FTO encodes a 2-oxoglutarate-dependent nucleic acid demethylase. Studies of wild-type mice indicate that *Fto* messenger RNA (mRNA) is most abundant in the brain, particularly in hypothalamic nuclei governing energy balance, and that *Fto* mRNA levels in the arcuate nucleus are regulated by feeding and fasting.⁷⁶ These data suggest that *FTO* participates in the central regulation of energy homeostasis.

ENERGY METABOLISM

Total daily energy expenditure (TEE) comprises resting energy expenditure (REE), which accounts for approximately 70% of TEE; energy expended in physical activity (approximately 20% of TEE); and the thermic effect of food (TEF), which accounts for approximately 10% of TEE. REE represents the energy expended for normal cellular and organ function under postabsorptive resting conditions.

Energy expended in physical activity includes the energy costs of both volitional activity, such as exercise, and non-volitional activity, such as spontaneous muscle contractions, maintaining posture, and fidgeting. The TEF represents the energy expended in digestion, absorption, and sympathetic nervous system activation after ingestion of a meal.

Cross-sectional studies have investigated whether alterations in energy metabolism are involved in obesity. Obese persons usually have greater rates of REE than lean persons of the same height because obese persons have greater lean and adipose tissue cell mass.⁷⁷

Defects in REE or TEE have not been detected in patients with “diet-resistant” obesity—that is, those who maintain their weight despite the claim of strict adherence to a low-calorie diet (LCD).^{78,79} Instead, such patients appear to underestimate their food intake and actually consume twice as many calories as they record in food-intake diaries. Currently, it is not known whether obese persons expend less total energy in daily physical activity because they are less active than lean individuals. During non-weight-bearing activity (e.g., cycling), obese persons expend the same amount of energy as lean persons to perform the same amount of work.⁸⁰ However, during weight-bearing activities, obese persons expend more energy than lean ones, because more work is required to carry their greater body weight.

Evidence from studies in obese and lean subjects matched for either fat mass or lean body mass suggests that obese subjects have a small (approximately 75 kcal/day) but potentially important reduction in TEF. This reduction in TEF might arise from the insulin resistance and blunted sympathetic nervous system activity that occur in obesity.⁸¹

Although extensive research has failed to reveal significant defects in the energy metabolism of persons who are already obese, the possibility remains that inherent abnormalities in energy metabolism contribute to the development of obesity. However, currently available research technology has only a limited ability to detect small but chronic defects in energy metabolism that may be clinically significant. Moreover, it is difficult to establish a causal relationship between energy expenditure and the development of obesity because energy metabolism measurements capture only a brief point in time and therefore may not reveal abnormalities that emerge during specific life stages.

Most studies do not support the involvement of a defect in metabolic rate in the development of obesity. In one longitudinal study, daily TEE at 3 months of age was 21% lower in infants who later became overweight compared with those who maintained a normal weight.⁸² However, larger subsequent studies (e.g., by Stunkard and associates⁸³) did not confirm this finding. In a longitudinal study of 126 Pima Indians, those in the lowest tertile of REE at baseline had the highest cumulative incidence of a 10-kg weight gain after 1 to 4 years.⁸⁴ In contrast, the Baltimore Longitudinal Study on Aging, which followed 775 men for an average of 10 years, did not detect a relationship between initial REE and weight change.⁸⁵

When energy intake exceeds energy expenditure, weight gain usually occurs. However, genetic factors may influence the amount of weight gained with overfeeding. Bouchard and colleagues⁸⁶ observed variable weight gain among 12 monozygotic twin pairs who were chronically overfed 1000 kcal/day, but members of each twin pair gained similar amounts of weight. In another study, increase in body fat after 8 weeks of overfeeding was inversely related to changes in nonvolitional energy expenditure (e.g.,

fidgeting).⁸⁷ Therefore, in some persons, nonvolitional energy expenditure during periods of overingestion could be a mechanism that limits weight gain through the dissipation of excess ingested energy.

Diet-induced weight loss decreases REE, which promotes weight regain. This observation underlies the set-point theory, which posits that body weight is predetermined such that weight loss (or gain) promotes a decrease (or increase) in metabolic rate that acts to restore body weight to a preset level. In both lean and obese persons, hypocaloric feeding reduces REE by 15% to 30%. This reduction in REE cannot be completely accounted for by the accompanying decrease in body size or lean body mass and is considered a normal part of the physiologic adaptation to energy restriction.⁸⁸

The reduction in REE that occurs during negative energy balance is transient and does not persist during maintenance of a lower body weight. As reported in several studies, long-term maintenance of weight loss is not associated with an abnormal decrease in REE or TEE when adjustments are made for changes in body composition.^{89,90} In a meta-analysis of 15 studies, the REE of subjects who were formerly obese was found to be similar to that of subjects who were never obese.⁹¹ Although the decrease in energy metabolism with weight loss is largely appropriate for the concomitant changes in body composition, this decrease might nonetheless promote weight regain.

ADIPOSE TISSUE AND TRIGLYCERIDE METABOLISM

Triglycerides stored within adipose tissue constitute the body's major energy reserve (Table 36-2). Triglycerides are a much more compact fuel than glycogen because of the energy density and hydrophobic nature of fat. Triglycerides yield 9.3 kcal/g on oxidation and are compactly stored as oil inside the fat cell, accounting for 85% of adipocyte weight. Glycogen, in contrast, yields only 4.1 kcal/g on oxidation and is stored intracellularly as a gel containing approximately 2 g of water for every 1 g of glycogen.

Adipose tissue is an effective storage mechanism for transportable fuel that allows mobility and survival when

TABLE 36-2

Endogenous Fuel Stores in a Man Weighing 70 Kg

Fuel Source	Mass	
	Grams	Kcal
Adipose Tissue		
Triglyceride	13,000	120,000
Liver		
Glycogen	100	400
Triglyceride	50	450
Muscle		
Glycogen	500	2,000
Triglyceride	300	2,700
Blood		
Glucose	15	60
Triglyceride	4	35
Free fatty acids	0.5	5

food is scarce. During starvation, the duration of survival is determined by the size of the adipose tissue mass. Lean persons die after only approximately 60 days of starvation, when more than 35% of body weight is lost.⁹² Obese persons have tolerated much longer therapeutic fasts, up to 1 year or longer, without adverse effects. In the longest reported fast, a 207-kg man ingested only acaloric fluids, vitamins, and minerals for 382 days and lost 126 kg, or 61% of his initial weight.⁹³

Triglyceride Storage

The major function of adipocytes is the storage of triglycerides for future use as energy substrate. Lipogenesis from glucose makes only a limited contribution to triglyceride storage in the adipocyte.⁹⁴ Most of the triglyceride in adipocytes is derived from chylomicrons and very-low-density lipoprotein (VLDL) triglycerides that originate, respectively, from dietary and hepatic sources. These plasma triglycerides are hydrolyzed by lipoprotein lipase (LPL), a key regulator of fat cell triglyceride uptake from circulating triglycerides. LPL is synthesized by adipocytes and transported to the endoluminal surface of endothelial cells. The interaction of LPL with chylomicrons and VLDL releases fatty acids from plasma triglycerides, which are then taken up by local adipocytes. Plasma free fatty acids themselves can also be taken up by adipose tissue, independently of LPL.

Insulin and cortisol are the principal hormones involved in regulation of LPL activity and expression.⁹⁵ The activity of LPL within individual tissues is a key factor in partitioning triglycerides among different body tissues. Insulin influences this partitioning through its stimulation of LPL activity in adipose tissue.⁹⁶ Insulin also promotes triglyceride storage in adipocytes through other mechanisms, including inhibition of lipolysis, stimulation of adipocyte differentiation, and escalation of glucose uptake. The importance of cortisol in fat distribution is supported by the clinical appearance of patients with Cushing's syndrome. The obesity-promoting effect of cortisol can involve a synergistic effect of cortisol and insulin on the induction of LPL in adipose tissue, as has been demonstrated *in vitro*. Testosterone, growth hormone, catecholamines, tumor necrosis factor (TNF), and other related cytokines inhibit LPL activity.⁹⁵

Lipolysis

The balance between triglyceride storage and lipolysis is regulated by complex hormonal and neuronal mechanisms. To become available as energy substrate, triglycerides stored within adipocytes must be hydrolyzed by hormone-sensitive lipase (HSL) into fatty acids. These fatty acids can be released from adipocytes into the circulation. The circulating half-life of plasma fatty acids is only 3 to 4 minutes. During resting conditions, fatty acid release by adipose tissue exceeds the rate of fatty acid oxidation.⁹⁷ The excess availability of fatty acids in plasma provides a ready supply of oxidizable substrate to respond to sudden changes in energy requirements, such as are induced by exercise. The plasma fatty acids that escape immediate oxidation are usually re-esterified to triglyceride in adipose tissue, muscle, or liver. These fatty acids are the major precursors of hepatic VLDL triglyceride synthesis.⁹⁸ In turn, VLDL triglycerides are secreted by the liver and redistributed throughout the body, depending on tissue-specific factors, such as the activity of LPL. These observations imply that there is continuous redistribution of triglycerides between adipose tissue and the rest of the body.

There is considerable variation within and between subjects in the rate of lipolysis and, consequently, in the level

of fatty acids in plasma. Insulin and catecholamines are the major circulating hormones that influence lipolysis in adipocytes. Insulin inhibits lipolysis through its effect on HSL, whereas catecholamines stimulate lipolysis. Small changes in the plasma concentrations of insulin and catecholamines have major effects on lipolytic rate. Half-maximal suppression of lipolysis occurs at postabsorptive insulin levels, and maximal suppression of lipolysis occurs at insulin levels within the range observed after a regular meal.⁹⁹ Minor increases in resting catecholamine levels stimulate lipolysis. Other factors also modulate the rate of lipolysis. For example, growth hormone and cortisol stimulate lipolysis. In general, the effects of these other factors are less potent than the effects of insulin and catecholamines.

In contrast to the tight feedback regulation of insulin secretion by glucose levels, insulin and catecholamine concentrations are not regulated by lipolysis or fatty acid levels. Although free fatty acid levels affect glucose-stimulated insulin release, there is no feedback between insulin release and rate of lipolysis. The wide physiologic variations in plasma free fatty acid concentrations between subjects can be explained, in part, by the finely tuned dose-response effects of insulin and catecholamines on lipolysis, in combination with the absence of tight feedback regulation of insulin and catecholamine levels by free fatty acids.

Basal plasma fatty acid concentrations are often increased in obese persons, particularly those with abdominal obesity. An increased rate of free fatty acid release into plasma because of an increased rate of lipolysis from upper-body subcutaneous fat is responsible for the higher levels of circulating fatty acids.^{100,101} The excess free fatty acid availability in plasma might lead to increased hepatic free fatty acid uptake, VLDL triglyceride synthesis, intramuscular triglyceride formation, and insulin resistance.

ADIPOSE TISSUE AS AN ENDOCRINE ORGAN

Traditionally, adipocytes have been viewed as energy depots that store triglycerides during feeding and release fatty acids during fasting to provide fuel for other tissues. However, adipose tissue secretes numerous proteins that have important physiologic functions (Table 36-3). These factors participate in autocrine and paracrine regulation

TABLE 36-3

Adipocyte-Secreted Proteins

Category	Protein
Hormones	Leptin, resistin, angiotensinogen, adiponectin, estrogens, visfatin, angiopoietin 4
Cytokines	Interleukins 1, 6, 8, 10, MCP-1, interferon- γ , tumor necrosis factor- α
Extracellular matrix proteins	Various subtypes of collagen- α 1, various metalloproteinases, fibronectin, osteonectin, laminin, entactin, thrombospondin 1 and 2
Complement factors	Adipsin, complement C3, factor B
Enzymes	Cholesterol ester transfer protein, lipoprotein lipase
Acute phase response proteins	A-1 Acid glycoprotein, haptoglobin
Other	Fatty acids, plasminogen activator inhibitor 1, prostacyclin

within adipose tissue, and, as circulating hormones, they can affect the functions of distant organs such as muscle, pancreas, liver, and the central nervous system.

The function of adipose tissue as an endocrine organ has important implications for understanding the pathophysiologic relationship between excess body fat and pathologic states such as insulin resistance and T2DM.^{102,103} Not all products released by adipose tissue are produced by adipocytes. Other cells contained within the adipose tissue, including endothelial cells, macrophages, and adipocyte precursor cells, can also participate in endocrine functions. Selected proteins produced by adipose tissue are reviewed next.

Leptin

Adipocytes produce leptin and secrete it into the bloodstream. Leptin has pleiotropic effects on food intake, hypothalamic neuroendocrine regulation, reproductive function, and energy expenditure.^{104,105} There is a direct relationship between plasma leptin concentrations and BMI or body fat percentage.¹⁰⁶ However, there can be considerable variability in leptin concentrations among persons with the same BMI, suggesting that leptin production is also regulated by factors other than adipose tissue mass. Leptin levels decrease rapidly within 12 hours after the start of starvation. Conversely, leptin levels increase in response to overfeeding.¹⁰⁷ Therefore, plasma leptin concentrations reflect adipose tissue mass and are influenced by energy balance. Leptin is a bidirectional signal that switches physiologic regulation between fed and starved states. Plasma leptin concentrations increase with increasing fat mass and decrease rapidly during early fasting. The relative importance of the central versus peripheral effects of leptin in body weight regulation in most obese persons is still unclear.¹⁰⁸

Resistin

Resistin is another signaling polypeptide secreted by adipocytes.¹⁰⁹ Resistin levels are increased in mice with diet-induced and genetic forms of obesity and insulin resistance. Administration of recombinant resistin to normal mice leads to impaired glucose tolerance and insulin action. Neutralization of resistin levels leads to reduced hyperglycemia in obese, insulin-resistant mice, in part by improving insulin sensitivity. Based on these findings, it has been proposed that resistin is a hormone that links obesity to diabetes by inducing insulin resistance.

Adiponectin

Adiponectin is the most abundant secretory protein produced by adipocytes. In contrast to other secretory products of adipocytes, the plasma concentrations of adiponectin are decreased in obesity and insulin resistance. There is a close association between hypo adiponectinemia, insulin resistance, and hyperinsulinemia.¹¹⁰ Conversely, adiponectin expression increases with improved insulin sensitivity and weight loss.¹¹¹ Interventions that improve insulin sensitivity, such as weight loss or treatment with thiazolidinediones, are associated with increased adipose tissue adiponectin gene expression and plasma concentrations.¹¹² Moreover, administration of recombinant adiponectin exerts glucose-lowering effects and ameliorates insulin resistance in mouse models of obesity or diabetes.¹¹³ These data suggest that decreased plasma levels of adiponectin contribute to some of the metabolic complications associated with obesity.

Visfatin

Visfatin corresponds with a protein previously known as pre-B cell colony-enhancing factor. The initial study

documenting the insulin-like effects of visfatin¹¹⁴ was later withdrawn. Subsequent studies in human subjects reported conflicting results regarding the relation of visfatin to adiposity, subcutaneous or visceral fat, and insulin resistance. The role of this protein in the development of obesity and insulin resistance is unclear. Additional studies are required to elucidate the potential physiologic and pathophysiologic roles of visfatin.

Estrogens

Adipose tissue has P450 aromatase activity. This enzyme is important for transforming androstenedione into estrone. Estrone is the second major circulating estrogen in premenopausal women and the most important estrogen in postmenopausal women.¹⁰³ The conversion rate of androstenedione into estrone increases with age and obesity, and it is higher in women with lower-body obesity than in those with upper-body obesity. In addition to a role in endocrine regulation, the effects of P450 aromatase on estrogen metabolism might also have a role in autocrine and paracrine action, because estrogen receptors are present in adipose tissue.

Selected Cytokines

Tumor Necrosis Factor- α . Adipocytes secrete TNF- α , and TNF- α expression is increased in the enlarged adipocytes of obese subjects.¹¹⁵ However, plasma TNF- α levels are generally at or below the detection limit of available assays, which suggests that the TNF- α produced in adipose tissue has paracrine, rather than endocrine, functions. The multiple effects of TNF- α on adipocytes include impairment of insulin signaling. Therefore, it has been proposed that TNF- α may partially contribute to insulin resistance in obesity.¹⁰²

Interleukin 6. Adipose tissue interleukin 6 (IL-6) secretion may account for 30% of circulating IL-6.^{116,117} Obesity is associated with increased plasma IL-6 concentrations, which may contribute to systemic inflammation and insulin resistance. Insulin sensitivity is inversely related to plasma IL-6 levels,¹¹⁸ and IL-6 directly impairs insulin signaling.¹¹⁹ Administration of IL-6 to human subjects induces dose-dependent increases in fasting blood glucose, probably by stimulating release of glucagon and other counter-regulatory hormones or by inducing peripheral resistance to insulin action, or both.¹²⁰

ADIPOCYTE BIOLOGY

White Adipose Tissue

Obesity is associated with an increased number of adipocytes. A lean adult has about 35 billion adipocytes, each containing approximately 0.4 to 0.6 μ g of triglyceride; an extremely obese adult can have four times as many adipocytes (125 billion), each containing twice as much lipid (0.8 to 1.2 μ g of triglyceride).¹²¹

Understanding of adipocyte differentiation is largely derived from studies conducted in preadipocytes in culture. The current concept is that adipocytes are derived from fibroblast precursor cells after the concerted actions of extracellular signals and intrinsic transcription factors and coactivators.

Many extranuclear factors and intracellular transduction pathways influence the adipogenic potential of cells in vitro and in vivo (Fig. 36-3).¹²² Although in the future it may be possible to regulate adipogenesis in vivo,

Figure 36-3 Progression of 3T3-L1 preadipocyte differentiation and subsequent changes in cellular characteristics. The distinct stages of differentiation (very early, early, intermediate, and late) are shown. C/EBP, CCAAT/enhancer binding protein; DEX, dexamethasone; LPL, lipoprotein lipase; MIX, methylisobutylxanthine; PPAR, peroxisome proliferator-activated receptor. (From Ntambi JM, Kim Y-C. Adipocyte differentiation and gene expression. *J Nutr*. 2000;130:3122S-3126S.)

decreasing adipogenesis without altering energy balance can result in the deposition of triglycerides in other tissues. Excessive amounts of triglycerides in nonadipose tissues can have deleterious effects, as was suggested by the liver steatosis, dyslipidemia, and diabetes observed when adipogenesis was prevented in mice.¹²³

The cornerstone of obesity therapy is to increase the use of endogenous fat stores as fuel by reducing energy intake below energy expenditure. With dieting, weight loss is composed of approximately 75% to 85% fat and 15% to 25% fat-free mass (FFM).¹²⁴ An energy deficit of approximately 3500 kcal is required to oxidize 1 lb of adipose tissue. However, because of the oxidation of lean tissue and associated water losses, a 3500-kcal energy deficit will reduce body weight by more than 1 lb.

The distribution of fat loss is characterized by regional heterogeneity.^{125,126} Particularly in men and women with initially increased intra-abdominal fat, there are greater relative losses of intra-abdominal fat than total body fat mass. A decrease in the size (triglyceride content) of existing adipocytes accounts for most, if not all, of the fat loss.¹²⁷ In humans, there is also evidence that the number of adipocytes is reduced with large, long-term fat loss.¹²⁸ However, it is possible that this perception of decreased fat cell number is false due to inability of standard cell counting techniques to detect adipocytes that have undergone marked shrinkage.

There are two possible mechanisms through which weight loss could eliminate fat cells: dedifferentiation, the morphologic and biochemical reversion of mature adipocytes to preadipocytes, and apoptosis. Adipocyte dedifferentiation has been observed *in vitro*, but there is no evidence that it occurs *in vivo*.¹²⁹ Adipocyte apoptosis has been induced *in vitro*,¹³⁰ and it has been demonstrated to occur *in vivo* in some patients with cancer.¹³¹ To date, it is not known whether diet-mediated weight loss induces adipocyte apoptosis.

Brown Adipose Tissue

Brown adipose tissue (BAT) is structurally different from white adipose tissue; it contains multilocular fat vacuoles and large mitochondria and is intensively innervated by sympathetic nerves. In rodents, BAT is very important for nonshivering thermogenesis. The uncoupling of phosphorylation in BAT results from the activity of uncoupling protein 1 (UCP1) within the inner mitochondrial membrane, which exhausts the electrochemical gradient needed for oxidative phosphorylation by creating a proton leak. BAT consequently affects energy expenditure by producing heat from uncoupled phosphorylation.¹³² Three recent studies conducted in human subjects provide conclusive evidence that UCP1 is present in adipose tissue. Biopsies of areas of UCP1 activity identified by positron emission tomography or computed tomography provided histologic confirmation of the presence of supraclavicular BAT.^{133,134} UCP1 activity was stimulated by cold exposure.¹³⁵ Another study in humans documented a very strong seasonal variation in the presence of BAT.¹³⁶ It is possible that altered regulation of BAT activity is involved in the pathogenesis of obesity.

PREVALENCE OF OBESITY

The worldwide prevalence of obesity has increased markedly over the last several decades. In the United States, about one third of adults aged 20 to 74 years are considered obese.¹³⁷ According to national population surveys conducted since 1960, the prevalence of obesity (BMI ≥ 30 kg/m²) has more than doubled, from 13% to 32%.^{137,138} The prevalence of obesity increases progressively from 20 to 50 years of age but then declines after 60 to 70 years of age.

