Neogest ----- 0.075 mg levonorgestrel.
4. Exluton 0.500 ----- mg lynestrenol.
5. Femulen 0.500 ----- mg ethynodiol diacetate.
6. CerazetteR ----- 0.075 mg desogestrel.

Mechanism of Action

After taking a progestin-only minipill, the small amount of progestin in the circulation (about 25% of that in combined oral contraceptives) will have a significant impact only on those tissues very sensitive to the female sex steroids, estrogen and progesterone. The contraceptive effect is more dependent upon endometrial and cervical mucus effects, because gonadotropins are not consistently suppressed. The endometrium involutes and becomes hostile to implantation, and the cervical mucus becomes thick and impermeable. Approximately 40% of patients will ovulate normally. Tubal physiology may also be affected, but this is speculative.

Because of the low dose, the minipill must be taken every day at the same time of day. The change in the cervical mucus requires 2–4 hours to take effect, and, most importantly, the impermeability diminishes 22 hours after administration, and by 24 hours sperm penetration is essentially unimpaired.

Ectopic pregnancy is not prevented as effectively as intrauterine pregnancy. Although the overall incidence of ectopic pregnancy is not increased (it is still much lower

than the incidence in women not using a contraceptive method), when pregnancy occurs, the clinician must suspect that it is more likely to be ectopic. A previous ectopic pregnancy should not be regarded as a contraindication to the minipill.

There are no significant metabolic effects (lipid levels, carbohydrate metabolism, and coagulation factors remain unchanged),³⁴⁷ and there is an immediate return to fertility on discontinuation (unlike the delay seen with the combination oral contraceptive). Only one disturbing observation has been reported; progestin-only oral contraception was associated with about a 3-fold increased risk of diabetes mellitus in lactating women with recent gestational diabetes (an observation that is difficult to explain).¹³⁰ Because this increased risk is not observed with the use of combined oral contraceptives, it is speculated that the low levels of estrogen associated with breastfeeding allow an unimpeded progestin effect on insulin resistance.

Efficacy

Failure rates have been documented to range from 1.1 to 9.6 per 100 women in the first year of use.³⁴⁸ The failure rate is higher in younger women (3.1 per 100 woman-years) compared with women over age 40 (0.3 per 100 woman-years).³⁴⁹ In motivated women, the failure rate is comparable to the rate (less than 1 per 100 woman-years) with combination oral contraception.^{350, 351 and 352}

Pill Taking

The minipill should be started on the first day of menses, and a backup method must be used for the first 7 days because some women (very few) ovulate as early as 7–9 days after the onset of menses. The pill should be keyed to a daily event to ensure regular administration at the same time of the day. If pills are forgotten or gastrointestinal illness impairs absorption, the minipill should be resumed as soon as possible, and a back-up method should be used immediately and until the pills have been resumed for at least 2 days. If 2 or more pills are missed in a row and there is no menstrual bleeding in 4–6 weeks, a pregnancy test should be obtained. **If more than 3 hours late in taking a pill, a backup method should be used for 48 hours.**

Problems

In view of the unpredictable effect on ovulation, it is not surprising that irregular menstrual bleeding is the major clinical problem. The daily progestational impact on the endometrium also contributes to this problem. Patients can expect to have normal, ovulatory cycles (40%), short, irregular cycles (40%), or a total lack of cycles ranging from irregular bleeding to spotting and amenorrhea (20%). This is the major reason why women discontinue the minipill method of contraception.³⁵²

Women on progestin-only contraception develop more functional, ovarian follicular cysts.³⁵³ Nearly all, if not all, regress. This is not a clinical problem of any significance. Women who have experienced frequent ovarian cysts would be happier with methods that effectively suppress ovulation (combined oral contraceptives and depot-medroxyprogesterone acetate).

The levonorgestrel minipill may be associated with acne. The mechanism is similar to that seen with Norplant. The androgenic activity of levonorgestrel decreases the circulating levels of sex hormone-binding globulin (SHBG). Therefore free steroid levels (levonorgestrel and testosterone) will be increased despite the low dose. This is in contrast to the action of combined oral contraception where the effect of the progestin is countered by the estrogen-induced increase in SHBG.

The incidence of the other minor side effects is very low, probably at the same rate that would be encountered with a placebo.

Clinical Decisions

There are two situations where excellent efficacy, probably near total effectiveness, is achieved: lactating women and women over age 40. In lactating women, the contribution of the minipill is combined with prolactin-induced suppression of ovulation, adding up to very effective protection.³⁵⁴ In breastfeeding, overweight, Latina women with prior gestational diabetes, the progestin-only minipill was associated with a 3-fold increased risk of non-insulin dependent diabetes mellitus.¹³⁰ It is not known whether this might be a risk in all women who have experienced gestational diabetes; a prudent course would be to advise other methods for this special group of women. In women over age 40, reduced fecundity adds to the minipill's effects.

There is another reason why the minipill is a good choice for the breastfeeding woman. There is no evidence for any adverse effect on breastfeeding as measured by milk volume and infant growth and development.^{236, 355, 356} In fact, there is a modest positive impact; women using the minipill breastfeed longer and add supplementary feeding at a later time.²⁴³ Because of the slight positive impact on lactation, the minipill can be started soon after delivery, but at least a 3-day postpartum delay is recommended to allow the decline in pregnancy levels of estrogen and progesterone and the establishment of lactation.²⁴⁴

The minipill is a good choice in situations where estrogen is contraindicated, such as patients with serious medical conditions (diabetes with vascular disease, severe systemic lupus erythematosus, cardiovascular disease). It should be noted that the freedom from estrogen effects, although likely, is presumptive. Substantial data, for example on associations with vascular disease, blood pressure, and cancer, are not available because relatively small numbers have chosen to use this method of contraception. On the other hand, it is logical to conclude that any of the progestin effects associated with the combination oral contraceptives can be related to the minipill according to a dose-response curve; all effects should be reduced. The World Health Organization case-control study could find no indication for increased risks of stroke, myocardial infarction, or venous thromboembolism with oral progestin-only contraceptives.³⁵⁷ No impact can be measured on the coagulation system.^{358, 359} The minipill can probably be used in women with previous episodes of thrombosis, and the package insert in the United States has been revised, eliminating vascular disease as a contraindication.

The minipill is a good alternative for the occasional woman who reports diminished libido on combination oral contraceptives, presumably due to decreased androgen levels. The minipill should also be considered for the few patients who report minor side effects (gastrointestinal upset, breast tenderness, headaches) of such a degree that the combination oral contraceptive is not acceptable.

Because of the relatively low doses of progestin administered, patients using medications that increase liver metabolism should avoid this method of contraception. These drugs include the following:

- Rifampin.
- Phenobarbital.
- Phenytoin (Dilantin).
- Primidone (Mysoline).
- Carbamazepine (Tegretol).
- Possibly* ethosuximide, griseofulvin, and troglitazone.

Do the noncontraceptive benefits associated with combination oral contraception apply to the minipill? Studies are unable to help us with this issue, again because of the relatively small numbers of users. However, the progestin impact on cervical mucus, endometrium, and ovulation leads one to think the benefits will be present (reduced risks of pelvic infection, endometrial cancer, and ovarian cancer), but probably at reduced levels.

Good efficacy with the minipill requires regularity, taking the pill at the same time each day. There is less room for forgetting, and, therefore, the minipill is probably not a good choice for a disorganized adult or for the average adolescent.

Emergency Postcoital Contraception

The use of large doses of estrogen to prevent implantation was pioneered by Morris and van Wagenen at Yale in the 1960s. The initial work in monkeys led to the use of high doses of diethylstilbestrol (25–50 mg/day) and ethinyl estradiol in women.³⁶⁰ It was quickly appreciated that these extremely large doses of estrogen were associated with a high rate of gastrointestinal side effects. Yuzpe developed a method utilizing a combination oral contraceptive, resulting in an important reduction in dosage.³⁶¹ The following treatment regimens have been documented to be effective:

Ovral: 2 tablets followed by 2 tablets 12 hours later.

Alesse: 5 tablets followed by 5 tablets 12 hours later.

Lo Ovral, Nordette, Levlen, Triphasil, Trilevlen: 4 tablets followed by 4 tablets 12 hours later.

Levonorgestrel in a dose of 0.75 mg given twice, 12 hours apart, is more successful and better tolerated than the combination oral contraceptive method, but this dose is equivalent to 10 pills

of the levonorgestrel progestin-only minipill.^{362, 363} In some countries, special packages of 0.75 mg levonorgestrel are available for emergency contraception. Greater efficacy and fewer side effects make low-dose levonorgestrel the treatment of choice.

In the United States, a kit is available containing 4 tablets, each containing 50 µg ethinyl estradiol and 0.250 mg levonorgestrel, to be used in the usual fashion, 2 tablets followed by 2 tablets 12 hours later.

This method has been more commonly called postcoital contraception, or the “morning after” treatment. Emergency contraception is a more accurate and appropriate name, indicating the intention to be one-time protection. It is an important option for patients, and should be considered when condoms break, sexual assault occurs, if diaphragms or cervical caps dislodge, or with the lapsed use of any method. In studies at abortion units, 50–60% of the patients would have been suitable for emergency contraception and would have used it if readily available.^{364, 365} In the U.S., it is estimated that emergency contraception could annually prevent 1.7 million unintended pregnancies and the number of induced abortions would decrease by about 40% to 800,000 per year.³⁶⁶

Many women do not know of this method, and it has been difficult to obtain.^{365, 367} In Europe and New Zealand, special packages with printed instructions are marketed specifically for emergency contraception, and this is now available in the U.S. Even if women are aware of this method, accurate and detailed knowledge is lacking.³⁶⁸ A favorable attitude toward this method requires knowledge and availability. Information can be obtained from the following web site maintained by the Office of Population Research at Princeton University: <http://opr.princeton.edu/ec/>.

Clinicians should consider providing emergency contraceptive kits to patients (a kit can be a simple envelope containing instructions and the appropriate number of oral contraceptives) to

be taken when needed. It would be a major contribution to our efforts to avoid unwanted pregnancies, for all patients without contraindications to oral contraceptives to have emergency contraception available for use when needed. In our view, this would be much more effective in reducing the need for abortion than waiting for patients to call. In a study of such an approach, self-administration by appropriately screened and educated women was found to be effective and free of unwanted effects.³⁶⁹

Mechanism and Efficacy

The mechanism of action is not known with certainty, but it is believed with justification that this treatment combines delay of ovulation with a local effect in the endometrium.^{370, 371} The efficacy has been confirmed in large clinical trials and summarized in complete reviews of the literature.^{372, 373} and ³⁷⁴ Treatment with high doses of estrogen or with levonorgestrel yields a failure rate of approximately 1%, with the combination oral contraceptive, about 2–3%. The failure rate is lowest with high doses of ethinyl estradiol given within 72 hours (0.1%), but the side effects make the combination oral contraceptive a better choice. In general clinical use, the method can reduce the risk of pregnancy by about 75%; this degree of reduction in probability of conception (given the relatively low chance, about 8%, for pregnancy associated with one act of coitus³⁷⁵) yields the 2% failure rate measured in clinical studies (in other words, 98% effective).^{376, 377} Results with levonorgestrel will be even better, 99% effective.

Treatment Method

Treatment should be initiated as soon after exposure as possible, and the standard recommendation is that it be no later than 72 hours. Careful assessment of the reported experience with emergency contraception indicated that the method is equally effective when started on the first, second, or third day after intercourse (which would allow user-friendly scheduling), and that efficacy might extend beyond 72 hours.³⁷⁸ Data from randomized, clinical trials, however, support the importance of timing, finding a reduction in efficacy after 72 hours.³⁶³ Because of possible, but unlikely, harmful effects of these high doses to a fetus, an already existing pregnancy should be ruled out prior to use of postcoital hormones. Furthermore, the patient should be offered induced abortion if the method fails. This patient encounter also provides an important opportunity to screen for STDs.

The combination oral contraceptive method delivers significantly less steroid hormone, and this reduction in the total dose and the number of doses reduces the side effects and limits them to a shorter time period. It is worth adding an antiemetic, oral or suppository, to the treatment; the long-acting nonprescription agent, meclizine, is recommended, to be taken one hour before the emergency contraception treatment. Side effects reflect the high doses used: nausea (50%), vomiting (20%), breast tenderness, headache, and dizziness. If a patient vomits within an hour after taking pills, additional pills must be administered as soon as possible. Although short-term treatment with combined oral contraceptives has been documented to have no effect on clotting factors, the usual contraindications for oral contraception apply to this use.³⁷⁹ **In view of the high dose of estrogen, emergency contraception with combined oral contraceptives should not be provided to women with either a personal or close family history (parent or sibling) of idiopathic thrombotic disease.** For women with a contraindication to exogenous estrogen, the progestin-only minipill can be used for emergency contraception; e.g., administering 10 levonorgestrel tablets (75 µg), for each of the two doses, or in some countries using the special commercial package.

A 3-week follow-up visit should be scheduled to assess the result, and to counsel for routine contraception.

Could other combination oral contraceptive products be used? Because other doses and other formulations have never been tested, the efficacy is unknown. It would not be appropriate to expose patients to an unknown failure rate.

The use of danazol for emergency contraception is not effective.³⁸⁰ Mifepristone (RU486), the progesterone antagonist, has been without failures and with lower side effects in clinical trials.

The 3 major problems with the available methods of emergency contraception are the high rate of side effects, the need to start treatment within 72 hours after intercourse, and the small, but important, failure rate. Mifepristone in a single oral dose of 600 mg is associated with markedly less nausea and vomiting and an efficacy rate of nearly 100%.^{380, 381} Mifepristone is used for emergency contraception in China in a dose as low as 50 mg. Clinical studies have indicated that doses as low as 5 mg or 10 mg daily are effective. Because the next menstrual cycle is delayed after mifepristone, contraception should be initiated immediately after treatment. Ironically, mifepristone, around which swirls the abortion controversy, can make an effective contribution to preventing unwanted pregnancies and induced abortions.

Another method of emergency contraception is the insertion of a copper IUD, up to 5 days after unprotected intercourse. The failure rate (in a small number of studies) is very low, 0.1%.^{372, 373} This method definitely prevents implantation, but it is not suitable for women who are not candidates for intrauterine contraception, e.g., multiple sexual partners, rape victim.

Oral Contraception for Older Women

Women of the post-World War II generation have faced a unique evolutionary change. They were the first to be able to exercise control over their fertility, and then as they aged and deferred pregnancy, they had to deal with the problem of unintended infertility. After World War II, the U.S. total fertility rate reached a modern high of 3.8 births per woman. The last women born in this period will not reach their 45th birthday until around 2010. For approximately a 20-year period, therefore, there will be an unprecedented number of women in the later child-bearing years. The aging of the World War II population boom is giving current times a greater number of women who are delaying marriage and childbirth. This demographic change has 3 specific impacts on couples.

1. A need for effective contraception.
2. The problem of achieving pregnancy later in life.
3. The problem of being pregnant later in life.

This combination of increasing numbers, deferment of marriage, and postponement of pregnancy in marriage is responsible for the fact that we will be seeing more and more older women who will need reversible contraception. This is underscored by the fact that from ages 20–44, American women have the highest proportion of pregnancies aborted compared to other countries, indicating an unappreciated, but real, problem of unintended pregnancy existing beyond the teenage years, especially after age 35. More than half of all pregnancies in the U.S. are estimated to be unplanned, and more than half of these are aborted.³⁸² The best way to minimize the number of induced abortions is effective contraception.

From 1970 to 1986, the number of births in women over 30 quadrupled; however, since 1990, the fertility rate among women over 30 has remained relatively stable.³⁸³ As more and more couples defer pregnancy until later in life, the use of sterilization under age 35 will decline, and the need for reversible contraception will increase. Between 1988 and 1995, oral contraceptive use decreased in women younger than 25 and increased in women aged 30–44.³⁸⁴ These numbers changed because clinicians and patients have come to understand and accept that low-dose oral contraception is safe for healthy, nonsmoking older women.

Oral Contraception for the Transition Years

The years from age 35 to menopause can be referred to as the transition years. Preventive health care for women is especially important during the transition years. The issues of preventive health care are familiar ones. They include contraception, cessation of smoking, prevention of heart disease and osteoporosis, maintenance of mental well-being (including sexuality), and cancer screening. Management of the transition years should be significantly oriented to preventive health care, and the use of low-dose oral contraception can now legitimately be viewed as a component of preventive health care. A discussion of the noncontraceptive health benefits of low-dose oral contraception is especially important with patients in their transition years. This group of women appreciates and understands decisions made with the risk:benefit ratio in mind.

During this period of time, there are several medical needs that must be addressed: the need for contraception, the management of persistent anovulation, and finally, menopausal and postmenopausal hormone therapy.

At approximately 40 years of age, the frequency of ovulation decreases. This initiates a period of waning ovarian function called the climacteric that will last several years, carrying a woman through decreased fertility and menopause to the postmenopausal years. Prior to menopause, the remaining follicles perform less well. As cycles become irregular, vaginal bleeding occurs at the end of an inadequate luteal phase or after a peak of estradiol without subsequent ovulation and corpus luteum formation. Eventually, many women will live through a period of anovulation. Occasionally, corpus luteum formation and function occur, and therefore the older woman is not totally safe from the threat of an unplanned and unexpected pregnancy.

Fortunately clinicians and patients have recognized that low-dose oral contraception is very safe for healthy, nonsmoking older women. However, their use is still not sufficient to meet the need. Besides fulfilling a need, we would argue that this population of women has a series of benefits to be derived from oral contraception that tilts the risk:benefit ratio to the positive side. The benefits of oral contraceptives reviewed in this chapter are especially pertinent for older women. A case-control study could find no evidence for an increased risk of breast cancer in women who used oral contraceptives *after age 40*.³⁸⁵

Despite the widespread teaching and publicity that smoking is a contraindication to oral contraceptive use over the age of 35, more older women who use oral contraceptives smoke and smoke heavily, compared with young women.⁹⁷ This strongly implies that older smokers are less than honest with clinicians when requesting oral contraception. ***A former smoker must have stopped smoking for at least 12 consecutive months to be regarded as a nonsmoker. Women who have nicotine in their bloodstream obtained from patches or gum should be regarded as smokers.*** Smokers over age 35 should continue to be advised that combined oral contraceptives are not a good choice, regardless of the number of cigarettes smoked. In view of the unreported high rate of smoking in older women who use oral contraceptives, clinicians should consider using 20 µg estrogen products for women over age 35.

A product containing 20 µg ethinyl estradiol and 150 µg desogestrel has been demonstrated in multicenter studies of women over age 30 to have the same efficacy and side effects as pills containing 30 and 35 µg of estrogen.^{386, 387 and 388} In a randomized study of women over age 30, this formulation was associated with the virtual elimination of any effects on coagulation factors.³⁸⁹ Indeed, the 20 µg formulation has no significant impact on the measurements of clotting factors, even in smokers.^{31, 32, 389, 390}

Although it is true that the implied safety of the lowest estrogen dose remains to be documented by epidemiologic studies, it seems clinically prudent to maximize the safety margin in this older age group of women. Although there may be some increase in breakthrough bleeding, we believe that older women who understand the increased safety implicit in the lowest estrogen dose are more willing to endure breakthrough bleeding and maintain continuation. With avoidance of risk factors and use of lowest dose pills, health risks are probably negligible for healthy nonsmoking women. For healthy nonsmoking women, no specific laboratory screening is necessary, beyond that which is usually incorporated in a program of preventive health care.

We should also mention the progestin-only minipill. Because of reduced fecundity, the minipill achieves near total efficacy in women over age 40. Therefore, the progestin-only minipill is a good choice for older woman, and especially for those women in whom estrogen is contraindicated. Older women are more accepting of irregular menstrual bleeding when they understand its mechanism, and, thus, are more accepting of the progestin-only minipill.

Anovulation and Bleeding. Throughout the transitional period of life there is a significant incidence of dysfunctional uterine bleeding due to anovulation. While the clinician is usually alerted to this problem because of irregular bleeding, clinician and patient often fail to diagnose anovulation when bleeding is not abnormal in schedule, flow, or duration. As a woman approaches menopause, a more aggressive attempt to document ovulation is warranted. A serum progesterone level measured approximately one week before menses is simple enough to obtain and worth the cost. The prompt diagnosis of anovulation (serum progesterone less than 300 ng/dL) will lead to appropriate therapeutic management that will have a significant impact on the risk of endometrial cancer.

In an anovulatory woman with proliferative or hyperplastic endometrium (unaccompanied by atypia), periodic oral progestin therapy is mandatory, such as 10 mg medroxyprogesterone acetate given daily the first 10 days of each month. If hyperplasia is already present, follow-up aspiration office curettage after 3–4 months is required. If progestin treatment is ineffective and histological regression is not observed, more aggressive treatment is warranted. Monthly progestin treatment should be continued until withdrawal bleeding ceases or menopausal symptoms are experienced. These are reliable signs (in effect, a bioassay) indicating the onset of estrogen deprivation and the need for the addition of estrogen in a postmenopausal hormone program.

If contraception is desired, the clinician and patient should seriously consider the use of oral contraception. The anovulatory woman cannot be guaranteed that spontaneous ovulation and pregnancy will not occur. The use of a low-dose oral contraceptive will at the same time provide contraception and prophylaxis against irregular, heavy anovulatory bleeding and the risk of endometrial hyperplasia and neoplasia. In some patients, oral contraceptive treatment achieves better regulation of menses than monthly progestin administration.

Clinicians have been made so wary of providing oral contraceptives to older women that a traditional postmenopausal hormone regimen is often utilized to treat a woman with the kind of irregular cycles usually experienced in the transitional years. This addition of exogenous estrogen when a woman is not amenorrheic or experiencing menopausal symptoms is inappropriate, and even risky (exposing the endometrium to excessively high levels of estrogen). ***And something that is often unappreciated, the standard doses of estrogen and progestin in a postmenopausal regimen will not suppress gonadotropins and prevent ovulation.***³⁹¹ The appropriate response is to regulate anovulatory cycles with monthly gestational treatment or to utilize low-dose oral contraception.

When to Change From Oral Contraception to Postmenopausal Hormone Therapy

A common clinical dilemma is when to change from oral contraception to postmenopausal hormone therapy. It is important to change because even with the lowest estrogen dose oral contraceptive available, the estrogen dose is four-fold greater than the standard postmenopausal dose, and with increasing age, the dose-related

risks with estrogen become significant. One approach to establish the onset of the postmenopausal years is to measure the FSH level, beginning at age 50, on an annual basis, being careful to obtain the blood sample on day 6 or 7 of the pill-free week (when steroid levels have declined sufficiently to allow FSH to rise). Friday afternoon works well for patients who start new packages on Sunday. When FSH is greater than 20 IU/L, it is time to change to a postmenopausal hormone program. Because of the variability in FSH levels experienced by women around the menopause, this method is not always accurate.³⁹² But there is no harm in retesting after another year or two on low-dose oral contraceptives. Some clinicians are comfortable allowing patients to enter their midfifties on low-dose oral contraception, and then empirically switching to a postmenopausal hormone regimen.

Concluding Thoughts

In the 1970s, as epidemiologic data first became available, we emphasized in our teaching and in our communication with patients the risks and dangers associated with oral contraceptives. In the 1990s, with better patient screening and epidemiologic data documenting the effects of low-dose products, we appropriately emphasized the benefits and safety of modern oral contraceptives. In the new millennium, we can with confidence promote the idea that the use of oral contraceptives yields an overall improvement in individual health, and from a public health point of view, the collection of effects associated with oral contraceptives leads to a decrease in the cost of health care.

Contraceptive advice is a component of good preventive health care, and the clinician's approach is a key factor. This is an era of informed choice by the patient. Patients deserve to know the facts and need help in dealing with the state of the art and those issues clouded by uncertainty. But there is no doubt that patients are influenced in their choices by their clinician's advice and attitude. Although the role of a clinician is to provide the education necessary for the patient to make proper choices, one should not lose sight of the powerful influence exerted by the clinician in the choices ultimately made. Emphasizing the safety and benefits of oral contraceptives, and the contribution of oral contraceptives to individual and public health, allows a clinician to present oral contraception with a very positive attitude, an approach that makes an important contribution to a patient's ability to make appropriate health choices.

[Long-Acting Methods for Older Women](#)

[Chapter References](#)

The high rate of unintended pregnancies and the relatively high failure rates with the typical use of reversible methods of contraception are strong indications of a need for long-acting contraceptive methods that simplify compliance. Two effective and popular methods are available, the Norplant system and depot-medroxyprogesterone acetate (Depo-Provera). Once-a-month injectable contraceptives are used in many parts of the world, and are a new option for U.S. women.

Norplant is a “sustained-release” system using Silastic tubing permeable to steroid molecules to provide stable circulating levels of synthetic progestin over years of use. Norplant was first introduced into clinical trials in Chile in 1972. Assessment of this method was completed in more than 45 countries, and in 1990, Norplant was approved for marketing in the U.S., the 20th country of approximately 60 to do so.¹

The progestin in Norplant, circulating at levels one-fourth to one-tenth of those obtained with combined oral contraceptives, prevents conception by suppressing ovulation and thickening cervical mucus to inhibit sperm penetration so that fertilization rarely occurs.² Because serum levels of progestin remain low and because no estrogen is administered, this long-acting contraceptive method does not cause any serious health effects.¹ This method does, however, cause some bothersome side effects attributable to sustained administration of progestin, such as changes in menstrual pattern, weight gain, headache, and effects on mood.

Injectable medroxyprogesterone acetate (Depo-Provera) is a long-acting (3–6 months) agent that has been part of the contraceptive programs of many countries for more than 20 years. This experience has demonstrated it to be safe, effective, and acceptable. It is not a “sustained-release” system, but its action is the same.

The long-acting progestin methods (including Norplant and Depo-Provera) are as effective as sterilization and IUDs, and more effective than oral and barrier contraception.³ An important reason for this high efficacy in actual use is the nature of the delivery systems themselves which require little effort on the part of the user. Because compliance does not require frequent resupply or instruction in use, as with oral contraception, theoretical (lowest expected) effectiveness is very close to the actual or typical (use) effectiveness.

Sustained-release methods require less of the user, but they demand more of the clinician. Norplant involves minor operative procedures for placement and for discontinuation. Clinicians have a special responsibility to become skillful in the operations required to remove implants and to be available to women when those skills are required to terminate use. Disturbances of menstrual patterns and other side effects prompt many more questions from patients about these methods than about use of the familiar oral, intrauterine, and barrier contraceptives.⁴

The Norplant System

The Norplant subdermal implant system is a long-acting, low-dose, reversible, progestin-only method of contraception for women. It was developed by the Population Council. The implants are manufactured, under license of the Population Council, by Huhtamaki Oy/Leiras Pharmaceuticals in Finland.

The currently available Norplant system consists of 6 capsules, each measuring 34 mm in length with a 2.4 mm outer diameter and containing 36 mg crystalline levonorgestrel. The capsules are made of flexible, medical grade silastic (polydimethylsiloxane and methylvinyl siloxane copolymer) tubing that is sealed shut with silastic medical adhesive (polydimethylsiloxane). The cavity of the capsule has an inner diameter of 1.57 mm, with an inner length of 30 mm. The 6 capsules contain a total of 216 mg levonorgestrel, which is very stable and has remained unchanged in capsules examined after more than 9 years of use.

The implants come packaged in heat-sealed pouches that have a shelf life of 5 years from the date of manufacture and have an additional 5 to 7 years of effective life once inserted. Storage at room temperature with uncontrolled humidity has not altered their composition or lifespan after 4 years, but, optimally, the implants should be stored in a cool, dry area away from direct sunlight. The implants can be ethylene oxide sterilized, but cannot be sterilized by ionizing radiation, dry heat, or autoclaving.

The components of Norplant are not new. The silastic in the tubing has been used in surgical applications such as prosthetic devices, heart valves, and drainage tubes, since the 1950s, and in the most common method of female sterilization (Fallopian Rings) since 1970. The progestin, levonorgestrel, has been widely used in oral contraceptives since the 1960s. The toxicology, teratogenicity, and pharmacology of levonorgestrel have been well studied. What is relatively new is the way the system delivers a sustained level of levonorgestrel for a long time — in ongoing trials, up to 7 years, although currently approved for 5 years.

Mechanism of Action

The release rate of the capsule is determined by its total surface area and the thickness of the capsule wall. The levonorgestrel diffuses through the wall of the tubing into the surrounding tissues where it is absorbed by the circulatory system and distributed systemically, avoiding an initial high level in the circulation as with orally or injected steroids. Within 24 hours after insertion, plasma concentrations of levonorgestrel range from 0.4 to 0.5 ng/mL, high enough to prevent conception; however, a study of cervical mucus changes indicates that a backup method should be used for 3 days after insertion. ^{5,6}

The capsules release approximately 85 µg of levonorgestrel per 24 hours during the first 6–12 months of use. This rate declines gradually to 50 µg daily by 9 months and 30 µg per day for the remaining duration of use. The 85 µg of hormone released by the implants during the first few months of use is about equivalent to the daily dose of levonorgestrel delivered by the progestin-only, minipill oral contraceptive, and 25–50% of the dose delivered by low-dose combined oral contraceptives.

Mean plasma concentrations below 0.20 ng/mL are associated with increased pregnancy rates. After 6 months of use, daily levonorgestrel concentrations are about 0.35 ng/mL; at 2.5 years, the levels decrease to 0.25–0.35 ng/mL. Until the 5-year mark, mean levels remain above 0.25 ng/mL. ⁷

Body weight affects the circulating levels of levonorgestrel. The greater the weight of the user, the lower the levonorgestrel concentrations at any time during Norplant use. The greatest decrease over time occurs in women weighing more than 70 kg (154 pounds), but even for heavy women, the release rate is high enough to prevent pregnancy at least as reliably as oral contraceptives.

Levonorgestrel levels may also be affected by the levels of sex hormone-binding globulin (SHBG). Levonorgestrel has a high affinity for SHBG. In the week after Norplant insertion, SHBG levels decline rapidly, and then return to approximately half of preinsertion levels by 1-year of use. This effect on SHBG is not uniform and may account for some of the individual variations in plasma levonorgestrel concentrations. ⁸

The mechanism by which Norplant prevents conception is only partially explained. There are 3 probable modes of action, which are similar to those attributed to the contraceptive effect of the progestin-only minipills.

1. The levonorgestrel suppresses at both the hypothalamus and the pituitary the luteinizing hormone (LH) surge necessary for ovulation. As determined by progesterone levels in many users over several years, approximately one-third of all cycles are ovulatory. ^{7,9} During the first 2 years of use, only about 10% of women are ovulatory, but by 5 years of use, more than 50% are. In those cycles that are ovulatory, there is a high incidence of luteal insufficiency.
2. The constant level of levonorgestrel has a marked effect on the cervical mucus. The mucus thickens and decreases in amount, forming a barrier to sperm penetration. ^{5,10}
3. The levonorgestrel suppresses the estradiol-induced cyclic maturation of the endometrium, and eventually causes atrophy. These changes could prevent implantation should fertilization occur; however, no evidence of fertilization can be detected in Norplant users. ¹¹

Specific Advantages

Norplant is a safe, highly effective, continuous method of contraception that requires little user effort or motivation and, unlike long-acting injectable contraception, is rapidly reversible. Because this is a progestin-only method, it can be utilized by women who have contraindications for the use of estrogen-containing oral contraceptives. The sustained release of low doses of progestin avoids the high initial dose delivered by injectables and the daily hormone surge associated with oral contraceptives. Norplant is not a coitus-related contraceptive method. The use effectiveness closely approximates the theoretical effectiveness. Norplant is an excellent choice for a breastfeeding woman (there is no effect on breastfeeding) and can be inserted immediately postpartum, but at least a 3-day postpartum delay is recommended to allow the decline in pregnancy levels of estrogen and progesterone and the establishment of lactation. ¹²

General Advantages

One of the major advantages of sustained-release methods is the high degree of efficacy, nearly equivalent to the theoretical effectiveness. In couples for whom elective abortion is unacceptable in the event of an unplanned pregnancy, the high efficacy rate is especially important. There are no forgotten pills, broken condoms, or lost diaphragms. For women who are at high risk of medical complications should they become pregnant, these methods present a significant safety advantage. Users should be reassured that Norplant use has not been associated with changes in carbohydrate or lipid metabolism, coagulation, liver or kidney function, or immunoglobulin levels. Since many women wanting Norplant will have had negative experiences with other contraceptives, it is important that the differences between this method and previous methods be explained.

Norplant is a good method for breastfeeding women. There are no effects on breast milk quality or quantity, and infants grow normally. ^{13,14} Another advantage of Norplant is that it allows women to plan their pregnancies precisely; return of fertility after removal is prompt, in contrast to the 18-month delay in ovulation that can follow Depo-Provera injections. ^{15,16} In addition, anemia is less likely in Norplant users. ¹⁷

Disadvantages

There are some disadvantages associated with the use of the Norplant system. Norplant causes disruption of bleeding patterns in up to 80% of users, especially during the first year of use, and some women or their partners find these changes unacceptable. ⁴ Endogenous estrogen is nearly normal, and unlike the combined oral contraceptives, progestin is not regularly withdrawn to allow endometrial sloughing. Consequently, the endometrium sheds at unpredictable intervals.

The implants must be inserted and removed in a surgical procedure performed by trained personnel. Women cannot initiate or discontinue the method without the assistance of a clinician. The incidence of complicated removals is approximately 5%, an incidence that can be best minimized by good training and experience in Norplant insertion. ¹⁸ Because the insertion and removal of Norplant require minor surgical procedures, initiation and discontinuation costs will be higher than with oral contraceptives or barrier methods.

The implants can be visible under the skin. This sign of the use of contraception may be unacceptable for some women, and for some partners. ⁴ Norplant is not known to provide protection against sexually transmitted diseases (STDs) such as herpes, human papillomavirus, HIV, gonorrhea, or chlamydia. Users at risk for STDs must consider adding a barrier method to prevent infection.

The cost of implants plus fees for insertion total an amount that seems high to many patients unless they compare it with the total cost of using other methods for up to 5 years. ¹⁹ Nevertheless, short-term use is expensive compared with the relatively low initial costs of other reversible methods, and most women cannot be expected to use long-acting methods for their full duration of action.

Sustained-release, progestin-only methods do not increase the risk of developing STDs, but it is not known whether they provide any protection. Women who have multiple partners, or whose partners do, should use condoms as well. All users must be aware of the possible menstrual changes. It is important to stress that all of the menstrual changes are expected, that they do not cause or represent illness, and that most women revert back to a more normal pattern with increasing duration

of use.

Cultural factors can influence the acceptability of menstrual changes. Hispanic users of Norplant, for example, are very accepting of irregular or prolonged bleeding.⁴ Some cultures restrict a woman from participating in religious activity, household activities, or sexual intercourse while menstruating.

Insertion and removal of implants will be a new experience for most women. As with any new experience, women will approach it with varying degrees of apprehension and anxiety. In reality, most patients are able to watch in comfort as implants are inserted or removed. Women should be told that the incisions used for the procedures are very small and heal quickly, leaving small scars that are usually difficult to see because of their location and size.

Prospective users should be allowed to see and touch implants. Women should be reassured that the implants will not be damaged or move if the skin above them is accidentally injured. Normal activity cannot damage or displace the implants. Most women become unaware of their presence. A few women report sensing the implants if they have been touched or manipulated for a prolonged period of time, or after vigorous exercise. The implants can be visible in slender women with good muscle tone. Darker-skinned users may notice further darkening of the skin directly over the implants; this resolves after removal.

Indications

The Norplant system is indicated for use by women of reproductive age who are sexually active and desire continuous contraception. Norplant should be considered for women who:

1. Desire spacing of future pregnancies.
2. Desire a highly effective, long-term method of contraception.
3. Experience serious or minor estrogen-related side effects with oral contraception.
4. Have difficulty remembering to take pills every day, have contraindications or difficulty using IUDs, or desire a non-coitus-related method of contraception.
5. Have completed their childbearing but do not desire permanent sterilization.
6. Have a history of anemia with heavy menstrual bleeding.
7. Are considering sterilization, but are not yet ready to undergo surgery.
8. Women with chronic illnesses, whose health will be threatened by pregnancy.

Absolute Contraindications

Norplant use is contraindicated in women who have:

1. *ACTIVE* thrombophlebitis or thromboembolic disease.
2. Undiagnosed genital bleeding.
3. *ACUTE* liver disease.
4. Benign or malignant liver tumors.
5. Known or suspected breast cancer.

Relative Contraindications

Based on clinical judgment and appropriate medical management, Norplant *MAY BE USED* by women with a history of or current diagnosis of the following conditions:

1. Heavy cigarette smoking (15 or more daily) in women older than 35 years.
2. History of ectopic pregnancy.
3. Diabetes mellitus. Because multiple studies have failed to observe a significant impact on carbohydrate metabolism, Norplant, in our view, is particularly well suited for diabetic women.
4. Hypercholesterolemia
5. Hypertension.
6. History of cardiovascular disease, including myocardial infarction, cerebral vascular accident, coronary artery disease, angina, or a previous thromboembolic event. Patients with artificial heart valves.
7. Gallbladder disease
8. Chronic disease, such as immunocompromised patients.

Norplant is not contraindicated in the following situations, but other methods are probably preferable:

1. Severe acne
2. Severe vascular or migraine headaches.
3. Severe depression.
4. Concomitant use of medications that induce microsomal liver enzymes (phenytoin, phenobarbital, carbamazepine, rifampin). In this case, we do not recommend the use of Norplant because of a likely increased risk of pregnancy due to lower blood levels of levonorgestrel.^{1, 20}

Efficacy

Norplant is a highly effective method of birth control. In studies conducted in 11 countries, totaling 12,133 woman-years of use, the pregnancy rate was 0.2 pregnancies per 100 woman-years of use.^{1, 15} All but one of the pregnancies that occurred during this evaluation were present at the time of implant insertion. If these luteal phase insertions are excluded from analysis, the first-year pregnancy rate was 0.01 per 100 woman-years. In adolescents, Norplant implants provide better protection against unwanted pregnancy, compared with oral contraceptives, and an important factor is the better continuation rate with Norplant.²¹

The overall pregnancy rate after 2 years of use in 9 countries was 0.2 per 100 woman-years of use.¹ The pregnancy rate achieved in the U.S. trials during the second year of use was higher (2.1 per 100 woman-years). Two factors account for this difference. First, users in the U.S. weighed, on the average, more than study participants in other countries. Clinical trials have demonstrated a direct correlation between weight greater than 70 kg (154 pounds) and an increased risk of pregnancy, but even for heavy women, pregnancy rates are lower than with oral contraception. Second, two different types of silastic tubing were used in the manufacture of Norplant capsules.²³ The first type contained a larger proportion of inert filler and was more dense, while the second type contained less filler and was less dense. Higher pregnancy rates have been observed among women using the more dense capsules, and in the U.S. trials, capsules were more often of the more dense variety. The less dense tubing is now the only one used in the manufacture of Norplant and has a 15% higher release rate than denser tubing. The 5-year pregnancy rate with the less dense (soft) tubing is comparable to that of tubal ligation.²⁴

Pregnancy Rates According to Years of Use^{1, 15}

First Year	Second Year	Third Year	Fourth Year	Fifth Year
0.2%	0.2%	0.9%	0.5%	1.1%

Using the less dense tubing, there now are no weight restrictions for Norplant users, but heavier women (more than 70 kg) may experience slightly higher pregnancy rates in the fourth and fifth years of use compared with lighter women. Even in the later years, however, pregnancy rates for heavier women using Norplant are lower than with oral contraception. The differences in pregnancy rates by weight are probably due to the dilutional effect of larger body size on the low, sustained serum levels of levonorgestrel. Heavier women should not rely on Norplant beyond the 5-year limit. For slender women the duration of Norplant's efficacy may extend well past the fifth year of use. In some extended trials, no pregnancies have occurred into the 7th year.

Failure Rates During the First Year of Use, United States⁷

Method	Percent of Women with Pregnancy Lowest Expected	Typical
No method	85.0%	85.0%
Combination Pill	0.1	3.0
Progestin only	0.5	3.0
IUDs		
Progesterone IUD	1.5	2.0
Levonorgestrel IUD	0.6	0.8
Copper T 380A	0.1	0.1
Norplant	0.05	0.05
Female sterilization	0.05	0.05
Male sterilization	0.1	0.15
Depo-Provera	0.3	0.3
Spermicides	6.0	26.0
Periodic abstinence		25.0
Calendar	9.0	
Ovulation method	3.0	
Symptothermal	2.0	
Post-ovulation	1.0	
Withdrawal	4.0	19.0
Cervical cap		
Parous women	26.0	40.0
Nulliparous women	9.0	20.0
Sponge		
Parous women	9.0	28.0
Nulliparous women	6.0	18.0
Diaphragm and spermicides	6.0	20.0
Condom		
Male	3.0	14.0
Female	5.0	21.0

Ectopic Pregnancy

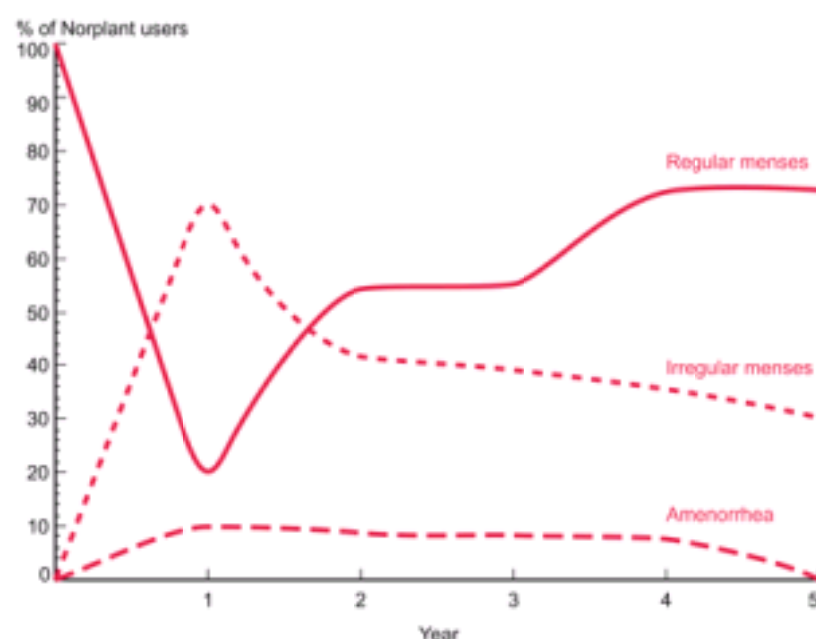

The ectopic pregnancy rate during Norplant use has been 0.28 per 1000 woman-years.¹ Although the risk of developing an ectopic pregnancy during use of Norplant is low, when pregnancy does occur, ectopic pregnancy should be suspected, because approximately 30% of Norplant pregnancies are ectopic.

Ectopic Pregnancy Rates per 1000 Woman-Years^{1, 25, 26}

Non-contraceptive users, all ages	3.0–4.5
Copper T-380 IUD	0.20
Norplant	0.28

Menstrual Effects

Menstrual bleeding patterns are highly variable among users of Norplant. Some alteration of menstrual patterns will occur during the first year of use in approximately 80% of users, later decreasing to about 40%, and by the fifth year, to about 33%.^{27, 28} The changes include alterations in the interval between bleeding, the duration and volume of menstrual flow, and spotting. Oligomenorrhea and amenorrhea also occur, but are less common, less than 10% after the first year and diminishing thereafter. Irregular and prolonged bleeding usually occurs during the first year. Although bleeding problems occur much less frequently after the second year, they can occur at any time.^{28, 29} Studies of the endometrium in Norplant users experiencing abnormal bleeding indicate the presence of enlarged venous sinusoids (fragile vessels) and a reduction in the expression of a protein factor (perivascular stromal cell tissue factor) involved in the initiation of hemostasis.³⁰

Despite an increase in the number of spotting and bleeding days over preinsertion menstrual patterns, hemoglobin concentrations rise in Norplant users because of a decrease in the average amount of menstrual blood loss.^{17, 31}

Patients who can no longer tolerate the presence of prolonged bleeding will benefit from a short course of oral estrogen: conjugated estrogens, 1.25 mg, or estradiol, 2 mg, administered daily for 7 days. A therapeutic dose of one of the prostaglandin inhibitors given during the bleeding will help to diminish flow, but estrogen is the

most effective.³² Another approach is to administer an estrogen-progestin oral contraceptive for 1–3 months.³³

Although the Norplant system is very effective, pregnancy must be considered in women reporting amenorrhea who had been ovulating previously, as evidenced by regular menses prior to an episode of amenorrhea. A sensitive urine pregnancy test should be obtained. Women who remain amenorrheic throughout their use of Norplant are unlikely to become pregnant.²⁸ It is important to explain to patients the mechanism of the amenorrhea: the local progestational effect causing decidualization and atrophy.

Metabolic Effects

Exposure to the sustained, low dose of levonorgestrel delivered by the implants is not associated with significant metabolic changes. Studies of carbohydrate metabolism,^{34, 35} liver function,^{36, 37} and³⁸ blood coagulation,^{38, 39, 40} and⁴¹ immunoglobulin levels,^{34, 42} serum cortisol levels,⁴³ and blood chemistries^{34, 37} have failed to detect changes outside of normal ranges.

No major impact on the lipoprotein profile can be demonstrated.^{2, 36, 44} Minor changes are transient, and with prolonged duration of use, lipoproteins return to preinsertion levels. Long-term exposure to the low dose of levonorgestrel released by Norplant is unlikely to affect users' risk of atherogenesis, just as prolonged exposure to combined oral contraception has not (see [Chapter 22](#)). There are no clinically important effects on carbohydrate metabolism.^{35, 45} No effect on insulin sensitivity can be detected.⁴⁶

Measurements of bone density in adolescents reveal that Norplant does not affect the teenage gain in bone; similar gains were recorded in Norplant users and control subjects.⁴⁷ In older women, an increase in forearm bone density was documented after 6 months of Norplant use.⁴⁸

Effects on Future Fertility

Circulating levels of levonorgestrel become too low to measure within 48 hours after removal of Norplant. Most women resume normal ovulatory cycles during the first month after removal. The pregnancy rates during the first year after removal are comparable with those of women not using contraceptive methods and trying to become pregnant. There are no long-term effects on future fertility, nor are there any effects on sex ratios, rates of ectopic pregnancy, spontaneous miscarriage, stillbirth, or congenital malformations.^{1, 15} The return of fertility after Norplant removal is prompt, and pregnancy outcomes are within normal limits. The rate and outcome of subsequent pregnancies are not influenced by duration of use.

For women who are spacing their pregnancies, the difference between Norplant and Depo-Provera in the timing of the return to fertility can be critical. Norplant allows precise timing of pregnancy because the return of ovulation after Norplant removal is so prompt. Depo-Provera, on the other hand, can cause up to 18 months' delay in return to fertility. By that time, 90% of users of either method will have ovulated, but in the first several months, the difference is dramatic. By 3 months after removal, half of Norplant users will have ovulated, but 10 months must elapse before half of Depo-Provera users are ovulatory.

Side Effects

The occurrence of serious side effects is very rare, no different in incidence than that observed in the general population. In addition to the menstrual changes, the following side effects have been reported: headache, acne, weight change, mastalgia, hyperpigmentation over the implants, hirsutism, depression, mood changes, anxiety, nervousness, ovarian cyst formation, and galactorrhea.^{1, 15, 27, 29, 49}

It is difficult, of course, to be certain which of these effects were actually caused by the levonorgestrel. For example, careful study fails to reveal a relationship between Norplant use and depressive symptoms.⁵⁰ Although most of these side effects are minor in nature, they can cause patients to discontinue the method. Patients often find common side effects tolerable after assurance that they do not represent a health hazard.⁴ Many complaints respond to reassurance; others can be treated with simple therapies. The most common side effect experienced by users is headache; approximately 20% of women who discontinue use do so because of headache.^{4, 49}

Stroke, thrombotic thrombocytopenic purpura, thrombocytopenia, and pseudotumor cerebri have been reported with Norplant.⁵¹ However, it is by no means established that the incidence of these problems is increased, and there is little reason to suspect a cause-and-effect relationship. In the follow-up study conducted by the World Health Organization in 8 countries, no significant excess of cardiovascular events or malignant disease has been observed.⁵²

Weight Change

Women using Norplant more frequently complain of weight gain than of weight loss, but findings are variable. In the Dominican Republic, 75% of those who changed weight lost, while in San Francisco, two-thirds gained. Assessment of weight change in Norplant users is confounded by changes in exercise, diet, and aging. Although an increase in appetite can be attributed to the androgenic activity of levonorgestrel, it is unlikely that the low levels with Norplant have any clinical impact. Counseling for weight changes should include dietary review and focus on dietary changes. Indeed, a 5-year follow-up of 75 women with Norplant implants could document no increase in the body mass index (nor was there a correlation between irregular bleeding and body weight).⁵³

Mastalgia

Bilateral mastalgia, often occurring premenstrually, is usually associated with complaints of fluid retention. After pregnancy has been ruled out, reassurance and therapy aimed at symptomatic relief are indicated. This symptom decreases with increasing duration of Norplant use. Most Norplant users respond to treatment and do not elect to remove the implants. Careful assessments of the relationship between methylxanthines and mastalgia have failed to demonstrate a link. The most effective treatments are the following: danazol (200 mg/day), vitamin E (600 units/day), bromocriptine (2.5 mg/day), or tamoxifen (20 mg/day), but there are no studies of these treatments in Norplant users.

Galactorrhea

Galactorrhea is more common among women who have had insertion of the implants on discontinuation of lactation. Pregnancy and other possible causes should be ruled out by performing a pregnancy test and a thorough breast examination. Patients should be reassured that this is a common occurrence among implant and oral contraceptive users. Decreasing the amount of breast and nipple stimulation during sexual relations might alleviate the symptom, but if amenorrhea accompanies persistent galactorrhea, a prolactin level should be obtained.

Acne

Acne, with or without an increase in oil production, is the most common skin complaint among Norplant users. The acne is caused by the androgenic activity of the levonorgestrel that produces a direct impact and also causes a decrease in sex hormone-binding globulin (SHBG) levels leading to an increase in free steroid levels (both levonorgestrel and testosterone). This is in contrast to combined oral contraceptives that contain levonorgestrel, where the estrogen effect on SHBG (an increase) produces a decrease in unbound, free androgens. Common therapies for complaints of acne include dietary change, practice of good skin hygiene with the use of soaps or skin cleansers, and application of topical antibiotics (e.g., 1% clindamycin solution or gel, or topical erythromycin). Use of local antibiotics helps most users to continue Norplant.

Ovarian Cysts

Unlike oral contraception, the low serum progestin levels maintained by Norplant do not suppress follicle-stimulating hormone (FSH), which continues to stimulate ovarian follicle growth in most users. The LH peak during the first two years of use, on the other hand, is usually abolished so that these follicles do not ovulate.⁹ However, some continue to grow and cause pain or be palpated at the time of pelvic examination.⁵⁴ Adnexal masses are approximately 8 times more frequent in Norplant users compared with normally cycling women. Because these are simple cysts (and most regress spontaneously within one month of detection), they need not be sonographically or laparoscopically evaluated. Further evaluation is indicated if they became large and painful or fail to regress. Regular ovulators are less

likely to form cysts so the situation is likely to improve after two years of Norplant use.

Herpes Simplex

Some users have complained of outbreaks of genital herpes simplex lesions occurring more frequently than prior to insertion. Most commonly, the lesions develop during periods of prolonged spotting or bleeding with the wearing of sanitary napkins. Use of vaginal tampons for bleeding and suppression of the virus with oral acyclovir (200 mg tid for up to 6 months) have been successful in dealing with this problem.

Cancer

Levonorgestrel and silastic have been thoroughly evaluated in animals and humans for their carcinogenic effects, and none has been found. Epidemiologic evaluation awaits long-term use by large numbers of women. We can speculate on possible effects of Norplant based on our experience with oral contraceptives and Depo-Provera. The risk of endometrial cancer ought to be reduced. A study of the endometrial effects of Norplant failed to find any evidence of hyperplasia, even when levonorgestrel levels were low and endogenous estradiol production was normal.⁵⁵ The risk of ovarian cancer is also probably reduced, but not as much as with methods that completely suppress ovulation. Breast and cervical cancer effects will be as difficult to assess because of confounding variables as they are with oral contraception and Depo-Provera. The low dose of Norplant, however, would be unlikely to have effects different from other hormonal contraceptives.

Patient Evaluation

The usual personal and family medical history and physical examination should concentrate on factors that might contraindicate use of the various contraceptive options. If a patient elects to use Norplant, a detailed description of the method, including effectiveness, side effects, risks, benefits, as well as insertion and removal procedures, should be provided. Before insertion, the patient should read and sign a written consent for the surgical placement of Norplant. It should include a review of the potential complications of the procedure which include reaction to the local anesthetic, infection, expulsion of the implants, superficial phlebitis, bruising, and the possibility of a subsequent difficult removal.

Insertion can be performed at any time during the menstrual cycle as long as pregnancy can be ruled out. If the patient's last menstrual period was abnormal, if she has recently had sexual intercourse without contraception, or if there are reasons to suspect pregnancy, a sensitive urine pregnancy test should be performed. Based on cervical mucus changes, a backup method need be used no more than 3 days after insertion.⁶ Norplant can be inserted immediately postpartum (after 3 days in breastfeeding women), but certainly should be initiated no later than the third postpartum week in non-breastfeeding women and the 3rd postpartum month in breastfeeding women. Acne and headache are less common in women who receive Norplant immediately postpartum, and there is no difference in post-pregnancy weight loss compared with women who receive it 4–6 weeks later.⁵⁶

Patients should be questioned about allergies to local anesthetics, antiseptic solutions, and tape. A discussion about the technique of insertion and anticipated sensations is an important part of preparing the patient for the experience. All patients approach insertion with some degree of apprehension that can be decreased by detailed explanations and preparation.^{23, 57}

Selection of the site for placement of Norplant is based on both functional and aesthetic factors. Various sites (the upper leg, forearm, and upper arm) have been used in clinical trials. The nondominant, upper, inner arm is usually the best site. This area is easily accessible to the clinician with minimal exposure of the patient. It is well protected during most normal activities. It is not highly visible, and immigration of the implants from this site has not been documented. The site of placement does not affect circulating levonorgestrel levels.

Reasons for Termination

Although Norplant is a 5-year method, only approximately 30% of women continue use for that long (although in some cultures 5-year continuation rates reach 65–70%). Discontinuation occurs at a rate of 10–15% yearly, about the same as for intrauterine contraception, but lower than for barrier or oral contraception.^{1, 23, 29} Bothering side effects, such as menstrual changes, headache, or weight change, are the primary reasons for termination of implant use.^{4, 45, 58} Users who cannot tolerate these symptoms request removal in the first two years of use while women who want another pregnancy, the most common personal reason for removal, are more likely to terminate use in the third or fourth year.

Menstrual changes are the most common cause for discontinuation of Norplant in the first year of use. An unspoken concern for many patients and their partners is the fact that bleeding irregularity interferes with sexual interactions. The next most common reasons for discontinuing Norplant are headache, weight change, mood change, anxiety or nervousness, depression, ovarian cyst formation, and lower abdominal pain. Presence of ovarian cysts is not usually an indication for removal of Norplant and is almost never a reason for surgery. Most will resolve spontaneously within 4 weeks. Skin conditions, including rashes, dermatitis, and acne, account for about 0.8% of terminations.

User Acceptance of Norplant

Overall, interview surveys throughout the world have indicated that women perceive sustained-release methods, Norplant in particular, as highly acceptable methods of contraception.^{57, 59, 60 and 61} The most popular feature of Norplant is the ease of use. Approximately 20% of U.S. patients report that friends and relatives notice their implants. This may be a greater problem in warmer climates with less encompassing clothing. Only 25% of the women who report that the implants were noticed were bothered by this attention.⁴

In the U.S., the primary motivations for Norplant use have been problems with previous contraceptive methods and ease of Norplant use. Although fear of pain during Norplant insertion is a prominent source of anxiety for many women, the actual pain experienced does not match the expectations. The level of satisfaction has been high in self-motivated and well-informed users.²⁴ Teenagers provide an example of well-documented success. Their one-year pregnancy rates are much lower, and continuation rates much higher than that with oral contraceptives.^{62, 63, 64 and 65} However, teenage discontinuation of the method due to side effects (especially irregular bleeding and weight gain) is more common with Norplant.²¹

Studies of women's attitudes toward sustained-release contraceptives indicate that the great majority of women find them highly acceptable and perceive them as desirable alternatives to conventional contraceptives, although not everyone finds Norplant preferable.^{66, 67} Around the world, women who have used Norplant say they have recommended Norplant to friends and would like to use it again.^{4, 15, 49}

Counseling Women

Frank information about negative factors such as irregular bleeding and possible weight changes will avoid surprise and disappointment, and encourage women to continue use long enough to enjoy the positive attributes such as convenience, safety, and efficacy. Open discussion of side effects will lead to public and media awareness of the disadvantages as well as the advantages of these methods. Helping women decide if they are good candidates for use of Norplant, for example, before they invest too much time and money in this long-acting contraceptive, is a very important objective of good counseling.

Common patient questions regarding Norplant are as follows;

- Is it effective?
- How is it inserted and removed; how long do these procedures take; does it hurt; and will it leave scars?
- Will the implants be visible under the skin?
- Will the implants be uncomfortable or restrict movement of the arm?
- Will the implants move in the body?
- Will the implants be damaged if they are touched or bumped?

- Will this contraceptive change sexual drive and enjoyment?
- What are the short- and long-term side effects?
- Are there any effects on future fertility?
- What do the implants look and feel like?
- What happens if pregnancy occurs during use?
- How long will it take for the method to be effective after insertion?
- Can a partner tell if this method is being used?

LNG ROD — The Two Rod System

The two-implant system, “Norplant-2,” uses levonorgestrel suspended in a silastic matrix and covered with a silastic membrane. Bleeding, pregnancy, and continuation rates were like those of the 6-capsule system, but insertion and removal were easier.¹⁵ However, the manufacturer of the elastomer used in Norplant-2 ceased production. A new system is composed of 2 levonorgestrel rods, called LNG ROD, encased in silicone rubber tubing, sealed at each end with silastic adhesive.⁶⁸ Each rod measures 2.5 mm in diameter and 4.3 cm in length, contains 75 mg levonorgestrel, and releases the drug at the same dose as Norplant.⁶⁹ A 3-year clinical trial indicates that the performance and side effects are similar to Norplant, but removal is faster and easier.⁶⁸

New Developments in Implant Contraception

The newer progestins (desogestrel, gestodene, norgestrel, norgestimate, and norgestimate) are less androgenic than levonorgestrel and are useful in contraceptive implants. An example is Implanon, a single implant 4 cm long, that contains 60 mg of 3-keto desogestrel in a core of ethinyl vinyl acetate wrapped with a membrane of the same material. The hormone is released at a rate of about 60 µg per day. Implanon is designed to provide contraception for 2–3 years after which the implant should be removed. Efficacy and side effects are similar to those with Norplant.^{38, 70, 71} Another single implant contraceptive is Uniplant, containing 38 mg norgestrel acetate in a 4 cm silastic tube with a 100 µg per day release rate. It provides contraception for one year.^{72, 73 and 74}

Biodegradable implants deliver sustained levels of progestin for variable periods of time from a vehicle that dissolves in body tissues. The utility of implant contraception would be improved by the elimination of the need for surgical removal. Two types are under evaluation: Capronor and norethindrone pellets.

Capronor is a single capsule, biodegradable, levonorgestrel-releasing subdermal implant composed of the polymer E-caprolactone. Implants measure 0.24 cm in diameter and either 2.5 or 4 cm in length, providing contraception for one year. The shorter capsule contains 16 mg levonorgestrel, and the longer contains 26 mg. Levonorgestrel escapes from caprolactone at a rate 10 times faster than from silastic. The shorter implant maintains circulating levels of levonorgestrel of 0.2–0.3 ng/mL, while the longer implant maintains higher levels equivalent to those found in Norplant users. The longer capsule suppresses ovulation in a higher proportion (about 50%) of cycles than reported with Norplant, but the shorter implant allows ovulation in most users. The higher release rate allows the use of a smaller implant. Experience is still too limited to report pregnancy rates, but the longer implant should provide contraception comparable to Norplant.

When exposed to tissue fluids, E-caprolactone slowly breaks down into E-hydroxycaproic acid, and then finally to carbon dioxide and water. The capsule remains intact during the first 12 months of use, allowing easy removal. After 12 months, the capsule begins to disappear.

Capronor shares the advantages of Norplant with convenience of use and few metabolic effects. There is no adverse impact on the lipoprotein profile. Removal is easier and quicker. The disadvantages are also similar to Norplant: changes in menstrual patterns and the other side effects typical of low-dose, continuous progestin systems. Biodegradable implants could continue to release small, noncontraceptive amounts of hormone after their period of use as a contraceptive has expired. Although it is unlikely that such low serum levels of progestin would be harmful to users or to their pregnancies, this question needs to be resolved. The degrading implants can be removed in the event of pregnancy.⁷⁵

Anuelle is a biodegradable norethindrone pellet that, when injected subdermally, is expected to maintain circulating concentrations of this progestin at contraceptive levels for up to 3 years. The pellets are composed of 10% pure cholesterol and 90% norethindrone, and are about the size of a grain of rice. This method is currently under development to determine the correct size and number of pellets and the cholesterol:hormone ratio necessary to obtain the release rates that provide contraception. Preliminary trials of 2, 3, and 4 pellets have demonstrated that bleeding patterns are disrupted during the first few months of use, then return to normal patterns. Users of 4 and 5 pellets are more likely to be amenorrheic and anovulatory.⁷⁶

Depo-Provera (Depot-Medroxyprogesterone Acetate)

Depo-Provera (depot-medroxyprogesterone acetate) is the most thoroughly studied progestin-only contraceptive. Although its approval for contraception in the U.S. is recent (1992), it has been available in some countries since the mid-1960s. Much of our knowledge of the safety, efficacy, and acceptability of long-acting hormonal contraception comes from Indonesia, Sri Lanka, Thailand, and Mexico where Depo-Provera has been used and studied for decades. The long-delayed approval as a contraceptive in the U.S. was based on political and economic considerations, not scientific ones.⁷⁷

Depo-Provera comes as microcrystals, suspended in an aqueous solution. The correct dose for contraceptive purposes is 150 mg intramuscularly (gluteal or deltoid) every 3 months. A comparative trial established that the 100 mg dose is significantly less effective.⁷⁸ The contraceptive level is maintained for at least 14 weeks, providing a safety margin for one of the most effective contraceptives available, about 1 pregnancy per 100 women after 5 years of consistent use.^{78, 79}

Depo-Provera is not a “sustained-release” system; it relies on higher peaks of progestin to inhibit ovulation and thicken cervical mucus. The difference between serum levels of progestins in a sustained-release system like Norplant and a depot system like Depo-Provera is illustrated in the diagram.

Mechanism of Action

The mechanism of action of Depo-Provera is different from the other lower dose, progestin-only methods because, in addition to thickening of the cervical mucus and alteration of the endometrium, the circulating level of the progestin is high enough to effectively block the LH surge, and, therefore, ovulation does not occur. Suppression of FSH is not as intense as with the combination oral contraceptive, therefore follicular growth is maintained sufficiently to produce estrogen levels comparable to those in the early follicular phase of a normal menstrual cycle.⁸⁰ Symptoms of estrogen deficiency, such as vaginal atrophy or a decrease in breast size, do not occur.

The injection should be given within the first 7 days of the current menstrual cycle, otherwise a back-up method is necessary for 1 week.^{81, 82 and 83} The duration of action can be shortened if attention is not paid to proper administration. The injection must be given deeply in muscle by the Z-track technique and not massaged. It is prudent to avoid locations at risk for massage by daily activities.

Efficacy

The efficacy of this method is equal to that of sterilization, and better than that of all the other temporary methods.⁸⁴ Because serum concentrations are relatively high, efficacy is not influenced by weight or by the use of medications that stimulate hepatic enzymes. On the contrary, Depo-Provera is an excellent contraceptive choice for women taking antiepileptic drugs because the high progestin levels raise the seizure threshold.⁸⁵

Indications

1. At least one year of birth spacing desired.
2. Highly effective long-acting contraception not linked to coitus.
3. Estrogen-free contraception needed.

4. Breastfeeding.
5. Sickle cell disease.
6. Seizure disorder.
7. Private, coitally independent method desired.

Absolute Contraindications

1. Pregnancy.
2. Unexplained genital bleeding.
3. Severe coagulation disorders.
4. Previous sex steroid-induced liver adenoma.

Relative Contraindications

1. Liver disease.
2. Severe cardiovascular disease.
3. Rapid return to fertility desired.
4. Difficulty with injections.
5. Severe depression.

Advantages

Like other sustained-release forms of contraception, Depo-Provera is not associated with compliance problems and is not related to the coital event. Continuation rates are better and repeat pregnancy rates are reduced compared with oral contraceptive use in teenagers.⁸⁶ Depo-Provera is useful for women whose ability to remember contraceptive requirements is limited. It should be considered for women who lead disorganized lives or who are mentally retarded.