The prevalence of obesity has also risen in children and adolescents. Overweight is defined as a BMI greater than the 95th percentile for age and gender on the revised National Center for Health Statistics growth charts; based on this definition, the prevalence of overweight among children and adolescents aged 6 to 17 years in the United States is 17%,^{137,139} double the rate reported in earlier surveys. Diseases commonly associated with obesity in adults, such as T2DM, hypertension, hyperlipidemia, gallbladder disease, nonalcoholic steatohepatitis, sleep apnea, and orthopedic complications, are now increasingly observed in children.¹⁴⁰

METABOLICALLY NORMAL OBESITY

Obesity is commonly associated with alterations in metabolic function, namely insulin resistance, diabetes, dyslipidemia (increased serum triglyceride and decreased serum high-density lipoprotein-cholesterol [HDL-C]), and increased blood pressure.^{50,141} However, approximately 25% of obese adults are "metabolically normal" based on insulin sensitivity as measured by the hyperinsulinemic euglycemic clamp technique.^{142,143} In addition, NHANES data covering 1994 to 2004 indicated that 32% of obese adults were metabolically normal, defined as having no more than one cardiometabolic abnormality (i.e., blood pressure, a homeostasis model assessment of insulin resistance [HOMA-IR] value, and concentrations of plasma glucose, triglyceride, HDL-C, and C-reactive protein).¹⁴⁴

The recognition that a subset of obese persons are resistant to the typical metabolic complications of obesity has led to several studies that attempted to characterize the

distinguishing features of metabolically healthy but obese individuals.¹⁴⁵ In general, these studies found that persons with metabolically normal obesity (also called uncomplicated obesity¹⁴⁶ or metabolically benign obesity¹⁴⁷) had a similar percentage of body fat but less visceral and liver fat than metabolically abnormal obese persons; moreover, they had normal values for insulin sensitivity, blood pressure, lipid profile, and inflammatory profile (plasma C-reactive protein).^{142,145-149} Metabolically normal obese adults who were monitored for up to 11 years did not show a greater risk of developing diabetes or cardiovascular disease than normal-weight, metabolically normal subjects.⁵⁴ In contrast, metabolically abnormal, lean or obese subjects had a 4- to 11-fold increased relative risk of diabetes compared with normal-weight, metabolically normal subjects.¹⁵⁰

CLINICAL FEATURES AND COMPLICATIONS OF OBESITY

Obesity causes many serious medical complications that impair quality of life and lead to increased morbidity and premature death (Fig. 36-4).¹⁵¹ The complications associated with obesity have been reviewed in detail elsewhere.⁵

Endocrine and Metabolic Diseases

The Dysmetabolic Syndrome

In the dysmetabolic syndrome, also known as metabolic syndrome, insulin-resistance syndrome, or syndrome X, the specific phenotype of upper-body (or abdominal) obesity is associated with a cluster of metabolic risk factors for CHD. Features of this syndrome include insulin resistance with associated hyperinsulinemia, impaired glucose tolerance, impaired insulin-mediated glucose disposal, and T2DM; dyslipidemia, characterized by hypertriglyceridemia and low serum HDL-C levels; and hypertension. Other metabolic risk factors, including increased serum levels of apolipoprotein B; small, dense low-density lipoprotein (LDL) particles; and plasminogen activator inhibitor 1 (PAI1, encoded by *SERPINE1*) with impaired fibrinolysis have also been associated with abdominal obesity.^{152,153} The dysmetabolic syndrome usually occurs in persons with

frank obesity, but it has also been reported in normal-weight persons who presumably have an increased amount of abdominal fat.¹⁵⁴

The dysmetabolic syndrome was originally identified and defined on the basis of epidemiologic associations. The underlying pathogenesis and the interrelationships among the individual features have not been completely elucidated. Insulin resistance has been hypothesized to be the common underlying pathogenic mechanism.¹⁵⁵ However, according to a factor analysis of data obtained from non-diabetic subjects in the Framingham Offspring Study, insulin resistance may not be the only precedent condition, and more than one independent physiologic process may be involved.¹⁵⁶

Abdominal obesity is associated with insulin resistance. However, it is unclear whether visceral (omental and mesenteric) or subcutaneous deposits of abdominal fat are more closely related to insulin resistance, because data from different studies are contradictory. In addition, visceral fat mass often correlates with subcutaneous fat mass, so it is difficult to separate the contribution of each depot to insulin resistance. Furthermore, it is not known whether visceral fat actually participates in the pathogenesis of the dysmetabolic syndrome or merely serves as a marker of increased risk for the metabolic complications of obesity.¹⁵⁷

The ectopic distribution of triglycerides in nonadipose tissue is also closely correlated with the metabolic complications of obesity. Data from a series of studies showed that insulin resistance to glucose metabolism in skeletal muscle is correlated with the intramyocellular concentration of triglyceride.¹⁵⁸ In addition, excessive intrahepatic triglyceride content is associated with serious cardiometabolic abnormalities, including T2DM, dyslipidemia (high plasma triglyceride, low plasma HDL-C, or both), hypertension, the dysmetabolic syndrome, and CHD.^{159,160} It is not known whether triglycerides interfere with insulin action or whether triglycerides serve as surrogate markers for some other fatty acid-derived entity (from plasma or intracellular sources) that impairs insulin signaling.¹⁶¹

Type 2 Diabetes Mellitus

The marked increase in the prevalence of obesity has played an important role in the 25% increase in the prevalence of diabetes that has occurred in the United States over the last 20 years.¹⁶² According to data from NHANES III, two thirds of the men and women in the United States with diagnosed T2DM have a BMI of 27.0 kg/m² or greater.¹³⁹ The risk of diabetes increases linearly with BMI; for example, the prevalence of diabetes in NHANES III increased from 2% in those with a BMI of 25.0 to 29.9 kg/m², to 8% with a BMI of 30 to 34.9 kg/m², and to 13% with a BMI greater than 35 kg/m².¹⁶² In the Nurses' Health Study, the risk of diabetes began to increase when BMI exceeded the "normal" value of 22 kg/m² (see Fig. 36-2).^{35,163} In addition, the risk of diabetes increases with increases in abdominal fat mass, waist circumference, or waist-to-hip circumference ratio at any given BMI value.¹⁶⁴⁻¹⁶⁶ The risk of diabetes also increases with weight gain during adulthood. Among men and women aged 35 to 60 years, the risk of diabetes was three times greater in those who had gained 5 to 10 kg since the age of 18 to 20 years, compared with those who had maintained their weight within 2 kg of their earlier value.^{35,36}

Dyslipidemia

Obesity is associated with several serum lipid abnormalities, including hypertriglyceridemia, reduced HDL-C levels, and an increased fraction of small, dense LDL particles.^{167,168}

Figure 36-4 Medical complications associated with obesity.

This association is especially strong in persons with abdominal obesity. In addition, most studies suggest that serum concentrations of total cholesterol and LDL-cholesterol (LDL-C) are elevated in obesity. Data from NHANES III showed that, in men, there was a progressive increase in the prevalence of hypercholesterolemia (total blood cholesterol ≥ 240 mg dL or 6.21 mmol/L) with increasing BMI.¹⁶⁹ In women, by contrast, the prevalence of hypercholesterolemia was highest at a BMI of 25.0 to 27.0 kg/m², and it did not increase further at higher BMI values. The serum lipid abnormalities associated with obesity are important risk factors for CHD.^{170,171}

Cardiovascular Disease

Hypertension

There is a linear relationship between hypertension and BMI.^{172,173} In NHANES III, the age-adjusted prevalence rates of hypertension (defined as a systolic blood pressure ≥ 140 mm Hg, a diastolic blood pressure ≥ 90 mm Hg, or use of antihypertensive medication) in obese men and women were 42% and 38%, respectively. These rates are more than twice as high as those in lean men and women (approximately 15%).¹⁶⁹ The risk of hypertension also increases with weight gain. Among subjects in the Framingham Study, there was a 6.5-mm Hg increase in blood pressure with every 10% increase in body weight.¹⁷⁴

Coronary Heart Disease

The risk of CHD is increased in obese persons, particularly in those with increased abdominal fat distribution and in those who gained weight during young adulthood. Moreover, CHD risk starts to increase at the “normal” BMI levels of 23.0 kg/m² in men and 22.0 kg/m² in women.¹⁷⁵ In the Nurses’ Health Study, the risk of fatal and nonfatal myocardial infarctions was greater in women who had the lowest BMI but the highest waist-to-hip circumference ratio than it was in women with the highest BMI but the lowest waist-to-hip circumference ratio.¹⁷⁶ At any BMI level, the risk of CHD increases with the presence of increased abdominal fat. The risk of fatal and nonfatal myocardial infarction also increases when 5 kg or more is gained after 18 years of age.¹⁷⁷

Obesity-related CHD risk factors—particularly hypertension, dyslipidemia, impaired glucose tolerance, and diabetes—are largely responsible for the increase in CHD. However, even after adjusting for other known risk factors, several long-term epidemiologic studies still found that overweight and obesity increased the risk of CHD.¹⁷⁷ As a result, the American Heart Association recently classified obesity as a major preventable risk factor for CHD.^{178,179}

Cerebrovascular and Thromboembolic Disease

The risk of fatal and nonfatal ischemic stroke is approximately twice as great in obese as in lean persons and increases progressively with increasing BMI.^{180,181} The risks of venous stasis, deep vein thrombosis, and pulmonary embolism are also increased in obesity, particularly in persons with abdominal obesity.¹⁸² Lower-extremity venous disease can result from increased intra-abdominal pressure, impaired fibrinolysis, and the increase in inflammatory mediators.^{183,184}

Pulmonary Disease

Restrictive Lung Disease

Obesity increases the pressure placed on the chest wall and thoracic cage, which restricts pulmonary function by

decreasing respiratory compliance, increasing the work of breathing, restricting ventilation (measured as decreased total lung capacity, decreased forced vital capacity, and decreased maximal ventilatory ventilation), and limiting ventilation of lung bases.¹⁸⁵

Obesity-Hypoventilation Syndrome

In obesity-hypoventilation syndrome, the partial pressure of carbon dioxide (PCO₂) is less than 50 mm Hg because of decreased ventilatory responsiveness to hypercapnea or hypoxia (or both) and an inability of respiratory muscles to meet the increased ventilatory demand imposed by the mechanical effects of obesity. There is reduced alveolar ventilation because of shallow and inefficient ventilation related to decreased tidal volume, inadequate inspiratory strength, and elevation of the diaphragm. Symptoms increase when patients are lying down because of increased abdominal pressure on the diaphragm. The resulting increase in intrathoracic pressure further compromises lung function and respiratory capacity.

The pickwickian syndrome is a severe form of the obesity-hypoventilation syndrome. Named after an obese character in Charles Dickens’ *The Pickwick Papers*, this syndrome involves extreme obesity, irregular breathing, somnolence, cyanosis, secondary polycythemia, and right ventricular dysfunction.

Obstructive Sleep Apnea

In obstructive sleep apnea, excessive episodes of apnea and hypopnea during sleep are caused by partial or complete upper airway obstruction despite persistent respiratory efforts. Daytime sleepiness and cardiopulmonary dysfunction result from the interruption in nighttime sleep and arterial hypoxemia. In general, patients with sleep apnea are characterized by a BMI greater than 30.0 kg/m², excess abdominal fat, and a large neck girth (>17 inches in men, >16 inches in women).¹⁸⁶⁻¹⁸⁸

Musculoskeletal Disease

Gout

Hyperuricemia and gout are associated with obesity.^{189,190}

Osteoarthritis

The risk of osteoarthritis of weight-bearing joints is increased in overweight and obese persons. The knees are most often involved because much more body weight is exerted across the knees than across the hips during weight-bearing activity.¹⁹¹ There is a stronger relationship between body size and osteoarthritis in women than in men; in women, even small increases in body weight can promote osteoarthritis. In a study of twins, symptomatic or asymptomatic lower-extremity osteoarthritis was found in persons who were only 3 to 5 kg heavier than their twin sibling.¹⁹²

Cancer

Overweight and obesity increase the risk of cancer. Based on data from a prospective study in more than 900,000 U.S. adults,¹⁹³ it was estimated that overweight and obesity could account for 14% of all deaths from cancer in men and 20% of such deaths in women. In both men and women, BMI was also significantly associated with higher rates of death due to cancers of the esophagus, colon and rectum, liver, gallbladder, pancreas, and kidney, as well as non-Hodgkin’s lymphoma and multiple myeloma. Significant trends of increasing risk with higher BMI values were observed for death from cancers of the stomach and

prostate in men and for death from cancers of the breast, uterus, cervix, and ovary in women.¹⁹³ Most^{193,194} but not all¹⁹⁵ epidemiologic studies have found a direct relationship between BMI and colon cancer in both men and women. The risks of breast and endometrial cancer mortality increase with obesity and weight gain after age 18 years.¹⁹⁶ Specifically, the risk of breast cancer appears to increase with increasing BMI only in postmenopausal women; in premenopausal women, increased BMI may actually protect against breast cancer.¹⁹⁷

Obesity is often correlated with ingestion of a high-fat, high-calorie diet, which is another risk factor for cancer. Therefore, it is difficult to distinguish how much of the relation between obesity and cancer is attributable to obesity and how much to dietary factors.

Genitourinary Disease in Women

Obese women are often affected by irregular menses, amenorrhea, and infertility.¹⁹⁸ Pregnant obese women are at increased risks for gestational diabetes and hypertension¹⁹⁹ and delivery complications,²⁰⁰ and their babies are at increased risk for congenital malformations.²⁰¹ The risk of urinary incontinence is also increased in obese women.²⁰² In extremely obese patients, incontinence typically resolves after considerable weight loss, usually achieved by bariatric surgery.²⁰³

Neurologic Disease

Obesity increases the incidence of ischemic stroke. Obesity is also associated with idiopathic intracranial hypertension (IIH), also known as *pseudotumor cerebri*. This syndrome is manifested by headache, vision abnormalities, tinnitus, and sixth cranial nerve paresis. Although the prevalence of IIH increases with increasing BMI, the risk is increased even in persons who are only 10% above ideal body weight.^{204,205} The observation that weight loss in extremely obese patients with IIH decreases intracranial pressure and resolves most associated clinical signs and symptoms suggests there is a causal relationship between obesity and IIH.^{206,207}

Cataracts

Overweight and obesity are associated with an increased prevalence of cataracts.²⁰⁸ Moreover, persons with abdominal obesity are at greater risk than those with lower-body obesity, suggesting that insulin resistance may be involved in the pathogenesis of cataract formation.

Gastrointestinal Disease

Gastroesophageal Reflux Disease

The relationship between gastroesophageal reflux disease and obesity is unclear because of conflicting data from different studies. A higher incidence of reflux symptoms in obese compared with lean persons has been found in most^{209,210} but not all²¹¹ large epidemiologic studies. In addition, studies that evaluated gastroesophageal acid reflux by 24-hour pH monitoring have reported the presence of both a significant relationship²¹² and no relationship²¹³ between BMI and pathologic reflux (defined as the occurrence of esophageal pH <4 more than 5% of the time).

Gallstones

The risk of symptomatic gallstones increases linearly with BMI.^{38,214} The Nurses' Health Study found that the annual

incidence of symptomatic gallstones was 1% in women with a BMI greater than 30.0 kg/m² and 2% in women with a BMI greater than 45.0 kg/m².²¹⁴ The risk of gallstones increases during weight loss, particularly if the weight loss is rapid. This increased risk is related to increased bile cholesterol supersaturation, enhanced cholesterol crystal nucleation, and decreased gallbladder contractility.²¹⁵

If the rate of weight loss exceeds 1.5 kg (or about 1.5% of body weight) per week, the risk of gallstone formation increases exponentially.²¹⁶ Among obese patients who underwent rapid weight loss with a very-low-calorie (600 kcal/day) and low-fat (1 to 3 g/day) diet^{217,218} or with gastric surgery,²¹⁹ the incidence of new gallstones was approximately 25% and 35%, respectively. Gallstone formation is also promoted by the low-fat content of very-low-calorie diets (VLCD), because more than 4 to 10 g of fat in a meal is needed to stimulate maximal gallbladder contractility.²²⁰ Therefore, increasing the fat content of a VLCD can prevent the development of new gallstones.²²¹ Increasing dietary fat content might not be as important in preventing gallstones in patients consuming an LCD rather than a VLCD. Administration of ursodeoxycholic acid (600 mg/day) during weight loss markedly decreases gallstone formation.²²²

Pancreatitis

Obese patients would be expected to be at increased risk for gallstone pancreatitis because of their increased prevalence of gallstones. However, few studies have addressed this issue. Several studies showed that overweight and obese patients with pancreatitis had a higher risk of local complications, severe pancreatitis, and death than lean patients.²²³ It has been hypothesized that the increased deposition of fat in the peripancreatic and retroperitoneal spaces predisposes obese patients to develop peripancreatic fat necrosis and subsequent local and systemic complications.

Liver Disease

Obesity is associated with a spectrum of liver abnormalities known as nonalcoholic fatty liver disease (NAFLD), which is characterized by an increase in intrahepatic triglyceride content (i.e., steatosis) with or without inflammation and fibrosis (i.e., steatohepatitis). NAFLD has become an important public health problem because of its high prevalence, potential progression to severe liver disease, and association with serious cardiometabolic abnormalities, including T2DM, the dysmetabolic syndrome, and CHD.²²⁴ The prevalence rate of NAFLD increases with increasing BMI.²²⁵ The prevalence rates of steatosis and steatohepatitis are approximately 15% and 3%, respectively, in nonobese persons; 65% and 20% in persons with class I or II obesity (BMI 30.0 to 39.9 kg/m²); and 85% and 40% in extremely obese patients (BMI > 40 kg/m²).²²⁶⁻²²⁹ The relationship between BMI and NAFLD is influenced by racial or ethnic background and by genetic variation in specific genes.²³⁰⁻²³²

The presence of NAFLD is an important marker of metabolic dysfunction in obese persons, independent of BMI, percent body fat, or visceral fat mass.²³³⁻²³⁷ NAFLD is associated with insulin resistance in liver, skeletal muscle, and adipose tissue^{233,238,239}; with increased hepatic de novo lipogenesis^{240,241}; and with increased VLDL-triglyceride secretion rate.²³⁴ However, it is not clear whether the relationship between NAFLD and metabolic abnormalities is causal or simply an association.

In fact, steatosis is not always associated with insulin resistance. Overexpression of hepatic diacylglycerol acyltransferase (DGAT),²⁴² blockade of hepatic VLDL

secretion,²⁴³ and pharmacologic blockade of beta oxidation²⁴⁴ in mice causes hepatic steatosis but not hepatic or skeletal muscle insulin resistance. Steatosis in patients with familial hypobetalipoproteinemia, which is caused by genetic deficiency of apolipoprotein B synthesis and decreased VLDL secretion rate, is not accompanied by hepatic or peripheral insulin resistance.²⁴⁵ This dissociation between steatosis and insulin resistance suggests that other factors associated with steatosis (e.g., inflammation, circulating adipokines, endoplasmic reticulum stress) or other, unidentified metabolites affect insulin sensitivity.

Calorie restriction and subsequent weight loss is an effective therapy for obese patients with NAFLD. A marked decrease in intrahepatic triglyceride content and improvement in hepatic insulin sensitivity occurs very rapidly, within 48 hours after calorie restriction (approximately 1100 kcal/day) begins.²⁴⁶ A weight loss of 5% to 10% improves liver biochemistry and liver histology (steatosis and inflammation) findings, decreases the hepatic VLDL-triglyceride secretion rate, and increases muscle insulin sensitivity.²⁴⁶⁻²⁴⁹ There has been concern that the large and rapid weight loss induced by bariatric surgery can actually worsen NAFLD by increasing hepatic inflammation and fibrosis.²⁵⁰ However, data from most surgical series demonstrate that weight loss induced by bariatric surgery decreases the cellular factors involved in the pathogenesis of hepatic inflammation and fibrogenesis²⁵¹ and improves the histologic findings of steatosis, inflammation, and fibrosis.^{252,253}

BENEFITS OF INTENTIONAL WEIGHT LOSS

Effect on Morbidity

Intentional weight loss improves many of the medical complications associated with obesity. Many of these beneficial effects have a dose-dependent relationship with the amount of weight lost, and they begin after a modest weight loss of only 5% of initial body weight.⁵ In addition, weight loss can decrease the risk of developing new obesity-related diseases such as diabetes.^{254,255}

Type 2 Diabetes Mellitus

In obese patients with T2DM, weight loss improves insulin sensitivity and glycemic control. A 1-year study, conducted in obese patients with T2DM treated with oral hypoglycemic agents, showed that even a 5% weight loss decreased fasting blood glucose, insulin, and hemoglobin A_{1c} (HbA_{1c}) concentrations as well as the dosage of hypoglycemic medication.²⁵⁶ All patients who lost 15% or more of their body weight decreased or eliminated the need for hypoglycemic medication. In patients with severe obesity who underwent gastric bypass surgery, the average loss of approximately 30% of initial body weight promoted marked long-term improvements in glucose homeostasis.²⁵⁷ In that study, normal fasting blood glucose, insulin, and HbA_{1c} concentrations were achieved by 83% of the patients who had T2DM and by 99% of the those who had impaired glucose tolerance. However, a subset of obese patients with severe diabetes may not experience improved glycemic control with weight loss.²⁵⁸

In obese patients with mild T2DM, energy restriction and weight loss have important beneficial effects on insulin action and glycemic control. Calorie restriction rapidly improves hepatic insulin sensitivity within 48 hours.²⁵⁹ Subsequent weight and fat losses further improve glycemic

control and insulin-mediated glucose uptake by skeletal muscle.²⁵⁹⁻²⁶¹

Sustained weight loss can prevent the development of new cases of diabetes.^{262,263} For example, the Swedish Obese Subjects (SOS) Study found that a 16% weight loss induced by bariatric surgery in extremely obese patients (BMI 41 kg/m²) reduced the risk of diabetes fivefold over an 8-year period.²⁶³ Data reported from the Finnish Diabetes Prevention Study and the U.S. Diabetes Prevention Program demonstrated that changes in lifestyle resulting in a modest (5%) weight loss decreased the incidence of diabetes after 3 to 4 years by 58% in subjects with impaired glucose tolerance.²⁶⁴

Several studies have found that weight loss is more difficult in obese patients with T2DM than in those without diabetes.^{265,266} Moreover, successful weight loss may be inversely related to the duration and severity of diabetes.²⁶⁶ The reasons obese patients with diabetes are less responsive to weight-loss therapy are not known but may involve the energy-conserving effects of improved glycemic control (e.g., reduced glycosuria) and the tendency for weight gain associated with most drug treatments for diabetes.²⁶⁷

Dyslipidemia

Weight loss usually decreases serum triglyceride, total cholesterol, and LDL-C concentrations, and serum HDL-C concentrations increase.^{5,268} Improvements in serum triglyceride, total cholesterol, and LDL-C concentrations are generally greatest during the first 4 to 8 weeks of a weight-loss program.²⁶⁹ Serum HDL-C concentrations decrease during active weight loss but tend to increase once weight loss stabilizes.²⁶⁸ A greater reduction in LDL-C is observed when weight loss is induced by a program of diet plus exercise than with either treatment alone.²⁷⁰

Hypertension

Systolic and diastolic blood pressures decrease with weight loss, independent of sodium restriction.²⁷¹ In the Trials of Hypertension Prevention Phase II (TOHP II), one of the largest intervention studies to date, approximately 1200 overweight and obese patients were randomly assigned to a dietary weight loss intervention or usual care.²⁷² The study showed a dose-response relationship between weight loss and change in blood pressure at 36 months. During the first 6 months, patients who successfully lost weight experienced a marked reduction in blood pressure. However, among patients who regained most or all of their lost weight, blood pressure steadily increased to near-baseline values.