The freedom from the side effects of estrogen allows Depo-Provera to be considered for patients with congenital heart disease, sickle cell anemia, patients with a previous history of thromboembolism, and women over age 30 who smoke or have other risk factors. The absolute safety in regard to thrombosis is mainly theoretical; it has not been proven in a controlled study. However, an increased risk of thrombosis has not been observed in epidemiologic evaluation of Depo-Provera users, and a World Health Organization case-control study could find no evidence for increased risks of stroke, myocardial infarction, or venous thromboembolism.^{78, 87}

A further advantage exists for patients with sickle cell disease because evidence indicates an inhibition of in vivo sickling with hematologic improvement during treatment.⁸⁸ Both the frequency and the intensity of painful sickle cell crises are reduced.⁸⁹

Another advantage is the finding that Depo-Provera increases the quantity of milk in nursing mothers, a direct contrast to the effect seen with combination oral contraception. The concentration of the drug in the breast milk may be negligible, and no effects of the drug on infant growth and development have been observed,^{90, 91} and⁹² In a careful study of male infants being breastfed by women treated with Depo-Provera, no metabolites of depot-medroxyprogesterone acetate could be detected in the infant's urine and no alterations could be observed in the infant levels of FSH, LH, testosterone, and cortisol.⁹³ Because of the slight positive impact on lactation, Depo-Provera can be administered soon after delivery, but at least a 3-day postpartum delay is recommended to allow the decline in pregnancy levels of estrogen and progesterone and the establishment of lactation.¹²

As noted, Depo-Provera should be considered in patients with seizure disorders; an improvement in seizure control can be achieved probably because of the sedative properties of progestins.⁸⁵

Other benefits associated with Depo-Provera use include a decreased risk of endometrial cancer comparable with that observed with oral contraceptives,⁹⁴ and probably the same benefits associated with the progestin impact of oral contraceptives: reduced menstrual flow and anemia, less PID, less endometriosis, fewer uterine fibroids,⁹⁵ and fewer ectopic pregnancies. A failure to document a reduced risk of ovarian cancer by the World Health Organization probably reflects the study's low statistical power and the high parity in the Depo-Provera users.⁹⁶

Depo-Provera, like oral contraception, may reduce the risk of pelvic inflammatory disease; however, the only study was hampered by small numbers.⁹⁷ Suppression of ovulation means that ectopic pregnancies are abolished and ovarian cysts are rare.

The greater the number of choices women have, the more likely they are to find a contraceptive that works well for them. For some women the primary advantages of Depo-Provera are privacy and ease of use. No one but the user need know about the injection, and the 3-month schedule can be easy to maintain for women who don't mind injections. In some societies, injections are respected as efficacious; in these situations, Depo-Provera is the most popular contraceptive despite bleeding changes and other side effects.

Summary of Advantages

1. Easy to use, no daily or coital action required.
2. Safe, no serious health effects.
3. Very effective, as effective as sterilization and intrauterine and implant contraception.
4. Free from estrogen-related problems.
5. Private, use not detectable.
6. Enhances lactation.
7. Has noncontraceptive benefits.

Problems With Depo-Provera

Major problems with Depo-Provera are irregular menstrual bleeding, breast tenderness, weight gain, and depression.^{78, 79} By far, the most common problem is the change in menstrual bleeding. Up to 25% of patients discontinue in the first year because of irregular bleeding.⁶² The bleeding is rarely heavy; in fact, hemoglobin values rise in Depo-Provera users. The incidence of irregular bleeding is 70% in the first year, and 10% thereafter. Bleeding and spotting decrease progressively with each re-injection so that after 5 years, 80% of users are amenorrheic (compared with 10% of Norplant users).⁹⁸ Irregular bleeding can be disturbing and annoying, and for many patients, it inhibits sexuality.

If necessary, the bleeding can be treated with exogenous estrogen, 1.25 mg conjugated estrogens, or 2 mg estradiol, given daily for 7 days. A nonsteroidal anti-inflammatory product given for a week is also effective, and another option is to administer an oral contraceptive for 1–3 months. Giving the Depo-Provera injection earlier (more frequently) does not change the bleeding pattern.⁹⁹ Most women can wait for amenorrhea without treatment if they know what to expect with time.

About one-third of patients discontinue Depo-Provera by the end of one year, 50% by the end of two years, and about 80% by the end of three years.¹⁰⁰ In a large international study, the most common medical reasons for discontinuing Depo-Provera during the first two years of use were the following:⁷⁹

- | | |
|-------------------|-------|
| 1. Headaches | —2.3% |
| 2. Weight gain | —2.1% |
| 3. Dizziness | —1.2% |
| 4. Abdominal pain | —1.1% |
| 5. Anxiety | —0.7% |

In western societies, depression, fatigue, decreased libido, and hypertension are also encountered. Whether medroxyprogesterone acetate causes these side effects is difficult to know since they are very common complaints in nonusers as well.¹⁰¹ When studied closely, no increase in depressive symptoms can be observed, even in women with significant complaints of depression prior to treatment.¹⁰²

Even attempts to document a greater weight gain specifically associated with Depo-Provera are unable to do so.^{103, 104 and 105} As with oral contraception, the weight gain may not be hormone-induced, but reflect lifestyle and aging. Remember if symptoms are truly due to the progestin, unlike pills and implants, Depo-Provera takes 6–8 months to be gone after the last injection. Clearance is slower in heavier women.

Approximately half of women who discontinue Depo-Provera can expect normal menses to return in 6 months after the last injection, but 25% will wait a year before resumption of a normal pattern.⁹⁸

Breast Cancer

Medroxyprogesterone acetate, in large continuous doses, produced breast tumors in beagle dogs (perhaps because in dogs progestins stimulate growth hormone secretion, known to be a mammatrophic agent in dogs).¹⁰⁶ This is an effect unique with dogs, and has not appeared in women after years of use. A very large, hospital-based case-control WHO study conducted over 9 years in 3 developing countries indicated that exposure to Depo-Provera is associated with a very slightly increased risk in breast cancer in the first 4 years of use, but there was no evidence for an increase in risk with increased duration of use.¹⁰⁷ The results were interpreted to suggest that growth of already existing tumors is enhanced. The number of cases with recent use was not large, and the confidence intervals reflected this. Another possible explanation for this finding is the combination of detection/surveillance bias and accelerated growth of an already present tumor, a situation similar to those described with oral contraceptives ([Chapter 22](#)) and postmenopausal hormone therapy ([Chapter 18](#)).

Two earlier population-based case-control studies indicated a possible association between breast cancer and Depo-Provera. One, from Costa Rica, was based on only 19 cases.¹⁰⁸ The other, from New Zealand, did not find an increased relative risk in ever users but did find an indication of increased risk shortly after initiating use at an early age, less than age 25.¹⁰⁹ A pooled analysis of the WHO and New Zealand data indicated that the highest risk was in women who had received a single injection.¹¹⁰ The risk, if real, is very slight, and it is equally possible that the suggestions of increased risk based on a small number of cases have not been free of confounding variables. Because recent use appears to be the key factor, it is appropriate to emphasize that these studies did not find evidence for an overall increased risk of breast cancer, and the risk did not increase with duration of use. However, clinicians should consider informing patients that Depo-Provera might accelerate the growth of an already present occult cancer. We would expect such tumors to be detected at an earlier stage and grade of disease and be associated with a better outcome.

Other Cancers

An increased risk of cervical dysplasia cannot be documented even with long-term use (4 or more years).¹¹¹ No increase in adenocarcinoma or adenocarcinoma could be detected in the WHO study.¹¹² The WHO study has not detected an increased risk of invasive squamous cell cancer of the cervix in Depo-Provera users; however, the risk of cervical carcinoma *in situ* was slightly elevated in the WHO case-control study, and it is not certain whether this is a real finding or a consequence of unrecognized biases.^{113, 114} In New Zealand, a modest increase in the risk of cervical dysplasia among users of Depo-Provera could be attributed to an increased prevalence of known risk factors for dysplasia among women who choose this method of contraception.¹¹¹ Nevertheless, it is prudent to insist on annual Pap smear surveillance in all users of contraception, no matter what method. Women at higher risk because of their sexual behavior (multiple partners, history of STDs) should have Pap smears every 6 months.

As noted, Depo-Provera is associated with a reduction in the risk of endometrial cancer, and there is probably a modest reduction in the risk of ovarian cancer. There is no evidence that liver cancer risk is changed by the use of Depo-Provera.¹¹⁵

Metabolic Effects

The impact of Depo-Provera on the lipoprotein profile is uncertain. While some fail to detect an adverse impact, and claim that this is due to the avoidance of a first-pass through effect in the liver,¹¹⁶ others have demonstrated a decrease in HDL-cholesterol and increases in total cholesterol and LDL-cholesterol.^{116, 117} In a multicenter clinical trial by the World Health Organization, a transient adverse impact was present only in the few weeks after injection when blood levels were high.¹¹⁸ The clinical impact of these changes, if any, have yet to be reported. It seems prudent to monitor the lipid profile annually in women using Depo-Provera for long durations. The emergence of significant adverse changes in LDL-cholesterol and HDL-cholesterol warrant reconsideration of contraceptive choice.

There are no clinically significant changes in carbohydrate metabolism or in coagulation factors.^{119, 120}

Concern has been raised because the blood levels of estrogen with this method of contraception are relatively lower over a period of time compared with a normal menstrual cycle, and, therefore, patients might lose bone to some degree, and, indeed, bone loss has been documented in cross-sectional studies.^{47, 121, 122} This bone loss has also been observed in women receiving a high oral dose of medroxyprogesterone acetate, 50 mg daily.¹²³ However, bone density measurements in women who stopped using Depo-Provera indicated that the loss was regained even after long-term use.¹²⁴ Furthermore, a cross-sectional study in Thailand found no bone

loss in long-term (greater than 3 years) users of Depo-Provera.¹²⁵ And most importantly, longitudinal, prospective studies of bone fail to document bone loss in users of Depo-Provera. Loss of forearm bone density could not be detected despite 3 years of Depo-Provera use, suggesting that previous adverse findings could be explained by inadequate control of factors that affect bone, such as smoking and alcohol intake.¹²⁶ A small prospective study documented stable forearm bone density over a 6-month period of time.⁴⁸ This concern will require ongoing surveillance of past users, but at the present time, this should not be a reason to avoid this method of contraception. *It is unlikely that bone loss occurs sufficiently to raise the risk of osteoporosis later in life.*

Effect on Future Fertility

The delay in becoming pregnant after ceasing use of Depo-Provera is a problem unique to injectable contraception; all the other temporary methods allow a more prompt return to fertility.¹²⁷ However, medroxyprogesterone acetate does not permanently suppress ovarian function, and the concern that infertility with suppressed menstrual function may be caused by Depo-Provera has not been supported by epidemiologic data. The pregnancy rate in women discontinuing the injections because of a desire to become pregnant is normal.¹²⁸ By 18 months after the last injection, 90% of Depo-Provera users have become pregnant, the same proportion as for other methods.¹²⁹ The delay to conception is about 9 months after the last injection, and the delay does not increase with increasing duration of use. Because of this delay, women who want to conceive promptly after discontinuing their contraceptive should not use Depo-Provera. Suppressed menstrual function persisting beyond 12 months after the last injection is not due to the drug and deserves evaluation.

Accidental pregnancies occurring at the time of the initial injection of Depo-Provera have been reported to be associated with higher neonatal and infant mortality rates, probably due to an increased risk of intrauterine growth retardation.^{130, 131} The timing of the first injection is, therefore, very important. To ensure effective contraception, the first injection should be administered within the first 5 days of the menstrual cycle (before a dominant follicle emerges), or a back-up method is necessary for 2 weeks.

Short-Term Injectable Contraceptives

Monthly or every other month injectable combinations of estrogen and progestin are not new, having been developed over several decades.¹³² This method of contraception is popular in China, Latin America, and Eastern Asia. A preparation widely used in China consists of 250 mg 17 α -hydroxyprogesterone caproate and 5 mg estradiol valerate, known as Chinese Injectable No.1.

Cyclo-Provera (or Cyclofem)

Cyclo-Provera consists of 25 mg depot-medroxyprogesterone acetate and 5 mg estradiol cypionate and is administered monthly as a deep intramuscular injection. This method is as effective as Depo-Provera, but avoids the problems of menstrual irregularity and heavy bleeding, as well as amenorrhea.^{133, 134, 135 and 136} In addition, the method is rapidly reversible. Besides the need for a monthly injection, another disadvantage is the likelihood that the combination of estrogen and progestin will inhibit lactation. The requirement for a monthly injection can be made more convenient by the utilization of an automatic device for self-administration.¹³⁷ Approximately 80% of women who are amenorrheic on Depo-Provera will develop vaginal bleeding if switched to Cyclo-Provera.¹³⁸

Norethindrone Enanthate

Norethindrone enanthate is given in a dose of 200 mg intramuscularly every 2 months. This progestin acts in the same way as Depo-Provera, and has the same problems.⁷⁹ A combination (Mesigyna) of norethindrone enanthate (50 mg) with estradiol valerate (5 mg) given monthly provides effective contraception with good cycle control.¹³⁹ Compared with Cyclofem (25 mg medroxyprogesterone acetate and 5 mg estradiol cypionate), Mesigyna has less bleeding problems.¹⁴⁰ Fertility returns rapidly (by one month) after discontinuation with once-a-month methods.¹⁴¹

Dihydroxyprogesterone Acetophenide and Estradiol Enanthate

The combination of 150 mg dihydroxyprogesterone acetophenide with 10 mg estradiol enanthate (various brand names) is the most widely used injectable contraceptive in Latin America. As with Mesigyna and Cyclofem, the monthly regimen allows regular, and even reduced, cyclic bleeding.¹⁴² A lower dose (90 mg dihydroxyprogesterone acetophenide and 6 mg estradiol enanthate) provides the same effective contraception as the higher dose with similar bleeding patterns.¹⁴³

New Developments in Injectable Contraception

Microspheres or microcapsules have been studied for several years.^{144, 145} They consist of a biodegradable copolymer and one or more hormones. Like other injectable contraceptives, they are easy to administer and are highly effective. Unlike implants, injectables do not require surgical skills of the clinician and can be discontinued by the patient simply by declining to have another injection. Unlike implants, the microspheres cannot be removed once they are injected. If a woman experiences side effects or becomes pregnant, the hormone will remain in her body until completely metabolized. For this reason, the duration of action of the norethindrone capsules has been limited to a few months.

The carrier of the microsphere is composed of a polymer commonly used in biodegradable suture, poly-dl-lactide-co-glycolide. The size of the microspheres varies from 0.06 to 0.1 mm in diameter, and each is composed of about 50% norethindrone dispersed within the polymer. The release of norethindrone occurs initially by diffusion and later by degradation of the carrier. The size of the microspheres, the amount of hormone contained within the carrier, and the quantity of microspheres delivered by injection determine the daily dose of norethindrone delivered. Injections currently under evaluation contain a total dose of either 65 mg or 100 mg norethindrone, and the amount released daily is approximately the same as that delivered by low-dose oral contraception, but circulating levels are more stable.

The microspheres come preloaded in a syringe and are put into suspension with the addition of 2.5 mL of dextran diluent and vigorously agitated. The mixture must be shaken until all of the microspheres are in suspension, and again immediately prior to injection. The microspheres are deposited in the gluteal muscle using a 21-gauge needle and Z-track intramuscular injection technique.

As with other progestin-only methods of contraception, menstrual changes occur and are the most common cause of discontinuation during the first year of use. Users may experience amenorrhea or persistent or irregular spotting or bleeding. In contrast to Depo-Provera, hormone levels decline rapidly after the microspheres have degraded, so that contraceptive effectiveness ends promptly at the predicted time. Most users will resume ovulatory cycles within 2–3 months after the predicted duration of the injection. If pregnancy occurs shortly after expiration of the norethindrone microspheres, the fetus will not be exposed to significant levels of norethindrone.

Microsphere preparations containing norethindrone combined with ethinyl estradiol are also under development. It is hoped that the addition of estrogen at a low dose

will lead to fewer menstrual irregularities.

Long-Acting Methods for Older Women

The long-acting methods of hormonal contraception deserve consideration in those situations where combination estrogen-progestin is unacceptable because of health problems (where estrogen is contraindicated), or where oral contraception has already proved to be unsuccessful. These methods are especially advantageous for smokers and for women with a history of thromboembolic disease. Progestin-only contraception is a good choice for women with hypertriglyceridemia, for diabetic women (even if they are older and smoke), and for women with severe migraine headaches or hypertension.

Older women, as they approach the menopause, may be more comfortable with the irregular bleeding or amenorrhea associated with these methods. However, the irregular bleeding patterns can cause more concern in some women regarding possible pathology. Postmenopausal hormone treatment can be initiated if menopausal symptoms develop or when annual measurement of the FSH level, beginning at age 50, indicates a rise above 20 IU/L (progestins do not suppress FSH secretion, and, therefore, this measurement can be obtained even while the patient has therapeutic circulating levels of progestin).

A frequently told, but not well-documented story, assigns the first use of IUDs to caravan drivers who allegedly used intrauterine stones to prevent pregnancies in their camels during long journeys.

The forerunners of the modern IUD were small stem pessaries used in the 1800s, small button-like structures that covered the opening of the cervix and which were attached to stems extending into the cervical canal.¹ It is not certain whether these pessaries were used for contraception, but this seems to have been intended. In 1902, a pessary that extended into the uterus was developed by Hollweg in Germany and used for contraception. This pessary was sold for self-insertion, but the hazard of infection was great, earning the condemnation of the medical community.

In 1909, Richter in Germany, reported success with a silkworm catgut ring having a nickel and bronze wire protruding through the cervix.² Shortly after, Pust combined Richter's ring with the old button-type pessary, and replaced the wire with a catgut thread.³ This IUD was used during World War I in Germany, although the German literature was quick to report infections with its insertion and use. In the 1920s, Gräfenberg removed the tail and pessary because he believed this was the cause of infection. He reported his experience in 1930, using rings made of coiled silver and gold, and then steel.⁴

The Gräfenberg ring was short-lived, falling victim to Nazi political philosophy that was bitterly opposed to contraception. The non-Aryan Gräfenberg was finally sent to jail, but he managed to flee Germany, dying in New York City in 1955. He never received the recognition that was his just due.

The Gräfenberg ring was associated with a high rate of expulsion. This was solved by Ota in Japan who added a supportive structure to the center of his gold or silver plated ring in 1934.⁵ Ota also fell victim to World War II politics, being sent into exile, but his ring continued to be used.

The Gräfenberg and Ota rings were essentially forgotten by the rest of the world throughout the World War II period. An awareness of the explosion in population and its impact began to grow in the first two decades after World War II. In 1959, reports from Japan and Israel by Ishihama and Oppenheimer once again stirred interest in the rings.^{6,7} The Oppenheimer report was in the American Journal of Obstetrics and Gynecology, and several American gynecologists were stimulated to use rings of silver or silk, and others to develop their own devices.

In the 1960s and 1970s, the IUD thrived. Techniques were modified and a plethora of types introduced. The various devices developed in the 1960s were made of plastic (polyethylene) impregnated with barium sulfate so that they would be visible on an x-ray. The Margulies Coil, developed by Lazer Margulies, in 1960, at Mt. Sinai Hospital in New York City, was the first plastic device with a memory, allowing the use of an inserter and reconfiguration of the shape when it was expelled into the uterus. The Coil was a large device (sure to cause cramping and bleeding), and its hard plastic tail proved risky for the male partner.

In 1962, the Population Council, at the suggestion of Alan Guttmacher, who that year became president of the Planned Parenthood Federation of America, organized the first international conference on IUDs in New York City. It was at this conference that Jack Lippes of Buffalo presented experience with his device, which fortunately as we will see, had a single filament thread as a tail. The Margulies Coil was rapidly replaced by the Lippes Loop, which quickly became the most widely prescribed IUD in the United States in the 1970s.

The 1962 conference also led to the organization of a program established by the Population Council, under the direction of Christopher Tietze, to evaluate IUDs, the Cooperative Statistical Program. The Ninth Progress Report in 1970 was a landmark comparison of efficacy and problems with the various IUDs being used.⁸

Many other devices came along, but, with the exception of the four sizes of Lippes Loops and the two Saf-T-Coils, they had limited use. Stainless steel devices incorporating springs were designed to compress for easy insertion, but the movement of these devices allowed them to embed in the uterus, making them too difficult to remove. The Majzlin Spring is a memorable example.

The Dalkon Shield was introduced in 1970. Within 3 years, a high incidence of pelvic infection was recognized. There is no doubt that the problems with the Dalkon Shield were due to defective construction, pointed out as early as 1975 by Tatum.⁹ The multifilamented tail (hundreds of fibers enclosed in a plastic sheath) of the

Dalkon Shield provided a pathway for bacteria to ascend protected from the barrier of cervical mucus.

Although sales were discontinued in 1975, a call for removal of all Dalkon Shields was not issued until the early 1980s. The large number of women with pelvic infections led to many lawsuits against the pharmaceutical company, ultimately causing its bankruptcy. Unfortunately, the Dalkon Shield problem tainted all IUDs, and ever since, media and the public in the U.S. have inappropriately regarded all IUDs in a single, generic fashion.

About the time of the introduction of the Dalkon Shield, the U.S. Senate conducted hearings on the safety of oral contraception. Young women who were discouraged from using oral contraceptives following these hearings turned to IUDs, principally the Dalkon Shield, which was promoted as suitable for nulliparous women. Changes in sexual behavior in the 1960s and 1970s, and failure to use protective contraception (condoms and oral contraceptives), led to an epidemic of sexually transmitted diseases (STDs) and pelvic inflammatory disease (PID) for which IUDs were held partially responsible. ¹⁰

The first epidemiologic studies of the relationship between IUDs and PID used as controls women who depended on oral contraception or barrier methods, and who were, therefore, at reduced risk of PID compared with non-contraceptors and IUD users. ^{11,12} In addition, these first studies failed to control for the characteristics of sexual behavior that are now accepted as risk factors for PID (multiple partners, early age at first intercourse, and increased frequency of intercourse). ¹³ The Dalkon Shield magnified the risk attributed to IUDs because its high failure rate in young women who were already at risk of STDs led to septic spontaneous abortions and, in some cases, death. ¹⁴ Reports of these events led the American public to regard all IUDs as dangerous, including those that, unlike the Dalkon Shield, had undergone extensive clinical trials and post-marketing surveillance.

The 1980s saw the decline of IUD use in the United States as manufacturers discontinued marketing in response to the burden of litigation. Despite the fact that most of the lawsuits against the copper devices were won by the manufacturer, the cost of the defense combined with declining use affected the financial return. It should be emphasized that this action was the result of corporate business decisions related to concerns for profit and liability, not for medical or scientific reasons. It was not until 1988 that the IUD was returned to the U.S. market. The number of reproductive age women using the intrauterine device decreased by two-thirds from 1982 to 1988, and further decreased in 1995, from 7.1% to 2% to 0.8%, respectively. ¹⁵ Nevertheless, in the rest of the world, the IUD is the most widely used method of reversible contraception; currently, over 100 million women use the IUD.

Use of the IUD in the U.S. and the World^{15, 16}

U.S.A.	China	Total World
1981 2.2 million women	42 million	60 million
1988 0.7 million women	59 million	83 million
1995 0.3 million women	75 million	106 million

The reason for the decline in the U.S. was the consumer fear of IUD-related pelvic infection. The final blow to the IUD in the U.S. came in 1985 with the publication of two reports indicating that the use of IUDs was associated with tubal infertility. ^{17, 18} Later, better controlled studies identified the Dalkon Shield as a high-risk device, and failed to demonstrate an association between PID and other IUDs, except during the period shortly after insertion. Efforts to point out that the situation was different for the copper IUDs, and that, in fact, pelvic inflammatory disease was not increased in women with a single sexual partner, ¹⁹ failed to prevent the withdrawal of IUDs from the American market and the negative reaction to IUDs by the American public.

Ironically, the IUD declined in the country that developed the modern IUD. It is time for a revival!

The Modern IUD

The addition of copper to the IUD was suggested by Jaime Zipper of Chile, whose experiments with metals indicated that copper acted locally on the endometrium. ²⁰ Howard Tatum combined Zipper's suggestion with the development of the T-shape to diminish the uterine reaction to the structural frame, and produced the copper-T. The first copper IUD had copper wire wound around the straight shaft of the T, the TCU-200 (200 mm² of exposed copper wire), also known as the Tatum-T. ²¹ Tatum's reasoning was that the T-shape would conform to the shape of the uterus in contrast to the other IUDs that required the uterus to conform to their shape. Furthermore, the copper IUDs could be much smaller than those of simple, inert plastic devices and still provide effective contraception. Studies indicate that copper exerts its effect before implantation of a fertilized ovum; it may be spermicidal, or it may diminish sperm motility or fertilizing capacity. The addition of copper to the IUD and reduction in the size and structure of the frame improved tolerance, resulting in fewer removals for pain and bleeding.

The Cu-7 with a copper wound stem was developed in 1971 and quickly became the most popular device in the U.S. Both the Cu-7 and the Tatum-T were withdrawn from the U.S. market in 1986 by G. D. Searle and Company.

IUD development continued, however. More copper was added by Population Council investigators, leading to the TCU-380A (380 mm² of exposed copper surface area) with copper wound around the stem plus a copper sleeve on each horizontal arm). ²² The "A" in TCU-380A is for arms, indicating the importance of the copper sleeves. Making the copper solid and tubular increased effectiveness and the lifespan of the IUD. The TCU-380A has been in use in more than 30 countries since 1982, and in 1988, it was marketed in the U.S. as the "ParaGard."

The "Progestasert" was developed by the Alza Corporation at the same time that the copper IUDs were developed. This T-shaped device releases 65 µg of progesterone per day for at least one year. The progesterone diminishes the amount of cramping and the amount of blood loss; thus, it is especially useful for women who have heavy periods and cramping. The short lifespan can be and has been solved by using a more potent progestin, such as levonorgestrel.

Efforts continue to develop IUDs that address the main problems of bleeding and cramping. The IUDs of the future will possibly be medicated and frameless.

Types of IUDs

Unmedicated IUDs

The Lippes Loop, made of plastic (polyethylene) impregnated with barium sulfate, is still used throughout the world (except in the U.S.). Flexible stainless steel rings

are widely used in China, but not elsewhere.²³

Copper IUDs

The first copper IUDs were wound with 200 to 250 mm² of wire, and two of these are still available (except in the U.S.), the TCu-200 and the Multiload-250. The more modern copper IUDs contain more copper, and part of the copper is in the form of solid tubular sleeves, rather than wire, increasing efficacy and extending lifespan. This group of IUDs is represented in the U.S. by the TCu-380A (the ParaGard), and in the rest of the world, by the TCu-220C, the Nova T, and the Multiload-375. The modern generation of IUDs in China includes a stainless steel ring with copper wire that also releases indomethacin (very effective with a low expulsion rate and less blood loss), a V-shaped copper IUD, and a copper IUD shaped like the uterine cavity.²³ The Sof-T is a copper IUD used only in Switzerland.

The TCu-380A is a T-shaped device with a polyethylene frame holding 380 mm² of exposed surface area of copper. The pure electrolytic copper wire wound around the 36 mm stem weighs 176 mg, and copper sleeves on the horizontal arms weigh 66.5 mg. A polyethylene monofilament is tied through the 3 mm ball on the stem, providing two white threads for detection and removal. The ball at the bottom of the stem helps reduce the risk of cervical perforation. The IUD frame contains barium sulfate, making it radiopaque. The TCu-380Ag is identical to the TCu-380A, but the copper wire on the stem has a silver core to prevent fragmentation and extend the lifespan of the copper. The TCu-380 Slimline has the copper sleeves flush at the ends of the horizontal arms to facilitate easier loading and insertion. The performance of the TCu-380Ag and the TCu-380 Slimline is equal to that of the TCu-380A.^{24, 25}

The Multiload-375 has 375 mm² of copper wire wound around its stem. The flexible arms were designed to minimize expulsions. This is a popular device in many parts of the world. The Multiload-375 and the TCu-380A are similar in their efficacy and performance.²⁶

The Nova T is similar to the TCu-200, containing 200 mm² of copper; however, the Nova T has a silver core to the copper wire, flexible arms, and a large, flexible loop at the bottom to avoid injury to cervical tissue. There was some concern that the efficacy of the Nova T decreased after 3 years in WHO data; however, results from Finland and Scandinavia indicate low and stable pregnancy rates over 5 years of use.²⁶

Hormone-Releasing IUDs

The Progestasert is a T-shaped IUD made of ethylene/vinyl acetate copolymer containing titanium dioxide. The vertical stem contains a reservoir of 38 mg progesterone together with barium sulfate dispersed in silicone fluid. The horizontal arms are solid and made of the same copolymer. Two blue-black, monofilament strings are attached at a hole in the base of the stem. Progesterone is released at a rate of 65 µg per day.

The LNG-20, manufactured by Leiras in Finland, releases *in vitro* 20 µg of levonorgestrel per day.²⁷ This T-shaped device has a collar attached to the vertical arm, which contains 52 mg levonorgestrel dispersed in polydimethylsiloxane and released at a rate of 15 µg per day *in vivo*. The levonorgestrel IUD lasts up to 10 years and reduces menstrual blood loss and pelvic infection rates.^{28, 29 and 30}

Future IUDs

Modifications of the copper IUD are being studied throughout the world. The Ombrelle-250 and Ombrelle-380, designed to be more flexible in order to reduce expulsion and side effects, have been marketed in France. A frameless IUD, the FlexiGard (also known as the Cu-Fix or the GyneFix), consists of 6 copper sleeves (330 mm² of copper) strung on a surgical nylon (polypropylene) thread that is knotted at one end. The knot is pushed into the myometrium during insertion with a notched needle that works like a miniature harpoon. Because it is frameless, it has a low rate of removal for bleeding or pain, but a more difficult insertion may yield a higher expulsion rate.^{31, 32} However, when inserted by experienced clinicians, the expulsion rate is very low, and the device is especially suited for nulligravid and nulliparous women.³³

Mechanism of Action

The contraceptive action of all IUDs is mainly in the uterine cavity. Ovulation is not affected, nor is the IUD an abortifacient.^{34, 35} It is currently believed that the mechanism of action for IUDs is the production of an intrauterine environment that is spermicidal.

Nonmedicated IUDs depend for contraception on the general reaction of the uterus to a foreign body. It is believed that this reaction, a sterile inflammatory response, produces tissue injury of a minor degree, but sufficient enough to be spermicidal. Very few, if any, sperm reach the ovum in the fallopian tube. Normally cleaving, fertilized ova cannot be obtained by tubal flushing in women with IUDs in contrast to noncontraceptors, indicating the failure of sperm to reach the ovum, and thus fertilization does not occur.³⁶ If this action should fail, the inflammatory response would also prevent implantation. In women using copper IUDs, sensitive assays for human chorionic gonadotropin (HCG) do not find evidence of fertilization.^{37, 38} This is consistent with the fact that the copper IUD protects against both intrauterine and ectopic pregnancies (see below).

The copper IUD releases free copper and copper salts that have both a biochemical and morphological impact on the endometrium, and also produce alterations in cervical mucus and endometrial secretions. There is no measurable increase in the serum copper level. Copper has many specific actions, including the enhancement of prostaglandin production and the inhibition of various endometrial enzymes. The copper IUD is associated with an enhanced inflammatory response, marked by production in the endometrium of cytokine peptides known to be cytotoxic.³⁹ An additional spermicidal effect probably takes place in the cervical mucus.

The progestin-releasing IUDs add the endometrial action of the progestin to the foreign body reaction. The endometrium becomes decidualized with atrophy of the glands. The progesterone IUD (serum progesterone levels are not increased) probably has two mechanisms of action: inhibition of implantation and inhibition of sperm capacitation and survival. The levonorgestrel IUD produces serum concentrations of the progestin about half those of Norplant so that ovarian follicular development and ovulation are also partially inhibited; after the first year, cycles are ovulatory in 85% of women, regardless of their bleeding patterns.⁴⁰ Finally, the progestin IUDs thicken the cervical mucus, creating a barrier to sperm penetration. The progestin IUDs decrease menstrual blood loss (about 40–50%) and dysmenorrhea; with the levonorgestrel IUD, bleeding can be reduced by 90% one year after insertion.⁴¹ Average hemoglobin and iron levels increase over time compared with preinsertion values.

Following removal of IUDs, the normal intrauterine environment is rapidly restored. ***In large studies, there is no delay, regardless of duration of use, in achieving pregnancy at normal rates, which belies the assertion that IUD use is associated with infection leading to infertility.***^{42, 43, 44 and 45} There has been no significant difference in cumulative pregnancy rates between parous and nulliparous or nulligravid women.^{44, 45}

Efficacy of IUDs

Intrauterine Pregnancy

The TCu-380A is approved for use in the United States for 10 years. However, the TCu-380A has been demonstrated to maintain its efficacy over at least 12 years of use.⁴⁶ The TCu-200 is approved for 4 years and the Nova T for 5 years. The progesterone-releasing IUD must be replaced every year because the reservoir of progesterone is depleted in 12–18 months. The levonorgestrel IUD can be used for at least 7 years, and probably 10.²⁶ The progesterone IUD has a slightly higher failure rate, but the levonorgestrel device that releases 15–20 mg levonorgestrel per day is as effective as the new copper IUDs.^{25, 28, 47, 48}

The nonmedicated IUDs never have to be replaced. The deposition of calcium salts on the IUD can produce a structure that is irritating to the endometrium. If bleeding increases after a nonmedicated IUD has been in place for some time, it is worth replacing it. Some clinicians (as do we) recommend replacing all older IUDs with the new, more effective copper IUDs.

Device	Pregnancy	Expulsion	Removal
	Rate	Rate	Rate
Lippes Loop	3%	12–20%	12–15%
Cu-7	2–3	6	11
TCu-200	3	8	11
TCu-380A	0.5–0.8	5	14
Progesterone IUD	1.3–1.6	2.7	9.3
Levonorgestrel IUD	0.2	6	17

Considering all IUDs together, the actual use failure rate in the first year is approximately 3%, with a 10% expulsion rate, and a 15% rate of removal, mainly for bleeding and pain. With increasing duration of use and increasing age, the failure rate decreases, as do removals for pain and bleeding. The performance of the TCu-380A in recent years, however, has proved to be superior.

Ten-Year Experience with Paragard, TCu-380A Rate per 100 users per year

	Year									
	1	2	3	4	5	6	7	8	9	10
Pregnancy	0.7	0.3	0.6	0.2	0.3	0.2	0.0	0.4	0.0	0.0
Expulsion	5.7	2.5	1.6	1.2	0.3	0.0	0.6	1.7	0.2	0.4
Bleeding/pain removal	11.9	9.8	7.0	3.5	3.7	2.7	3.0	2.5	2.2	3.7
Medical removals	2.5	2.1	1.6	1.7	0.1	0.3	1.0	0.4	0.7	0.3
Continuation	76.8	78.3	81.2	86.2	89.0	91.9	98.7	98.8	192.0	91.8
Number starting each year	4,932	3,149	2,018	1,121	872	621	563	483	423	325

Data from Population Council (n = 3,536) and WHO (n = 1,396) trials.

In careful studies, with attention to technique and participation by motivated patients, the failure rate with the TCu-380A and the other newer copper IUDs is less than one per 100 women per year.^{26, 46, 50} The cumulative net pregnancy rate after 7 years of use is 1.5 per 100 woman-years, and after 12 years, only 1.9 per 100 women (not a single pregnancy was reported after 8 years of use).^{46, 51} In developing countries, the failure rate with IUDs is less than that with oral contraception.⁵² Failure rates are slightly higher in younger (less than age 25), more fertile women.

Women use IUDs longer than other reversible methods of contraception. The IUD continuation rate is higher than that with oral contraception, condoms, or diaphragms. This may reflect the circumstances surrounding the choice of an IUD (older, parous women).

Expulsion

Approximately 5% of patients spontaneously expel the TCu-380A within the first year. This event can be associated with cramping, vaginal discharge, or uterine bleeding. However, in some cases, the only observable change is lengthening or absence of the IUD strings. Patients should be cautioned to request immediate attention if expulsion is suspected. A partially expelled IUD should be removed. If pregnancy or infection is not present, a new IUD can be inserted immediately (in this instance, antibiotic prophylaxis is recommended).

Ectopic Pregnancy

The previous use of an IUD does not increase the risk of a subsequent ectopic pregnancy.^{45, 53, 54} The current use of an IUD, other than the progesterone-releasing device, offers some protection against ectopic pregnancy.^{53, 54, 55, 56, 57} and ⁵⁸ The largest study, a WHO multicenter study, concluded that IUD users were 50% less likely to have an ectopic pregnancy when compared with women using no contraception.⁵³ This protection is not as great as that achieved by inhibition of ovulation with oral contraception. Therefore, when an IUD user becomes pregnant, the pregnancy is more likely to be ectopic. However, the actual occurrence of an ectopic pregnancy in an IUD user is a rare event.

The lowest ectopic pregnancy rates are seen with the most effective IUDs, like the TCu-380A (90% less likely compared with noncontraceptors).⁵⁸ The rate is about one-tenth the ectopic pregnancy rate associated with the Lippes Loop or with devices with less copper such as the TCu-200.⁵⁹ The progesterone-releasing IUD has a higher rate, probably because its action is limited to a local effect on the endometrium,⁵⁶ while very few ectopic pregnancies have been reported with the levonorgestrel IUD, presumably because it is associated with a partial suppression of gonadotropins with subsequent disruption of normal follicular growth and development, and, in a significant number of cycles, inhibition of ovulation.^{25, 30, 48, 58, 60}

The risk of ectopic pregnancy does not increase with increasing duration of use with the TCu-380A or the levonorgestrel IUD.^{25, 51} In a 7-year prospective study, not a single ectopic pregnancy was encountered with the levonorgestrel IUD.²⁵ In 8000 woman-years of experience in randomized multicenter trials, there has been only a single ectopic pregnancy reported with the TCu-380A (which is one-tenth the rate with the Lippes Loop or TCu-200).²⁵

The protection against ectopic pregnancy provided by the TCu-380A and the levonorgestrel IUD makes these IUDs acceptable choices for contraception in women with previous ectopic pregnancies.

Ectopic Pregnancy Rates per 1000 Woman-Years^{59, 61}

Non-contraceptive users, all ages	3.00–4.50
Progesterone IUD (based on small numbers, thus probably the same as non-contraceptive users)	6.80
Levonorgestrel IUD	0.20
TCu-380A IUD	0.20

Side Effects

With effective patient screening and good insertion technique, the copper and medicated IUDs are not associated with an increased risk of infertility after their removal. Even if IUDs are removed for problems, subsequent fertility rates are normal.^{44, 45, 48}

The symptoms most often responsible for IUD discontinuation are increased uterine bleeding and increased menstrual pain. Within one year, 5–15% of women discontinue IUD use because of these problems. Smaller copper and progestin IUDs have reduced the incidence of pain and bleeding considerably, but a careful menstrual history is still important in helping a woman consider an IUD. Women with prolonged, heavy menstrual bleeding or significant dysmenorrhea may not be able to tolerate copper IUDs but may benefit from a progestin IUD.⁴¹ Because bleeding and cramping are most severe in the first few months after IUD insertion, treatment with a nonsteroidal anti-inflammatory (NSAID) agent (an inhibitor of prostaglandin synthesis) during the first several menstrual periods can reduce bleeding and cramping and help a patient through this difficult time. Even persistent heavy menses can be effectively treated with NSAIDs.⁶² NSAID treatment should begin at the onset of menses and be maintained for 3 days. A copper IUD is available in China that also releases a small amount of indomethacin; this device is associated with markedly less bleeding.⁶³

It is not unusual to have a few days of intermenstrual spotting or light bleeding. Although aggravating, this does not cause significant blood loss. Such bleeding deserves the usual evaluation for cervical or endometrial pathology. These changes can be objectionable for women who are prevented from having intercourse while bleeding.

Following insertion of a modern copper IUD, menstrual blood loss increases by about 55%, and this level of bleeding continues for the duration of IUD use.⁶⁴ This is associated with a slight (1–2 day) prolongation of menstruation. Over a year's time, this amount of blood loss does not result in changes (e.g., serum ferritin) indicative of iron deficiency. Assessment for iron depletion and anemia should be considered, however, in long-term users and in women susceptible to iron deficiency anemia.

Because of a decidualizing, atrophic impact on the endometrium, amenorrhea can develop over time with the progestin-containing IUDs. With the levonorgestrel IUD, 70% of patients are oligomenorrheic and 30% amenorrheic within 2 years. For some women, the lack of periods is so disconcerting that they request removal. On the other hand, this effect on menstruation is manifested by an increase in blood hemoglobin levels.^{25, 49} Sufficient progestin reaches the systemic circulation from the levonorgestrel-containing IUD so that androgenic side effects, such as acne and hirsutism, can occur. More extensive clinical studies are needed to assess the impact of this IUD on the lipoprotein profile; however, it is unlikely that the low dose of levonorgestrel has an important effect on cardiovascular risk.

Some women report an increased vaginal discharge while wearing an IUD. This complaint deserves examination for the presence of vaginal or cervical infection. Treatment can be provided with the IUD remaining in place.

Long-term use of the IUD is associated with impressive safety and lack of side effects. In a 7-year prospective study, the use of either the copper IUD or the levonorgestrel IUD beyond 5 years led to no increase in pelvic infection, no increase in ectopic pregnancy rates, no increase in anemia, and no increase in abnormal Pap smears.²⁵ Duration of use does not affect pregnancy rates or outcome.

The presence of copper may yield some benefits. There are epidemiologic data indicating that both the copper IUD and the inert IUD reduce the risks of endometrial cancer and invasive cervical cancer.^{65, 66, 67, 68 and 69} Presumably, this protective effect is due to induced biochemical alterations that affect cellular responses.

The copper IUD is not affected by magnetic resonance imaging, and therefore, the copper IUD need not be removed prior to MRI, and neither patients nor workers need be excluded from MRIs or the MRI environment.^{70, 71}

Infections

IUD-related bacterial infection is now believed to be due to contamination of the endometrial cavity at the time of insertion. Mishell's classic study indicated that the uterus is routinely contaminated by bacteria at insertion.⁷² Infections that occur 3–4 months after insertion are believed to be due to acquired STDs, not the direct result of the IUD. The early, insertion-related infections, therefore, are polymicrobial, derived from the endogenous cervicovaginal flora, with a predominance of anaerobes.

A review of the World Health Organization data base derived from all of the WHO IUD clinical trials concluded that the risk of pelvic inflammatory disease was 6 times higher during the 20 days after the insertion compared with later times during follow-up, but, most importantly, PID was extremely rare beyond the first 20 days after insertion.⁷³ In nearly 23,000 insertions, however, only 81 cases of PID were diagnosed, and a scarcity of PID was observed in those situations where STDs are rare. There was no statistically significant difference comparing the copper IUD to the inert Lippes Loop or progestin-containing IUDs. These data confirm earlier studies that the risk of infection is highest immediately after insertion and that PID risk does not increase with long-term use.^{14, 19} The problem of infection can be minimized with careful screening and the use of aseptic technique. Even women with insulin-dependent diabetes mellitus do not have an increased risk for infection.^{74, 75}

Doxycycline (200 mg) or azithromycin (500 mg) administered orally one hour prior to insertion can provide protection against insertion-associated pelvic infection, but prophylactic antibiotics are probably of little benefit for women at low risk for STDs.

Compared with oral contraception, barrier methods, and hormonal IUDs, there is no reason to think that nonmedicated or copper IUDs can confer protection against STDs.⁷⁶ However, the levonorgestrel-releasing IUD has been reported to be associated with a protective effect against pelvic infection, and the copper IUD is associated with lower titers of anti-chlamydial antibody.^{29, 77} In vitro, copper inhibits chlamydial growth in endometrial cells.⁷⁸ Thus, the association between IUD use and pelvic infection (and infertility) is now seriously questioned.⁷⁹ Women who use IUDs must be counseled to use condoms along with the IUD whenever they have intercourse with a partner who could be an STD carrier. Because sexual behavior is the most important modifier of the risk of infection, clinicians should ask prospective IUD users about numbers of partners, their partner's sexual practices, the frequency and age of onset of intercourse, and history of STDs.⁸⁰ Women at low risk are unlikely to have pelvic infections while using IUDs.¹⁹

It is not certain that the IUD is inappropriate for women who are at increased risk of bacterial endocarditis (previous endocarditis, rheumatic heart disease, or the presence of prosthetic heart valves). The bacteriologic contamination of the uterine cavity at insertion is short-lived.⁷² Three studies have attempted to document bacteremia during IUD insertion or removal.^{81, 82 and 83} Only one of the three could find blood culture evidence of bacteremia, and it was present transiently in only a few patients.⁸³ In our view, the IUD is acceptable for patients at risk of bacterial endocarditis, **but antibiotic prophylaxis (amoxicillin 2 g) should be provided one hour before insertion or removal.**

Asymptomatic IUD users whose cervical cultures show gonorrheal or chlamydia infection should be treated with the recommended drugs without removal of the IUD. If, however, there is evidence that an infection has ascended to the endometrium or fallopian tubes, treatment must be instituted and the IUD removed promptly. Vaginal bacteriosis should be treated (metronidazole, 500 mg bid for 7 days), but the IUD need not be removed unless pelvic inflammation is present. There is no evidence that the prevalence of bacterial vaginosis is influenced by IUD use.⁸⁴

For simple endometritis, in which uterine tenderness is the only physical finding, doxycycline (100 mg bid for 14 days) is adequate. If tubal infection is present, as evidenced by cervical motion tenderness, abdominal rebound tenderness, adnexal tenderness or masses, or elevated white blood count and sedimentation rate, parenteral treatment is indicated with removal of the IUD as soon as antibiotic serum levels are adequate. The previous presence of an IUD does not alter the treatment of PID. IUD-associated pelvic infection is more likely to be caused by non-STD organisms.⁸⁵

Appropriate outpatient management of less severe infections:

Cefoxitin (2 g IM) plus probenecid (1 g orally), or
Ceftriaxone (250 mg IM) plus doxycycline (100 mg bid orally), for 14 days.

Severe infections require hospitalization and treatment with:

Cefoxitin (2 g IV q 6 h), or
Cefotetan (2 g IV q 12 h)
Plus doxycycline (100 mg bid orally or IV)
Followed by 14 days of an oral regimen of antibiotics.

The following is an alternative regimen:

Clindamycin (900 mg IV q 8 h), plus
Gentamicin (2 mg/kg IV or IM followed by 1.5 mg/kg q 8 h).

There is a suggestion (in cross-sectional studies) that IUD use increases the risk of HIV transmission from man to woman, especially when the IUD is inserted or removed during exposure to the infected man.^{86, 87} However, this is not a strong suggestion, because the risk with IUD use was ascertained compared with other contraceptive methods (which can protect against transmission), and the many and various influencing factors are difficult to adjust and control. In the only longitudinal study, no association was observed between IUD use and HIV acquisition by women.⁸⁸ In the only study reported, no evidence for female-to-male HIV transmission with IUD use was detected.⁸⁹ HIV-infected women who utilize IUDs for contraception *do not* have a greater incidence of complications (including pelvic

inflammatory disease).⁹⁰

Actinomyces

The significance of actinomycosis infection in IUD users is unclear. There are several reports of IUD users with unilateral pelvic abscesses containing *Actinomyces*.^{91, 92} However, *Actinomyces* are found in Pap smears of up to 30% of plastic IUD wearers when cytologists take special care to look for the organisms. The rate is much lower (less than 1%) with copper devices and varies with duration of use.^{91, 92, 93 and 94} Furthermore, *actinomyces* are commonly present in the normal vagina.⁹⁵ The clinician must decide whether to remove the IUD and treat the patient, treat with the IUD in place, or simply remove the IUD. These patients are almost always asymptomatic and without clinical signs of infection. If uterine tenderness or a pelvic mass is present, the IUD should always be removed after the initiation of treatment with oral penicillin G, 500 mg qid that should continue for a month. If *Actinomyces* are present on the Pap smear of an asymptomatic well woman, in our view, it is not necessary to administer antibiotic treatment or to remove the IUD. Although it has been recommended that the IUD should be removed in this instance and replaced when a repeat Pap smear is negative, there is no evidence to support this recommendation. Another anaerobic, gram-positive rod, *Eubacterium nodatum*, resembles *Actinomyces* and has also been reported to be associated with colonization of an IUD.⁹⁶ *E. nodatum* can be mistaken for *Actinomyces* on Pap smears. Our recommendations can be applied to both *E. nodatum* and *Actinomyces*.

Pregnancy With an IUD In Situ

Spontaneous Miscarriage

Spontaneous miscarriage occurs more frequently among women who become pregnant with IUDs in place, a rate of approximately 40–50%. Because of this high rate of spontaneous miscarriage, IUDs should always be removed if pregnancy is diagnosed and the string is visible. Use of instruments inside the uterus should be avoided if the pregnancy is desired, unless sonographic guidance can help avoid rupture of the membranes.⁹⁷ After removal of an IUD with visible strings, the spontaneous miscarriage rate is approximately 30%.^{98, 99} Combining ultrasonography guidance with carbon dioxide hysteroscopy, an IUD with a missing tail can be identified and removed during early pregnancy.¹⁰⁰ **If the IUD is easily removed without trauma or expelled during the first trimester, the risk of spontaneous miscarriage is not increased.**^{101, 102}

Septic Abortion

In the past, if the IUD could not be easily removed from a pregnant uterus, the patient was offered induced abortion because it was believed that the risk of life-threatening septic, spontaneous miscarriage in the second trimester was increased 20-fold if the pregnancy continued with the IUD in utero. However, this belief was derived from experiences with the Dalkon Shield. There is no evidence that there is an increased risk of septic abortion if pregnancy occurs with an IUD in place other than the Shield.^{102, 103} There have been no deaths in the United States since 1977 among women pregnant with an IUD.¹⁰⁴

If a patient plans to terminate a pregnancy that has occurred with an IUD in place, the IUD should be removed immediately. If there is no evidence of infection, the IUD can safely be removed in a clinic or office.

If an IUD is in an infected, pregnant uterus, removal of the device should be undertaken only after antibiotic therapy has been initiated, and equipment for cardiovascular support and resuscitation is immediately available. These precautions are necessary because removal of an IUD from an infected, pregnant uterus can lead to septic shock.

Congenital Anomalies

There is no evidence that exposure of a fetus to medicated IUDs is harmful. The risk of congenital anomalies is not increased among infants born to women who become pregnant with an IUD in place.^{102, 105} A case-control study did not find an increased incidence of IUD use in pregnancies resulting in limb reduction deformities.¹⁰⁶

Preterm Labor and Birth

The incidence of preterm labor and delivery is increased approximately 4-fold when an IUD is left in place during pregnancy.^{102, 107, 108 and 109}

Other Complications

Obstetrical complications at delivery (such as hemorrhage, stillbirth, and difficulties with placenta removal) have been reported only with the Dalkon Shield in situ.

IUD Insertion

Patient Selection

Patient selection for successful IUD use requires attention to menstrual history and the risk for STDs. Age and parity are not the critical factors in selection; the risk factors for STDs are the most important consideration. Women who have multiple sexual partners, whose partners have multiple partners, who are drug or alcohol dependent, and who are not in a stable sexual relationship are at greater risk of pelvic infection at the time of IUD insertion and at greater risk of acquiring a sexually transmitted disease after IUD insertion.^{17, 18 and 19} It would be appropriate for these women to use condoms for STD protection and an IUD for effective contraception. Current, recent, or recurrent PID is a contraindication for IUD use. Hormonal and barrier methods are better choices for these women. Nulliparous and nulligravid women can safely use the IUD if both sexual partners are monogamous. In a national U.S. survey, only 13% of adults had more than one sexual partner in the previous year.¹¹⁰ Most women are good candidates for the IUD.

Patients with heavy menstrual periods should be cautioned regarding the increase in menstrual bleeding associated with the copper IUD. Women who are anticoagulated or have a bleeding disorder are obviously not good candidates for the copper IUD, but might benefit from a progestin IUD.

There are other conditions that can compromise success. Women who have abnormalities of uterine anatomy (bicornuate uterus, submucous myoma, cervical stenosis) may not accommodate an IUD. The IUD is not a good choice when the uterine cavity is distorted by leiomyomata. According to conventional wisdom, the few individuals who have allergies to copper or have Wilson's disease (a prevalence of about 1 in 200,000) should not use copper IUDs; however, no cases of difficulty have ever been recorded and it is doubtful, considering the low exposure to copper, that there would be a problem. The amount of copper released into the circulation per day is less than that consumed in a normal diet.¹¹¹

Immunosuppressed patients should not use IUDs. Patients at risk for endocarditis should be treated with prophylactic antibiotics at insertion and removal. In our view, cervical dysplasia does not preclude IUD insertion or continued use.

Because many older women have diabetes mellitus, it is worth emphasizing that no increase in adverse events has been observed with copper IUD use in women with either insulin-dependent or noninsulin-dependent diabetes.^{74, 75, 112} Indeed, the IUD can be an ideal choice for a woman with diabetes, especially if vascular disease is present.

The IUD should not be dismissed just because the patient is an adolescent. Although the clinical performance of the IUD in a study of parous adolescents was not as good as in older women, it was still similar or slightly better than other reversible methods used by adolescents.¹¹³ Given appropriate screening, counseling, and care, the IUD can provide long-term effective contraception for adolescents.

A careful speculum and bimanual examination is essential prior to IUD insertion. It is important to know the position of the uterus; undetected extreme posterior uterine position is the most common reason for perforation at the time of IUD insertion. However, perforation is rare; the incidence is estimated to be less than 1 per

3000 insertions.¹¹⁴ A very small or large uterus, determined by examination and sounding, can preclude insertion. For successful IUD use, the uterus should preferably not sound less than 6 cm or more than 9 cm.

Preferably, the absence of cervical or vaginal infection should be established before insertion. If this is not feasible, insertion should definitely be delayed if a mucopurulent discharge of the cervix or a significant vaginitis (including vaginal bacteriosis) is present.

Key Points in Patient Counseling

Prospective IUD users should be aware of the following important possibilities:

1. Protection against unwanted pregnancy begins immediately after insertion.
2. Menses can be longer and heavier (except with hormonal IUDs); tampons can be used.
3. There is a slightly increased risk of pelvic infection in the first few months after insertion.
4. Protection against infections transmitted through the vaginal mucosa requires the use of condoms.
5. Ectopic pregnancies can still occur.
6. The IUD can be spontaneously expelled; monthly palpation of the IUD strings is important to avoid unwanted pregnancies. If the strings are not felt or something hard is palpable (suggestive of the IUD frame), a clinician should be notified as soon as possible. Backup contraception should be provided until the patient can be examined.

Timing

An IUD can be safely inserted at any time after delivery, spontaneous miscarriage or induced abortion, or during the menstrual cycle. Expulsion rates were higher when the older, large plastic IUDs were inserted sooner than 8 weeks postpartum, however studies indicate that the copper IUDs can be inserted between 4 and 8 weeks postpartum without an increase in pregnancy rates, expulsion, uterine perforation, or removals for bleeding and/or pain.^{115, 116} Insertion can even occur immediately after a vaginal delivery; it is not associated with an increased risk of infection, uterine perforation, postpartum bleeding, or uterine subinvolution.¹¹⁷ Postvaginal delivery insertion is not recommended if intrauterine infection is present, and a slightly higher expulsion rate is to be expected compared with insertion 4–8 weeks postpartum. The IUD can also be inserted at cesarean section; the expulsion rate is slightly lower than that with insertion immediately after vaginal delivery.¹¹⁸

Insertion of an IUD in breastfeeding women is relatively easier, and is associated with a lower removal rate for bleeding or pain.¹¹⁷ Reports disagree whether perforation is more common in lactating women.^{117, 119, 120}

An IUD can be inserted immediately after a first-trimester abortion, but after a second-trimester abortion, it is recommended to wait until uterine involution occurs.^{121, 122}

Insertions can be more difficult if the cervix is closed between menses. The advantages of insertion during or shortly after a menstrual period include a more open cervical canal, the masking of insertion-related bleeding, and the knowledge that the patient is not pregnant. These relative advantages may be outweighed by the risk of unintended pregnancy if insertion is delayed to await menstrual bleeding. In addition, there is evidence that the expulsion rate and termination rates for pain, bleeding, and pregnancy are lower if insertions are performed after day 11 of the menstrual cycle, and the infection rate may be lower with insertions after the 17th cycle day.¹²³

Technique for the TCU-380A and the Progestasert

Inserting an IUD requires only a few minutes, has few complications, and is rarely painful, but preoperative examination, medication, and the right equipment will ensure a good experience for your patient. After introducing a vaginal speculum, the cervix is cleaned with chlorhexidine or povidone-iodine. Leave the antiseptic-soaked cotton-tipped applicator in the cervical canal during the procedures prior to insertion of the IUD. Place a paracervical block by injecting one mL of local anesthetic (1% chlorprocaine) into the cervical lip (anterior if the uterus is anterior in the pelvis and posterior if it lies posteriorly). Inclusion of atropine, 0.4 mg, in the anesthetic will reduce the incidence of vasovagal reactions. After one minute, grasp the cervical lip with the tenaculum ratcheting it only to the first position in a slow, deliberate fashion. Use the tenaculum to move the cervix to the patient's right, revealing the left lateral vaginal fornix. Place the needle tip in the cervical mucosa at 3 o'clock, 1–2 cm lateral to the cervical os, advance it about 1.5 inches (4 cm) under the mucosa and inject about 4 mL of anesthetic, leaving an additional 1 mL behind under the mucosa as the needle is withdrawn. Now deflect the cervix to the patient's left and inject local anesthetic at 9 o'clock in similar fashion. **Wait 2–3 minutes before proceeding.** A very common mistake is to not allow sufficient time for anesthetic action.

Many women can tolerate IUD insertion, especially at the time of menses, without a paracervical block. For some women, however, insertion is less painful with local anesthetic and with administration of a nonsteroidal anti-inflammatory agent 30 minutes to one hour prior to the procedure. If a paracervical block is not used, having the patient cough just as the tenaculum is applied reduces pain and the chance of a vasovagal reaction.

Sound and measure the depth of the uterus (the insertion tube can be used for this purpose). The IUD is loaded into its insertion tube immediately prior to insertion. The arms of the TCU 380A must be folded manually, either with sterile gloves or through the sterile wrapper, and maneuvered into the end of the insertion tube, just enough to hold them in place during insertion. The insertion tube is advanced into the uterus to the correct depth as marked on the tube either by a sliding plastic flange (TCU-380A) or printed gradations (Progestasert). The flange should be twisted to be in the same plane as the horizontal arms. When the insertion tube and IUD reach the fundus, withdraw a few mm. Check to make sure that the transverse arm of the IUD is in the horizontal plane so that the tips of the T will rest in the cornual regions of the endometrial cavity. Placement in the vertical plane increases the risk of expulsion and pregnancy.¹²⁴ To release the Progestasert, remove the thread-retaining plug, and withdraw the inserter tube. To release the TCU-380A, advance the solid rod until the resistance of the IUD is felt, fix the rod against the tenaculum which is held in traction, and withdraw the insertion tube while the solid insertion rod is held against the stem of the T, releasing the transverse arms into high fundal position. Remove the solid rod and finally the inserter tube taking care not to pull on the strings. You can ensure that the TCU-380A is in a high fundal position if, after removing the solid rod, you push the inserter tube up against the cross arm of the T prior to withdrawing it completely from the cavity. Trim the strings to about 4 cm from the external os, and record their length in the chart. Shorter strings can cause unpleasant bristle-like sensations. With the Progestasert, the shorter string verifies correct placement; the longer thread should be trimmed.

Patients with newly inserted IUDs should attempt to feel the strings before they leave the examining room. Giving them the cut ends of the strings as a sample of what to feel is helpful. Palpation should be performed monthly by the patient to verify continuing presence of the IUD after each menstrual flow. Patients should return within 3 months, preferably after the first menses, to confirm the presence of the IUD and to provide support, because bleeding changes and expulsion are most likely to occur during this time. Caution the patient that the first 2 menses are typically heavier. As with all office procedures, patients should be provided a 24-hour phone number for urgent questions or concerns, and especially to report unusual pain, bleeding, or vaginal discharge.

Prophylactic Antibiotics

Doxycycline (200 mg) administered orally one hour prior to insertion can provide protection against insertion-associated pelvic infection, but three double-blind randomized studies, two conducted in Africa and one in Turkey, found no significant advantage in the treated groups.^{125, 126 and 127} Azithromycin in a dose of 500 mg has also been used prophylactically, presumably offering more protection because of a longer half-life.¹²⁸ However, a randomized trial in low-risk women could find no effect on the subsequent rate of IUD removal or morbidity when 500 mg azithromycin was administered 1 hour before IUD insertion.¹²⁹ In women at low risk for STDs, the incidence of infection is so low that there is little benefit to be expected with prophylactic antibiotics.

Summary: IUD Use and Medical Conditions

1. A woman with a previous ectopic pregnancy can use a copper IUD or the levonorgestrel IUD.
2. Women with heavy menses and dysmenorrhea, including women who have a bleeding disorder or are anticoagulated, should consider a progestin-releasing IUD.
3. Women at risk for bacterial endocarditis should receive prophylactic antibiotics at insertion and removal.

4. Current, recent, or recurrent PID is a contraindication for IUD use.
5. Women with diabetes mellitus, either insulin-dependent or noninsulin-dependent, can use IUDs.
6. IUD insertion is relatively easier in breastfeeding women, and the rates of expulsion and uterine perforation are not increased.

IUD Removal

Removal of an IUD can usually be accomplished by grasping the string with a ring forcep or uterine dressing forcep and exerting firm traction. If strings cannot be seen, they can often be extracted from the cervical canal by rotating two cotton-tipped applicators or a Pap smear cytobrush in the endocervical canal. If further maneuvers are required, a paracervical block should be administered. Oral administration of a nonsteroidal anti-inflammatory drug beforehand will reduce uterine cramping.

If IUD strings cannot be identified or extracted from the endocervical canal, a light plastic uterine sound should be passed into the endometrial cavity after administration of a paracervical block. A standard metal sound is too heavy and insensitive for this purpose. The IUD can frequently be felt with the sound and localized against the anterior or posterior wall of the uterus. The device can then be removed using a Facit polyp or alligator-type forcep directed to where the device was felt, taking care to open the forcep widely immediately on passing it through the internal cervical os so that the IUD can be caught between the jaws. If removal is not easily accomplished using this forcep, direct visualization of the IUD with sonography or hysteroscopy can facilitate removal. Sonography is less painful and more convenient, and should be tried first.

Fertility returns promptly and pregnancies after removal of an IUD occur at a normal rate, sooner than after oral contraception.^{42, 43, 44} and ^{45, 47, 48} Pregnancy outcome after IUD removal is associated with a normal incidence of spontaneous miscarriage and ectopic pregnancy.⁴⁸

If a patient wishes to continue use of an IUD, a new device can be placed immediately after removal of the old one. In this case, antibiotic prophylaxis is advised.

Embedded IUDs

If removal is not easily accomplished, direct visualization of the IUD with sonography or hysteroscopy can be helpful. Sonography is safer and less expensive.^{97, 130} Transvaginal ultrasonography provides the best image to confirm the location of the IUD, but there is little room for the removal procedure. A better approach is to fill the bladder and use an abdominal sector transducer to image the uterine cavity as the forceps are introduced. Open the forceps widely and see if the IUD moves when the forceps close on it. If it moves, close the forceps tightly and extract the IUD. If unsuccessful, re-introduce the forceps in a different plane, keeping one jaw of the open forceps firmly against first the anterior and then the posterior uterine wall. If this approach is not successful, hysteroscopy is indicated.

Finding a Displaced IUD

When an IUD cannot be found, besides expulsion, one has to consider perforation of the uterus into the abdominal cavity (a very rare event) or embedment into the myometrium. All IUDs are radiopaque, but localizing them radiographically requires 2–3 views, is time-consuming and expensive, and does not allow intrauterine direction of instruments. A quick, real-time sonographic scan in the office is the best method to locate a lost IUD, whether or not removal is desired. If the IUD cannot be visualized with ultrasonography, abdominal x-rays are necessary because the IUD can be high and hidden.

If the IUD is identified perforating the myometrium or in the abdominal cavity, it should be removed using operative laparoscopy, usually under general anesthesia. If the IUD is in the uterine cavity, but cannot be grasped with a forcep under sonographic guidance, hysteroscopy is the best approach. Both routes may be helpful if an IUD is partially perforated.

Copper in the abdominal cavity can lead to adhesion formation, making laparoscopic removal difficult.¹³¹ Although inert perforated devices without closed loops were previously allowed to remain in the abdominal cavity, current practice is to remove any perforated IUD. Because IUD perforations usually occur at the time of insertion, it is important to check for correct position by identifying the string within a few weeks after insertion. Uterine perforation itself is unlikely to cause more than transient pain and bleeding, and can go undetected at the time of IUD insertion. If you believe perforation has occurred, prompt sonography is indicated so that the device can be removed before adhesion formation can occur.

This problem should be put into perspective. With the new generation of IUDs (copper and medicated), adhesion formation appears to be an immediate reaction which does not progress, and rarely leads to serious complications.¹³² In appropriate situations (where the risk of surgery is considerable), clinician and patient may elect not to remove the translocated IUD. However, a case has been reported of sigmoid perforation occurring 5 years after insertion, and the general consensus continues to favor removal of a perforated IUD immediately upon diagnosis.¹³³

IUD Myths

We hope the information in this chapter will lay to rest 4 specific myths associated with IUDs. For emphasis, the following sentences provide the correct responses to what we believe are common misconceptions among clinicians:

1. IUDs are **NOT** abortifacients.
2. An increased risk of infection with the modern IUD is related **ONLY** to the insertion.
3. The modern IUD **HAS NOT** exposed clinicians to litigation.
4. IUDs **DO NOT** increase the risk of ectopic pregnancy.

The IUD for Older Women

The IUD is a good reversible contraceptive choice for older women. An older woman is more likely to be mutually monogamous and less likely to develop PID, and for those women who have already had their children, concern with fertility and problems with cramping and bleeding are both lesser issues. If protection from STDs is not a concern, insertion of a copper IUD can provide very effective contraception until the menopause without the need to do anything other than check the string occasionally. On the other hand, because alterations of bleeding patterns become more common in this age group, it may be necessary to remove an IUD.

The use of vaginal contraceptives is probably as ancient as homo sapiens. References to sponges and plugs appear in the earliest of writings. Substances with either barrier or spermicidal properties (or both) have included honey, alum, spices, oils, tannic acids, lemon juice, and even crocodile dung. However, the diaphragm and the cervical cap were not invented until the late 1800s, the same time period that saw the beginning of investigations with spermicidal agents.

Intravaginal contraception was widespread in isolated cultures throughout the world. The Japanese used balls of bamboo paper; Islamic women used willow leaves; and the women in the Pacific Islands used seaweed. References can be found throughout ancient writings to sticky plugs, made of gumlike substances, to be placed in the vagina prior to intercourse. In preliterate societies, an effective method had to have been the result of trial and error, with some good luck thrown in.

How was contraceptive knowledge spread? Certainly, until modern times, individuals did not consult physicians for contraception. Contraceptive knowledge was folklore, undoubtedly perpetuated by the oral tradition. The social and technical circumstances of ancient times conspired to make communication of information very difficult. But even when knowledge was lacking, the desire to prevent conception was not. Hence, the widespread use of potions, body movements, and amulets; all of which can be best described as magic.

Egyptian papyri dating from 1850 BC refer to plugs of honey, gum, acacia, and crocodile dung. The descriptions of contraceptive techniques by Soranus are viewed as the best in history until modern times.¹ Soranus of Ephesus lived from 98 to 138, and has often been referred to as the greatest gynecologist of antiquity. He studied in Alexandria, and practiced in Rome. His great text was lost for centuries, and was not published until 1838.

Soranus gave explicit directions how to make concoctions that probably combined a barrier with spermicidal action. He favored making pulps from nuts and fruits (probably very acidic and spermicidal) and advocated the use of soft wool placed at the cervical os. He described up to 40 different combinations.

The earliest penis protectors were just that, intended to provide prophylaxis against infection. Gabriello Fallopius, one of the early authorities on syphilis, described, in 1564, a linen condom that covered the glans penis. The linen condom of Fallopius was followed by full covering with animal skins and intestines, but use for contraception cannot be dated to earlier than the 1700s.

There are many versions accounting for the origin of the word, "condom." Most attribute the word to a Dr. Condom, a physician in England in the 1600s. The most famous story declares that Dr. Condom invented the sheath in response to the annoyance displayed by Charles II at the number of his illegitimate children. All attempts to trace this physician have failed. This origin of the word can neither be proved nor disproved.

By 1800, condoms were available at brothels throughout Europe, but nobody wanted to claim responsibility. The French called the condom the English cape; the English called condoms French letters.

Vulcanization of rubber dates to 1844, and by 1850, rubber condoms were available in the U.S. The vulcanization of rubber revolutionized transportation and contraception. The introduction of liquid latex and automatic machinery ultimately made reliable condoms both plentiful and affordable.

Diaphragms first appeared in publication in Germany in the 1880s. A practicing German gynecologist, C. Haase, wrote extensively about his diaphragm, using a pseudonym of Wilhelm P.J. Mensinga. The Mensinga diaphragm retained its original design with little change until modern times.

The cervical cap was available for use before the diaphragm. A New York gynecologist, E.B. Foote, wrote a pamphlet describing its use around 1860. By the 1930s, the cervical cap was the most widely prescribed method of contraception in Europe. Why was the cervical cap not accepted in the U.S.? The answer is not clear. Some blame the more prudish attitude towards sexuality as an explanation for why American women had difficulty learning self-insertion techniques.

Scientific experimentation with chemical inhibitors of sperm began in the 1800s. By the 1950s, more than 90 different spermicidal products were being marketed, and some of them were used in the first efforts to control fertility in India.² With the availability of the intrauterine device and the development of oral contraception, interest in spermicidal agents waned, and the number of products declined.

In the last decades of the 1800s, condoms, diaphragms, pessaries, and douching syringes were widely advertised; however, they were not widely utilized. It is only since 1900 that the knowledge and application of contraception have been democratized, encouraged, and promoted. And it is only since 1960, that contraception teaching and practice became part of the program in academic medicine, but not without difficulty.

In the 1960s, Duncan Reid, chair of obstetrics at Harvard Medical School, organized and cared for women in a clandestine clinic for contraception. Called "Dr. Reid's Clinic," women of Boston were able to receive contraceptives not available elsewhere in the city.

In 1961, C. Lee Buxton, chair of obstetrics and gynecology at Yale Medical School, and Estelle Griswold, the 61-year-old executive director of Connecticut Planned Parenthood, opened four Planned Parenthood clinics in New Haven, in a defiant move against the current Connecticut law. In an obvious test of the Connecticut law, Buxton and Griswold were arrested at the Orange Street clinic, in a pre-arranged scenario scripted by Buxton and Griswold at the invitation of the district attorney. Found guilty, and fined \$100, imprisonment was deferred because the obvious goal was a decision by the United States Supreme Court. Buxton was forever ranked by the trivial amount of the fine. On June 7, 1965, the Supreme Court voted 7-2 to overturn the Connecticut law on the basis of a constitutional right of privacy. It was not until 1972 and 1973 that the last state laws prohibiting the distribution of contraceptives were overthrown.

Failure Rates During the First Year of Use, United States⁷

Method	Lowest Expected	Percent of Women with Pregnancy	
			Typical

Risks and Benefits Common to all Barrier Methods

Barrier (condoms and diaphragms) and spermicide methods provide protection (about a 50% reduction) against sexually transmitted diseases (STDs) and pelvic inflammatory disease (PID).^{4,5,6,7 and 8} This includes infections with chlamydia, gonorrhea, herpes simplex, cytomegalovirus, human papillomavirus, and human immunodeficiency virus (HIV); however, only the condom has been proven to prevent HIV infection. STD protection has a beneficial impact on the risk of tubal infertility and ectopic pregnancy.^{6,9} There have been no significant clinical studies on STDs and cervical caps or the female condom, but these methods should be effective. Women who have never used barrier methods of contraception are almost twice as likely to develop cancer of the cervix.^{9,10} The risk of toxic shock syndrome is increased with female barrier methods, but the actual incidence is so rare that this is not a significant clinical consideration.¹¹ Women who have had toxic shock syndrome, however, should be advised to avoid barrier methods.

Barrier Methods and Preeclampsia. An initial case-control study indicated that methods of contraception that prevented exposure to sperm were associated with an increased risk of preeclampsia.¹² This was not confirmed in a careful analysis of two large prospective pregnancy studies.¹³ This latter conclusion was more compelling in that it was derived from a large prospective cohort data base.

The Diaphragm

The first effective contraceptive method under a woman's control was the vaginal diaphragm. Distribution of diaphragms led to Margaret Sanger's arrest in New York City in 1918. This was still a contentious issue in 1965 when the Supreme Court's decision in *Griswold v. Connecticut* ended the ban on contraception in that state. By 1940, one-third of contracepting American couples were using the diaphragm. This decreased to 10% by 1965 after the introduction of oral contraceptives and intrauterine devices, and fell to about 1.9% in 1995. ([Chapter 21](#)).

Efficacy

Failure rates for diaphragm users vary from as low as 2% per year of use to a high of 23%. The typical use failure rate after one year of use is 18–20%.^{3,14} Older, married women with longer use achieve the highest efficacy, but young women can use diaphragms very successfully if they are properly encouraged and counseled. There have been no adequate studies to determine whether efficacy is different with and without spermicides.¹⁵

Side Effects

The diaphragm is a safe method of contraception that rarely causes even minor side effects. Occasionally, women report vaginal irritation due to the latex rubber or the spermicidal jelly or cream used with the diaphragm. Less than 1% discontinue diaphragm use for these reasons. Urinary tract infections are 2–3-fold more common among diaphragm users than among women using oral contraception.^{16,17} Possibly, the rim of the diaphragm presses against the urethra and causes irritation which is perceived as infectious in origin, or true infection may result from touching the perineal area or incomplete emptying of the bladder. It is more probable that spermicides used with the diaphragm can increase the risk of bacteriuria with *E coli*, perhaps due to an alteration in the normal vaginal flora.¹⁸ Clinical experience suggests that voiding after sexual intercourse is helpful, and if necessary, a single postcoital dose of a prophylactic antibiotic can be recommended. Postcoital prophylaxis is effective, using trimethoprim-sulfamethoxazole (1 tablet postcoitus), nitrofurantoin (50 or 100 mg postcoitus), or cephalexin (250 mg postcoitus).

Improper fitting or prolonged retention (beyond 24 hours) can cause vaginal abrasion or mucosal irritation. There is no link between the normal use of diaphragms and the toxic shock syndrome.¹⁹ It makes sense, however, to minimize the risk of toxic shock by removing the diaphragm after 24 hours and during menses.

Benefits

Diaphragm use reduces the incidence of cervical gonorrhea,²⁰ pelvic inflammatory disease,²¹ and tubal infertility.^{4,9} This protection may be due in part to the simultaneous use of a spermicide. There are no data, as of yet, regarding the effect of diaphragm use on the transmission of the AIDS virus (HIV). An important advantage of the diaphragm is low cost. Diaphragms are durable, and with proper care, can last for several years.

Choice and Use of the Diaphragm

There are three types of diaphragms, and most manufacturers produce them in sizes ranging from 50 to 105 mm diameter, in increments of 2.5 to 5 mm. Most women use sizes between 65 and 80 mm.

The diaphragm made with a *flat metal spring* or a *coil spring* remains in a straight line when pinched at the edges. This type is suitable for women with good vaginal muscle tone and an adequate recess behind the pubic arch. However, many women find it difficult to place the posterior edge of these flat diaphragms into the

posterior cul-de-sac, and over the cervix.

Arcing diaphragms are easier to use for most women. They come in two types. The All-Flex type bends into an arc no matter where around the rim the edges are pinched together. The hinged type must be pinched between the hinges in order to form a symmetrical arc. The hinged type forms a narrower shape when pinched together, and, thus, may be easier for some women to insert. The arcing diaphragms allow the posterior edge of the diaphragm to slip more easily past the cervix and into the posterior cul-de-sac. Women with poor vaginal muscle tone, cystocele, rectocele, a long cervix, or an anterior cervix of a retroverted uterus use arcing diaphragms more successfully.

Fitting

Successful use of a diaphragm depends on proper fitting. The clinician must have available aseptic fitting rings or diaphragms themselves in all diameters. These devices should be scrupulously disinfected by soaking in a bleach solution. At the time of the pelvic examination, the middle finger is placed against the vaginal wall and the posterior cul-de-sac, while the hand is lifted anteriorly until the pubic symphysis abuts the index finger. This point is marked with the examiner's thumb to approximate the diameter of the diaphragm. The corresponding fitting ring or diaphragm is inserted, the fit to be assessed by both clinician and patient.

If the diaphragm is too tightly pressed against the pubic symphysis, a smaller size is selected. If the diaphragm is too loose (comes out with a cough or bearing down), the next larger size is selected. After a good fit is obtained, the diaphragm is removed by hooking the index finger under the rim behind the symphysis and pulling. It is important to instruct the patient in these procedures during and after the fitting. The patient should then insert the diaphragm, practice checking for proper placement, and attempt removal.

Timing

Diaphragm users need additional instruction about the timing of diaphragm use in relation to sexual intercourse and the use of spermicide. None of this advice has been rigorously assessed in clinical studies; therefore, these recommendations represent the consensus of clinical experience.

The diaphragm should be inserted no longer than 6 hours prior to sexual intercourse. About a tablespoonful of spermicidal cream or jelly should be placed in the dome of the diaphragm prior to insertion, and some of the spermicide should be spread around the rim with a finger. The diaphragm should be left in place for approximately 6 hours (but no more than 24 hours) after coitus. Additional spermicide should be placed in the vagina before each additional episode of sexual intercourse while the diaphragm is in place.

Reassessment

Weight loss, weight gain, vaginal delivery, and even sexual intercourse can change vaginal caliber. The fit of a diaphragm should be assessed every year at the time of the regular examination.

Care of the Diaphragm

After removal, the diaphragm should be washed with soap and water, rinsed, and dried. Powders of any sort need not and should not be applied to the diaphragm. It is wise to use water to periodically check for leaks. Diaphragms should be stored in a cool and dark location.

The Cervical Cap

The cervical cap was popular in Europe long before its re-introduction into the United States. There are several types of cervical caps, but only the cavity rim (Prentif) cap is approved in the U.S. U.S. trials have demonstrated the cervical cap to be about as effective as the diaphragm, but somewhat harder to fit (it comes in only four sizes) and more difficult to insert (it must be placed precisely over the cervix).^{22,23} Efficacy is significantly reduced in parous women.

The cervical cap has several advantages over the diaphragm. It can be left in place for a longer time (up to 48 hours), and it need not be used with a spermicide. However, a tablespoonful of spermicide placed in the cap before application is reported to increase efficacy (to a 6% failure rate in the first year) and to prolong wearing time by decreasing the incidence of foul-smelling discharge (a common complaint after 24 hours).²³

The size of the cervix varies considerably from woman to woman, and the cervix changes in individual women in response to pregnancy or surgery. Proper fitting can be accomplished in about 80% of women. Women with a cervix that is too long or too short, or with a cervix that is far forward in the vagina, may not be suited for cap use. However, women with vaginal wall or pelvic relaxation, who cannot retain a diaphragm, may be able to use the cap.

Those women who can be fitted with one of the 4 sizes must first learn how to identify the cervix, and then how to slide the cap into the vagina, up the posterior vaginal wall and onto the cervix. After insertion, and after each act of sexual intercourse, the cervix should be checked to make sure it is covered.

To remove the cap (at least 8 hours after coitus), pressure must be exerted with a finger tip to break the seal. The finger is hooked over the cap rim to pull it out of the vagina. Bearing down or squatting or both can help to bring the cervix within reach of the finger.

The cervical cap can be left in place for 2 days, but some women experience a foul-smelling discharge by 2 days. Like the diaphragm, it must be left in place for at least 8 hours after sexual intercourse in order to ensure that no motile sperm are left in the vagina.

The most common cause of failure is dislodgment of the cap from the cervix during sexual intercourse. There is no evidence that cervical caps cause toxic shock syndrome or dysplastic changes in the cervical mucosa.²⁴ It seems likely (although not yet documented) that cervical caps would provide the same protection from sexually transmitted diseases as the diaphragm.

The Fem Cap, made of nonallergic silicone rubber, is shaped like a sailor's hat, a design that allows a better fit over the cervix and in the vaginal fornices.²⁵ This cap may be easier to fit and use, and provides better efficacy. There are two sizes, one for nulliparous women and a larger size for women who have had a vaginal delivery.

The Contraceptive Sponge

The vaginal contraceptive sponge is a sustained-release system for a spermicide. The sponge also absorbs semen and blocks the entrance to the cervical canal. The "Today" sponge is a dimpled polyurethane disc impregnated with one gram of nonoxynol-9. Approximately 20% of the nonoxynol-9 is released over the 24 hours the sponge is left in the vagina. Production of the "Today" sponge in the U.S. ceased in 1995, and availability awaits a new manufacturer. "Protectaid" is a polyurethane sponge available in Canada and Hong Kong that contains 3 spermicides and a dispersing gel.²⁶ The spermicidal agents are sodium cholate, nonoxynol-9, and benzalkonium chloride. This combination exerts antiviral actions in vitro.²⁷ The dispersing agent, polydimethylsiloxane, forms a protective coating over the entire vagina, providing sustained protection.

To insert, the Today sponge is moistened with water (squeezing out the excess) and placed firmly against the cervix. There should always be a lapse of at least 6 hours after sexual intercourse before removal, even if the sponge has been in place for 24 hours before intercourse (maximal wear time, therefore, is 30 hours). It can be inserted immediately before sexual intercourse or up to 24 hours beforehand. It is removed by hooking a finger through the ribbon attached to the back of the sponge. The Protectaid sponge can be inserted up to 12 hours before intercourse, and it is easier to remove than the Today sponge. Obviously, the sponge is not a good choice for women with anatomical changes that make proper insertion and placement difficult.

In most studies, the effectiveness of the sponge exceeds that of foam, jellies, and tablets, but it is lower than that associated with diaphragm or condom use.^{14,28} Some studies indicated higher failure rates (twice as high) in parous women, suggesting that one size may not fit all users.²⁹

Discontinuation rates are generally higher among sponge users, compared to diaphragm and spermicide use. For some women, however, the sponge is preferred because it provides continuous protection for 24 hours regardless of the frequency of coitus. In addition, it is easier to use and less messy.

Side effects associated with the sponge include allergic reactions in about 4% of users. Another 8% complain of vaginal dryness, soreness, or itching. Some women find removal difficult. There is no risk of toxic shock syndrome, and in fact, the nonoxynol-9 retards staphylococcal replication and toxin production. There has been some concern that the sponge may damage the vaginal mucosa and enhance HIV transmission.³⁰

Spermicides

Jellies, creams, foams, melting suppositories, foaming tablets, foaming suppositories, and soluble films are used as vehicles for chemical agents that inactivate sperm in the vagina before they can move into the upper genital tract. Some are used together with diaphragms, caps, and condoms, but even used alone, they can provide protection against pregnancy.

Various chemicals and a wide array of vehicles have been used vaginally as contraceptives for centuries. The first commercially available spermicidal pessaries were made in England in 1885 of cocoa butter and quinine sulfite. These or similar materials were used until the 1920s when effervescent tablets that released carbon dioxide and phenyl mercuric acetate were marketed. Modern spermicides, introduced in the 1950s, contain surface active agents that damage the sperm cell membranes (this same action occurs with bacteria and viruses, explaining the protection against STDs). The agents currently used are nonoxynol-9, octoxynol-9, benzalkonium chloride, and menfegol. Most preparations contain 60–100 mg of these agents in each vaginal application, with concentrations ranging from 2–12.5%.

Representative Products:

Vaginal Contraceptive Film – Foams —

VCF (70 mg nonoxynol-9)
Delfen (nonoxynol-9, 12.5%)
Emko (nonoxynol-9, 8%)
Koromex (nonoxynol-9, 12.5%)

Jellies and Creams —

Conceptrol (nonoxynol-9, 4%)
Delfen (nonoxynol-9, 12.5%)
Ortho Gynol (nonoxynol-9, 3%)
Ramses (nonoxynol-9, 5%)

Suppositories —

Encare (nonoxynol-9, 2.27%)
Koromex Inserts (nonoxynol-9, 125 mg)
Semicid (nonoxynol-9, 100 mg)

“Advantage 24” is a contraceptive gel that adheres to the vaginal mucosa and provides longer availability of nonoxynol-9; it is intended to be effective for 24 hours. Although available without prescription, adequate clinical trial data are not available. Allendale-N9 is a new vaginal contraceptive film that contains more nonoxynol-9 than VCF.³¹ An Allendale film has also been developed that contains benzalkonium chloride instead of nonoxynol-9.³² In addition to spermicidal activity, benzalkonium chloride is microbicidal and demonstrates activity against HIV.³³ Benzalkonium chloride is available for contraceptive use in the form of a suppository, in a sponge, or as a cream in several countries.

Efficacy

Only periodic abstinence demonstrates as wide a range of efficacy in different studies as do the studies of spermicides. Efficacy seems to depend more on the population studied than the agent used. Efficacy ranges from less than 1% failure to nearly one-third in the first year of use. Failure rates of approximately 20–25% during a year's use are most typical.^{3,14} There are no comparative studies to indicate which preparations, if any, are better or worse.

Spermicides require application 10–30 minutes prior to sexual intercourse. Jellies, creams, and foams remain effective for as long as 8 hours, but tablets and suppositories are good for less than one hour. If ejaculation does not occur within the period of effectiveness, the spermicide should be reapplied. Reapplication should definitely take place for each coital episode.

Vaginal douches are ineffective contraceptives even if they contain spermicidal agents. Postcoital douching is too late to prevent the rapid ascent of sperm (within seconds) to the fallopian tubes.

Advantages

Spermicides are relatively inexpensive and widely available in many retail outlets without prescription. This makes spermicides popular among adolescents and others who have infrequent or unpredictable sexual intercourse. In addition, spermicides are simple to use.

Spermicides provide protection against sexually transmitted diseases. In vitro studies have demonstrated that contraceptive spermicides kill or inactivate most STD pathogens, including HIV. Spermicides have been reported to prevent HIV seroconversion as well as to have no effect.^{34, 35, 36 and 37} Clinical studies indicate reductions in the risk of gonorrhea,^{38, 39, 40} pelvic infections,²¹ and chlamydial infection.^{38, 40} There is little difference in the incidence of trichomoniasis, candidiasis, or bacterial vaginosis among spermicide users.⁴¹ ***It is probably that spermicides do not provide additional protection against STDs over that associated with condoms, and, therefore, spermicides should not be used without condoms if a primary objective is to prevent infection with HIV, gonorrhea, or chlamydia.***⁴²

Side Effects

No serious side effects or safety problems have arisen in all the years that spermicides have been used. The only serious question raised was that of a possible association between spermicide use and congenital abnormalities or spontaneous miscarriages. Epidemiologic analysis, including a meta-analysis, concluded that there is insufficient evidence to support these associations.^{43, 44 and 45} Spermicides are not absorbed through the vaginal mucosa in concentrations high enough to have systemic effects.⁴⁶ Vaginal and cervical mucosal damage (de-epithelialization without inflammation) has been observed with nonoxynol-9, and the overall impact on HIV transmission, although unknown, is of concern.^{47, 48}

The principal minor problem is allergy that occurs in 1–5% of users, related to either the vehicle or the spermicidal agent. Using a different product often solves the problem. Spermicide users also have an altered vaginal flora promoting the colonization of *E. coli*, leading to a greater susceptibility to urinary tract infections as noted with diaphragm/spermicide users.^{17, 49}

The Search for Contraceptives to Prevent STDs

Research is underway to develop microbicides and contraceptives to prevent STDs. The ideal agent would be a topical microbicide that would prevent infection and be spermicidal. The road is long, extending from in vitro work to clinical application. An acceptable agent must avoid damage to vaginal epithelial cells and disruption of vaginal flora, and the delivery system must be user-friendly. However, it is unlikely that any new agent can match the latex condom, which is nearly 100% effective in blocking bacteria and viruses.

Condoms

Although awareness of condoms as an effective contraceptive method as well as protectors against STDs has increased tremendously in recent years, a great deal remains to be accomplished in order to reach the appropriate level of condom use. Contraceptive efficacy and STD prevention must be linked together and publicly

promoted. The male condom is the only contraceptive proven to prevent HIV infection.

There are three specific goals: correct use, consistent use, and affordable, easy availability. If these goals are met, the early 2000s will see the annual manufacture of 20 billion condoms per year.

Various types of condoms are available. Most are made of latex; polyurethane and silicone rubber condoms are also now manufactured. "Natural skin" (lamb's intestine) condoms are still obtainable (about 1% of sales). Latex condoms are 0.3–0.8 mm thick. Sperm that are 0.003 mm in diameter cannot penetrate condoms. The organisms which cause STDs and AIDS also do not penetrate latex condoms, but they can penetrate condoms made from intestine.^{50, 51} Condom use (latex) also probably prevents transmission of human papillomavirus (HPV), the cause of condylomata acuminata. Because spermicides provide significant protection against STDs, condoms and spermicides used together offer more protection than either method used alone. The use of spermicides or spermicide-coated condoms, however, increases the incidence of *E. coli* bacteriuria and urinary tract infections in women because of the spermicide-induced alteration in vaginal flora.^{18, 52} Consistent use of condoms when one partner is HIV seropositive is highly effective in preventing HIV transmission (there was no seroconversion in 124 couples who used condoms consistently compared to 12.7% conversion after 24 months in couples with inconsistent use.⁵³ Women who are partners of condom users are less likely to be HIV-positive.⁵⁴

Polyurethane condoms are expected to protect against STDs and HIV, based upon in vitro efficacy as a barrier to bacteria and viruses. They are odorless, may have greater sensitivity, and are resistant to deterioration from storage and lubricants. Those individuals who have the infrequent problem of latex allergy can use polyurethane condoms. Breakage and slippage have been reported to be comparable with latex condoms.⁵⁵ However, in a randomized, well-designed study, the polyurethane condom had a 6-fold higher breakage rate.⁵⁶

Condoms can be straight or tapered, smooth or ribbed, colored or clear, lubricated or nonlubricated. These are all marketing ventures aimed at attracting individual notions of pleasure and enjoyment.⁵⁷ Condoms that incorporate a spermicidal agent coating the inner and outer surfaces logically promise greater efficacy, but this remains to be determined. Some women are allergic to the spermicide, and it is a concern (not documented) that mucosal lesions can promote HIV transmission should a condom break.

An often repeated concern is the alleged reduction in penile glans sensitivity that accompanies condom use.⁵⁷ This has never been objectively studied, and it is likely that this complaint is perception (or excuse) not based on reality. A clinician can overcome this obstruction by advocating the use of thinner (and more esoteric) condoms, knowing that any difference is also more of perception than reality.

As is true for most contraceptive methods, older, married couples experienced in using condoms and strongly motivated to avoid another pregnancy are much more effective users than young, unmarried couples with little contraceptive experience. This does not mean that condoms are not useful contraceptives for adolescents, who are likely to have sex unexpectedly or infrequently. The recent decline in the teen pregnancy rate partly reflects wider use of condoms by teens concerned about avoiding HIV infection.

Prospective users need instructions if they are to avoid pregnancy and STDs. A condom must be placed on the penis before it touches a partner. Uncircumcised men must pull the foreskin back. Prior to unrolling the condom to the base of the penis, air should be squeezed out of the reservoir tip with a thumb and forefinger. The tip of the condom should extend beyond the end of the penis to provide a reservoir to collect the ejaculate (a half-inch of pinched tip). If lubricants are used, they must be water based. Oil-based lubricants (such as Vaseline) will weaken the latex. Couples should be concerned that any vaginal medication can compromise condom integrity. After intercourse, the condom should be held at the base as the still erect penis is withdrawn. Semen must not be allowed to spill or leak. The condom should be handled gently because fingernails and rings can penetrate the latex and cause leakage. If there is evidence of spill or leakage, a spermicidal agent should be quickly inserted into the vagina.

Summary — Key Steps for Maximal Condom Efficacy

1. **Use condoms for every act of coitus.**
2. **Place the condom before vaginal contact.**
3. **Withdraw while the penis is still erect.**
4. **Hold the base of the condom during withdrawal.**
5. **Use a spermicide or a condom lubricated with a spermicide.**

These instructions should be provided to new users of condoms who are likely to be reluctant to ask questions. Most condoms are acquired without medical supervision, and therefore, clinicians should use every opportunity to inform patients about their proper use.

Inconsistent use explains most condom failures. Incorrect use accounts for additional failures, and also, condoms sometimes break. Breakage rates range from 1–8 per 100 episodes of vaginal intercourse (and somewhat higher for anal intercourse), and slippage rates range from 1% to 5%.^{58, 59} With experienced couples, condom failure due to breakage and slippage (sufficient to increase the risk of pregnancy or STDs) occurs at a rate of about 1%.⁶⁰ In a U.S. survey, one pregnancy resulted for every 3 condom breakages.⁶¹ Concomitant use of spermicides lowers failure rates in case of breakage.

Breakage is a greater problem for couples at risk for STDs. An infected man transmits gonorrhea to a susceptible woman approximately two-thirds of the time.⁶² If the woman is infected, transmission to the man occurs one-third of the time.⁶³ The chances of HIV infection after a single sexual exposure ranges from one in 1000 to one in 10.^{64, 65}

Condom breakage rates depend on sexual behavior and practices, experience with condom use, the condition of the condoms, and manufacturing quality. Condoms remain in good condition for up to 5 years unless exposed to ultraviolet light, excessive heat or humidity, ozone, or oils. Condom manufacturers regularly check samples of their products to make sure they meet national standards. These procedures limit the proportion of defects to less than 0.1% of all condoms distributed. Contraceptive failure is more likely to be due to nonuse or incorrect use.

When a condom breaks, or if there is reason to believe spillage or leakage occurred, a woman should contact a clinician within 72 hours. Emergency contraception, as discussed in [Chapter 22](#), should be provided. Couples who rely on condoms for contraception should be educated regarding emergency contraception, and an appropriate supply of oral contraceptives should be kept available for self-medication (see [Chapter 22](#)).

For the immediate future, prevention of STDs and control of the AIDS epidemic will require a great increase in the use of condoms. We must all be involved in the effort to promote condom use. Condom use must be portrayed in the positive light of STD prevention. The main motivation for condom use among women continues to be prevention of pregnancy, not prevention of STDs.^{54, 66} An important area of concentration is the teaching of the social skills required to ensure use by a reluctant partner. We believe that bans on condom advertising should be eliminated. Using scare tactics about STDs in order to encourage condom use is not sufficient. A more positive approach can yield better compliance. It is useful to emphasize that prevention of STDs will preserve future fertility.

We suggest that clinicians consider making free condoms available in their office. Manufacturers will sell condoms at a bulk rate, from \$50—\$100 per 1000, depending on style and lubrication.

The Female Condom

The female condom is a pouch made of polyurethane, which lines the vagina.⁶⁷ An internal ring in the closed end of the pouch covers the cervix and an external ring remains outside the vagina, partially covering the perineum. The female condom is prelubricated with silicone, and a spermicide need not be used. The female condom should be an effective barrier to STD infection;⁶⁸ however, high cost and acceptability are major problems. The devices are more cumbersome than condoms, and studies have indicated relatively high rates of problems such as slippage.⁶⁹ Women who have successfully used barrier methods and who are strongly motivated to avoid STDs are more likely to choose the female condom. With careful use, the efficacy rate should be similar to that of the diaphragm and the cervical cap.^{70, 71} and ⁷²

	Diaphragm Cap		SpongeFemale Condom	
Insertion before coitus, no longer than:	6 hrs.	6 hrs.	24 hrs.	8 hrs.
After coitus, should be left in place for:	6 hrs.	8 hrs.	6 hrs.	6 hrs.
Maximal wear time:	24 hrs.	48 hrs.	30 hrs.	8 hrs.

Future Developments

New barrier devices are being pursued, such as sponges incorporating several spermicides and cervical caps made of different materials. Chemical agents are being investigated that can combine spermicidal and antimicrobial actions, and vaginal spermicidal films of different materials and containing other spermicidal agents are being tested. Disposable diaphragms that release spermicide are in development.

Lea's Shield is a vaginal barrier contraceptive composed of silicone.^{73, 74} This soft, pliable device comes in one size and fits over the cervix, held in place by the pressure of the vaginal wall around it. There is a collapsible valve that communicates with a 9 mm opening in the bowl that fits over the cervix. This valve allows equalization of air pressure during insertion and drainage of cervical secretions and discharge, permitting a snug fit over the cervix. A thick U-shaped loop attached to the anterior side of the bowl is used to stabilize the device during insertion and for removal. The thicker part of the device is shaped to fill the posterior fornix, thus contributing to its placement and stability over the cervix. The addition of a spermicide, placed in the bowl, is recommended to enhance STD protection. Lea's Shield is designed to remain in place for 48 hours after intercourse. Pregnancy rates are similar to other barrier methods, and no serious adverse effects have been reported.⁷⁵

Infertility is defined as one year of unprotected coitus without conception. It affects approximately 10–15% of couples in the reproductive age group, which makes it an important component of the practices of many physicians.¹ **Fecundability** is the probability of *achieving a pregnancy* within one menstrual cycle (about 25% in normal couples); **fecundity** is the ability to *achieve a live birth* within one menstrual cycle.

There have been 3 striking changes in infertility practice during the past 2 decades. First was the introduction of in vitro fertilization and other assisted reproductive technologies (ART) that have enlarged the possibilities for successful treatment and provided an opportunity to study basic reproductive processes. ART refers to all techniques involving direct retrieval of oocytes from the ovary ([Chapter 31](#)). Second, and partially because of the media attention focused on ART, the public has become more aware of potential treatments, and this has generated a marked increase in patient visits for infertility. The third change is the increase in the proportion of women over 35 seeking medical attention for infertility. One of every five women in the United States is having a first child after 35, a marked increase over earlier figures. This reflects both a later age for marriage and postponement of pregnancy in marriage as women, by choice or by circumstances, commit to the work place. There also has been a slight increase in the proportion of couples considered infertile. More importantly, there is an increasing number of infertile couples due to the aging of the large post World War II population boom generation.

The Epidemiology of Infertility in the U.S.

The first United States census was in 1790. At that time, the birth rate was 55 per 1000 population; 200 years later, it is 15.5 per 1000 population, a decrease from 8 births per woman to 1.2.² There are some obvious and some speculative explanations for the decline in U.S. fertility.

Popular Explanations for the Decline in U.S. Fertility

- Changing roles and aspirations for women.
- Postponement of marriage.
- Delayed age of childbearing.
- Increasing use of contraception.
- Liberalized abortion.
- Concern over the environment.
- Unfavorable economic conditions.

The deferment of marriage and postponement of pregnancy in marriage are the most significant changes in modern society. Only 16% of the decline in the total fertility rate in the U.S. is accounted for by the increase in the average age at first marriage; 83% of the decline in the total fertility rate is accounted for by a change in marital fertility rates (avoiding pregnancy in the first years of marriage).^{1,3}

After World War II, the U.S. total fertility rate reached a modern high of 3.8 births per woman. The last women born in this period won't be reaching their 45th birthdays until around 2010. For the next decade, therefore, there will continue to be an unprecedented number of women in the later child-bearing years. The aging of the World War II population boom is giving current times a greater number of women who are delaying marriage and childbirth. The proportion of births accounted for by this older group of women increased by about 72% from 1982 to 2000.⁴ These couples, pressed for time, have a desire to get pregnancies accomplished in a shorter time period. In 1996, the U.S. birth rate for women aged 30–34 was the highest since 1966, for women aged 35–39, the highest since 1968, and for women aged 40–44, the highest since 1971.⁵

Concern With Infertility

In 1995, approximately one in 6 women of reproductive age reported that they had sought professional help during their lifetimes because of infertility.² A sharp escalation of demand for infertility services began in 1981. From approximately 600,000 visits in 1968, the total increased to nearly 1 million in the early 1970s, then in the early 1980s, the total went over 2 million visits. In 1995, 15% of reproductive age women (9.3 million) reported some use of an infertility service, compared with 12% (6.8 million women) in 1988.² Approximately 1% of 60.2 million women of reproductive age used one of the methods of assisted reproductive technology, and 3% used ovulation drugs.

There was no significant change in the proportion of U.S. infertile couples in the 1980s.⁶ However, the overall percentage of infertile women increased from 8.4% in 1982 and 1988 to 10.2% (6.2 million) in 1995.^{2,7} Although this increase is significantly due to the increase in older women who were born in the years after World War II, there is also an increase across all age groups, partly reflecting the effect of sexually transmitted diseases and partly an increasing concern for infertility.

Why then is there this increasing concern for infertility? First, there is an increasing number of infertile couples. As noted, the aging of the post World War II generation is yielding a greater number of women who are delaying marriage and childbirth. From 1982 to 1995, the number of childless women aged 35–44 years increased by about 1 million, from 1.9 million in 1982 to 2.8 million in 1995.² In addition, there is a greater awareness of modern treatments and a greater ability to afford health care. The impact of widespread publicity is significant. There is an increased availability of services, and there is a greater knowledge of the diagnosis and management of infertility among clinicians. Finally, infertility is now more socially acceptable as a problem.

The post World War II generation has faced a unique evolutionary change. They were the first to be able to exercise control over their fertility, and then as they aged and deferred pregnancy, they had to deal with the problem of unintended infertility. Because many couples defer pregnancy and then desire their families within a condensed interval of time, there is a sudden urgency regarding fertility. These factors have combined to substantially increase the number of couples seeking and using infertility services. Nevertheless, in the 1995 U.S. National Survey of Family Growth, the majority of women (56%) with impaired fecundity had not obtained any

professional services.²

Aging and Fertility

Age alone impacts on fertility; aging of the reproductive system plays a role and spontaneous abortion provides another factor. The majority of early spontaneous abortions after age 35 are due to autosomal trisomies, the incidence of which increases with maternal age. The risk of clinically recognized spontaneous abortion increases from about 10% under age 30, to 18% in the late 30s, and 34% in the early 40s.⁸ Indeed, once pregnancy is achieved by an older woman, the greatest obstacle to successful delivery is the risk of spontaneous loss. The frequency of both euploid (normal) and aneuploid (abnormal) abortuses increases with maternal age. The overall abortion risk (recognized and unrecognized) in women over age 40 is approximately 75%!^{9,10} Studies of oocytes from older women have suggested that older oocytes have impaired meiotic spindle formation or function that could cause the failure of proper chromosome migration.¹¹

In addition, as women enter their 30s, there is a greater likelihood of being affected by a number of diseases, for example endometriosis, that can interfere with fertility. Cumulative exposures to occupational or environmental hazards also could lessen fertility as a woman ages. Another factor that has contributed to infertility at all ages is the spread of sexually transmitted diseases with their damaging effect on the fallopian tubes.

What is the exact impact of age on fertility? The classic study is that of the Hutterites who live in the Dakotas, Montana, and the adjacent parts of Canada. The sect originated in Switzerland in the 1500s, and practically all of the living Hutterites came to South Dakota in the 1870s. Four colonies of 443 Hutterites grew, by 1950, to 93 colonies containing 8,542 Hutterites. Contraception is condemned, and because of the communal arrangement of their society, there is no incentive to limit the size of families. All families are provided for equally.

In the 1950s, Christopher Tietze analyzed the fertility rates of the Hutterites.¹² Only 5 of 209 women had no children for an infertility rate of 2.4%. The average age of the women at the last pregnancy was 40.9 years, and there was a definite decrease in fertility with age. Eleven percent of the women bore no children after age 34; 33% of the women were infertile by age 40, and 87% were infertile at age 45.

The fertility of the Hutterites has become legendary. Their fertility rate is an example of how high fertility can be when a population is healthy, stable, and not using contraception. Based on the Hutterite data, it can be concluded that a population that marries around age 22, has some lactational amenorrhea, and some age-related and parity-related decline in coital frequency, can produce 11 live births per married woman. Hypothetically, if marriage were earlier, there were no lactational amenorrhea, and no sterilization or decline in coitus, the total fertility rate would be about 15 live births per woman.¹³

The French studied the pregnancy rate in a donor insemination program, including only women with azoospermic husbands.¹⁴ These women were less likely to have infertility factors than those women married to oligospermic males. Below the age of 31 the pregnancy rate over one year was 74%. This decreased to 62% at ages 31 to 35 and to 54% when the women were older than 35. Because donor insemination was used, the effect of reduced coital frequency in older couples did not influence the results. An American study with donor insemination has demonstrated a similar relationship with age.¹⁵ Of note was the requirement for more treatment cycles to achieve pregnancy in older women, 9–10 cycles rather than the usual 6. In a donor insemination program in the Netherlands, the probability of having a healthy baby decreased 3.5% per year after age 30.¹⁶ A woman age 35 had 50% the chance of having a healthy baby compared to a woman age 25. In a study of almost 3000 donor insemination cycles in one center, the cumulative conception rates after 3, 6, and 12 cycles were 21%, 40%, and 62% for patients less than 30 years old, compared with 17%, 26%, and 44% for women 30 years and older.¹⁷

The decline of fertility among married couples with advancing age has been repeatedly documented.¹⁸ It is safe to say that about one-third of women who defer pregnancy until the mid to late 30s will have an infertility problem, as will at least half of women over age 40. In programs of assisted reproductive technologies, delivery rates in women over age 40 are one-third to one-half of those in younger women, and many programs have only rare successful pregnancies in women over age 40.^{19, 20 and 21}

The oldest spontaneous pregnancy in modern times (according to The Guinness Book of World Records) occurred in a woman from Portland, Oregon, who delivered when she was 57 years and 120 days old. In older times, a Scottish woman was reputed to have delivered 6 children after the age of 47, the last at age 62!²²

There are changes in the male reproductive system with aging.²³ A decline in testosterone and an increase in gonadotropins are associated with a decrease in sperm production and the number of normal sperm. There are reasons to believe that the quality of sperm decreases. A paternal age greater than 40 is associated with a 20% greater chance of birth defects in the offspring.²⁴ These changes in the male with aging are modest, but significant, although the capacity to fertilize is maintained.²⁵ A short report in 1935 told of a North Carolina farmer born in 1840.²⁶ Over a period of 30 years, his first wife had 16 children. At age 93, he remarried to a 27-year-old widow; one year later, a child was born. Reading the detailed physical examination provided in this report, it is obvious that this 94-year-old man was very unattractive, with leathery, wrinkled skin and no teeth. It is by no means certain that he was the father of the child.

Endocrine Changes With Aging

The early fetal mitotic multiplication of germ cells produces a total of 6–7 million oogonia by 16–20 weeks of pregnancy. From this point in time, the germ cell content will irretrievably decrease. At the onset of puberty, the germ cell mass has already been reduced to approximately 300,000 units. Over the next 35–40 years of reproductive life, during which time only 400–500 oocytes will ovulate, these units will be depleted by atresia to a point at menopause when only a few hundred remain.

In the last 10–15 years before menopause, there is an acceleration of follicular loss.²⁷ This accelerated loss begins when the total number of follicles reaches approximately 25,000, a number reached in normal women at age 37–38.²⁸ This loss correlates with a subtle but real increase in follicle-stimulating hormone (FSH) and decrease in inhibin. These changes reflect the reduced quality and capability of aging follicles. These subtle changes (which influence fertility) are not associated with any noteworthy and observable changes, other than an alteration in menstrual cycle characteristics.

Prior to the menopause, there is a period with shorter follicular phases, with increased FSH levels, but normal luteinizing hormone (LH) levels and luteal phases.^{29, 30} The menstrual periods for 10–15 years before the menopause are regular, but there is a steady decrease in cycle length due to the shortened follicular phase. Cycle lengths are the shortest (with the least variability) in the late 30s, a time when subtle but real increases in FSH and decreases in inhibin are occurring.^{31, 32, 33 and 34} For a period of several years (as much as 10 years in some women) prior to menopause, the cycles lengthen again.

Women who present with “incipient” ovarian failure have elevated FSH levels and decreased levels of inhibin, but normal levels of estradiol.^{35, 36} The rise in FSH during the later years is in response to declining inhibin production.^{37, 38, 39 and 40} Inhibin levels are lower in the follicular phase in women 45–49 years old compared to younger women. The specific inhibin involved in this feedback effect on FSH during the follicular phase is inhibin B.^{41, 42} In addition, a decline in luteal phase inhibin A can contribute to a greater rise in FSH during the luteal-follicular transition.^{43, 179} This decline in inhibin begins early, but accelerates after 40 years of age. The rise in FSH is very apparent after age 40, but there is no change in LH levels until menopause. The changes in the later reproductive years reflect either lesser follicular competence as the better primordial follicles respond early in life, leaving the lesser follicles for later, or the fact that the total follicular pool is reduced in number (or both factors). Arguing in favor of a role for a reduced follicular pool is the observation that follicular fluid obtained from preovulatory follicles of older women contains amounts of inhibin A and B that are similar to that measured in follicular fluid from young women.⁴⁴

These endocrine changes and the decline in ovarian follicles are correlated with a decrease in ovarian volume.⁴⁵ A measurement of volume by ultrasonography that is equal to or less than 3 cm³ predicts a poor response to ovulation induction.⁴⁶

Testing the Ovarian Reserve

The measurement of baseline hormonal levels provides important and helpful prognostic information. Because FSH levels increase with age, elevated FSH levels on cycle day 3 (greater than 12 IU/L, but especially greater than 20 IU/L) are associated with poor performance with in vitro fertilization.⁴⁷ A cycle day 3 FSH level that is 25 IU/L or more, or an age of 44 years or more, are both independently associated with a chance of pregnancy close to zero during ovulation induction or with assisted reproductive technologies.⁴⁸ **Values can vary between laboratories, significantly due to differences in antibodies and standards used to measure**

gonadotropin levels.⁴⁹ With the most recent assays, day 3 values above 10 IU/L are abnormal and are comparable with values greater than 20 IU/L with older assays.

Women with one ovary have higher day 3 FSH levels that correlate with reduced outcomes in in vitro fertilization.⁵⁰ It is not certain whether this reflects the loss of the other ovary or the factors that were responsible for the unilateral oophorectomy.

Keep in mind that there is no abrupt change at 40, and therefore, these changes can apply to younger women. The age of change is determined by the rate of oocyte loss, a rate that is genetically programmed in most women. An elevated FSH at any age is correlated with fewer available oocytes, and advancing age adds the factor of lesser oocyte quality. An elevated estradiol level on day 3 (greater than 80 pg/mL) is also predictive of difficulty in achieving pregnancy;^{51,52} premature estradiol elevations are associated with a hurried recruitment of follicles in response to increased FSH secretion, changes characteristic of the years preceding menopause. When both FSH and estradiol are elevated on day 3, ovarian response to stimulation is very poor.

The Clomiphene Challenge Test. Navot and colleagues developed the clomiphene challenge test as a bioassay of FSH response (which in turn reflects ovarian follicular inhibin capability).⁵³ Clomiphene is administered in a dose of 100 mg/day on days 5–9. The level of FSH on day 10 is compared with the baseline level on day 3. An exaggerated FSH response of 26 IU/L or more was two standard deviations above the control values in this study, and this increase in FSH was associated with a significant prospect for failure to achieve pregnancy. **Remember that there is a wide variety of FSH assays (the newer assays provide numbers that are approximately 70% of the older results), and clinicians must become familiar with the values provided by their own laboratories.** There is a high incidence of abnormal responses in women over age 35, and 85% of women with increased FSH levels respond poorly to ovarian stimulation.⁵⁴ In a general infertility population, about 10% of women have an abnormal response to the clomiphene challenge test. As expected, the percentage increased with increasing age (from 3% under age 30 to 26% over age 39), and women with unexplained infertility had a 38% incidence of abnormal tests.⁵⁵ This test of ovarian reserve is more sensitive than just measuring basal FSH levels in predicting the potential for pregnancy in both assisted and natural reproduction. An abnormal response to the clomiphene challenge test indicates a poor prognosis no matter the woman's age.⁴⁹ However, because age alone is an important factor (presumably due to other age-related oocyte conditions of quality), older women with normal hormone levels and normal responses to clomiphene still have diminished chances of pregnancy.

We believe it is worthwhile to screen all infertile women beginning at age 30, women of any age with unexplained infertility, and women who respond poorly to ovulation induction with the clomiphene challenge test and a day 3 estradiol level. For practical purposes, equivalent results can be expected on days 2, 3, and 4 of the cycle. Far less certain is the need for these tests in the woman over 40, because even normal tests do not provide reassurance of adequate ovarian reserve. An abnormal test in a woman over 40, however, can be used to bolster advice to consider ovum donation. Although an abnormal test at any age indicates a very poor prognosis, it does not indicate an absolute inability to achieve pregnancy. Testing the ovarian reserve is just another part of the decision making process for patients and clinicians.

Assisted Reproduction in Older Couples

Experience has repeatedly demonstrated a reduction in IVF pregnancy rates when the oocytes are of advanced age. When embryos from the same cohort of young donated oocytes were simultaneously transferred to young and older recipients, however, the pregnancy rates were similar.⁵⁶ The high rate of implantation and pregnancy in older women receiving donated younger oocytes argues that uterine factors are not involved with the decline in fecundity with aging. Uterine factors that could suffer with age include responses of the endometrium to implantation, capillary permeability and hyperemia, and decidual differentiation.

The reproductive endocrine group at the University of Southern California has concluded that the problems of decreased fecundability and increased pregnancy wastage can be attributed to the effect of aging on oocytes. In 100 consecutive patients in an oocyte donor program, there was no decline in success over the age range from 40 to 50.⁵⁷ Furthermore, excellent outcomes have been achieved in women aged 50–62.^{58,59} There are two important observations regarding these older women. First, the older recipients of young oocytes received extensive medical screening, infectious disease screening, reproductive function assessment, and psychological assessment. The good obstetrical outcomes in these patients must reflect, to an important degree, the youthful good health of this older group of patients. Second, the stimulation protocol utilized a 100 mg dose of progesterone.

Meldrum reported a lesser percentage of delivered pregnancies in women over 40 compared with women under 40 going through an identical donor oocyte-IVF program.¹⁹ However, he then achieved pregnancy rates in women over 40 similar to those in women under 40 by increasing the progesterone dose in the stimulation protocol from 50 mg to 100 mg per day. Meldrum argued that this age-related decline in endometrial receptivity for progesterone might be due to an age-related decline in estrogen receptors as demonstrated in animal studies. Others have also concluded that hormone treatment produces a better endometrium and corrects any uterine factor.⁶⁰ On the other hand, the uterine factor must not be a major obstacle in older women because in a carefully designed study, good quality ova derived from the same cohort yielded similar pregnancy rates in younger and older recipient women (even though the progesterone dose was 50 mg per day).⁵⁶ A pregnancy rate in older women of approximately 40–50% per cycle can be achieved in a donor oocyte program. A cumulative birth rate per patient can reach 90% with 4 or more cycles.^{57, 58, 59, 60 and 61}

The experience with donor oocyte programs argues strongly that the age-related decline in fecundity is primarily due to aging oocytes. These results further point out that the increased risks of spontaneous abortion and chromosomal anomalies associated with older age are also due primarily to aging oocytes. In a large series, the rate of spontaneous abortion in recipients correlated with the age of the donors. The abortion rate increased from 14% in recipients who received oocytes from donors aged 20–24 years to 44.5% when the recipient received oocytes from donors older than age 35.⁶⁰ Pregnancy wastage directly correlates with the age of the woman who produces the oocytes.

We know that we can establish pregnancy in women over age 50, now we have to consider whether this feat is a wise accomplishment. We have little control over natural events, but moral and social questions do arise when we have the opportunity to assist a woman to achieve a pregnancy. There can be no objection to the use of these procedures to achieve pregnancies in women who undergo ovarian failure at an early age. But when are couples too old to have a child? It can be argued that the risk involved in the pregnancy (a relatively high incidence of hypertension and gestational diabetes),⁵⁹ and the risks involved in raising a teenager when you are yourself a senior citizen are issues that patients and clinicians must resolve. On the other hand, couples over 40 may be ideal parents: high degree of motivation, increased maturity and wisdom, better financial circumstances. They are more able and willing to devote attention to their children. Certainly it is a wise precaution to discourage the use of these techniques by women who are not biologically young and healthy no matter what their age. Besides the health and medical circumstances of the individuals involved, it seems appropriate to also consider the provisions for child rearing. In our view, Paulson and Sauer put it well when they stated that "It seems unlikely that these children will be so disturbed that they would prefer not to have been born than to have suffered this indignity."⁶²

Clinicians can appropriately advise older women that there is no time to waste, and serious consideration should be given to an early resort to hormonal stimulation for both oocyte response and support of the endometrium. Older couples should be provided the option of oocyte donation from young donors instead of standard assisted reproductive technologies.

The Role of the Physician

When is a medical success really a success? Approximately one-half of couples presenting after one year of infertility can be expected to become pregnant spontaneously in the following year. In an English study, only 20% of women who had failed to have a birth within the first two years of marriage never had a child.¹⁸ In a life-table analysis of 58 untreated apparently normal infertile couples, 74% were pregnant by two years; however, normal couples achieve this rate in 9 months.⁶³ Overall, approximately 40% of couples become pregnant after discontinuation of treatment, and 35% of couples never treated can expect to become pregnant.⁶⁴ Therefore, achieving pregnancy is not the only measure of success. One of the important missions for the infertility physician is to speed up the period of time required to achieve pregnancy. For couples in their 30's, the recommendation to seek help promptly is valid — the sooner a problem is detected, the better. Because the incidence of spontaneous pregnancy is significant until 3 years have passed, it is appropriate to require 3 years of infertility in women less than 30 years old before making a diagnosis of infertility. Because age is an important determinant, evaluation and therapy should not be deferred in older women.

In response to the needs of infertile individuals, physicians should have four goals in mind:

1. The first goal is to seek out and to correct the causes of infertility. With proper evaluation and therapy, the majority of women will become pregnant.

2. The second goal is to provide accurate information and to dispel the misinformation commonly gained from friends and mass media.
3. The third goal is to provide emotional support for the couple during a trying period. The inability to conceive generates a feeling in many couples that they have lost control over a very significant segment of their lives. The burden is aggravated by the manipulations that couples have to undergo during the infertility investigation, including the need to have intercourse on schedule. Couples need to have an opportunity to ventilate their concerns and dispel some of their fears. A valuable adjunct to the efforts of the physician are support groups for infertile couples such as those organized by RESOLVE. Meetings in groups allows individuals to realize that their problems are not unique, and it enables them to obtain information on how others cope with infertility. It must be emphasized that, while severe anxieties can interfere with ovulation and frequency of intercourse, there is no substantial evidence that infertility is caused by the usual anxieties besetting a couple trying to conceive.
4. An often neglected goal is that of counseling a couple concerning the proper time to discontinue investigation and treatment, to consider adoption, and/or to move on to the assisted reproductive technologies. This is especially important in the 10–15% of couples with no known cause for their infertility.

Counseling also should be an ongoing process during the infertility investigation and treatment. At least every 3 months the physician and couple should review the status of their care and outline the anticipated management; thereby, changes in plans due to medical, emotional, or financial reasons can be instituted in a timely fashion.

The Female Infertility Investigation

Infertility problems, once thought to be refractory to treatment, have progressively responded to newer therapies. Occlusive tubal disease now is bypassed by in vitro fertilization. Even the most unpromising cases of male infertility can be overcome by the intracytoplasmic injection of sperm. The deleterious effects of aging on female reproduction can be neutralized by the use of ovum donation from younger women.

There are, however, many cases of infertility that yield to less intrusive and less expensive therapy. Even this area has undergone major changes, with a decreased emphasis on diagnosis, and rapid movement toward empiric therapy with superovulation and intrauterine insemination (IUI).

We find it very helpful to mail a detailed questionnaire to our patients prior to their initial visit. The questionnaire is very complete, providing information that ranges from previous medical events and sexuality to recreational, social, and vocational activities. Patients often write comments regarding their past history and their feelings that are difficult to express during an office interview.

There are advantages to having the male present during the initial interview. He may contribute valuable historical and attitudinal information. It also gives the physician the opportunity to emphasize that both partners are involved in the infertility investigation. A male who has been acquainted at its inception with the clinician's treatment of the infertility problem will be less reluctant, as time progresses, to ask for clarification of any aspect of the testing and treatment. This can prevent misunderstandings engendered when the male partner's only source of information is the woman. Early in the clinician-couple interaction, frequency of coitus, and possible sexual problems should be ascertained.

Failure to ovulate is the major problem in approximately 40% of female infertility; another 40% is due to tubal pathology and pelvic pathology, and less than 10% is due to problems such as anatomic abnormalities or thyroid disease. It should be noted that induced abortions do not influence subsequent pregnancy rates.⁶⁵ Fetal wastage is definitely higher in diethylstilbestrol-exposed women, and while there is still some uncertainty, evidence suggests that primary infertility is also more common.⁶⁶ Besides the well-known impact of smoking on pregnancy, there is good evidence that fecundity is reduced in men and women who smoke, and the risk is greater with smoking at an early age.^{67, 68} and ⁶⁹ There is a dose-response relationship between the number of cigarettes smoked and how long it takes to achieve pregnancy.⁷⁰ Marijuana inhibits the secretion of GnRH and can suppress reproductive function in both men and women, and cocaine use is known to reduce spermatogenesis.^{71, 72} Studies have failed to confirm an adverse impact of caffeine on fertility, although high levels of intake may be associated with a delay in conception.^{69, 73, 74}

Couples need to be aware that there is a normal time requirement to achieve pregnancy. In each ovulatory cycle, normal couples have only about a 30% chance of becoming pregnant. Guttmacher's classic table has been a standard since 1956.

Time Required for Conception in Couples Who Will Attain Pregnancy⁷⁵

Time of Exposure	% Pregnant
3 months	57%
6 months	72%
1 year	85%
2 years	93%

Because the male factor accounts for approximately 35% of infertility, examination of the semen should be an early diagnostic step in the investigation. If abnormal, further diagnostic procedures in the woman should be deferred until decisions are reached regarding the man (see [Chapter 29](#)). If the semen is normal, attention is directed to the woman.

Laboratory testing should be directed by clinical judgment. However, there are a few specific recommendations. Women with a negative rubella titer should be immunized and attempts for pregnancy delayed for 3 months. When personnel are exposed to sperm and/or oocytes, many states now mandate tests for syphilis, antihepatitis B core, hepatitis B surface antigen, antihepatitis C, and antibody to HIV 1/2 (AIDS) and HTLV-I. Screening for cystic fibrosis should be considered.

The Postcoital Test

The postcoital test provides information regarding both the receptivity of cervical mucus and the ability of sperm to reach and survive in the mucus. Estrogen levels peak just prior to ovulation, and this provides maximal stimulation of the cervical glands. An outpouring of clear, watery mucus is fostered, which may be of sufficient quantity to be noted by the woman. Earlier in the cycle, when estrogen output is lower, and starting 2 to 3 days after ovulation when progesterone levels increase and counteract the estrogen, the mucus is thick, viscid, and opaque.

The postcoital test is performed around the time of the expected luteinizing hormone (LH) surge as determined by a previous basal body temperature chart or by the length of prior cycles. Timing also can be obtained with ultrasonography and LH monitoring, but this usually is not necessary. Between 2 and 8 hours after coitus, cervical mucus is removed with a nasal polyp forceps or tuberculin syringe and examined for macroscopic and microscopic characteristics. Attempts to refine the postcoital test by studying individual fractions from different levels in the cervical canal, with emphasis on the sample from the internal os, have not produced convincing evidence of value. Sperm distribution is uniform throughout the cervical canal, and selective sampling at the level of the internal os is not necessary.⁷⁶ A

less than 2-hour interval between coitus and examination has been recommended as giving maximal information, but this early evaluation may be deceptive because complement dependent reactions in mucus, which can immobilize sperm may not be apparent for a few hours. Others have suggested that a 16- to 24-hour interval provides a better assessment of sperm longevity, and a study has indicated that there is no drop in the number of sperm at any time during the first 24 hours.⁷⁷ There are other indications, however, that the number of sperm does decrease after 8 hours, and this is more in keeping with our experience. Therefore, we suggest that the couple have coitus in the morning or late at night, and that the test be performed 2 to 8 hours later. It is also suggested that the couple abstain from intercourse for 48 hours prior to the postcoital test.

The need for scheduling the postcoital test at precise times in the cycle may produce problems for the couple who cannot have sex on demand. This may further burden a couple already troubled by the need to cope with their infertility and the loss of control involved in the infertility investigation. A physician must be sympathetic to this problem, and on occasion, precise timing must be sacrificed and the woman told to come to the office following unscheduled intercourse.

The stretchability (*spinnbarkeit*) of the mucus at midcycle should be 8–10 cm or more. This characteristic can be assessed as the mucus is pulled from the cervix, or alternatively, by placing the mucus on a slide, covering it with a coverslip and then lifting the coverslip. At midcycle the mucus contains 95–98% water and should be watery, thin, clear, acellular, and abundant. When dried on a slide, it should form a distinct fern pattern.

If the mucus is thick rather than thin, opaque instead of clear, the proximity of the test to ovulation should be determined by the onset of the next period (or by the temperature chart if one is being taken during that cycle). The best time for the postcoital test is the day prior to the first temperature elevation. If poor mucus quality is related to inaccurate timing, the test should be repeated in a subsequent cycle with scheduling based on urinary LH testing. Poor mucus at midcycle can be a physical barrier that decreases sperm penetration. In one study 54% of women with good mucus became pregnant, compared to 37% with poor mucus, a statistically significant difference.⁷⁸ In all likelihood some of these poor tests were reflections of inaccurate timing, and pregnancies do occur even with poor mucus at ovulation time.⁷⁹ It remains our impression, however, that poor mucus is associated with a decreased chance for fertility.

Treatment of poor mucus has been attempted by giving 0.625 mg of conjugated estrogens daily for the 8 or 9 days preceding the expected time of ovulation. In a 28-day cycle that would be between days 5 and 13. There is no advantage to continuing the hormone treatment through the luteal phase of the cycle. If the initial treatment with estrogen fails to produce a change in the mucus, the dose is increased to 1.25 mg/day. In refractory cases, 5 mg of conjugated estrogens can be given starting a few days prior to expected ovulation. However, evidence for the value of estrogen therapy is lacking, and it has no demonstrable benefit for the poor mucus which is, on occasion, associated with the use of clomiphene citrate.⁸⁰ If there is evidence of chronic cervicitis with thick yellowish mucus, culture for chlamydia is important, and, where appropriate, systemic antibiotics should be used. On rare occasions, the cervix is treated with electrocautery or cryosurgery.

The most logical approach to overcome the barrier of thick cervical mucus is the method we prefer, the use of intrauterine insemination (IUI) of washed sperm (discussed below and in [Chapter 29](#)). If poor mucus is the sole problem, IUI for 3–4 cycles is associated with a cumulative pregnancy rate of 40–50%.⁸¹

In addition to providing an evaluation of mucus, the postcoital test also gives information concerning the male. Absence of sperm requires a review of the couple's coital technique. Repeated cancellations of appointments for the postcoital test may be a clue that there are sexual problems that have not been uncovered by the interview. However, most often the stress of performance for the scheduled postcoital test is responsible for the failure to achieve coitus. Most importantly, absence of sperm necessitates a detailed review of the semen specimen.

One of the most difficult problems in infertility is the postcoital test that repeatedly shows no sperm or only dead sperm despite good mucus. The patient should be cautioned that lubricants, such as K-Y Jelly and Surgilube, have a spermicidal effect in vitro and should not be used by infertile couples. If lubrication is necessary, vegetable oil can be used without interfering with sperm movement. As noted earlier, re-examination of the semen to check sperm count and motility is a necessity if the postcoital test is poor.

If the semen is normal, the pH of the cervical mucus at midcycle should be determined. Good results have been reported using a precoital douche of 1 tablespoon of sodium bicarbonate in 1 quart of water when a poor postcoital test was associated with a pH below 7.⁸² Cervical cultures should be obtained for chlamydia if the mucus is yellowish, and sperm antibody testing should be performed in cases where there are no sperm or mostly nonmotile sperm. In addition, sperm antibody testing ([Chapter 29](#)) is mandatory when, in a postcoital test with good mucus, the sperm are found shaking in place but not moving progressively. This shaking movement is a common finding in immunologic infertility.

In vitro cross testing, utilizing donor or bovine mucus and donor sperm, can help to determine whether the poor postcoital test is due to factors in the mucus or to defects in the sperm. However, in clinical practice this type of testing has little value because the next step is treatment with IUI regardless of results with cross testing.

A postcoital test cannot be considered a substitute for a semen analysis. While 21 or more sperm/high power field (HPF) is almost always associated with a sperm count above 20 million/mL, the postcoital test gives little information concerning the morphology of sperm in the ejaculate. There are considerably fewer abnormal forms in the cervical mucus compared to the ejaculate. This may represent a filtering effect of the cervical mucus or may indicate that abnormal forms do not have the motility to penetrate the cervical mucus.

The postcoital test has had a role in the infertility investigation for over 100 years.⁸³ The postcoital examination first received prominence in the late 1800s in the writings of J. Marion Sims who was primarily interested in how long sperm survived in the mucus. Sims' son, Harry, reported to the American Gynecological Society in 1888 the details and purpose of the postcoital test, essentially as still performed today. The major impetus to general clinical use can be attributed to a book published in 1913 by Max Hühner, entitled *Sterility in the Male and Female*. Hühner, born in Berlin and a graduate of the College of Physicians and Surgeons of Columbia University, was a urologist in New York City. His second book, *A Practical Treatise on Disorders of the Sexual Function in the Male and Female*, was published in 1916 and went through 3 editions and a Spanish translation; this was followed by a third book in 1937. Thus, the postcoital test is also known as the Sims-Hühner test.

The postcoital test has always had its detractors because of limited correlations with fertility, the inability to establish universally agreed upon normal values, and controversies concerning the proper treatment of a poor postcoital test. One study could find no difference in the subsequent pregnancy rates among groups having no sperm, no motile sperm, 1–5 motile sperm, 6–10 motile sperm, and 11 or more motile sperm.⁷⁶ Another study indicated that there was a statistically significant increase in the percentage of pregnancies only when there were more than 20 sperm/HPF.⁷⁸ Moreover, in a study of postcoital tests in *fertile* couples, 20% had either no sperm or less than one sperm/HPF.⁸⁴ A newer argument raised against use of the postcoital test is that widespread use of intrauterine inseminations (IUI) combined with superovulation has made the assessment of sperm-cervical mucus interactions merely an academic exercise. In this view, whether the postcoital test is

normal or abnormal, the treatment is the same.

Given the array of negative assessments of the postcoital test, what can be said in its defense beyond that it provides an opportunity to observe interactions of sperm and a product of the female reproductive tract. If the mucus is clear and abundant with good spinnbarkeit, the patient has a better chance for pregnancy than if it is thick and sparse. If sperm are found in the mucus, it is reasonable assurance that coital technique is adequate. Additional reassurance is provided by the finding of motile sperm in the postcoital test. If live sperm are found in the cervical mucus, the pH is not hostile and the pregnancy rate is higher than if the sperm are all immotile. If there are more than 20 sperm/HPF, the male, in all likelihood, has a sperm count above 20 million/mL, and the couple has a significantly better chance for pregnancy than if the postcoital test contains fewer than 20 sperm/HPF. A poor result in the postcoital test can raise a suspicion of an immunologic problem. A poor result also can suggest the need for intrauterine inseminations. Individuals with progressively motile sperm in the postcoital test have significantly higher pregnancy rates.⁸⁵ In addition, sperm numbers in the postcoital test correlate with the length of time it takes to become pregnant. We believe there is still a limited usefulness for the postcoital test. When postcoital tests repeatedly reveal no sperm, only sperm shaking in place, only immotile sperm, or only a few motile sperm, despite good mucus, and when the mucus is repeatedly poor, timed IUI, without the risks and expense of superovulation, is appropriate therapy for 3–4 cycles.

What constitutes a poor postcoital test in terms of sperm numbers is controversial. Intrauterine insemination has been reported to enhance the chances for pregnancy when there were 3 or fewer sperm/HPF in the postcoital test but not when there were 5 or more sperm/HPF.⁸⁶ We continue to support a minimum level of one motile progressive sperm/HPF as compatible with normality. The finding of no sperm, all dead sperm or a large proportion of shaking sperm suggests a possible immunologic factor. These findings, specifically immotile or absent sperm, also should prompt inquiry concerning use of vaginal lubricants. If there are no motile sperm in the postcoital test, the pH of the mucus should be determined.