The marked weight loss induced by gastric surgery improves or completely resolves hypertension in about two thirds of extremely obese hypertensive patients.²⁷³ However, data recently compiled by the SOS Study indicated that the beneficial effect of weight loss on blood pressure might not persist.²⁷⁴ Much of the improvement in blood pressure observed at 1 and 2 years after gastric surgery disappeared by 3 years, and both systolic and diastolic pressures increased over the next 5 years. These findings imply that the current energy balance and the direction of weight change are important in blood pressure control.

A decreased incidence of hypertension with weight loss has been reported by several large, prospective, epidemiologic and intervention studies. For example, TOHP II found that persons who maintained a weight loss of at least 4.5 kg at 36 months had a 65% decrease in the risk of hypertension compared with control group participants who gained 1.8 kg.²⁷² The Nurses' Health Study observed a direct correlation between the risk of developing

hypertension and changes in body weight among normotensive women who were observed for 12 to 15 years. With weight losses of 5.0 to 9.9 kg, the risk of developing hypertension decreased by 15%; with a loss of 10 kg or more, it decreased by 26%.²⁷⁵

The SOS Study also questioned the ability of weight loss to prevent development of hypertension. In that study, the preventive effect of weight loss on the development of hypertension that was observed 2 years after gastric surgery²⁵⁴ had disappeared by 3 years.²⁷⁴ In contrast, the SOS Study found a marked effect of weight loss on the incidence of other obesity-related diseases. For example, long-term maintenance of major weight loss after gastric surgery was associated with a marked and persistent reduction in the risk of diabetes.

Cardiovascular Disease

Modest weight loss can simultaneously affect the entire cluster of cardiovascular risk factors associated with obesity. In the Framingham Offspring Study, a weight loss of 5 lb (2.25 kg) or more over 16 years was associated with reductions of 48% (in men) and 40% (in women) in the sum of these risk factors (defined as the highest quintile of systolic blood pressure, serum triglyceride, serum total cholesterol, fasting blood glucose, and BMI and the lowest quintile of HDL-C).²⁷⁶

Improvements in cardiovascular structure and function associated with weight loss include reductions in blood volume and hemodynamic demands on the heart, left ventricular mass and chamber size, and septal wall thickness.²⁷⁷ Such improvements in cardiac function may be responsible for the reduced frequency of chest pain and dyspnea reported by patients who lost weight after bariatric surgery.²⁷⁸ Weight loss may also delay the progression of atherosclerosis. In one study, the progression of carotid artery intimal wall thickening over 4 years was three times higher in untreated obese subjects who did not lose weight than in obese subjects who lost weight after gastric surgery.²⁵⁸

Pulmonary Disease

Weight loss improves pulmonary function, obstructive sleep apnea, and the obesity-hypoventilation syndrome. Even modest weight loss reduces the severity of sleep apnea, improves sleep patterns, and decreases daytime hypersomnolence.^{279,280} More marked weight loss, induced by bariatric surgery, has been shown to improve the obesity-hypoventilation syndrome by correcting resting room-air arterial blood gas values, lung volume, and cardiac filling pressure.²⁸¹ Sustained weight loss maintains these improvements in sleep apnea and obesity hypoventilation; however, pulmonary symptoms recur when weight is regained.

Reproductive and Urinary Tract Function in Women

Marked weight loss (>20% of initial body weight) has been shown to correct urinary overflow incontinence,²⁰² resolve amenorrhea, and improve fertility.

Effect on Mortality

Although several epidemiologic studies have indicated that weight loss or weight fluctuation increases mortality,²⁸² these studies did not distinguish between intentional and unintentional weight loss, so their results may have been confounded by unintentional weight loss caused by concomitant illness.

The effect of intentional weight loss on mortality was addressed in three studies that obtained baseline data between 1959 and 1960 and monitored the participants for an average of 12 years.²⁸³⁻²⁸⁵ The composite results of these studies suggested that intentional, and possibly transient, weight loss increases survival among overweight and obese persons who have T2DM. However, these data are not conclusive, because weight loss was self-reported and occurred at any time before the initial interview and changes in weight that occurred during follow-up were not determined.

More recently, data from two large trials demonstrated that weight loss induced by bariatric surgery improves long-term survival in morbidly obese patients.^{286,287} A total of 10,000 obese subjects who underwent bariatric surgery and a matched cohort of obese subjects who did not have surgery were monitored for up to 15 years. Subjects who had surgery lost between 14% and 25% of body weight, whereas the average weight change among control subjects was less than 2%. The overall mortality rate, particularly deaths from diabetes, heart disease, and cancer, was 20% to 40% lower in patients who had surgery than in those who did not have surgery.

OBESITY THERAPY

Many obese persons can achieve short-term weight loss by dieting alone, but successful long-term weight maintenance is much more difficult to achieve. "Weight cycling" and "yo-yo dieting" are popular terms used to describe repetitive cycles of weight loss and subsequent regain.²⁸⁸ Although some adverse consequences have been associated with weight cycling,²⁸⁹ available data on the health effects of weight cycling are inconclusive and should not deter obese persons from attempting to lose weight.²⁸⁸ Currently available weight-loss treatments include dietary intervention, increased physical activity, behavior modification, pharmacotherapy, and surgery.

Dietary Intervention

For most obese persons, negative energy balance is more readily achieved by decreasing food intake than by increasing physical activity. Therefore, dietary intervention is considered the cornerstone of weight-loss therapy. Weight-loss diets typically involve modifications of energy content and macronutrient composition. However, the degree of weight loss achieved depends primarily on the energy content rather than the relative macronutrient composition of the diet.

Energy Content

Weight-loss diets can be classified according to their energy content. A balanced-deficit diet of conventional foods usually contains less than 1500 kcal/day and an appropriate balance of macronutrients. LCDs contain 800 to 1500 kcal/day and are consumed as liquid formula, nutritional bars, conventional food, or a combination of these items. VLCDs contain less than 800 kcal/day and are usually high in protein (70 to 100 g/day) and low in fat (<15 g/day). Such diets may be consumed as a commercially prepared liquid formula and may include nutritional bars. VLCDs consumed as conventional foods (mostly lean meat, fish, or fowl) are known as *protein-sparing modified fasts*.

According to the treatment guidelines issued by the U.S. National Institutes of Health (NIH),⁵ persons who are

overweight (BMI 25.0 to 29.9 kg/m²) and have two or more cardiovascular disease risk factors and persons who have class I obesity (BMI 30.0 to 34.9 kg/m²) should decrease their energy intake by approximately 500 kcal/day. This deficit in energy intake will promote a weight loss of 1 lb (0.45 kg) per week and result in reduction of initial weight by about 10% at 6 months. The NIH guidelines recommend a more aggressive energy deficit of 500 to 1000 kcal/day for persons with more severe obesity (BMI \geq 35.0 kg/m²). This will produce a weight loss of 1 to 2 lb/wk and result in a 10% weight loss at 6 months.

Total daily energy requirements can be estimated by using standard equations, such as the Harris-Benedict equation²⁹⁰ or the WHO equation,²⁹¹ which are based on the patient's size, age, sex, and activity level. However, the use of standard equations is cumbersome and may be unreliable in obese persons. The simple diet guidelines outlined in Table 36-4 are suggested as an alternative to a specific energy-deficit diet based on the patient's daily energy requirements. Patients who follow these guidelines typically lose weight. Because many patients do not fully adhere to their prescribed diet, the energy content of the diet should be regularly adjusted according to the patient's weight loss response.

More than 30 prospective RCTs have investigated the effectiveness of LCDs for weight loss.⁵ The composite results of these trials indicate that a 1000 to 1500 kcal/day LCD induces a weight loss of about 8% after 16 to 26 weeks of treatment. However, these results may not be typical for LCDs prescribed in routine clinical practice, because the trial participants volunteered to enroll in a weight-loss study and most study protocols included some form of behavior modification therapy.

VLCDs induce a weight loss of about 15% to 20% in 12 to 16 weeks of treatment, but this loss is not usually maintained.^{292,293} In fact, several randomized trials have shown that weight regain is greater after VLCD than after LCD therapy.²⁹⁴⁻²⁹⁷ Therefore, 1 year after treatment, weight loss with a VLCD is often similar to that obtained with an LCD. In addition, initial weight loss is similar for VLCDs and LCDs when the diets are consumed in the same manner. For example, the weight loss observed in patients given a liquid diet providing 420 kcal/day was not significantly greater than that observed in persons who consumed a liquid diet providing 800 kcal/day.²⁹⁸ This suggests that patients treated with VLCDs are either less compliant with the diet or sustain a greater decline in energy expenditure than those treated with LCDs. With VLCDs, there is greater risk of medical complications associated with dieting, such as hypokalemia, dehydration, and gallstone formation. Therefore, patients treated with a VLCD require closer medical supervision than those treated with an LCD.

TABLE 36-4

Suggested Energy Composition of Initial Reduced-Calorie Diet

Body Weight (lb)	Suggested Energy Intake (kcal/day)
150-199	1000
200-249	1200
250-299	1500
300-349	1800
\geq 350	2000

Macronutrient Composition

Altering the macronutrient composition of the diet does not induce weight loss unless total energy intake is reduced. Low-fat diets have traditionally been prescribed for weight loss because such diets facilitate energy restriction. Triglycerides, the principal component of dietary fat, increase the palatability and energy density of food. The results of epidemiologic and diet intervention studies suggest that increased dietary fat intake is associated with increases in total energy intake and body weight.²⁹⁹ Conversely, data from a large number of studies suggest that decreased fat intake is associated with spontaneous decreases in total energy intake and body weight, even when carbohydrate and protein intakes are not restricted.

A direct relationship between change in dietary fat intake and body weight was found in a meta-analysis of 37 intervention studies involving the Step I or Step II low-fat diet (approximately 30% kcal as fat) recommended by the National Cholesterol Education Program to lower cardiovascular risk.³⁰⁰ Data from another meta-analysis suggest that the amount of weight loss induced by a low-fat diet is directly related to the severity of obesity.³⁰¹

The weight-loss effects of a low-fat diet may be related to the effect of dietary fat on energy density. Energy density is defined as the energy (i.e., calories) present in a given weight (grams) of food. Because the energy density of fat is so high, there is a high correlation between dietary fat content and diet energy density. According to short-term studies lasting up to 14 days, energy intake is regulated according to the weight of ingested food rather than its fat or energy content.³⁰² For example, the weight of food ingested was the same when lean and obese subjects were given either an ad libitum high-fat/high-energy-density (1.5 kcal/g) diet or a low-fat/low-energy-density (0.7 kcal/g) diet.³⁰³ As a result, energy intake on the high-fat/high-energy-density diet (3000 kcal/day) was almost double the intake on the low-fat/low-energy-density diet (1570 kcal/day). In other studies, the weight of food ingested remained the same when subjects were given liquid diets that had the same energy density but varied in fat content (20% to 60%)³⁰⁴ and when energy density was varied but fat content remained constant.³⁰⁵ The results of these short-term studies show that dietary fat content itself does not affect total energy intake, apart from its effects on dietary energy density and food palatability. Whether diets of low energy density can help induce and maintain weight loss remains to be confirmed by long-term studies in obese subjects.

Low-carbohydrate diets have been evaluated as a potential therapy for obesity in RCTs. Several short-term (approximately 12 weeks) trials (e.g., Yang and Van Itallie³⁰⁶) have compared the effects of low-carbohydrate and high-carbohydrate diets on weight loss when energy intake was kept constant. These studies suggest weight loss during the first 4 weeks may be greater with a low-carbohydrate diet despite equal energy intake but that weight loss between 6 and 12 weeks is the same with either diet. Five of six RCTs conducted in adults³⁰⁷⁻³¹² found that subjects consuming a low-carbohydrate diet (approximately 25% to 40% carbohydrate) achieved greater weight loss in the short term (6 months)³⁰⁷⁻³⁰⁹ but not in the long term (12 months),^{307,311,312} compared with those consuming a low-fat diet (approximately 25% to 30% fat and 55% to 60% carbohydrate). The data from these studies also found greater improvements in serum triglyceride and HDL-C, but not in serum LDL-C, in the low-carbohydrate versus the low-fat group. The decrease in body weight associated with a low-carbohydrate diet can be completely explained by a decrease in total

energy intake.³¹³ However, the mechanism responsible for decreased energy consumption when dietary carbohydrates are restricted but fats and proteins are unlimited is not known.

Data from a 2-year study found that a calorie-restricted Mediterranean diet—one that is rich in vegetables and low in red meat (with poultry and fish replacing beef and lamb), with up to 35% of calories from fat, primarily from olive oil and nuts—is just as effective as a low-fat, unrestricted-calorie diet and resulted in greater weight loss than conventional low-fat, restricted-calorie diet therapy.³¹⁴ Another randomized trial evaluated four diets that varied in the percentage of calories from fat, carbohydrate, and protein and found that all diets achieved the same weight loss, with maximum weight loss at 1 year and subsequent weight regain thereafter.³¹⁵ In summary, these data demonstrate that different dietary approaches can be used to achieve moderate weight in obese patients and that rigid prescription of a conventional low-fat diet is unwarranted.

Physical Activity

Metabolic Rate

Although there is a profound increase in energy expenditure during an actual episode of exercise, the addition of regular exercise to a weight-loss program has negligible effects on REE. In a meta-analysis of prospective RCTs that assigned obese subjects to treatment with diet alone or diet plus exercise, the addition of exercise did circumvent the expected decline in REE when REE was adjusted for body mass.³¹⁶

Body Composition

The composition of weight loss can be influenced by the addition of exercise to a diet program. Pooled data from two meta-analyses found that exercise can reduce the loss of FFM that occurs with weight loss.³¹⁷ When diet-induced weight loss was approximately 10 kg, regular exercise of low or moderate intensity reduced the percentage of weight lost as FFM from approximately 25% to 12%. Although the difference in weight lost as FFM was large on a percentage basis, it nonetheless represented only a small (approximately 1 kg) difference in the absolute amount of FFM lost. This preservation of FFM with exercise might not necessarily reflect preservation of muscle protein; instead, it may involve increased retention of body water and muscle glycogen. Indeed, nitrogen balance studies have not been able to detect any nitrogen-sparing effect of exercise during diet-induced weight loss in women.³¹⁸ Whether there is a difference between the effects of endurance and those of resistance exercise on FFM conservation is not clear because the available data are limited and conflicting.

Diabetes and Coronary Heart Disease

Endurance exercise increases insulin sensitivity³¹⁹ and is associated with decreased risks of developing diabetes^{320,321} and of dying from cardiovascular disease.³²²

Weight Loss

Increasing physical activity alone is not an effective strategy for promoting initial weight loss. Most studies have shown that moderate endurance exercise (e.g., brisk walking for 45 to 60 minutes, 4 times a week, for up to 1 year) usually induces only minor weight loss.³¹⁶ In obese

persons, the energy deficit created by exercise is usually much less and requires more effort than the energy deficit created by a reduced-calorie diet. For example, to lose 1 lb of fat, an obese patient would have to walk or run approximately 4.5 miles/day for 1 week or consume a 500-kcal/day energy-deficit diet for 1 week.

Although exercise alone is not an effective strategy for inducing initial weight loss, increasing physical activity may be an important component of successful long-term weight management. Several large-scale, cross-sectional case studies have shown that obese subjects who were successful in maintaining weight loss for 1 year or longer engaged in regular exercise.^{323,324} Retrospective analyses of data from prospective randomized studies found that subjects treated with diet-plus-exercise who continued to exercise sustained significantly larger long-term weight losses than subjects who stopped exercising or subjects treated with diet alone.³²⁵

The amount of exercise that is associated with weight-loss maintenance is considerable and requires expending approximately 2500 kcal/wk.^{326,327} This level of energy expenditure can be accomplished through vigorous activity (aerobics, cycling, or jogging) for approximately 30 min/day or more moderate activity (brisk walking) for 60 to 75 min/day. However, when the data are analyzed on an intention-to-treat basis, most prospective randomized trials do not find a statistically significant effect of exercises on the long-term maintenance of weight loss, presumably because adherence to the exercise program is often poor.³²⁸ Therefore, it is possible that the putative long-term beneficial effects of exercise on weight maintenance could reflect a selection bias: people who are able to maintain an aggressive physical activity program are those who are also able to maintain dietary compliance. In some people, exercise training results in compensatory mechanisms, such as increased energy intake or reduced activity during the rest of the day, that attenuate weight loss.³²⁹

Behavior Modification

Principles

Behavior-modification therapy attempts to enable obese patients to recognize and subsequently alter eating and activity habits that promote their obesity. Behavior modification is derived from the classic conditioning principle that behavior is often triggered by an antecedent event. The association between the antecedent event (e.g., watching television) and the behavior (e.g., eating) is strengthened by repetition: the more often the two are paired, the stronger the association between them becomes.

Behavior modification for the treatment of obesity usually involves multiple strategies to modify eating and activity habits. These strategies include stimulus control (avoiding the cues that prompt eating), self-monitoring (keeping daily records of food intake and physical activity), problem-solving skills (developing a systematic manner of analyzing a problem and identifying possible solutions), cognitive restructuring (thinking in a positive manner), social support (cooperation from family members and friends in altering lifestyle behavior), and relapse prevention (methods to promote recovery from bouts of overeating or weight regain).

Effectiveness

Treatment by a comprehensive group behavior therapy approach typically results in the loss of about 9% of initial

weight in 20 to 26 weeks.³²⁹ After treatment ends, weight regain is commonly observed. During the year after treatment, patients usually regain about 30% to 35% of their lost weight; however, most patients sustain clinically significant weight loss of more than 5% of initial body weight.³³⁰ Increasing the duration of behavior therapy programs has only marginally improved total weight loss, but it probably prevents the weight regain that usually occurs after treatment is stopped.³³¹

Pharmacotherapy

Conventional obesity therapy is associated with a high rate of recidivism. Therefore, the most important goal of pharmacotherapy is to maintain long-term weight loss. Pharmacotherapy should not be considered a short-term approach for weight loss, because patients who lose weight with drug therapy usually regain weight when the therapy is discontinued.^{332,333} Some obese patients do not respond to drug therapy, and long-term success is unlikely if weight loss does not occur within the first 4 weeks of drug treatment.³³⁴

Weight loss usually plateaus by 6 months of treatment and weight begins to increase after 1 year.^{332,333} This observation implies that the efficacy of weight loss medications declines with time or that obesity is a progressive disease, or both. Treatment outcome is less successful when pharmacotherapy is administered alone than when pharmacotherapy is administered as part of a comprehensive weight-loss program that includes diet, exercise, and behavior modification (Fig. 36-5).³²⁸ The use of obesity pharmacotherapy alone exposes patients to the full risks of the drug without the full medical benefits of more comprehensive treatment.

Table 36-5 lists the drugs currently approved by the U.S. Food and Drug Administration (FDA) for the treatment of obesity. All currently approved weight-loss drugs act as anorexiant with the exception of orlistat, which inhibits the absorption of dietary fat. Three anorexiants have been withdrawn from the market because of the increased incidence of valvular heart disease (fenfluramine and dexfenfluramine)³³⁵ or hemorrhagic stroke (phenylpropionamine)³³⁶ associated with their use.

All anorexiants except mazindol are derived from phenylethylamine, the amphetamine precursor. The structures of these drugs have been chemically altered to reduce the potential for abuse. Anorexiants affect the monoamine (norepinephrine, serotonin, and dopamine)

Figure 36-5 Weight loss in obese subjects treated with anorexiant medication (sibutramine) alone, group behavioral therapy alone, or medication plus group behavioral therapy. These data demonstrate that greater weight loss is achieved when antiobesity medications are used in conjunction with lifestyle modification than when they are used alone. (Adapted from Wadden TA, Berkowitz RI, Womble LG, et al. Randomized trial of lifestyle modification and pharmacotherapy for obesity. *N Engl J Med*. 2005;353:2111-2120.)

system in the hypothalamus and thereby enhance satiation (level of fullness during consumption of a meal, which influences the amount of food consumed), satiety (level of hunger after consumption of a meal, which influences the frequency of eating), or both.

Monoamine neurotransmitters are synthesized from tyrosine and stored in granules that release their contents from presynaptic nerve terminals into the interneuronal cleft between presynaptic and postsynaptic nerves. Only a small portion of the monoamines released into the interneuronal cleft actually bind to postsynaptic receptors and thereby transmit a signal from one nerve to the other. Most of the released monoamines are taken back up into the presynaptic nerve terminal, where they are either degraded or repackaged into granules for future release.

Weight-loss pharmacotherapy is approved for patients who have no contraindications to therapy and who have a BMI greater than 30.0 kg/m², or a BMI between 27.0 and 29.9 kg/m² and an obesity-related medical condition. Sibutramine and orlistat are the only drugs currently approved by the FDA for long-term use in the management of obesity.

Sibutramine

Sibutramine inhibits the neuronal reuptake of norepinephrine, serotonin, and, to a lesser degree, dopamine. It enhances satiation (level of fullness during consumption of a meal) rather than satiety (level of hunger after consumption of a meal). In humans, sibutramine also appears to promote a small increase in metabolic rate several hours after its administration.³³⁷ The currently recommended initial dose of sibutramine is 10 mg/day.³³⁸ This daily dose can be decreased or increased by 5 mg if tolerance is poor or weight loss is inadequate. Administration of sibutramine at doses between 1 and 30 mg/day for 24 weeks produced a dose-dependent weight loss, patients taking placebo lost 0.9% of initial body weight, compared with 7.7% for those taking 30 mg/day of sibutramine.³³⁹

Several RCTs have evaluated the effect of long-term (1-year) treatment with sibutramine on body weight in

TABLE 36-5

Drugs Approved by the U.S. Food and Drug Administration for the Treatment of Obesity

Year Approved	Generic Name	Trade Name
1959	Phendimetrazine tartrate	Bontril, Plergine, Prelu-2, X-Trozone
1959	Phentermine	Ionamine, Adipex-P, Fastin, Oby-trim
1959	Diethylpropion hydrochloride	Tenuate, Tenuate Dospan
1960	Benzphetamine HCl	Didrex
1973	Mazindol	Sanorex, Mazanor
1997	Sibutramine HCl	Meridia
1999	Orlistat	Xenical, Ally (over the counter)

obese persons.³⁴⁰⁻³⁴⁶ These studies were conducted in different patient populations, including obese patients with few obesity-related medical complications and patients with T2DM or hypertension. Data from two meta-analyses of long-term RCTs^{347,348} found that subjects treated with sibutramine lost approximately 4.5% (4.5 kg) more weight than those who received placebo. In addition, two to three times as many subjects randomized to sibutramine lost at least 5% or at least 10% of their initial weight, compared with those randomized to placebo. Intermittent therapy with sibutramine may be just as effective as continuous daily therapy in inducing weight loss; at the end of 48 weeks, weight loss in subjects who received intermittent therapy (daily sibutramine during three 12-week periods separated by two 6-week intervals of placebo therapy) was equal to that in subjects who received daily sibutramine therapy.³⁴²

Results have also been reported from two prospective RCTs that evaluated the efficacy of sibutramine therapy in long-term weight management after a predetermined amount of weight was lost.^{349,350} In the first trial, obese subjects who lost at least 6 kg after a 4-week VLCD resumed a regular diet with diet counseling and were randomly assigned to 1 year of treatment with placebo or sibutramine.³⁴⁹ In the year after randomization, sibutramine-treated subjects lost an additional 5.2 kg and placebo-treated subjects gained 0.5 kg. Total study weight losses were 12.9 kg in sibutramine-treated subjects and 6.9 kg in subjects treated with placebo. The initial weight loss achieved with the VLCD was maintained or increased in 74% of sibutramine-treated subjects compared with only 41% of placebo-treated subjects. In the second trial, obese subjects who lost more than 5% of initial weight after 6 months of treatment with sibutramine (10 mg/day) and a 600-kcal/day energy-deficit diet were randomized to treatment with either sibutramine (increased to 15 or 20 mg/day) or placebo.³⁵¹ All subjects received diet counseling. Almost half of the subjects who entered the study failed to complete the 18-month treatment program. Among those who completed the study, 43% of those treated with sibutramine but only 16% of those treated with placebo maintained 80% or more of their original 6-month weight loss. On average, subjects who continued sibutramine maintained their weight loss for 1 year and then experienced a slight and progressive increase in weight, but subjects who were switched to placebo experienced a progressive increase in weight as soon as sibutramine therapy was stopped.

The most common side effects of sibutramine therapy are dry mouth, headache, constipation, and insomnia. Sibutramine also causes small increases in blood pressure (2 to 4 mm Hg) and heart rate (4 to 6 beats/minute).³³⁹ However, some patients experience much larger increases in blood pressure or heart rate and require dose reduction or discontinuation of therapy.

Orlistat

Orlistat is synthesized from lipstatin, a product of *Streptomyces toxytricini* mold that inhibits most mammalian lipases.²⁵¹ Orlistat binds to lipases in the gastrointestinal tract and thereby blocks the digestion of dietary triglycerides. This inhibition of fat digestion reduces micelle formation and, consequently, the absorption of long-chain fatty acids, cholesterol, and certain fat-soluble vitamins. The degree of fat malabsorption is directly related in a curvilinear fashion to the dose of orlistat administered.³⁵² Excretion of about 30% of ingested triglycerides, which is near the maximum plateau value, occurs at a dose of 360 mg/day (120 mg three times daily with meals). Orlistat has no

effect on systemic lipases because less than 1% of the administered dose is absorbed.³⁵³

Several long-term (1 to 4 years) RCTs have evaluated the efficacy of orlistat therapy in initiating and maintaining weight loss. Data from two meta-analyses^{347,348} showed that subjects treated with orlistat lost about 3% (3 kg) more weight than those randomized to placebo. In addition, about twice as many subjects randomized to orlistat lost at least 5% or at least 10% of their initial body weight, compared with those randomized to placebo. In one study, weight loss was 5% greater (11% versus 6%) at 1 year and 3% greater (7% versus 4%) at 4 years for those treated with orlistat compared with placebo.³⁵⁴

The results of several RCTs suggest that orlistat administration is associated with a reduction of serum LDL-C that is independent of the effect of weight loss alone. Even after adjusting for percent weight loss, these studies found that subjects treated with orlistat sustained a greater reduction in serum LDL-C concentrations than those treated with placebo.^{355,356} The mechanism responsible for this effect may be related to orlistat-induced inhibition of dietary cholesterol absorption.³⁵⁷

The most common side effects associated with orlistat therapy are gastrointestinal complaints. Approximately 70% to 80% of subjects treated with orlistat experienced one or more gastrointestinal events, compared with 50% to 60% of those treated with placebo.^{355,356,358-360} These gastrointestinal events were induced by fat malabsorption, usually occurred within the first 4 weeks of treatment, and were of mild or moderate intensity. Subjects rarely reported more than two episodes despite continued orlistat treatment. Orlistat treatment can also affect fat-soluble vitamin status and the absorption of some lipophilic medications.^{355-357,361} Therefore, it is recommended that all patients treated with orlistat also receive a daily multivitamin supplement and that orlistat not be taken for at least 2 hours before or after the ingestion of vitamin supplements or lipophilic drugs.

Diabetes Medications That Cause Weight Loss

Diabetes therapy usually results in weight gain.³⁶² However, several medications used to treat diabetes, including metformin, GLP1 agonists, and amylin, cause weight loss.

The effect of metformin on body weight was recently reviewed.³⁶³ The data from most studies indicated that metformin does not cause weight gain and that treatment with metformin reduces the amount of weight that is gained with other diabetes medications. However, the effect of metformin on body weight in patients with diabetes is modest. For example, 10-year follow-up data from the U.K. Prospective Diabetes Study (UKPDS) found that subjects randomized to metformin therapy gained about 1.5 kg, compared with a gain of 2 kg in those treated with diet, 4 kg with glibenclamide, and 6 kg with insulin.³⁶² Subjects enrolled in the Diabetes Progression Outcomes Trial were randomized to monotherapy with either metformin, glyburide, or rosiglitazone for 4 years; those treated with metformin lost an average of 3 kg, whereas the glyburide and rosiglitazone groups gained an average of 1.5 kg and 5 kg, respectively.³⁶⁴ The weight loss effect of metformin has also been studied in nondiabetic obese subjects. A systematic review of RCTs of metformin (duration 15 days to 1 year) in subjects without diabetes or polycystic ovary syndrome found that weight loss was usually small (≤ 2 kg) and insufficient to consider metformin as an effective obesity therapy.³⁶⁵

Treatment of diabetes with short- or long-acting GLP1 agonists is usually accompanied by a decrease in body

weight. A meta-analysis of 21 RCTs evaluated the effect of treatment with short-acting (exenatide) and once-daily (liraglutide) GLP1 agonists on body weight in diabetic subjects who were treated for at least 12 weeks.³⁶⁶ The data show that GLP1 agonists caused a mean reduction in BMI of 0.4 kg/m² compared with placebo. These results are similar to those reported in another meta-analysis of 29 RCTs of at least 12 weeks' duration, which showed that treatment with exenatide in combination with other oral agents or treatment with liraglutide alone resulted in 1.4 kg weight loss compared with placebo and a 4.8 kg weight differential compared with insulin.³⁶⁷ In addition, compared with placebo therapy, liraglutide added to metformin and rosiglitazone therapy resulted in a weight loss of 1 kg (with 1.2 mg/day of liraglutide) or 2 kg (with 1.8 mg/day of liraglutide) at 6 months in obese diabetic subjects.³⁶⁸ Liraglutide also causes a dose-dependent weight loss in obese patients who do not have diabetes: liraglutide given as 1.2, 1.8, 2.4, or 3.0 mg/day caused a 2- to 4-kg greater weight loss than placebo therapy and a 1- to 2-kg greater weight loss than orlistat therapy.³⁶⁹

Pramlintide, a synthetic analogue of human amylin, causes greater weight loss than placebo treatment in obese subjects with and without diabetes. In one 16-week RCT, pramlintide therapy resulted in a 3.7% placebo-corrected reduction in body weight.³⁷⁰ In a second 4-month RCT, conducted in nondiabetic obese subjects, pramlintide resulted in a dose-dependent weight loss of 4.5 to 8 kg, compared with a 2.5-kg weight loss in the placebo group.³⁷¹

Surgical Therapy

Gastrointestinal surgery is the most effective approach for achieving major weight loss in extremely obese patients. In 1991, guidelines for the surgical treatment of obesity were established by an NIH Consensus Conference.³⁷² According to these guidelines, eligible candidates for surgery include patients with a BMI of 40 kg/m² or more and those with a BMI of 35.0 to 39.9 kg/m² with one or more severe medical complications of obesity (e.g., hypertension, heart failure, T2DM, sleep apnea). Additional

eligibility criteria are the inability to maintain weight loss with conventional therapy, acceptable operative risks, absence of active substance abuse, and ability to comply with the long-term treatment and follow-up required. All surgical procedures for obesity can be performed laparoscopically, but the laparoscopic approach is technically challenging and usually requires more operating room time.

Roux-en-Y Gastric Bypass Procedure

The Roux-en-Y gastric bypass (RYGB) procedure involves creating a small (10 to 30 mL) proximal gastric pouch that empties into a segment of jejunum that is anastomosed as a Roux-en-Y limb. The size of the patient determines the length of the Roux-en-Y limb (Fig. 36-6A). In patients with a BMI lower than 50 kg/m², a 45- to 60-cm limb is used, but in patients with a BMI of 50 kg/m² or more, a 150-cm limb (long-limb gastric bypass) is used, based on the belief that this promotes better weight loss.³⁷³ Specific complications associated with the RYGB procedure include marginal ulcers, stomal stenosis, dilation of the bypassed stomach, staple line disruption, internal hernias, malabsorption of specific nutrients, and the dumping syndrome.

Gastroplasty

Vertical banded and Silastic ring gastroplasties, also known as gastric stapling, involve creation of a small pouch from the gastroesophageal junction along the lesser curvature of the stomach; the pouch has a stoma that is restricted by a 1-cm polypropylene or Silastic ring and empties into the rest of the stomach.^{374,375} Specific complications associated with gastroplasty include staple line disruption, stomal stenosis, and gastroesophageal reflux.

Gastric Bypass versus Gastroplasty

Data obtained from four prospective, randomized trials found that weight loss several years after surgery was consistently greater with the RYGB procedure (loss of approximately 65% of excess weight) than with gastroplasty (approximately 40% of excess weight).³⁷⁶⁻³⁷⁹ In addition, independent evaluations of each procedure suggested

Figure 36-6 Schematic diagram of the Roux-en-Y gastric bypass procedure (A) and the laparoscopic adjustable gastric banding procedure (B). (Adapted from Steinbrook R. Surgery for severe obesity. *N Engl J Med*. 2004;350:1075-1079.)

better long-term results (10 to 14 years) with the gastric bypass than with gastroplasty.^{222,380} As a result of these findings, most centers no longer perform gastroplasty.

Laparoscopic Adjustable Gastric Banding

In the laparoscopically inserted adjustable gastric banding (LAGB) procedure, a silicone band is placed around the upper stomach, just below the gastroesophageal junction. The band's circumference can be adjusted by inflating or deflating a balloon connected to a subcutaneously implanted port that is accessed percutaneously (see Fig. 36-6B). The degree of weight loss achieved with LABD has been similar to that achieved with vertical banded gastroplasty³⁸¹ and over time may equal that achieved by RYGB surgery.³⁸²

Complications associated with LAGB include esophageal dilation, erosion of the band into the stomach, band slippage, band or port infections, and balloon or system leaks that lead to inadequate weight loss.^{383,384} Esophageal dilation and dysphagia can result from placement of the band at the gastroesophageal junction.³⁸³ Although loosening the band usually relieves the dilation, removal of the band is sometimes necessary.³⁸⁴ In some patients, the band erodes into the stomach and must be surgically removed. If the posterior stomach wall herniates through the band, the band slips. This can cause gastric obstruction and requires surgical revision.

Biliopancreatic Bypass Procedures

The biliopancreatic bypass and the biliopancreatic bypass with duodenal switch result in gastric restriction, maldigestion, and malabsorption. Both procedures involve a partial gastrectomy and bypass of a considerable amount of small intestine receiving biliary and pancreatic secretions.^{385,386} Partial biliopancreatic bypass induces malabsorption of protein, fat, fat-soluble vitamins, iron, calcium, and vitamin B₁₂; it therefore promotes more nutritional deficits than gastric restrictive procedures do.^{385,387} The incidence of protein deficiency is probably less common, and gastrointestinal side effects are not as severe, after partial biliopancreatic bypass with duodenal switch than after partial biliopancreatic bypass. Presumably these procedures cause greater weight loss (approximately 75% of excess weight) than a standard gastric bypass, but the techniques have never been compared directly in a prospective randomized trial.

Effect of Bariatric Surgery on Type 2 Diabetes

Weight loss induced by bariatric surgery is a successful therapy for T2DM and results in better glucose control than conventional treatment with lifestyle intervention and drug therapy. A 24-month RCT conducted in obese patients with recently diagnosed (<2 years) diabetes demonstrated that remission of diabetes (defined as plasma glucose <126 mg/dL and HbA_{1c} <6.2% without diabetes medications) was achieved in 73% of subjects randomized to LAGB (20% weight loss) but in only 13% of those randomized to lifestyle and medical therapy (1.4% weight loss).³⁸⁸ The beneficial effects of bariatric surgery were further validated by retrospective analyses of surgical series. The results obtained from a meta-analysis that included some 30,000 obese patients with diabetes found that diabetes resolved completely in 78% of patients after bariatric surgery.³⁸⁹

A series of observations from clinical studies led to the concept that bypassing the upper gastrointestinal tract has additional benefits on glucose homeostasis beyond weight loss alone. First, the rates of remission of diabetes are greater in patients who have had biliopancreatic diversion or RYGB surgery, compared with those who have had

restrictive banding procedures.³⁹⁰ Second, glycemia is normalized within days after RYGB surgery in patients with T2DM, before any significant weight loss is achieved.³⁹¹⁻³⁹³ Third, oral glucose tolerance improves more after a 10-kg weight loss induced by RYGB surgery than after calorie restriction alone.^{394,395} Finally, complete resolution of T2DM (defined as normalization of blood glucose and HbA_{1c} concentrations without the need for diabetes medications) has been achieved without weight loss in patients who have had duodenal-jejunal bypass surgery (bypassing the duodenum and 30 cm of the proximal jejunum).³⁹⁶

The mechanisms responsible for the weight loss-independent effects of intestinal bypass on glucose homeostasis are not clear but could be related to improved metabolic response to a meal, increased beta-cell function, or increased insulin sensitivity.³⁹⁷⁻⁴⁰⁰ Data from one study that compared the effect of a 10-kg weight loss induced by RYGB surgery or by diet therapy in obese patients with diabetes found that those who had RYGB surgery had greater improvement in oral glucose tolerance, which was associated with recovery of the early phase of insulin secretion and increased plasma GLP1 concentrations.^{394,395} However, no change in the insulin secretion after intravenously infused glucose was detected after RYGBP surgery, suggesting that the improvement in beta-cell function is limited to the gastrointestinal response to ingested glucose.³⁹⁴

The effect of intestinal bypass on disposition index, which is a measure of beta-cell function in relation to insulin sensitivity, is unclear because of conflicting data from different studies. Disposition index values after weight loss induced by RYGB surgery did not change compared with the values in unoperated morbidly obese control subjects,⁴⁰¹ whereas disposition index values markedly improved to normal after biliopancreatic diversion.⁴⁰² Therefore, it is possible that biliopancreatic diversion has additional therapeutic effects on beta-cell function compared with RYGB. Insulin sensitivity is often fully restored to normal range after bariatric surgery, even though most patients are still extremely obese.⁴⁰³ The improvement in muscle insulin sensitivity, assessed by the hyperinsulinemic-euglycemic clamp procedure, was the same after weight loss induced by RYGB surgery as after diet-induced weight loss. However, improvement in insulin sensitivity after biliopancreatic diversion was greater than that predicted by weight loss alone, suggesting that other factors might be involved in improving insulin action after this procedure (Fig. 36-7).⁴⁰³

Figure 36-7 Effects of bariatric surgery and diet-induced weight loss on insulin sensitivity. FFM, fat-free mass. (Adapted from Ferrannini E, Mingrone G. Impact of different bariatric surgical procedures on insulin action and beta-cell function in type 2 diabetes. *Diabetes Care*. 2009;32:514-520.)

TABLE 36-6

Suggested Weight-Loss Treatment Options Based on BMI and Risk Factors

BMI (kg/m ²)	Conventional Therapy*	Pharmacotherapy†	Surgery‡
25.0-26.9	With CHD risk factors or obesity-related disease	No	No
27.0-29.9	With CHD risk factors or obesity-related disease	With obesity-related disease	No
30.0-34.9	Yes	Yes	No
35.0-39.9	Yes	Yes	With obesity-related disease
≥40	Yes	Yes	Yes

BMI, body mass index; CHD, coronary heart disease.

*Conventional therapy comprises diet, physical activity, and behavior therapy.

†Pharmacotherapy should be considered only for patients who are unable to achieve adequate weight loss with available conventional therapy and who do not have any absolute contraindications for drug therapy.

‡Bariatric surgery should be considered only for patients who are unable to lose weight with available conventional therapy and who do not have any absolute contraindications for surgery.

Severe postprandial hypoglycemia with hyperinsulinemia has been described as a rare complication of RYGB surgery.^{404,405} Patients with this condition present with repeated episodes of profound symptomatic postprandial neuroglycopenia associated with endogenous hyperinsulinemia. This syndrome is not usually responsive to nutritional or medical therapy and can necessitate partial pancreatectomy to reduce the frequency of hypoglycemic episodes. The pathophysiologic mechanisms leading to endogenous hyperinsulinemic hypoglycemia after RYGB are not clear but could be related to an inappropriately enlarged beta-cell mass and beta-cell function caused by long-term exposure to augmented GLP1 response to a meal.⁴⁰⁶ However, data from a recent study found that the GLP1 response to a meal did not differ between subjects who had or did not have hypoglycemic episodes after RYGB surgery. Moreover, even though the GLP1 response to the meal increased, this did not result in excessive insulin secretion or hypoglycemic episodes.⁴⁰¹

In summary, weight loss induced by bariatric surgery causes marked improvement in glucose homeostasis and diabetes remission in most patients. Upper gastrointestinal bypass has additional therapeutic benefits beyond weight loss, possibly by improving the incretin response to a meal or by other yet unidentified effects. However, it is not known how much additional clinical benefit in glucose control is gained by anatomic bypass in the face of known large weight loss-dependent effects of bariatric surgery. Additional, carefully controlled studies are needed to answer this question.

Inadequate Weight Loss after Surgery

About 15% of patients fail to lose more than 40% of their excess weight (10% to 15% of total weight) after a gastric bypass.^{257,407} This percentage is even higher after a gastrectomy procedure.³⁸⁰ The major cause of inadequate weight loss after gastric bypass is the frequent ingestion of high-calorie soft foods and liquids (e.g., ice cream, cookies, milk shakes, sodas) and high-fat snacks and fried foods (e.g., potato chips, fried potatoes). In patients who have undergone either a stapled gastrectomy or gastric bypass, increased food intake may be related to staple line disruption, particularly if the patient is able to eat much larger quantities of food at a time.

Perioperative Mortality

The perioperative mortality rate after bariatric surgery is less than 0.5% when the procedure is performed by experienced surgeons in experienced centers.^{257,376} Approximately three fourths of the deaths that occur are caused by

anastomotic leaks and peritonitis, and one fourth are caused by pulmonary embolism.

TREATMENT GUIDELINES

A practical guide to the management of overweight and obesity was developed by the North American Association for the Study of Obesity in conjunction with the NIH.³³⁸ An overview of these guidelines is shown in Table 36-6, which outlines a stepwise approach for weight loss.

Weight management is a key component in the treatment of overweight or obese patients with T2DM. Even a modest weight loss of 5% of initial body weight improves glycemic control and reduces the need for hypoglycemic medication. Moreover, modest weight loss also improves other diabetes-related risk factors for CHD. However, successful weight management is more difficult to achieve in obese patients with T2DM than in those without diabetes.^{265,266} In fact, treatment of diabetes itself is usually associated with an increase in body weight.²⁶⁷ Therefore, therapeutic lifestyle intervention, weight loss medications, diabetes medications that are associated with the least amount of weight gain, and bariatric surgery should be considered as part of the potential therapeutic options for obese patients with diabetes.

Disorders of Lipid Metabolism

CLAY F. SEMENKOVICH • ANNE C. GOLDBERG • IRA J. GOLDBERG

LIPID BIOCHEMISTRY AND METABOLISM

Almost every endocrine disorder has important effects on serum or tissue lipids, making the mechanisms underlying primary and secondary disorders of lipid metabolism relevant to clinicians as well as basic scientists. Some primary disorders of lipid metabolism, such as familial hypercholesterolemia (FH), are uncommon but important to understand because they help explain genetic predispositions to heart disease¹ and the mechanism of action of statin drugs, which decrease the risk of vascular events and prolong life.² The quintessential secondary disorder of lipid metabolism is that seen in diabetes, a disease so frequently characterized by abnormalities of fat that lipids have been implicated in its pathogenesis.³

Lipids are ubiquitous. They constitute the physical bilayer that allows the formation of cell membranes, which are required for specialized organelles inside the cell and for regulating transport between the extracellular and intracellular environments. They circulate in the blood, with fatty acids and triglycerides providing an energy source to tissues such as heart and skeletal muscle and non-nutritive sterols providing substrates for hormone production by gonads and adrenals. Their specialized

functions include the development of surfactant in lung to maintain patency of alveoli, formation of bile to facilitate excretion of a variety of metabolites, and constitution of myelin throughout the nervous system to ensure the fidelity of nerve transmission. Lipids are also signaling molecules, serving as targets of lipid kinases that perpetuate signaling cascades, substrates for cyclooxygenases and related enzymes that generate prostaglandins, and ligands for nuclear receptors such as the peroxisome proliferator-activated receptors (PPARs). The broad spectrum of lipid functions results in part from their biophysical characteristics.

Simple and Complex Lipids

Lipids owe their functional versatility to their hydrophobic structure. Because of the presence of fairly long carbon chains, lipids tend to associate with each other and have limited or no solubility in water. Fatty acids and cholesterol are simple lipids, whereas triglycerides and phospholipids are complex lipids (Fig. 37-1).

Fatty Acids

Chemical structures for the fatty acids are determined by the number of carbon atoms and the number of double bonds (see Fig. 37-1A). For example, stearic acid has 18

Figure 37-1 Structures of common lipids, exemplified by the stearic, oleic, and linoleic fatty acids (**A**), the triglyceride tristearin (**B**), the phospholipid phosphatidylcholine (**C**), and cholesterol (**D**).

carbon atoms and is saturated, meaning that it has no double bonds; this is designated by the abbreviation C18:0. The 18-carbon monounsaturated fatty acid oleic acid (C18:1) has one double bond, and the polyunsaturated fatty acid linoleic acid (C18:2) has two double bonds.

Linoleic acid and arachidonic acid (C20:4) are ω -6 fatty acids, meaning that a double bond is present at the sixth carbon from the end of the molecule farthest from the carboxyl (-COOH) terminus. Fish oils, which lower lipids and are both cardioprotective and neuroprotective, are ω -3 fatty acids, with a double bond present at the third carbon from the end opposite the COOH. Saturated fatty acids and some unsaturated fatty acids such as oleic acid are nonessential, meaning that they can be synthesized in the body. Most ω -6 and ω -3 fatty acids are essential; they cannot be synthesized and are usually required for health, especially during development and in times of physiologic stress. Table 37-1 shows major food sources of fatty acids.