Hysterosalpingography

A history of pelvic inflammatory disease, septic abortion, ruptured appendix, tubal surgery, or ectopic pregnancy alerts the physician to the possibility of tubal damage. Pelvic inflammatory disease is unquestionably the major contributor to tubal infertility and ectopic pregnancies. Westrom's classic studies with laparoscopically confirmed pelvic inflammatory disease indicated that the incidence of subsequent tubal infertility is approximately 12% after one episode of pelvic infection, 23% after two episodes, and 54% after three episodes.⁸⁷ The risk of ectopic pregnancy is increased 6–7-fold after pelvic infection. Almost one-half of patients who are eventually found to have tubal damage and/or pelvic adhesions, however, have no history of antecedent disease. Many of these women will have elevated anti-Chlamydia antibodies, suggestive of prior infection. There have been a few reports of damaged tubes showing histologic evidence of viral infection which could explain the absence of traditional causes of tubal damage.

Tubal disease is diagnosed by the hysterosalpingogram (HSG) and by laparoscopy. The HSG is performed 2 to 5 days after cessation of a menstrual flow. If there is a history suggestive of pelvic inflammatory disease, a sedimentation rate is obtained prior to the HSG and, if elevated, antibiotic therapy is given. The procedure is then postponed for a month when a repeat sedimentation rate is obtained. Only if this is normal is the HSG scheduled. If masses or tenderness are revealed by the pelvic examination at any time, the HSG should be bypassed and the pelvis evaluated by laparoscopy. If there is a documented history of pelvic inflammatory disease, the risk of a serious reinfection following HSG is too high, and it should be replaced by laparoscopy. If an HSG is performed in a patient who is at questionable risk for infection, a water-soluble rather than an oil dye should be used because of the faster absorption. The overall risk of infection with HSG is probably less than 1%, although in a high-risk population serious infection can occur in approximately 3% of cases.⁸⁸ Clinically apparent infections were not present in 398 women who had nondilated tubes on HSG; however, 11% of those with dilated tubes developed pelvic inflammatory disease following an HSG.⁸⁹ Doxycycline, 200 mg after the procedure, can be administered if the tubes are dilated, followed by 100 mg bid for 5 days. Many clinicians routinely administer prophylactic antibiotics (doxycycline, 100 mg bid for 5 days, beginning 2 days before the procedure).

HSG should be performed under image intensification fluoroscopy, and a minimal number of films taken. Too often, multiple oblique views are taken to delineate small filling defects in the uterus that are of no clinical significance. In our experience, the oblique films are of little help even in diagnosing tubal patency. Only 3 films are usually required — a preliminary before dye is injected, a film showing spill of dye from one or both tubes, and a delayed film to show spread of dye through the peritoneal cavity. The dye can be injected either using a classic Jarcho cannula with a single-tooth tenaculum, or its more modern variants through a cannula contained within a suction apparatus that attaches to the cervix, or by using a pediatric Foley catheter threaded through the cervix into the uterus. Use of a prostaglandin synthesis inhibitor 30 minutes prior to the procedure can decrease the pain many women experience with HSG.

The dye should be injected slowly so that abnormalities of the uterine cavity are not missed. This is of special importance in diethylstilbestrol-exposed women, many of whom have abnormalities of uterine contour. Usually no more than 3 to 6 mL of dye are required to fill the uterus and tubes. If the patient complains of cramping, the injection of dye should be stopped for a few minutes and fluoroscopy temporarily discontinued. Spasm is rare with Ethiodol, an oil dye that is our preferred medium; if it does occur, slow injection with pauses is helpful. If the tubes fill but dye droplets do not spill from the ends of the tubes, the uterus should be pushed up in the abdomen by means of the tenaculum or suction cup. This puts the tubes on stretch and may help to release dye from the fimbriated ends. The droplets seen coming from the tube are the result of mixing of the oil dye and peritoneal fluid. On occasion, injection of dye into a hydrosalpinx will produce a similar pattern, and a delayed film to show loculation of dye is crucial in differentiating this condition from normal spill where the dye is distributed throughout the pelvis.

If dye goes through one tube rapidly and fails to enter the other tube, it usually means that the dye-containing tube presents the path of least resistance. In this situation, the nonfilling tube is usually normal. In our own series, when both tubes were patent on x-ray, the pregnancy rate was only slightly higher (58%) than when there was unilateral patency and nonfilling of the other tube (50%).⁹⁰ This finding has been confirmed in a more recent study.⁹¹

Evidence of distal tubal disease on HSG is usually confirmed when laparoscopy is performed. However, a normal study does not rule out pelvic pathology, especially adhesions or endometriosis. While the diagnostic usefulness of the HSG is established, its value as a therapeutic procedure in infertility is a subject of some controversy. Does an HSG enhance fertility, and, if so, is the effect seen with both oil and water-soluble dyes? A conception rate of 41.3% within 1 year of an HSG with oil media has been reported, whereas the rate was only 27.3% when water-soluble agents were employed.⁹² This is in accord with other reports where the great majority of pregnancies that followed HSG occurred within 7 months of the procedure. A review of the question of oil versus aqueous dye noted that in every retrospective study in which increased pregnancy rates were noted after HSG, an oil dye was used.⁹³

In a randomized, prospective study of close to 400 women, the pregnancy and live birth rates were increased in women who had their HSG performed with oil dye.⁹⁴ Within 9 ovulation cycles following an HSG, the pregnancy rate was 33% in the oil dye group and 17% in the water dye group. However, another prospective, randomized study indicated no difference in subsequent pregnancy rates following HSG with oil or water dye.⁹⁵ Nevertheless, most of the evidence indicates that HSG with Ethiodol is a very useful therapeutic as well as diagnostic tool in women with infertility.⁹⁶

The effect of the oil dye on fertility could involve any of a number of mechanisms:

1. It may produce a mechanical lavage of the tubes, dislodging mucus plugs.
2. It may straighten the tubes and thus break down peritoneal adhesions.
3. It may provide a stimulatory effect for the cilia of the tube.
4. It may improve the cervical mucus.
5. The iodine may exert a bacteriostatic effect on the mucous membranes.
6. Ethiodol decreases *in vitro* phagocytosis by peritoneal macrophages. If the same effect occurs *in vivo* it could decrease macrophage activity and thus aid fertility by inhibiting the release of cytokines and decreasing phagocytosis of sperm.^{97, 98}

The use of an oil medium has been criticized on grounds that it is only slowly absorbed and may cause granuloma formation. Granulomas are found very infrequently, and they also can follow the use of water dyes. An additional fear with oil dye is embolization. However, only 13 cases of dye intravasation were encountered in 533 HSGs performed with Ethiodol.⁹⁹ Six of these women had embolization of the dye, but there were no symptoms, and no morbidity was noted. When fluoroscopy is used, venous or lymphatic intravasation can be detected immediately, and injection of dye halted. A common approach is to demonstrate tubal patency with a water soluble dye, then follow with Ethiodol for its fertility-enhancing effects.

HSG is less sensitive than sonohysterography in the identification of uterine polyps or myomas. Sonohysterography involves the injection of saline into the uterine cavity by means of a #8 pediatric Foley catheter with the balloon inflated in the cervix, followed by ultrasonography of the uterus. Similarly, saline or albumin-based fluids can be tracked by ultrasound as they course through the tubes into the peritoneal cavity, providing evidence of tubal patency without the use of x-ray.¹⁰⁰

Sonohysterography with a contrast solution of galactose microbubbles in galactose (Echovist) is being utilized in Europe to provide an overall evaluation of the pelvis, the uterus, and the fallopian tubes.^{101, 102}

Hysteroscopy

Hysteroscopy is a technique that complements hysterosalpingography. Direct visualization of the uterine cavity with a hysteroscope is good for differentiating between endometrial polyps and submucous leiomyomas, establishing the definitive diagnosis and treatment of intrauterine adhesions, and for the diagnosis and treatment of intrauterine congenital anomalies. One can argue from a cost-effective point of view that hysterosalpingography and sonohysterography are more useful screening procedures. The hysteroscope should be reserved to pursue abnormalities identified by other techniques, especially when operative intervention is planned.

Fallopscopy

Because of its narrow and tortuous character, it has been difficult to pass probes via the uterine cavity into the fallopian tube. This problem was overcome by the development of self-seeking guidewires and the adaptation of techniques used for coronary angioplasty. Hysteroscopic directed fallopscopy can be utilized to transvaginally examine the entire length of the tubal lumen.¹⁰³ This technique requires considerable expertise, but it has verified that the tubal ostium can undergo spasm, and intraluminal debris is present that can be a cause of tubal obstruction. The latter can be cleared by cannulation or balloon tuboplasty, or even be by hysterosalpingography. Visualization of the inner aspect of the tube can also be accomplished from the distal end of the tube at the time of laparoscopy. Fallopscopy, originating at either end of the tube, can provide a good assessment of the tubal lining, indicating the prospect of success with tubal surgery.

Outpatient Canalization of the Tube

Proximal tubal obstruction can be treated by outpatient tubal cannulation or balloon tuboplasty. Transcervical tuboplasty can be performed by either a fluoroscopic or hysteroscopic approach, although most of the experience thus far is with the fluoroscopic technique.^{104, 105 and 106} Discomfort can be minimized with intravenous sedation and a paracervical block. Cannulation and balloon tuboplasty success is achieved in at least one tube in 80–90% of attempts. Approximately 30% of patients will become pregnant in the 3–6 months following the procedure. The advantage of these accomplishments is the avoidance of expensive surgery or assisted reproductive technology.

Disorders of Ovulation

Disorders of ovulation account for approximately 20% of all infertility problems in couples. These can be anovulation or severe oligoovulation. In the latter cases, even though ovulation does occur, its relative infrequency decreases the woman's chances for pregnancy. If periods occur only every 3 or 4 months, for practical purposes it matters little whether these are ovulatory or anovulatory. Anovulatory or oligoovulatory women should be promptly treated with clomiphene citrate to increase the frequency of, or to initiate, ovulation (see [Chapter 30](#)), and the drug can be started immediately, even before other areas have been investigated. If anovulation is the only infertility factor, most couples will become pregnant within 3 months of ovulation induction. Women with amenorrhea or hyperandrogenic anovulation should be evaluated and managed according to the clinical approaches detailed in [Chapter 11](#), [Chapter 12](#), and [Chapter 13](#).

Basal Body Temperature

Women who have menstrual periods at monthly intervals marked by premenstrual symptoms and dysmenorrhea are almost always ovulatory, but not always; 5% are anovulatory. Indirect confirmatory evidence of ovulation can be obtained by use of basal body temperature (BBT) charts. The temperature can be taken orally with a regular thermometer or with special instruments (unnecessarily expensive however) that show a range of only a few degrees and thus are easier to read. The temperature is best taken immediately upon awakening and before any activity. The woman may be surprised to find that the basal temperatures are substantially lower than the usual 98.6° F (37° C). Days when intercourse takes place should be noted on the chart, and this may give the physician an indication that coital frequency is a problem.

Use of the BBT chart has been criticized because a small percentage of women who ovulate have monophasic graphs, and there is often disagreement concerning interpretation of individual charts. Moreover, the time of ovulation predicted by the BBT does not always correlate well with measurements of the LH surge or with perceptions of maximal cervical mucus production. There is a relationship between a nadir in the BBT and the LH surge, but the BBT is reliable in predicting the day of the LH surge only within 2–3 days.¹⁰⁷ Although the nadir is believed to represent the beginning of the LH surge, the occurrence of a nadir is variable and often is not detected. To be used prospectively to predict ovulation, nearly absolute cycle regularity is required, and this occurs infrequently.

Nevertheless, we still find the BBT helpful as a preliminary indicator of ovulation and as a tool for advising patients about the timing of intercourse. Patients should not become fixated on taking their temperatures, and usually several months of charts are sufficient.

A significant increase in temperature is not noted until 2 days after the LH peak, coinciding with a rise in peripheral levels of progesterone to greater than 4 ng/mL.¹⁰⁸ Physical release of the ovum probably occurs on the day prior to the first temperature elevation. The temperature elevation should be sustained for 11 to 16 days, falling at the time of the subsequent menstrual period.

If an approximate time of ovulation can be determined by temperature charts, a sensible schedule for coitus is every 36 to 48 hours in a period encompassed by 3 to 4 days prior to and 2 days after expected ovulation. It is unwise, however, to demand rigid adherence to a schedule. This may produce psychological stress sufficient to inhibit sexual relations.

In discussing coital timing, the patients frequently want to know the fertilizable life of the sperm and the egg. The fertilizable life of the human oocyte is unknown, but most estimates range between 12 and 24 hours. However, immature human eggs recovered for in vitro fertilization can be fertilized even after 36 hours of incubation. Equally uncertain is knowledge of the fertilizable lifespan of human sperm. The most common estimate is 48–72 hours, although motility can be maintained after the sperm have lost the ability to fertilize. The extreme intervals that have achieved pregnancy documented after a single act of coitus are 6 days prior to and 3 days after ovulation.¹⁰⁹ The great majority of pregnancies occur when coitus takes place within the 3-day interval just prior to ovulation.¹¹⁰

Home urinary LH testing is commonly used to assist diagnostic and therapeutic timing. The postcoital test should be performed within 12 hours of a positive urinary LH test.¹¹¹ However, appropriate use of the basal body temperature chart yields results equivalent to those obtained with the more expensive methods of urinary LH

assays, and also directs the patients regarding “timing” of further urinary LH testing.. ¹¹²

Endometrial Biopsy

A reliable assessment of ovulation can be obtained by endometrial biopsy. Endometrial biopsy is performed 2 to 3 days prior to the expected period, although a biopsy performed in the midluteal phase is superior for diagnosing luteal phase defects. ¹¹³ The histology is read by the criteria outlined by Noyes, Hertig, and Rock, ¹¹⁴ Although premenstrual biopsy could interrupt a pregnancy if performed in a conception cycle, the danger is not great. ¹¹⁵ We recommend the use of the plastic endometrial suction curette. It is easy to use, requires cervical dilation only occasionally, and is usually painless.

Progesterone Measurements

A serum progesterone level of less than 3 ng/mL is consistent with follicular phase levels. ¹¹⁶ To confirm ovulation, values at the midluteal phase, just at the midpoint between ovulation and the onset of the subsequent menstrual period, should be at least 6.5 ng/mL and preferably 10 ng/mL or more. The consensus of opinion is that a single midluteal phase progesterone level is *insufficient* evidence upon which to judge the adequacy of the luteal phase. ^{117, 118, 119, 120, 121} and ¹²² The progesterone level is subject to the variation associated with pulsatile secretion, but more importantly, there is often poor correlation with the histologic state of the endometrium.

Luteal Phase Defect (Inadequate Luteal Phase)

A luteal phase defect, historically defined as a lag of more than two days in histologic development of the endometrium compared to day of the cycle (presumably due to inadequate progesterone secretion or action), can be found in up to 30% of isolated cycles of normal women, and only if the defect is found repeatedly is it thought to be a possible factor in infertility. Approximately 3 to 4% of infertile women will be diagnosed as having luteal phase defect, and the incidence may be higher (approximately 5%) in women with a history of recurrent abortions. ¹²³

Although luteal phase defect is often a direct result of decreased hormone production by the corpus luteum, the underlying causes of this dysfunction can be multiple. Decreased levels of FSH in the follicular phase of the cycle, abnormal patterns of LH secretion, decreased levels of LH and FSH at the time of the ovulatory surge, or decreased response of the endometrium to progesterone have been implicated. ¹²¹ Elevated prolactin levels and hypothyroidism can be associated with luteal phase defect, emphasizing the importance of assessing prolactin and TSH levels in infertile women with less than normal ovulatory cycles.

The diagnosis should be considered in women with normal cycles and unexplained infertility, women with short luteal phases demonstrated by basal body temperature charts, and women with a history of recurrent spontaneous abortions.

Controversies surrounding the concept of luteal phase defect have revolved around issues of diagnosis, endometrial biopsy versus progesterone levels, and treatment, progesterone versus clomiphene citrate. However, a more fundamental question must be addressed. Is there really such an entity as luteal phase defect, and even if there is, does it play any role in infertility?

As noted above, although measuring progesterone levels has been advocated as a means of diagnosing luteal phase defect, the majority of clinical studies on this subject have used endometrial biopsy as the standard. The endometrium must lag behind the day of the cycle by greater than two days, and the lag must occur in more than one cycle. Whereas it is common to date the cycle day from the onset of the subsequent menstrual period, there is evidence that better dating can be achieved by counting forward from the LH surge. ^{124, 125}

An important issue is how well can the physician, usually a pathologist, date the endometrium. When the same observer viewed 63 endometrial biopsies on two separate occasions, there was exact agreement in only 15 (24%). ¹²⁶ Disagreement of more than two days in the dating of the endometrium occurred in six instances (10%). A further problem in establishing luteal phase defect as a clinical entity is the finding in most studies of an out-of-phase biopsy in approximately 20% to 30% of normal cycles and repetitive lags in more than one normal cycle of approximately 5%. ^{125, 127} These figures suggest that luteal phase defect occurs by chance alone.

The frequency of luteal phase defect in women with infertility, when strictly defined, is no greater than that found by chance in normal cycles. ¹²⁷ In a series of 1492 biopsies in 1055 women reported by Balasch, there were 26 biopsies in conception cycles. ¹²⁸ With an in-phase biopsy, 15 of 20 pregnancies went to term but 4 out of 6 pregnancies with out-of-phase biopsies also went to term. Similarly, the term pregnancy rates were almost identical in women treated and untreated for luteal phase defect. There is a window of endometrial hormonally-induced development during which successful embryo transfer with in vitro fertilization can occur. ¹²⁹ The window extends over a 6-day period, and this indicates that precise synchronization of the endometrium and the embryo may not be needed for successful implantation.

Given the uncertainties surrounding the diagnosis of luteal phase defect, it becomes difficult to justify putting women through the expense and possible pain of endometrial biopsy.

In common practice, again because of the discomfort, the difficulties of precise dating, and the expense associated with endometrial biopsy, attention has turned to measurements of serum progesterone levels as a means of diagnosing, if not luteal phase defect, then at least a “hormone deficiency.” Whereas exact normal values for progesterone are in some dispute, many physicians believe that a level of less than 10 ng/mL one week prior to the onset of menstruation or 5–7 days after the LH surge is a good indication of a luteal phase defect. Frequently a diagnosis of “hormone deficiency” is made based on an isolated and not always well timed progesterone level of less than 10 ng/mL. It is also common practice to utilize such a finding as a rationale for treating as if a luteal phase defect were present. Daily progesterone measurements taken throughout the luteal phase could provide strong evidence for a luteal phase defect if the values are low, but such frequent sampling is impractical. An assessment of various approaches for progesterone measurements concluded that the best correlation with endometrial histology is achieved with 3 progesterone levels obtained randomly during days 5–9 after ovulation (normal equal to or greater than a sum of 30 ng/mL or a pooled concentration, a less expensive alternative, greater than 9 ng/mL). ¹³⁰ Most important, however, is the impressive evidence documenting poor correlation between progesterone measurements and endometrial histology. ^{117, 118, 119, 120, 121} and ¹²²

Other methods of diagnosis include the basal body temperature chart, ultrasonography of follicular size, and salivary progesterone measurements. All have been studied, and all demonstrate poor correlations with multiple progesterone levels and endometrial histology. ^{130, 131}

Treatment of Luteal Phase Defect

Based on findings that low FSH values prior to ovulation can be associated with luteal phase defect, it would seem reasonable, in selected cases, to use human gonadotropins or clomiphene citrate. Gonadotropin treatment is expensive, has the potential for causing hyperstimulation of the ovaries, and is associated with an increased incidence of multiple births. Because of these effects, gonadotropin treatment is seldom, if ever, used for this indication. Clomiphene citrate is the first choice of many clinicians for the treatment of luteal phase defect. The only significant risk is a 5% (twice normal) chance of multiple births, essentially all twins. The initial dose is 50 mg a day for 5 days starting on day 3, 4, or 5 of the cycle ([Chapter 30](#)).

Because there is a suspected deficiency of progesterone in luteal phase defect, exogenous progesterone has been utilized. A vaginal suppository compounded by a pharmacist and containing 25 mg of progesterone is inserted bid starting approximately 2–3 days after ovulation. Treatment is maintained until menstruation occurs or through the 10th week of a pregnancy. Once pregnancy is diagnosed, a switch can be made to weekly injections of 17-hydroxyprogesterone caproate (250 mg) through the 10th week of pregnancy. Oral micronized progesterone can be utilized in a dose of 100 mg tid; however, the oral administration of progesterone leads to metabolic products that cause somnolence and other CNS side effects. Progesterone in a gel that adheres to the vaginal mucosa (Crinone) is available in a prefilled vaginal applicator, applied with one 8% (90 mg progesterone) application daily. Vaginal administration accomplishes targeted delivery to the uterus without producing high circulating levels. Using progesterone therapy, success rates of approximately 50% have been achieved, but good controlled studies are lacking.

There is no difference in pregnancy rates in studies comparing clomiphene and progesterone treatment. ^{132, 133 and 134} In our view, this is an argument in favor of clomiphene because of a significant disadvantage associated with progesterone therapy. Progesterone supplementation prolongs the luteal phase and can delay the onset of menses. This is not a problem for the clinician, but for the couple the disappointment at the time of delayed menses or a negative pregnancy test is profound.

Dopamine agonist treatment has been reported to correct luteal phase defect associated with hyperprolactinemia, but its value in women with normal prolactin levels has not been demonstrated. In a subgroup of patients with unexplained infertility, high normal prolactin levels, and expressible galactorrhea, treatment with bromocriptine enhanced fertility compared to similar women treated with pyridoxine. ¹³⁵ If galactorrhea is present, even if the prolactin is normal, ovulatory dysfunction responds well to dopamine agonist therapy. ¹³⁶ In the absence of galactorrhea, a prolactin elevation may be subtle (such as an increase in nocturnal peaks), and this could explain occasional good responses to dopamine agonist treatment. In evaluating any therapy it is important to keep in mind that pregnancies can occur without treatment in women who are diagnosed as having luteal phase defect.

Many physicians dispense with the diagnostic evaluation of hormone adequacy and proceed to treatment with clomiphene citrate. It is a reasonable argument that there may be subtle hormonal abnormalities that cannot be diagnosed with current technology but that can be successfully treated by stimulating the ovaries. Moreover, there is a theoretical advantage in having more than one oocyte in the fallopian tube at the time of fertilization. Randomized placebo-controlled studies support the efficacy of this approach (reviewed with references in [Chapter 30](#)). By contrast, some have not found a benefit for the use of clomiphene citrate in unexplained infertility. ¹³⁷

We do not object to the empirical use of clomiphene, provided there is a clear understanding of the potential side effects and the uncertain efficacy of the medication.

Luteinized Unruptured Follicle

On occasion, a corpus luteum will form despite the failure of release of the oocyte. Initially it was thought that this problem could be identified at laparoscopy by visualizing an absence of the ovulatory stigma, but now it is apparent that the stigma can be epithelialized rapidly and thus obscured from view. ¹³⁸ Currently, clinical diagnosis of a luteinized unruptured follicle (LUF) is made on the basis of ultrasound monitoring. The preovulatory growth of the follicle usually is normal but the follicle does not collapse following the LH surge, and there may be increased growth in the luteal phase. The interior of the follicle lacks the echoes often seen in corpora lutea. Whereas these criteria seem straightforward, establishing the diagnosis of LUF is often difficult. Even if ultrasonography is performed daily, the collapse of the follicle can be missed, and a corpus luteum refilled with blood can be mistaken for a persistent follicle. Therefore, serial ultrasound screening of women with unexplained infertility is of questionable value, not only for the diagnosis of LUF, but also for determining the size of the follicle just prior to rupture. Whereas ovulation usually occurs in the normal cycle when the follicle is 17–23 mm in diameter, some fertile women ovulate from a smaller follicle. In the evaluation of unexplained infertility, a single ultrasound examination in the late follicular phase is of value to detect endometrial polyps and myomas.

It is doubtful that LUF is a significant cause of infertility, and furthermore, the suggested treatments are superovulation, either alone or in conjunction with one of the assisted reproductive technologies, treatment choices that will be empirically offered even without a diagnosis of LUF. Because inhibition of prostaglandin synthesis can cause a luteinized unruptured follicle, patients should be cautioned to avoid the use of nonsteroidal antiinflammatory agents. ^{139, 140 and 141}

Mycoplasma

Mycoplasma, a pleuropneumonia-like organism, has been implicated as a possible cause of recurrent abortion and salpingitis. A markedly higher prevalence of T mycoplasma (*ureaplasma urealyticum*) was detected in the cervical mucus and semen of infertile couples compared with a group of fertile couples. ¹⁴² Treatment with doxycycline decreased the number of couples with mycoplasma and also was associated with pregnancy in 15 of 52 couples (29%), all of whom had had primary infertility of at least 5 years duration. However, a series of reports from England agreed with these findings in only one respect. ^{143, 144} They confirmed that treatment with doxycycline could eliminate mycoplasma from the genital tract of the majority of individuals. There was no difference, however, in the frequency of either T strain or *Mycoplasma hominis* between infertile and fertile couples. In a double-blind study, treatment with doxycycline for 28 days had no effect on the rate of conception, and an English group suggested that culturing for mycoplasma in the routine investigation of infertility was unrewarding. ¹⁴⁴

Since those early publications, a number of studies have established the widespread distribution of *ureaplasma urealyticum* in both fertile and infertile populations. Some have found higher colonization in infertile couples, whereas others have found no relationship between the organisms and infertility. In a study that received a great deal of media attention, it was reported that 60% of males who were culture positive for *ureaplasma urealyticum* and were cleared of infection by antibiotic treatment achieved a pregnancy. ¹⁴⁵ Failure to clear the infection resulted in a 5% pregnant rate. This study suffered from lack of clarity on the criteria for entry into treatment and from any mention of individuals lost to follow-up. The incidence of ureaplasma infection is only significantly higher in those women whose male partners have semen abnormalities. ¹⁴⁶

Ureaplasma urealyticum is widespread, but there is no compelling evidence that it causes infertility. Empiric treatment with antibiotics is not warranted.

Endoscopy

Traditionally, laparoscopy has been the final diagnostic procedure of any infertility investigation. As the success rates with in vitro fertilization improve ([Chapter 31](#)), patients and clinicians increasingly believe that turning to the assisted reproductive technologies is appropriate, even without laparoscopy. In most hands, in vitro fertilization will be more successful than treating significant tubal disease through the laparoscope. Mild, asymptomatic endometriosis of prolonged duration may also require in vitro fertilization if superovulation, combined with intrauterine inseminations, does not achieve pregnancy. Considerations of cost and healthcare coverage often influence the types of treatment selected by couples.

If laparoscopy is contemplated after a normal HSG, the endoscopic procedure is usually performed after an interval of 6 months from the x-ray. This allows time for the fertility enhancing effect of the x-ray procedure. An exception can be made for a woman who is at high risk for pelvic infection or the older woman who has no time to wait. The findings at laparoscopy agree with those of HSG in approximately two-thirds of the cases. The major area of disagreement is the failure of the HSG to detect pelvic adhesions or endometriosis. Approximately 50% of apparently normal infertile patients undergoing laparoscopy will have pelvic pathology, usually pelvic adhesions or endometriosis (but ordinarily a degree of endometriosis not requiring treatment). ¹⁴⁷ With due care in selection of cases these abnormalities can be treated through the laparoscope either by lysis of adhesions, salpingostomy, or fulguration or vaporization of implants of endometriosis. Patients with significant tubal disease are best advised to proceed to in vitro fertilization.

Lysis of adhesions	50% pregnancy rate
Distal tubal obstruction:	
Mild disease	80% pregnancy rate
Moderate disease	30% pregnancy rate
Severe disease	15% pregnancy rate

Unexplained Infertility

An infertile couple has what is called unexplained infertility when all standard clinical investigations (semen analysis, the postcoital test, assessment of ovulation, demonstration of tubal patency) yield normal results. It is estimated that from 10% to 15% of infertile couples will ultimately reach this clinical diagnosis, and, using normal findings on laparoscopy as a criterion, the prevalence may be less than 10%.¹⁴⁹ Important variables are age of the woman and duration of the infertility.⁶⁴

The average monthly fecundity in normal couples is 30%; the monthly pregnancy rate in couples with unexplained infertility is 1.5–3%. After 3 years of infertility, the prospect of pregnancy decreases by 24% each year.¹⁴⁹ Approximately 60% of couples with unexplained infertility of less than 3 years duration will become pregnant with 3 years of *expectant* management.^{150, 151} Because the incidence of spontaneous pregnancy is significant until 3 years have passed, it is appropriate to require 3 years of infertility in women less than 30 years old before making this diagnosis. Because age is an important determinant, further evaluation and therapy should not be deferred in older women.

A meticulous review of available results is essential to avoid overlooking a treatable factor. The use of sperm function tests may be helpful. There is some correlation between absent sperm penetration of hamster eggs and subsequent outcome (see [Chapter 29](#)). If these tests are not available, keep in mind that a definite diagnosis of unexplained infertility requires successful fertilization in vitro. Thus, a human egg test (in vitro fertilization) is the ultimate test of sperm fertility, and it is more time and cost efficient to move promptly to assisted reproduction, rather than testing sperm function.

Superovulation and Intrauterine Insemination

Empiric treatment for suspected endometriosis or with dopamine agonists has no impact on unexplained infertility. However, the methods of assisted reproductive technology and superovulation with intrauterine insemination do increase the prospect of pregnancy. The results with superovulation alone are inferior to those achieved with one of the assisted reproductive techniques, but the overall cost is also less.¹⁵² Studies indicate that subtle hormonal abnormalities do exist in women with unexplained infertility.^{153, 154} These changes (elevated gonadotropins and estradiol in the follicular phase and decreased luteal phase progesterone) have been attributed to a reduction in ovarian reserve as usually seen in older women.¹⁵⁴ Thus, there is a rational basis to provide ovarian stimulation.

A cumulative pregnancy rate of 40% can be achieved in couples with unexplained infertility after 6 cycles of superovulation or 3 cycles of in vitro fertilization.¹⁵⁵ In randomized, controlled clinical trials, the monthly pregnancy rates in couples with unexplained infertility is increased 2–3-fold (a monthly fecundity rate of 9%) with clomiphene treatment, and with human gonadotropins, the monthly fecundity rate is approximately 10–15%.^{156, 157 and 158} **Although some studies have failed to yield increased pregnancy rates with the empiric use of clomiphene,^{137, 159} we believe couples with unexplained infertility should be offered superovulation or one of the assisted reproductive technologies. However, superovulation should be limited to 3 or 4 cycles.**

The addition of intrauterine insemination of washed sperm (IUI) to clomiphene treatment increased fecundity in couples with unexplained infertility or surgically treated endometriosis, compared with intercourse without hormonal stimulation).¹⁵⁷ As with almost all infertility, success is age-related, with pregnancy rates 3–4-fold greater in women under age 20.¹⁶⁰ Although the combination of IUI with clomiphene may enhance the pregnancy rate in couples with unexplained infertility, **IUI by itself does not.**^{161, 162 and 163}

The combination of IUI with gonadotropin stimulation provides even better results than clomiphene and IUI. In two studies, the pregnancy rate per cycle with gonadotropins and IUI was 19% and 14.3% compared to 4% and 7.7% with clomiphene and IUI respectively.^{158, 164} In a meta-analysis of randomized trials comparing gonadotropin stimulation with IUI or with timed intercourse, IUI was associated with approximately a 2-fold greater pregnancy rate.¹⁶⁵ In a randomized trial, superovulation and IUI resulted in a 3-fold greater pregnancy rate compared with intracervical insemination and 2-fold greater compared with either IUI alone or a combination of superovulation and intracervical insemination.¹⁸⁰

The effectiveness of gonadotropin treatment combined with IUI has been repeatedly demonstrated for a variety of infertility disorders, including endometriosis, cervical factor, and unexplained infertility.^{166, 167 and 168} As with clomiphene, few pregnancies occur after 4 cycles of treatment.

Thus, there exist a number of options for the empiric treatment of unexplained infertility before considering the more complex and costly assisted reproductive technologies ([Chapter 31](#)). These options and the timing of their use should always be considered in the context of the known spontaneous cure rate for unexplained infertility. Approximately 60% of couples with unexplained infertility of less than 3 years duration will become pregnant within 3 years of expectant management. However, as time progresses, the monthly fecundity rate decreases, and this can be improved by active management with superovulation and IUI. For older women, decreasing the time to achieve a pregnancy is an important objective.

In a meta-analysis of methods used to treat unexplained infertility, pregnancy rates were estimated to be as follows:

Pregnancy Rate per Cycle ¹⁶⁹	
No treatment	1.3–4.1%
IUI	3.8%
Clomiphene	5.6%
Clomiphene & IUI	8.3%
Gonadotropins	7.7%
Gonadotropins & IUI	17.1%
IVF	20.7%

Because it is relatively inexpensive, easy to administer, and not usually burdened with major side effects (except for a 2-fold increase in twinning), clomiphene is usually the first treatment choice. Patient demand for this treatment is substantial, and it is not unreasonable to respond to that demand with 3–4 clomiphene cycles. The uncertainty regarding the efficacy of adding IUI to clomiphene influences us to proceed from clomiphene treatment to the combination of gonadotropins and IUI, with an expectation of achieving a pregnancy rate of 15% per cycle. The combination of clomiphene and IUI is still appropriate in circumstances where cost, time, and avoidance of complications are paramount. The use of IUI alone or gonadotropins without IUI is not recommended for the treatment of unexplained infertility.^{162, 170}

The success of treatment is influenced by the number of sperm inseminated. Pregnancies are rare if less than 1–3 million sperm are inseminated.^{163, 171} Once this baseline is surpassed, increasing the number of sperm inseminated does not increase the pregnancy rate; although one study achieved higher pregnancy rates with inseminations of greater than 10 million motile sperm.^{172, 173} Morphology plays only a minor role. Once the percentage of normal forms exceeds 5–10%, there is no influence on success.^{174, 175}

The effects of age remain critical whatever the method of ovarian stimulation. In one series of 136 treatment cycles, no pregnancies were achieved in women who were 43 or older.¹⁷⁶ Despite rare successes in older women, it borders on the exploitive to treat women over age 40 with superovulation and IUI. Indeed, pregnancy rates begin to decline with this treatment around age 35.¹⁶⁰

Adoption

With proper assessment and therapy, the majority of couples evaluated for infertility will become pregnant. For those who are refractory to the usual treatments, consideration of assisted reproductive technologies or adoption is appropriate. Couples thinking about adoption have a range of choices including social agency adoptions, private adoptions, and international adoptions. In some states, private adoption is not legal; however, where it is legal, it can provide an effective, more rapid alternative to adoption through a social agency. In most cases the biologic mother has the opportunity to know the adopting parents, and this lack of anonymity may direct some individuals away from private adoption. In addition, there is a short time period during which the biologic mother can reclaim the baby. In our experience, this devastating event occurs in approximately 5% of private adoptions.

To facilitate private adoption, patients should be encouraged to “spread the word” that they are interested in adoption. In addition, letters can be directed to obstetricians throughout the country describing the couple and their desire for adoption. Both lawyers and non-lawyers have practices devoted to counseling couples (and individuals) on approaches to private adoption and regarding the adoption laws in individual states.

Myths and Appropriate Goals

It is important for physicians and other health care professionals to dispel the myths that are associated with infertility. Women should not be told that they are infertile because they are too nervous. Unless anxiety interferes with ovulation or coital frequency, there is no present evidence that infertility is caused by the usual anxieties besetting a couple attempting to conceive. Despite many anecdotes to the contrary, adoption does not increase a couple's fertility.¹⁷⁷ The treatment of euthyroid infertile women with thyroid has been shown repeatedly to be worthless. A dilation and curettage (D and C) is not a legitimate part of a routine infertility investigation. It provides minimal information beyond that obtained by endometrial biopsy and is both expensive and potentially hazardous because it subjects the woman to the risk of general anesthesia. There is also no evidence to support the old belief that a woman becomes more fertile following D and C. Quite the contrary, one study indicates a decreased fertility potential for those women undergoing D and C.¹⁷⁸ A retroverted uterus is not a cause for infertility, although it can be found in association with pelvic adhesions or endometriosis that does influence infertility.

The routine ordering of laboratory tests, such as imaging and hormone determinations not indicated by clinical judgment, is ill advised. These may be of value in selected cases but certainly not in every case.

Remember that a substantial number of pregnancies occur in infertile couples without treatment, irrespective of the diagnoses.⁶⁴ Thus, the physician should not feel obligated to render a treatment just to do something. The goals of the practitioner should be to accomplish a thorough investigation, to treat any abnormalities that are uncovered or to provide empiric therapy based upon the evidence reviewed in this text, to educate the couple in the workings of the reproductive system, to give the couple some estimate of their fertility potential, to counsel for adoption where appropriate, and to provide emotional support either directly or through staff members or groups like RESOLVE. If these goals are achieved by a sympathetic, understanding clinician, they will satisfy most couples who suffer from infertility.

- [Chapter References](#)

Early pregnancy loss (abortion or miscarriage) is defined as the termination of pregnancy before 20 weeks of gestation (dated from the last menstrual period) or below a fetal weight of 500 g. Approximately 15% of all pregnancies between 4–20 weeks of gestation will undergo clinically recognized spontaneous miscarriages. The true early pregnancy loss rate is closer to 50% because of the high rate of unrecognized miscarriages in the 2–4 weeks immediately following conception. The majority of these very early cases are caused by chromosomal abnormalities in the sperm or the egg.

“Habitual” abortion was classically defined as 3 or more consecutive spontaneous miscarriages. In 1938, Malpas, using theoretical calculations, stated that a woman with a history of 3 consecutive spontaneous miscarriages had a 73% chance of aborting in the next pregnancy.¹ In 1946, Eastman presented statistical calculations indicating that after 3 miscarriages the risk was 83.6%.² These early conclusions, based primarily upon intuition rather than clinical studies, established the notion that the chance for a subsequent miscarriage increases dramatically with each successive miscarriage; and that after 3 miscarriages the chances for a successful pregnancy are very low. Studies on the efficacy of many types of treatments used these pessimistic figures for comparison rather than containing their own controls. If treatment increased the salvage rate to 70% it was considered curative. However, clinical studies have indicated that the risk of pregnancy loss after 3 successive spontaneous miscarriages is in fact 30–45%.^{3, 4 and 5} The chance of a successful live birth after 3 consecutive miscarriages without a live birth is 55–60%; with at least one previous normal pregnancy (live birth) in addition to the repetitive miscarriages, the chance is approximately 70%.^{4, 5} However, keep in mind that these numbers are derived from younger women, and older women have a risk of pregnancy loss that is twice that of younger women.

The Risk of Recurrent Early Pregnancy Loss in Young Women^{4, 5 and 6}

	Number of Prior Miscarriages	% Risk of Miscarriage in Next Pregnancy
Women who have had at least one liveborn infant:	0	12%
	1	24%
	2	26%
	3	32%
	4	26%
	6	53%
Women who have not had at least one liveborn infant:	2 or more	40–45%

The projections by Malpas and Eastman were theoretical exercises that were not confirmed when appropriate data were collected. Thus, it is not surprising that treatment with a wide range of approaches, including vitamins and psychotherapy, produced successful pregnancies in a reasonable percentage of women with recurrent miscarriages. These cures were not due to the therapy; the claims for success were based on a comparison with the discredited statistics of Malpas and Eastman.

The diagnostic and therapeutic response to a couple with pregnancy loss is not dictated by the number of miscarriages. The response is significantly influenced by the woman's age, the couple's level of anxiety, and factors readily identified in the family and medical history. The degree of response will range from an educational discussion to a full diagnostic evaluation with appropriate treatment. It is helpful to consider recurrent pregnancy losses according to the following categories:

1. Normal statistics,
2. Genetic factors,
3. Environmental factors,
4. Endocrine factors,
5. Anatomic causes,
6. Infectious causes,
7. Thrombophilia,
8. Immunologic problems.

Normal Statistics

The reproductive loss between conception and clinically recognizable pregnancy is significant; about 50% of fertilized ova do not progress to a viable pregnancy.^{7, 8} The use of sensitive assays for human chorionic gonadotropin (HCG) suggests that up to 30% of pregnancies are lost between implantation and the 6th week.⁹ It is important for physicians and their patients to be aware of the high degree of reproductive loss, especially in older women due in part to the increasing frequency of trisomies with advancing age. However, the frequency of both euploid (normal) and aneuploid (abnormal) abortuses increases with maternal age.

Approximately 80% of spontaneous miscarriages occur in the first 12 weeks of pregnancy, and nearly 70% of these miscarriages in early pregnancy are due to chromosomal anomalies.¹⁰ Clinically recognized miscarriage occurs in only 12% of women younger than age 20, but the incidence increases to 26% in women older than age 40. The overall rate of loss (recognized and unrecognized) in women over age 40 is approximately 75%! An appreciation for these statistics contributes significantly to a couple's ability to cope with an early pregnancy loss.

Once a live embryo is detected by ultrasonography in normal young women or in young women with infertility, the rate of fetal loss is 3–5%. However, in women with recurrent pregnancy loss, the rate of loss after detection of fetal cardiac activity is 4–5 times higher.¹¹ The rate of spontaneous miscarriage in women with two or more recurrent losses was 22.7% after ultrasound documentation of fetal cardiac activity.¹² Keep in mind that the risk of spontaneous miscarriage is higher in older woman; spontaneous miscarriage occurred in 29% of women 40 or more years old, undergoing in vitro fertilization, after the demonstration of fetal heart motion by ultrasonography.¹³

Genetic Factors

Despite the knowledge that the spontaneous success rate is 55–70%, it is still worth trying to uncover causes for repetitive first-trimester miscarriages. A recognized cause of the problem is a genetic abnormality, and karyotyping of couples will reveal that 3–8% have some abnormality, most frequently a balanced chromosomal

rearrangement, a translocation.^{14, 15, 16, 17, 18 and 19} Other abnormalities usually encountered include sex chromosome mosaicism, chromosome inversions, and ring chromosomes. Besides spontaneous miscarriages, these abnormalities are associated with a high risk of malformations and mental retardation. Karyotyping is especially vital if the couple has had a malformed infant or fetus in addition to miscarriages. It is important to emphasize that karyotyping uncovers only a percentage of those pregnancies lost due to genetic abnormalities. There may be single gene defects that are not manifested by chromosomal abnormalities, and it is very likely that a percentage of those patients now considered to have unexplained repetitive pregnancy loss have this type of genetic defect. In addition, karyotyping of blood cells misses abnormalities of meiosis, which can be found in sperm cell lines.

If the karyotype is abnormal, nothing can be done to lessen the chances for another miscarriage, however with many abnormalities there is a 50% chance the next pregnancy will be normal. Amniocentesis or chorionic villus biopsy should be encouraged in any pregnancy in couples with an abnormal karyotype because of the risk of an abnormal child. Today, couples with serious high risk abnormalities may elect to pursue a pregnancy by means of donor sperm or in vitro fertilization with donor oocytes (or both).

As noted, approximately 70% of early spontaneous miscarriages are associated with fetal chromosomal abnormalities.^{20, 21} In addition, 30% of second-trimester miscarriages and 3% of stillbirths have abnormal chromosomes. In most cases, the couple is chromosomally normal and the fetal chromosomal abnormality is a random event. The abnormalities include maternal and paternal accidents in gametogenesis, as well as miscues after fertilization. The fetal chromosomal abnormalities in single spontaneous miscarriages are different than those in recurrent miscarriages. Autosomal trisomy is the most frequent anomaly (about 50% of early pregnancy miscarriages), due to nondisjunction or translocation.²² Trisomies of chromosomes 13, 16, 18, 21, and 22 are the most common. The next most common anomaly (about 25%) is 45,X which is responsible for Turner syndrome when the fetus survives. Of the remaining anomalies, most are polyploidies.

Fetuses that abort later in gestation usually have normal chromosomes. Perhaps in this situation, the responsible factors are external to the fetus. Subtle chromosomal defects, however, may be revealed as our analytic techniques improve.

According to McDonough, treatment of endocrine factors yields a 90% normal child rate; correction of anatomic factors yields a 60–70% rate, but known genetic factors are associated with only a 32% expectation for a normal child.²³

It is helpful to have a karyotype on a previous miscarriage to determine aneuploidy or euploidy. Once determined, there is an increased likelihood that subsequent miscarriages will be the same, although there is still a chance for women with recurrent pregnancy loss to have a normal pregnancy. If aneuploidy is documented, accurately timed inseminations could be considered based on animal studies relating aneuploidy to aging of ovum and sperm; otherwise the choice is between hoping for the best or donor insemination. Once pregnant, chorionic villus sampling should be considered. If euploidy has been documented, anatomic and endocrine factors should be corrected.

Karyotyping is expensive. A factor that can help in decision making is a positive family history for recurrent miscarriages.²⁴ Translocations within families are usually associated with a mixed history: some normal pregnancies intermixed with recurrent miscarriages. Karyotyping is indicated when family members can be identified with multiple spontaneous miscarriages or the family has a malformed or mentally retarded child or a child with a known chromosomal abnormality. In any event, we recommend a karyotype when there is a history of 3 consecutive spontaneous early pregnancy losses and no previous normal liveborn.

Environmental Factors

Smoking, alcohol, and heavy coffee consumption have been reported to be associated with an increased risk of recurrent pregnancy losses.^{10, 25, 26} The increase in risk is proportional to the number of cigarettes smoked. In these cases, the fetal chromosomes are normal. More recently, the link with caffeine intake could not be supported.²⁷ Anesthetic gases and tetrachloroethylene (used in dry cleaning) have been implicated as causative agents of miscarriage, but exposure to video terminals is not a factor.²⁸ Exercise programs do not increase the risk of spontaneous miscarriage, and bed rest will not influence the risk of recurrent miscarriage. Isotretinoin (Accutane) is definitely associated with an increased incidence of spontaneous miscarriage.²⁹ An increased risk of spontaneous miscarriage has not been documented among laboratory workers or women in the pharmaceutical industry.^{30, 31} The use of electric blankets and heated water beds is also not associated with an increased risk of spontaneous miscarriage.³²

Endocrine Factors

Mild or subclinical endocrine diseases are not causes of recurrent miscarriages. Patients who have significant thyroid disease or uncontrolled diabetes mellitus may suffer spontaneous miscarriages, but it is unlikely that laboratory assessments of thyroid function and carbohydrate metabolism are worthwhile in relatively healthy women.^{33, 34 and 35} Nevertheless, the high frequency of hypothyroidism warrants screening with a measurement of thyrotropin-stimulating hormone (TSH).¹⁶ No convincing evidence exists linking endometriosis with an increased risk of spontaneous miscarriage.³⁶

Elevated luteinizing hormone (LH) levels have been associated with an increased risk of miscarriage in women with polycystic ovaries who become pregnant.^{37, 38} There is no reason to believe that this is a factor in ovulatory women with recurrent miscarriages. Even in women with polycystic ovaries and a history of 3 or more consecutive early pregnancy losses, suppression of LH secretion with a GnRH agonist prior to ovulation induction yielded no difference in outcome.³⁹

An endocrine abnormality that may cause recurrent miscarriages is the inadequate luteal phase. Studies of the role of hormone deficiency as a cause of recurrent miscarriage have largely focused on deficiencies of progesterone or its metabolites. Attempts to implicate low progesterone or pregnanediol levels in early pregnancy as a cause for miscarriage, and, as a corollary, to treat with exogenous progesterone or progestins have been fruitless.^{40, 41}

Another approach has been to diagnose an inadequate luteal phase during the nonpregnant state and to initiate treatment with progesterone a few days after ovulation. Jones and Delfs⁴² claimed that 30% of women with pregnancy wastage had an inadequate luteal phase, whereas more recent studies have found that 20–25% of women with recurrent miscarriages have an inadequate luteal phase.^{14, 15, 16, 17, 18 and 19} Yet it is by no means certain that progestational treatment makes a difference. Indeed, a meta-analysis of randomized trials of pregnancies treated with progestational agents failed to find any evidence for a positive effect on the maintenance of pregnancy.⁴¹ Nevertheless, clinicians continue to report, as we have noted, a significant incidence of luteal phase inadequacy in their series of patients with recurrent miscarriages.^{18, 43, 44}

The uncertainty that plagues physicians in dealing with the inadequate luteal phase in infertility, therefore, is also apparent when considering recurrent miscarriages. If repetitive endometrial biopsies indicate a lag in histologic development of more than 2 days or if the basal body temperature chart shows a luteal phase of less than 11 days, it is reasonable to treat with clomiphene or progesterone ([Chapter 26](#)) and with a dopamine agonist if galactorrhea or an elevated prolactin is present. In the absence of galactorrhea or hyperprolactinemia, we prefer clomiphene because this avoids the situation of a prolonged luteal phase due to progesterone treatment, a false expectation of pregnancy, and a more difficult time for the couple in coping with the results of a negative pregnancy test.

Should clomiphene be offered empirically (for 6 cycles) when no other cause for recurrent miscarriages can be identified? Placebo treatment may be useful in maintaining a clinician-patient relationship in which the patient derives needed psychologic sustenance. Furthermore, there is no evidence of any major harmful consequences with clomiphene treatment (see [Chapter 30](#)). In view of the difficulty in establishing the diagnosis of an inadequate luteal phase and the uncertainties that surround this diagnosis, we believe there is a place for empirical treatment. It must be remembered, however, that there is a reasonable cure rate in unexplained recurrent miscarriage, even without treatment.

Anatomical Causes

Uterine abnormalities can result in impaired vascularization of a pregnancy and limited space for a fetus due to distortion of the uterine cavity. Approximately 12–15% of women with recurrent miscarriages have a uterine malformation, and this can be best diagnosed by vaginal ultrasonography (especially with saline instillation), and confirmed by magnetic resonance imaging. Hysterosalpingography is relatively inaccurate and decisions should not be based upon hysterosalpingography alone.⁴⁵ The various uterine anomalies, including leiomyomata and diethylstilbestrol (DES) exposure, are discussed in detail in [Chapter 4](#) . Surgical repair of these defects, often by hysteroscopy, is rewarded with delivery rates in the 70–80% range; however, this high rate of success must be tempered by the realization that it is not derived from randomized clinical trials. The septate uterus is the most frequent anatomic abnormality associated with recurrent early spontaneous miscarriages, and

the results with hysteroscopic repair have been impressive.⁴⁶ Repeat procedures are occasionally necessary; the surgical result should be evaluated several weeks postoperatively by hysterosalpingography (which is sufficiently accurate for this purpose) or office hysteroscopy. Surgery is unlikely to make a difference in a patient who has successfully delivered a live born term infant. The prophylactic use of cervical cerclage has not been supported by results from randomized trials.⁴⁷ However, when there is nothing else to offer, cervical cerclage is worthwhile; e.g., in patients with late losses and müllerian anomalies such as a bicornuate or unicornuate uterus and in DES-exposed women with a hypoplastic cervix.

In addition to müllerian anomalies, another anatomic cause, although uncommon, of recurrent miscarriages is intrauterine synechiae (Asherman's syndrome). If an appropriate predisposing factor, such as uterine curettage or a severe uterine infection, can be identified, diagnostic hysterosalpingography or hysteroscopy should be performed.

Infectious Causes

Despite periodic reports that have implicated specific infectious agents as etiologic factors in recurrent miscarriages, there currently is no hard evidence that bacterial or viral infections cause recurrent pregnancy losses. An impressive incidence of antichlamydial antibody has been reported in women with 3 or more spontaneous miscarriages, but it is not certain whether this is an association with *Chlamydia trachomatis* or whether this is a marker of a different immune response in women with recurrent miscarriages.⁴⁸ In a prospective study, no association could be detected between antichlamydia antibodies and spontaneous miscarriage.⁴⁹

Claims of effective antibiotic treatment have been derived without benefit of randomized studies. Perhaps an exception is infection with *Ureaplasma urealyticum*.⁵⁰ Other organisms that have been implicated, but not substantiated, include *Toxoplasma gondii*, *Listeria monocytogenes*, *Mycoplasma hominis*, herpes virus, and cytomegalovirus. It is more cost-effective and time efficient to prescribe both partners a course of doxycycline (100 mg bid for 14 days) or erythromycin (250 mg qid for 14 days) than to pursue multiple and repeated cultures.

Thrombophilia

The major cause of thrombosis in pregnancy is an inherited predisposition for clotting, especially the factor V Leiden mutation. Deficiencies of antithrombin III, protein C, and protein S are inherited in an autosomal dominant pattern, accounting for 10–15% of familial thrombosis. Mutations in the prothrombin gene and the factor V Leiden mutation are the most common inherited causes of venous thromboembolism.⁵¹ An inherited resistance to activated protein C has been identified as the basis for about 50% of cases of familial venous thrombosis, due in almost all cases to a gene alteration recognized as the factor V Leiden mutation.^{52, 53} The factor V Leiden mutation is found in approximately 30% of individuals who develop venous thromboembolism.⁵⁴ Activated protein C inhibits coagulation by degrading factors V and VIII. One of the 3 cleavages sites in factor V is the precise site of a mutation (known as the factor V Leiden mutation) that substitutes glutamine instead of arginine at this site (adenine for guanine at nucleotide 1691 in the gene).⁵⁴ This mutation makes factor V resistant to degradation (and activation in fibrinolysis). The entire clotting cascade is then resistant to the actions of the protein C system.

Heterozygotes for the factor V Leiden mutation have an 8-fold increased risk of venous thrombosis, and homozygotes, an 80-fold increased risk, and this risk appears to be further enhanced by oral contraceptive use. The highest prevalence (3–4% of the general population) of factor V Leiden is found in Europeans, and its occurrence in populations not of European descent is very rare, perhaps explaining the low frequency of thromboembolic disease in Africa, Asia, and in native Americans.⁵⁵ The mutation is believed to have arisen in a single ancestor approximately 21,000 to 34,000 years ago.⁵⁶ It has been suggested that this was a useful adaptation in heterozygotes in response to life-threatening bleeding, such as with childbirth. The next most common inherited disorder (after the factor V Leiden mutation) is a mutation a guanine to adenine change in the gene encoding prothrombin.^{51, 57} The prevalence of this abnormality in the white population is estimated to range from 0.7% to 4%.⁵⁸

In a group of 39 women with recurrent miscarriages, the factor V Leiden mutation was identified in nearly half, and 5 women treated with anticoagulation had normal term deliveries.⁵⁹ Others have found an increased incidence of the factor V Leiden mutation in women with second-trimester losses, but either not at all or only a slight increase in women with first-trimester losses.^{60, 61, 62 and 63} In a survey of 500 consecutive women with unexplained recurrent pregnancy losses, von Willebrand's disease, fibrinogen deficiency, deficiencies in antithrombin, protein C, and proteins S, and resistance to activated protein C were not more frequent.⁶⁴ In a prospective cohort study, inherited deficiencies were associated with increased risks of late loss, but not for early miscarriage.⁶⁵ Elevated homocysteine levels are a risk factor for venous thrombosis, and this condition has also been suggested to be a factor in recurrent early pregnant losses.⁶⁶ Overall, these results are less than clear-cut.

In view of the new recognition for the clinical importance of inherited disorders that predispose to venous thrombosis, we believe that women with recurrent miscarriages who have no obvious identified cause should consider hematologic screening. This is definitely necessary in women with a previous episode or a close family history (parent or sibling) of thromboembolism. The list of laboratory tests is long, and because this is a dynamic and changing field, the best advice is to consult with a hematologist. A positive result warrants treatment with low molecular weight heparin after pregnancy is diagnosed.

Hypercoaguable Conditions

- Antithrombin III deficiency
- Protein C deficiency
- Protein S deficiency
- Factor V Leiden mutation
- Prothrombin gene mutation
- Antiphospholipid syndrome

Thrombophilia Screening

- Antithrombin III
- Protein C
- Protein S
- Activated protein C resistance ratio
- Activated partial thromboplastin time
- Hexagonal activated partial thromboplastin time
- Anticardiolipin antibodies
- Lupus anticoagulant
- Fibrinogen
- Prothrombin G mutation (DNA test)
- Thrombin Time
- Homocysteine level
- Complete blood count

Immunologic Problems

Autoimmunity (Self Antigens)

In autoimmunity, a humoral or cellular response is directed against a specific component of the host. The lupus anticoagulant and anticardiolipin antibodies are antiphospholipid antibodies, which arise as the result of an autoimmune disease. The lupus anticoagulant is present in a variety of clinical conditions, not just with lupus erythematosus. The antiphospholipid antibodies are directed against platelets and the vascular endothelium and cause thrombosis, spontaneous miscarriage, and fetal wastage. These antibodies block prostacyclin formation, which results in unbalanced thromboxane activity, leading to vasoconstriction and thrombosis.⁶⁷ In several series, 10–16% of women with recurrent miscarriages have had antiphospholipid antibodies.⁶⁸ These antibodies are also associated with fetal growth retardation and fetal death in addition to recurrent miscarriages, and when present, there is a high rate of second-trimester fetal deaths. The mechanism of pregnancy loss is probably decidual and placental insufficiency due to the thrombotic tendency. Annexin-V is a phospholipid-binding protein that inhibits coagulation; the levels of annexin-V on trophoblasts and endothelial cells are reduced in the presence of antiphospholipid antibodies.⁶⁹

Despite activating thrombosis, the antiphospholipid antibodies prolong the prothrombin time and the partial thromboplastin time. The activated partial thromboplastin time is a relatively sensitive screening test, but we also obtain a kaolin clotting time. The anticardiolipin antibody and lupus anticoagulant can be identified and titered by specific immunoassays; other individual antiphospholipid antibodies have not been associated with recurrent miscarriages.⁷⁰ The antiphospholipid antibodies all produce the same clinical impact and have identical effects on clotting tests. Although the prevalence is uncertain, patients with recurrent miscarriages should be screened with the activated partial thromboplastin time, a kaolin clotting time, lupus anticoagulant, and the anticardiolipin antibody.^{71, 72, 73, 74 and 75} It is not clinically helpful to measure antinuclear antibodies, IGA antibodies, or leukocyte antibodies.

Our preferred treatment for significant titers of antiphospholipid antibodies consists of the combination of low-dose aspirin (80 mg daily) and low-dose heparin as soon

as pregnancy is diagnosed.^{76, 77} Treatment is not always successful.⁷⁸ Studies of low-dose aspirin alone do not demonstrate a favorable effect on pregnancy outcome in either women with unexplained recurrent losses or in women with detectable anticardiolipin antibodies.^{79, 80} Others advocate the addition of a glucocorticoid in a dose sufficient to restore the clotting studies to normal.⁸¹ However, the addition of glucocorticoids is not very effective in eliminating the anticardiolipin antibody, and in a randomized trial, a combination of prednisone and aspirin (100 mg daily) was no better than placebo treatment.⁸² Many of these patients develop preeclampsia, often very severe, but approximately 75% of patients with antiphospholipid antibodies will deliver a viable infant in a treated pregnancy. Because of the risks associated with anticoagulation, aspirin and heparin treatment should be confined to women with recurrent pregnancy losses who have antiphospholipid antibodies. Indeed, it can be argued that treatment should be offered only to women with antiphospholipid antibodies who have experienced both first-trimester and second-trimester losses.⁸³

Alloimmunity (Foreign Antigens)

Alloimmunity refers to all causes of pregnancy losses related to an abnormal maternal immune response to antigens on placental or fetal tissues.⁶⁸ Normally, maintenance of pregnancy may require the formation of blocking factors (probably complexes of antibody and antigen) that prevent maternal rejection of fetal antigens. It has been argued that couples with repetitive miscarriages have an increased sharing of human leukocyte antigens (HLA), a condition that would not allow the mother to make blocking antibodies.

Immunotherapy to stimulate antibody formation has been offered to produce a favorable maternal immune response in order to protect the developing embryo. Women with recurrent miscarriages have been treated with infusions of their partner's lymphocytes. In one study, 77% of women receiving their husband's cells gave birth compared to 37% receiving their own cells.⁸⁴ Critics of this study have contended that success in the control group raises the question of the adequacy of matching in the selection of control patients. Others have claimed good results with transfusion of leukocyte-rich, erythrocyte-rich donor blood (3 transfusions every 4–8 weeks) or with intravenous immunoglobulin or seminal plasma vaginal suppositories.^{85, 86 and 87}

Women have been selected for immunotherapy by HLA typing, but its use is no longer supported. Many investigators have failed to confirm that sharing of HLA antigens is found to a greater degree in couples with recurrent miscarriages.^{88, 89 and 90} This agrees with experiments in animals where sharing of HLA antigens has not been found to affect reproduction. The sharing of genetic loci may be a broader problem that includes genetic loci critical for embryonic development, and the antigens available for measurement serve only as markers for a more fundamental genetic immunologic failure in pregnancy. There is also concern that immunization of mothers may affect placenta and fetus. **There is no specific immunologic test or clinical method which will predict the need for treatment.**⁹¹

Immunotherapy remains experimental with potential risks of adverse consequences on the immune systems of mother and child. At least 5 randomized placebo-controlled studies have failed to demonstrate a beneficial effect of immunotherapy.^{92, 93, 94, 95 and 96} In a study of women with 5 or more early miscarriages, paternal leukocyte immunization appeared to have a beneficial effect; suggesting that 25% of multiple aborters (without a live birth) would benefit.⁹⁷ In a re-analysis of the world-wide raw data, the difference in birth rate between treatment and control groups amounted to 10%, a difference so small that it may not be clinically significant.⁹⁸ Our recommendation is that women with an extreme number of recurrent early pregnancy losses should be referred to a center operating an immunotherapy protocol.⁹⁹

Summary of Immunologic Causes

Women whose recurrent miscarriages are more likely to have an immunologic cause have the following characteristics:⁹¹

1. Many previous spontaneous miscarriages.
2. No recent full term pregnancies.
3. Less than 35 years old.
4. Aborted conceptus with a normal karyotype.
5. Usually at least one loss after the first-trimester.

Summary of Laboratory Evaluation and Management for Repeated Early Pregnancy Losses

Category	Evaluation	Treatment
Normal Statistics	Numbers review, No lab tests	Education and support
Genetic Factors	Karyotypes of both parents	Counseling Donor gametes where appropriate
Environmental Factors	No lab tests	Counseling
Endocrine Factors	TSH, prolactin, luteal phase assessment	Empiric clomiphene
Anatomic Causes	Vaginal ultrasound with saline instillation, confirmed by MRI	Surgery
Infectious Causes	Cultures if clinically indicated	Empiric doxycycline or erythromycin
Thrombophilia	Screen for inherited predisposition for thrombosis	Low molecular weight heparin anticoagulation
Immunologic	Activated partial thromboplastin time, kaolin clotting time, anticardiolipin antibody, lupus anticoagulant	Low-dose aspirin and heparin

Conclusion

The patient with early miscarriages usually presents as an anxious, frustrated individual on the verge of despair. Evaluation should be spaced over several visits, allowing the clinician to establish communication and rapport with the patient. Frequent communication between the clinician and the patient during the first-trimester of the next pregnancy is essential. The emotional support that the clinician can bring to this interaction will be most useful and in some cases may be therapeutic.¹⁶ It should be emphasized that continued attempts at conception are rewarded with success in the majority of women (70–75%) labeled as recurrent aborters and who have no identifiable cause.⁵ Except in the case of a second-trimester loss which is associated with a poor prognosis in the subsequent pregnancy with increased risks for preterm delivery, stillbirth, and neonatal death, approximately 50% of women with histories of recurrent pregnancy losses have no identifiable abnormalities and do well in their next pregnancies.^{16, 17, 18 and 19, 96, 100} All subsequent pregnancies should be closely monitored because there is a higher rate of ectopic pregnancies in women with recurrent miscarriages.¹⁰¹

The expectant management of spontaneous early miscarriages is now known to provide an outcome (both medical and psychologic morbidity) equivalent to surgical evacuation of the uterus, with no adverse effect on future fertility.^{102, 103 and 104} For appropriate patients, this approach with effective support can be easier and less distressing.

Finally, the outcome of the assisted reproductive technologies is not certain in women with a large number of recurrent miscarriages. In one series of 12 women, 8 women delivered at term after in vitro fertilization.¹⁰⁵ In addition, in vitro fertilization outcome is not reduced in women with positive antiphospholipid antibodies.¹⁰⁶ However, in another in vitro fertilization experience, although pregnancy rates were good, a high rate of spontaneous miscarriage (50%) occurred in women with 3 or more consecutive losses.¹⁰⁷ Good results have been reported with oocyte donation in women with recurrent losses.¹⁰⁸ These are individual decisions, heavily

influenced by psychologic and financial resources.

Endometriosis is a disease involving ectopic (outside the uterus) endometrial glands and stroma. In its clinical manifestations, it is a progressive disease that is a vexing problem for both patient and clinician. However, clinical studies over the past 2 decades have provided information for a better understanding of the disease and better decision-making regarding management options. This chapter will review the more recent information regarding treatment as well as what is known concerning the etiology and pathogenesis of endometriosis.