Triglycerides

The structure of tristearin, a triglyceride with three molecules of stearic acid connected to a glycerol molecule by means of ester linkages, is shown in Figure 37-1B. Other triglycerides have a similar structure with alternative fatty acids esterified to the glycerol backbone.

Most of the mass of adipose tissue in the body is composed of triglycerides; triglycerides that circulate in the blood mostly reflect the fatty acid composition of adipose tissue triglycerides, and both sources reflect dietary fatty acid composition. Butter as a source of triglycerides in Western diets consists of similar amounts of palmitate and oleate with a lesser amount of stearate, so adipose tissue and circulating triglycerides in persons consuming such a diet consist mostly of these fatty acids. Olive oil as a source of triglycerides in Mediterranean diets is predominantly

oleate with much less palmitate, so fat and circulating triglycerides in people consuming that diet are enriched in oleic acid. Extremely high levels of triglycerides in the blood predispose to pancreatitis.

Phospholipids

The chemical structure for a generic phosphatidylcholine, a type of phospholipid, is shown in Figure 37-1C. As with triglycerides, phospholipids have a glycerol backbone to

TABLE 37-1

Major Fatty Acids

Chemical Designation	Common Name	Common Food
Saturated Fatty Acids (No Double Bonds)		
C12 : 0	Lauric	Coconut oil
C14 : 0	Myristic	Coconut oil, butter fat
C16 : 0	Palmitic	Butter, cheese, meat
C18 : 0	Stearic	Beef, chocolate

which fatty acids are esterified at the first two alcohols. However, the third position is occupied by a phosphate moiety to which another charged molecule, such as choline, ethanolamine, or serine, is attached.

The presence of long-chain fatty acids comprising hydrophobic regions and the charged species at the end of the molecule make phospholipids perfect for generating cell membranes and lipoprotein surface components: The bilayer is oriented so that the hydrophobic regions point toward each other, and the hydrophilic regions interact with the aqueous environment. Phospholipids are distributed asymmetrically in cell membranes, with choline-containing lipids directed toward the outer surface and amine-containing lipids directed toward the cytoplasmic surface. Appearance of the aminophospholipid phosphatidylserine on the cell surface initiates blood clotting and marks apoptotic cells for phagocytosis.⁴

Cholesterol

The structure of cholesterol is shown in Figure 37-1D. The presence of cholesterol in the plasma membrane is critical for maintaining membrane fluidity, probably by disrupting the interactions between phosphatidylcholine and other molecules.⁵ The concentration of cholesterol is enriched in the plasma membrane, with much lower levels detected in the membranes of most intracellular organelles. Cholesterol is necessary for the synthesis of estrogen, progestins, androgens, aldosterone, vitamin D, glucocorticoids, and bile acids. Cholesterol deficiency is associated with severe developmental defects, as manifested in the rare Smith-Lemli-Optiz syndrome, which is likely caused by disruption of the Hedgehog signal transduction pathway.⁶ Cholesterol excess is associated with gallstones and vascular disease.

Fatty Acid Metabolism

Fatty Acid Biosynthesis

In humans eating a typical Western diet, the overall contribution of de novo lipogenesis to lipid metabolism is small⁷ because the ingestion of exogenous fat is sufficient to suppress the energy-requiring process of synthesizing fats from carbohydrates. However, high-carbohydrate diets, especially those containing fructose,⁸ substantially increase lipogenesis in liver and adipose tissue of humans.

Most tissues carry out fatty acid biosynthesis to at least a small degree regardless of nutritional status. Several of the key steps in fatty acid biosynthesis, presented in Figure 37-2, also have major effects on systemic metabolism. Citrate derived from the tricarboxylic acid (TCA) cycle is converted to acetyl-coenzyme A (acetyl-CoA) in the cytoplasm by the action of adenosine triphosphate (ATP) citrate lyase. Acetyl-CoA is then converted to malonyl-CoA by acetyl-CoA carboxylase (ACC), which exists in two isoforms. ACC1 (encoded by the gene *ACACA*) is cytosolic and important in liver and fat for de novo lipogenesis. ACC2 (*ACACB*) is associated with mitochondria and also plays a role in liver metabolism, but is expressed at highest levels in muscle and heart. Antisense targeting of ACC isoforms has been shown to improve lipid metabolism and insulin sensitivity.⁹

Malonyl-CoA inhibits carnitine palmitoyltransferase 1 (CPT1), which transports fatty acids into mitochondria, thereby preventing the catabolism of fats under physiologic conditions in which energy is being stored as fat through fatty acid biosynthesis. Malonyl-CoA also serves as substrate for fatty acid synthase, which sequentially connects two carbon fragments to generate saturated fatty acids such as palmitate. Inhibition of fatty acid synthase

Figure 37-2 Fatty acid metabolism. Fatty acids are substrates for acyl-CoA synthase (ACS), which generates CoA moieties that are transported into mitochondria by carnitine palmitoyltransferase I (CPT-1). Here, β -oxidation generates acetyl-CoA, which can also be generated from glycolysis (bottom left). Acetyl-CoA can be used to produce ketones, or it may enter the TCA cycle, leading to production of citrate; in the cytoplasm, citrate is a substrate for ATP citrate lyase, which produces acetyl-CoA. The acetyl-CoA serves as a substrate for de novo synthesis of fatty acids, as depicted on the right side of the figure. ATP, adenosine triphosphate; CoA, coenzyme A; ELOVL6, elongation of very-long-chain fatty acids protein 6; SCD-1, stearoyl-CoA desaturase 1; TCA tricarboxylic acid.

in the hypothalamus suppresses appetite, inducing weight loss and improving insulin sensitivity.¹⁰ Palmitate is converted to stearate through the action of a long-chain fatty acid elongase, which, when inactivated, promotes obesity but prevents insulin resistance.¹¹ Stearate is subsequently converted to oleate by stearoyl-CoA desaturase 1, which, when inactivated, increases fatty acid oxidation and protects against diet-induced obesity and insulin resistance.¹²

Fatty Acid Oxidation

Metabolism of fatty acids provides more energy than does metabolism of carbohydrates or proteins. This facile production of ATP occurs in mitochondria after fatty acids undergo the process of β -oxidation (see Fig. 37-2). Fatty acids are transported across (or diffuse across) the plasma membrane, are converted to acyl-CoA species by acyl-CoA synthase, and are then translocated to the mitochondrial matrix by CPT1 and CPT2. β -Oxidation removes two carbon fragments through the sequential actions of acyl-CoA dehydrogenases (e.g., MCAD and VLCAD), enoyl-CoA hydratase, hydroxy-CoA dehydrogenase, and thiolase. This process generates reduced nicotinamide adenine dinucleotide (NADH) and reduced flavin adenine dinucleotide (FADH), which participate in electron transport to yield ATP. After multiple cycles, acetyl-CoA is produced, which is a substrate for the TCA cycle and for ketogenesis.

Ketogenesis is necessary for life during times of nutritional deprivation. Extreme production of ketones occurs in the setting of insulin deficiency and represents a threat to life. 3-Hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) synthase (rate-limiting in mitochondria) converts acetyl-CoA to hydroxy-methylglutaryl-CoA, which is converted to acetoacetate by HMG-CoA lyase. Acetoacetate is either reduced to β -hydroxybutyrate or converted to acetone.

Defects in fatty acid oxidation are among the most common inborn errors of metabolism. Presentations include nonketotic hypoglycemia, liver dysfunction, and cardiomyopathy.¹³

Triglyceride and Phospholipid Metabolism

Dietary fat consists of mostly triglycerides with lesser amounts of phospholipids, which are digested in the stomach and proximal small intestine. Triglycerides are broken down into component fatty acids in part through the action of pancreatic lipase, which is activated by bile acids. Bile salts form micelles that acquire fatty acids and interact with the unstirred water layer of the intestine, where fatty acids are absorbed. Long-chain fatty acids are taken up by enterocytes, re-esterified into triglycerides, and exported into the lymph as lipoproteins. Medium-chain (\leq C10) fatty acids directly enter the portal vein to access the liver.

Lipolysis of Triglyceride Stores in Adipose Tissue

The greatest triglyceride mass resides in adipose tissue, and turnover of energy stores at this site has important effects on lipid metabolism, normal physiology, and human health. Increased lipolysis in adipose tissue of the obese results in elevated circulating levels of free fatty acids, which may contribute to so-called lipotoxicity in tissues such as pancreatic beta cells, liver, skeletal muscle, and heart.¹⁴ Otherwise healthy subjects whose parents have type 2 diabetes mellitus have impaired insulin-mediated suppression of circulating fatty acids,¹⁵ consistent with an early defect in adipose tissue fatty acid metabolism contributing to the evolution of diabetes.

Figure 37-3 Lipolysis in adipocytes. Stored triglycerides are metabolized to yield the fatty acids that circulate in plasma through the action of three distinct lipases with separate substrate specificities. Triglycerides are acted on by adipose triglyceride lipase (ATGL) in complex with the coactivator protein CGI-58 to yield diglycerides, which are acted on by hormone-sensitive lipase to yield monoglycerides. The monoglycerides, in turn, are acted on by monoglyceride lipase to yield glycerol. Lipid droplet proteins modulate this lipolytic process.

Release of free fatty acids and glycerol from adipose tissue is controlled by a variety of hormones, many of which act through G protein-coupled receptors. The most robust mediators of fatty acid release are catecholamines, which bind to β -adrenergic receptors, activating stimulatory G proteins (G_s) that prompt an increase in the activity of cyclic adenosine monophosphate and protein kinase A. Glucagon, adrenocorticotrophic hormone, α -melanocyte-stimulating hormone, and thyroid-stimulating hormone also induce lipolysis through activity of G_s proteins. Several agents suppress lipolysis by binding to receptors that activate inhibitory G proteins (G_i). These include adenosine and the clinically useful vitamin niacin, which binds to the nicotinic G-protein receptor GPR109A.¹⁶ A major mediator of lipolytic inhibition is insulin, which activates the insulin receptor signaling cascade and suppresses lipolysis at many steps, one of which includes a decrease in protein kinase A activity.

At least three enzymes and two accessory proteins are required for the normal process of hormone-induced lipolysis in adipose tissue.¹⁷ Stored triglycerides are acted on by the recently discovered enzyme, adipose triglyceride lipase (encoded by *PNPLA2*), which requires the coactivator protein CGI-58. Diglycerides are hydrolyzed by hormone-sensitive lipase, yielding monoglycerides that are metabolized by monoglyceride lipase. This process cannot occur unless perilipin, a protein that coats small lipid droplets, is phosphorylated by protein kinase A. This process is depicted schematically in Figure 37-3. Human mutations in adipose triglyceride lipase or CGI-58 are responsible for two variants of neutral lipid storage disease that are characterized by hepatic steatosis, lipid accumulation in muscle tissues, neurologic problems, and, in one variant, skin defects.

Triglyceride and Phospholipid Synthesis and Tissue Delivery of Lipids

Triglyceride Synthesis. As with fatty acid biosynthesis, some of the key steps in triglyceride synthesis also have major effects on systemic metabolism. Most triglycerides

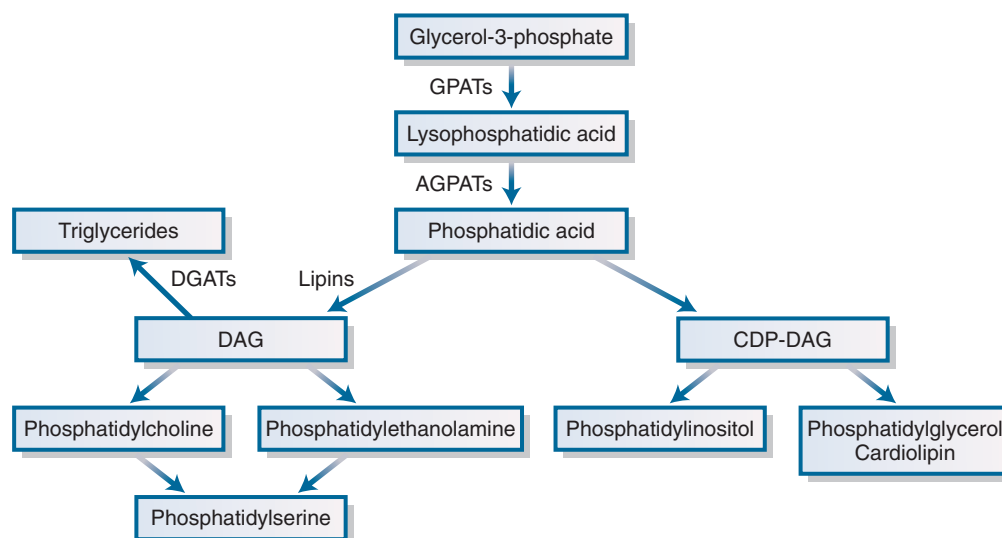

Figure 37-4 Phospholipid and triglyceride synthesis. Glycerol-3-phosphate is converted by glycerol-3-phosphate acyltransferases (GPATs) to lysophosphatidic acid, which is converted to phosphatidic acid by acylglycerol-phosphate acyltransferases (AGPATs). Phosphatidic acid can be converted to cytidine diphosphate diacylglycerol (CDP-DAG), to fuel one arm of phospholipid synthesis, or to diacylglycerol (DAG), which is a substrate for another arm of phospholipid synthesis and for acyl-CoA:diacylglycerol acyltransferases (DGATs), which generate triglycerides.

are synthesized through the glycerol phosphate pathway (Fig. 37-4, top portion) by a sequence of acylations. Another pathway, the monoacylglycerol pathway, is believed to be active only in the small intestine. Glycerol-3-phosphate is acted on by one of the glycerol-3-phosphate acyltransferases (GPATs) to generate lysophosphatidic acid. An important isoform is GPAT1, which is thought to compete with CPT1 for fatty acyl-CoA molecules inside the cell, with GPAT1 prevailing when energy is to be stored and CPT1 dominant when energy is required. The next acylation is mediated by acylglycerol-phosphate acyltransferases (AGPATs) and generates phosphatidic acid. Human mutations in AGPAT2 are responsible for the disease known as congenital generalized lipodystrophy.¹⁸

Phosphatidic acid represents an important branch point in lipid metabolism: It serves as substrate for synthesis of either cytidine diphosphate diacylglycerol (CDP-DAG), the precursor for molecules such as phosphatidylinositol) or diacylglycerol (DAG). Synthesis of DAG requires a phosphatase activity provided by lipins.¹⁹ These recently described proteins modulate insulin sensitivity in adipose tissue,²⁰ perhaps by affecting expression of glucose transporter 4. DAG can serve as a signaling molecule and as substrate for synthesis of either triglycerides or common phospholipids. The acylation of DAG to form triglycerides is catalyzed by acyl-CoA:diacylglycerol acyltransferases (DGATs). Inactivation of DGAT1 renders mice resistant to diet-induced obesity.²¹

Phospholipid Synthesis. As shown in the bottom portion of Figure 37-4, phospholipid synthesis is intimately related to triglyceride synthesis. Generation of one of the most important phospholipids, phosphatidylcholine, occurs mostly through the Kennedy pathway, which utilizes choline as an initial substrate and DAG at the final step.²² Mammalian liver is also able to generate phosphatidylcholine from phosphatidylethanolamine through successive methylations. Both phosphatidylcholine and phosphatidylethanolamine can be converted to phosphatidylserine.

Lipoprotein Lipase. Most lipids are delivered to peripheral tissues such as muscle and fat through the activity of lipoprotein lipase (LPL). LPL, which is rate-limiting for clearance of plasma triglycerides and essential for generation of high-density lipoprotein (HDL) particles,²³ hydrolyzes triglycerides (and, to a lesser extent, phospholipids) in circulating triglyceride-rich lipoproteins to allow peripheral sites such as adipose tissue and muscle access to preformed fatty acids. Much of this lipid flux is controlled by insulin, which increases LPL in fat and decreases LPL in muscle.²⁴ Exercise tends to have the opposite effect,²⁵ ensuring appropriate energy supplies are to meet metabolic demands.

Free fatty acids released from lipoproteins by the action of LPL presumably diffuse into resident cells in the local tissues, where they are converted to acyl-CoA species and either stored as triglycerides or subjected to fatty acid oxidation. This hydrolytic release reaction occurs at the capillary endothelium. LPL is not synthesized in endothelial cells but is produced in adipocytes, cardiac myocytes, and skeletal myocytes, then secreted and targeted to the luminal surface of the endothelium through mechanisms that are poorly understood. At the endothelium, LPL and triglyceride-rich lipoproteins bind to a recently discovered protein, glycosylphosphatidylinositol-anchored high-density lipoprotein-binding protein 1 (GPIHBP1).²⁶ GPIHBP1 is believed to serve as a platform for lipolysis in the plasma.

Cholesterol Metabolism

In adults, dietary cholesterol is not required because many tissues are capable of cholesterol synthesis. However, most diets include animal products, the source of cholesterol. Plants do not have cholesterol, but their membranes do contain phytosterols, which are structurally similar to cholesterol and are useful in the dietary treatment of hypercholesterolemia because they compete with cholesterol for absorption. The liver²⁷ and intestine are quantitatively the most important sites for cholesterol metabolism in humans,

although a very small amount of cholesterol is also lost through the normal turnover of skin.

Cholesterol Absorption, Synthesis, and Excretion

Cholesterol is absorbed through a process that requires the formation of bile salt micelles. The efficiency of absorption varies widely in humans.²⁸ There is a gradient of absorption through the intestine that is greatest in the proximal small intestine and least in the ileum. This gradient parallels the expression of Niemann-Pick C1-like 1 (NPC1L1), a transmembrane protein with a sterol-sensing domain that is involved in cholesterol absorption.²⁹ NPC1L1 is the target of ezetimibe, a drug with cholesterol-lowering properties but an uncertain role in atherosclerosis. NPC1L1 also absorbs phytosterols such as sitosterol. Sterols are pumped out of the enterocyte and into the intestinal lumen by two ATP-binding cassette (ABC) transporters, ABCG5 and ABCG8. Human mutations in these transporters cause the rare disorder sitosterolemia,³⁰ which is characterized by increased absorption and circulating levels of sitosterol and cholesterol, xanthomas, and heart disease (see later discussion).

Figure 37-5A illustrates cholesterol synthesis. Acetate is converted to 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA). The latter is a substrate for HMG-CoA reductase, the enzyme that is rate-limiting for cholesterol biosynthesis and is inhibited by statin drugs. Cells exquisitely regulate cholesterol acquisition.³¹ When levels are low, mechanisms are activated to increase cholesterol biosynthesis and import cholesterol from the extracellular environment. Statins, by lowering cholesterol and preventing cholesterol biosynthesis, work predominantly by increasing liver uptake of cholesterol from the plasma through the low-density lipoprotein (LDL) receptor (see later discussion) and promoting its excretion. Free cholesterol in cells

Figure 37-5 **A**, Cholesterol biosynthesis. 3-Hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase is the rate-limiting enzyme regulating cholesterol biosynthesis. The enzyme is downregulated by excess cholesterol in the cell. (Modified from Brown MS, Goldstein JL. A receptor-mediated pathway for cholesterol homeostasis. *Science*. 1986;232:34-47.) **B**, Enterohepatic circulation of cholesterol and bile acids. Approximately 50% of cholesterol and 97% of bile acids are reabsorbed from the intestine and recirculated to the liver.

Figure 37-6 Nuclear receptors in lipid metabolism. Peroxisome proliferator-activated receptors (PPARs) are active in adipose tissue, which is a source of fatty acids that are transported to liver, where PPARα, the liver X receptors (LXR), and farnesoid X receptor (FXR) are active. Bile acids produced by the liver participate in an enterohepatic circulation with the intestine, another site of LXR and FXR expression. Very-low-density lipoprotein (VLDL), produced by liver, and chylomicrons, from intestine, are metabolized to release fatty acids that fuel muscle (another site of PPAR expression) and may be stored by adipose tissue.

is esterified to form cholesteryl esters for storage. This esterification reaction is carried out by acyl-CoA:cholesterol acyltransferases (ACATs). These endoplasmic reticulum enzymes exist in two forms, ACAT1, which is present in macrophages and has been implicated in atherosclerosis, and ACAT2, which is present in liver and intestine and is implicated in cholesterol absorption. Nonspecific ACAT inhibition in humans does not affect serum lipids and does not have beneficial effects on atherosclerosis.³²

Cholesterol, which is non-nutritive and cannot be catabolized to carbon dioxide and water, is either secreted into the bile as free cholesterol (about half of which is reabsorbed) or converted to bile acids for secretion into bile. Most bile acids are reabsorbed in the terminal ileum. This enterohepatic circulation of cholesterol and bile acids is shown in Figure 37-6B. The rate-limiting enzyme for bile acid synthesis is cholesterol 7α-hydroxylase, which is under feedback regulation by bile acids. Interruption of the enterohepatic circulation of bile acids through the use of bile acid sequestrants (BAS) increases bile acid synthesis, lowers plasma cholesterol, and decreases vascular disease events.

NUCLEAR RECEPTORS AND LIPID METABOLISM

Nuclear receptors, usually transcription factors with ligand-binding and DNA-binding domains, affect lipid metabolism. Classic hormones that interact with nuclear receptors and have important lipid effects include thyroid hormone, glucocorticoids, estrogen, and testosterone.

Thyroid hormone regulates cholesterol metabolism through direct effects on the gene for a transcription factor that controls LDL-receptor expression, called sterol regulatory element-binding protein 2 (SREBP2).³³ This explains why lipid levels tend to be high in hypothyroid patients and low with hyperthyroidism. Glucocorticoids have robust effects on multiple aspects of lipid metabolism, inducing expression of HMG-CoA reductase to promote cholesterol synthesis, increasing expression of fatty acid synthase to promote fatty acid synthesis, and decreasing LPL to impair clearance of circulating lipids. Accordingly, hyperlipidemia is seen commonly in the setting of

glucocorticoid treatment, and this effect is amplified by insulin resistance induced by this treatment. Estrogens and selective estrogen receptor modulators such as raloxifene lower cholesterol³⁴ by inducing LDL-receptor activity; they tend to increase triglyceride levels, especially when higher oral doses are administered. Recent evidence suggests that derivatives of cholesterol can serve as selective estrogen-receptor modulators (SERMs) to affect the vasculature.³⁵ Androgens, by activating the androgen receptor, decrease levels of HDL.³⁶

Aside from the classic hormones and their receptors, other nuclear receptors affect lipid metabolism after interacting with several types of metabolic byproducts. These receptors include the PPARs, the liver X receptors (LXRs), and the farnesoid X receptor (FXR). A schematic view of the role of these receptors in lipid metabolism is presented in Figure 37-6.

There are three known types of PPARs: α , γ , and δ . PPAR α promotes fatty acid oxidation as well as ketogenesis and is induced by starvation. It is expressed at highest levels in tissues that are adapted to metabolize fats, such as liver and skeletal muscle, but is also present at numerous other sites. In humans, pharmacologic activation of PPAR α with fibrates lowers triglycerides and increases HDL. Fatty acids interact with the receptor, but a phosphatidylcholine species was recently identified as an endogenous ligand for PPAR α .³⁷

Whereas PPAR α facilitates energy utilization, PPAR γ activates genes that promote energy storage. It is expressed at highest levels in adipose tissue and is also found in macrophages, where it may help coordinate the complex relationship between inflammation and metabolism. Pharmacologic activation of PPAR γ in humans with thiazolidinediones results in insulin sensitization and weight gain. The latter effect occurs because this nuclear receptor promotes adipogenesis as well as fluid retention through effects on the kidney. Thiazolidinedione treatment in humans tends to lower triglycerides and increase HDL, probably by modulating insulin signaling, but the impact of these agents on atherosclerosis is controversial. Investigational dual agonists for PPAR α and PPAR γ effectively lower hemoglobin A_{1c} as well as serum lipids in humans and appear to be safe.³⁸

PPAR δ has important effects in tissues such as skeletal muscle, and its activation may mimic the effects of exercise.³⁹ Agents targeting this receptor in humans appear to show benefit, in part by increasing fatty acid oxidation.⁴⁰

LXRs and FXR are also involved in lipid metabolism. LXR α and LXR β are activated by oxysterols (modified derivatives of cholesterol) to increase the conversion of cholesterol into bile acids, increase bile acid excretion, and decrease cholesterol absorption.⁴¹ Consistent with a coordinated response to limit cholesterol acquisition, recent data show that LXR activation inhibits cholesterol uptake by inducing the degradation of the LDL receptor.⁴² LXRs also induce fatty acid and triglyceride synthesis. FXR is activated by bile acids to stimulate bile acid secretion as well as reabsorption. Administration of a BAS to humans with diabetes lowers blood sugar, which may be a consequence of complex effects on FXR and LXR signaling.⁴³

Additional nuclear receptors also play important roles in lipogenesis—the process of converting carbohydrates to triglycerides rather than glycogen. Carbohydrate response element-binding protein (ChREBP) may control as much as 50% of this process: It responds to carbohydrate excess by transactivating a series of glycolytic and lipogenic genes.⁴⁴ SREBP1 is also critical for this process. Recently, the transcription factor XBP1, which regulates the

endoplasmic reticulum stress response in some tissues, was reported to mediate hepatic lipogenesis through effects independent of ChREBP and SREBP.⁴⁵

PLASMA LIPOPROTEINS, APOLIPOPROTEINS, RECEPTORS, AND OTHER PROTEINS

Despite the complexities of lipid synthesis and catabolism in specific tissues and cell types, a variety of demands at sites remote from the source of external lipids (i.e., the gut) have resulted in selective pressure to develop a system capable of moving nutrients, vitamins, structural components, and proteins with specialized functions through the plasma compartment. The effectors of this system are lipoproteins, spherical particles that circulate in the blood. The appropriate concentrations of lipoproteins are essential for health. When certain lipoproteins are present at high levels in the circulation, cardiovascular disease and pancreatitis may result. When other lipoproteins are absent or present at very low levels, vitamin deficiency syndromes and cardiovascular disease may develop. The roles of the various lipoproteins are discussed in detail in the following sections.

Major Lipoproteins

A prototypical lipoprotein is shown in Figure 37-7. The fundamental structure of a lipoprotein exploits the biochemical characteristics of its components. These particles are moving through an aqueous environment, so the surface consists of charged molecules that can interact with water, such as phospholipids and free cholesterol. Amphipathic proteins (with hydrophilic and as well as hydrophobic domains), known as apolipoproteins (or simply apoproteins), are also present on the surface, with their hydrophilic domains oriented toward the plasma and their hydrophobic domains oriented toward the core of the particle. Apolipoproteins direct lipoproteins toward their appropriate sites of metabolism. The lipoprotein core consists of neutral (uncharged) lipids such as triglycerides and cholesteryl esters.

Figure 37-7 General structure of lipoproteins: schematic representation of a very-low-density lipoprotein (VLDL) particle.

TABLE 37-2

Major Classes of Plasma Lipoproteins

Type	Density (g/mL)	Origin	Major Lipids	Major Apolipoproteins	Size (nm)
Chylomicrons	<0.95	Intestine	85% Triglyceride	B48, AI, AIV, E, CI, CII, CIII	~100-500
Chylomicron remnants	<1.006	Derived from chylomicrons	60% Triglyceride 20% Cholesterol	B48, E	~80-125
VLDL	<1.006	Liver	55% Triglyceride 20% Cholesterol	B100, E, CI, CII, CIII	30-80
IDL	1.006-1.019	Derived from VLDL	35% Cholesterol 25% Triglyceride	B100, E	25-35
LDL	1.019-1.063	Derived from IDL	60% Cholesterol 5% Triglyceride	B100	18-25
HDL	1.063-1.21	Liver; intestine; plasma	25% Phospholipid 20% Cholesterol 5% Triglyceride	AI, AII, CI, CII, CIII, E	5-12
Lp(a)	1.05-1.09	Liver	60% Cholesterol 5% Triglyceride	B100, apo(a)	~30

IDL, intermediate-density lipoproteins; LDL, low-density lipoproteins; Lp(a), lipoprotein(a); VLDL, very-low-density lipoproteins.

Lipoprotein movement through the plasma compartment is dynamic. Humans spend most of their lives in the postprandial state. Eating a meal is associated with generation of lipoproteins, induction of enzymes that metabolize those lipoproteins, interactions among lipoproteins in the plasma involving the exchange of both lipid and protein components, rapid alterations of lipoprotein size as large particles are metabolized to smaller ones, genesis of new lipoproteins in the circulation as excess surface components of shrinking particles are extruded, and movement of critical nutrients and vitamins into tissues. Clinical assessment of disease risk is based on fasting measurements, but most of the migration of lipoproteins that causes disease occurs in the fed state.

The major classes of lipoproteins are listed in Table 37-2. Their original identification was accomplished based on migration in an ultracentrifuge, and classes were defined based on density. An alternative original classification scheme, which is no longer useful, involved electrophoretic mobility in agarose gels. Chylomicrons, chylomicron remnants, and very-low-density lipoproteins (VLDL) are rich in triglycerides. Intermediate-density lipoproteins (IDL), low density lipoproteins (LDL), and lipoprotein(a), or Lp(a), are rich in cholesterol. High density lipoproteins (HDL) are enriched in phospholipids. Triglyceride-rich lipoproteins such as chylomicrons are large and generally insoluble, which accounts for the cloudy appearance of plasma when it is obtained in nonfasting subjects or in fasting subjects with some types of hyperlipidemia. Table 37-2 provides general ranges for particle size, which differs substantially among lipoproteins and within each class. Certain lipoprotein subtypes, such as small dense LDL, may promote cardiovascular disease and are more likely to occur with insulin resistance.⁴⁶

Chylomicrons originate in the gut. They are lighter than water and float to the top of a plasma sample. The particles are cleared fairly rapidly after a meal and should be absent after an overnight fast. Their distinguishing apolipoprotein is apoB48, which is the only form of apolipoprotein B produced by intestinal cells in humans.⁴⁷ Chylomicrons acquire apoC and apoE molecules by interacting with HDL particles, a process that promotes chylomicron metabolism and conversion to chylomicron remnants. Chylomicron remnants, also characterized by the presence of apoB48, are cleared rapidly from the plasma⁴⁸ and are thought to be atherogenic.

VLDL particles are of hepatic origin. Smaller than chylomicrons, their distinguishing apolipoprotein is apoB100, the form of apoB produced by the liver. VLDL also carry apoC molecules that modulate the conversion of VLDL to IDL, which are VLDL remnants and are thought to be atherogenic. IDL particles contain apoB100 and apoE, and they are converted to LDL, which is characterized by carrying essentially only apoB100 as an apolipoprotein. LDL, popularly known as “bad cholesterol,” is the major carrier of cholesterol in most humans, and its measurement forms the basis for coronary heart disease (CHD) risk stratification and treatment goals. For most clinical laboratories, LDL results represent both IDL and LDL particles.

HDL particles have a complex biology. They can be generated by liver and intestine or assembled in the plasma as a consequence of the metabolism of other lipoproteins. They are arbitrarily divided into HDL₂ (less dense, at 1.063 to 1.125 g/mL), which typically contains apoAI as well as apoCs, and HDL₃ (more dense, at 1.125 to 1.21 g/mL), which typically contains apoAI, apoAII, and apoCs. There is also a minor subclass known as HDL₁ that carries a large percentage of plasma apoE. HDL is popularly known as “good cholesterol” and high levels are associated with low cardiovascular risk, but the role of HDL in vascular disease is complex. Lp(a) is produced by the liver. It consists of an LDL particle in which the apolipoprotein apo(a) has been covalently linked to apoB100. Apo(a) has substantial protein homology to plasminogen, which is required for the endogenous thrombolytic response, and it exists in isoforms based on kringle repeats (so named because their structure resembles a type of pastry). Isoforms with fewer repeats, and therefore lower mass, tend to circulate at higher concentrations. Higher levels increase the risk of myocardial infarction.⁴⁹

Major Apolipoproteins

The chromosomal location, size, sites of synthesis, and major functions of important apolipoproteins are summarized in Table 37-3.

Apolipoproteins AI, AII, AIV, and AV

ApoAI is the most abundant apolipoprotein in HDL. It is synthesized by the liver and intestine and is known to activate the enzyme lecithin:cholesterol acyltransferase (LCAT), which transfers a fatty acid from lecithin to the

TABLE 37-3

Major Apolipoproteins

Apolipoprotein (Chromosome No.)	Molecular Weight (kd)	Synthesis	Functions
Ai (11)	~29	Liver; intestine	Structural protein (HDL) Cofactor for LCAT Crucial role in reverse cholesterol transport Ligand for ABCA1 and SR-B1
AII (1)	~17 (dimer)	Liver	Inhibits apoE binding to receptors Activates hepatic lipase Inhibits LCAT
AIV (11)	~45	Intestine	Potential satiety factor Activator of LCAT Facilitates lipid secretion from intestine
AV (11)	39	Liver	Activator of LPL-mediated lipolysis Might inhibit hepatic VLDL synthesis
BI00 (2)	~500	Liver	Structural protein (VLDL and LDL) Ligand for LDL receptor
B48 (2)	~200	Intestine	Structural protein (chylomicrons)
CI (19)	6.6	Liver	Modulates remnant binding to receptors Activates LCAT
CII (19)	8.9	Liver	Cofactor for LPL
CIII (11)	8.8	Liver	Modulates remnant binding to receptors Inhibitor of LPL
E (19)	~34	Liver; brain, skin, testes, spleen	Ligand for LDL and remnant receptors Local lipid redistribution Reverse cholesterol transport (HDL with apoE)
apo(a) (6)	~400-800	Liver	Modulates thrombosis/fibrinolysis

ABCA1, adenosine triphosphate-binding cassette transporter A1; apo, apolipoprotein; HDL, high-density lipoproteins; LCAT, lecithin:cholesterol acyltransferase; LDL, low-density lipoproteins; LPL, lipoprotein lipase; SR-B1, scavenger receptor B1; VLDL, very-low-density lipoproteins.

free hydroxyl group on cholesterol to generate cholesteryl ester.⁵⁰ This activity is involved in the maturation of HDL particles, which begin as lipid-poor discs containing apoAI and then acquire free cholesterol; they convert this cholesterol to cholesteryl ester through the activity of LCAT and expand into spheres as cholesteryl ester is stuffed into the growing core. ApoAI is important for mediating the efflux of cholesterol from peripheral tissues, an important step in the process of reverse cholesterol transport.⁵¹ Human genetic mutations in apoAI cause low levels of HDL and corneal opacities. ApoAI is considered to be an antiatherogenic protein, but genetic defects in apoAI are not consistently associated with coronary artery disease. Current concepts suggest that its presence is important in the setting of an atherosclerotic environment such as the presence of atherogenic lipoproteins, a notion supported by mouse experiments.⁵²

ApoAII is present with apoAI in some HDL particles. Synthesized mostly in the liver, it has been implicated in the activation of hepatic lipase, an enzyme involved in lipoprotein processing including HDL metabolism, and in the inhibition of LCAT. ApoAII may disrupt the ability of HDL to promote reverse cholesterol transport, so it is considered to be a proatherogenic protein, but the genetic absence of this protein in humans does not seem to be associated with a phenotype.⁵³

ApoAIV originates in the gut, and its secretion is induced by the consumption of a high-fat meal. It has several putative functions, but perhaps the most interesting is its role as a potential satiety factor by suppressing food intake signals in the hypothalamus.⁵⁴

ApoAV is encoded by a locus near the apoAIV gene in the apoAI/CI/II/AIV/AV gene cluster on chromosome 11. It is produced by liver and circulates at low concentrations in association with VLDL particles in humans. ApoAV is involved in the hydrolysis of triglyceride-rich lipoproteins by LPL, and its expression in mice is inversely related to

triglyceride levels,⁵⁵ but studies of humans with apoAV variants suggest that several mechanisms may be involved in the hypertriglyceridemia seen in these individuals.⁵⁶

Apolipoprotein B

There are two forms of this apolipoprotein, apoB100 and apoB48, which are derived from a single gene by a unique mechanism that involves RNA editing (Fig. 37-8). In both liver and intestinal cells, the same messenger RNA is transcribed, but an editing protein complex⁵⁷ interacts with the message only in the intestine (in humans) to change the cytosine at nucleotide position 6666 to a uracil. This enzymatic effect converts a glutamine codon to a stop codon, resulting in an intestinal protein that is approximately 48% of the length of apoB100—hence, the name apoB48.

ApoB48, in essence a truncated form of apoB100, thus originates in the gut, where it is important for the assembly

Figure 37-8 Synthesis of apolipoprotein B100 and apo-B48 by a messenger (mRNA) editing mechanism. In the human intestine, a specific cytosine (C) is changed to a uracil (U) in the apo-B mRNA. This change results in a stop codon and the formation of apo-B48, which contains only the first 2152 amino acids of the full-length apo-B100 (4536 amino acids). COOH, carboxy terminus; Gln, glutamine; H₂N, amino-terminus.

of chylomicrons.⁵⁸ There are one or two B48 molecules on each chylomicron, where they provide structural support to the particle. The C-terminus of apoB100, missing in apoB48, determines interaction with the LDL receptor, so apoB48 does not appear to be involved in the clearance of gut-derived lipoproteins. However, there is a receptor for apoB48 on macrophages that has been implicated in atherosclerosis.⁵⁹

ApoB100 originates in the liver, where it is cotranslationally associated with lipids to coordinate the formation of VLDL particles. VLDL assembly and export, which affect the levels of circulating atherogenic lipoproteins, are determined not by transcriptional control of the apoB gene but by a unique mechanism involving stabilization of the apoB protein by lipid. VLDL production is shown in Figure 37-9. Assembly is thought to involve two distinct processes. First, as the apoB message is translated on the rough endoplasmic reticulum, it binds to lipids that are provided by microsomal triglyceride transfer protein (MTP). This protein heterodimerizes with protein disulfide isomerase, which remodels the apoB protein by rearranging the positions of disulfide bonds in the molecule to accommodate incoming lipid. Most of this lipid originates in adipose tissue, where triglyceride lipolysis releases free fatty acids that are transported to the liver. Phospholipids and cholesterol also

associate with apoB at this step. If sufficient lipids are not available in the liver, apoB (which is constitutively produced) is ubiquitinated and degraded in the proteasome.⁶⁰ Second, maturing VLDL particles fuse with additional lipid droplets in the Golgi apparatus, a process facilitated by apoE. The triglyceride-rich particles are then secreted into the space of Disse. Because these particles carry the apolipoproteins that determine VLDL binding to liver receptors, it might be expected that they would be taken up immediately and never access the circulation. This does not occur, probably because high concentrations of phosphatidylethanolamine in nascent VLDL obscure receptor binding sites. These sites are revealed in the circulation as phospholipids are removed. Transfer of apolipoproteins from other lipoproteins in the circulation also modifies VLDL structure to promote metabolism in the periphery.

Increased VLDL production, fueled by the increased availability of lipid, is predominantly responsible for the dyslipidemia seen with obesity and diabetes. Hepatitis C, a major cause of human liver disease, circulates in VLDL particles, and recent data indicate that this virus assimilates the VLDL assembly machinery.⁶¹ There is one copy of apoB100 on each VLDL particle, and this relationship is retained as these lipoproteins are metabolized to IDL and then to LDL. Therefore, measurements of apoB100 in the plasma reflect particle number, and higher levels of apoB are associated with cardiovascular disease. The complete absence of apoB, which occurs in the rare human disorder abetalipoproteinemia, is not caused by mutations in apoB but by defects in MTP.⁶² Patients with this disease have severe neurologic deficits, probably reflecting vitamin E deficiency, because triglyceride-rich lipoproteins transport this lipid-soluble vitamin. Very low, but not absent, apoB, which occurs in the human disorder hypobetalipoproteinemia, is caused by mutations in apoB. These individuals present with low levels of cholesterol and triglycerides and appear to be healthy. A mutation at amino acid residue 3500 of the apoB100 protein, within the C-terminal region of the molecule that mediates binding to the LDL receptor, causes familial defective apoB100. These individuals have high levels of LDL cholesterol, mimicking the presentation of FH.⁶³

Apolipoproteins CI, CII, and CIII

These apolipoproteins are quite small and are encoded by loci residing at two different locations in the genome. ApoCI and apoCII are transcribed from a site on chromosome 19 near the apoE gene. The apoCIII gene is a component of the apoAI/CIII/AIV/AV cluster on chromosome 11. ApoCs, which can be exchanged freely among lipoprotein particles, are important for triglyceride metabolism because their presence either interferes with the recognition of apoE by lipoprotein receptors or displaces apoE from lipoproteins (both of which would increase triglycerides by impairing their clearance). The function of apoCII is more complex than that of CI and CIII. High levels in mice cause elevated triglycerides by displacing apoE, but normal levels of apoCII are required for normal lipid clearance because this apolipoprotein is a cofactor for the enzyme LPL. Mutations of apoCII in humans cause severe hypertriglyceridemia mimicking LPL deficiency.

ApoCIII may be particularly relevant to human health. Its levels are increased in the setting of many dyslipidemias, and most lipid-lowering medications lower apoCIII levels.⁶⁴ A mutation in the apoCIII gene causing lower apoCIII levels is associated with an improved lipid profile and less atherosclerosis,⁶⁵ suggesting that therapies targeted at apoCIII might provide clinical benefit.

Figure 37-9 Very-low-density lipoprotein (VLDL) biosynthesis by hepatocytes. The nascent apolipoprotein B (apo-B)-containing apolipoproteins synthesized by the rough endoplasmic reticulum (RER) are thought to combine with lipids in the smooth endoplasmic reticulum (SER). The VLDLs are processed in the Golgi apparatus and accumulate in large secretory vesicles. They are then released into the space of Disse and enter the plasma. (Modified from Alexander CA, Hamilton RL, Havel RJ. Subcellular localization of B apoprotein of plasma lipoproteins in rat liver. *J Cell Biol.* 1976;69:241-263; by copyright permission of The Rockefeller University Press.)

Apolipoprotein E

ApoE biology is more complex than that of other apolipoproteins. The highest level of apoE expression is found in liver, with the second highest in brain. Many other cell types synthesize the protein, including macrophages. In brain, astrocytes and microglial cells make apoE, but it can also be produced by injured neurons. ApoE circulates in plasma as a part of every lipoprotein with the probable exception of LDL. Its principal function involves interactions with the two major receptors mediating the clearance of plasma lipoproteins, the LDL receptor and the LDL receptor-related protein (i.e., LRP1, also known as the chylomicron remnant receptor).⁶⁶ Therefore, it is apoE that is primarily responsible for the clearance of intestinal-derived lipoproteins after a meal and for the clearance of VLDL and IDL particles before they are converted to LDL.

There are three major apoE isoforms: E2, E3, and E4. They are encoded, respectively, by alleles referred to as $\epsilon 2$,

$\epsilon 3$, and $\epsilon 4$, which exist because of charge differences caused by variations in amino acids at residues 112 and 158 in the protein.⁶⁷ ApoE3 is considered to be the “normal” isoform; it has a cysteine at residue 112 and an arginine at 158. ApoE2 has cysteines at both 112 and 158, and apoE4 has an arginine at both 112 and 158. These variations have structural and functional consequences (Fig. 37-10). The protein has two domains, an amino-terminus that interacts with lipoprotein receptors, and a C-terminus that interacts with lipids (Fig. 37-10A). In apoE4, the isoform associated with disease, these domains interact; this does not occur with apoE3 (Fig. 37-10B).