Etiology of Endometriosis

Endometriosis was described in the medical literature in the 1800s, but it was not until the 20th century that its common occurrence was appreciated. Based on clinical observation and examination of histopathologic specimens, John Sampson of Albany, New York, in 1921, suggested that peritoneal endometriosis in the pelvis arose from seedings from ovarian endometriosis. Subsequently, in 1927, he published his classic paper, "Peritoneal Endometriosis Due to Menstrual Dissemination of Endometrial Tissue Into the Peritoneal Cavity," which introduced the term "endometriosis" and established retrograde flow of endometrial tissue through the fallopian tubes and into the abdominal cavity as the probable cause of the disease.¹ The conclusions of Sampson have been validated by the following observations:

1. During laparoscopy, flow of blood from the fimbriated end of the tube has been observed in virtually all menstruating women.²
2. Endometriosis is most commonly found in dependent portions of the pelvis, most frequently on the ovaries, the anterior and posterior cul-de-sac, and the uterosacral ligaments, followed by the posterior uterus and posterior broad ligaments.^{3, 4 and 5}
3. Endometrial fragments from the menstrual flow can grow both in tissue culture and following injection beneath the abdominal skin, and can be retrieved from the peritoneal fluid of most menstruating women.⁶
4. Endometriosis developed when the cervixes of monkeys were transposed so that menstruation occurred into the peritoneal cavity.⁷ The retroperitoneal injection of menstrual endometrium caused peritoneal endometriosis in baboons.⁸
5. A higher incidence of endometriosis is observed in women who have obstructions to the outward flow of the menstrual effluvium.⁹
6. The risk of endometriosis is increased in women with shorter menstrual cycles and longer flows, characteristics that give greater opportunity for ectopic endometrial implantation.^{10, 11}
7. Retrograde menstruation has been observed to occur more frequently in baboons with spontaneous endometriosis.¹²

However, there may be other pathways for the development of endometriosis. Endometriosis at sites distant from the pelvis may be due to vascular or lymphatic transport of endometrial fragments.¹³ Even the common occurrence of endometriosis on the ovaries can be explained by lymphatic flow from the uterus to the ovary.¹⁴

Endometriosis can occur in almost every organ of the body.¹⁵ For example, pulmonary endometriosis occurs and can be manifested by asymptomatic nodules or as pneumothorax, hemothorax, or hemoptysis during menses.¹⁶ Urologic endometriosis is of importance because of the possibility for ureteral obstruction.

Extrapelvic endometriosis is occasionally encountered years after surgical removal of the uterus and the ovaries.¹⁷ This endometriosis can be hormone-resistant, and we can only speculate as to why it grows. One possibility is transplantation of endometrial implants during the original surgery, or activation of residual disease. Another possibility is transformation by metaplasia of other tissue or activation of embryonic rest tissue. When the endometriosis is hormone-sensitive, a good possibility is that an ovarian remnant was left behind during the complicated surgery, and this allows continuing hormonal stimulation of residual endometriosis.

There are case reports of endometriosis in men who received treatment with estrogen, and therefore, another possible cause of endometriosis is the transformation of coelomic epithelium into endometrial-type glands as a result of unspecified stimuli. The following arguments can be used to support the coelomic metaplasia theory:¹⁸

1. Endometriosis occurs in adolescent girls in the absence of müllerian anomalies, and it can be discovered a few years after menarche before many menstrual cycles have been experienced.¹⁹
2. Endometriosis has been reported in a prepubertal girl.²⁰
3. Endometriosis has been encountered in women who never menstruated.²¹
4. Endometriosis in unusual sites, such as thumb, thigh, or knee, can be explained by the fact that mesenchymal limb buds develop adjacent to coelomic epithelium during early embryogenesis.
5. Endometriosis does occur in men, usually associated with high-dose estrogen treatment.^{22, 23}

Because many women have reflux seeding of menstrual debris into the peritoneal cavity, and not all develop endometriosis, there may be genetic or immunologic factors that influence the susceptibility of a woman to the disease. Simpson and coworkers reported 6.9% of first-degree relatives of patients with endometriosis had the disease, compared with 1.0% in a control group.²⁴

Monozygotic twins are markedly concordant for endometriosis.²⁵ A worldwide collaborative project (The Oxford Endometriosis Gene Study) has been organized to identify a genetic basis for endometriosis.²⁶ A web site is available and can be used to provide access to the study for affected families:
<http://www.medicine.ox.ac.uk/ndog/oxegene/oxegene.htm>

Dmowski and coworkers demonstrated that monkeys with endometriosis had decreased cellular immunity to endometrial tissue, suggesting that specific immunologic defects can render some individuals susceptible to endometriosis.²⁷ Others have found an increased prevalence of humoral antibodies directed against endometrial and ovarian tissue in the sera of women with endometriosis.²⁸ In addition, women with endometriosis demonstrate a decrease in various measurements of immune response.^{29, 30}

A consideration of the etiologic theories regarding endometriosis leads to the conclusion that all of these mechanisms can contribute to the clinical problem in an individual patient, and the degree of contribution for each probably varies from patient to patient. Endometrial cells can be spread by mechanical means, or perhaps

can arise by metaplasia, and progression of the disease is influenced by the individual's immune mechanisms, especially leukocyte and cytokine responses.

Prevalence of Endometriosis

Widely varying figures for the prevalence of endometriosis have been published, and a rough estimate is that 3–10% of women in the reproductive age group and 25–35% of infertile women have endometriosis.^{5, 31, 32} About 4 per 1000 women age 15–64 are hospitalized with endometriosis each year, slightly more than those admitted with breast cancer. The common perceptions that endometriosis only occurs in goal-oriented women over the age of 30 and is not found often in black women have now been discredited. Whereas endometriosis essentially does not occur before menarche, there are increasing reports of its occurrence in the teenage years.³³ A number of these cases involve anatomic abnormalities that obstruct the outflow tract.³⁴ Endometriosis is not confined to nulliparous women, and physicians should be alert to the presence of endometriosis in cases of secondary infertility.

Diagnosis of Endometriosis

Endometriosis should be suspected in any woman complaining of infertility. Suspicion is heightened when there are also complaints of dysmenorrhea and dyspareunia.

Symptoms and Signs

Dysmenorrhea and deep dyspareunia are even more suggestive of endometriosis if the symptoms begin after years of relatively pain-free menses and coitus.³⁵ It should be recognized, however, that many women who have endometriosis are asymptomatic. A common observation is that some women with extensive endometriosis have little or no pain, whereas others with only minimal endometriosis complain of severe pain. Very severe pain, however, is associated with deeply infiltrating endometriosis.^{36, 37 and 38} Thus, the lack of correlation between pain and visible endometriosis is because the degree of pain is determined by the depth of infiltration. In addition, it has been our observation that midline disease is usually more symptomatic than lesions that are laterally placed.

Pain can be diffuse in the pelvis or it can be more localized, often in the area of the rectum. Symptoms also can arise from rectal, ureteral, or bladder involvement with endometriosis, and can be present throughout the month. Blockage of the ureter can occur, and urinary tract symptoms should be investigated with urologic and radiologic techniques. Low back pain, too, may be due to endometriosis. An association of endometriosis and premenstrual spotting has been suggested, but in most cases menstrual dysfunction is not increased with endometriosis. An association between galactorrhea and endometriosis has been claimed, but baseline elevations of prolactin are not higher in patients with endometriosis than in normal women.^{39, 40}

The CA-125 Assay

CA-125 is a cell surface antigen found on derivatives of the coelomic epithelium (which includes endometrium), and it is a useful marker in the monitoring of women with epithelial ovarian carcinoma. In addition, serum CA-125 levels are often elevated in patients with endometriosis and correlate with both the degree of disease and the response to treatment.^{41, 42} The sensitivity of this assay is too low to use it as a screening test, but it can be a marker of response to treatment and for recurrence; however, elevated levels which suppress during medical treatment often promptly return to pretreatment concentrations immediately after cessation of therapy, limiting its clinical usefulness.⁴³ Serum CA-125 determinations may be able to differentiate endometriotic from nonendometriotic benign adnexal cysts, especially when combined with transvaginal ultrasonography.^{44, 45} Note that CA-125 levels can be elevated by early pregnancy, acute pelvic inflammatory disease, leiomyomata, and menstruation.

Examination

We recommend that pelvic examination be performed at the time of menses when tenderness is easier to detect. The uterus is often in fixed retroversion and the ovaries may be enlarged. However, retroversion of the uterus is not an etiologic factor, and prophylactic uterine suspension is no longer recommended. Nodularity (which is usually tender) of the uterosacral ligaments and cul-de-sac can be found in one-third of patients with endometriosis. The diagnosis almost always should be confirmed by laparoscopy before treatment is initiated. Minimal findings, such as slight beading and tenderness of the uterosacral ligaments in the young, asymptomatic patient, can be treated initially, however, with combined, low dose oral contraceptives.

The classic chocolate cyst of the ovary is the result of a blood-filled cavity within an endometrioma. Ultrasonography and magnetic resonance imaging can be helpful in diagnosing endometriomas.^{46, 47 and 48} However, neither can diagnose small peritoneal implants or adhesions. Although transvaginal ultrasonography is highly accurate in diagnosing ovarian endometriomas, hemorrhagic cysts account for a significant false positive rate.⁴⁵

The appearance of endometriosis is quite varied. All too often the clinician fails to observe endometrial lesions because of a preconceived expectation limited to the classic blue or black powder burn appearance. Lesions can be red, black, blue, or white and nonpigmented.⁴⁹ Biopsies from visibly normal peritoneum can contain endometriosis in 6–13% of infertile women; however, the clinical significance of this presence is uncertain (and, in our view, unlikely to be important).⁵⁰ Adhesions, peritoneal defects, and tan, creamy, fresh-appearing endometrium also can be observed. The dark pigmented lesions are later consequences of tissue bleeding responses to cyclic hormones. The ovary is the most common site for both implants and adhesions, followed by widespread distribution, anteriorly and posteriorly, over the broad ligament and cul-de-sac.^{3, 4 and 5}

A Classification System

Because both treatment and prognosis are determined to some extent by the severity of the disease, it is desirable to have a uniform system of classification that takes into account both the extent and severity of the disease. A uniform classification is also crucial for comparing the results of different treatments. The American Society for Reproductive Medicine developed a classification system based on findings at laparoscopy or laparotomy.⁵¹ However, there were weaknesses in the classification system, especially the fact that it was based upon the arbitrary impressions of the clinician. A revised classification system was produced to standardize the documentation of findings in patients who have pelvic pain and endometriosis, and forms are available from the Society.⁵² There can be a high intraobserver and interobserver variability in the evaluation of endometriosis using any classification system.^{53, 54} Therefore, efforts must continue to provide an accurate method for staging.

Endometriosis and Infertility

When endometriosis involves the ovaries and causes adhesions that block tubal motility and pickup of the egg, there is no question of its role in causing mechanical interference with fertility. Less secure is the information on the role of peritoneal endometriosis on fertility. Many physicians believe that even minimal endometriosis can cause infertility, impairing tubal function or gamete quality. This argument has been weakened by a failure to find benefit from medical treatment of infertility associated with minimal to mild endometriosis.^{55, 56 and 58}

The absence of benefit from therapy, however, could represent a problem with the treatment rather than a lack of association between infertility and endometriosis.⁵⁹ Endometriosis diagnosed by laparoscopy is reported in a higher proportion of infertile women (38.5%) compared with fertile women (5.2%).⁶⁰ Moreover, fecundity rates in women with endometriosis tend to be lower than the normal fecundity rate.^{32, 61, 62} However, the long-term cumulative pregnancy rates are very high in women who have minimal to mild endometriosis and are not treated.⁶³

If minimal or mild endometriosis does affect fertility, what are the mechanisms? Certainly, dyspareunia secondary to endometriosis could play a role.

Another mediator could be prostaglandins produced by the implants, which could, in turn, affect tubal motility, or folliculogenesis and corpus luteum function. Patients with endometriosis have been reported to have an increase in both the volume of peritoneal fluid and the concentration of thromboxane B₂ and 6-keto-prostaglandin F_{1a} in the fluid.^{64, 65} Others, however, found neither an increase in peritoneal fluid nor an increase in concentration of peritoneal fluid prostaglandin E₂, prostaglandin

F_{2a}, 15-keto-13,14-dihydroprostaglandin F_{2a}, and thromboxane B₂.^{66, 67}

Subsequent studies also have provided contradictory information. No elevation in peritoneal fluid prostanoid levels during the proliferative phase in women with endometriosis has been reported, and similarly no peritoneal fluid elevation in 6-keto prostaglandin F_{1a} levels has been observed in the luteal phase.^{68, 69} However, others have reported elevated concentrations of prostanoids in the peritoneal fluid of women with endometriosis.⁷⁰ These differences could be accounted for by differing levels of prostaglandin synthesis according to different morphologic characteristics of the lesions.⁷¹ In summary, it has not been established that women with endometriosis have higher levels of prostanoids in peritoneal fluid compared to other infertile women. Even if higher levels were found consistently, their role in infertility still would be speculative. Nevertheless, interest in prostaglandins continues. A correlation can be demonstrated between the degree of dysmenorrhea experienced by women with endometriosis and the amount of prostaglandins produced by the endometriosis tissue.⁷²

Peritoneal macrophages have been suggested as possible mediators of infertility, and increased activation of macrophages has been found in association with endometriosis.^{73, 74} Phagocytosis of sperm by macrophages could be one mechanism of action.⁷⁵ However, patients with and without endometriosis have the same number of motile sperm recoverable from the peritoneal cavity. Peritoneal macrophages from women with endometriosis secrete interleukin-1 which is toxic to mouse embryos.⁷⁶ In addition, cytokines are elevated in the peritoneal fluid, which could recruit macrophages and lymphocytes and perpetuate the inflammatory reaction.⁷⁷ Macrophages and endometrial cells also produce vascular endothelial growth factor (VEGF), an important angiogenic factor involved in endometrial proliferation.⁷⁸

Endometriosis has been implicated as a factor in disordered follicle growth, ovulatory dysfunction, and failure of embryo development. Ultrasonography studies suggest that there is some retardation in growth of follicles in women with endometriosis. Luteinized unruptured follicle syndrome (LUF) in which the oocyte is not released at the time of follicle rupture (or there is a failure of the follicle to rupture) has been suggested as a cause of both unexplained infertility and infertility secondary to endometriosis. Although an unruptured follicle can occur in women, there currently is no impressive evidence that this syndrome is secondary to endometriosis or is even a cause of infertility.⁷⁹

The question of how minimal or mild endometriosis can affect fertility now has been superseded by the question of whether there is *any* effect of mild endometriosis on fertility. More importantly, should endometriosis be treated if the complaint is infertility and not pain? Many articles purporting to show that therapy overcomes endometriosis-associated infertility are flawed by lack of control groups and the failure to use life-table analyses.⁶⁶ Moreover, expectant management of mild endometriosis is rewarded with reasonable pregnancy rates that are comparable to those obtained with treatment.^{55, 56, 57 and 58, 80, 81, 82 and 83} A cumulative pregnancy rate after 5 years of 90% has been reported in women not treated for minimal or mild endometriosis.⁶³

Whereas the studies cited above strongly suggest that medical or surgical treatment of mild endometriosis may not be worthwhile, there are those who champion fulguration treatment under laparoscopic visualization.⁸⁴ In a randomized trial involving 341 infertile women with minimal or mild endometriosis, comparing diagnostic laparoscopy with laparoscopic resection or ablation of visible endometriosis, the surgically-treated group experienced a 48% pregnancy rate (over 9 months) compared with 35% in the non-treated group.⁸⁵ Of note was the observation that this improvement only occurred in women with blue or black lesions, not with red lesions. Furthermore, an argument can be made that active treatment of even mild endometriosis is warranted because endometriosis is often a progressive disease.

The increase (only a modest one) in the pregnancy rate associated with laparoscopic treatment is consistent with the good pregnancy rates associated with expectant management of mild endometriosis. Nevertheless, it is currently recommended that resection or ablation should be immediately performed when minimal or mild endometriosis is diagnosed during laparoscopy for infertility. Moderate and severe endometriosis should be treated surgically at the time of diagnosis. If pregnancy is not achieved after surgery, infertility should be treated first with superovulation and IUI, and then with IVF.⁸⁶

Surgical Treatment of Endometriosis

In contrast to the dispute over the proper treatment of mild endometriosis, there is little doubt that adhesive disease associated with endometriosis, or large (>2 cm) endometriomas, is best treated by surgery. The object of surgery should be to restore normal anatomical relationships and to excise or fulgurate as much of the endometriosis as possible. Removal of severely diseased adnexa when the other side is more normal produces better results than attempts to do major repairs. Presacral neurectomy does not enhance fertility, although many surgeons advocate it to alleviate dysmenorrhea. This may be less compelling now that prostaglandin inhibitors are available to accomplish the same purpose. A careful study of presacral neurectomy concluded that this procedure is only indicated in patients with pain limited to the midline area.⁸⁷

The success of surgery in relieving infertility is directly related to the severity of endometriosis. Patients with moderate disease can expect a pregnancy success of approximately 60%, whereas the comparable figure is 35% in those with severe disease.⁸⁸ As noted above, surgical treatment of blue or black lesions yielded a slightly higher (13%) pregnancy rate compared to expectant management in a randomized trial.⁸⁵ Of note was the observation that this improvement only occurred in women with blue or black lesions, not with red lesions. There is support for selective use of medical treatment for 2–3 months following laparoscopy and prior to conservative surgery, especially in patients with pain due to major disease.⁸⁹ Preoperative treatment aids surgery by softening endometrial implants.

Postoperative use of hormones has been the subject of greater controversy. The highest pregnancy rates following conservative surgery occur in the first year after surgery, and most physicians have been reluctant to use hormones that prevent pregnancy even for a few months. If pregnancy does not occur within 2 years of surgery for endometriosis, the chances are poor that pregnancy will occur. The recurrence rate reported for endometriosis after surgery is 20% within 5 years,^{90, 91} and when it does recur, second surgeries to aid fertility have only a limited chance for success. When the objective of laparoscopic surgery is symptomatic relief and not pregnancy, a return of symptoms is delayed with as little as 6 months of postoperative medical treatment.⁹²

The type of surgery that we have been discussing is labeled “conservative” to indicate that reproductive function is maintained. When endometriomas are removed a vigorous attempt should be made to leave behind any normal ovarian tissue. Even one-tenth of an ovary can be enough to preserve function and fertility. Conservative surgery can be accomplished by laparoscopy which decreases costs and morbidity, yet provides results that are as efficacious in all stages of disease as laparotomy.⁹³

“Conservative” surgery is in contradistinction to “radical” surgery, which includes hysterectomy and usually bilateral salpingo-oophorectomy. When radical surgery is performed, an uninvolved ovary can be preserved in some cases if all of the nonovarian endometriosis is removed by fulguration or excision. However, this does provide a risk for recurrent disease. Patients who undergo hysterectomy with ovarian conservation have a 6-fold increased risk of developing recurrent symptoms compared with women who have oophorectomy.⁹⁴

Medical Treatment of Endometriosis

Although hormonal therapy of infertility associated with endometriosis is not of proven value,⁹⁵ medical therapy for dysmenorrhea, dyspareunia, and pelvic pain associated with endometriosis is very successful (although relief may be short-term). **The various agents used are comparable in terms of efficacy, and choice of treatment is determined by cost and side effects.** Implants of endometriosis react to steroid hormones in a manner somewhat, but not exactly, similar to normally stimulated endometrium. However, endometriotic tissue displays histologic differences and biochemical differences, including enzyme activity and receptor levels that differ in concentration and response compared to normal endometrium. Nevertheless, estrogen stimulates growth of the implants. For this reason, endometriosis usually regresses following menopause and is usually not found prior to menarche unless there is a blockage of the outflow tract.

Hormonal therapy is designed to interrupt the cycle of stimulation and bleeding. An early approach was the use of massive doses of diethylstilbestrol (DES), which, because of variable success, the risk of affecting the fetus, and side effects of severe bleeding and nausea, is now of only historical interest. Treatment with androgens (methyltestosterone linguets 5–10 mg/day) can provide only transient relief of the pain of endometriosis, and its effect on infertility appears to be negligible. In addition, ovulation can occur while on treatment, and there is a risk of exposure of the fetus to the androgen.

Until the late 1970s the most important alternative to conservative surgery was the use of combination oral contraceptives taken in a continuous fashion.⁹⁶ It seems to matter little which low dose monophasic product is used to accomplish the conversion of endometrial implants into decidualized cells associated with a few inactive endometrial glands.⁹⁷ At this time the efficacy of the multiphasic formulations is unknown. The usual dose of the combined oral contraceptive is one pill per day continuously for 6–12 months. Estrogen (conjugated estrogens 1.25 mg or estradiol 2.0 mg daily for 1 week) is added if breakthrough bleeding occurs. The treatment

with oral contraceptives was called pseudopregnancy because of the amenorrhea and the decidualization of the endometrial tissue induced by the estrogen-progestin combination. It also reflected the commonly held belief that pregnancy can improve endometriosis, a belief that has been disputed. The side effects of treatment are those associated with oral contraceptives ([Chapter 22](#)). Pregnancy rates after stopping medication are reported to be in the 40–50% range. Whereas published recurrence rates are not excessive, this therapy, as with all medical treatment for endometriosis, must be viewed as suppressive rather than curative.

Treatment With Danazol

The golden age for danazol has passed. Although its expense and side effects seemed a reasonable tradeoff for an effective treatment, it is now apparent that danazol is no more effective than the other medications used to treat endometriosis. In distinction to the pseudopregnancy induced by oral contraceptives, danazol produces what has been incorrectly termed as pseudomenopause. Danazol is an isoxazole derivative of the synthetic steroid 17 α -ethinyltestosterone. It originally was thought to exert its effect solely by inhibition of pituitary gonadotropins. Although danazol can decrease follicle-stimulating hormone (FSH) and luteinizing hormone (LH) in castrated individuals, it does not alter basal gonadotropin concentrations in premenopausal women. It does, however, eliminate the midcycle surge of FSH and LH. Danazol inhibits steroidogenesis in the human corpus luteum.⁹⁸ Danazol is metabolized to at least 60 different products, some of which may contribute to its many effects. The multiple effects of danazol produce a high-androgen, low-estrogen environment that does not support the growth of endometriosis, and the amenorrhea that is produced prevents new seeding from the uterus into the peritoneal cavity.⁹⁹

Danazol

The side effects of danazol are related both to the hypoestrogenic environment it creates and to its androgenic properties. The most common side effects are weight gain, fluid retention, fatigue, decreased breast size, acne, oily skin, growth of facial hair, atrophic vaginitis, hot flashes, muscle cramps, and emotional lability. Some of these side effects occur in approximately 80% of women who are taking danazol, but less than 10% find the side effects sufficiently troublesome to warrant discontinuation of the drug. Because danazol has been associated with the development *in utero* of female pseudohermaphroditism, it should not be given if there is the possibility of pregnancy.¹⁰⁰ The androgenic action of danazol can irreversibly deepen the voice.^{101, 102} It is worth inquiring whether singing is an important part of your patient's life before prescribing this drug.

Danazol is metabolized largely in the liver, and in some patients it causes hepatocellular damage. Its use, therefore, is contraindicated in women with liver disease. Furthermore, liver enzymes should be monitored during treatment with danazol. The fluid retention that is often associated with danazol makes it dangerous to use when there is severe hypertension, congestive heart failure, or impaired renal function. It can produce increased cholesterol and low-density lipoprotein levels and decreased levels of high-density lipoprotein. It is unlikely that these short-term effects on lipids and lipoproteins are clinically important. The drug has been used to treat autoimmune disease, but it is not known if this action plays a role in its effects on endometriosis.

It should be noted again that medical treatment of mild endometriosis associated with infertility has been called into question because women with untreated mild endometriosis have pregnancy rates equal to women who have received medical treatment for the endometriosis. Thus, danazol treatment of infertility associated with mild endometriosis has no scientific support.

On the other hand, danazol is useful to relieve the pain of endometriosis and to prevent progression of the disease. Pain relief is obtained in 90% of patients. The usual dose is two 200 mg tablets twice a day (although some claim that spacing the drug at 6-hour intervals may be more effective) for 6 months. Dmowski and Cohen reviewed 99 women who completed danazol treatment for a period of 3–18 months (average 6 months) and who were reevaluated an average of 37 months later.¹⁰³ During the course of treatment all the patients had symptomatic improvement, and the majority (85%) were clinically improved. At the time of the reevaluation, however, approximately one-third were symptomatic and had clinical findings suggestive of recurrent endometriosis. In the majority of these patients, the symptoms recurred within the first year after discontinuation of the drug.

The success of danazol treatment is greatest in cases of peritoneal endometriosis or those with small lesions of the ovary. Endometriomas larger than 1.0 cm are less likely to respond to danazol, although quite surprising regression of endometriomas larger than 1.0 cm is sometimes seen.

Because of the significant side effects encountered with danazol, and its cost, there has been a trend toward the use of lower doses than the usual 800 mg daily. However, doses below 800 mg may be less effective.¹⁰⁴ The occurrence of amenorrhea appears to be correlated with improved outcome, and this is more consistently obtained at the 800 mg level. Others, however, do not believe that amenorrhea is an important consideration because many of the patients will bleed from an atrophic endometrium.

There is a general perception, but only limited experimental evidence, that danazol is more effective than oral contraceptives for the treatment of endometriosis.¹⁰⁵ Noble and Letchworth compared danazol with a high dose estrogen-progestin combination (Enovid).¹⁰⁶ The dose of both danazol and the oral contraceptive was increased until the patients became amenorrheic. One of 25 patients taking danazol could not complete 5 months of treatment, whereas 7 of 17 (41%) of the group taking oral contraceptives dropped out because of side effects. Danazol was more effective than estrogen-progestin in relieving symptoms, and laparoscopic assessment showed much better results with danazol. Seven of 12 danazol-treated patients became pregnant compared with 4 of the 10 women who had taken oral contraceptives. Unfortunately, the study size was too small to allow statistical analysis.

Treatment With a Progestational Agent

Both oral and injectable medroxyprogesterone acetate have been effective in treating endometriosis by causing decidualization and subsequent atrophy of endometrial tissue.¹⁰⁷ Medroxyprogesterone acetate in an oral dose of 30 mg daily has been demonstrated to be as effective as danazol in treating endometriosis.⁸² Similar results have been obtained with higher doses.¹⁰⁸ Although not studied, it is likely that lower doses (10–20 mg daily) would be effective. For this reason and because it is more cost-effective and there are fewer side effects, medroxyprogesterone acetate is often the first choice for medical treatment of endometriosis. High doses of medroxyprogesterone can adversely affect the lipoprotein profile; there is no reason to use a dose greater than 30 mg/day. Megestrol acetate has been administered in a dose of 40 mg daily with good results.¹⁰⁹ These progestin doses suppress luteinizing hormone (LH) secretion, and, therefore, patients can be relatively hypoestrogenic. As a result, some loss in spinal bone can occur, but recovery follows discontinuation of treatment, and there should be no effect on fracture risk.¹¹⁰

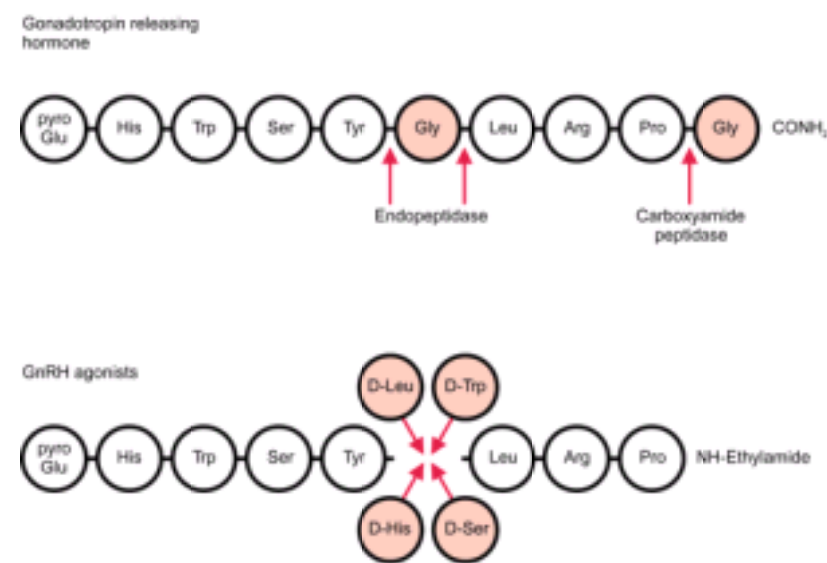

Side effects include weight gain, fluid retention, and breakthrough bleeding. Breakthrough bleeding is a common occurrence although it is usually cleared by short-term (7 days) administration of estrogen. Depression is a significant problem, and both patient and physician should be alert for its development. The usefulness of depo-medroxyprogesterone acetate (150 mg im every 3 months) in infertile patients is limited by the varying length of time it takes for ovulation to resume after discontinuation of therapy. This is not a problem with oral administration.

Medroxyprogesterone acetate, like danazol, can relieve the symptoms of endometriosis, but it is not effective in treating infertility. In a prospective, randomized clinical trial, there was no difference in pregnancy rates following treatment with medroxyprogesterone acetate (100 mg/day) or placebo.¹¹¹

Treatment With GnRH Agonists

Gonadotropin-releasing hormone (GnRH) has a short half-life because it is rapidly cleaved between amino acids 5–6, 6–7, and 9–10. Analogues of GnRH have been produced by altering the amino acids at these positions. Substitutions of amino acids at the 6 position and/or replacement of the C-terminal glycine-amide (inhibiting

degradation) produce agonists. The GnRH agonists are administered intramuscularly, subcutaneously, or by intranasal absorption. After an initial agonistic action (the so-called flare response), down-regulation and desensitization of the pituitary produce a hypogonadotropic, hypogonad state. The depot formulation of leuprolide is administered intramuscularly and monthly. Goserelin comes in a small biodegradable cylinder that is inserted subcutaneously and monthly using a prepackaged syringe.

A long-acting GnRH agonist can create a pseudomenopause for the treatment of endometriosis.^{112, 113} At the end of 2–4 weeks of daily administration of the agonist, estrogen levels will decrease to those found in oophorectomized women. Dosage can be adjusted by monitoring serum estradiol levels; the best therapeutic effect is associated with a range of 20–40 pg/mL. Thus, the “medical oophorectomy” caused by the continuous use of a GnRH agonist has provided a new approach to the treatment of endometriosis. Excellent, large, well-designed studies (with advanced disease in nearly 50% of the patients) have compared GnRH agonist therapy (with various agents) with danazol.^{114, 115, 116, 117 and 118} The results in terms of reduction of disease (as demonstrated by post-treatment laparoscopies) and pregnancy rates have been the same with either treatment. However, GnRH agonist treatment does not have an adverse impact on serum lipids and lipoproteins compared to that observed with danazol.¹¹⁹ An experimental comparison of agonist and progestin treatment in monkeys concluded that the progestin was just as effective as the agonist.¹²⁰

GnRH Agonists in Clinical Use

Position	1	2	3	4	5	6	7	8	9	10
Native GnRH	pGlu	His	Trp	Ser	Tyr	Gly	Leu	Arg	Pro	Gly-NH ₂
Leuprolide						D-Leu				NH-Ethylamide
Buserelin						D-Ser (tertiary butanol)				NH-Ethylamide
Nafarelin						D-Naphthylalanine (2)				
Histrelin						D-His (tertiary benzyl)				NH-Ethylamide
Goserelin						D-Ser (tertiary butanol)				Aza-Gly
Deslorelin						D-Trp				NH-Ethylamide
Tryptorelin						D-Trp				

An uneventful pregnancy with delivery of a normal infant has been reported despite GnRH agonist treatment (monthly treatment with a long-acting agonist was continued through the first two months of pregnancy).¹²¹

As with all other drug therapies of endometriosis, the GnRH agonist provides suppression rather than cure of the disease. The long-term consequences of the hypoestrogenic state on calcium metabolism and bone are of concern. Therefore, treatment is usually limited to 6 months to avoid bone loss, although even during this time period there can be a 6–8% decrease in trabecular bone density. This short-term bone loss is reversed after cessation of therapy, but many patients have not regained the bone that was lost, as much as one year later.^{122, 123 and 124} A study with longer follow-up indicated that bone density was restored by 2 years after 6 months of GnRH agonist treatment.¹²⁵ Because long-term therapy carries with it the concern over a lasting impact on the risk of osteoporosis, consideration should be given to add-back therapy. The addition of a 19-nortestosterone progestin as add-back treatment is effective in decreasing bone loss.^{126, 127 and 128} A postmenopausal estrogen-progestin program can be utilized (conjugated estrogens 0.625 mg daily and medroxyprogesterone acetate 2.5 mg daily or any of the other estrogen-progestin combinations available). This combined add-back treatment is effective for endometriosis and prevents the hypoestrogenic symptoms (especially hot flushes and vaginal dryness) associated with GnRH agonist therapy, including loss of bone.¹²⁹ Other effective options for add-back therapy to prevent bone loss are tibolone (2.5 mg daily) and bisphosphonate treatment.^{130, 131} Endometriosis by itself is not a cause of accelerated bone loss.^{132, 133 and 134}

In well-designed trials, treatment with GnRH agonists has not increased pregnancy rates in women with infertility associated with minimal or mild endometriosis.⁹⁵

Treatment With Gestrinone

Gestrinone, a 19-nortestosterone derivative, decreases the secretion of FSH and LH and has the advantage of requiring only twice a week administration. Used in Europe, it has been as effective as danazol in treating endometriosis.¹³⁵ The clinical side effects are also similar to those seen with danazol. As with other hormonal treatments, gestrinone has been ineffective for the infertility associated with endometriosis.⁹⁵

Recurrence of Endometriosis

Endometriosis tends to recur unless definitive surgery (total hysterectomy and bilateral oophorectomy) is performed. The recurrence rate with medical treatment is approximately 5–20% per year (reaching an overall cumulative rate at 5 years as much as 40%). The recurrence rates 5 years after women were treated with various GnRH agonists were 37% for minimal disease and 74% for severe disease.¹³⁶ After 7 years, 56% of all treated women had a recurrence. In women treated for pelvic pain, the symptoms usually return rather quickly after cessation of medical therapy.^{97, 107} For a period of time after medical treatment, however, the intensity of symptoms is less severe.^{115, 137} **It should be emphasized that pain relief, pregnancy rates, and recurrence rates are similar with all methods of medical treatment.** A randomized clinical trial comparing a low-dose oral contraceptive with a GnRH agonist measured no difference in the recurrence of pain.⁹⁷ The recurrence rates after treatment with GnRH agonists are similar to those after danazol, and both are greater than that obtained with surgical excision. After conservative laparoscopy, approximately 10% of patients experience a recurrence within 1 year, and 20% within 5 years.^{90, 91}

Speculation regarding the reason for recurrence focuses on endometriosis (perhaps microscopic) which escaped detection, incomplete treatment, or reestablishment of primary disease by whatever mechanism is responsible. **The treatment choices and results are no different than when originally confronted.** Successful treatment with total pelvic irradiation has been reported in rare patients who have repeatedly failed standard therapy.¹³⁸

Hormone Treatment After Surgery

Definitive surgery for severe endometriosis, which includes abdominal hysterectomy and bilateral salpingo-oophorectomy as well as resection of all endometriosis, is the only cure for the disease. If oophorectomy is performed, estrogen-progestin therapy at usual doses can be started immediately postoperatively with an essentially negligible risk of inciting growth of residual endometriosis or a return of pain.¹³⁹ **The addition of a progestational agent is strongly recommended because of reported cases of adenocarcinoma in endometriosis tissue in women treated with**

Long-Term Medical Therapy

Long-term medical therapy without surgery is useful in patients with severe symptoms but with little in the way of palpable findings. Before undertaking prolonged therapy, diagnosis should be established by laparoscopy. Prolonged medical therapy also is indicated if symptoms recur after conservative surgery.

Prevention of Infertility

A common clinical problem is the incidental finding at surgery of mild endometriosis in a young woman who has no immediate interest in pregnancy. As previously stated, we favor immediate surgical treatment of visible endometriosis when the opportunity presents itself. Consideration should be given, however, to prophylactic therapy. Combination oral contraceptives to decrease the risk of further seeding are appropriate for treatment of very mild disease, for example a few implants in the cul-de-sac. More advanced disease should be treated with 6 months of medroxyprogesterone acetate, a GnRH agonist, or danazol, followed by oral contraceptives to decrease the risks of progression of the disease. Although not well documented, clinical experience has suggested that continuous oral contraceptives are more effective as prophylaxis than the usual cyclic regimen. Indeed, we favor the continuous regimen without a break for this purpose.

As with all medical treatments, as time passes after treatment, endometriosis emerges. Although spontaneous regression occurs, endometriosis is usually progressive. The risk of endometriosis is reduced in women currently using oral contraceptives; however, effective prophylaxis requires long-term treatment. [144](#) Nevertheless, treatment of endometriosis does have a beneficial impact on the natural history of the disease. Consideration should be given to the prophylactic use of oral contraceptives in women with impressive family histories of endometriosis.

Endometriosis and Spontaneous Miscarriage

Endometriosis has been purported to be associated with an increased risk of spontaneous miscarriage, a risk that is said to be substantially lessened by either medical or surgical treatment. [145](#) In appropriately controlled studies, however, the miscarriage rate was in the normal range in women with endometriosis who were not treated, and it is likely that previous studies were flawed by their choice of control miscarriage rates. [85](#), [146](#), [147](#)

Endometriosis and Ovulation

The frequency of anovulation and luteal phase defects is similar in women with and without endometriosis. [148](#), [149](#) Thus, a woman need not be ovulating in order to have endometriosis. One report has suggested, however, that the success of ovulation induction in women with endometriosis is enhanced by prior treatment with danazol. [150](#)

Endometriosis and Assisted Reproduction

The use of superovulation with intrauterine insemination ([Chapter 30](#) and [Chapter 31](#)) has been reported to increase fecundity rates (as high as 5- or 6-fold) in women with infertility associated with endometriosis. [151](#), [152](#) and [153](#) However, although superovulation raised fecundity rates, it did not raise cumulative pregnancy rates. [154](#) This treatment may accelerate the occurrence of pregnancy without changing overall fertility.

Individuals with mild to moderate endometriosis do as well in in vitro fertilization programs as those with tubal disease. [155](#), [156](#) Although results with severe endometriosis have been poor in the past, more recent experience (perhaps reflecting improved technique and technology) has yielded good pregnancy rates ([Chapter 31](#)). [157](#), [158](#)

A Patient Support Organization

The Endometriosis Association is an international organization that provides education and support for women with endometriosis. Their information prepared for teenagers is especially helpful.

Endometriosis Association International Headquarters
8585 N. 76th Place
Milwaukee, WI 53223

The perception of the degree of male involvement in infertility has undergone a number of revisions during the past 50 years. Initially, infertility was considered primarily a female problem. This notion gave way to the realization that 40–50% of infertility is wholly or in part due to a male factor. More recently, there has been a trend to redefine, in a downward direction, the lower limit of “normal” for a sperm count. Thus, some men who in the past would have been categorized as subfertile now are considered normal.

Despite these changes, there is no doubt that a substantial percentage of infertility is due to deficiencies in the semen. For this reason it is important to be knowledgeable concerning male infertility. It usually depends on the woman's clinician to order and review the results of the initial semen analysis, and to determine the need for urologic consultation. This chapter will consider the analysis of semen and other tests of sperm function, indicate factors responsible for abnormalities of the semen, and consider available treatments for problems of male infertility, including artificial insemination. Influencing the entire field of male infertility is the striking success achieved with intracytoplasmic sperm injection (ICSI), the direct injection of a single spermatozoon or spermatid into the cytoplasm of an oocyte. Men who in the past have been considered hopelessly infertile now have reasonable chances for fertility with the use of ICSI.

Regulation of the Testes

The testes have 2 distinct components, the seminiferous tubules (site of spermatogenesis) and the Leydig cells (source of testosterone). The function of these 2 components requires both pituitary gonadotropins, follicle-stimulating hormone (FSH) and luteinizing hormone (LH). The primary effect of LH is to stimulate the synthesis and secretion of testosterone by Leydig cells (about 5–10 mg per day), an effect that is enhanced by FSH, which also binds to Leydig cells and increases the number of LH receptors on the cells. Increasing levels of testosterone, in turn, inhibit LH secretion, acutely through the hypothalamus and chronically at the pituitary level. This negative feedback action does not require aromatization to estrogen. In men virtually all the estrone and estradiol present is derived from androstenedione and testosterone; there is essentially no direct secretion of estrogen.

FSH, in conjunction with testosterone, acts on the seminiferous tubules to stimulate spermatogenesis. This effect may be mediated by activation of Sertoli cell function, which is controlled by both FSH and testosterone. FSH binds to Sertoli cells and stimulates the production of several proteins, chief of which is ABP, the androgen-binding protein. Spermatogenesis requires a very high local concentration of testosterone and dihydrotestosterone, 50 times higher than that present in the circulation and greater than can be administered exogenously. The ABP is secreted into the tubule lumen and binds testosterone and dihydrotestosterone as they diffuse into the lumen, concentrating the androgens in the seminiferous epithelium for spermatogenesis and in the epididymis for sperm maturation. Spermatogenesis and fertility can occur in men who have an inactivating mutation in the FSH receptor gene, indicating that testosterone can compensate for a deficiency in FSH. ¹

In contrast to the effects of testosterone on LH, steroid hormones at physiologic levels do not suppress FSH secretion. Orchiectomy is followed, however, by a rise in FSH levels. This phenomenon led to the discovery of inhibin. Inhibin B is synthesized in the Sertoli cells in response to FSH, secreted into the circulation, and specifically inhibits FSH secretion in the pituitary. ^{2, 3 and 4} Inhibin has been found in seminal fluid, spermatozoa, Sertoli cells, and Leydig cells. Inhibin A is absent in the circulation of males. The secretion of inhibin B is further modulated by LH, human chorionic gonadotropin (HCG), and testosterone. Undoubtedly, autocrine/paracrine regulation by growth factors and local peptides is involved in a system similar to the complex interaction in the ovarian follicle. ⁵ The Sertoli cells of the testis are analogous to the granulosa cells of the ovary, and the Leydig cells are comparable to the theca cells.

Leydig cells contain receptors for prolactin. Prolactin at normal levels stimulates testosterone secretion, whereas hypersecretion of prolactin leads to reduced testosterone secretion. Although studies suggest that prolactin synergizes with LH and testosterone in the testes, a role for prolactin has not been established for normal testicular function.

The seminiferous tubules and the intraluminal environment are controlled by the Sertoli cells. Tight junctions between the Sertoli cells effectively seal off the tubules, creating the blood-testis barrier. The seminiferous tubules, therefore, are essentially avascular, and regulatory substances must enter by diffusion. The blood-testis barrier protects the germ cells from antigens, antibodies, and environmental toxins. The Leydig cells are in the connective tissue between the seminiferous tubules.

Developing sperm are enveloped by Sertoli cells that influence the sequential process of spermatogenesis. Spermatogonia undergo mitotic division to form the primary spermatocytes, which, in turn, form the haploid (23 chromosomes) secondary spermatocytes by meiotic division. The secondary spermatocytes proceed through a maturation process to the spermatid stage, ultimately becoming the spermatozoa. One X chromosome is inactivated in female somatic cells; however, in the oocyte both X chromosomes are genetically active. The opposite situation prevails in the male where the single X chromosome is genetically active in somatic cells but inactive in spermatogenesis. Normal spermatogenesis is directed by the genes on the Y chromosome, although many required regulating proteins are derived from autosomal chromosomes.⁶

Most of the testis is composed of the tightly coiled seminiferous tubule, which, if uncoiled, would reach a length of 70 cm. Approximately 74 days are required to produce spermatozoa, about 50 days of which are spent in the tubule. After leaving the testes, sperm take 12–21 days to travel the epididymis (which is 5–6 meters long) and appear in the ejaculate. The vas deferens is 30–35 cm in length, begins at the cauda epididymis and terminates in the ejaculatory duct near the prostate. Because of the long development and transit times the semen analysis can reflect events that occurred weeks earlier. The semen is composed of secretions contributed in a sequential fashion, first the prostatic fluid and contents of the distal vas deferens, followed by seminal vesicle secretions.

Semen Analysis

An abstinence period of 2–3 days prior to semen collection is adequate, although some urologists favor 5 days. Increasing the ejaculatory frequency reduces the volume and count but has no significant impact on quality (morphology and motility). The specimen should be collected directly into a clean container and not into a condom because the latter contains spermicidal agents. Sheathes are available that do not contain a spermicidal agent, and they can be used during intercourse if the man cannot, or will not, obtain a specimen by masturbation. Collection of a specimen by withdrawal runs the risk of losing the first part of the specimen that contains the highest concentration of sperm. Ideally, the specimen should be collected in a private room near the laboratory. If collected at home, the specimen should be protected from the cold and delivered to the laboratory within 1 hour of collection.

Semen liquefaction, which occurs 20–30 minutes after ejaculation, is a necessary prerequisite for doing an accurate analysis. On occasion, a specimen does not undergo normal liquefaction or is abnormally viscid, and, if this is associated with a poor postcoital test, it may be a factor in infertility. Techniques used to break up a viscid specimen in preparation for doing a sperm count or for artificial insemination include mechanically dispersing the gel by running the semen repeatedly through a number 19 needle, collecting the semen as a split ejaculate because the first part may be less gelatinous, or, rarely, treating the semen with a proteolytic enzyme. If the postcoital test is normal, however, poor liquefaction and high viscosity are probably not infertility factors.

It has been suggested that the average sperm count has been decreasing over the past 50 years.^{7,8} Environmental toxins, and specifically chemicals with estrogen-like activity (xenoestrogens), have been blamed for this change. However, many studies have failed to document a decline.^{9,10,11} and ¹² Most importantly, infertility has not increased significantly during the periods studied, and this argues that even if a decrease in sperm count has occurred, it is not clinically meaningful.

The World Health Organization (WHO) suggests the following for normal values, but these should be viewed as rough guidelines only.¹³

Volume	2.0 mL or more
Sperm concentration	20 million/mL or more
Motility	50% or more with forward progression, or 25% or more with rapid progression within 60 minutes of ejaculation
Morphology	30% or more normal forms
White blood cells	fewer than 1 million/mL
Immunobead test	fewer than 20% spermatozoa with adherent particles
SpermMar test	fewer than 10% spermatozoa with adherent particles

Defining male infertility on the basis of sperm count or motility is more complicated than suggested by the above criteria. Whereas it is still true that very poor sperm counts (less than 5 million/mL) and very low motilities (less than 20%) indicate compromised fertility, even these low values or lower can, on occasion, be associated

with a pregnancy. Adding to the difficulties of diagnosing male infertility is the variability in count and motility that can be seen in successive semen specimens from the same individual.¹⁴ This is the basis of a fundamental recommendation: at least two, and preferably three, samples should be screened before an individual can be categorized as potentially fertile, subfertile, or infertile (azoospermia). Because it can take 2.5 months for the testes to recover from an insult, it is reasonable to space the specimens over a longer period of time.

There have been conflicting statements in textbooks and articles pertaining to the lower limit of normal for the sperm count. The most commonly cited figures are 60 million/mL, 40 million/mL, 20 million/mL, and 10 million/mL, with the 20 million/mL figure being the generally accepted standard.^{15, 16} Confidence in any figure is limited by the inaccuracies inherent in the methods used for counting sperm. When a group of technicians and pathologists used a counting chamber to do a semen analysis on the same pooled specimen, the mean sperm count was 46.7 million/mL with a range of values lying between 10 and 98 million/mL, giving a coefficient of variation of 37.8%.¹⁷ These inconsistent results are not necessarily remedied with computer-assisted semen analysis (CASA). Significant errors can still occur with CASA, especially with specimens containing low numbers where other cells can be miscounted as sperm.¹⁸

In an attempt to increase the prognostic value of the routine semen analysis, the results of the sperm count and the percentage of motility have been combined to give total motile sperm count (total sperm in the ejaculate x percent motility) or motile sperm per milliliter (sperm per mL x percent motility). The combining of count and motility allows determination of the number or concentration of active sperm and may provide a more informative way to present the data. Males with less than 24 months of infertility and a motile sperm count of greater than 10 million/mL have a higher pregnancy rate than those with 2–10 million/mL motile sperm.¹⁹ Even with motile sperm counts less than 5.1 million/mL, the pregnancy rate was 37.5%.²⁰ However, with counts between 60.1 and 100 million motile sperm/mL, the pregnancy rate rose to 78.6%. Whereas trends are evident, the overlapping results limit the prognostic power of combining sperm count and sperm motility.

Sperm Morphology

Until recently, the evaluation of sperm morphology was beset with the same variations that plague sperm counts. Katz and Overstreet introduced an overlay to use with video microscopy, which allowed a more standardized assessment of morphology.²¹ With this method the coefficient of variation between observers was markedly reduced; 50% of sperm should have normal morphology when assessed with this technique.

Kruger and coworkers championed morphology as the best prognostic indicator for subsequent successful fertilization with in vitro fertilization.²² They utilized “strict criteria” that shift many sperm out of the normal category, by including as abnormal, sperm with even minor abnormalities as well as those with abnormalities of the acrosome. Using these strict criteria, males with greater than 14% normal forms had normal rates of fertilization with in vitro fertilization, whereas those with less than 4% normal forms had fertilization rates of only 7–8%.²² Values between 4% and 14% normal forms were associated with intermediate rates of fertilization. Many andrology laboratories have adopted “strict criteria” for the assessment of sperm morphology. In a dissenting study, the usual criteria for assessment of sperm morphology provided better prognostic information than did assessment by strict criteria.²³ Technicians well trained in using strict criteria can provide highly reproducible results, but the standardization may not be possible on a more widespread scale. Interobserver differences in assessing sperm morphology could be decreased with the utilization of computer-assisted morphometric evaluations.²⁴

Other Parameters

Whereas the count, motility, and morphology of the specimen constitute the major parameters on which the male's fertility is categorized, there are other characteristics of the semen that may impact on fertility potential. A volume of less than 1 mL may be too small to make contact with the cervix, and a volume greater than 7 mL may dilute the sperm concentration so that insufficient numbers are in close proximity to the cervix.

Round cells in the specimen can be either white cells or immature cells, and these look similar in wet preparations. The WHO standards manual states that a normal ejaculate should not contain more than 5 million round cells per mL (5 per high power field) while the number of leukocytes should not exceed 1 million per mL.¹³ There are staining methods, biochemical tests, and immunologic techniques to differentiate immature cells from white cells.²⁵ In laboratories where these tests are not performed, all round cells are lumped together and reported as white blood cells. It is reasonable to obtain a culture, perhaps by prostatic massage, when the report states that there are 5 or more white cells per high power field, even though some of these may be immature cells, and the presence of white cells does not always correlate with infection.

Repetitive agglutination of sperm (except when it is on pieces of debris) is suggestive of an immunologic effect or an infection. It can, however, be nonspecific and of no significance. Although it is common practice to evaluate the pH of semen because abnormalities may provide a clue to disorders of the accessory glands, in practice this measurement is of little value.

Tests of Sperm Function

Although all of the major elements of the semen analysis (numbers, motility, and morphology) have some bearing on fertility, especially when markedly deficient, the lack of precise correlations has led to a search for tests of the functional capacity of sperm. Despite enthusiasms generated by a variety of assays over the past 4 decades, no test has emerged as a reliable standard for the fertilizing ability of sperm. One problem is that the functional tests individually measure only one aspect of the many functions performed by sperm, whether it is attachment to the zona, penetration of the egg membrane, or the release of enzymes. Recently, there has been a trend in centers of assisted reproductive technologies to dispense with functional tests because the ultimate end point of fertilization of the human egg can now be tested by ICSI. If the functional tests were better prognosticators and less cumbersome to perform, they still could play a role in clinical practice. For example, a couple with unexplained infertility and an abnormal result might consider donor insemination as a therapeutic option.

Sperm Penetration Assay (SPA)

The zona pellucida of most mammalian species presents not only a block to polyspermia but also a barrier to fertilization of an egg by sperm of a different species. However, foreign sperm can fuse with and penetrate an egg if the zona is removed by gentle enzyme digestion. In the sperm penetration assay, eggs are collected from superovulated golden hamsters, the zonae are removed by enzyme digestion, and the denuded eggs are cultured for 2–3 hours with human sperm that have been washed and incubated overnight in culture media.²⁶ Presence of a swollen sperm head in the egg cytoplasm is evidence of successful penetration. Most laboratories report the percentage of eggs penetrated and compare this figure to the percent penetrated by a known fertile sperm specimen (some laboratories use the criterion of number of sperm penetrations per egg with 2 or more considered normal).

Whereas the concept of the SPA as a measure of sperm fertilizing ability is an attractive one, the practical aspects of the test have hindered its standardization. For example, the source of the albumin used as the protein supplement in the media can influence the result as can use of resuspended compared to swim-up sperm. Moreover, an individual's results in the SPA can vary over time. In addition, different laboratories utilize different cutoff points for the lower limit of normal penetration with the most common points being 0, 10, 14, and 20%.

Equally important has been a continuing controversy over the prognostic value of the test. A meta-analysis concluded that the test was not of value.²⁷ Other authors, however, have found correlations with eventual fertility. An SPA result of greater than 19% was associated with a pregnancy rate of 48%, whereas below 20% eggs penetrated was associated with a pregnancy rate of 20%.²⁸ However, even with an SPA of 0%, the pregnancy rate in this series was 16%. Thus, failure of the sperm to penetrate the hamster egg is not an absolute indication that the sperm cannot penetrate the human egg. Because of this limitation of the SPA, attempts have been made to optimize the test with a goal of eliminating these false-negative results. Strategies to eliminate or to lower the number of false-negative tests include treatment of sperm with follicular fluid, test yolk buffer, calcium ionophore, miniaturizing the test, and adjusting the concentration of albumin or the ions in the culture media.^{29, 30} With any of these maneuvers an SPA showing no or low penetration is a more accurate (although not 100%) indicator of poor sperm fertilizing ability. If an optimized SPA has zero penetration, the couple should be given the option of considering use of donor sperm or ICSI. In contrast to the problems with low SPAs, normal levels of sperm penetration correlate quite well, although not absolutely, with human fertilization in vivo and in vitro.

If there is a place in clinical practice for the SPA, it is to identify abnormalities of sperm not evident by studies of count, motility, or morphology. In cases of unexplained infertility, this could shorten the time period before pursuing either donor insemination or ICSI.

Human Zona Binding Assay

Whereas the SPA tests the ability of sperm to penetrate or to be engulfed by the egg, it does not test the critical ability to pass through the zona pellucida. The zona is, of course, removed in preparation for the SPA because it is, with rare exceptions, impervious to foreign sperm. Thus, to test zona penetrating or zona binding ability of human sperm requires the use of human zonae. One approach is to use zonae obtained from surgically removed ovarian tissue and slit them in half so that both patient sperm and donor sperm can be tested in parallel on different portions of the same zona.³¹ The ratio of the number of sperm bound for the test subject to the number of sperm bound for fertile control sperm has been labeled the hemizona assay index (HZI). A breakpoint at an HZI value of 36 has provided a good correlation with results in human IVF.³² The limited availability of zonae and the technical requirements of the assay will always restrict its application to a small number of committed laboratories. In the future, the development of materials that mimic the properties of the zona could lead to simpler tests. However, the widespread use of ICSI, which bypasses the zona, renders such tests superfluous, unless they can determine with certainty which couples require ICSI.

In Vitro Tests of Sperm Penetration into Mucus

Some of the vagaries of the postcoital test can be eliminated by use of in vitro testing with bovine cervical mucus or an artificial mucus. A drop of sperm is placed next to mucus on a slide and progression of sperm into the mucus monitored through a microscope. To better standardize the test, tubes filled with bovine cervical mucus, available commercially, can be utilized and the length of mucus traversed by the sperm measured. One problem is that antibody-affected sperm are not handicapped in moving through bovine mucus, whereas they usually move poorly in human cervical mucus. Because couples with poor postcoital tests and those with unexplained infertility will almost always be treated with intrauterine inseminations of washed sperm (IUI), with or without gonadotropins, there is little practical value for the in vitro sperm mucus tests in current practice.

Assessments of Sperm Motility

A sperm quality analyzer uses an electro-optical method to provide an assessment of the number of motile sperm in a specimen and, to some extent, the quality of the motility.³³ This test provides some indication of the functional capacity of the sperm, but it has not gained widespread use.

Measurement of Sperm Velocity

The CASA systems are best at supplying information on sperm velocity and specific movements, such as lateral head displacement. However, it is unlikely that these measurements provide information that cannot be obtained with less expensive methods. The computer printouts of multiple measurements by CASA instruments provide a wealth of information, but little that is of current value for the clinician.

Hypo-osmotic Swelling Test

When sperm are placed in a hypo-osmotic solution of sodium citrate and fructose, a sperm tail with normal membrane function will swell and coil as fluid is transported across the membrane.³⁴ Conversely, if there is a functional disturbance of the tail membrane, the tail will appear unaffected. This test has been scrutinized by a number of investigators with no clear-cut decision regarding its clinical usefulness. A specific niche has been suggested for the test. Non-motile sperm, but positive with the hypo-osmotic test, may provide better results with ICSI than those obtained with non-motile and hypo-osmotic negative sperm.³⁵

Measurement of Adenosine Triphosphate (ATP)

ATP is an important component of sperm metabolism related to tail movement. In one report, levels of ATP in semen were a strong discriminator between populations of fertile and infertile males.³⁶ A multicenter study sponsored by the World Health Organization concluded, however, that levels of semen ATP could not predict the occurrence of pregnancy when the female was normal and the male partner had a sperm concentration greater than 20 million/mL.³⁷

Measurement of the Acrosome Reaction

The acrosome reaction that allows the release of enzymes from the acrosome (see [Chapter 7](#)) occurs on or near the zona pellucida. However, a low percentage of sperm will also become reactive while in media or following treatment with a calcium ionophore that induces capacitation. Although the artificial initiation of the acrosome reaction has been correlated with IVF results, the relatively small difference in acrosome-reactive sperm in the different groups indicates that this approach is not clinically important.³⁸

Measurement of Acrosin

Acrosin is a proteolytic enzyme associated with the acrosome that may be important for aiding sperm to traverse the zona.³⁹ Low acrosin concentrations could be associated with infertility. Although theoretically appealing, the test has little application in clinical practice.

Sperm Antibodies

Whereas the previous assays measure sperm function or sperm numbers, sperm antibody tests determine reactions to sperm. It has been known for more than 100 years that animals, both male and female, can be rendered infertile by immunization with sperm.⁴⁰ Semen is very antigenic and, fortunately, is normally isolated from the immune system by the blood-testis barrier. Disruption of this anatomic and functional barrier in the seminiferous tubules can lead to antibody formation; hence antibody production in the male can follow vasectomy, testicular torsion, infections, or trauma. In addition, there are women who have allergic reactions to semen manifested by reactions as diverse as irritation of the vagina and cardiovascular collapse following intercourse. The basic question is whether more subtle immunologic reactions can occur that interfere with fertility.

Initial efforts to detect sperm antibodies involved incubating sperm in the sera of both males and females with agglutination being the endpoint. Despite the fact that substantial agglutination of sperm in semen on a repetitive basis is an indication of the presence of antibodies, agglutination in serum often is nonspecific. Thus, testing with serum alone has been abandoned.⁴¹ It is now recognized that sperm antibodies in the circulation of men or women have no influence on fertility.^{42, 43}

The two most widely used tests for sperm antibodies use immunologically mediated attachment of particles or beads to sperm that are assessed with a microscope.⁴⁴ The immunobead test uses beads labeled with anti-IgG, anti-IgA, or anti-IgM, and, thus, it provides identification of the class of antibodies on the sperm. The site on the sperm where the beads are adherent also can be noted. Anti-IgA usually localizes to the tail and anti-IgG to the head of the sperm. Antibody localized only to the tip of the tail usually is not significant, whereas antibody on the rest of the tail may interfere with sperm motility. Antibodies on the head of the sperm can cause failure of fusion with the egg. A second test, the mixed agglutination test (SpermMar), uses antibody to IgG to bridge antibody-coated sperm and latex particles that have been conjugated with human IgG. The endpoint in this test is clumping, and the reactions against individual segments of the sperm cannot be identified. The SpermMar test can be used on unprepared semen, as opposed to the immunobead test where sperm washing is required.

With the SpermMar test, the diagnosis of immunologic infertility is suggested when 10–39% of motile sperm are attached to the particles, whereas immunologic infertility is very probable when 40% or more of the motile sperm are covered with beads. Using the immunobead test, when over 50% of sperm were antibody-bound, the subsequent pregnancy rate was 15.3%, whereas when the percentage of sperm positive for antibody was less than 50%, the pregnancy rate was 66.7%.⁴⁵ Others have used a cut off of 20%, and it is not clear at this time which is the more valid number.¹³

An additional difficulty in diagnosing immunologic infertility is the fluctuations in antibody levels even without therapy. In males receiving a placebo, 58% had a decrease in sperm-bound immunoglobulins.⁴⁶

A high percentage of positive sperm antibody tests is associated with poor postcoital tests, and it would seem cost-effective to initially screen for antibodies only in individuals whose postcoital tests show no sperm, all dead sperm, a high percentage of shaking sperm, or less than 3 motile sperm per high power field. This latter

number is somewhat arbitrary, and some may choose to use less than 5 or even less than 1 as the cut off value.

Because both unexplained infertility and immunologic infertility are treated with intrauterine inseminations, the usefulness of sperm antibody testing is limited.

Treatment of Sperm Antibodies

Use of condoms to avoid contact between sperm and the female with antibodies has been abandoned because of lack of efficacy. The current office treatments for sperm antibodies in the male are the use of steroids or, preferably, intrauterine inseminations with prepared specimens.^{47, 48} In an alternative, but experimental, treatment, the sperm are separated on Percoll gradients, and then incubated with antibody beads.⁴⁹ A population of sperm without antibody can be separated from the mix and utilized for insemination.

Moderate to high doses of corticosteroids have been used to treat sperm antibodies in the male. Reports of efficacy in reducing antibody levels and marginal increases in pregnancy rate have been balanced by sporadic reports of serious side effects such as aseptic necrosis of the femoral head and less severe side effects such as irritability.⁵⁰

A more popular therapeutic approach is the intrauterine insemination of washed spermatozoa in conjunction with gonadotropin treatment (superovulation) of the female.^{47, 48, 51} Determination of the efficacy of this treatment has been hindered by difficulties in deciding what constitutes a positive sperm antibody test in the female and reports that lumped together patients who were antibody positive with others who may not have been afflicted with antibodies but who had poor postcoital tests. Nevertheless, the reported pregnancy rates warrant several cycles of IUI-superovulation before considering the more expensive methods of assisted reproduction.

Use of in vitro fertilization is a reasonable final approach to the treatment of sperm antibodies. Success with in vitro fertilization is reduced in couples with sperm antibodies, but once fertilization occurs, the probability of pregnancy is not affected.⁵² The results with ICSI are very good, even in the presence of high levels of antisperm antibodies.⁵³

Donor insemination should be considered as an alternative to the more expensive methods of assisted reproduction.

Investigation and Treatment of Male Infertility

If the semen analysis is abnormal, inquiry should be made concerning the presence of the following factors, any of which can produce abnormal sperm quality and quantity.

1. History of testicular injury, surgery, or mumps.
2. Exposure to excessive heat. A small rise in scrotal temperature can adversely affect spermatogenesis, and a febrile illness can produce striking changes in sperm count and motility. The effect of the illness can be seen in the sperm count and motility even 2–3 months later. This reflects the 74 days required for a spermatozoon to be generated from a primary germ cell. Environmental sources of heat, such as the use of jockey shorts instead of boxer shorts, excessively hot baths, hot tubs, or occupations that require long hours of sitting; e.g., long distance truck driving, may all decrease fertility potential; however, none of these factors has ever been substantiated by clinical study.⁵⁴
3. Severe allergic reactions.
4. Exposure to radiation or to industrial or environmental toxins Those who believe there is a downward trend in sperm counts commonly place blame on environmental pollutants or chemicals, including chemicals that mimic the effects of estrogen. A study from Scandinavia did show lower sperm counts in males from an urban area compared to males in rural areas, suggesting an effect of urban pollutants.⁵⁵ More direct evidence of a deleterious effect of environmental hazards is difficult to obtain because there is a reluctance of workers to produce the serial semen specimens that would be required for a thorough industrial study. In any case, the clinician should determine if a male with an abnormal semen specimen has had exposure to industrial or environmental toxins.
5. Heavy marijuana and alcohol use can depress sperm counts and testosterone levels. Marijuana inhibits the secretion of GnRH and can suppress reproductive function in both men and women, and cocaine use is known to reduce spermatogenesis.^{56, 57} There is no evidence to indicate that moderate alcohol intake affects fertility.⁵⁸ There is good evidence that fecundity is reduced in women who smoke, and this is probably true for men as well, although not all studies agree.^{59, 60 and 61} Studies have failed to confirm an adverse impact of caffeine on fertility, although high levels of intake may be associated with a delay in conception.^{62, 63}

Certain drugs, including cimetidine, spironolactone, nitrofurans, sulfasalazine, erythromycin, tetracyclines, anabolic steroids, and chemotherapeutic agents, can depress sperm quantity and quality. Cephalosporins, penicillins, quinolones, and the combination of sulfamethoxazole and trimethoprim are relatively safe to use when there is concern about effects on sperm.⁶⁴ Neurologic ejaculatory dysfunction can be caused by α -blockers, phentolamine, methyl dopa, guanethidine, and reserpine. Resumption of spermatogenesis has been reported to occur within 2 years following discontinuation of anabolic steroids; however, it is not known whether all individuals will return to normal function.⁶⁵

6. Coital frequency. Counts at the lower levels of the normal range may be depressed to below normal levels by ejaculations occurring daily or more frequently. Conversely, abstinence for 10–14 days or more to save up sperm may be counterproductive because the gain in numbers can be offset by the lower motility produced by the increased proportion of older sperm. For most couples, coitus every 36 hours around the time of ovulation will give the optimal chance for pregnancy. However, studies in men with oligospermia fail to detect a decline in sperm numbers with sequential ejaculations, suggesting that limitations on coital frequency are not necessary.^{66, 67}
7. Exposure to diethylstilbestrol in utero has been suggested, but not proven, as a cause of male infertility.⁶⁸ Indeed, in the largest follow-up of men born to the women treated with diethylstilbestrol, no impairment of fertility or sexual function was detected.⁶⁹

Urologic Evaluation

In the presence of semen abnormalities, referral is made to an urologist in order to look for an anatomic abnormality, an infection, an endocrine or genetic disorder, or a varicocele. Evaluation by an urologist detects serious medical pathology (such as a tumor) in approximately 1 of every 100 patients.⁷⁰

Anatomic Abnormalities

Examination may reveal a physical impairment such as a marked hypospadias, which can cause sperm to be deposited outside the vagina. In rare cases of diabetes, with some neurologic diseases, or occasionally following prostatectomy or pelvic lymphadenectomy, there can be retrograde ejaculation into the bladder. Pregnancies have been reported after insemination of sperm obtained from alkalinized urine or following treatment with a variety of drugs.⁷¹ Retrograde ejaculation may be only partial, and some men with this condition have small amounts of visible ejaculate.