Comprehensive data (>86,000 individuals for lipids, >37,000 for coronary events) have emerged regarding apoE allele and genotype frequencies, lipid levels, and coronary risk.⁶⁸ Allele frequencies in healthy adults are 7% for $\epsilon 2$, 82% for $\epsilon 3$, and 11% for $\epsilon 4$. Genotype frequencies are 0.7% for $\epsilon 2/\epsilon 2$, 11.6% for $\epsilon 2/\epsilon 3$, 2.2% for $\epsilon 2/\epsilon 4$, 62.3% for $\epsilon 3/\epsilon 3$ (the most abundant genotype), 21.3% for $\epsilon 3/\epsilon 4$, and 1.9%

Figure 37-10 **A**, The amino-terminal domain of apoprotein E is composed of a four-helix bundle. A region of random structure encompassing residues 165 to 200 forms a connector or hinge region linked to the carboxy-terminal domain. There are two major functional regions. Residues 136 to 150 (yellow helix) encompass the receptor-binding region; residues 240 to 260 in the carboxyl domain encompass the lipid-binding region. **B**, ApoE4 displays the unique property of domain interaction that distinguishes it from apoE3 (Arg61 in the amino-terminal domain interacts with Glu255 in the carboxyl-terminal domain). Arg, arginine; Cys, cysteine; Glu, glutamic acid.

for $\epsilon 4/\epsilon 4$. There is a linear relationship between the genotype and both LDL cholesterol level and coronary risk, from least to most as follows: $\epsilon 2/\epsilon 2 < \epsilon 2/\epsilon 3 < \epsilon 2/\epsilon 4 < \epsilon 3/\epsilon 3 < \epsilon 3/\epsilon 4 < \epsilon 4/\epsilon 4$. Compared to the reference group ($\epsilon 3/\epsilon 3$), the presence of the $\epsilon 2$ allele decreases coronary risk by about 20%, and the presence of the $\epsilon 4$ allele slightly increases risk. These observations are interesting for two reasons. First, $\epsilon 2/\epsilon 2$ individuals, although they are protected from CHD on a population basis, are at risk for dysbetalipoproteinemia. In the setting of appropriate additional conditions, about 5% of $\epsilon 2/\epsilon 2$ individuals will develop this disorder, which is associated with aggressive vascular disease. Second, the E2 protein binds less well to the LDL receptor than E3 and E4 do. This suggests that LDL cholesterol in patients with the E2 protein should be higher (because it is less likely to be cleared by this receptor), yet the opposite is observed. These data suggest that other receptor-mediated processes, such as those mediated by heparan sulfate proteoglycans (HSPG), may be critical for clearance of apoE-containing lipoproteins.⁶⁹

Data are also evolving about the critical role played by apoE in Alzheimer's disease. Risk of this neurodegenerative disease increases approximately threefold in those with one $\epsilon 4$ allele and 12-fold in those with two $\epsilon 4$ alleles.⁷⁰ The presence of an $\epsilon 2$ allele is protective. These relationships hold for both early- and late-onset Alzheimer's disease. There are HDL-like lipoproteins in the central nervous system, and apoE-mediated delivery of cholesterol at this site is important for normal synaptic function.⁷¹ The relation of lipid metabolism to Alzheimer's disease is incompletely understood, but some evidence suggests that deposition of amyloid- β (the major constituent of the plaques that characterize the disease) begins sooner in the brains of those with E4 protein. Because people with the $\epsilon 4$ allele are also more likely to have atherosclerosis, CNS vascular disease⁷² may help explain why this apoE variant is involved in neurodegeneration.

Major Receptors Involved in Lipid Metabolism

Low-Density Lipoprotein Receptor Gene Family

Including distant relatives, the LDL receptor family contains at least 10 members. The two most important ones for systemic lipid metabolism are the LDL receptor and LRP1. The LDL receptor recognizes apoB100 as well as apoE, whereas LRP1 recognizes apoE but not apoB100. Other core family members (those that share considerable structural homology) include the VLDL receptor (VLDLR), the apolipoprotein E receptor 2 (apoER2 or LRP8), LRP4, LRP1B, and megalin (LRP2, also known as gp330 and as the major Heymann nephritis antigen).

Three family members lack some of the structural features of the others. They are sortilin-related receptor L1 (LR11/SORL1), LRP5, and LRP6. Aside from the LDL receptor and LRP1, these receptors appear to be most important for brain development, synaptic function, and neuroprotection, making them relevant to Alzheimer's disease.⁷³ LRP5 and LRP6 are involved in endocrine disease. Both are coreceptors for a family of G protein-coupled receptors known as "frizzled receptors." Frizzled receptors bind the Wnt molecule to induce an important signaling cascade upstream of the transcription factor β -catenin. Genetic variants in LRP5 are associated with obesity,⁷⁴ and a human mutation in LRP6 results in the dysmetabolic syndrome and coronary artery disease.⁷⁵ Loss-of-function mutations in LRP5 or LRP6 cause osteoporosis in humans. These

observations suggest that insulin resistance, coronary disease, and osteoporosis, common comorbidities in patients, may be related to abnormal Wnt signaling.

Low-Density Lipoprotein Receptor. The LDL receptor is a glycoprotein that is fairly large (160 kd) and is expressed on most cells. Because it recognizes apoB100 as well as apoE, it is involved in the uptake of LDL, chylomicron remnants, VLDL, and IDL. Most HDL particles do not have apoE and therefore do not interact with this receptor or the LRP. The discovery of this receptor in the early 1970s by the Brown and Goldstein laboratory was important because its deficiency explained a human disease (FH), its physiologic regulation explained the mechanism of action of drugs that lower cholesterol, and its biology defined receptor-mediated endocytosis as a paradigm for providing cells with critical components from the external environment.⁷⁶

Five discrete domains that are shared with other members of this receptor family comprise the LDL receptor. Beginning at the N-terminus, these include the ligand-binding domain, the epidermal growth factor (EGF) precursor domain, the O-linked sugar domain, the membrane-spanning domain, and the cytoplasmic domain at the C-terminus (Fig. 37-11). In the ligand-binding domain, there are seven repeats of approximately 40 amino acids, each containing six cysteines that form three disulfide bonds within the repeat to stabilize the structure. Each repeat also includes negatively charged amino acids that interact with positive charged residues on apoB and apoE and with calcium ions that allow the repeat to bind to the ligand. The EGF precursor domain consists of three EGF-like repeats (see Fig. 37-11) with a structure known as a β -propeller located between repeats B and C.

Figure 37-11 Functional domains of the low-density lipoprotein receptor. Numbers 1 through 7 indicate repeats in the ligand-binding domain. A, B, and C are epidermal growth factor (EGF)-like repeats in the EGF precursor domain. See text for complete description.

Figure 37-12 Low-density lipoprotein (LDL) receptor pathway. LDL interacts with receptors on the cell surface. The complex enters the coated pit and is internalized. The coated vesicle loses its clathrin coat and becomes an endosome, the site of lipoprotein and receptor dissociation. The receptors recycle to the cell surface, and the lipoproteins are degraded. Alternatively, new receptors are synthesized in the rough endoplasmic reticulum and transported to the cell surface. (Modified from Brown MS, Goldstein JL. A receptor-mediated pathway for cholesterol homeostasis. *Science*. 1986;232:34-47; and Myant NB. *Cholesterol Metabolism, LDL, and the LDL Receptor*. San Diego: Academic Press, 1990.)

The O-linked sugar domain is the site at which carbohydrate moieties attach to the molecule, and this is followed by a short sequence that traverses the membrane. The cytoplasmic domain consists of 50 residues that include an NPXY (asparagine, proline, any amino acid, tyrosine) targeting sequence where adapter proteins dock, which leads to receptor clustering in coated pits.

Coated pits are specialized regions of the cell surface that are characterized by the presence of the protein complex, clathrin. When LDL receptors bind lipoproteins, they migrate to coated pits, and clathrin directs the receptors to a cell membrane region that folds inward, creating an intracellular vesicle or endosome (Fig. 37-12). Endosomes become acidic, which prompts the lipoprotein to be displaced from the LDL receptor by the β -propeller of the EGF precursor domain.⁷⁷ The unoccupied receptor recycles back to the cell surface, and lipoproteins are degraded in the lysosome. Apolipoproteins become component amino acids. Cholesterol is transported out of the lysosomes through the action of two proteins, Niemann-Pick C1 and C2 (NPC1 and NPC2), which are mutated in the human disease Niemann-Pick type C. Accumulation of cholesterol and other lipids characterizes this disorder. It is believed that NPC2, which is soluble, binds cholesterol after lipoprotein hydrolysis in the lysosome and moves this sterol to the membrane-associated NPC1⁷⁸ for subsequent release to the cell, where it serves structural and regulatory functions.

One of the key regulatory functions of cholesterol is control of LDL receptor expression. Intracellular sterol concentrations are thought to be sensed by SCAP (SREBP cleavage-activating protein), which binds to SREBPs in the endoplasmic reticulum. SREBPs are transcription factors that control LDL receptor expression as well as the expression of other genes important for lipid metabolism. SREBP2 is most important for LDL receptor transcription; as in the other SREBPs, its N-terminus contains a leucine zipper-type transcription factor structure that binds to a sterol regulatory element in the promoter of the LDL receptor gene. When cells are sterol-depleted (Fig. 37-13, left side),

SCAP migrates to the Golgi apparatus, where sugar moieties attached to the protein are modified. This allows SCAP to transport SREBPs to the S1P compartment. There, two proteases, site-1 protease (S1P) and site-2 protease (S2P), sequentially act on SREBPs to release their N-terminus, which migrates to the nucleus and binds to the sterol regulatory element in the promoter region of lipid genes such as the LDL receptor, increasing transcription and subsequent levels of functional proteins. In the presence of sterols (Fig. 37-13, right side), SCAP does not cycle to the Golgi, it cannot move SREBPs to the S1P compartment, and SREBPs are not cleaved to allow their transcription factor to migrate to the nucleus.

LDL Receptor-Related Protein 1. LRP1 is also known as the apoE receptor or the chylomicron remnant receptor. Much larger than the LDL receptor, LRP1 roughly consists of the equivalent of four LDL receptors with a multiplicity of ligand-binding domains. It is critical for normal development, because inactivation of LRP1 (but not of the LDL receptor) is lethal in mice. The major cell types in which LRP1 is expressed are hepatocytes, neurons (where it participates in critical functions), and syncytiotrophoblasts in the placenta. Perhaps understandably given its immense size, almost 20 different ligands bind to LRP1 and

Figure 37-13 Low-density lipoprotein (LDL) receptor gene regulation. S1P, site-1 protease; S2P, site-2 protease; SCAP, SREBP cleavage-activating protein; SRE, sterol regulatory element; SREBP, sterol regulatory element-binding protein.

participate in nutrient flow as well as signaling.⁷⁹ These ligands include amyloid precursor protein (relevant in Alzheimer's disease because it is processed to form the amyloid- β of plaques), bacterial byproducts, tissue plasminogen activator (which interacts with LRP1 to modulate physiology in the setting of brain ischemia), plasminogen activator inhibitors, and α_2 -macroglobulin (which plays multiple roles in inflammation, in part by inactivating matrix metalloproteinases). Given the promiscuity of LRP1 binding, it is not surprising it is linked with receptor-associated protein, a small protein that is involved in intracellular LRP1 processing and occupies the LRP1 binding sites during transport to the cell surface.

In terms of lipid metabolism, LRP1 binds apoE but not to apoB100. Therefore, it mediates the metabolism of the major apoE-containing lipoproteins, including chylomicron remnants and IDL (VLDL remnants), but is not involved in LDL metabolism. The interaction between LRP1 and lipoproteins is more complex than that between LDL and the LDL receptor. Multiple apoE molecules are required for LRP1 binding, and this interaction requires an initial binding of the lipoprotein to HSPG on the cell surface. Other moieties on apoE-containing lipoproteins also are believed to facilitate the binding process. LPL, which metabolizes chylomicrons and VLDL particles, adheres to particles after mediating the release of fatty acids and other substituents at the endothelium. Lipoprotein-bound LPL molecules (as well as hepatic lipase) are thought to interact with LRP1 and to facilitate the uptake of remnants by the liver.

Pattern Recognition Receptors

One of the most serious consequences of abnormal lipid metabolism is atherosclerosis, which requires the delivery of excess lipids to blood vessels. This process involves the innate immune system and at least two broad types of receptors—scavenger receptors and toll-like receptors (TLRs)—that preferentially recognize patterns instead of discrete species.

Scavenger Receptors. The discovery of scavenger receptors was prompted by the observation of Brown and Goldstein that macrophages can bind and internalize modified forms of LDL but not native LDL. There are now thought to be eight classes of these receptors (A through H)⁸⁰ that are generally characterized by the ability to bind altered (e.g., oxidized, acetylated) LDL or other polyanionic ligands. With the exception of class C receptors, which are found only in *Drosophila*, all may be involved in disease states such as atherosclerosis. Class A and class B receptors may be particularly important.

Class A receptors include scavenger receptor A (SR-A types 1 and 2, which consists of alternative splice variants), macrophage receptor with collagenous structure (MARCO), scavenger receptor A 5 (SCARA5), and scavenger receptor with C-type lectin domain (SRCL-I/II, also referred to as CL-P1). SR-A, the first to be discovered, binds a wide variety of ligands (including bacterial byproducts), activates stress signaling pathways including mitogen-activated protein kinases, and is believed to be involved in atherosclerosis, the clearance of apoptotic cells, and Alzheimer's disease.

Class B receptors include CD36 and SR-BI (called CLA-1 in humans). These receptors bind modified LDL, but, unlike the other classes of scavenger receptors, they also bind VLDL, native LDL, and HDL. CD36 is expressed on a wide variety of cell types, including monocytes, macrophages, adipocytes, platelets, endothelial cells, hepatocytes, microglial cells, and, curiously, the tongue, where it may

mediate the detection of dietary fat.⁸¹ In addition to lipoproteins, long-chain fatty acids are ligands for CD36.⁸² The tissue distribution of SR-BI is more limited, with expression on hepatocytes, monocyte/macrophages, and steroidogenic tissues. Given the panoply of ligands that bind to scavenger receptors and their effects on innate immunity, their roles in lipid metabolism and atherosclerosis may be complex.⁸³

Toll-Like Receptors. The TLR family comprises key effectors of the innate immune system that are required for host defense mechanisms against simple pathogens. Their activation has been implicated in many chronic inflammatory diseases, including atherosclerosis. Some scavenger receptors such as CD36 may be coreceptors for TLRs. TLRs are found on myeloid cells such as monocyte/macrophages but also on the gut epithelium; they bind ligands such as lipopolysaccharide (TLR4) and glycolipids found in bacteria (TLR2). TLR4 is also known to bind saturated fatty acids, an interaction that is believed to be involved in insulin resistance in mammals.⁸⁴ TLR4 perturbs cholesterol metabolism in macrophages.⁸⁵ TLR2 mediates monocyte activation by apoCIII on triglyceride-rich lipoproteins.⁸⁶

Other Enzymes and Transfer Proteins Mediating Lipid Metabolism

Hepatic Lipase

Primarily a phospholipase with some triglyceride lipase activity, hepatic lipase is made in hepatocytes and is found mostly on endothelial cells in the liver and on HSPG in the space of Disse. It is also found in steroidogenic tissues but is not thought to be synthesized at those sites. Unlike LPL, which is mostly present at tissues remote from the liver to ensure the peripheral delivery of lipids and vitamins, hepatic lipase coordinates lipoprotein metabolism centrally. Its functions include the conversion of IDL to LDL, the conversion of HDL₂ to HDL₃, and probably the final metabolism of chylomicron remnants to facilitate their uptake by LRP1. Unlike LPL, hepatic lipase does not require a cofactor such as apoCII, but both enzymes are displaced from their endothelial sites of activity by injection of heparin (postheparin lipase activity). High levels of hepatic lipase decrease HDL concentrations, whereas high levels of LPL increase HDL.

Endothelial Lipase

Evolutionarily related to hepatic lipase and LPL, endothelial lipase is a phospholipase with almost no triglyceride lipase activity. It is expressed at high levels in embryonic endothelial cells, with expression declining during maturation. Considerable levels are found in adult tissues that include the thyroid, lung, liver, placenta, and gonads (with expression in those tissues reflecting the endothelium and not parenchymal cells). In mice, overexpression decreases HDL and inactivation increases HDL. Endothelial lipase is expressed in aorta, where it may increase with atherosclerosis. Human loss-of-function mutations are associated with increased HDL cholesterol levels,⁸⁷ suggesting that inhibition of endothelial lipase could raise HDL levels.

Proprotein Convertase Subtilisin/Kexin Type 9

Proprotein convertase subtilisin/kexin type 9 (PCSK9) is a secreted protease that degrades the LDL receptor, but its catalytic activity is not required for receptor degradation. Mostly expressed in liver, intestine, and kidney, PCSK9 was

found to be important in lipid metabolism when missense mutations (subsequently determined to be gain-of-function mutations) in its gene were determined to be associated with hypercholesterolemia and coronary artery disease.⁸⁸ Overexpression of PCSK9 in mice decreases LDL-receptor protein. Human deficiency of PCSK9 is associated with low levels of LDL and possible protection from vascular disease.⁸⁹

Lipoprotein-Associated Phospholipase A₂

Phospholipases hydrolyze the ester bond at the sn2 position of phospholipids, usually resulting in the release of a fatty acid (typically unsaturated) and lysophosphatidylcholine (lysolecithin), which can induce inflammation. This type of enzyme was originally identified as a component of snake venom, and many distinct classes of phospholipases have subsequently been characterized. For most, membrane phospholipids are the substrate. Lipoprotein-associated phospholipase A₂ (Lp-PLA₂) is an exception because it can hydrolyze substrate in the aqueous phase. Lp-PLA₂ binds to LDL as well as HDL lipoproteins and is a biomarker for coronary artery disease.⁹⁰ Inhibition of this enzyme, which is also called platelet-activating factor acetylhydrolase, appears to decrease the expansion of the lipid core of atherosclerotic plaques in humans.⁹¹

Cholesteryl Ester Transfer Protein

Cholesteryl ester transfer protein (CETP) promotes the exchange between lipoproteins of two classes of neutral lipids: cholesteryl esters and triglycerides. HDL cholesteryl esters are transferred to VLDL, IDL, and chylomicron remnants; in return, triglycerides from VLDL, IDL, and remnants are transferred to HDL. Humans and other primates have CETP activity; the transfer of cholesteryl ester from HDL to apoB-containing lipoproteins ultimately leads to most of their cholesterol burden being carried by LDL, and this is thought to result in atherosclerosis. Rodents and dogs do not have CETP. Most of their cholesterol is carried in HDL; levels of LDL are low, and these animals are resistant to atherosclerosis. Such observations have led to the notion of inhibiting CETP activity as a treatment for atherosclerosis in humans. One CETP inhibitor was shown to increase HDL cholesterol and lower LDL cholesterol in

humans, but it also increased mortality, possibly because of off-target effects of the drug.⁹²

Lecithin:Cholesterol Acyltransferase

Lecithin:cholesterol acyltransferase (LCAT) is an enzyme synthesized mostly in the liver; it circulates in the plasma associated with HDL particles and, to a lesser extent, with LDL particles. LCAT is activated by several apolipoproteins (apoAI and others) and uses the phospholipid lecithin (phosphatidylcholine) and free cholesterol as substrates to generate lysolecithin (lysophosphatidylcholine) and cholesteryl ester. Most of the cholesteryl esters in lipoproteins are derived from LCAT activity. Rare human mutations in LCAT result in low HDL levels in the setting of a range of disorders, including fish-eye disease (in which activity is deficient on HDL particles but continues on LDL particles) and a more severe presentation with corneal clouding (resulting from free cholesterol in the cornea), hemolytic anemia, and renal failure. The role of LCAT in atherosclerosis is uncertain. Although LCAT deficiency might be expected to promote atherosclerosis because of low HDL levels, recent detailed studies of humans with loss-of-function LCAT mutations suggested that these individuals are not at increased risk for atherosclerosis.⁹³

INTEGRATIVE PHYSIOLOGY OF LIPID METABOLISM

Lipid metabolism is characterized by a dynamic flux of multiple lipid species from the external environment to the liver, from the liver to peripheral tissues, from peripheral tissues back to the liver, and eventually back to the external environment through the excretion of bile acids. Integrated views of the major pathways involved are shown in Figures 37-14 and 37-15.

Exogenous Lipid Transport

Dietary fat and cholesterol (Fig. 37-14, top left) absorbed by the duodenum and proximal jejunum are used to generate chylomicrons that are secreted at the lateral borders of

Figure 37-14 General scheme summarizing the major pathways involved in the metabolism of chylomicrons synthesized by the intestine and very-low-density lipoprotein (VLDL) synthesized by the liver. enterocytes and enter mesenteric lymphatics. They access the plasma via the thoracic duct and are rapidly metabolized by LPL to yield chylomicron remnants. These are taken up by remnant receptors (LRP1/HSPG) and by LDL receptors in the liver. Free fatty acids liberated by the action of LPL are available to adipose tissue for storage and to other tissues (e.g., skeletal muscle, heart) for use as energy substrates.

Endogenous Lipid Transport

Lipid derived from remnants and from lipolysis of adipose tissue is reassembled in the liver (Fig. 37-14, bottom left) as VLDL particles, which are secreted into the plasma. Abnormal lipid metabolism in insulin resistance is mediated in large part by overproduction of VLDL, an event that occurs through disruption of signaling downstream of the insulin receptor and the insulin receptor substrate (IRS) adapter proteins.⁹⁴ VLDL particles are metabolized by LPL to yield IDL particles, which are metabolized by LPL and hepatic lipase to yield LDL particles. Thus, LDL is derived from VLDL, which helps explain why treatment to lower triglycerides (carried by VLDL) is frequently associated with at least transient increases in LDL. IDL can be taken up by the liver through an apoE-dependent process, and LDL is taken up by the liver through the binding of apoB100 to LDL receptors. Small VLDL particles, IDL particles, and LDL particles may be taken up by peripheral tissues to deliver nutrients, cholesterol, and fat-soluble vitamins. When present in excess, each of these lipoproteins may be atherogenic.

Reverse Cholesterol Transport and Dysfunctional HDL

Cholesterol cannot be metabolized by peripheral tissues, so it must be returned to the liver for excretion in order to maintain homeostasis. This process, known as reverse cholesterol transport, is dependent on HDL and its precursors and is depicted in Figure 37-15. Excess cholesterol in tissues can be effluxed either to lipid-poor apoAI, mediated by the protein transporter ABCA1, or to nascent HDL particles, mediated by ABCG1. There is also evidence that cholesterol can be acquired by HDL without the assistance of transporters by following a concentration gradient at the cell surface. LCAT esterifies HDL-associated cholesterol to form cholesteryl ester and induce the maturation of HDL. HDL particles have three pathways for transporting sterols to the liver. First, they can directly bind to SR-BI (CLA-1) at the liver, which induces cholesteryl ester delivery through a mechanism involving lateral lipid transfer and not receptor internalization. Second, cholesteryl esters can be transferred to apoB-containing lipoproteins by CETP, and these particles can deliver cholesterol to the liver through the LDL receptor. Third, a small portion of HDL can acquire apoE and bind to the liver LDL receptor. Once in the liver, cholesterol is converted to bile acids for excretion.

HDL₂ particles are partially depleted of cholesteryl esters and enriched in triglycerides through the activity of CETP, which renders them suitable as substrates for hepatic lipase. Hepatic lipase hydrolyzes the triglyceride-enriched HDL₂ particles and regenerates HDL₃, yielding particles that are again suited to accept cholesterol from peripheral cells.

Because cholesterol is the principal component of atherosclerotic plaque, it is reasonable to pursue the notion that atherosclerosis could be treated by promoting the efflux of cholesterol from lesions. HDL participates in this process, but static levels of HDL cholesterol are poor predictors of reverse cholesterol transport. Measurements of the rate of flux of cholesterol from the periphery to the liver, which may be possible in humans, would represent a better predictor of beneficial therapies. The presence of high levels of HDL particles that have been modified to prevent their capacity to promote cholesterol efflux would not be expected to decrease vascular risk. Such dysfunctional particles may explain why some HDL-elevating interventions have not been associated with decreased cardiovascular disease.