Obstruction or absence of the vas deferens is a relatively uncommon cause of male infertility. If the ducts are congenitally absent, fructose which is produced in the seminal vesicles will be absent from the semen. Testicular biopsy can differentiate between a block in the outflow tract or primary damage to the testes. Testicular damage or maldevelopment can be found following mumps orchitis, cryptorchidism, or in association with Klinefelter's syndrome. Males with the latter genetic abnormality (XXY) usually have small testes and azoospermia. With blockage of the vas, sperm can be aspirated from the epididymis and vasa efferentia. Successful fertilization in vitro can result in pregnancy.⁷²

It is important that any infection in the genitourinary tract, including those caused by mycoplasma and chlamydia, be treated even though the specific effect on male fertility is not established.

Genetic Causes of Male Infertility

There is a high prevalence of Y chromosome submicroscopic deletions in men with oligospermia. A cluster of genes that are deleted in men with azoospermia or

oligospermia has been referred to as DAZ ("deleted in azoospermia").^{73, 74} Subsequently, at least 3 specific regions on Yq were identified and labeled as "azoospermia factors," AZFa, AZFb, and AZFc (the same region as DAZ).⁷⁵ From 7% to 10% of men with severe oligospermia have been reported to have deletions in the AZFb and AZFc regions on the long arm of the Y chromosome.^{76, 77} These microdeletions correlate poorly with the numbers of sperm present in the semen analysis. These could be normal genetic variants and not the cause of the infertility; however, these deletions can now be transmitted with the use of ICSI, and it is now appropriate to consider Y chromosome deletion analysis prior to treatment with assisted reproduction. On the other hand, Y chromosome deletions are rare in men participating in an ICSI program. Indeed, the prevalence of overall chromosomal abnormalities is greater in men with abnormal semen than the prevalence of Y chromosome microdeletions.^{78, 79} Although these genetic abnormalities are relatively infrequent, and there is uncertainty regarding the role of Y chromosome microdeletions, because of the consequences, there is strong support for genetic screening of all men considering ICSI.⁸⁰ Indeed, 90% of couples receiving genetic counseling elect to undergo genetic screening.⁸¹

Approximately 1–2% of infertile males have the congenital bilateral absence of the vas deferens.⁸² Most males with bilateral congenital absence of the vas deferens have at least two mutations in the cystic fibrosis transmembrane conductance regulator gene.⁸³ Screening for cystic fibrosis mutations should be considered in males with bilateral absent vas deferens who are considering ICSI. A reasonable approach involves screening the female partner; the absence of cystic fibrosis mutations in the female reduces the risk of having a child with cystic fibrosis to a very low level.

Primary ciliary dyskinesia refers to a group of disorders with autosomal inheritance and caused by abnormal or absent motility in ciliary structures. Kartagener syndrome includes sperm immotility, bronchiectasis, sinusitis, and situs inversus.

The presence of azoospermia or severe oligospermia with an intact vas warrants karyotyping. The most frequent diagnosis is Klinefelter syndrome, which occurs in approximately 1 in every 500 males. Among other genetic abnormalities, azoospermia and hypogonadism can result because of a mutation that causes an abnormality in the beta-subunit of LH.⁸⁴ An inactivating mutation in the gene for the FSH receptor is associated with varying degrees of suppression of spermatogenesis, indicating that FSH is not absolutely essential for sperm production.¹

Endocrine Disorders

Although endocrine disorders are an uncommon cause for infertility, testing for thyroid, gonadotropins, prolactin, and testosterone may occasionally uncover unsuspected abnormalities. FSH levels are elevated with germ cell aplasia, and testosterone levels are decreased in men who are hypogonadotropic. Hyperprolactinemia is commonly associated with impotence, and in the absence of impotence, measuring a prolactin level is unlikely to aid in the diagnosis.

Infusion of gonadotropin-releasing hormone (GnRH) can stimulate secretion of gonadotropins, and there have been occasional reports of the usefulness of this treatment as well as the administration of gonadotropins in males who have an isolated gonadotropin deficiency. Although nonspecific therapy with thyroid, clomiphene citrate, and human chorionic gonadotropin has been used extensively, there is no compelling evidence that it is beneficial. Clomiphene citrate can elevate the sperm count, but an associated increase in fertility does not occur.⁸⁵

A fundamental problem in most studies of the efficacy of drug therapy in male fertility is the lack of a control group for comparison. Investigators make the erroneous assumption that the spontaneous cure rate of male infertility is zero and that any pregnancy that occurs during or following treatment is due solely to that treatment. A number of studies, however, have attested to the spontaneous cure rate of male infertility. In one study approximately one-third of males, with counts below 10 million/mL and who were not treated, successfully impregnated their partners.¹⁶ In summary, hormone treatment of infertile males who do not have an endocrine disorder is almost always unrewarding, and it does not improve fertility beyond what occurs by chance.

Varicocele

A varicocele is an abnormal tortuosity and dilatation of the veins of the pampiniform plexus within the spermatic cord. Approximately 20% to 40% of infertile males, depending on the zeal of the search, have a varicocele, usually on the left side because of the direct insertion of the spermatic vein into the renal vein. Varicoceles, in all likelihood, exert their effects by raising testicular temperature, an effect mediated by increased arterial blood flow.⁸⁶

Approximately 10–15% of males in a general population have a varicocele on physical examination, but there is no evidence that males with normal semen characteristics need treatment even if a varicocele is present. They should be checked periodically, however, to be sure that there is no deterioration in their semen characteristics.

It has been difficult to perform randomized studies of varicocele repair. A trial in Melbourne, Australia, failed because of poor compliance.⁸⁷ Because the authors told their patients that varicocele repair might not make a difference, only 283 of 651 men chose to have it done. In those who had the repair, the only impact on the semen analysis was an improvement in motility from 33.5% to 39.3%, the classically reported finding. The same change, however, was noted in the nonoperated group, and the pregnancy rates in both the operated and nonoperated groups were the same! A small randomized trial in Germany observed a significant increase in sperm concentration in the treated group, but the pregnancy rates were the same in both treated and non-treated groups.⁸⁸ However, varicocele is more commonly found in men with abnormal semen, and there is evidence that a varicocele may exert an increasingly deleterious effect over time.⁸⁹

Ligation of varicoceles results in a 30–35% pregnancy rate. Although the beneficial effects of treatment of varicocele have been disputed by some investigators who found equal results without treatment, current clinical practice supports the utilization of varicocele ligation in those males who have infertility and an impaired semen specimen.⁸⁶

Larger varicoceles exert a greater effect than small ones. Very small varicoceles, diagnosed only by ultrasound, are not worth treating. Decreased size of the left testicle together with a varicocele is associated with a worse prognosis with treatment compared with cases in which the testicles are of normal size. Although surgical interruption of the internal spermatic vein is the usual treatment for clinically apparent varicoceles, there is also a nonsurgical approach that utilizes embolization to occlude the vein.⁸⁶

Reactive Oxygen Species

Increased levels of reactive oxygen species can cause damage to the sperm membrane.⁹⁰ Substances such as peroxidase and hydrogen peroxide can be released by abnormal sperm and by white blood cells, and when elevated levels of leukocytes are present in the semen (with a negative culture), treatment with vitamin E and glutathione is advocated.^{91, 92}

Intrauterine Insemination of Washed Sperm (IUI)

Inseminations of whole semen have a limited role in infertility. They are useful when, either because of physical or psychologic factors, it is not possible to deposit sperm in the vagina by intercourse. In addition they are obviously useful in donor insemination. In the past small amounts of untreated semen were used for intrauterine insemination, but the potential for reactions to the proteins, prostaglandins, and bacteria in semen have made this approach a historical relic. In its place has emerged the use of washed sperm for intrauterine insemination (IUI).

The initial indications for IUI were failure of sperm to penetrate cervical mucus and male infertility. During the past decade the indications for IUI have been liberalized and now it is frequently employed, often in conjunction with the woman's use of clomiphene citrate or gonadotropins. Current controversies revolve around issues of techniques and those of efficacy.

There are a variety of methods that allow the separation of a more promising population of sperm. Most commonly used are washing and swim-up or resuspension of sperm or separation of sperm on density gradients. Other methods include allowing the sperm to swim into hyaluronic acid or filtering the sperm on glass wool. All isolate a population of sperm with a higher percentage of motile forms and with a more uniform morphology than those found in untreated ejaculates. In the swim-up techniques, the semen is washed once or twice with one to three volumes of culture medium. A variety of media is available from commercial suppliers. After washing and centrifugation the supernatant is decanted and the pellet overlaid with 0.5 mL media. At this point the pellet is agitated to resuspend the sperm and the preparation is inseminated into the uterus. Because of the resuspension, the live sperm in the inseminate are accompanied by dead sperm and miscellaneous cellular

elements. In the alternative swim-up technique, the unagitated pellet and overlying medium are placed in an incubator at 37° for 30–60 minutes. This provides lower numbers of sperm in the medium portion compared to the resuspension technique, but it achieves a cleaner specimen and for this reason it is the method we prefer. However, with severely oligospermic specimens it may be necessary to use resuspension to obtain sufficient sperm for insemination.

Whereas all sperm separation methods produce specimens with better motility and more uniform morphology, this improvement may not necessarily translate into increased pregnancy rates. When equal numbers of motile sperm separated from good and from poor specimens were used in the sperm penetration assay, sperm separated from the good specimens were superior in achieving penetration.⁹³ Thus, there may be intrinsic defects in sperm from poor specimens that may affect even the best sperm from that cohort.

At least 1 million motile sperm should be inseminated because lower numbers are seldom associated with success.⁹⁴ When more than 15 million motile sperm were inseminated, there was no increase in the pregnancy rate; however, there was an increase in multiple births when the inseminate exceeded 20 million motile sperm.⁹⁵ In another study, pregnancy rates were substantially higher when more than 10 million motile sperm were inseminated compared with inseminations of less than 10 million.⁹⁶ Others have also reported increased pregnancy rates when higher numbers of donor sperm were inseminated.⁹⁷ Important factors in determining the final motile sperm count are the initial sperm count and sperm motility. Combining two ejaculates obtained 4 hours apart can increase the numbers of sperm available from oligospermic specimens.⁹⁸

Empiric therapy, consisting of clomiphene alone, gonadotropin alone, IUI, or IUI combined with clomiphene or gonadotropin, in the female increasingly has been used for treatment of infertility of any origin. The greatest enthusiasm supports IUI combined with gonadotropin, which offers a number of possible advantages. It increases the number of oocytes that have the potential for fertilization and increases the number of sperm reaching the uterine cavity. It raises the woman's hormone levels and eliminates seminal plasma, that may contain factors inimical to sperm. The enthusiasm was fueled not only by these postulated advantages of gonadotropin-IUI but by a series of positive reports that appeared in the literature in the late 1980s and early 1990s. In a population selected for male factor infertility or poor postcoital tests, superovulation combined with IUI increased the monthly probability of pregnancy approximately four times compared to that following IUI timed by the LH surge.⁹⁹ The most striking advantage was seen in the subgroup of women who were treated with gonadotropin and HCG rather than clomiphene alone or clomiphene-gonadotropin/HCG combinations. Another study in couples with unexplained infertility demonstrated a pregnancy rate per cycle of 2.7% with IUI alone, 6.1% with gonadotropin alone, but 26.4% when gonadotropin/IUI was used.¹⁰⁰ Very similar experiences have been reported by others (see [Chapter 30](#)).¹⁰¹ Dodson and Haney surveyed the literature and found that gonadotropin and IUI fecundity was 8.7% for male factor and 17% for unexplained infertility.¹⁰² Their own experience, which was included in the survey, was 15% for each category.

Our current formulation concludes that IUI without associated superovulation has little value in the treatment of male infertility. Gonadotropin-IUI marginally increases the pregnancy rate to approximately 7–8% per cycle (from a baseline of 2–3% per cycle) when an abnormality is present in the semen. Several treatment cycles are warranted, except in the presence of severely compromised semen specimens, where an early resort to ICSI is indicated.

The timing of inseminations and the number of inseminations per cycle may influence the ultimate pregnancy rates. Most commonly IUI is timed for the day following the LH surge measured in the urine or at approximately 36 hours after an injection of human chorionic gonadotropin (HCG). Variations on these schedules can still be associated with reasonable pregnancy rates. Increased pregnancy rates have been obtained by doing two IUI's in a cycle, the day of and the day after the LH surge or the ovulatory injection of HCG.^{103, 104} Others have reported no difference in results with one or two IUIs.¹⁰⁵ Because of the lesser expense and the greater convenience, we perform one insemination for several cycles before considering multiple inseminations.

Prior down-regulation with GnRH agonist treatment does not enhance results with gonadotropin/IUI.¹⁰⁶ Similarly, intraperitoneal or intratubal inseminations of sperm, although conceptually attractive, have no proven advantage over intrauterine insemination.¹⁰⁷ Moreover, intratubal transfer could increase the risk of infection. Infection with IUI is rare, probably in the range of 1 in 500 inseminations. Multiple pregnancies occur in approximately 20% of cases of gonadotropin/IUI, and the pregnancy loss rate is approximately 20%. Hyperstimulation of the ovaries can be minimized, but not eliminated, by monitoring of ovarian follicle numbers and growth by ultrasound (reviewed in [Chapter 30](#)). The cycle should be canceled by withholding HCG if more than 3–4 follicles with diameters of 14 mm or greater are present when the lead follicle size (18 mm or larger) indicates the time for HCG injection. Estrogen monitoring is not usually required, as opposed to IVF cycles where stimulation is more aggressive.

Estrogen monitoring can be helpful if a lead follicle displays an abnormal rate of growth, either too fast or too slow. A value of less than 200 pg/mL per mature follicle raises the suspicion that a follicle does not contain a normal oocyte. If there are excessive numbers of small follicles (10–13 mm) associated with 3 or 4 leading follicles, a high estrogen level (over 2000 pg/mL) indicates an increased risk of hyperstimulation, and HCG administration should not occur.

Treatment of sperm with methylxanthines such as caffeine and pentoxifylline seem to enhance motility. The compounds inhibit cyclic AMP phosphodiesterase which results in an increase in cyclic AMP. Despite some earlier enthusiasm, pentoxifylline offered no advantage in an IVF program, and a cautionary note was raised because the safety of the compound in early pregnancy has not been established.¹⁰⁸

Therapeutic Donor Insemination

The combined problems of male infertility and decreased availability of adoptable babies have increased the interest in, and the demand for, therapeutic donor inseminations (TDI). The procedure raises emotional, ethical, and legal questions that must be considered and discussed. The clinician must never do inseminations without the consent of both partners. Increasingly, single women are seeking TDI. McGuire and Alexander¹⁰⁹ reported that children in single head of household families are as psychologically adjusted as those from two-parent households and that TDI should not be denied to single women solely on the basis of their lack of a male partner.

Three points are worth emphasizing.

1. Donor inseminations do not guarantee pregnancy. In the past, the success rate with fresh semen was about 70% over 5–6 cycles. The current use of frozen semen lowers the success rate.^{110, 111} The fecundability (chance of getting pregnant per cycle) has been reported to be 18.9% with fresh semen and only 5.0% with frozen semen.¹¹⁰ However, with exceptionally good frozen specimens, success can approach that achieved with fresh specimens. Over 80% of pregnancies that will occur do so within 6 months with fresh semen and within 12 months with frozen semen. In a summary of nearly 3000 treatment cycles with frozen sperm, the cumulative pregnancy rates were 21% at 3 months, 40% at 6 months, and 62% at 12 months for women less than 30 years old.¹¹² For women over the age of 30, the pregnancy rates were 17%, 26%, and 44%, respectively. Because of the risk of acquired immunodeficiency syndrome (AIDS), use of frozen sperm that has been quarantined for 6 months is now accepted clinical practice. The donor is tested for HIV at the time of collection and again at 6 months. In highly selected cases, washed, swim-up sperm for intrauterine insemination from an HIV-infected man has been used to achieve a healthy pregnancy in his partner.¹¹³ Despite an absence of seroconversion of the female partner, the full safety of this approach has not been established. Of course, sperm prepared in this manner should not be used in a donor program.
2. The couple needs to give some thought to their feelings should the child be born with a congenital anomaly. This will occur in 4–5% of all pregnancies, irrespective of whether they follow intercourse or therapeutic donor insemination.¹¹⁴
3. Both the woman and her partner, or the woman alone if there is no partner, should sign a consent form. The procedure is covered by law in many, but not all, states. It is worthwhile for the clinician to know the legal status of TDI in his or her state so that correct information can be conveyed to patients.

As a rule the donor should be unknown to the couple. However, there has been discussion of sealing personal information on the donor with the understanding that, if he gives permission, the information can be conveyed to children conceived with his sperm, when those children reach adulthood.

The health and fertility of the donor must be unimpeachable, and there should be no family history of genetic diseases. Screening for thalassemia in Mediterranean races, Tay-Sachs heterozygosity in Jews, and sickle cell disease in blacks is a wise precaution. Donors can also be tested for cystic fibrosis. Potential donors who are at high risk for AIDS (homosexuals, bisexuals, intravenous drug users) should be excluded as should individuals who have multiple sexual partners. Similar exclusions include those individuals with histories of herpes, chronic hepatitis, and venereal warts. In addition, testing is recommended for human immunodeficiency virus (HIV), syphilis, hepatitis B antigen, antibody to hepatitis B, hepatitis C, gonorrhea, chlamydia, and cytomegalovirus. As noted above, an initial screening test for HIV, if negative, should be repeated after 6 months. If both results are negative, the semen, which should be cryopreserved and quarantined for the 6 months, can be used. The donor will not be a mirror image of the male partner, but an attempt should be made to match physical characteristics.

Most individuals undergoing TDI consider it a private matter and not subject to discussion with family and friends. If successful in achieving pregnancy, some individuals discuss the origins of the conception with their children, but most people prefer to leave it unsaid.

Use of friends or relatives as donors raises the potential for emotional problems in the future, although we have used a relative when it was requested by a stable, intelligent couple who understood the long-term implications. The related donor must be subjected to the same laboratory screening as all other donors. Requests to mix the partner's sperm with the donor's signifies that the couple may not have made the emotional adjustment to the thought of donor insemination. A partner's semen also may impair the donor's sperm, although this is in dispute.

Donor inseminations are useful in azoospermia, severe oligospermia, or asthenospermia refractory to treatment. They also are useful for the rare woman who has a history of fetal loss due to Rh sensitization. In that case an Rh-negative donor would be used. Genetic diseases may, on occasion, be an indication for donor insemination.

The basal body temperature (BBT) change, the woman's perception of vaginal wetness, and ovulatory pain, if present, are useful guides for timing of inseminations. More precise timing can be accomplished by monitoring of the day of the LH surge with measurements of LH in urine with any of a number of commercially available kits. In our experience approximately 75% of women can successfully use the kits at home to identify their LH surge. Insemination is performed the day after the LH surge is identified. In more difficult cases, monitoring and treatment approaches utilize ultrasound to monitor preovulatory follicle growth and an injection of 5000 or 10,000 IU human chorionic gonadotropin when the dominant follicle reaches 18 mm or greater in diameter.

If the BBT alone is used, an attempt is made to inseminate on the date just before or two days before the temperature rise with the timing based on reviewing 2 months of charts and/or the day of maximal vaginal wetness.

IUI with donor inseminations produces higher pregnancy rates compared with intracervical insemination.^{115, 116} However, the multiple pregnancy rate may be slightly higher.¹¹⁷ One IUI per cycle should be performed for two cycles, and then, if no success, increase to two inseminations per cycle. Double inseminations in a donor program increase the pregnancy rate and shorten the time required to achieve pregnancy.^{103, 118} IUI should be performed the day after a positive test with the urinary LH kit, or approximately 36 hours after HCG administration. When two IUIs are performed, they should be timed the day of and the day after the LH kit tests positive, or approximately 18 and 42 hours after HCG administration. A minimum of 6 months of donor inseminations, with or without superovulation, should be completed prior to moving on to in vitro fertilization. In a healthy woman, 3–4 cycles can be concluded prior to hysterosalpingography.

The children born after donor insemination have outcomes comparable to the general population.¹¹⁴ Interestingly, approximately half of couples do and half do not tell their children of their origins. The divorce rate in families with children conceived with donor insemination is lower than the general rate.¹¹⁴

Intracytoplasmic Sperm Injection (ICSI)

ICSI, the direct injection of a single spermatozoon or spermatid into the cytoplasm of an oocyte (described in [Chapter 31](#)), was first described in 1992.¹¹⁹ The results have been nothing short of amazing, with pregnancy rates equal to or slightly surpassing the normal fecundity rate.^{120, 121} Pregnancy rates are independent of any semen analysis parameter (number, motility, morphology). All that is required is the DNA material, and this can be derived from a barely moving spermatozoon or in men with no spermatozoa or spermatids in the semen analysis from a spermatid (or spermatocyte) obtained by epididymal aspiration or from a biopsy of the seminiferous tubules.^{122, 123 and 124}

Although ICSI avoids the natural process of sperm selection, the chromosomal abnormality rates in the offspring have been equal to the rate in the general population, with the exception of a slight increase in minor sex chromosome abnormalities (that could pass the male infertility problem to children), and, thus far, growth and development of the children have been normal.

Conclusion

For many years, the outlook for male infertility (with the exception of donor insemination) was very pessimistic. Today, in vitro fertilization with ICSI can overcome even the most grievous cases. The availability and expense of this technology, however, often are out of the reach of many couples. Therefore, less rigorous treatment continues to be an important part of the treatment of male infertility. It is important to identify a urologist in the local community who has both an interest and expertise in male infertility. Even without that resource, the clinician has the ability to offer IUI and superovulation.

In previous editions of this book, we began this chapter with a statement in celebration of one of the greatest achievements of reproductive endocrinology, the ability to induce ovulation and attain pregnancy in women who in the past had little basis or hope for reversal of their ovulatory dysfunction. As we approach a half century of ovulation induction for infertility, this elation remains justified. A variety of logical strategies, often empirically defined, designed to respond to specific indications do yield excellent results. In many clinical circumstances accurate data confirm the theoretical expectation that treatment can result in pregnancy rates equivalent to those in the normal population.

As the field has matured, however, the initial exuberance has been tempered by the realities of objective review. Results of treatment, despite restriction to a single indication, are not uniform. Complications occur, and escalation to more costly and hazardous treatments is a common occurrence. Perhaps most concerning is the vexingly persistent disparity between rates of successful ovulation (high) and pregnancy (relatively low). This paradox presents two challenges.

1. The informed consent dialogue with the infertile couple does not conclude with the initial outline of strategic options. Helping the couple deal with the frustration of repeated partial success but persistent ultimate failure requires special time, sensitivity, and compassion.
2. The disparity between ovulation and pregnancy rates is an emphatic reminder for the clinician of the imprecision of the diagnosis, "ovulatory dysfunction and/or failure," the inadequacy of the available tests to determine if induction of ovulation has actually occurred, and the existence of more basic inherent defects in the reproductive process not disclosed by our current thorough work up or simply not discovered.

These considerations are all the more reason for the clinician to understand thoroughly the various indications and the many options available for induction of ovulation. This chapter will review the principles which guide the use of clomiphene, human menopausal gonadotropins, purified follicle-stimulating hormone (FSH), recombinant FSH, bromocriptine, and gonadotropin-releasing hormone (GnRH), and consider the results and complications of the medical induction of ovulation. In addition, laparoscopic ovarian surgical procedures (modified wedge resection) and the impact of GnRH agonist therapy will be reviewed.

Despite the specificity of the therapy and the promise of successful results, it is incumbent upon the practitioner to perform the appropriate medical evaluation to ensure that a contraindication to therapy is not overlooked. The reader is referred to [Chapter 12](#) and [Chapter 13](#) for a consideration of anovulation and hirsutism, and [Chapter 11](#) for the evaluation of amenorrhea and galactorrhea.

For reference purposes, we provide the following definitions of ovulatory deficiencies according to the World Health Organization.

Group I: Hypothalamic-Pituitary Failure

This classification includes patients diagnosed as hypothalamic amenorrhea, and includes stress-related amenorrhea, anorexia nervosa and its variants, Kallmann's syndrome, and isolated gonadotropin deficiency. These patients display hypogonadotropic hypogonadism with low gonadotropin and estrogen levels, normal prolactin concentrations, and a failure to bleed after the administration of a progestational agent (the progestational challenge).

Group II: Hypothalamic-Pituitary Dysfunction

This classification includes normogonadotropic, normoestrogenic, anovulatory, oligoamenorrheic women. The classic anovulatory polycystic ovary syndrome is in this category.

Group III: Ovarian Failure

Patients in this classification are hypergonadotropic hypogonadal individuals with low estrogen levels. All variants of ovarian failure and ovarian resistance are in this category.

For the purposes of this chapter, as well as the expression of our clinical philosophy, hyperprolactinemic ovulatory dysfunction is treated as a specific treatment entity.

Induction of Ovulation With Clomiphene Citrate

Clomiphene citrate was first synthesized in 1956, introduced for clinical trials in 1960, and approved for clinical use in the United States in 1967. ^{1,2} Clomiphene citrate is an orally active nonsteroidal agent distantly related to diethylstilbestrol. Clomiphene is a racemic mixture of its 2 stereochemical isomers, originally described as the cis and trans isomers. This designation is now recognized to have been inaccurate, and the isomers have been relabeled as zuclomiphene and enclomiphene citrate. ³ Clomiphene is available in 50 mg tablets, which contain 38% of the more active zuclomiphene form.

The similarity of clomiphene's structure to an estrogenic substance is the clue to its mechanism of action. Clomiphene exerts only a very weak biologic estrogenic effect. The structural similarity to estrogen is sufficient to achieve uptake and binding by estrogen receptors; however, there are several important different characteristics. ^{4,5} Perhaps most importantly, clomiphene occupies the nuclear receptor for long periods of time, for weeks rather than hours. Clomiphene modifies hypothalamic activity by affecting the concentration of the intracellular estrogen receptors. Specifically, the concentration of estrogen receptors is reduced by

The similarity of clomiphene's structure to an estrogenic substance is the clue to its mechanism of action. Clomiphene exerts only a very weak biologic estrogenic effect. The structural similarity to estrogen is sufficient to achieve uptake and binding by estrogen receptors; however, there are several important different characteristics.^{4,5} Perhaps most importantly, clomiphene occupies the nuclear receptor for long periods of time, for weeks rather than hours. Clomiphene modifies hypothalamic activity by affecting the concentration of the intracellular estrogen receptors. Specifically, the concentration of estrogen receptors is reduced by inhibition of the process of receptor replenishment.

When exposed to clomiphene, the hypothalamic-pituitary axis is blind to the endogenous estrogen level in the circulation. Because receptor capacity is reduced and the true estrogen signal falsely lowered, negative feedback is diminished and the neuroendocrine mechanism for GnRH secretion is activated. When clomiphene is administered to normally cycling women, FSH and luteinizing hormone (LH) pulse frequency (but not amplitude) is increased, suggesting an increase in GnRH pulse frequency.⁶ Anovulatory women, however, respond in a different fashion. Clomiphene stimulates an increase in gonadotropin pulse amplitude, presumably because GnRH pulses are already operating at maximal frequency in anovulatory women with polycystic ovaries.⁷ Nevertheless, the experimental data indicate that the primary site of action is the hypothalamus.

During clomiphene administration, circulating levels of FSH and LH rise. The subsequent ovulation that occurs after clomiphene therapy is a manifestation of the hormone and morphologic changes produced by the growing follicles. Clomiphene therapy does not directly stimulate ovulation, but it retrieves and magnifies the sequence of events that are the physiologic features of a normal cycle. The effectiveness of the drug, however, may not be restricted to its ability to cause an appropriate GnRH discharge.

In animal models, clomiphene exerts an estrogenic effect on the pituitary and directly stimulates gonadotropin release, independent of its action on GnRH.⁵ In the presence of estrogen, clomiphene influences pituitary response to GnRH in women, preferentially promoting FSH secretion.⁸ In addition, clomiphene exerts a direct ovarian effect. In the absence of estrogen, clomiphene is an estrogen agonist, directly enhancing FSH stimulation of LH receptors in granulosa cells.⁹ In an important contrast, in the uterus, cervix, and vagina, clomiphene acts primarily as an antiestrogen. Thus vaginal cornification is attenuated, and the effect of estrogen on cervical mucus and endometrium is antagonized, potentially important actions affecting implantation, sperm transport, and early embryonic development.¹⁰ However, no significant effects on luteal phase endometrial morphology could be detected when clomiphene was administered to normal women.¹¹ Nor could a detrimental impact on cervical mucus be documented in either anovulatory or normal women.¹² In addition, the administration of clomiphene failed to affect endometrial concentrations of estrogen and progesterone receptors in normal ovulatory women.¹³ These latter observations indicate that the potential antiestrogenic, adverse effects of clomiphene do not appear when clomiphene is used clinically.

Clomiphene has no progestational, corticotropic, androgenic, or antiandrogenic effects. Clomiphene does not interfere with adrenal or thyroid function. Although the pharmacologic effect of the drug is brief, only 51% of the oral dose is excreted after 5 days, and radioactivity from labeled clomiphene appears in the feces up to 6 weeks after administration. Significant plasma concentrations of the active *zu* isomer can be detected up to 1 month after treatment with a single dose of 50 mg.¹⁴

This long half-life of clomiphene presents theoretical concern. The presence of clomiphene at the time of ovulation and during the luteal phase could have unwanted effects. *In vitro*, clomiphene inhibits progesterone production by luteal granulosa cells in a fashion that suggests that clomiphene in the presence of estrogen, by virtue of its antiestrogenic action, interferes with the induction of LH receptors.¹⁵ Because this inhibition is reversed by human chorionic gonadotropin (HCG), pregnancy and the appearance of HCG may prevent this unwelcome effect.

In rats and rabbits, a dose-dependent increase in the incidence of fetal malformations is seen when clomiphene is given during the period of organogenesis. Clomiphene has been found to cause disruptions of the organization of the uterine mesenchyme and tubal epithelium in human fetal reproductive tissue transplanted to athymic nude mice.¹⁶ Extremely high doses inhibit fetal development. In these experiments, exposure took place at later periods of gestation than those associated with clomiphene exposure when the drug is taken for the induction of ovulation. Although clomiphene therapy should be withheld if there is any possibility of pregnancy, there is no good evidence that clomiphene is teratogenic in humans.^{17, 18, 19} Furthermore, infant survival and performance after delivery are normal.

Selection of Patients for Clomiphene Treatment

Absent or infrequent ovulation is the chief indication for clomiphene therapy. It is the clinician's responsibility to rule out disorders of pituitary, adrenal, and thyroid origin requiring specific treatment before initiating clomiphene therapy. A complete history and physical examination are mandatory, but only a minimum of laboratory procedures is necessary. Liver function evaluation should precede clomiphene therapy if history and physical examination findings suggest liver disease. The vast majority of patients are healthy women suffering only from infertility secondary to oligoovulation or anovulation.

If periods are infrequent, it is not absolutely necessary to document infrequent or absent ovulation by basal body temperature records or endometrial biopsy. An endometrial biopsy is a wise precaution in a patient who has been anovulatory for a long period of time because of the tendency for these patients to develop hyperplasia and even carcinoma of the endometrium. It is also wise to precede therapy with an evaluation of the semen, to avoid an unnecessary waste of time and effort in the presence of azoospermia. A dedicated effort must be made to detect galactorrhea, and the prolactin level must be measured. Galactorrhea or hyperprolactinemia dictate a different therapeutic approach: dopamine agonist treatment. The remainder of the infertility workup in a patient with no previous medical or surgical problems is deferred until after a trial of clomiphene therapy. Because approximately 75% of pregnancies occur during the first 3 treatment cycles, the infertility workup is pursued only after the patient has responded with 3 months of ovulatory cycles and has not become pregnant.²⁰ This is appropriate because clomiphene is simple, safe, and cost-effective.

Cases of ovarian failure are unresponsive to any form of ovulation induction. Therefore, the presence of ovarian tissue capable of responding to gonadotropins must be documented. This is only a problem in the patient with amenorrhea, since the presence of menstrual bleeding confirms the function (although perhaps limited) of the hypothalamic-pituitary-ovarian axis. The patient with amenorrhea who fails to produce a withdrawal bleed after a course of a progestational agent (medroxyprogesterone acetate, 10 mg daily for 5 days) must be further evaluated ([Chapter 11](#)). A case has been made by others for the usefulness of an ovarian biopsy, perhaps via the laparoscope, to establish the presence of competent ovarian tissue. It is our practice, however, to rely on the immunoassay of gonadotropin levels and the response to a progestin, thus avoiding unnecessary surgical and anesthetic risks, to accurately rule out hypergonadotropic hypogonadism (ovarian failure). Attempts at medical induction of ovulation in these patients would be a waste of time and money.

The patients most likely to respond to clomiphene display some evidence of pituitary-ovarian activity as expressed in the biologic presence of estrogen (spontaneous or withdrawal menstrual bleeding). These are anovulatory women who have gonadotropin and estrogen production, but do not cycle, or women with inadequate luteal phases.

If the mechanism of an inadequate corpus luteum is inadequate FSH stimulation during the follicular phase, it makes sense to treat this condition with clomiphene, and a good response has been observed by ourselves and others.²¹ Two randomized trials comparing clomiphene to progesterone treatment for inadequate luteal phases demonstrated equal pregnancy rates with each treatment.^{22, 23} Clomiphene does not prolong the luteal phase (as progesterone supplementation does). This is an important advantage, avoiding the anxiety and heightened monthly emotional response of infertile couples.

The patient who is deficient in gonadotropin secretion and, as a result, is hypoestrogenic, cannot be expected to respond to further lowering of the estrogen signal and thus should not respond to clomiphene. However, this principle is not completely applicable to clinical practice. An occasional patient who is, by all criteria, hypoestrogenic will respond. Therefore, any otherwise medically uncomplicated patient with infertility secondary to lack of ovulation is a candidate for clomiphene

phases demonstrated equal pregnancy rates with each treatment; i.e., Clomiphene does not prolong the luteal phase (as progesterone supplementation does). This is an important advantage, avoiding the anxiety and heightened monthly emotional response of infertile couples.

The patient who is deficient in gonadotropin secretion and, as a result, is hypoestrogenic, cannot be expected to respond to further lowering of the estrogen signal and thus should not respond to clomiphene. However, this principle is not completely applicable to clinical practice. An occasional patient who is, by all criteria, hypoestrogenic will respond. Therefore, any otherwise medically uncomplicated patient with infertility secondary to lack of ovulation is a candidate for clomiphene therapy unless galactorrhea or hyperprolactinemia is present. Hypoestrogenic women respond so rarely, however, that it is appropriate to omit treatment with clomiphene and move to other more productive options.

In addition to anovulation, treatment with clomiphene is indicated to improve the timing and frequency of ovulation and to enhance the possibilities of conception in the patient who ovulates only occasionally. Clomiphene can also be used to regulate the timing of ovulation in women undergoing insemination.

There is one special group in whom clomiphene is indicated in women who ovulate regularly and spontaneously. Certain religious requirements, such as those in Orthodox Judaism, interfere with the normal reproductive process. In the devout Orthodox Jewish couple, intercourse is prohibited in the presence of menstrual flow and for 7 days following its conclusion. In some women menstrual flow is prolonged or the follicular phase is shortened, so that coitus cannot take place until after ovulation. In the usual mode of treatment, medication is begun on day 5 of the cycle. Ovulation can be delayed to a more appropriate time by starting clomiphene later, usually on day 7 or 8 of the cycle. Ovulation can be expected in the interval 5–10 days after the last day of medication. This manipulation has its limitations. Administration too late in the cycle, beyond day 9, may have no effect.

The question is often asked whether the indications for clomiphene therapy should be extended to include the initiation of cyclicity in the oligoamenorrheic patient who does not seek fertility. In our opinion, this is an inappropriate use of clomiphene for several reasons: 1) the effectiveness of clomiphene is restricted to the cycle in which it is used and it should not be expected to induce cyclicity following the conclusion of treatment, 2) the use of clomiphene may aggravate the clinical problems of acne and hirsutism during the treatment cycle by increasing LH stimulation of ovarian steroid production, and 3) the inability to induce cyclicity can be so discouraging to the patient that her acceptance of the drug will be impaired at some future date when it is legitimately offered as a fertility agent for the induction of ovulation.

Clomiphene and Unexplained Infertility

Clomiphene is used for the treatment of unexplained infertility; i.e., women who have prolonged (more than 3 years) infertility but who ovulate spontaneously and repeatedly by all available measures and do not have other abnormalities. While the spontaneous pregnancy rate is high in these patients (cumulative rates approach 50%), patient pressure and physician enthusiasm have led to superovulation induction in these couples. The rationale is appealingly clear. With more than one ovulation, surely there is an increased probability of successful fertilization, and such therapy would reverse (if present) episodic, unpredictable, recurrent, occult ovulatory dysfunction. Despite the high spontaneous pregnancy rate, clomiphene does have value in the empiric treatment of unexplained infertility, particularly prior to undertaking the more expensive and more complicated assisted reproductive technologies. In some studies, but not all, treatment with clomiphene has been associated with higher pregnancy rates. Superovulation for unexplained infertility is discussed in greater detail at the end of this chapter.

How to Use Clomiphene

A program of clomiphene therapy is begun on the 5th day of a cycle following either spontaneous or induced bleeding. It has not been established that a progestin withdrawal bleed is necessary before starting clomiphene treatment; we often omit this step if we are certain that the patient is not pregnant. The initial dose is 50 mg daily for 5 days. There is no advantage to beginning with a higher dose for the following two reasons: 1) in a random distribution of our patients begun with initial doses of either 50 mg or 100 mg daily, the pregnancy rate was identical; and 2) the highest incidence of side effects in our experience occurs at the 50 mg dose, and beginning with 100 mg, patients may develop more serious reactions. About 50% of patients conceive at the 50 mg dose, and another 20% at 100 mg. ^{20, 24} An occasional patient will be exceptionally sensitive to clomiphene and can achieve pregnancy at the reduced dose of 25 mg.

Beginning clomiphene on the 5th day is a method arrived at empirically; however, we can now offer a rational explanation based on ovarian physiology. The clomiphene-induced increase in gonadotropins during days 5–9 occurs at a time when the dominant follicle is being selected. Beginning clomiphene earlier can be expected to stimulate multiple follicular maturation resulting in a greater incidence of multiple gestation. Indeed, clomiphene is administered earlier in in vitro fertilization programs in order to obtain more than one oocyte. However, in standard ovulation induction protocols, no differences have been observed in the rates of ovulation, pregnancy, or spontaneous miscarriage whether clomiphene was started on day 2, 3, 4, or 5. ²⁵

If ovulation is not achieved in the very first cycle of treatment, dosage is increased to 100 mg. Thereafter, if ovulation and a normal luteal phase are not achieved in any cycle, dosage is increased in a staircase fashion by 50 mg increments to a maximum of 200–250 mg daily for 5 days. The highest dose is pursued for 3–4 months before considering the patient to be a clomiphene failure. The quantity of drug and the number of cycles go beyond those recommended by manufacturers. However, in our experience those recommendations are inappropriately limiting. We have achieved a 15% pregnancy rate at the 150 mg and 200 mg dose levels. ²⁰

There is a significant correlation between body weight and the dose of clomiphene required for ovulation. ^{26, 27 and 28} One must adhere to the usual regimen, however, because the weight cannot be used to predict prospectively the correct ovulatory dose. In other words, some obese women ovulate at the same low dose that achieves ovulation in thin women. Clomiphene is not stored in adipose tissue, and the increased dose often necessary in obese women is more likely due to a more intense anovulatory state with higher androgen levels producing a more resistant hypothalamic-pituitary-ovarian axis. Increasing the dose of clomiphene will eventually achieve the same level of success in overweight women as can be attained in lean women. ^{29, 30}

At the present time there is no clinical or laboratory parameter that can predict the dose of clomiphene necessary to achieve ovulation. Androgen and estrogen levels do not show any correlation with the dose of clomiphene that proves successful. ³¹

Following the 5-day course of clomiphene, the ovulatory surge of gonadotropins can occur anywhere from 5 to 12 days after the last day of clomiphene administration, but most commonly on cycle day 16 or 17 when clomiphene is administered on days 5–9. ³² Once ovulation is established, the subsequent treatment cycles are uniformly consistent. The patient is advised to have intercourse every other day for 1 week beginning 5 days after the last day of medication. In view of the role prostaglandins play in the physical expulsion of an oocyte, it is prudent to advise patients involved in programs of ovulation induction to avoid the use of agents that inhibit prostaglandin synthesis.

After the first treatment cycle the patient is evaluated for side effects, residual ovarian enlargement, and basal body temperature changes. We have found it unnecessary to perform a pelvic examination every month because significant ovarian enlargement is encountered infrequently, and it is usually symptomatic. It is more economical, for both patient and clinician, to mail the temperature chart to the office and several days later plan by telephone for the following month. Cysts within a reasonable size range (3–5 cm) do not require a rest from treatment; they do not respond to further stimulation, and they do not impact upon subsequent response.

After the first treatment cycle the patient is evaluated for side effects, residual ovarian enlargement, and basal body temperature changes. We have found it unnecessary to perform a pelvic examination every month because significant ovarian enlargement is encountered infrequently, and it is usually symptomatic. It is more economical, for both patient and clinician, to mail the temperature chart to the office and several days later plan by telephone for the following month. Cysts within a reasonable size range (3–5 cm) do not require a rest from treatment; they do not respond to further stimulation, and they do not impact upon subsequent response.

We recommend basal body temperature charting to follow the response. If an inadequate luteal phase is evident, (temperature elevation less than 11 days duration) the amount of clomiphene is increased to the next dose level. If the patient is already at the maximal level, consider the available options for dealing with clomiphene failure (detailed below). Biphasic changes are taken as an indication of ovulation and success. Maintenance of the temperature elevation beyond the expected time of menses is the earliest practical indication of pregnancy.

When the temperature chart is inconclusive or when the patient is not pregnant despite a period of apparently normal ovulations, an endometrial biopsy is indicated to document the adequacy of the luteal phase. One should also consider ultrasonographic monitoring for treatment failures, looking for follicles which do not reach mature size or the luteinized unruptured follicle syndrome (although it is by no means certain that luteinized unruptured follicles are a factor in infertility). **For most patients, adding ultrasonography and urinary LH testing to basal body temperature charting does not improve pregnancy rates.** ³³

The additional use of HCG is limited to those cases in which there is a failure to ovulate at the maximal dose level or, when at that level, a short luteal phase is demonstrated. The rationale is to improve on the midcycle LH surge; therefore, 10,000 IU of HCG can be given as a single intramuscular dose on the 7th day after clomiphene when follicular maturation is at its peak. Because premature HCG administration may interfere with normal ovulation by down-regulating LH receptors, more accurate timing of HCG administration may be desirable. This requires either measurement of the blood estradiol level or estimation of follicular size (18–20 mm diameter) by sonography. When HCG is administered, intercourse is advised for that night and for the next 2 days. **In our experience as well as in others reported in the literature, the addition of HCG has not had a significant impact on the pregnancy rate.** ³⁴

Care should be taken to review with the patient the pathophysiology of her condition, the principles of treatment, the prolonged course of therapy that may be necessary, and possible complications. Repeated failures accumulate frustration and despair in the couple, making each successive cycle of treatment more difficult. The anxiety and stress may hinder coital performance, and it is not uncommon for a couple to have difficulty performing scheduled intercourse.

Results With Clomiphene

In properly selected patients, 80% can be expected to ovulate, and approximately 40% become pregnant. ^{20, 24} The percent of pregnancies per induced ovulatory cycle is about 20–25%. The multiple pregnancy rate is approximately 10%, almost entirely twins. ³⁵ There have been rare cases of quintuplet and sextuplet births. In our own experience, with standardization of therapy, the incidence of twins has decreased.

The miscarriage rate is not increased. ^{19, 36} Most importantly, the incidence of congenital malformations is not increased, and infant survival and performance after delivery are no different from normal. ^{18, 19 and 37}

The discrepancy between ovulation rates and pregnancy rates is mainly due to 2 factors, the presence of other causes of infertility and a lack of persistence. **In those patients with no other cause of infertility, the cumulative 6-month conception rate approaches a normal rate of 60–75%** ^{24, 31, 35} The pregnancy rate per ovulatory cycle equals the normal rate. The pregnancy rate in 70 of our patients who received therapy sufficient to ovulate in at least 3 cycles was 55.7%, the same pregnancy rate after 3 months of exposure in the general population. ²⁰ With additional treatment cycles, the pregnancy rate decreases, although the ovulatory rate remains high. Approximately 15% of patients treated with the higher doses of 150–250 mg will become pregnant. ²⁰ Therefore there may be no need to attribute negative effects of clomiphene on oocyte, endometrium, the corpus luteum, and an early embryo.

If all factors are corrected, and conception has not occurred in 6 months, prognosis is poor.

In one large series, only 7.8% of those who had one or more infertility factors in addition to anovulation became pregnant. ²⁴

Complications With Clomiphene

Side effects do not appear to be dose related, occurring more frequently at the 50 mg dose. Patients requiring the high doses are probably less sensitive to the drug. The most common problems are vasomotor flushes (10%), abdominal distension, bloating, pain, or soreness (5.5%), breast discomfort (2%), nausea and vomiting (2.2%), visual symptoms (1.5%), headache (1.3%), and dryness or loss of hair (0.3%). Patients who are extremely sensitive to the side effects of clomiphene can be successfully treated with half a tablet (25 mg) daily for 5 days, and even with half a tablet daily for 3 days.

A common antiestrogenic effect is an increase in the basal body temperature during the 5-day period of clomiphene administration. This is sometimes incorrectly interpreted as evidence of an early ovulation.

Visual symptoms include blurring vision, scotoma (visual spots or flashes), or abnormal perception. The cause of these symptoms is unknown, but in almost all cases, the visual symptoms have disappeared upon discontinuation of the medication. Usually these symptoms disappear within a few days but may take 1 or 2 weeks. There is one report of 3 women who had a persistence of visual side effects (shimmering, afterimages, and photophobia) after discontinuing treatment. ³⁸ It is likely that this problem is increased with increasing dosage and duration of exposure. Persistence of treatment in the presence of this reaction is not recommended.

Significant ovarian enlargement is associated with longer periods of treatment and is infrequent (5%) with the usual 5-day course. Maximal enlargement of the ovary usually occurs several days after discontinuing the clomiphene (in response to the increase in gonadotropins). If the patient is symptomatic, pelvic examination, intercourse, and undue physical exercise should be avoided because the enlarged ovaries are very fragile. Ovarian enlargement dissipates rapidly and only rarely is a subsequent treatment cycle delayed.

Because of multiple ovulations in some patients, it is possible that the risk of ectopic pregnancy is increased. However, evidence in the literature indicates that this increase at most is only slight. ^{2, 19}

What to Do With Clomiphene Failures

Patients most likely to not respond to clomiphene are those who are most hyperandrogenic and overweight (and probably insulin resistant). ³⁹ There are several options available for the 10–20% of women who fail to become pregnant with clomiphene up to the highest dose. Knowledge gained from experience with in vitro fertilization provides us with several explanations for failure to respond to clomiphene. ³¹ These include the effects of excessive LH in the follicular phase, the dysfunctional effects of an untimely LH surge, excess local concentrations of androgens, and hyperinsulinemia. These mechanisms may yield impaired folliculogenesis, increased atresia, poor oocyte quality, precocious or impaired oocyte maturation, low fertilization rates, variable implantation rates, and deficient corpus luteum function. Strategies have developed to mitigate or avoid many of these detrimental effects: the treatment of hyperinsulinemia, the supplemental use of dexamethasone (to reduce androgen burden), GnRH agonists (to eliminate endogenous LH intrusion), pulsatile GnRH therapy (to preserve physiologic interactive feedback mechanisms), and, finally, the use of human gonadotropins. We are also seeing the return of modified ovarian wedge resection by laparoscopic multiple ovarian tissue destruction with cautery or laser techniques.

First, make sure galactorrhea has not been overlooked and a prolactin level has been obtained. The good results with dopamine agonist treatment make it essential that this cause of anovulation be detected. It is worth performing a postcoital test to assess the quality of the cervical mucus. Despite the antiestrogen action of clomiphene the incidence of poor cervical mucus on the postcoital test is only 15%. ²⁴ In the past, estrogen (0.625 to 2.5 mg conjugated estrogens daily) was administered from day 10 to day 16 (for 1 week starting the day after the last day of clomiphene administration) in an effort to improve mucus production. Although high doses of estrogen do not interfere with the gonadotropin response, ovulation, or the pregnancy rate, there is reason to believe that estrogen treatment is ineffective. ^{40, 41} Another alternative, the one we prefer, is to proceed with intrauterine inseminations of prepared sperm, bypassing the cervix.

After 6 months of clomiphene therapy, and in the absence of any other infertility factors, we proceed to one of the available options.

Treatment of Hyperinsulinemia

Anovulatory women with polycystic ovaries and hyperinsulinemia are more resistant to clomiphene treatment. The best therapy for these women who are obese is weight loss. Both the hyperinsulinemia and the hyperandrogenism can be reduced with weight loss, which is at least more than 5% of the initial weight. ^{42, 43, 44, 45, 46} and

Treatment of Hyperinsulinemia

Anovulatory women with polycystic ovaries and hyperinsulinemia are more resistant to clomiphene treatment. The best therapy for these women who are obese is weight loss. Both the hyperinsulinemia and the hyperandrogenism can be reduced with weight loss, which is at least more than 5% of the initial weight. ^{42, 43, 44, 45, 46} and ⁴⁷ These metabolic improvements are associated with an impressive rate of resumption of ovulation and pregnancy. ^{48, 49} In one study, 60 of 67 anovulatory women, who lost from 4 to 15 kg, resumed ovulation. ⁵⁰ A goal for weight loss that correlates with a good chance of achieving pregnancy, a reduction in insulin levels, and a decrease in free testosterone levels is a body mass index of less than 27 (see the nomogram for calculating body mass index in [Chapter 19](#)). It should be emphasized, that only a relatively small percentage of weight (5–10%) need be lost to have a beneficial impact upon insulin resistance and cardiovascular hemodynamic function. ⁵¹

It is reasonable to assume that all overweight, anovulatory women with polycystic ovaries are hyperinsulinemic. Nevertheless we recommend the measurement of the ratio of fasting glucose to fasting insulin in order to provide evidence that lends credence and importance to counseling efforts. **A ratio of less than 4.5 is consistent with insulin resistance.** ⁵²

All anovulatory women who are hyperandrogenic should be assessed for insulin resistance and glucose tolerance with measurements of:

1. **The fasting glucose:insulin ratio, followed by**
2. **The 2-hour glucose level after a 75 g glucose load:**

normal	— less than 140 mg/dL
impaired	— 140–199 mg/dL
noninsulin-dependent diabetes mellitus	— 200 mg/dL and higher

The best application of drugs, such as metformin and troglitazone, remains to be determined by data from appropriate clinical trials. Metformin improves insulin sensitivity, but the primary effect is a significant reduction in gluconeogenesis, thus decreasing hepatic glucose production. Metformin treatment (500 mg tid) reduces hyperinsulinemia, basal and stimulated LH levels, and free testosterone concentrations in overweight women with polycystic ovaries. ^{53, 54} and ⁵⁵ A significant number of these anovulatory women treated with metformin ovulate and achieve pregnancy. ^{56, 57} In a group of obese women with polycystic ovaries, 90% of the women treated with metformin and 50 mg clomiphene ovulated compared with 8% in the group treated with placebo and clomiphene. ⁵⁸ However, there has been controversy, suggesting that the improvement was the result of the weight loss that often accompanies the use of metformin. ⁵⁹ In a study designed to control the effect of body weight, the administration of metformin was without effect on insulin resistance in extremely overweight women with polycystic ovaries. ⁶⁰ In another well-designed study, metformin again had no effect on insulin resistance when body weights remained unchanged, and in this study baseline weights and hyperinsulinemia were only modestly increased. ⁶¹ In lean, anovulatory women with hyperinsulinemia, metformin treatment reduced hyperandrogenemia although there was no change in body weight; however, a decrease in the waist to hip ratio accompanied a reduction in the hyperinsulinemia. ⁶² This study indicates that both obese and nonobese patients with hyperinsulinemia respond to metformin treatment. The reasons for the differences among the studies is not apparent. Perhaps only certain patients will respond to metformin, and, thus, patient selection could influence the reported results. Lactic acidosis is a rare complication in patients treated with metformin; however, virtually all cases have occurred in patients with complicated medical problems, such as sepsis, renal insufficiency, and congestive heart failure. Patients who become ill should discontinue metformin treatment, and metformin should not be administered to women who have abnormal renal chemistries.

The thiazolidinediones markedly improve insulin sensitivity and insulin secretion (improved peripheral glucose utilization and b-cell function) without weight changes. Troglitazone (400 mg daily) decreases hyperinsulinemia, and improvements in metabolic abnormalities (decreased androgens, increased SHBG, decreased PAI-1 consistent with improved fibrinolytic capacity, and decreased LH), and a return to ovulation in very obese women have been reported with this agent. ^{63, 64} Although changes are uncommon, liver function must be monitored during troglitazone treatment. The pharmaceutical company's package information should be consulted for the currently recommended monitoring regimen of serum alanine aminotransferase levels.

There is little doubt that these drugs can produce significant and beneficial improvements in this condition, although metformin may be effective only when weight loss occurs. However, is short-term use better than our standard methods of the induction of ovulation, and are these drugs safe during pregnancy and lactation? How effective are these agents in women who are of normal or only slightly elevated body weight? Appropriate clinical trials are required to answer these questions. In the meantime, clinicians have offered treatment with these agents to patients who have failed to respond to clomiphene. If an ovulatory response does not occur within 3 months, clomiphene treatment, beginning again at the lowest dose, is resumed in addition to the drug therapy for hyperinsulinemia.

The Addition of Dexamethasone to Clomiphene

Patients with hirsutism and high circulating androgen concentrations are more resistant to clomiphene. ^{65, 66} and ⁶⁷ Dexamethasone, 0.5 mg at bedtime to blunt the nighttime peak of ACTH, is added to decrease the adrenal contribution to circulating androgens and, thus, diminish the androgen level in the microenvironment of the ovarian follicles. Higher ovulation and conception rates are achieved with this treatment when the circulating level of dehydroepiandrosterone sulfate (DHAS) is greater than the upper limit of normal. The dexamethasone is maintained daily until pregnancy is apparent. The dose of clomiphene is returned to the starting point of 50 mg and increased in incremental fashion as needed. One report indicated that even non-responders to clomiphene with normal DHAS levels achieved ovulation and pregnancy with the addition of a 10-day course of dexamethasone begun concurrently with clomiphene. ⁶⁸

Extended Clomiphene Treatment

Several approaches have been reported for extending clomiphene treatment. We have very little experience with extended clomiphene treatment. In one approach, 250 mg of clomiphene was given for 8 days, followed by 10,000 IU HCG 6 days later. Three pregnancies were achieved out of 25 treatment cycles. ⁶⁹ In another series, the clomiphene dose was increased every 5 days, with some patients receiving up to 25 days of consecutive treatment, the last 5 days at 250 mg daily. ⁷⁰ Eight of 21 patients conceived and, in those patients who responded, measurement of gonadotropin revealed sustained elevations in FSH. This latter approach requires estrogen monitoring with discontinuation of the clomiphene when an increase in estrogen is detected. No patient ovulated after more than 21 days of treatment. Extending a dose of 100 mg clomiphene to 10 days has been reported to achieve pregnancies in women previously resistant to a 5-day regimen. ⁷¹ A simple approach is to extend the duration of clomiphene treatment until a follicle of 18 mm diameter (on ultrasound) is obtained, then administer HCG.

Pretreatment Suppression

The anovulatory state is a dysfunctional condition. It is reasonable to expect suppression of the contributing factors to be followed by a reassertion of the harmony operating in a normal menstrual cycle, at least for a short time. Clinicians have long advocated (without benefit of careful study) a period of suppression (at least 6 months) with an oral contraceptive, followed immediately by resumption of clomiphene administration. The same principle applies to the use of a GnRH agonist. Spontaneous resumption of ovulation has been reported to follow suppression for 6 months with a combination of a GnRH agonist and an oral contraceptive. ⁷² Pretreatment suppression has an added attraction. There is reason to believe that women with elevated LH and testosterone levels not only have more difficulty achieving pregnancy, but also experience a higher spontaneous miscarriage rate. ^{73, 74} and ⁷⁵ However, an excellent, randomized trial, testing pituitary suppression in women with polycystic ovaries, elevated LH levels, and recurrent miscarriages, obtained equal and good live birth rates with gonadotropin treatment in both the GnRH agonist-suppressed group and the non-suppressed group. ⁷⁶

The Addition of Bromocriptine to Clomiphene

Although the use of bromocriptine to induce ovulation is indicated in the presence of galactorrhea or hyperprolactinemia, its use in the clomiphene failure patient with a normal prolactin and no galactorrhea is controversial. Anovulatory patients with normal levels of prolactin do respond to bromocriptine, but the effectiveness of this treatment has not been established by controlled studies. Nevertheless, the clinical response is occasionally impressive.

Bromocriptine. Elevated prolactin levels interfere with the normal function of the menstrual cycle by suppressing the pulsatile secretion of GnRH. This is manifested clinically by a spectrum, ranging from a subtle inadequate luteal phase to total suppression and hypoestrogenic amenorrhea. Regardless of the prolactin level, we interpret the presence of galactorrhea to indicate excessive prolactin stimulation. We screen all patients with galactorrhea or any ovulatory disorder with an assessment of the prolactin level. After a consideration of the problems of amenorrhea, galactorrhea, and the pituitary adenoma (as discussed in [Chapter 11](#)), bromocriptine emerges as the drug of choice for the induction of ovulation in these patients.

Ovulatory dysfunction in the presence of galactorrhea responds well to bromocriptine, even if the prolactin level is normal. ⁷⁷ Either biologic activity is not being detected by the immunoassay or a random blood sample fails to reveal subtle elevations in prolactin.

assessment of the prolactin level. After a consideration of amenorrhea, galactorrhea, and the pituitary adenoma (as discussed in [Chapter 11](#)), bromocriptine emerges as the drug of choice for the induction of ovulation in these patients.

Ovulatory dysfunction in the presence of galactorrhea responds well to bromocriptine, even if the prolactin level is normal. ⁷⁷ Either biologic activity is not being detected by the immunoassay or a random blood sample fails to reveal subtle elevations in prolactin.

Bromocriptine is examined in detail in [Chapter 11](#), but it would be helpful to review pertinent details here. Bromocriptine is a dopamine agonist that directly inhibits pituitary secretion of prolactin. Suppression of prolactin levels restores CNS-pituitary gonadotropin function and also appears to increase ovarian responsiveness. The increase in ovarian responsiveness is seen in patients with normal prolactin levels and no galactorrhea. This is the apparent mechanism for an increase in sensitivity to clomiphene when bromocriptine is added to the therapeutic regimen. In women with persistent anovulation and polycystic ovaries, LH secretion is decreased by bromocriptine treatment, thus providing a rationale for why it might enhance the ovulatory response in these patients. ⁷⁸

The gastrointestinal and cardiovascular systems react to the dopaminergic action of bromocriptine, and, therefore, the side effects are mainly nausea, diarrhea, dizziness, headache, and fatigue. Side effects can be minimized by slowly building tolerance toward the usual dose, 2.5 mg bid. We start treatment with an initial dose of 2.5 mg at bedtime. If intolerance occurs, the tablet can be cut in half, and a slower program, developed by the patient, can be followed to work up to the standard dose. Usually, the second dose is added after 1 week, at breakfast or at lunch. In some patients, elevated prolactin levels can be reduced to normal levels with very small doses of bromocriptine, as little as 0.625 or 1.25 mg. ⁷⁹ Patients extremely sensitive to the side effects of bromocriptine can be treated by administering the drug intravaginally. Usually one 2.5 mg tablet daily will be effective; if the prolactin level is elevated, the dose can be titrated to bring the prolactin level into the normal range.

The usual regimen is to administer bromocriptine daily until it is apparent the patient is pregnant, as usually determined by the basal body temperature chart. Although there has been no evidence of any harmful effects on the fetus, some patients and clinicians prefer to avoid bromocriptine in the luteal phase and, therefore, during early pregnancy. The drug is stopped when a temperature rise occurs and resumed when menses begin.

Ovulatory menses and pregnancy are achieved in 80% of patients with galactorrhea and hyperprolactinemia. Response is rapid, and, therefore, if there is no indication of ovulation (a rise in the basal body temperature) within 2 months, clomiphene is added to the regimen. The starting dose of clomiphene is 50 mg daily for 5 days, given and increased in the usual fashion.

Cabergoline is also an ergot-derived dopamine agonist. ⁸⁰ Patients resistant to both bromocriptine and quinagolide have been reported to respond to cabergoline. ⁸¹ Cabergoline can be administered orally at doses of 0.5 to 3.0 mg only once weekly, although it can be given twice weekly if necessary, with minimal dopamine agonist side effects (headache being the most common complaint). ^{82, 83, 84} and ⁸⁵ **The low rate of side effects and the once weekly dosage make cabergoline an attractive choice for initial treatment, replacing bromocriptine.** The only reservation (a small one) is a more limited experience documenting fetal safety for patients being treated for infertility. ⁸⁶ Cabergoline can also be administered vaginally for the rare patient who cannot tolerate it orally. ⁸⁷

Bromocriptine for Euprolactinemic Women. Clinical experience suggests that successful induction of ovulation and achievement of pregnancy with bromocriptine can occur in the absence of galactorrhea and with a normal prolactin level in women who have failed to respond to clomiphene. ⁸⁸ Some anovulatory women with normal prolactin levels who ovulated in response to bromocriptine have been found to have elevated nocturnal peaks of prolactin. ⁸⁹ The mechanism of action may be an increase in follicular responsiveness either due to suppression of prolactin or suppression of LH (a known action of dopamine). A decrease in LH may alter local follicular steroidogenesis in such a way to create a more favorable microenvironment. The method of administration is the same as above. If, after 2 months of treatment, there is no response, clomiphene is reinitiated, working up again from the starting dose of 50 mg daily. A carefully designed study has demonstrated that bromocriptine has nothing to offer for ovulatory women with unexplained infertility. ⁹⁰ On the other hand, bromocriptine or bromocriptine plus clomiphene treatment of ovulatory women with galactorrhea (and normal prolactin levels) yielded higher pregnancy rates when compared to a control group. ⁹¹ Once again the importance of detecting galactorrhea is emphasized.

Ovarian Surgical Procedures

The clomiphene-resistant patient can be treated by an ovarian surgical procedure. This subject is discussed near the end of this chapter.

Induction of Ovulation With Human Gonadotropins

For over 30 years, the only preparation used for gonadotropin treatment consisted of human menopausal gonadotropins, a preparation of gonadotropins extracted from the urine of postmenopausal women. The commercial preparation is still available, with either 75 units of FSH and 75 units of LH per ampule, or in an ampule with twice the amount, 150 units of each gonadotropin. Gonadotropins are inactive orally and, therefore, must be given parenterally; the heavy protein content of the urinary preparation requires intramuscular injections.

A more purified urinary preparation of FSH became available by removing most of the LH in the urinary product. This product still requires intramuscular injection. A more highly purified form is available that can be administered subcutaneously.

Recombinant FSH is now produced in Chinese hamster ovary cells transfected with the human FSH subunit genes. ⁹² Recombinant FSH is homogeneous and free of contamination by proteins (characteristic of menopausal gonadotropins from urinary extracts); this allows simpler subcutaneous administration.

Because of its structural and biologic similarity to LH, HCG, readily available from human pregnancy urine and placental tissue, is used to simulate the midcycle LH ovulatory surge.

Recombinant HCG and recombinant LH are now available. These preparations will allow patient self-administration by subcutaneous injections. It is unlikely that the results will be different; however, it is possible that the risk of ovarian hyperstimulation will be reduced.

PREPARATION

Human menopausal gonadotropins
Purified urinary FSH
Highly purified urinary FSH
Recombinant FSH
Human chorionic gonadotropin
Recombinant HCG
Recombinant LH

Selection of Patients for Gonadotropin Treatment

Not only because of its expense but because of its greater complication rate, patients should not receive gonadotropin therapy without a very careful evaluation. An absolute requirement is the demonstration of ovarian competence. Abnormally high serum gonadotropins with a failure to demonstrate withdrawal bleeding indicate ovarian failure and preclude induction of ovulation except in those special cases of ovarian failure discussed in [Chapter 11](#). Successful induction of ovulation and pregnancy has been reported in women with apparent ovarian failure, treated with a combination of estrogen (to suppress FSH to normal levels) and gonadotropins. Our own experience with this approach has been disappointing, and the chance of achieving pregnancy must be very low.

A thorough infertility investigation must be performed. In addition to the demonstration of ovarian competence, tubal and uterine pathology should be ruled out, anovulation documented, and semen analysis obtained. Nongynecologic endocrine problems must be treated. Hypogonadotropic function (low serum gonadotropins), including galactorrhea syndromes, requires evaluation for an intracranial lesion, with appropriate imaging and measurement of prolactin levels. It is imperative to take all steps necessary to exclude treatable pathology to which anovulation is secondary.

In our practice we sometimes, but not often, offer a course of clomiphene, not only because of the cost and complications associated with gonadotropin therapy, but also because some apparently hypogonadotropic patients will unpredictably respond to clomiphene. Because some patients cannot tolerate dopamine agonist treatment, it is important to know that hyperprolactinemia has no adverse effect on response to gonadotropins. ⁹³

How to Use Gonadotropin Therapy

In our practice we sometimes, but not often, offer a course of clomiphene, not only because of the cost and complications associated with gonadotropin therapy, but also because some apparently hypogonadotropic patients will unpredictably respond to clomiphene. Because some patients cannot tolerate dopamine agonist treatment, it is important to know that hyperprolactinemia has no adverse effect on response to gonadotropins.⁹³

How to Use Gonadotropin Therapy

Instruction and counseling of the couple are essential. A thorough understanding of the need for daily treatment and frequent observation is necessary prior to initiating therapy. As part of this instruction, the partner can be taught to administer injections. Daily recording of the basal body temperature and body weight is important for proper management. The couple should be told about the need for scheduled intercourse, the possibility that more than one course of treatment may be necessary, and the expense of the treatment. Above all, the patient must be prepared for the anguish that accompanies failure. Because this is a pressure-packed situation, unexpected impotence is occasionally encountered on the days of scheduled intercourse.

Although there is evidence indicating that recombinant FSH yields better results with in vitro fertilization, there is no clear-cut indication that better results are obtained with any of the gonadotropin preparations when used for ovulation induction.⁹⁴ Optimal results are dependent on the experience and judgment of the clinician, not on the preparation used. There is no doubt that some LH is necessary for normal ovarian steroidogenesis (see [Chapter 6](#)), and very low day 3 LH levels (less than 3 IU/L) have been reported to predict poor response to gonadotropin stimulation.⁹⁵ In this circumstance, perhaps a preparation containing some LH would be a better choice; for example, in patients with amenorrhea due to weight loss and anorexia.

A variable dosage method is used to achieve follicular growth and maturation. Follicle stimulation is achieved by 7–14 days of continuous gonadotropin, beginning with one ampule daily. Response is judged by the degree of estrogen produced by the growing follicles. The patient is monitored periodically with the measurement of the circulating estradiol level and vaginal ultrasound assessment of the number and size of follicles. The patient is seen on the 7th day of treatment, and a decision is made to continue or increase the dose (step up method). After the 7th day, the patient is seen anywhere from daily to every one or two days. Another approach, the step down method, starts with a higher dose (2–3 ampules) and reduces the dose to one ampule after the initial response, theoretically approximating the changes in FSH in a normal ovulatory cycle.

Patients with polycystic ovaries are handled more gingerly because they are more sensitive to gonadotropin stimulation, and, therefore, at greater risk for multiple pregnancy and the ovarian hyperstimulation syndrome. The increased sensitivity to FSH is apparently due to the availability of a larger cohort of small follicles ready to respond to FSH (recruitable follicles).⁹⁶ In these patients, monitoring begins on the 4th or 5th day of treatment. Excessive stimulation can be avoided in women with polycystic ovaries by using lower doses of gonadotropin extended over a longer duration of treatment.^{97,98} In addition, good results are inversely correlated with the degree of insulin resistance,⁹⁹ and consideration should be given to treatment that improves insulin sensitivity (see elsewhere in this chapter and [Chapter 12](#)).

It cannot be emphasized too strongly that dosage administration and the judicious use of estrogen measurements depend upon the experience of the clinician administering gonadotropin therapy. When estradiol and ultrasound monitoring indicate that the patient is ready to receive the ovulatory stimulus, 10,000 units of HCG are given as a single dose intramuscularly. Neither manipulation of HCG dosage nor time of administration has been successful in changing the rates of multiple gestation and hyperstimulation. The patient is advised to have intercourse the day of the HCG injection and for the next 2 days. In view of the fragility of hyperstimulated ovaries, further intercourse as well as strenuous physical exercise should be avoided.

Pregnancy is usually achieved with the administration of gonadotropins for 7–12 days. The best results are obtained when the treatment period covers 10–15 days; when less than 10 days, the spontaneous miscarriage rate is increased.¹⁰⁰ In general there is a direct relationship between dose and body weight; however, the same empiric approach is needed even in obese patients.¹⁰¹ In some individuals, presumably with extremely hyposensitive ovaries, adequate follicular stimulation requires doses up to 4, 6, and more ampules/day. In this group of amenorrheic women massive doses of gonadotropins are necessary, and with proper monitoring, pregnancy can be achieved safely.

The range between the dose that does not induce ovulation and the dose that results in hyperstimulation is narrow. The situation is made even more difficult because the ovaries may react differently to essentially similar doses from month to month. Close supervision and experience in the use of gonadotropin therapy are necessary to avoid difficulties. There is no reason to avoid consecutive cycles of ovarian stimulation; indeed, an increased cycle fecundity has been observed in consecutive treatment cycles when compared to alternating stimulation and nontreatment.^{102,103}

Estrogen Monitoring

The use of estrogen measurements is necessary to choose the correct moment for administering the ovulatory dose of HCG in order to prevent hyperstimulation. On day 7 of the therapeutic cycle, blood is assayed for estradiol. Depending on the findings, the dosage of gonadotropin is individualized for the duration of the cycle. With experience, the clinician can avoid daily estrogen measurements, although sometimes this is necessary.

What should the blood estradiol level be? Because the blood estradiol is determined on a single sample of blood, the timing of the sampling with relationship to the previous injection of gonadotropin becomes a significant variable. When gonadotropin injections are given between 5 and 8 PM and blood samples are obtained first thing in the morning, an estradiol window of 1000–1500 pg/mL is optimal.¹⁰⁴ The risk of hyperstimulation is significant from 1500 to 2000 pg/mL and, as a general rule, over 2000 pg/mL, HCG should not be given, and the ovarian follicles should be allowed to regress. Careful correlation of estrogen levels with the ultrasonographic picture allows a more aggressive approach. Haning has calculated that an upper limit for estradiol of 3800 pg/mL for anovulatory women (with polycystic ovaries) and 2400 for women with hypothalamic amenorrhea gives a risk of severe hyperstimulation of 5% in pregnant cycles and 1% in nonconception cycles.¹⁰⁵

Attempting to reproduce the normal midcycle levels of estradiol does not achieve a maximal pregnancy rate, and higher levels are required. The relative safety of this approach was seen in our series, where only 2 of 24 patients with estradiol levels over 1000 pg/mL developed hyperstimulation and it was moderate in both cases.¹⁰⁴ When a patient nears ovulation, timing of the HCG administration can be predicted fairly accurately by plotting the estradiol values on semilogarithmic paper. The rate of increase in estradiol is the same in spontaneous and induced cycles, and does not differ in cycles that result in multiple gestation.¹⁰⁶ The level which is reached at the time of HCG administration is more critical than the slope of increase. Once a linear rise of estradiol is established, there is no need to increase the dose.

Ultrasound Monitoring

Ultrasound assessment of the growth and development of the ovarian follicle indicates the degree of follicular maturity and capability.¹⁰⁷ During normal cycles, the growing cohort of follicles can be first identified by ultrasonography on days 5 to 7 as small sonolucent cysts. The dominant follicle will become apparent by days 8–10. The maximal mean diameter, indicating ovum maturity, of the preovulatory dominant follicle varies from 20 to 24 mm (range 14–28 mm) in normal, spontaneous cycles. Individual women tend to produce the same maximal diameter on repeated cycles. Pregnancies have not been observed with follicles less than 17 mm diameter in normal cycles.¹⁰⁷ Subordinate follicles rarely exceed 14 mm in diameter. In 5–11% of cycles, two dominant follicles develop.

During the 5 days preceding ovum expulsion, the dominant follicle exhibits a linear growth pattern of approximately 2 to 3 mm per day, followed by rapid exponential growth during the last 24 hours prior to ovulation. *Ultrasonographic surveillance of ovaries reveals that mittelschmerz is associated not with follicular rupture but with the rapid expansion of the dominant follicle, thus the pain precedes follicular rupture.*

Ovulation is associated with complete emptying of the follicular contents in 1 to 45 minutes. Fluid can be detected frequently, but not always, in the cul-de-sac. The follicle either disappears or more commonly appears as a smaller, irregular cyst which diminishes in size over the next 4–5 days.

In response to clomiphene treatment, follicles pursue a linear but generally accelerated rate of growth compared to spontaneous cycles.¹⁰⁸ The maximal diameter of clomiphene-induced preovulatory follicles is similar to that seen with spontaneous cycles, 20–24 mm, but ovulation can be successfully induced with HCG administration when the diameter reaches 18–20 mm (by the time of ovulation, the follicle will have grown another 2–3 mm). With gonadotropin therapy, the maximal follicular diameter (15–18 mm) is smaller than that seen during spontaneous and clomiphene-induced cycles. When follicles reach this size, ovulation will occur approximately 36 hours after HCG is administered.

Ultrasound monitoring does not eliminate the risks of multiple gestation and hyperstimulation. It is claimed that a higher pregnancy rate can be achieved when ultrasound is combined with estrogen monitoring.¹⁰⁹ The guiding principle has been to administer HCG when mature follicles correlate with an estrogen level of 200–400 pg per mature follicle (greater than 13 mm diameter). This principle only applies when there are several leading follicles, not when many intermediate (9–16 mm) and small (<9 mm) follicles are present. As a general rule, hyperstimulation is associated with the presence of more follicles. We believe that HCG should not be administered if there are more than 3–5 follicles 13 mm or greater in diameter (offering some protection against multiple gestation and hyperstimulation). Mild hyperstimulation has been associated with an increased number of intermediate size follicles, and severe hyperstimulation with an increase in small follicles.^{110,111} A large number (11 or more) of smaller follicles also should preclude HCG administration.

200–400 pg per mature follicle (greater than 13 mm diameter). This principle only applies when there are several leading follicles, not when many intermediate (9–16 mm) and small (<9 mm) follicles are present. As a general rule, hyperstimulation is associated with the presence of more follicles. We believe that HCG should not be administered if there are more than 3–5 follicles 13 mm or greater in diameter (offering some protection against multiple gestation and hyperstimulation). Mild hyperstimulation has been associated with an increased number of intermediate size follicles, and severe hyperstimulation with an increase in small follicles. ^{110 111} A large number (11 or more) of smaller follicles also should preclude HCG administration.

Measurement of Endometrial Thickness. Ultrasonographic studies in cycles of in vitro fertilization have revealed that successful implantation is correlated with endometrial thickness on the day of HCG administration. ¹¹² This same correlation has been observed in patients in non-IVF patients receiving gonadotropins for ovulation induction. ¹¹³ Consistent with the antiestrogenic action of clomiphene, endometrial thickness is reduced in women treated with clomiphene (and reversed with estrogen). In a program utilizing clomiphene and timed administration of HCG for the purposes of intrauterine inseminations, no pregnancies occurred when the endometrial thickness measured less than 6 mm. ¹¹⁴ The chance of pregnancy is greatest, no matter what program of ovarian stimulation is being used, if endometrial thickness is 9–10 mm or more. ^{115 116}

The Effect of Persistent Ovarian Cysts. In contrast to results with IVF or GIFT, the presence of a baseline ovarian cyst greater than 10 mm in diameter is associated with decreased fecundity in ovulation induction with gonadotropins. ¹¹⁷ With large cysts, treatment should be either delayed, or cyst suppression with a GnRH agonist or oral contraceptives should be considered, although it has never been proven that such treatment is effective. With this exception, there is no advantage in avoiding multiple successive treatment cycles (such as alternating treatment and nontreatment cycles). ^{102 103}

Clomiphene-Gonadotropin Combination

The combination of clomiphene and gonadotropin was explored in order to minimize the amount and the cost of gonadotropin alone. As long as treatment is monitored with estrogen levels, the side effects and complications should not be dissimilar to those with gonadotropin alone. It has not been demonstrated that patients unresponsive to gonadotropin alone would respond to the sequence method, and there is no logical reason to assume that this would be true.

The usual method of treatment is to administer clomiphene 100 mg for 5–7 days, then to immediately proceed with gonadotropin beginning with 2 ampules per day. Estrogen levels are monitored as usual. This method may decrease the amount of gonadotropin required by approximately 50%; however, the same risks of multiple pregnancy and hyperstimulation can be expected. This reduced requirement for gonadotropin is found only in those patients who demonstrate a positive withdrawal bleeding following progestin medication or who have spontaneous menses. ¹¹⁸

Pulsatile Administration of Gonadotropin

Gonadotropin can be administered in pulsatile fashion, either subcutaneously or intravenously, using an appropriate pump system. ^{119 120} The aim is to reproduce the pulsatile pattern of gonadotropin secretion during the normal menstrual cycle. The dose administered intravenously is 6–9 units per pulse every 90 minutes, with adjustments upward according to response. The usual monitoring with estradiol levels and ultrasonography is necessary. It is not certain whether this complicated method is better beyond a decrease in dose and possibly a response in patients unresponsive to the traditional intramuscular regimen.

Results With Gonadotropin Treatment

The most significant aspect of this method of treatment is that it does achieve pregnancy in otherwise untreatable situations. A cumulative conception rate of 90% after 6 treatment cycles can be achieved in women with hypothalamic amenorrhea (this rate exceeds that observed in spontaneously ovulating women), with a 23% rate of spontaneous miscarriage. ^{121 122} Women with normogonadotropic anovulation achieve only a slightly lower cumulative conception rate with relatively, but slightly, higher rates of miscarriage; however, with appropriate and careful gonadotropin treatment, these rates equal those in the normal population. ¹²³ A slightly higher rate of spontaneous miscarriage reflects the combination of better detection of early pregnancy loss, advanced maternal age, and the increased incidence of multiple pregnancies. As with clomiphene, there is a normal incidence of congenital malformations, and the children have a normal postnatal development. ¹⁸ **The risk of ectopic pregnancy is increased with ovulation induction, a consequence of multiple oocytes and high hormone levels.** ¹²⁴ These patients should be closely monitored in the early weeks of their pregnancies.

Women with polycystic ovaries and moderate obesity require larger doses of gonadotropin and ovulate at a lesser rate compared to leaner women with polycystic ovaries. ¹²⁵ A comparable pregnancy rate (40%) is achieved. However, spontaneous miscarriage is more frequent, which is consistent with the observation that spontaneous miscarriage is more frequent in obese women.

HCG disappears from the blood with an initial component having a half-life of about 6 hours and a second, slower, component with a half-life of about 24 hours. It is this relatively slow half-life that enables a single injection of 10,000 IU to maintain the corpus luteum until pregnancy takes over. The HCG concentration after the ovulation injection should be less than 50–100 IU/L by day 14 after the injection. A b-subunit assay of HCG at this time or one of the urine assays performed 2–4 weeks after the HCG injection are reliable tests for pregnancy. Additional HCG (during the luteal phase) does not improve pregnancy rates. ¹²⁶ Luteal supplementation is required only with concurrent treatment with a GnRH agonist.

The rate of serious hyperstimulation is 1–2%. Prior to the present era of more careful monitoring, the multiple pregnancy rate was reported as approximately 30% (triplets or more, 5%). Currently, the multiple pregnancy rate can be as low as 10% with careful monitoring and good medical judgment; however, rates as high as 40% are reported. ¹⁰⁹ A striking increase in multiple births in many countries, especially triplets and quadruplets, can be directly attributed to ovulation stimulation for the treatment of infertility. ^{127 128 and 129}

The multiple pregnancies are secondary to multiple ovulations, and, therefore, the siblings are not identical. The rate of spontaneous occurrence of twins is only about 1% and that of triplets 0.010–0.017% of the pregnant population. Dizygotic twinning varies among different populations and is inherited through the mother. The monozygotic twinning rate is about 0.3–0.4%, fairly constant, and uninfluenced by heredity. Surprisingly, induction of ovulation increases the frequency of monozygotic twinning 3-fold. ¹³⁰ It is not known whether the multiple pregnancy rate with gonadotropin is significantly affected by a maternal history of twinning.

Maternal complications and fetal loss caused by prematurity in the multiple pregnancies have been serious problems. In addition, the miscarriage rate with gonadotropin is somewhat higher (25%) than normal, probably a combination of the effect of age, multiple pregnancies, and recognition of early miscarriages. ¹³¹

After at least one gonadotropin-induced pregnancy, the subsequent spontaneous pregnancy rate reaches 30% after 5 years. ¹³² Most of the pregnancies occur within 3 years of the gonadotropin-induced pregnancy, and the more endogenous hypothalamic-pituitary-ovarian function a patient has, the more likely a spontaneous pregnancy will occur. ¹³³ This is consistent with a return to normal function in some women after suppression of a dysfunctional state. With time, it is logical to expect the original dysfunctional state to reestablish itself.

Multifetal Pregnancy Reduction. Induced abortion in the case of triplets or more is an option, but it would be surprising if patient and clinician would choose this solution. On the other hand, selective reduction of embryos in multiple pregnancy can be accomplished. ¹³⁴ Under ultrasound guidance, a gestational sac can be aspirated or a cardiotoxic drug (potassium chloride) can be injected into, or adjacent to, the fetal heart. The transvaginal procedure is best performed between the 8th and 9th weeks of gestation and the transabdominal procedure between the 11th and 12th weeks. A later procedure is worthwhile because the spontaneous disappearance of one or more gestational sacs in multiple gestations can occur, an incidence of approximately 5% after fetal heartbeats have been identified. ¹³⁵ Selection of which gestational sac to terminate is based solely on technical considerations, such as accessibility. The subsequent risk of losing one or more of the remaining fetuses is 4–9%, and of losing the pregnancy, 10% by experienced clinicians and higher with less experience. Reduction of a monochorionic pregnancy is not advisable because of shared vasculature and the high risk of losing all fetuses. The moral and ethical aspects of fetal reduction are significant, but in view of the potential problems associated with a multiple birth, it is a reasonable alternative for some.

The Hyperstimulation Syndrome

Ovarian hyperstimulation can be life-threatening. In mild cases the syndrome includes ovarian enlargement, abdominal distension, and weight gain. In severe cases, a critical condition develops with ascites, pleural effusion, electrolyte imbalance, and hypovolemia with hypotension and oliguria. ^{136 137 and 138} The ovaries are tremendously enlarged with multiple follicular cysts, stromal edema, and many corpora lutea. Because of this enlargement, torsion of the adnexa is a relatively common complication of this syndrome. ¹³⁹

The incidence of clinically important hyperstimulation is striking. Although it might be expected that the mild type would be relatively common, the moderate to severe form appears at an impressive rate (1–2%). Two-thirds of cases occur early in a conception cycle, the remainder in nonconception cycles. For purposes of one of the methods of assisted reproduction, the ovaries are stimulated at an even greater rate than for conventional ovulation induction; however, the incidence of

The incidence of clinically important hyperstimulation is striking. Although it might be expected that the mild type would be relatively common, the moderate to severe form appears at an impressive rate (1–2%). Two-thirds of cases occur early in a conception cycle, the remainder in nonconception cycles. For purposes of one of the methods of assisted reproduction, the ovaries are stimulated at an even greater rate than for conventional ovulation induction; however, the incidence of hyperstimulation is no greater, or even lower.^{140, 141} For this reason, it has been suggested that follicular aspiration offers partial protection against the hyperstimulation syndrome. Some reports have indicated a higher incidence of hyperstimulation in in vitro fertilization protocols using the combination of gonadotropin and a GnRH agonist.¹⁴⁰ Because support during the luteal phase is required when GnRH agonist treatment is used, the additional HCG administered is responsible for greater stimulation. The use of progesterone for luteal support is probably safer, and therefore, when estradiol levels are high (greater than 2500 pg/mL) and when the follicle number is greater than 15, progesterone supplementation is recommended instead of HCG.

Anovulatory women with polycystic ovaries are at greatest risk for the hyperstimulation syndrome. The use of a GnRH agonist in combined therapy does not eliminate this risk. These patients should be treated slowly with careful titration of dose as described earlier.

The basic disturbance in hyperstimulation is a shift of fluid from the intravascular space into the abdominal cavity, creating a massive third space. The resulting hypovolemia leads to circulatory and excretory problems. The genesis of the ascites is unclear. The very high level of estrogen secretion by the ovaries may be the primary factor, inducing increased local capillary permeability and leakage of fluid from the peritoneal capillaries as well as the ovaries. The leakage of fluid is also critically related to the mass, volume, and surface area of the ovaries. Therefore, the larger the ovaries and the greater the steroid production, the more severe the condition. Or the syndrome may result from overproduction of autocrine/paracrine factors that affect vascular permeability.

A growing body of evidence implicates vascular endothelial growth factor (VEGF) in the pathophysiology of the hyperstimulation syndrome. The origin of VEGF is presumed to be the ovarian follicle, and increased capillary permeability and the severity of the syndrome are correlated with circulating levels of VEGF.^{142, 143 and 144} Other cytokines, especially the interleukin family, are also believed to be involved in the permeability changes, and it is hypothesized that these agents affect the nitric oxide system.^{145, 146} Large amounts of angiotensin II are present in the ascites produced by ovarian hyperstimulation, presumably originating from HCG stimulation of the ovarian renin-angiotensin system.¹⁴⁷

The loss of fluid and protein into the abdominal cavity accounts for the hypovolemia and hemoconcentration. This in turn results in low blood pressure and decreased central venous pressure. The major clinical complications are increased coagulability and decreased renal perfusion. Blood loss as the cause of the clinical picture can be easily ruled out since a hematocrit will reveal hemoconcentration. The decreased renal perfusion leads to increased salt and water reabsorption in the proximal tubule, producing oliguria and low urinary sodium excretion. With less sodium being presented to the distal tubule, there is a decrease in the exchange of hydrogen and potassium for sodium, resulting in hyperkalemic acidosis. A rise in the blood urea nitrogen (BUN) is due to decreased perfusion and increased urea reabsorption. Because it is only filtered, creatinine does not increase as much as the BUN. Thus, the patient is hypovolemic, azotemic, and hyperkalemic. In response to these changes, aldosterone, plasma renin activity, and antidiuretic hormone levels are all elevated.¹⁴⁸

Treatment is conservative and empiric. When a patient displays excessive weight gain (usually 10 or more pounds), excessive pain, hemoconcentration (hematocrit over 50%, white blood count over 25,000), oliguria, dyspnea, or postural hypotension, she should be hospitalized. Pelvic and abdominal examinations are contraindicated in view of the extreme fragility of the enlarged ovaries. Ovarian rupture and hemorrhage are easily precipitated.

Upon admission, the patient is put on bed rest, with daily body weights, strict monitoring of intake and output, and frequent vital signs. Serial studies of the following are obtained: hematocrit, BUN, creatinine, electrolytes, total proteins with albumin:globulin ratio, coagulation studies, and urinary sodium and potassium. The electrocardiogram is utilized to follow and evaluate hyperkalemia. Fluid and salt restriction is controversial. It is argued that correction of the decreased circulating volume is not necessary as long as the BUN remains stable (an abnormally low urine output can be tolerated).¹⁴⁸ Others believe that plasma expanding agents and electrolyte supplements should be administered.¹⁴⁹ Human albumin (safe from viral contamination) is the volume expander of choice. Potassium exchange resins may be necessary. Diuretics are without effect and, indeed, may be disadvantageous. The fluid in the abdominal cavity is not responsive to diuretic treatment, and diuresis may further contract the intravascular volume and produce hypovolemic shock or thrombosis. Arterial and venous thromboses have been reported in both the upper and lower portions of the body, and anticoagulant therapy should be considered in severely hemoconcentrated patients.^{150, 151 and 152} Although both antihistamines and indomethacin have been demonstrated to ameliorate the hyperstimulation in animal studies, their efficacy and safety in early human pregnancy are unknown. Inhibition of prostaglandin synthesis can worsen renal perfusion.

In severe cases, life-threatening adult respiratory distress syndrome can occur.¹⁵³ These patients require intensive care monitoring, including central venous and pulmonary wedge pressures. Adult respiratory distress syndrome is associated with a 50% mortality rate. Chlorpheniramine maleate, an H-1 receptor blocker, appears to maintain membrane stability, allowing the use of fluids and mannitol to retain intravascular volume.¹⁵⁴ With ultrasound guidance to avoid the enlarged ovaries, abdominal paracentesis can relieve severe pulmonary compromise. Aspiration of ascites can also be accomplished (and probably more easily) transvaginally (with ultrasound guidance).^{155, 156} With repeated aspirations, it is very important to replace the lost plasma proteins (autotransfusion of the ascitic fluid has been used in a small number of cases). On the average, repeat aspirations are necessary in 3 to 5 days.

In severe cases, transvaginal aspiration of follicular structures should be considered to interfere with the intraovarian mechanism responsible for the clinical picture; progesterone supplementation will be necessary to maintain an on-going pregnancy.¹⁵⁷

The possibility of ovarian rupture should always be considered, and serial hematocrits may be the only clue to intraperitoneal hemorrhage. Of course, a falling hematocrit accompanied by diuresis is an indication of resolution, not hemorrhage. Laparotomy should be avoided in these precarious patients. If surgery is necessary, only hemostatic measures should be undertaken and the ovaries should be conserved if possible, since a return to normal size is inevitable. If torsion of the adnexa is encountered, unwinding the adnexa (and preserving the ovary in an infertile patient) is possible even when the adnexa are already ischemic.

The key point is that the hyperstimulation syndrome will undergo gradual resolution with time. In a patient who is not pregnant, the syndrome will cover a period of approximately 7 days. In a patient who is pregnant and in whom the ovaries are restimulated by the emerging endogenous HCG production, the syndrome will last 10–20 days.

The syndrome will not develop unless the ovulatory dose of HCG is given. Thus, the major emphasis in recent years has been to utilize monitoring to avoid hyperstimulation. The relationship between estrogen levels and hyperstimulation is not a perfect one. Hyperstimulation has been found with relatively low estrogen levels, and high estrogen is not necessarily followed by hyperstimulation. As a general rule, the more follicles present (on ultrasound examination) the greater the risk for hyperstimulation. But this too is not a perfect correlation. Nevertheless, monitoring is the major available deterrent to a potentially life-threatening situation.

What to Do With Gonadotropin Failures?

At one time, management of the couple who had failed ovulation induction with gonadotropin treatment was difficult, but straightforward. Short of another costly round if funds and emotional reserves were sufficient, nothing was left to offer except adoption. Today, a major option is now available in the assisted reproductive technologies ([Chapter 31](#)). Although even more costly and emotionally charged, these methods do offer significant additional opportunities for unsuccessful patients. Nevertheless, guidance to adoption services and emotional support continue to be part of the physician's obligation.

A very important question for patients is: when to stop? All clinicians have been confronted by the dismal and frustrating prospects of a woman who has squandered years in vain repetitive attempts at ovulation induction, only to arrive at age 40 for intervention with one of the methods of assisted reproductive technology. If a properly managed set of 6 gonadotropin cycles is unsuccessful, the prudent counsel is to recommend a turn toward the methods of assisted reproductive technology.

Can Failure to Respond Be Predicted?

Women who present with "incipient" ovarian failure have elevated FSH levels and decreased levels of inhibin, but normal levels of estradiol.^{158, 159} The rise in FSH during the later years is in response to declining inhibin production.^{160, 161, 162 and 163} Inhibin levels are lower in the follicular phase in women 45–49 years old compared with younger women. The specific inhibin involved in this feedback effect on FSH during the follicular phase is inhibin B.^{164, 165} In addition, a decline in luteal phase inhibin A can contribute to a greater rise in FSH during the luteal-follicular transition.¹⁶⁶ This decline in inhibin begins early, but accelerates after 40 years of age. The rise in FSH is very apparent after age 40, but there is no change in LH levels until menopause. The changes in the later reproductive years reflect either lesser follicular competence, as the better primordial follicles respond early in life, leaving the lesser follicles for later, or the fact that the total follicular pool is reduced in number (or both factors). Arguing in favor of a role for a reduced follicular pool is the observation that follicular fluid obtained from preovulatory follicles of older women contains amounts of inhibin A and B that are similar to that measured in follicular fluid from young women.¹⁶⁷

inhibin A can contribute to a greater rise in FSH during the luteal-follicular transition.¹⁶⁶ This decline in inhibin begins early, but accelerates after 40 years of age. The rise in FSH is very apparent after age 40, but there is no change in LH levels until menopause. The changes in the later reproductive years reflect either lesser follicular competence, as the better primordial follicles respond early in life, leaving the lesser follicles for later, or the fact that the total follicular pool is reduced in number (or both factors). Arguing in favor of a role for a reduced follicular pool is the observation that follicular fluid obtained from preovulatory follicles of older women contains amounts of inhibin A and B that are similar to that measured in follicular fluid from young women.¹⁶⁷

These endocrine changes and the decline in ovarian follicles are correlated with a decrease in ovarian volume.¹⁶⁸ A measurement of volume by ultrasonography that is equal to or less than 3 cm³ predicts a poor response to ovulation induction.¹⁶⁹

Testing the Ovarian Reserve

The measurement of baseline hormonal levels provides important and helpful prognostic information. Because FSH levels increase with age, elevated FSH levels on cycle day 3 (greater than 12 IU/L, but especially greater than 20 IU/L) are associated with poor performance with in vitro fertilization.¹⁷⁰ A cycle day 3 FSH level that is 25 IU/L or more, or an age of 44 years or more, are both independently associated with a chance of pregnancy close to zero during ovulation induction or with assisted reproductive technologies.¹⁷¹ **Values can vary between laboratories, significantly due to differences in antibodies and standards used to measure gonadotropin levels.¹⁷² With the most recent assays, day 3 values above 10 IU/L are abnormal and are comparable with values greater than 20 IU/L with older assays.**

Keep in mind that there is no abrupt change at 40, and, therefore, these changes can apply to younger women. The age of change is determined by the rate of oocyte loss, a rate that is genetically programmed in most women. An elevated FSH at any age is correlated with fewer available oocytes, and advancing age adds the factor of lesser oocyte quality. An elevated estradiol level on day 3 (greater than 80 pg/mL) is also predictive of difficulty in achieving pregnancy;^{173, 174} premature estradiol elevations are associated with a hurried recruitment of follicles in response to increased FSH secretion, changes characteristic of the years preceding menopause. When both FSH and estradiol are elevated on day 3, ovarian response to stimulation is very poor.

The Clomiphene Challenge Test. Navot and colleagues developed the clomiphene challenge test as a bioassay of FSH response (which in turn reflects ovarian follicular inhibin capability).¹⁷⁵ Clomiphene is administered in a dose of 100 mg/day on days 5–9. The level of FSH on day 10 is compared with the baseline level on day 3. An exaggerated FSH response of 26 IU/L or more was two standard deviations above the control values in this study, and this increase in FSH was associated with a significant prospect for failure to achieve pregnancy. **Remember that there is a wide variety of FSH assays (the newer assays provide numbers that are approximately 70% of the older results), and clinicians must become familiar with the values provided by their own laboratories.** There is a high incidence of abnormal responses in women over age 35, and 85% of women with increased FSH levels respond poorly to ovarian stimulation.¹⁷⁶ In a general infertility population, about 10% of women have an abnormal response to the clomiphene challenge test. As expected, the percentage increased with increasing age (from 3% under age 30 to 26% over age 39), and women with unexplained infertility had a 38% incidence of abnormal tests.¹⁷⁷ This test of ovarian reserve is more sensitive than just measuring basal FSH levels in predicting the potential for pregnancy in both assisted and natural reproduction. An abnormal response to the clomiphene challenge test indicates a poor prognosis no matter the woman's age.¹⁷⁸ However, because age alone is an important factor (presumably due to other age-related oocyte conditions of quality), older women with normal hormone levels and normal responses to clomiphene still have diminished chances of pregnancy.

We believe it is worthwhile to screen all infertile women beginning at age 30, women of any age with unexplained infertility, and women who respond poorly to ovulation induction with the clomiphene challenge test and a day 3 estradiol level. For practical purposes, equivalent results can be expected on days 2, 3, and 4 of the cycle. Far less certain is the need for these tests in the woman over 40, because even normal tests do not provide reassurance of adequate ovarian reserve. An abnormal test in a woman over 40, however, can be used to bolster advice to consider ovum donation. Although an abnormal test at any age indicates a very poor prognosis, it does not indicate an absolute inability to achieve pregnancy.

Regardless of age, women with elevated day 3 FSH levels and/or abnormal responses to the clomiphene challenge test should consider in vitro fertilization with young, donated oocytes. Patients should also be informed that a failure to respond to gonadotropin treatment despite normal screening hormonal levels places them at risk for progressing to ovarian failure in a relatively short time.¹⁷⁹

GnRH Agonist and Gonadotropin Combined Treatment

Recognizing that women with significant estrogen, androgen, and gonadotropin levels do not respond well to induction of ovulation, attention was turned to a method that could turn off a woman's endogenous reproductive hormone production. The availability of GnRH agonists provided such a method. The thesis underlying the use of a GnRH agonist as an adjunctive therapy in ovulation induction is straightforward: convert normogonadotropic anovulators to a hypogonadotropic hypogonad state by the process of pituitary GnRH receptor desensitization and down-regulation.^{180, 181} Premature LH effects on the follicle and the burden of excess local androgen can be diminished and an improved therapeutic response achieved. There is reason to believe that women with anovulatory polycystic ovaries have a higher incidence of spontaneous miscarriage following induction of ovulation with gonadotropin;^{73, 74} and⁷⁵ combining the GnRH agonist with gonadotropin not only yields a greater pregnancy rate, but also reduces the miscarriage rate.¹⁸² Furthermore, premature LH release is believed to contribute to the risk of ovarian hyperstimulation in women with polycystic ovaries.¹⁸³ Combining a GnRH agonist with gonadotropin treatment could reduce (although not eliminate) the risk of this serious complication.

Leuprolide acetate (Lupron) is administered twice daily (0.5 mg subcutaneously) for 2 weeks.¹⁸¹ Suppression of gonadotropin secretion is confirmed by measurement of the estradiol level; a concentration less than 25 pg/mL should be achieved before treatment is initiated with gonadotropins. Lupron treatment is maintained throughout the gonadotropin regimen until HCG is administered. It is not unusual to require higher doses of gonadotropin. With this combination, no difference has been observed in the number of follicles recruited, the rate of rise and final estradiol level achieved, or the number of cycles canceled compared with gonadotropin alone. Hyperstimulation is not avoided, but per cycle fecundity appears to be modestly increased. Any of the available GnRH agonists can be used for this purpose. Pituitary suppression can be combined with highly purified or recombinant FSH; it appears that very little LH is necessary for normal responses.¹⁸⁴

The administration of a GnRH agonist to a woman who has menstrual function will initially produce a stimulatory response, known as the "flare." The magnitude of the flare response depends upon when in the cycle the agonist is administered. During the follicular phase or in anovulatory women, the flare is greater, and enlarged follicular cysts can occur. This response can be minimized by beginning therapy during the midluteal phase or by administering a progestational agent (e.g., 10 mg medroxyprogesterone acetate daily for 10 days) and beginning GnRH agonist treatment after 3 days of progestin.

During the hypoestrogenic period of time, menopausal-like symptoms are common, especially hot flashes. Forewarning and reassurance are usually sufficient to help patients tolerate these short-lived reactions.

Utilization of a GnRH agonist suppresses endogenous LH levels to such a low level that, after ovulation, the corpus luteum requires additional exogenous support. One can administer HCG (2000 IU) twice, 3 days, and 6 days after ovulation, or progesterone supplementation beginning 3 days after ovulation (4 days after the LH surge): intravaginal progesterone suppositories, 25 mg twice per day, intramuscular progesterone, 50 mg per day, or oral micronized progesterone, 300 mg per day. The dose of micronized progesterone is relatively high and should be administered at bedtime to avoid side effects. Progesterone in a gel that adheres to the vaginal mucosa (Crinone) is available in a prefilled vaginal applicator, applied with one 8% (90 mg progesterone) application daily. Vaginal administration accomplishes targeted delivery to the uterus without producing high circulating levels. The pregnancy rates with either HCG or progesterone treatment are the same, but the use of HCG adds to the risk of hyperstimulation.^{185, 186}

GnRH Antagonists

More extensive alterations in the GnRH structure yield compounds that bind to the GnRH receptor and totally block any stimulation of the pituitary gonadotropin-secreting cells. GnRH antagonists can be used concomitantly with gonadotropin induction of ovulation to prevent premature LH surges.¹⁸⁷ Because GnRH antagonists are competitive inhibitors, a GnRH agonist could be used for the ovulatory signal, possibly avoiding the use of HCG and reducing the risk of ovarian hyperstimulation. The optimal use of GnRH antagonists is currently being explored.

Adding Growth Hormone

As discussed in [Chapter 6](#), the primate ovarian follicular cycle is very dependent upon autocrine/paracrine factors. In view of the critical role played by insulin-like growth factor-I, it was quickly recognized that the addition of growth hormone (which stimulates insulin-like growth factor-I production), usually in a dose of 24 IU given

Adding Growth Hormone

As discussed in [Chapter 6](#), the primate ovarian follicular cycle is very dependent upon autocrine/paracrine factors. In view of the critical role played by insulin-like growth factor-I, it was quickly recognized that the addition of growth hormone (which stimulates insulin-like growth factor-I production), usually in a dose of 24 IU given intramuscularly every other day, might facilitate ovulation induction by gonadotropins, and especially, might convert poor responders to good responders. Initial results in poor responders were favorable, although this may be limited to patients with polycystic ovaries. ^{188, 189} In women with normal responses, however, the addition of growth hormone did not improve results or reduce the total dose of gonadotropin. ¹⁹⁰ Thus, in normally responding women, the growth hormone and IGF-I system may be operating at maximal levels. In poorly responding women, concomitant treatment with growth hormone can reduce the amount of gonadotropin necessary, shorten the duration of treatment, and increase the chance of pregnancy. However, not all poorly responding women respond favorably to growth hormone treatment. ¹⁹¹ The effective selection of patients, dosage, and treatment regimens remains to be standardized, and the extreme cost of growth hormone is a significant disadvantage. Another approach is to administer growth hormone-releasing hormone. In a small randomized trial (13 women), the addition of growth hormone-releasing hormone to gonadotropin treatment was associated with a higher pregnancy rate. ¹⁹² However, others have administered 500 µg of growth hormone releasing hormone twice daily to poor responders with little effect, although the dosage of gonadotropin may be reduced. ^{193, 194}

Induction of Ovulation With Gonadotropin-Releasing Hormone (GnRH)

Numerous advantages can be cited in favor of pulsatile GnRH therapy for ovulation induction. GnRH methodology, once established, is simple to use, requires no extensive (or expensive) follicular monitoring, and, relative to its counterparts, is quite safe. Ovarian hyperstimulation and multiple gestations are rare because only “physiologic” levels of FSH should be generated. Because GnRH serves largely a permissive role, the internal feedback mechanisms between the ovary and pituitary should be operative, yielding follicular growth and development similar to a normal menstrual cycle in response to the “turning on” of the system by GnRH.

GnRH is administered constantly in a pulsatile fashion by a programmable portable minipump. Induction of ovulation with the GnRH pump is most effective in women with hypothalamic amenorrhea (absence of menstrual bleeding following a progestin challenge) where endogenous GnRH is dysfunctional or absent. Unfortunately, although it has been successful in some anovulatory women with polycystic ovaries, this success is far less than anticipated, and these patients are at greater risk for hyperstimulation and multiple pregnancy, therefore requiring a lower dose (2.5 µg per bolus). ^{195, 196} Nevertheless, the GnRH pump is a safer, less expensive alternative for these patients than gonadotropin therapy. The GnRH pump is also effective in women with hyperprolactinemia, providing a good alternative if dopamine agonist treatment cannot be tolerated.

GnRH is available in crystalline form that when reconstituted in the aqueous diluent is stable for at least 3 weeks at room temperature. The pump must be worn constantly around the clock, requiring some ingenuity for bathing and sleeping. GnRH can be administered by either the intravenous or subcutaneous routes. The subcutaneous route requires a higher dose. Failure with subcutaneous administration is associated with a polycystic ovary-like picture, with high LH levels, anovulation, and even symptoms of androgen excess. This is not surprising because subcutaneous administration results in an absorption curve with a broad base without a definite peak. For intravenous administration, heparin is added to the GnRH solution in a concentration of 1000 U/mL. We favor starting with the intravenous route. The needle is left in place until there are signs of local reaction and then changed. Women at risk for bacterial endocarditis should be restricted to the subcutaneous route of administration.

Although some argue in favor of near physiologic duplication of the pulse frequency, similar results can be obtained with empiric 90-minute cycles throughout treatment. The dose for subcutaneous administration is 20 µg per bolus, for intravenous administration, 5 µg per bolus. If the patient fails to respond (assessed by weekly measurement of estradiol), the dose should be increased by 5 µg increments.

After ovulation, the luteal phase is maintained by either continuing the pump or administering HCG (2000 IU intramuscularly at the time of the temperature rise and then every 3 days for 3 doses). In our experience, most patients would rather discontinue the pump.

One of the reasons that the GnRH pump is less expensive is that it reproduces physiologic hormonal events, and intensive monitoring is not necessary. The main problem is knowing with some accuracy when to have intercourse. Usually ovulation occurs by 14 days of treatment, but the range extends from 10 days to 22 days. Intercourse every other day during this period of time can be a formidable challenge. Ultrasonic monitoring of follicular development may be required, or more conveniently, the couple can use one of the urinary LH test kits to detect the LH surge and have intercourse for 2–3 days beginning the day of the color change.

Side effects with the GnRH pump are minimal, principally related to pump functioning and local reactions to the needle placement. The patient must be educated to pay close attention to proper function of the pump and maintenance of the GnRH reservoir. Hyperstimulation and multiple births have been encountered, but this is rare and associated with higher than recommended doses. The risk of dangerous hyperstimulation is essentially zero. Several cases of allergic response with the development of circulating antibodies have been reported.

The pregnancy rate in anovulatory women is 20–30% per treatment cycle, which approximates the pregnancy rate of normal couples. ^{197, 198} Persistence with repeated cycles is rewarded with high cumulative pregnancy rates, approximately 80% after 6 cycles and 93% after 12 cycles. ¹⁹⁹ The miscarriage rate of 20% is typical of all methodologies. The incidence of multiple pregnancy is low (4–5%). The cumulative pregnancy rate in women with polycystic ovaries is approximately 30–40%. If this method is to be used for women with polycystic ovaries, it is recommended that desensitization and down-regulation of the pituitary with a GnRH agonist precede treatment (and retreatment will be necessary with each cycle). This approach can yield a cumulative pregnancy rate of 60%. ²⁰⁰ Even then, obese patients are less likely to respond, and they have higher rates of spontaneous miscarriage.

The safety and simplicity of GnRH administration are powerful attractions. Despite the clear advantages, the GnRH pump has not received wide acceptance by patients. Many are irrationally fearful of the risk of needle displacement or equipment problems associated with the technology. Because of this low acceptance, appropriate pumps for the administration of GnRH are no longer available in many countries.

Ovarian Surgical Procedures

Irving Stein and Michael Leventhal, in 1935, at the Michael Reese Hospital in Chicago, described 7 cases of the syndrome that bears their names. ²⁰¹ They developed wedge resection of the ovaries when they observed that several of their amenorrheic (anovulatory) patients with polycystic ovaries menstruated after ovarian biopsies. In their original procedure, they removed 50 to 75% of each ovary. They concluded that the thickened surface of the ovary prevented follicles from reaching the surface. For years, the wedge resection was the only method available to induce ovulation in these patients, and it wasn't until 30–40 years later that an accurate understanding of the mechanism was achieved.

The purpose of wedge resection of the ovaries is to remove a significant amount of hormone-producing tissue. Documentation of hormone changes following wedge resection indicates that an important change is a sustained reduction in testosterone levels. ^{202, 203} This suggests that the barrier to ovulation is the intraovarian, atresia-promoting effects of the high testosterone production. Removal of androgen-producing tissue effectively lowers this barrier, and ovulatory cycles can ensue. The success of wedge resection is directly proportional to the volume of androgen-producing tissue removed. Tissue removal and destruction are the key factors, not the shape and procedure of the “wedge.” Indeed, even a unilateral oophorectomy is followed by resumption of ovulation in anovulatory women with polycystic ovaries. ²⁰⁴

Another contributing factor is a reduction in circulating levels of inhibin, which follows the loss of ovarian tissue. ²⁰⁵ A rise in FSH occurs in the days after wedge resection; successful ovulation reflects the combined effects of increased FSH and the removal of the local androgen obstruction to the emergence of a dominant follicle.

The response to ovarian wedge resection is variable. Some patients resume ovulation permanently. However, most patients return to their anovulatory state. Some patients fail to respond at all. Furthermore, the surgical procedure carries with it the potential problem of postoperative adhesion formation.

The operative risk, the variable response, and the possibility of postoperative adhesion formation are the liabilities of wedge resection. These must be weighed against the excellent results obtained with medical induction of ovulation (approximating the normal conception rate when anovulation is the only fertility problem present). It should truly be a rare patient in whom wedge resection of the ovaries is necessary.

Today, a new type of “wedge resection” is available. Using either cautery, diathermy, or laser vaporization by means of the laparoscope, destruction of ovarian tissue at multiple sites (15–20 per ovary) can achieve spontaneous ovulations or an increased sensitivity to clomiphene, ultimately achieving pregnancy rates equivalent to those with gonadotropin treatment (but without the risks of hyperstimulation and multiple pregnancies). ^{206, 207, 208, 209 and 210} These procedures are associated with the

present). It should truly be a rare patient in whom wedge resection of the ovaries is necessary.

Today, a new type of “wedge resection” is available. Using either cautery, diathermy, or laser vaporization by means of the laparoscope, destruction of ovarian tissue at multiple sites (15–20 per ovary) can achieve spontaneous ovulations or an increased sensitivity to clomiphene, ultimately achieving pregnancy rates equivalent to those with gonadotropin treatment (but without the risks of hyperstimulation and multiple pregnancies).^{206, 207, 208, 209 and 210} These procedures are associated with the same decrease in androgens and inhibin as observed with wedge resection. When clomiphene is reinstated, 70–80% of patients will ovulate, and approximately 60% will achieve pregnancy. Adhesion formation remains a problem, but perhaps it is less profound than in the traditional surgery.^{210, 211} Second look laparoscopy with lysis of adhesions is indicated if pregnancy does not follow successful ovulations. This therapy can be performed at the time of a planned diagnostic laparoscopy in a patient with known anovulation and polycystic ovaries. These procedures are worth considering by patients who are reluctant to pursue the more expensive and difficult methods of the assisted reproductive technologies. These methods are the modern equivalent of the original ovarian wedge resection pioneered by Stein and Leventhal.

Superovulation and IUI for Unexplained Infertility

The methods of assisted reproductive technology and superovulation with intrauterine insemination (IUI) increase the prospect of pregnancy in couples with unexplained infertility. The results with superovulation alone are inferior to those achieved with one of the assisted reproductive techniques, but the overall cost is also less.²¹² Studies indicate that subtle hormonal abnormalities do exist in women with unexplained infertility.^{213, 214} These changes (elevated gonadotropins and estradiol in the follicular phase and decreased luteal phase progesterone) have been attributed to a reduction in ovarian reserve as usually seen in older women.²¹⁴ Thus, there is a rational basis to provide ovarian stimulation.

A cumulative pregnancy rate of 40% can be achieved in couples with unexplained infertility after 6 cycles of superovulation or 3 cycles of in vitro fertilization.²¹⁵ In randomized, controlled clinical trials, the monthly pregnancy rates in couples with unexplained infertility is increased 2–3-fold (a monthly fecundity rate of 9%) with clomiphene treatment, and with human gonadotropins, the monthly fecundity rate is approximately 10–15%.^{216, 217 and 218} **Although some studies have failed to yield increased pregnancy rates with the empiric use of clomiphene,^{219, 220} we believe couples with unexplained infertility should be offered superovulation or one of the assisted reproductive technologies. However, superovulation should be limited to 3 or 4 cycles.**

The addition of intrauterine insemination of washed sperm (IUI) to clomiphene treatment increased fecundity in couples with unexplained infertility or surgically treated endometriosis, compared with intercourse without hormonal stimulation.²¹⁷ As with almost all infertility, success is age-related, with pregnancy rates 3–4-fold greater in women under age 20.²²¹ Although the combination of IUI with clomiphene may enhance the pregnancy rate in couples with unexplained infertility, **IUI by itself does not.**^{222, 223 and 224}

The combination of IUI with gonadotropin stimulation provides even better results than clomiphene and IUI. In two studies, the pregnancy rate per cycle with gonadotropins and IUI was 19% and 14.3% compared to 4% and 7.7% with clomiphene and IUI respectively.^{218, 225} In a meta-analysis of randomized trials comparing gonadotropin stimulation with IUI or with timed intercourse, IUI was associated with approximately a 2-fold greater pregnancy rate.²²⁶ In a randomized trial, superovulation and IUI resulted in a 3-fold greater pregnancy rate compared with intracervical insemination and 2-fold greater compared with either IUI alone or a combination of superovulation and intracervical insemination.²⁴¹

The effectiveness of gonadotropin treatment combined with IUI has been repeatedly demonstrated for a variety of infertility disorders, including endometriosis, cervical factor, and unexplained infertility.^{227, 228 and 229} As with clomiphene, few pregnancies occur after 4 cycles of treatment.

In summary, a meta-analysis of methods used to treat unexplained infertility, pregnancy rates were estimated to be as follows:

Pregnancy Rate per Cycle¹⁶⁹

No treatment	1.3–4.1%
IUI	3.8%
Clomiphene	5.6%
Clomiphene & IUI	8.3%
Gonadotropins	7.7%
Gonadotropins & IUI	17.1%
IVF	20.7%

Because it is relatively inexpensive, easy to administer, and not usually burdened with major side effects (except for a 2-fold increase in twinning), clomiphene is usually the first treatment choice. Patient demand for this treatment is substantial, and it is not unreasonable to respond to that demand with 3–4 clomiphene cycles. The uncertainty regarding the efficacy of adding IUI to clomiphene influences us to proceed from clomiphene treatment to the combination of gonadotropins and IUI, with an expectation of achieving a pregnancy rate of 15% per cycle. The combination of clomiphene and IUI is still appropriate in circumstances where cost, time, and avoidance of complications are paramount. The use of IUI alone or gonadotropins without IUI is not recommended for the treatment of unexplained infertility.^{223, 231}

The effects of age remain critical whatever the method of ovarian stimulation. In one series of 136 treatment cycles, no pregnancies were achieved in women who were 43 or older.²³² Despite rare successes in older women, it borders on the exploitive to treat women over age 40 with superovulation and IUI. Indeed, pregnancy rates begin to decline with this treatment around age 35.²²¹

The incidence of multiple births and ovarian hyperstimulation is higher with this empiric treatment. Patients and clinicians undertaking empiric superovulation should have ready recourse to in vitro fertilization. **If gonadotropin stimulation is excessive, several choices are available: avoiding HCG administration and cancelling the cycle, aspirating most of the ovarian follicles with ultrasound guidance and proceeding with in vitro fertilization.**

Fertility Drugs and the Risk of Ovarian Cancer

An analysis of 3 case-control studies of ovarian cancer conducted in the U.S. from 1987–1989 concluded that the risk was increased among women who had used fertility drugs and among women who had been exposed to long periods of sexual activity without contraception.²³³ However, this conclusion was limited by the small number of cases, and the exact drugs and dosage used by these cases were unknown. Concern over this issue was further fueled by a report that prolonged use of clomiphene (12 or more cycles) was associated with an increased risk of borderline or invasive ovarian tumors.²³⁴ The conclusion in this comparison of a cohort of women with the rate of ovarian tumors in the general population was based on only 5 cases of borderline tumors and 4 cases of invasive tumors. Nevertheless, the idea that superovulation can increase the risk of ovarian cancer is biologically plausible because there is a decreasing risk for invasive epithelial ovarian cancer associated with those conditions marked by a decrease in the number of ovulations: multiparity, increasing duration of breastfeeding, and the use of oral contraception.

It is worth noting that a long-term follow-up of 2632 women in Israel who had received drugs for induction of ovulation did not record an increased incidence of ovarian cancer in the subsequent years.²³⁵ More recently, stimulated by the above reports, several epidemiologic studies appeared with the strength of larger case numbers. A study from Israel indicated an increased risk, but the relative risk was not statistically significant.²³⁶ Two case-control studies from Italy and a Danish case-control study (the largest in size) failed to find a relationship between fertility drugs and the risk of epithelial ovarian cancer.^{237, 238 and 239}

The best evidence does not indicate an increased risk of ovarian cancer with less than 12 months of clomiphene treatment (there is no reason to pursue clomiphene treatment for more than 12 months), or with gonadotropin treatment. Nulliparity and infertility in nulliparous women are associated with a slight increase in the risk of ovarian cancer, but ovarian stimulation with fertility drugs does not change this baseline risk.^{240d}

Assisted reproductive technology (ART) refers to all techniques involving direct retrieval of oocytes from the ovary. The first and still most common procedure is in vitro fertilization, but there is an ever increasing list of technologies.

IVF —In Vitro Fertilization: extraction of oocytes, fertilization in the laboratory, transcervical transfer of embryos into the uterus.

GIFT —Gamete Intrafallopian Transfer: the placement of oocytes and sperm into the fallopian tube.

ZIFT —Zygote Intrafallopian Transfer: the placement of fertilized oocytes into the fallopian tube.

TET —Tubal Embryo Transfer: the placement of cleaving embryos into the fallopian tube.

POST—Peritoneal Oocyte and Sperm Transfer: the placement of oocytes and sperm into the pelvic cavity.

In addition, techniques of sperm retrieval and sperm injection are now part of the assisted reproductive technology armamentarium:

ICSI —Intracytoplasmic Sperm Injection (of a single spermatozoon).

TESE —Testicular Sperm Extraction.

MESA—Microsurgical Epididymal Sperm Aspiration.

It has been over two decades since the birth of the first child conceived by in vitro fertilization (IVF). During the intervening years, the number of IVF programs has increased to over 250 in the United States alone, technology has evolved, the success rate has improved dramatically, and indications for IVF have enlarged. In addition, procedures that utilize some, but not all, of the methodology of IVF have become a part of clinical practice.

Numerous volumes have been published which extensively cover all aspects of ART, and we will not duplicate that effort. Rather, this chapter will focus on the evolving techniques with an emphasis on ICSI, and will review briefly the place of ART in the treatment of nontubal disease.

Patient Selection for IVF

The initial experience with in vitro fertilization involved women with tubal disease, but early in the 1980s, the treatment was extended to individuals with male factor infertility, unexplained infertility, endometriosis, and immunologic causes for infertility. In addition, a high degree of success has been obtained using donor oocytes for women with premature ovarian failure or decreased ovarian function.¹ Although it is reasonable to recommend tubal surgery in young women with mild distal tubal disease, IVF is the treatment of choice for patients with more severe distal disease, proximal obstruction (especially after 6 months have elapsed following cannulation or balloon tuboplasty), and for patients who have failed to achieve pregnancy within 2 years after tubal surgery or when tubal obstruction persists after surgery. Large hydrosalpinges can reduce the success rate with IVF, and removal is recommended prior to treatment.²

Couples undergoing IVF should be screened for antibodies to HIV-1/2 and HTLV-1, hepatitis B antigen, and antibodies to hepatitis B and C. Testing for chlamydia, syphilis, gonorrhea, and cytomegalovirus should also be considered. Smoking, as always, should be discouraged; smokers require twice as many IVF cycles to achieve pregnancy.³

Whereas IVF can overcome a number of the barriers to fertility, it suffers the same limitation as does in vivo fertilization when it comes to age (discussed in [Chapter 26](#)). In successful IVF programs, where the delivery rate per oocyte retrieval can be over 30% in women age 35 or younger, the figure is 10% or less in women age 40 and over. Beyond the simple effect of age on oocyte quality, there also is a negative influence on IVF success from decreased ovarian responsiveness. This can be manifested by poor response to exogenous gonadotropin stimulation with abnormal hormone profiles and the retrieval of small numbers of oocytes.

There is no exact definition of a poor responder, but it encompasses those who respond to stimulation with the development of 4 or fewer follicles or with depressed estrogen levels. Pretreatment diagnosis of these individuals can be achieved by measuring basal FSH and estradiol levels, and by using the clomiphene challenge test (see [Chapter 26](#)).

Three distinct populations have been identified on the basis of the cycle day three FSH.⁴ With FSH values less than 15 IU/L, the pregnancy rate with IVF was 24%, whereas when the FSH values were 15 to 24.9 IU/L, the pregnancy rate was 13.6%. When the FSH was 25 IU/L or higher, the initial pregnancy rate was 10.7%, and the ongoing pregnancy rate was only 3.6%. Remember in all discussions pertaining to specific hormone levels that these may differ between laboratories, depending on which assay system is used. Assays using new standards have an upper limit of normal of 10–12 IU/L compared with the 25 IU/L cited in the above study.

Older women (certainly 40 and older, but perhaps even women in their late 30s) with infertility and younger women with abnormal basal FSH and estradiol values and an abnormal response to a clomiphene challenge should seriously consider an early resort to hormonal stimulation for both multiple oocyte response and better support of the endometrium. Older couples should be provided the option of oocyte donation from young donors instead of standard assisted reproductive technologies.

Stimulation Protocol

The momentous work of Edwards and Steptoe that produced the first birth from IVF was developed over more than 10 years. Success was finally achieved by utilizing a nonstimulated cycle with timing of oocyte retrieval based on measurements of luteinizing hormone (LH) at 3-hour intervals. Nonstimulated cycles are still used as a means of decreasing expenses, but the delivery rate per retrieval is only approximately 6%.⁵ The very low success rate associated with nonstimulated cycles led to the use of clomiphene citrate and human menopausal gonadotropins to stimulate the development of multiple ovarian follicles. Injections of human chorionic gonadotropin (HCG), whose biologic activity mimics that of LH, were utilized to allow more certain timing of oocyte retrieval.

In the late 1980's, gonadotropin-releasing hormone agonists (GnRH agonists) were introduced as a means of down-regulating the pituitary to prevent premature ovulation, which in the past had necessitated canceling approximately 15% of IVF cycles prior to egg retrieval. The down-regulating effects of GnRH agonists, as opposed to the stimulatory effects of GnRH, are related to the frequency of administration and the prolonged occupation of GnRH receptors by the agonists. Since their introduction, pregnancy rates have increased because of the opportunity to retrieve cycles that would have been lost to early ovulation and because of the increase in the number of oocytes obtained in GnRH agonist cycles.⁶ However, use of an agonist increases the amount of gonadotropins needed to stimulate follicular growth, and, thus, it also increases the expense. Despite this negative aspect, the combination of GnRH agonist and gonadotropin controlled hyperstimulation of the ovary, and substitution of exogenous HCG for the endogenous LH surge, is now utilized by most IVF programs. This approach has another beneficial attribute. Because the fear of premature ovulation is virtually eliminated, there is more flexibility in scheduling the necessary interventions.

Protocols starting standard doses of GnRH agonists in the follicular phase of the cycle preceding the one in which gonadotropin is started have the drawback, because of an initial stimulatory effect, the flare, of the GnRH agonist, of causing a larger number of ovarian cysts and higher androgen levels than cycles in which the agonist is started in the midluteal phase of the cycle.⁷ In a further variation, GnRH agonist is started on the second or third day of menses, and gonadotropin is started 2 days later. This "flare" protocol tries to capture the initial stimulatory effect of the GnRH agonist and build on it with gonadotropin before the inhibitory effect of the agonist is established. This flare approach is particularly useful for poor responder patients. To aid timing, a common pretreatment for women with irregular menses uses oral contraceptives for one or two cycles.

Most commonly, the GnRH agonist is started in the midluteal phase, and gonadotropin treatment is started following menses. Ultrasonography is used prior to initiation of gonadotropin treatment to rule out the presence of an ovarian cyst larger than 15 mm. Ovarian cysts form in approximately 10% of women when the GnRH agonist is started in the midluteal phase, but these cysts almost always regress spontaneously in 1–3 weeks. Gonadotropin treatment is postponed until the cysts disappear or decrease to less than 15 mm in size.

GnRH agonist administration is continued for the duration of gonadotropin treatment. Whereas leuprolide (Lupron) injected subcutaneously is the most commonly used GnRH agonist in the United States, equally good results, if not better, have been achieved with the use of nafarelin (Synarel), which is administered as a nasal spray, one inhalation bid.⁸ The initial dose of gonadotropin is usually 225–300 IU/daily, except in young women or those with polycystic ovarian disease where a lower dose (75–150 IU/daily) is appropriate. The dose can be adjusted as cycle monitoring proceeds with ultrasonography and estradiol measurements.

Intramuscular injections of urinary menopausal gonadotropins containing both FSH and LH were the mainstays of treatment until the development of a urinary gonadotropin that contained primarily FSH (see [Chapter 30](#)). One of the goals in limiting or eliminating LH is to decrease stimulation of the androgenic component of the ovarian response because excessive androgens block ovarian follicular growth and development. However, in clinical practice, there was no clear-cut advantage for the predominately FSH product. Still newer, highly purified urinary FSH products introduced the advantage of being effective with subcutaneous administration. Recombinant FSH also allows subcutaneous administration. Differences comparing recombinant FSH with the urinary hormones include enhanced purity, the need for less medication, the achievement of slightly lower estradiol levels, and a modest increase in the pregnancy rate.⁹

Whichever product or protocol is used, there is a 10–15% cancellation rate because of inadequate follicular response. Measurements of basal FSH and estradiol and the clomiphene challenge test can provide information for discussing with patients the expectations for success. Ideally, a stimulation protocol can be tailored to boost the chances for an adequate response. However, it is evident that most poor responders are resistant to conversion to good responders. The 5 most common changes in protocol designed to accomplish that elusive goal are:

1. Increase the gonadotropin dose or change the mix of FSH-LH and FSH. This is usually not successful. No improvement was noted when the gonadotropin dose was increased from 300 to 450 IU beginning on day 1 or 2 of the cycle.¹⁰
2. Use of the flare protocol, including the use of a microdose flare (20 µg leuprolide bid), approximately 1/50 the usual dose.¹¹
3. Lower the dose of the GnRH agonist to allow some pituitary action, but starting as usual in the midluteal phase.
4. Omit the GnRH agonist and use gonadotropin alone or a combination of clomiphene and gonadotropin. To prevent premature ovulation in the absence of down-regulation by the GnRH agonist, a single dose of a GnRH antagonist can be given at midcycle to prevent the LH surge.
5. A less common approach, limited by expense and availability of drug, is the use of growth hormone in conjunction with gonadotropin. Moreover, results with this combination have been mixed; a double-blind study found no benefit associated with the addition of growth hormone.¹²

Monitoring Ovarian Response

Measurements of serum estradiol and ultrasound imaging of ovarian follicles are used to monitor the ovarian response to stimulation. The minimum goal of stimulation is to achieve the growth of a lead follicle to at least 18 mm diameter, and to have at least 3 or 4 other follicles with diameters of 14 mm or greater, combined with estradiol levels of approximately 200 pg/mL per large (14 mm or greater) follicle. Once this level of stimulation is achieved, a single injection of 5000 or 10,000 IU of HCG is given to induce final follicular maturation. The time interval between HCG injection and retrieval is critical. Whereas 34–36 hours is standard and believed to allow good oocyte maturation, intervals up to 39 hours may allow for better maturation of the oocytes while only marginally increasing the risk for ovulation.¹³ The values given for follicle size and estradiol levels on the day of decision for HCG injection are only rough guidelines because ultrasound measurements can differ among observers and machines. In addition, each program must establish, based on its own experience, its criteria for determining the adequacy of follicle size. Moreover, estradiol assays will differ from one laboratory to another, and comparisons, therefore, are difficult. Estradiol levels per follicle can vary widely and still be compatible with successful IVF. Concern has been expressed that elevated levels of progesterone, signifying premature luteinization, just prior to HCG injection can disrupt the cycle. The weight of evidence indicates that the frequently seen modest rise in progesterone does not interfere with pregnancy rates.¹⁴

To avoid the significant medical risks of hyperstimulation, cancellation of the cycle and avoidance of HCG injection should be strongly considered if the ovaries are markedly hyperstimulated (more than 25 follicles or a total estradiol greater than 4000 pg/mL). (Hyperstimulation is discussed in [Chapter 30](#).) Again, the specific values may not be valid with other assays, and each program must establish which estradiol level is its warning sign. Alternatives to cancellation include proceeding with the regular IVF cycle in the face of markedly elevated estradiol levels, but cryopreserving all the embryos for transfer in subsequent cycles to avoid further HCG stimulation accompanying a pregnancy, or discontinuing the daily gonadotropin injections (coasting) and delaying retrieval until the estradiol level (measured daily) drops to 2500–3000 pg/mL or lower, at which point HCG is administered.¹⁵ However, cycles in which coasting produces very precipitous drops in estradiol to below 1000 pg/mL warrant cancellation. The pregnancy rates with coasting are lower than those obtained with the usual methods.

The risk of hyperstimulation can be decreased by lowering the dose of gonadotropin used to initiate the cycle. The use of FSH as opposed to mixtures of FSH and LH in women with polycystic ovaries is not protective; with all stimulation protocols, the key is careful use of appropriate doses. An important protection against hyperstimulation is the use progesterone after retrieval, rather than HCG injections, to support the luteal phase. Retrieval itself, with aspiration of follicular fluid and granulosa cells, is somewhat, but not absolutely, protective against hyperstimulation.¹⁶

When follicles are fully developed, the endometrium viewed by ultrasonography should be at least 8 mm wide. If the width is 6 mm or less, there is a reduced chance for pregnancy.^{17, 18 and 19} Although there is some dispute over the significance of the endometrial pattern, most reports indicate a superior pregnancy rate if there is a trilaminar appearance on the day of HCG administration compared to a homogenous whiteout pattern.

Oocyte Retrieval

Ultrasonically guided vaginal oocyte retrieval is performed approximately 34–35 hours after the HCG injection, but as late as 39 hours with the combined use of a GnRH agonist and gonadotropin.²⁰ The HCG injection allows for confidence in this precise timing. Intravenous analgesia and/or light anesthesia provide an acceptable level of comfort. In all cases, monitoring by a pulse oximeter is mandatory, as is immediate access to emergency resuscitation equipment. A number 16 or 17 long needle is placed down a sterile needle guide that is attached to the upper side of the vaginal ultrasound transducer. A line on the monitor screen indicates the path the needle will traverse once it enters the peritoneal cavity and the ovary. The ultrasound transducer is manipulated to position a follicle along this pathway. Usually only one puncture of each ovary is needed to allow sequential aspiration of the follicles. Accessibility of the ovaries is rarely a problem. Rare complications of the procedure are intra-abdominal bleeding or introduction of infection into the ovary and pelvis.

Oocyte Culture

Oocytes, surrounded by their cumulus masses, are identified under either a dissecting or an invert microscope. Exposure to ambient temperature and room air is minimized. One of the major breakthroughs in IVF was the discovery that sperm need not be added to the eggs immediately after retrieval; oocytes have a higher chance for fertilization if insemination follows retrieval by 4 to 6 hours. ²¹

Sperm are prepared by washing, centrifugation, discarding the supernatant, and overlaying the sperm pellet with fresh media. Sperm that swim up into the media are used for insemination, with approximately 50,000 sperm (100,000 or more if the sperm specimen is poor) placed in each petri dish containing an oocyte. Isolation of the most motile sperm can also be accomplished by separating the sperm on columns of liquid albumin, hyaluronate, glass wool, or gradients of silica particles.

A variety of media has been used for embryo culture. Most media for IVF contain a protein source, such as maternal serum, fetal cord serum, albumin and/or serum globulin. All protein components require screening for HIV and hepatitis. Because proteins, on occasion, may be deleterious to embryos, protein free media have been successfully used in limited studies. ²²

Culture of oocytes and embryos on cell monolayers from a variety of sources has been advocated as a means of enhancing development. ²³ Pregnancy rates were increased and blastomere fragmentation reduced when human embryos were cultured on outgrowths of bovine tissue. ²⁴ The explanation for the beneficial effect could be the secretion of an "embryotrophic" factor by the somatic cells or their removal of detrimental components from the media. Bavister suggested that greater attention to culture media quality can yield the same gains as those seen with co-culture, and this has been confirmed by recent experience. ^{25, 26} In addition, co-culture with granulosa cells has not helped couples with previous fertilization failures. ²⁷

Fertilization

The day after insemination, cumulus cells that remain attached to the zona pellucida are removed, and the egg is examined for evidence of fertilization (the presence of 2 pronuclei). 65–80% of mature oocytes will fertilize. Approximately 6% of oocytes contain 3 or more pronuclei, indicating penetration by more than one sperm. It is important to identify and discard these abnormal embryos at this early stage because they have the potential to cleave and appear normal at later preimplantation stages. If the diagnosis is missed at the pronuclear stage, the embryos will be transferred and the result will be a failure to implant or a spontaneous miscarriage.

A failure to fertilize is sometimes viewed by clinicians as a "human egg test" for that specific couple. However, fertilization failure in one cycle, despite normal sperm and eggs, is not an absolute indication of an insurmountable problem. Indeed, a high rate of fertilization has been reported in subsequent cycles after an initial fertilization failure, although the eventual pregnancy rate is a little lower than the usual rate in IVF programs. ^{28, 29} To demonstrate a complete failure of fertilization, at least 3 IVF cycles are necessary. Surprisingly the use of ICSI in a cycle following one with unexplained fertilization failure does not always overcome the failure to fertilize.

Extra embryos can be cryopreserved at the pronuclear stage. There is no known limit on duration of cryopreserved embryo storage. About two-thirds of embryos survive the freezing and the subsequent thawing process. The transfer of cryopreserved embryos adds significantly (15% delivery per transfer) to the success rate with a single retrieval and lowers the cost. Older age of the woman is associated with a decrease in pregnancy rates, not only because of a decrease in the number of oocytes and a reduction in oocyte and embryo quality, but also because fewer embryos are available for cryopreservation. ³⁰

Embryo Transfer

Embryos have been transferred successfully at any stage from the pronuclear to the blastocyst, although most commonly, they are transferred when development is between the 8- and 10-cell stage, approximately 72–80 hours after retrieval. Transfer of more than one embryo increases the chances for pregnancy, but the multiple pregnancy rate with IVF is approximately 35%.

High order multiples can create unfortunate outcomes for the pregnancy, the children, and for subsequent family life. It is not unusual for patients to welcome the prospects for a multiple birth, and they must be informed of the associated risks. To decrease the incidence of multiple birth, programs in the U.K. transfer a maximum of 2 embryos. The guidelines of the American Society for Reproductive Medicine are more liberal, and they are influenced by the age of the woman. The recommendation is for no more than 3 embryos to be transferred in women younger than age 35, no more than 4 at age 35–40, and no more than 5 in women older than age 40. Our preference is to transfer 2 good quality 8–10 cell embryos in women under the age of 35, whereas women between age 35–39 may have 2–3 good quality embryos transferred. It may be reasonable to place higher numbers in women age 40 and older, but this is influenced by the experience of the individual program. At least one study did not experience a decrease in multiple birth risk in older women. ³¹ While we cite "good quality" of the embryos as a qualification, it must be recognized that this assessment is highly subjective. On occasion, transfer of "poor" quality embryos results in pregnancy. The ability to use fetal reduction to limit the number of continuing fetuses lessens somewhat the concerns over the major hazards of multiple pregnancies. In experienced hands, the risk of losing the entire pregnancy from selective fetal reduction is less than 10%. ³² However, moral concerns and the psychological impact of fetal reduction are important considerations.

Success with culture to the blastocyst stage has raised the hope that high pregnancy rates can be achieved with the transfer of only one blastocyst (reaching this stage in culture is predictive of excellent potential). ²⁶

Ancillary medications given around the time of transfer, such as prostaglandin inhibitors, tranquilizers, or antibiotics are of no proven value. It is common practice to supplement the luteal phase with progesterone. Several options are available, including progesterone vaginal suppositories, 50–100 mg daily, progesterone in oil, 50–100 mg im daily, one application of vaginal progesterone daily, or oral micronized progesterone, 200 mg tid. An alternative therapy is the use of HCG, 1500 IU every 3 days for 4 doses; however, HCG supplementation increases the risk of ovarian hyperstimulation. The value of luteal phase supplementation can be questioned, but there is no doubt that it provides some psychologic benefit for both patient and physician. An initial quantitative HCG measurement can be obtained 12 days after transfer. If the test is positive, a follow-up test is obtained 3 days later. This will establish the trend of the HCG and provide prognostic information.

A rise in the HCG level indicates pregnancy, whereas a drop indicates a failed cycle. If weekly determinations demonstrate appropriate elevations, ultrasonography 5 weeks after the transfer should reveal a fetal heart beat. If not, repeat ultrasonography can be performed in one week. The presence of a rapid heartbeat is an excellent prognostic sign, and if the woman is under age 30, the chance for a spontaneous miscarriage is near zero; between age 31–35, the risk of spontaneous miscarriage is 4%. ³³ If the woman is over age 40, the prognosis is less sanguine, with spontaneous miscarriage rates close to 20%. If the woman has a history of recurrent early pregnancy losses, a positive heartbeat still leaves the chance of a spontaneous miscarriage in the 20–25% range.

Assisted hatching consists of making an opening in the zona pellucida just prior to transfer to help the embryo emerge. This can be accomplished by slitting open the zona with a microneedle, by treating a localized area of the zona with an acid Tyrode's solution, or by using a laser to breach the zona. Assisted hatching has been reported to increase the implantation rate in poor prognosis patients, especially in older women. ^{34, 35 and 36} However, two studies, one in women older than age 36, and the other in women older than age 38, could find no benefit with assisted hatching. ^{37, 38}

IVF Results

Some skepticism has been expressed concerning the pregnancy rates reported by IVF programs. ³⁹ Competition for patients is a motivation for some of the exaggerations and half-truths contained in advertisements and public statements. An associated confusion is generated by the differing criteria that can be used to determine what constitutes a success. A slight unsustained rise in the HCG is properly termed a "chemical pregnancy," and it should not be counted as a success. The most important indicators of success are the delivery rate per retrieval and the delivery rate per cycle initiated. Even these figures cannot be properly evaluated without knowledge of the specific age mix of the treated women. Obviously, a program with a higher percentage of older women should not be expected to do as well as one with mostly younger women. In addition, clinics that transfer large numbers of embryos to each woman can marginally inflate their pregnancy numbers but at a significant price of multiple pregnancies.

Uniform reporting by clinics, monitored by the Society for Assisted Reproductive Technology, has produced yearly statistics available to the public. ⁴⁰ Results from the U.S. and Canada are published nearly 3 years later, reflecting a significant lag because of the need to await deliveries resulting from cycles initiated and the

difficulties in obtaining timely submission of data from 281 programs.

In 1995, the deliveries per retrieval were 22.3% for standard IVF, 27.0% with GIFT, and 27.9% with ZIFT.⁴⁰ Women under age 35 had a 27.2% delivery rate per retrieval with IVF compared with 10.5% in women older than age 39. With transfers of donor embryos, the delivery rate was 36.0%, whereas with the transfer of cryopreserved embryos, the delivery rate was 15.2%. These figures for 1995, reported in 1998, are probably already outmoded. Many clinics are achieving delivery rates in the 35% range, especially in women under age 35. The advantages noted for GIFT and ZIFT disappear when comparisons are made within the same program.⁴¹

Surprisingly, 3% of pregnancies achieved through IVF are ectopic, emphasizing the need for close ultrasonographic and HCG titer surveillance (see [Chapter 32](#)). Pregnancies occurring simultaneously in different body sites (heterotropic pregnancies) are a rare condition, occurring in 1 of 30,000 spontaneous pregnancies. The incidence of combined pregnancy among patients who have undergone one of the assisted reproduction procedures is much higher, closer to 1 in 100 pregnancies.^{42, 43 and 44} A case-control study has concluded that the risk of ectopic pregnancy with assisted reproduction is due to the multiple ovulations and high hormone levels secondary to the stimulation protocols.⁴⁵

Twenty percent of clinical pregnancies result in spontaneous miscarriages, which is close to the rate in infertility populations; there is no increase in the rate of congenital malformations.⁴⁶ The children experience normal growth and development.⁴⁷

The multiple pregnancy rate is approximately 35% (30% twins, 5% triplets, and about 0.6% higher multiples). This leads to an increase in cesarean sections, prematurity, and perinatal mortality. As noted previously, selective reduction can be offered as an option with multiples greater than two.³² This can be a difficult decision for some couples, but in view of the potential problems associated with a multiple pregnancy, it is an option deserving consideration.

A major factor influencing IVF results is the gross inefficiency of human reproduction in vivo. A number of studies have attested to the low fecundability of humans. Only 30% of normal women who attempt pregnancy in a given cycle are successful.⁴⁸ There is a large loss of embryos prior to or around the time of implantation in vivo, and thus, many women have pregnancy losses without realizing that they have been pregnant because the menstrual period comes at the expected time. It can be concluded that many sperm and many oocytes, even from individuals who are fertile, do not have the ability to contribute to a normal pregnancy. This affects the success of both in vivo and in vitro fertilization.

The chance for success in successive IVF cycles decreases after 3 cycles.⁴⁹ However, approximately 50% of women under age 35 have a live birth within 6 cycles of treatment.^{50, 51} Most individuals find the emotional, physical, and financial consequences of going beyond 3 to 6 cycles too difficult, and adoption or donor embryos should be considered. Patients should also be aware that occasional spontaneous pregnancies occur even after failure of IVF.

Male Infertility and IVF

The limited effectiveness of treatments for male infertility has provided a sizable number of individuals who desire IVF to overcome problems with sperm. Early experience with male factor infertility in IVF indicated that even placing sperm in the dish with the oocyte still left many sperm specimens with a handicap. Fertilization rates tended to be approximately one-half those achieved with normal sperm, and the pregnancy rates were correspondingly lower. On occasion, however, fertilization occurred with surprisingly few sperm available.

IVF provides the ability to visualize the results of sperm and egg interaction and thus to quickly determine if specific manipulations of the sperm can affect fertilization. A variety of sperm treatments have been attempted. One approach is to increase the number of sperm in the dish with the hope that even with abnormal specimens there will be a few normal sperm that can achieve fertilization. By increasing the numbers in each dish there will be more normal sperm per egg. A second approach is to isolate the best sperm from the specimen, not by the standard swim-up technique, but by using a variety of gradients. In some hands this has provided increased fertilization rates, but others have not found it to be a significant advantage. Similar contradictory results have been reported with drug treatment of the semen; the most popular such treatment has utilized pentoxifylline, which acts by increasing cyclic AMP in cells.⁵² The drug must be washed out from the sperm specimen before incubation with the egg because it may have adverse effects. Another treatment that has been used to enhance sperm is incubation in follicular fluid.⁵³ In men with sperm autoantibodies, in vitro fertilization is correlated with the extent the sperm are covered with antibodies.

Micromanipulation

The early techniques of making a hole in the zona to facilitate sperm entry and the injection of sperm through the zona into the perivitelline space have been superseded by the intracytoplasmic injection of single sperm (ICSI). The pioneering success of Van Steirteghem and his coworkers in Belgium⁵⁴ has now been duplicated in many laboratories. The results have surpassed all expectations, with pregnancy rates equal to or slightly surpassing the normal fecundity rate.⁵⁵ Pregnancy rates are independent of any semen analysis parameter (number, motility, and morphology).⁵⁶

Sperm for injection have been obtained not only from the ejaculate, but in azoospermia by microsurgery from the epididymis (MESA) or from the testis (TESE).⁵⁷ Both percutaneous aspirations and open biopsies have been used. Fine-needle biopsy on occasion will locate small pockets of sperm or spermatids in otherwise hopeless appearing cases, such as the Sertoli cell only syndrome. Even the use of the sperm precursors in ICSI has produced successful pregnancies.^{57, 58} The success with spermatids and with immotile sperm, however, is substantially lower than with motile sperm.⁵⁹ It is worthwhile, therefore, to vigorously search poor quality ejaculates for motile sperm.

ICSI is the treatment of choice for azoospermia and severe oligospermia (including the absence of sperm because of blockage in the ejaculatory ducts), and it is also indicated when antisperm antibodies are present, for cases of poor fertilization despite normal semen, and as a last resort for refractory unexplained infertility. In the collected 1995 U.S. and Canadian results, the delivery rate per retrieval after ICSI was 23.5%, marginally higher than the 22.3% without ICSI.⁴⁰ In women younger than age 34, the pregnancy rate per transfer after ICSI has been reported to be as high as 49%.⁶⁰ A pregnancy rate of 14.8% per cycle has even been achieved with ICSI one day after oocytes had failed conventional fertilization.⁶¹ As with regular IVF, ICSI pregnancies, including singletons, have higher than normal rates of preterm delivery, low birth weight, and perinatal mortality.⁶²

Concern arose that the gains achieved with ICSI, by bypassing the selection process exerted by the zona pellucida, might exact a price. The zona is a barrier to fertilization by morphologically abnormal sperm that have a higher rate of genetic abnormalities compared with normal shaped sperm. However, even sperm that are normally shaped can harbor genetic aberrations, and there is continuing concern regarding the transmission of genetic abnormalities with ICSI.

Chromosomal analyses of testicular biopsies indicate chromosomal abnormalities in approximately 5–7% of infertile males.⁶³ There is a high prevalence of Y chromosome submicroscopic deletions in men with oligospermia. A cluster of genes that are deleted in men with azoospermia or oligospermia has been referred to as DAZ (“deleted in azoospermia”).^{64, 65} Subsequently, at least 3 specific regions on Yq were identified and labeled as “azoospermia factors,” AZFa, AZFb, and AZFc (the same region as DAZ).⁶⁶ From 7% to 10% of men with severe oligospermia have been reported to have deletions in the AZFb and AZFc regions on the long arm of the Y chromosome.^{67, 68} These microdeletions correlate poorly with the numbers of sperm present in the semen analysis. These could be normal genetic variants and not the cause of the infertility; however, these deletions can now be transmitted with the use of ICSI, and it is now appropriate to consider Y chromosome deletion analysis prior to treatment with assisted reproduction. On the other hand, Y chromosome deletions are rare in men participating in an ICSI program. Indeed, the prevalence of overall chromosomal abnormalities is greater in men with abnormal semen than the prevalence of Y chromosome microdeletions.^{69, 70}

Approximately 10% of sperm from fertile males carry an extra chromosome, but the rate of newborns with chromosomal abnormalities is under 1%.⁶³ Prenatal selection is protective against the majority of abnormalities. Prenatal testing of ICSI pregnancies revealed an incidence of 0.83% of sex chromosome abnormalities and a similarly low figure for autosomal abnormalities.⁷¹ These figures, however, are higher than those reported for spontaneous pregnancies.

Although these genetic abnormalities are relatively infrequent, and there is uncertainty regarding the role of Y chromosome microdeletions, because of the consequences, there is strong support for genetic screening of all men considering ICSI.⁷² Indeed, 90% of couples receiving genetic counseling elect to undergo genetic screening.⁷³ Nevertheless, because of the relative infrequency of the various abnormalities, most IVF programs do not routinely karyotype prospective ICSI patients. However, males with azoospermia and severe oligospermia should have genetic screening because their risk of genetic abnormalities is higher than men

with mild sperm impairment. The most frequent diagnosis is Klinefelter syndrome, which occurs in approximately 1 in every 500 males. Among other genetic abnormalities, azoospermia and hypogonadism can result because of a mutation that causes an abnormality in the beta-subunit of LH.⁷⁴ An inactivating mutation in the gene for the FSH receptor is associated with varying degrees of suppression of spermatogenesis, indicating that FSH is not absolutely essential for sperm production.⁷⁵

Approximately 1–2% of infertile males have congenital bilateral absence of the vas deferens.⁷⁶ Most males with bilateral congenital absence of the vas deferens have at least two mutations in the cystic fibrosis transmembrane conductance regulator gene.⁷⁷ Screening for cystic fibrosis mutations should be considered in males with bilateral absent vas deferens who are considering ICSI. A reasonable approach involves screening the female partner; the absence of cystic fibrosis mutations in the female reduces the risk of having a child with cystic fibrosis to a very low level.

Delayed mental development at one year of age has been reported in children born as the result of ICSI.⁷⁸ 17% of ICSI children had mild or significantly delayed development (memory, problem solving, language skills) compared with 2% of IVF children and 1% of natural conception children. More reassuring are the reports of low rates of neurologic or developmental problems at 2 months of age, and normal mental development at age 2.^{79, 80} With the large numbers of ICSI pregnancies, the long-term outcome of ICSI children will soon be apparent.

IVF for Endometriosis

Early experience with IVF in cases of endometriosis suggested that more severe disease exerted an adverse effect on oocyte recruitment, embryo development, and pregnancy rates. With greater experience, however, pregnancy rates (uninfluenced by the severity of the disease) have been achieved that are comparable to those with tubal disease.^{81, 82}

IVF for Autoimmunity

ICSI is recommended for cases of sperm autoimmunity, and results are comparable to those obtained with other diagnoses.^{83, 84} ICSI bypasses the zona, which is a major barrier to antibody-laden sperm.

Other Techniques

In addition to IVF, individuals with unexplained infertility have been offered a number of tactics to overcome hypothesized problems with gamete transport. For gamete intrafallopian transfer (GIFT), minilaparotomy or laparoscopy is used to aspirate oocytes following hyperstimulation of the ovary. Alternatively, aspiration can be performed more easily through the vagina, and laparoscopy is then used only for oocyte and sperm transfer (transfer via the uterus produces poorer results). After the oocytes are identified in the laboratory, they are taken up into a transfer catheter that contains 100,000 sperm isolated by the swim-up technique. The transfer catheter is guided into the distal 4 cm of a fallopian tube and the contents gently discharged. Two oocytes can be placed in each tube although placement in one tube is more common and equally successful. Extra eggs obtained at retrieval can be fertilized and cryopreserved for future use. Success with GIFT in the collected statistics from the United States and Canada (1995) was 27.0% deliveries per retrieval.⁴⁰ In the same year the success with IVF was 22.5% deliveries per retrieval. This difference is believed to be due largely to differences in patient selection. Ectopic pregnancy occurs in approximately 4.2% of GIFT pregnancies, somewhat higher than the 2.6% reported with IVF. The multiple pregnancy rate with GIFT is similar to that of IVF, approximately 35%.

In a variation of GIFT, called ZIFT, oocytes are obtained by vaginal aspiration, fertilized in vitro, and then 1 day later at the pronuclear stage placed in the fallopian tubes by the GIFT technique. The 1995 figures for ZIFT were 27.9% deliveries per retrieval.⁴⁰ Whereas these figures continue to reflect an early impression that ZIFT was decidedly superior to IVF, this is not the case in current statistics. Indeed, prospective comparisons within the same clinics demonstrate similar results with uterine (IVF) versus tubal transfers (GIFT or ZIFT).^{41, 85}

The choice of method, IVF, GIFT, or ZIFT, can be made on the basis of infertility factors, cost, and risk. If there is tubal damage, GIFT or ZIFT is not a good choice. In rare instances, where there is severe scarring of the cervix, one of the intratubal techniques is preferable. The comfort level of the program with each of the techniques and the program's experience in terms of pregnancy results are important considerations. Use of GIFT or ZIFT can incur greater costs, depending on the setting for the surgery and the anesthesia used.

Other attempts to overcome problems of gamete transport include injections of washed sperm and oocytes into the peritoneal cavity (POST) and cannulation of the fallopian tube via the cervix, as a conduit for injecting sperm directly into the tube.⁸⁶ These methods have not gained wide usage. In a technique of limited applicability, because it risks pregnancy in a donor, a fertilized human ovum at the blastocyst stage can be removed by uterine lavage from a donor and placed transcervically in the uterus of an infertile recipient.⁸⁷

Ovum Donation

A technique of proven value is ovum donation for older women, those with premature ovarian failure or women who are unresponsive to gonadotropin stimulation. The donor, who ideally should be under the age of 33 and has been both physically and psychologically screened, is down-regulated with a GnRH agonist, and then stimulated with gonadotropins as in IVF.⁸⁸ Following retrieval, the donor's oocytes are fertilized with sperm from the recipient's partner. If the recipient is having periods, indicative of endogenous hormone production, she is down-regulated with a GnRH agonist before starting on at least 10 days of estrogen (a common dose is estradiol, 4–8 mg per day). When ultrasonography indicates adequate endometrial development, progesterone is added to synchronize the endometrium with the egg retrieval. If pregnancy occurs, the hormone supplementation continues for at least 10 weeks, until placental steroidogenesis is firmly established. Success rates are lower in older recipients unless high doses of progesterone are provided for uterine support.⁸⁹ A delivery rate in older women of approximately 40–50% per cycle can be achieved in a donor oocyte program. A cumulative birth rate can reach 90% with 4 or more cycles.^{90, 91}

Experimental Methods

Oocytes can be matured in vitro and then cryopreserved. This technique would allow young women who require chemotherapy or pelvic irradiation to preserve a possibility for fertility in the future. However, fertilization rates and survival of cryopreservation is low for oocytes compared with the excellent survival obtained with cryopreserved embryos.

Preimplantation Genetic Diagnosis

Diagnosing genetic disorders before implantation provides couples with the option of foregoing the attempt to establish a pregnancy. This avoids the difficult decision whether or not to continue an affected pregnancy when the diagnosis is made at amniocentesis or by chorionic villus biopsy. There are 3 possible approaches for preimplantation diagnosis.^{92, 93} The first is the removal of a polar body, but greater accuracy is obtained by studying both polar bodies. The polar body contains only one copy of the gene, but if the copy is found to be normal, it can be presumed that the oocyte contains a normal copy. However, this method is technically very difficult and subject to error if crossing-over occurs and both copies are present in the polar body. A second method is to biopsy cells that are destined to become the placenta. This requires culturing the embryo to the blastocyst stage, and then opening the zona pellucida in the 5–6 day embryo. The disadvantage is the lower pregnancy rate when the embryo is transferred at this later stage. The third method is the removal of a single cell from the 6–8 cell embryo (blastomere biopsy) for DNA amplification by polymerase chain reaction and analysis with fluorescent probes specific for chromosomes 13, 18, 21, and the X and Y chromosomes.⁹⁴ The biopsy procedure does not affect development and implantation, and the diagnostic testing is rapid; the biopsy and DNA analysis are accomplished within 8 hours.

Preimplantation genetic diagnosis has successfully detected single gene defects in disorders such as cystic fibrosis, Duchene's muscular dystrophy, sickle cell disease, hemophilia, Tay-Sachs disease, Lesch-Nyhan syndrome, and at least 11 other diseases. These methods can also be used to determine the sex of the embryo for couples who are at risk for transmitting X-linked disorders.

The utilization of molecular biology techniques for preimplantation genetic diagnosis is associated with some significant risks. Polymerase chain reaction amplification does not always succeed. An erroneous diagnosis can occur because of contamination by DNA from surrounding cells or from sperm that are attached to the zona

pellucida. This type of genetic diagnosis is only available in a limited number of centers.

Concluding Thoughts

The new reproductive techniques and the technology associated with in vitro fertilization have been presented in a somewhat mechanistic way in this chapter. This should not obscure the fact that, despite the excellent success rates, this is an emotionally trying experience for almost everyone undertaking therapy. Psychological stresses can be acute, and anxiety is accentuated with each step of the process. Failures at every stage are exceptionally difficult for both patients and clinicians. Psychologic counseling services associated with IVF programs, and support groups, such as those organized by RESOLVE, are helpful for almost every couple going through an ART program.

The modern management of ectopic pregnancy is one of medicine's greatest success stories. Ectopic pregnancy has been recognized for a very long time (it was first described in the 11th century), and for a long time, only as a universally fatal event. In medieval times, the ectopic pregnancy was believed to be located outside the uterus because of a violent emotion, usually fright or surprise, experienced by the woman during the coitus of conception. ¹ Treatment was so unavailable that the only recourse was speculation.

The first documentation of an unruptured ectopic pregnancy was recorded in 1693 in the results of an autopsy performed on a woman prisoner condemned to death and executed. Previous infertility was linked to ectopic pregnancy in 1752 with the report of an extrauterine pregnancy in a prostitute with 20 years of sterility. In the mid 19th century, pathology reports began to stress pelvic inflammation as a cause of ectopic pregnancy. This knowledge was derived from women who died because of tubal rupture and hemorrhage. Although data were gradually accumulated from autopsies and the pathology was described, treatment remained unavailable.

Because the ectopic fetus was obviously responsible for the death of the mother, physicians recommended measures to kill the fetus. These measures included starvation, purging, bleeding, and even large doses of strychnine. Early attempts to surgically puncture ectopic sacs or to introduce electric current into the fetus were followed by sepsis and maternal death.

Around 1600, there were several isolated reports of abdominal surgical procedures in women with repeat ectopic pregnancies. Then for more than 100 years there was no mention of a surgical operation for this purpose. The first case in the 18th century was reported in France in 1714. The first American surgeon to operate abdominally and successfully (for the removal of a macerated fetus) was John Bard of New York City in 1759. The second successful American operation was performed in 1791 by William Baynham, a country physician in Virginia. In 30 abdominal operations in the first 80 years of the 1800s, only 5 women survived. ¹ The survival rate in those not treated (one out of three) was better!

W.W. Harbert of Louisville was the first, in 1849, to suggest surgery early enough to stop fatal bleeding. ² But the problem was that diagnosis was only certain when it was too late. In 1876, John S. Parry (of the Philadelphia Hospital) wrote: ³

...when one is called to a case of this kind, it is his duty to look upon his unhappy patient as inevitably doomed to die, unless he can by some active measure wrest her from the grave already yawning before her.

Robert Lawson Tait in London, after experiencing the death of several women and at autopsy recognizing that appropriate dissection and ligation of bleeding vessels would be effective, for the first time in 1883, deliberately and successfully performed a laparotomy to ligate the broad ligament and a ruptured tube. ⁴ By 1885, Tait had accumulated a relatively large number of successful cases.

Asepsis, anesthesia, and antibiotics (and blood transfusions) combined to save the lives of many women. But diagnosis was still difficult, and surgical intervention was relatively late. Even in the first half of the 20th century, the maternal mortality rate in the United States ranged from 200 to 400 per 10,000 cases of ectopic pregnancies. As dramatic as the contribution of immediate salpingectomy coupled with simultaneous blood transfusion was, progress in the last 20 years has been even more impressive. Treatment has shifted from the saving of lives to the preservation of fertility.

The Centers for Disease Control first began to report the incidence of ectopic pregnancies in the U.S. in 1970. In 1970, there were 17,800 ectopic pregnancies, and by 1992, the number had increased to 108,800, a rate increase of 4.5 to 19.7 ectopic pregnancies per 1000 pregnancies. ⁵ **However, at the same time, the fatality rate decreased from 35.5 to 3.4 per 10,000 ectopic pregnancies, a decrease of 90%.**

The increase in ectopic pregnancies has not been paralleled by a similar increase in sexually transmitted diseases (STDs), and, therefore, the increased incidence of ectopic pregnancies is not due to STDs alone. ⁶ Ectopic pregnancies do occur in totally normal tubes, suggesting that abnormalities of the conceptus or maternal hormonal changes can function as etiologic factors. The other important contributing factors are reconstructive tubal surgery, assisted reproductive technologies, and, most importantly, earlier and more accurate diagnosis.

Today, management intervention occurs prior to tubal rupture in more than 80% of cases. ⁷ This can be attributed directly to three diagnostic advances: a highly specific and sensitive immunoassay for human chorionic gonadotropin (HCG), ultrasonography, and the use of laparoscopy.

Etiology and Clinical Presentation

Even though the risk of death from ectopic pregnancy has declined dramatically, ectopic pregnancy is the second leading cause of overall maternal mortality in the United States and the leading cause of pregnancy-related deaths during the first trimester. ⁸ This represents a combination of a lack of access to appropriate services and misdiagnosis.

Ectopic pregnancy is the great masquerader. The clinical presentation can vary from vaginal spotting to vasomotor shock with hemoperitoneum. The classic triad of delayed menses, irregular vaginal bleeding, and abdominal pain is most commonly **not** encountered. The exact frequency of clinical symptoms and signs is hard to assess. Standard descriptions in texts are based upon older reports and, thus, older methods of diagnosis. Suspicion of the diagnosis and rapid recourse to the methods of early diagnosis represent the best and most rewarding approach. Patients who present because of acute symptoms (frequently in emergency rooms) are

usually at a more advanced gestational age compared to asymptomatic infertility patients being followed closely because of their increased risk for ectopic pregnancy.

Differential Diagnosis

- Normal intrauterine pregnancy.
- Ruptured ovarian cyst.
- Bleeding corpus luteum.
- Spontaneous miscarriage.
- Salpingitis.
- Appendicitis.
- Adnexal torsion.
- Endometriosis.
- Diverticulitis.

Relevant factors in a patient's medical history include prior tubal surgery, the use of assisted reproductive technology, exposure to diethylstilbestrol (DES), previous pelvic inflammatory disease, vaginal douching,⁹ and the method of contraception. In addition, cigarette smoking is associated with a 2-fold increased risk for ectopic pregnancy.¹⁰ However, most patients presenting with an ectopic pregnancy do not have a recognized risk factor, suggesting dysfunctional problems in tubal transport or impaired implantation due to some abnormality in the conceptus. Nevertheless, pregnancies following tubal surgery or treatment with one of the methods of assisted reproduction should, ideally, be diagnosed immediately and followed closely with HCG titers and ultrasonography.

Previous Pelvic Inflammatory Disease

In Westrom's classic report, women with a history of salpingitis (verified by laparoscopy) had a four-fold increased risk of ectopic pregnancy.¹¹ Salpingitis damages the endosalpinx, resulting in agglutination of the mucosal folds and adhesion formation. The risk of an ectopic pregnancy increases with each inflammatory episode. Evidence of chlamydial infection (circulating antibodies) is associated with a greater than two-fold increased risk of ectopic pregnancy.¹² A similar increased risk is associated with douching, but the presence of infection may be the reason for the douching.

Prior Tubal Surgery

Women who have had tubal surgery have an increased risk of ectopic pregnancy. High-risk surgery includes any infertility surgery on the tube, but not abdominal or pelvic surgery that avoids the tubes.¹³ Women with an ectopic pregnancy treated by conservative surgery have a ten-fold increased risk of a subsequent ectopic. Ectopic pregnancies occur after tubal occlusion procedures for sterilization that are not performed immediately postpartum (interval sterilization); the risk with postpartum sterilization is very low, comparable to that observed in oral contraceptive users.^{14, 15 and 16} With interval sterilization, bipolar tubal coagulation is more likely to result in ectopic pregnancy than is mechanical occlusion.^{16, 17 and 18} This is attributed to fistula formation that allows sperm passage, and this may explain the difference in ectopic pregnancy rates between interval and postpartum sterilization because postpartum procedures are mostly by the Pomeroy method. Ectopic pregnancies following tubal ligation usually occur two or more years after the sterilization, rather than immediately after. In the first year after sterilization, about 6% of sterilization failures will be ectopic pregnancies, but the majority of pregnancies that occur 2–3 years after occlusion will be ectopic.¹⁷ Overall, the ectopic risk in women with interval sterilizations is 80% less than that in nonsterilized women; however, the relative risk is 3.7 times that of women using oral contraception and 2.8 times that with barrier methods of contraception.¹⁵ About one-third of pregnancies that occur after tubal sterilization are ectopic.¹⁶

Estimated Relative Risk of Ectopic Pregnancy^{10, 19, 20 and 21}

Risk Factor	Relative Risk
Tubal surgery	20.0
Previous ectopic	10.0
Previous salpingitis	4.0
Assisted reproduction	4.0
Age < 25	3.0
Previous pelvic infection	3.0
Infertility	2.5
Cigarette smoking	2.5
Vaginal douching	2.5

The Use of Assisted Reproductive Technology

Pregnancies occurring *simultaneously* in different body sites (*heterotopic pregnancies*) are a rare condition, occurring in 1 of 30,000 spontaneous pregnancies. The incidence of combined pregnancy among patients who have undergone one of the assisted reproduction procedures (in vitro fertilization, gamete intrafallopian transfer, and even superovulation) is much higher, closer to 1 in 100 pregnancies.^{22, 23 and 24} Close monitoring of pregnancies in these programs is important to prevent a deleterious delay in the treatment of an ectopic pregnancy.

Is the increased risk with these treatment methods due to ovulation induction (with superovulation and elevated levels of hormone influence on the tubes) or due to previous tubal disease? A case-control study has concluded that the risk of ectopic pregnancy was increased four-fold with ovulation induction, but not further increased when ovulation induction was used for in vitro fertilization.²⁵ This would indicate that the multiple eggs and high hormone levels are the important factors. Retrograde embryo migration is believed to be a major mechanism.

Method of Contraception

The risk of ectopic pregnancy is reduced with all methods of contraception except the progesterone-containing intrauterine device.^{14, 26, 27}

The IUD has been traditionally listed as a risk factor for ectopic pregnancy. The previous use of an IUD does not increase the risk of a subsequent ectopic pregnancy.²⁸ And it should be emphasized that the current use of modern copper-bearing IUDs does **NOT** increase the risk of ectopic pregnancy and, in fact, offers considerable protection.^{14, 29, 30, 31 and 32} The largest study, a World Health Organization multicenter study, concluded that IUD users were 50% less likely to have an ectopic pregnancy when compared to women using no contraception.¹⁴ However, if an IUD user becomes pregnant, the pregnancy is more likely to be ectopic. About 3–4% of IUD pregnancies have been ectopic, making the actual occurrence a rare event.

Ectopic Pregnancy Rates per 1000 Woman-Years^{5, 14, 26, 27}

All U.S. women	1.50
Noncontraceptive users	3.00
Copper T-380 IUD	0.20
Progesterone IUD	6.80
Levonorgestrel IUD	0.20
Norplant	0.28

The lowest ectopic pregnancy rates are seen with the most effective IUDs, like the TCU-380A (90% less likely compared to noncontraceptors).²⁷ The rate is about

one-tenth the ectopic pregnancy rate associated with the Lippes Loop or with devices with less copper such as the TCU-200.²⁷ The progesterone-releasing IUD has a higher rate, probably because its action is limited to a local effect on the endometrium,³¹ while very few ectopic pregnancies have been reported with the levonorgestrel IUD, presumably because it is associated with a partial suppression of gonadotropins with subsequent disruption of normal follicular growth and development, and in a significant number of cycles, inhibition of ovulation.^{27, 33, 34, 35 and 36}

The risk of ectopic pregnancy does not increase with increasing duration of use with the TCU-380A or the levonorgestrel IUD.^{33, 37} In a 7-year prospective study, not a single ectopic pregnancy was encountered with the levonorgestrel IUD.³³ In 8000 woman-years of experience in randomized multicenter trials, there has been only a single ectopic pregnancy reported with the TCU-380A (which is one-tenth the rate with the Lippes Loop or TCU-200).³³

The protection against ectopic pregnancy provided by the TCU-380A and the levonorgestrel IUD makes these IUDs acceptable choices for contraception in women with previous ectopic pregnancies.

The risk of an ectopic pregnancy during use of Norplant is lower than the general rate. However, because of the impressive contraceptive efficacy of Norplant, when pregnancy does occur, ectopic pregnancy should be suspected. With the progestin-only minipill, ectopic pregnancy is not prevented as effectively as intrauterine pregnancy. Although the overall incidence is not increased, the situation is similar to that with Norplant. When pregnancy occurs, an ectopic gestation must be suspected.

Ectopic Sites

Almost all ectopic pregnancies are located in the tube. Although relatively uncommon, ectopic pregnancies in nontubal sites are very susceptible to complications, especially hemorrhage. For example, abdominal pregnancies are often misdiagnosed, and the mortality rate is 17 times greater compared to the overall ectopic rate.³⁸ Contrary to the experience with tubal pregnancy, recurrence in nontubal sites is rare.

Sites of Ectopic Implantation³⁹

Fallopian tube:	
Ampullary segment	80 %
Isthmic segment	12 %
Fimbrial end	5 %
Cornual and interstitial	2 %
Abdominal	1.4%
Ovarian	0.2%
Cervical	0.2%

The Methods of Early Diagnosis

Patients with normal intrauterine pregnancies can present with the same symptoms encountered in patients with unruptured ectopic pregnancies. The best way to diagnose ectopic pregnancy is to be highly suspicious and sensitive to its possibility, and to utilize the new tools of diagnosis: the quantitative measurement of b-HCG and ultrasonography. Laparoscopy is necessary only when the diagnosis is in doubt, or when laparoscopy is the technique selected for surgical treatment.

The Quantitative Measurement of HCG

HCG is secreted by the syncytiotrophoblast and reaches a maximal level of 50,000–100,000 IU/L at 8–10 weeks of gestation. The maternal circulating HCG concentration is approximately 100 IU/L at the time of the expected but missed menses. Virtually 100% (but not absolutely all) of patients suspected of an ectopic pregnancy, but not pregnant, will have a negative blood assay for b-HCG.⁴⁰ Contrast this present day sensitivity of the HCG assay with the urinary tests of the past. In the 1960s and early 1970s, the urinary pregnancy tests were positive in only 50% of patients with ectopic pregnancies.

The modern assay for HCG measures the serum level of the HCG beta subunit. b-HCG is the largest gonadotropin b-subunit, containing a larger carbohydrate moiety and 145 amino acid residues, including a unique carboxyl terminal tail piece of 24 amino acid groups. It is this unique part of the HCG structure which allows the production of highly specific antibodies and the utilization of highly specific immunologic assays. In some laboratories, the lower limit of the assay is 4–6 IU/L, but even that level is almost never associated with a false negative. With a detection limit of less than 5 IU/L for the serum b-HCG assay, there should be no false-negative results; however, this situation (very rarely) can be encountered.⁴¹ When the clinical picture is confusing, a definitive diagnosis by laparoscopy is warranted.

A landmark observation was reported from Yale in 1981, documenting that HCG levels approximately double every 2 days in early, normal intrauterine pregnancies, and that a lesser increase is associated with ectopic pregnancies and spontaneous miscarriages.⁴² In the first 6 weeks of normal pregnancy, the concentration of HCG in the maternal blood follows a well-recognized pattern.⁴³ The rate of increase is nonlinear, changing with advancing gestational age and increasing HCG concentrations.⁴⁴ However, during the time period when the diagnosis of ectopic pregnancy is most important, from 2 to 4 weeks after ovulation, the relationship between HCG titers and gestational age is linear, approximately doubling every 2 days until the titer is greater than 10,000.⁴⁵ Use of the HCG titer requires medical judgment. Some ectopic pregnancies will display a normal rise in titer (at least for awhile), and some normal pregnancies (about 10%) will have an abnormal doubling time.

The Clinical Usefulness of the Quantitative Measurement of b-HCG

- Assessment of pregnancy viability.**
Most of the time, but not always, a normal rate of rise indicates a normal pregnancy. Clinical decisions require serial measurements of HCG.
- Correlation with ultrasonography.**
When the titer exceeds 1000–1500 IU/L, vaginal ultrasonography should identify the presence of an intrauterine gestation. With multiple gestation, a gestational sac will not be apparent until the titer is a little higher.⁴⁶ In an asymptomatic patient, repeat ultrasonography 2–3 days later is warranted.
- Assessment of treatment results.**
Declining levels are consistent with effective medical or surgical treatment. Persistent or rising levels indicate the presence of viable trophoblastic tissue.

Vaginal Ultrasonography

The difficulty in diagnosis is establishing the cause of abnormal HCG levels: is it an ectopic pregnancy or a spontaneous miscarriage? The addition of ultrasonography has made an important contribution to this differential diagnosis. A “gestational sac” is an ultrasonographic landmark, located beneath the endometrial surface, and visualized by transvaginal ultrasonography beginning 30–35 days after the last menstrual period.^{47, 48} It is a sonolucent center surrounded by a thick echogenic rim, formed by a decidual reaction round the chorionic sac. The yoke sac is the first structure visualized within the gestational sac, at 5 weeks after the last menstrual period. Cardiac motion is first observed at 5.5–6 weeks gestation.

The discriminatory zone is that HCG titer above which a gestational sac can be identified with ultrasonography. Previously, with abdominal ultrasonography, this level was approximately 6000 IU/L. Transvaginal ultrasonography has now established the discriminatory zone at a level that varies from 1000 to 1500 IU/L. This level is achieved approximately one week after the time of expected menses. Institutions must establish their own exact discriminatory zone based on the sensitivity of their immunoassay and their equipment and the ability of their ultrasonographers. Keep in mind that in a multiple pregnancy, the discriminatory zone will be a little higher, requiring an extra 2–3 days for a gestational sac to become visible. Thus, an accurate gestational age is very helpful; failure to demonstrate the presence of a gestational sac 24 or more days after conception (38 or more gestational days) usually indicates an ectopic pregnancy.⁴⁹

Demonstration of a viable intrauterine pregnancy does not absolutely exclude the possibility of an ectopic pregnancy. Along with the increase in incidence of ectopic pregnancy associated with superovulation, dizygotic twinning is more common, and thus a combined intrauterine pregnancy and extrauterine pregnancy (heterotopic pregnancy) is more frequent. **Heterotopic pregnancy should especially be considered when the pregnancy is the result of one of the methods of assisted reproductive technology.**

Color and pulsed Doppler increases the sensitivity of vaginal ultrasonography. This method adds physiologic information to the anatomic picture of regular ultrasonography. A small intrauterine gestational sac, without the double sac sign (decidua and membranes) or the presence of a yolk sac is hard to distinguish from the pseudosac of an ectopic pregnancy. A pseudogestational sac due to endometrial bleeding occurs in about 10% of ectopic pregnancies.⁵⁰ Local vascular changes associated with a true gestational sac differentiate an intrauterine pregnancy from the pseudosac of ectopic pregnancy. Vascular pulses increase with pregnancy and produce a “warm” appearance with color Doppler ultrasonography. In addition, high-velocity arterial flow is detected even with very early pregnancies.

A failed intrauterine pregnancy can be associated with either elevated flow velocity around the trophoblast or very low velocities. Thus, a characteristic peritrophoblastic arterial flow correlates with gestational sac size and HCG levels.⁵¹ Ectopic masses can also be distinguished by the surrounding abnormal color mapping. Doppler ultrasound, therefore, has greater sensitivity and is technically less challenging (and quicker). Although traditional ultrasonography can reveal an adnexal mass, Doppler flow imaging can indicate that the mass is an ectopic pregnancy by documenting abnormal vascular activity of the mass combined with the relatively cool uterine vasculature. This difference between Doppler and standard ultrasonography is greatest in early pregnancy, and thus this greater accuracy can allow earlier initiation of medical treatment.

Important Observations With Vaginal Ultrasonography

1. Documentation of an intrauterine sac.

An experienced ultrasonographer should be able to identify a viable intrauterine pregnancy if the HCG titer is 1000–1500 IU/L or greater. An HCG titer of greater than 1000–1500 IU/L with no intrauterine sac is consistent with an ectopic pregnancy.

2. Adnexal masses.

An ectopic equal to or greater than 2 cm in diameter should be identified by ultrasonography. Vaginal ultrasonography should also establish large ectopics that require different consideration. Currently an ectopic pregnancy with a diameter of 4 cm or more is a relative contraindication to medical treatment.

3. Adnexal cardiac activity.

The presence of cardiac activity in an ectopic pregnancy, detectable when the HCG titer is approximately 15,000–20,000 IU/L, is a relative contraindication to medical treatment.

The Progesterone Level

Single serum progesterone levels have a wide spectrum with considerable overlap between normal and ectopic pregnancies. This measurement must be viewed as an adjunct to HCG levels and ultrasonography. The concentration of the serum progesterone is usually lower in ectopic pregnancies. A value of 25 ng/mL or more is 98% of the time associated with a normal intrauterine pregnancy, while a value of less than 5 ng/mL identifies a nonviable pregnancy, regardless of location.⁵² The value of the serum progesterone is to help make a decision regarding the viability of a possible intrauterine pregnancy prior to curettage. In most cases, however, this is a decision easily made by the combined results of the clinical presentation, the HCG titers, and ultrasonography. The great majority of patients will have a progesterone level between 10 and 20 ng/mL at presentation, significantly limiting the clinical usefulness of progesterone measurement.⁵³ The value of 25 ng/mL as an indicator of a normal intrauterine pregnancy was established in women with spontaneous ovulations and pregnancies. The appropriate number for women receiving medication for the induction of ovulation is probably higher, and in these cases, the use of the progesterone level is even more limited.

Uterine Curettage

The purpose of uterine curettage is to determine the presence or absence of villi to rule out a nonviable intrauterine pregnancy. In most cases, curettage is helpful when a serum progesterone is less than 5 ng/mL and a non-rising HCG titer is below 1000 IU/L. Curettage with examination of the curettings can be used to prevent unnecessary laparoscopies in patients undergoing spontaneous miscarriages. Floating the curettings in saline will usually identify villi if present, but not always. The saline flotation of curettings has been reported to be incorrect in 6.6% of patients with ectopic pregnancies and incorrect in 11.3% of patients with intrauterine pregnancies.⁵⁴ Because of this inaccuracy, permanent sections and follow-up HCG titers are necessary for confirmation.

Culdocentesis

Culdocentesis to seek the presence of unclotted blood was for a period of time a valuable technique to aid in the diagnosis of an ectopic pregnancy. We have progressed to the point where the relative accuracy of culdocentesis is no longer sufficient. Furthermore, the presence of blood in the cul-de-sac does not mean that an ectopic pregnancy has ruptured. Therefore, a positive culdocentesis is of no help in deciding whether to treat medically or surgically. Culdocentesis no longer has a place in the differential diagnosis of ectopic pregnancy.

The Treatment of Ectopic Pregnancy

Expectant Management

Part of the increased incidence of ectopic pregnancy is due to earlier diagnosis detecting ectopic pregnancies, which previously resolved and remained clinically undiagnosed. Not all tubal pregnancies progress to clinical manifestations, and, therefore, expectant management of ectopic pregnancies diagnosed very early is an appropriate choice.⁵⁴ Expectant management includes the monitoring of clinical symptoms, HCG titers, and ultrasonography findings. Approximately one-fourth of women presenting with ectopic pregnancy can be managed expectantly, and 70% of this select group of patients will avoid surgery and experience successful outcomes.⁵⁵ Success with expectant management decreases with increasing HCG levels; best results are achieved when the initial HCG level is less than 2000 IU/L.^{56, 57} The long-term outcome (subsequent intrauterine and ectopic pregnancies) is similar to that with active treatment interventions.⁵⁸ The following criteria are reasonable requirements for expectant management:

Criteria for Expectant Management

1. Falling HCG titer.
2. Ectopic pregnancy definitely in the tube.
3. No significant bleeding.
4. No evidence of rupture.
5. Ectopic mass not larger than 4 cm in greatest diameter.

Medical Treatment

Medical treatment of unruptured ectopic pregnancies is appealing for several reasons: less tubal damage, less cost, and, hopefully, enhanced potential for future fertility. Methotrexate, a folic acid antagonist that interferes with DNA synthesis, has a long history of effectiveness against trophoblastic tissue, derived from experience in the treatment of hydatiform moles and choriocarcinoma. Methotrexate was used in the 1960s to treat the difficult problem of trophoblastic tissue left in situ after removal of an abdominal pregnancy. Methotrexate was first used to treat an ectopic pregnancy in Japan in 1982.⁵⁹ The first U. S. experience was reported by Ory in 1986.⁶⁰ The guidelines for the safe and effective use of methotrexate were established by Stovall and his colleagues.^{61, 62}

Criteria for Patient Selection

1. The patient is healthy, hemodynamically stable, reliable, and compliant.
2. Ultrasonography should fail to find an intrauterine pregnancy, and uterine curettage should fail to obtain villi.
3. The ectopic pregnancy measures 4 cm or less in its greatest diameter.
4. There is no evidence of rupture of the ectopic pregnancy.
5. HCG titers greater than 10,000 IU/L and fetal cardiac activity are relative contraindications. However, even patients with fetal cardiac activity have been successfully treated.

Prior to Methotrexate Treatment

1. Administer Rhogam if patient is Rh-negative and greater than 8 weeks gestation.
2. Obtain baseline liver and renal function tests, complete blood and platelet counts.
3. Consider uterine curettage.

Patient Instructions

The following are avoided until HCG titers are negative: alcohol use, sexual intercourse, and the use of folic acid-containing vitamins.

The Multiple Dose Method. The initial protocols for treatment utilized multiple doses of methotrexate together with citrovorum factor (folic acid) to minimize side effects. Treatment with this method has been reported to be 70–94% successful. Failures have been more common with HCG levels greater than 5000 IU/mL, and thus the presence of fetal cardiac activity is generally a contraindication. Side effects (in 3–4% of patients) include mild stomatitis, gastritis, diarrhea, and transient elevations in liver enzymes. Significant reactions (bone marrow suppression, dermatitis, pneumonitis) have been very rare.^{63, 64} The incidence of nonresponders and/or tubal rupture is 3–4%.

In our own experience, the onset of abdominal cramping occurring 3–4 days after the initiation of methotrexate treatment (in approximately 60% of patients) produces some anxious moments. The concern, of course, is that the ectopic pregnancy is rupturing. Although this is always a possibility, the cramping is usually a side effect of the methotrexate and resolves in a day or two. Occasionally, hospitalization is necessary until hemodynamic stability is verified.

Multiple Dose Methotrexate Protocol

Treatment is discontinued when a decline is observed in two consecutive daily HCG titers, or after 4 doses of methotrexate.

Day 1: Baseline studies. Methotrexate	1.0 mg/kg im
Day 2: Citrovorum factor	0.1 mg/kg im.
Day 3: Methotrexate	1.0 mg/kg im.
Day 4: Citrovorum factor HCG titer.	0.1 mg/kg im.
Day 5: Methotrexate HCG titer.	1.0 mg/kg im.
Day 6: Citrovorum factor HCG titer.	0.1 mg/kg im.
Day 7: Methotrexate HCG titer.	1.0 mg/kg im.
Day 8: Citrovorum factor HCG titer. Complete blood and platelet counts. Renal and liver function tests.	0.1 mg/kg im.

Weekly: HCG titer until negative.

Approximately 20% of patients will require only one dose of methotrexate, and 20% will require 4 doses.^{62, 65, 66} The side effects are encountered in those patients who require multiple doses. Changes in blood counts and liver enzymes are so infrequent and so mild, that daily monitoring is unnecessary.

In terms of subsequent fertility, methotrexate compares favorably with conservative laparoscopic surgery, and the rate of subsequent ectopic pregnancy is lower.^{21, 67} In a randomized trial comparing multiple dose methotrexate with laparoscopy, the results were as follows:⁶⁸

	Multiple Dose Methotrexate	Laparoscopy
No further treatment	82%	72%
Treatment for persistent trophoblast	4%	20%

The ultrasonographic picture of a mass persists after HCG titers become negative.⁶⁹ The time for resolution of the mass is variable, and often it takes several months. Thus, the persistence of a mass should not be interpreted as a treatment failure.

The Single Dose Method. Experience with the multiple dose method indicated that a significant number of patients responded promptly and did not require several doses. With lesser dosing, fewer side effects could be anticipated, and the use of citrovorum factor could be abandoned. The results with a single dose are very good (80–90%), even with very high HCG titers and the presence of fetal cardiac activity.^{65, 70, 71} The HCG titers usually keep rising for 3 days after treatment but by day 7 are declining. Full resolution requires 3 to as much as 6 weeks. Serious side effects are virtually absent. If there is less than a 15% decline on day 7 (the usual assay variation), the treatment protocol is repeated (necessary in approximately 8% of patients).²¹

Single Dose Methotrexate Protocol

Day 1: Baseline studies. 50 mg/M² im.
Methotrexate

Day 4: HCG titer.

Day 7: HCG titer
Complete blood and platelet count.
Liver and renal function tests.

Weekly: HCG titer until negative.

Oral Methotrexate. Experience with the oral method of treatment is not encouraging. One comparison with placebo in the expectant management of ectopic pregnancy found no indication of any effect.⁷²

Important Cautions The medical treatment of ectopic pregnancy requires compulsive compliance. An ectopic pregnancy can exist in the absence of detectable HCG.⁷³ Although in this instance, the extrauterine pregnancy is usually degenerating and associated with an indolent clinical course, rupture can still occur. Clinicians should always be alert for the possibility of rupture (3–4% of medically treated cases). A satisfying decline in HCG titers does not guarantee against rupture.⁷⁴ The average time for HCG to return to nondetectable levels is about 4 weeks.

The risk of tubal rupture is about 10% when the HCG titer is less than 1000 IU/L, and if the ectopic is isthmic, a risk of rupture is still present with a titer of 100 or less. Remember that a negative HCG assay means that HCG is not present in levels greater than the sensitivity of the assay; therefore, trophoblastic tissue can still be present, secreting minimal amounts of HCG (below the limits of the assay). Ectopic pregnancies will continue to adhere to their historical record; always expect behavior that is an exception to the general rule.

Although experience is limited with the medical treatment of relatively large masses (with a fetus present and high levels of HCG), case reports indicate a greater risk of bleeding and problems. Carefully selected cases with HCG titers greater than 10,000 IU/L might warrant medical treatment, but as a general rule these cases deserve surgical treatment.

Special Indications for Methotrexate. Treatment with methotrexate is especially useful when the pregnancy is located in a site (cervix, ovary, or cornua) where surgical treatment carries significant risk.^{75, 76 and 77} Methotrexate treatment is an attractive option when an ectopic pregnancy is in the interstitial portion of the tube or growing in the wall of the uterus (diagnosed by ultrasonography).⁷⁸

Salpingocentesis

Salpingocentesis is the injection of a substance directly into the gestational sac within the tube, either at laparoscopy or under ultrasound guidance. Various substances have been used, including methotrexate, potassium chloride, prostaglandins, and hyperosmotic glucose. The efficacy, safety, and the long-term impact on fertility have not been established. Thus far local injections have been associated with inconsistent results; at least one clinical trial was discontinued because of poor results with tubal injection of methotrexate while another claimed excellent results, especially when the HCG level was under 5000 IU/L.^{79, 80 and 81} Circulating levels of methotrexate are similar when gestational sac injection is compared to intramuscular injection.⁸² Thus, local treatment with methotrexate offers no obvious advantage over systemic treatment. Hyperosmotic glucose (a 50% solution) appears to be safe and effective when the HCG titers are less than 2500 IU/L.⁸³

Surgical Treatment

With earlier diagnosis, conservative surgery to preserve fertility has replaced the life-saving procedure of salpingectomy. Linear salpingostomy along the antimesenteric border to remove the products of conception is the procedure of choice for ectopic pregnancies in the ampullary portion of the tube. Ectopic pregnancies in the ampulla are usually located between the lumen and the serosa, and thus these are ideal candidates for linear salpingostomy. Segmental excision with either simultaneous or delayed microsurgical anastomosis is the preferred procedure for isthmic pregnancies. Although linear salpingostomy is possible for a small and unruptured gestation, isthmic pregnancies reflect a damaged endosalpinx, and these patients do poorly with linear salpingostomy (with a high rate of recurrent ectopic pregnancy).

Occasionally, an ampullary pregnancy can be expressed through the fimbrial end of the tube (milking the tube), but this procedure is associated with a higher incidence of persistent and recurrent ectopic pregnancy, undoubtedly due to invasion of the tube by the trophoblastic tissue. However, fimbrial expression of an ectopic pregnancy that is easily dislodged is acceptable. Interstitial pregnancy at the utero-tubal junction usually requires surgical excision, and even hysterectomy if bleeding cannot be controlled. The first unruptured ectopic pregnancy treated with methotrexate was an interstitial pregnancy, and this is now the treatment of choice if diagnosis is achieved early enough.

Patients with compromised fertility do better when the tube that contains the ectopic pregnancy is conserved (even when the opposite tube appears to be normal). However, in patients with a history positive for previous tubal disease, the risk of a recurrent ectopic pregnancy in the same tube is very much higher, and in this case, some argue in favor of salpingectomy. When performing a salpingectomy, a cornual wedge excision as prophylaxis against recannulation and a subsequent ectopic pregnancy is no longer considered to be necessary. An effort should be made to retain both ovaries when appropriate as a resource for the future use of in vitro fertilization.

Indications for Salpingectomy

Childbearing completed.
Second ectopic pregnancy in the same tube.
Uncontrolled bleeding.
Severely damaged tube.

These procedures can be accomplished either by laparotomy or laparoscopy. The choice of surgical method and specific procedure is determined by the patient's condition, desire for future fertility, the location, size, and state of the ectopic pregnancy, and the experience of the surgeon. The relative contraindications to laparoscopy include extensive pelvic adhesions, hemoperitoneum, and an ectopic pregnancy greater than 4 cm diameter. Hemodynamic instability is an absolute contraindication.

Linear salpingostomy through the laparoscope achieves results comparable with those obtained at laparotomy.^{84, 85} Hemostasis is the key and several methods are used, including the use of vasopressin, microcautery, and laser. The gains are notable: outpatient versus inpatient cost and a more rapid recovery. Almost all patients can now be successfully treated with conservative surgery. Comparisons of the different types of surgery (laparoscopic salpingostomy, laparotomy salpingostomy, and laparotomy salpingectomy) indicate that the surgical technique chosen is less important in determining future fertility than the causes of the ectopic pregnancy.^{86, 87}

Results with Laparoscopic Surgery

Subsequent intrauterine pregnancy	70%
Subsequent tubal patency	84%
Subsequent ectopic pregnancy	12%
Persistent trophoblast	15%

Treatment of an Ectopic Pregnancy After Tubal Ligation

An ectopic pregnancy after a previous tubal ligation is usually located in the segment of tube containing the fimbria. The pregnancy occurs because of small channel recannulation through the ligation site, allowing sperm to migrate toward the oocyte. A prophylactic procedure should be highly considered. Removing both fimbrial segments and fulgurating the proximal segments (either by laparoscopy or laparotomy) will prevent the recurrence of another ectopic pregnancy.

Treatment of Persistent Trophoblastic Tissue

The risk of a persistent ectopic pregnancy with conservative surgery by laparotomy is 5%.⁸⁸ Laparoscopic salpingostomy is associated with a higher rate of persistent trophoblastic tissue; approximately 15% of patients will require further treatment.⁸⁹ Persistence of ectopic trophoblastic tissue can be associated with hemorrhage and tubal rupture (usually within 2 weeks); however, regression without clinical sequelae is the general rule. For this reason, **weekly HCG measurements are necessary following conservative surgery.** The incidence of persistent trophoblastic tissue is greater (not surprising) with higher HCG titers, and relatively rare with a titer less than 3000 IU/L.⁹⁰ The risk of persistent trophoblastic tissue is very significant with a hematosalpinx greater than 6 cm in diameter, an HCG titer greater than 20,000 IU/L, and a hemoperitoneum greater than 2000 mL.⁹¹ Rupture is unlikely for an ampullary pregnancy with an HCG level of 100 or less, but not so for an isthmic pregnancy.

The average time for HCG levels to become undetectable is 4 weeks, but it can take 6 weeks. The need for treatment of persistent trophoblastic tissue can emerge in a few days or not until 1 month later. Although reoperation is always a treatment option, the use of methotrexate is preferable. Prophylactic treatment can be administered with a single dose of methotrexate (1mg/kg), or a single dose of methotrexate (15 mg/m²) can be administered after diagnosis.^{92, 93}

Low and declining HCG levels warrant only close surveillance; only persistent or rising titers require treatment (a small minority of patients). Symptomatic patients, of course, usually demand surgical therapy.

The problem of persistent trophoblastic tissue after surgery makes earlier diagnosis of an ectopic pregnancy even more important. With sufficiently early diagnosis, medical treatment becomes the method of choice.

Rh Sensitization

Despite underutilization of Rhogam in Rh-negative women, no apparent increase in sensitization has been observed.^{94, 95} This indicates that ectopic pregnancies do not contain sufficiently large quantities of fetal red blood cells. The use of Rhogam should be considered only for ectopic pregnancies that are older than 8 weeks gestation.

Fertility After Ectopic Pregnancy

Having had one ectopic pregnancy, a woman is at increased risk for another, especially if infectious pathology is present.²¹ Nevertheless, after one ectopic pregnancy, the chance of having a live-born infant is 85% with the next pregnancy. After 2 ectopic pregnancies, the risk of ectopic pregnancy is increased nearly 10-fold, and consideration should be given to in vitro fertilization.

Laboratory Values for Selected Measurements in Urine

Substance	Conventional Units	Conversion Factor	SI Units
Cortisol, free	10–90 µg/24 hr	2.759	28–250 nmol/24 hr
Estrogens, total	5–25 µg/24 hr	3.67	18–92 nmol/24 hr
17-Hydroxycorticosteroids	2–6 mg/24 hr	2.759	5.5–15.5 µmol/24 hr
17-Ketosteroids	6.0–15 mEq/24 hr	3.467	21–52.5 µmol/24 hr

SI Prefixes and Their Symbols

10^9	giga	G
10^6	mega	M
10^3	kilo	k
10^2	hecto	h
10^1	deka	da
10^{-1}	deci	d
10^{-2}	centi	c
10^{-3}	milli	m
10^{-6}	micro	µ
10^{-9}	nano	n
10^{-12}	pico	p
10^{-15}	femto	f
10^{-18}	atto	a

Laboratory Values for Selected Measurements in Blood, Plasma, and Serum

Substance	Conventional Units	Conversion Factor	SI Units
ACTH, adrenocorticotropin hormone	10–80 pg/mL	0.2202	2.2–17.6 pmol/L
6:00 AM	<50 pg/mL	0.2202	<11 pmol/L
6:00 PM			
Androstenedione	60–300 ng/dL	0.0349	2.1–10.5 nmol/L
Calcium, total	8.5–10.5 mg/dL	0.25	2.1–2.6 mmol/L
Cholesterol	<200 mg/dL	0.0259	<5.2 mmol/L
LDL-cholesterol	60–130 mg/dL	0.0259	1.6–3.4 mmol/L
HDL-cholesterol	30–70 mg/dL	0.0259	0.8–1.8 mmol/L
Cortisol	5–25 µg/dL	27.6	140–690 nmol/L
8:00 AM	3–12 µg/dL	27.6	80–330 nmol/L
4:00 PM	<50% of AM value	27.6	<50% of AM value
10:00 PM			
DHAS, Dehydroepiandrosterone sulfate	80–350 µg/dL	0.0027	2.2–9.5 µmol/L
11-Deoxycortisol	0.05–0.25 µg/dL	28.86	1.5–7.3 nmol/L
11-Deoxycorticosterone	2–10 ng/dL	30.3	60–300 pmol/L
Estradiol	20–400 pg/mL	3.67	70–1500 pmol/L
Estrone	30–200 pg/mL	3.7	110–740 pmol/L
FSH, reproductive years	5–20 mIU/mL	1.0	5–20 IU/L
Glucose, fasting	70–110 mg/dL	0.0556	4.0–6.0 mmol/L
Growth hormone	<10 ng/mL	1.0	<10 µg/L
17-Hydroxyprogesterone	100–300 ng/dL	0.03	3–9 nmol/L
Insulin, fasting	5–20 µU/mL	7.175	35–145 pmol/L
Insulin-like growth factor-I	0.3–2.2 U/mL	1000	300–2200 U/L
LH, reproductive years	5–20 mIU/mL	1.0	5–20 IU/L
Progesterone	<3 ng/mL	3.18	<9.5 nmol/L
Follicular phase	5–30 ng/mL	3.18	16–95 nmol/L
Secretory phase			
Prolactin	1–20 ng/mL	44.4	44.4–888 pmol/L
Testosterone, total	20–80 ng/dL	0.0347	0.7–2.8 nmol/L
Testosterone, free	100–200 pg/dL	0.0347	35–700 pmol/L
TSH, thyroid stimulating hormone	0.35–5.0 µU/mL	1.0	0.35–5.0 mU/L

Thyroxine, free T ₄	0.8–2.3 ng/dL	1.29	10–30 nmol/L
Triglycerides	40–250 mg/dL	0.0113	0.5–2.8 mmol/L
Triiodothyronine, T ₃ , total	80–220 ng/dL	0.0154	1.2–3.4 nmol/L
Triiodothyronine, T ₃ , free	0.13–0.55 ng/dL	15.4	2.0–8.5 pmol/L
Triiodothyronine, reverse	8–35 ng/dL	15.4	120–540 pmol/L