In addition to participating in reverse cholesterol transport, HDL has other properties that could be impaired by a variety of processes leading to a dysfunctional particle. These include the induction of endothelial nitric oxide synthase through interactions with caveolae as well as signaling through SR-BI, the transport of a large number of proteins involved in the acute phase response and inflammation, and the suppression of thrombosis through induction of prostacyclin (which decreases thrombin production via the protein C pathway and decreases platelet activation).

OVERVIEW OF HYPERLIPIDEMIA AND DYSLIPIDEMIA

Two major clinical disorders are associated with common lipoprotein disorders. Very elevated triglyceride levels are a potent risk factor for development of pancreatitis. Elevated cholesterol due to greater concentrations of LDL and remnant lipoproteins and reduced levels of HDL promote

atherosclerosis. Clinicians are often faced with evaluation and treatment of patients who have hypertriglyceridemia, hypercholesterolemia, combined hyperlipidemia due to elevated cholesterol and triglycerides, and low HDL syndromes. A summary of the primary and secondary causes of each condition is presented in Table 37-4.

Plasma lipid levels are highly dependent on lifestyle; for example, the high-fat, high-cholesterol diets eaten in Western societies raise plasma cholesterol, and vigorous exercise lowers both atherogenic particles and triglycerides. For this reason, normal blood concentrations—those that are within 2 standard deviations of the mean—vary among countries and over time. In the United States, the age-adjusted mean plasma cholesterol concentration is 202 mg/dL (5.26 mmol/L) in men.⁹⁵ For Western adults, cholesterol concentrations higher than 240 mg/dL (6.2 mmol/L) or triglyceride concentrations higher than 150 mg/dL (1.7 mmol/L) constitute high-risk hyperlipidemia. The overriding influences of diet and lifestyle on plasma cholesterol were illustrated by studies of ethnic Japanese populations. Plasma cholesterol was markedly increased in Japanese-Americans and was associated with a more Westernized food intake.⁹⁶ Because serum total cholesterol levels correlate with the risk for CHD over a broad range (Fig. 37-16), “normal” levels are often defined as those associated with minimal cardiovascular risk rather than population averages. If this logic is assumed, then the majority of the Western population have abnormal lipoprotein levels that put them at risk for heart disease.

The National Cholesterol Education Program (NCEP) created a standard for cholesterol levels and pioneered a practical approach to treatment by dividing the population according to cardiac risk, based on the presence of vascular disease or other cardiac risk factors. In 2001, the NCEP classified plasma cholesterol levels lower than 200 mg/dL as desirable, those between 200 and 240 mg/dL as borderline high, and levels greater than 240 mg/dL as high.⁹⁷

(Because plasma lipid levels increase with age,⁹⁷ cutoff values in children are lower.⁹⁸) Total cholesterol concentrations between 170 and 200 mg/dL are considered borderline high, and levels greater than 200 mg/dL are high. Triglyceride levels greater than 500 mg/dL carry a high risk of pancreatitis, and those greater than 150 mg/dL are considered elevated.

Hyperlipidemias are caused by increased concentrations of plasma lipoproteins; although the clinical diagnosis is made solely on the basis of circulating lipids, the diseases are classified by abnormalities of lipoproteins (see

Figure 37-16 Relation between plasma cholesterol levels and coronary heart disease (CHD) mortality in the Multiple Risk Factor Intervention Trial. (Modified from Stamler J, Wentworth D, Neaton JD. Is relationship between serum cholesterol and risk of premature death from coronary heart disease continuous and graded? Findings in 356,222 primary screenees of the Multiple Risk Factor Intervention Trial [MRFIT]. *JAMA*. 1986;256:2823-2828; Copyright © 1986, by the American Medical Association.)

TABLE 37-5

Criteria for Diagnosis of the Dysmetabolic Syndrome

Measure*	Categorical Threshold
Waist circumference	Whites, African Americans, Latin Americans: Men, ≥ 40 in; women, ≥ 35 in Asians: Men, ≥ 35 in; women, ≥ 32 in
Elevated triglycerides	≥ 150 mg/dL or On drug treatment for elevated triglycerides
Reduced HDL-C	Men, < 40 mg/dL; women, < 50 mg/dL or On drug treatment for reduced HDL-C
Elevated blood pressure	≥ 130 mm Hg systolic or ≥ 85 mm Hg diastolic or On antihypertensive drug treatment
Elevated fasting glucose	≥ 100 mg/dL or On drug treatment for elevated glucose

*Three of the five measures are required for diagnosis.

HDL-C, high-density lipoprotein cholesterol.

Table 37-2) and are often referred to as hyperlipoproteinemias. As noted earlier, lipoproteins differ in their physiologic functions, metabolic pathways, and pathologic significance.

The NCEP also recognized the existence of the dysmetabolic syndrome, an extremely common condition that is linked to insulin resistance but is without a unifying mechanistic cause. The presence of at least three of the five features described in Table 37-5 is sufficient to make the diagnosis. This condition is clearly associated with increased risk of vascular disease and development of type 2 diabetes. Evaluation and therapy for the dysmetabolic syndrome should be directed at individual components including hypertriglyceridemia and low HDL-cholesterol (HDL-C).

HYPERTRIGLYCERIDEMIA

Fasting Hyperchylomicronemia

The most dramatic example of severe hypertriglyceridemia is that of fasting hyperchylomicronemia. This can result either from a primary defect in chylomicron metabolism, or it can occur secondary to increased VLDL and saturation of LPL actions to metabolize triglycerides into free fatty acids and generate remnant lipoproteins that are amenable to uptake by the liver through pathways mediated by the LDL receptor, LRP1, and proteoglycans. LPL saturation occurs when triglyceride levels exceed about 500 mg/dL.⁹⁹ Therefore, familial hypertriglyceridemia, familial combined hyperlipidemia, and dysbetalipoproteinemia can manifest with fasting hyperchylomicronemia. One common cause of such exacerbations is out-of-control diabetes leading to increased adipose intracellular lipolysis, return of fatty acids to the liver, greater secretion of VLDL triglyceride, and saturation of LPL. Several dietary and environmental factors also modulate triglyceride production. The most dramatic is alcohol, a major substrate for triglyceride production.¹⁰⁰ In addition, diets that are rich in free carbohydrates, and especially simple sugars, induce triglyceride production. Fructose also increases de novo

production of lipids in the liver but has less effect on circulating triglycerides.⁸

Defective clearance of plasma lipids is a major cause of fasting hyperchylomicronemia. Genetic defects in LPL prevent chylomicron clearance. LPL deficiency usually, but not always, manifests in childhood. The symptoms vary from difficulty feeding young infants to frank pancreatitis, which is sometimes mistaken as appendicitis. The plasma is often milky, and whole blood may have a pinkish, "cream of tomato" hue. The trigger level of triglyceride elevation leading to pancreatitis is variable; some patients have triglycerides in excess of 10,000 mg/dL with no symptoms, whereas others develop pancreatitis at much lower triglyceride levels, but usually in excess of 1000 to 2000 mg/dL.

The pathophysiology of the relationship between hyperchylomicronemia and pancreatitis is unknown. One theory is that the lipid-rich blood sludges, leading to pancreatic ischemia. Another is that the small amount of lipases that normally leak from the acinar cells lead to exuberant local lipolysis, creation of toxic local concentrations of free fatty acids and lysolecithin, a toxic lipid produced by lipase hydrolysis of phosphatidylcholine, and further acinar cell damage to adjacent cells.¹⁰¹ Additional insults to the acinar cells (such as that provided by alcohol) can fan this process.

Although most patients with severe hyperchylomicronemia who do not develop pancreatitis are asymptomatic, a few with extreme levels exceeding 10,000 mg/dL develop the hyperchylomicronemia syndrome.¹⁰² These patients have dyspnea and confusion that may be indistinguishable from early dementia. Presumably this is the result of reduced blood flow or defective oxygen delivery.

The marked increase in blood triglyceride concentration can lead to accumulation of triglycerides in several organs and can be observed in the blood. The latter is best appreciated by examining the blood directly, allowing the red cells to settle and observing a creamy layer on the plasma, or by noting the pinkish discoloration of the blood on funduscopic examination, known as lipemia retinalis (Fig. 37-17B). Eruptive xanthomas, as shown in Fig. 37-17G, are 2- to 5-mm papules with a yellow center surrounded by erythema. They are caused by triglyceride-enriched skin macrophages. These lesions are sometimes confused with acne or folliculitis. For unclear reasons, eruptive xanthomas are most commonly found on the buttocks, extensor surfaces of the arms, and the back. Enlargement of the liver and spleen is not uncommon and is thought to be caused by triglyceride engorgement of these organs.

Aside from the severe hypertriglyceridemia, other laboratory indices are sometimes abnormal. Plasma sodium is reduced; liver functions are sometimes elevated. Despite the presence of pancreatitis, amylase may be normal due to an assay artifact; serum lipase is a more reliable indicator in this setting. Often the clinical laboratory will note the severe lipemia and fail to report measurements of routine chemistries due to the turbidity of the serum. If these other measurements are required, plasma can be centrifuged, the chylomicron layer removed, and the remaining plasma examined.

Fasting hyperchylomicronemia in adults is frequently accompanied by comorbidities such as uncontrolled diabetes and excessive alcohol intake.

Lipoprotein Lipase Deficiency

Almost every racial group has been reported to have patients with genetic defects in LPL,¹⁰³ and a founder mutation makes the defect especially common among French

Figure 37-17 Physical examination findings associated with hyperlipidemia. **A**, Xanthelasma. **B**, Lipemia retinalis. **C**, Achilles tendon xanthomas. Canadians. Overall, it is estimated that approximately half of the cases of severe primary hypertriglyceridemia are the result of LPL defects. Most LPL enzyme deficiencies are caused by inactive LPL protein. However, lack of protein production has also been reported, and because LPL might have receptor functions that do not require catalytic function, patients with these defects may have a more severe phenotype.

Although genetic LPL deficiency has been reported to manifest in adulthood, most cases of severe hyperchylomicronemia in adulthood are associated with partial LPL deficiency or other causes. In adults, the most important of these causes are type 2 diabetes and obesity, because insulin resistance is associated with defective clearance of lipoproteins.¹⁰⁴ Postprandial lipemia is a prominent feature of diabetes.¹⁰⁵ A thorough history of triglyceride-raising medications should be taken (see later discussion).

Regulation of LPL is complicated, and defects in its actions are associated with genetic or acquired abnormalities that are exclusive of genetic defects in the LPL molecule. Defective apoCII, the obligate cofactor for LPL, leads to deficient LPL activity.¹⁰⁶ Two recent molecular defects initially found in mice are the cause of occasional severe human hypertriglyceridemia. GPIHBP (discussed earlier) is a molecule expressed by endothelial cells whose deficiency leads to defective association of LPL with its binding site on the capillary lumen and defective intravascular lipolysis.^{26,107} Lipase maturation factor 1 is an intracellular protein that is required for correct intracellular folding and activation of LPL.¹⁰⁸

LPL deficiency also occurs as a secondary phenomenon. Autoimmune conditions can be associated with defective triglyceride catabolism due to inhibition of LPL, apoCII, or heparin.¹⁰⁹ Antibodies against heparin are thought to prevent normal LPL association with the endothelial surface. In addition, patients with vascular disease or generalized intravascular reactions to transfusions or chemotherapy can occasionally develop defects in LPL. Transient episodes of fasting hyperchylomicronemia have been attributed to viral infections and to excessive fat/calorie intake after fasting.

Postprandial Hyperlipidemia

Although plasma lipid levels are usually measured after an overnight fast, chylomicron remnants are associated with vascular disease in a number of animal models and with genetic or dietary causes of hyperlipidemia. This has led to a widely accepted hypothesis that remnant lipoproteins are an overlooked cause of human vascular disease. Indeed, several studies have correlated postprandial lipidemia, measured as triglyceride increase, with greater risk of heart disease.^{110,111} However, postprandial triglyceride elevations are also correlated with fasting triglycerides and reduced HDL levels, so the use of postprandial measurements in clinical practice is not currently recommended.

Diagnostic Evaluation of Severe Hypertriglyceridemia

Assessment of underlying medical conditions, consideration of age at onset, and, in some cases, biochemical evaluation of LPL are required. Conditions that cause fasting hypertriglyceridemia (discussed later) can lead to severe hypertriglyceridemia when exacerbated by diet, drugs, or other conditions such as diabetes or pregnancy. Genetic LPL deficiency is diagnosed by both the clinical setting and biochemical deficiency of LPL activity in

postheparin blood; LPL deficiency is more typically associated with younger age at onset, especially onset in childhood. A family history of low HDL is the most common lipid abnormality in heterozygous carriers.¹¹² LPL variants are also a determinant of HDL levels within the general population. A family history of French Canadian ancestry is suggestive. Although a presumptive diagnosis can be made on clinical grounds, it is sometimes useful for genetic reasons and treatment approach to confirm the diagnosis of LPL deficiency.

More than 100 mutations of the LPL gene have been described,¹¹³ and for this reason biochemical rather than genetic evaluation is still performed. Fasting patients are given an intravenous injection of 60 units/kg of heparin, which releases LPL into the bloodstream.¹¹⁴ Ten minutes later, a sample of postheparin blood is obtained and stored on ice, after which the plasma is frozen and sent to a lipid specialty laboratory for analysis. Heparin species are calibrated by their anticoagulant activity and their ability to release LPL into the plasma varies, so a normal control postheparin plasma obtained with use of the same heparin is needed. Hepatic lipase (see later discussion) is also routinely measured in these samples. Postheparin samples should not clot. If they do, it may be an indicator of a defective injection or antibodies to heparin (e.g., in the case of a patient with an autoimmune disease). Postheparin plasma is not usually obtained during an acute episode of pancreatitis. Patients with a history of bleeding disorders or recent use of anticoagulant or anti-platelet drugs should be studied with caution, if at all. Deficiency of apoCII, the LPL activator, and inhibitors of LPL such as antibodies¹¹⁵ can be detected by mixing the patient's serum with a standard human or bovine source of LPL and then assessing activity.

Moderate Fasting Hypertriglyceridemia Due to Elevated Very-Low-Density Lipoprotein

Less dramatic elevations of triglyceride are not a cause of acute symptoms. They are of concern if serum triglycerides begin to exceed 500 mg/dL. Otherwise, the major issue is the relationship of triglycerides to cardiovascular disease. Triglyceride levels of 150 to 500 mg/dL are considered to be abnormal, but their pathologic importance is uncertain. The NCEP categorizes triglyceride levels of 200 to 499 mg/dL as high and those of 150 to 199 mg/dL as borderline high.⁹⁷ Several different clinical conditions lead to fasting hypertriglyceridemia. Familial combined hyperlipidemia is associated with increased apoB production, and at different times and in different family members it can manifest with hypertriglyceridemia (increased VLDL), increased cholesterol (LDL), or both. This disorder is associated with increased risk of vascular disease.¹¹⁶ The concomitant insulin resistance, obesity, and/or overt diabetes in many hypertriglyceridemic patients often make it difficult to isolate one specific cause of this metabolic disturbance. In contrast, it has been suggested that isolated triglyceride elevations do not lead to more vascular disease. In the presence of the dysmetabolic syndrome, triglyceride elevations probably predispose to vascular disease through unclear mechanisms.

Some cases of isolated hypertriglyceridemia have been associated with hepatic overproduction of bile acids in the setting of impaired intestinal absorption of bile acids.¹¹⁷ This is analogous to the hypertriglyceridemia associated with use of bile acid-binding resins and reduced bile interaction with the liver FXR receptor.¹¹⁸ There is uncertainty as to whether the large, triglyceride-rich VLDLs seen in this and similar clinical circumstances are atherogenic.

Dysbetalipoproteinemia is caused by a homozygous mutation in apoE, apoE2/E2, leading to defective clearance of chylomicron and small VLDL remnants (see earlier discussion). These patients, with a prevalence of approximately 1 of every 10,000 in the general population, present with elevated triglyceride and cholesterol due to defective lipid clearance of remnant lipoproteins. Patients with dysbetalipoproteinemia sometimes have tuberous and palmar xanthomas and a propensity to peripheral vascular disease (see later discussion).

Heterozygous LPL deficiency can be relatively common in some populations. As these individuals age or if the LPL deficiency is superimposed on other conditions that tend to elevate triglycerides, hypertriglyceridemia may be uncovered.

Genetic hypoalphalipoproteinemia syndromes are invariably associated with moderate hypertriglyceridemia. These included LCAT deficiency, Tangiers disease, and apoAI Milano. Because mice that are defective in apoAI production also show a similar tendency to hypertriglyceridemia,¹¹⁹ it is assumed that the reduced apoCII reservoir on HDL is responsible.

Secondary Causes of Hypertriglyceridemia

Diabetes Mellitus. Diabetes mellitus is the most prominent cause of hypertriglyceridemia, which is found in up to one third of all patients with type 2 diabetes. Insulin reduces fatty acid flux from adipose tissue, reduces liver apoB production, inhibits de novo triglyceride synthesis, and optimizes LPL production.¹²⁰ In addition, diabetes is associated with increased postprandial lipemia. The most common diabetic dyslipidemia is moderate hypertriglyceridemia and low HDL. The reduced HDL results from greater exchange of VLDL triglyceride for HDL cholesterol, hydrolysis of the triglyceride-rich HDL by hepatic lipase, and more rapid clearance of the smaller HDL from the circulation. CETP also enhances transfer of triglyceride to LDL, allowing these lipoproteins to be converted to smaller, denser forms that may be more atherogenic. This lipoprotein phenotype is also commonly found in nonhyperglycemic patients with dysmetabolic syndrome. Although most patients with diabetes do not have increased LDL, some do, and LDL reduction will occur with improved diabetes control. As stated earlier, diabetes is associated with severe fasting chylomicronemia. Although many such patients also have an underlying dyslipidemia (e.g., due to heterozygous LPL deficiency), others do not have a defined lipid disorder.

Patients with type 1 diabetes in poor control also develop hypertriglyceridemia. However, because insulin stimulates HDL production, patients in good control sometimes develop high levels of HDL.

Renal Failure. Renal failure is also associated with hypertriglyceridemia and low HDL levels. The reasons for this are not clear, but it may reflect underlying insulin resistance and defects in lipolysis of plasma triglycerides.¹²¹

Drugs. Various drugs can elevate triglycerides. Diabetes, obesity, and renal disease are common causes of fasting hypertriglyceridemia. The most common drugs associated with hypertriglyceridemia are estrogen-like compounds, thiazides, β -blockers, protease inhibitors, glucocorticoids, immunosuppressives, retinoids (isotretinoin, Accutane), bile acid-binding resins, and newer antipsychotic medications.

Oral estrogen therapy increases plasma triglyceride levels due to greater liver production of VLDL,

but combined estrogen-progestin therapy does not raise triglycerides and is sometimes associated with reduced LDL.¹²² In the setting of an underlying hypertriglyceridemia, severe hyperchylomicronemia and pancreatitis can occur in patients taking oral estrogen alone or birth control pills. For this reason, triglyceride levels should be measured in women before estrogen therapy is initiated. Transdermal estrogen administration, which does not lead to high liver exposure, does not result in triglyceride elevation.¹²³ Tamoxifen, an SERM, can cause severe hypertriglyceridemia and pancreatitis,¹²⁴ but raloxifene, another SERM, does not raise triglycerides.¹²⁵

Diet and Alcohol. Diets lead to marked changes in plasma triglyceride levels. Most lipoprotein profiles use fasting blood to avoid the postprandial increase in triglycerides that represent both dietary fat and de novo triglyceride production by the liver. Liver production of triglyceride is especially robust after the intake of simple sugars such as those found in sweetened foods (especially beverages including high fructose corn syrup) and other carbohydrates (bread, pasta, rice, and potatoes). Excessive intake of simple carbohydrates usually leads to moderate hypertriglyceridemia, but it can also exacerbate underlying genetic hypertriglyceridemias. Fat intake, especially in the setting of triglyceride levels greater than 500 mg/dL, can cause severe hyperchylomicronemia.

A major clinical cause of hypertriglyceridemia is alcohol intake. Sensitivity to the triglyceride-raising effects of alcohol is variable, but removal of alcohol from the diet of hypertriglyceridemic patients is often curative. Alcohol has many effects on lipid metabolism, including inducing de novo fatty acid synthesis and inhibiting fatty acid oxidation in the liver.¹²⁶ A common clinical conundrum is deciding whether hypertriglyceridemia alone is responsible for pancreatitis in an alcohol-using patient. Subjects with dysbetalipoproteinemia are particularly sensitive to the effects of alcohol consumption because the alcohol-induced overproduction of VLDL and subsequent production of remnant particles occur in the setting of impaired remnant clearance. Because alcohol also raises HDL, the presence of elevated triglycerides without reduced HDL is a clinical clue that an alcohol effect may be contributing to the lipid disorder.

Diagnostic Evaluation of Moderate Hypertriglyceridemia

A search for associated disorders, review of medication use, and delineation of dietary choices are appropriate. If both triglycerides and cholesterol are elevated, a search for the underlying lipoprotein disorder is sometimes useful. By ultracentrifugation, dysbetalipoproteinemia due to the presence of cholesterol-enriched VLDL can be differentiated from that of familial combined hyperlipidemia: The usual ratio of VLDL triglyceride to cholesterol of approximately 5 is reduced to 3 or less in dysbetalipoproteinemia. ApoE genotyping is also useful. Cholesterol-enriched VLDL are also found in patients with hypothyroidism, renal failure, or hepatic lipase deficiency.

HYPERCHOLESTEROLEMIA WITHOUT HYPERTRIGLYCERIDEMIA

Because all lipoproteins contain cholesterol, dramatic increases in triglycerides will invariably also lead to elevated blood cholesterol values. However, the ratio of

triglyceride to cholesterol will be greater than 5. Disorders associated with primarily increased cholesterol are discussed in this section. The clinical presentation of hypercholesterolemia is limited. Although patients with severe disease occasionally present with cosmetic concerns or orthopedic issues associated with tendon xanthomas, hypercholesterolemia is usually clinically occult and uncovered by blood testing during routine assessment or in the setting of vascular disease.

Genetic Familial Hypercholesterolemia

The centrality of the LDL receptor to the understanding of cholesterol metabolism was uncovered through investigations by the Brown and Goldstein laboratory (discussed earlier) into the cause of FH. This relatively common cause of severe hypercholesterolemia results from one of many defects in production of the LDL receptor leading to impaired function or production of the LDL receptor protein.¹²⁷ Patients with FH (most with heterozygous forms of the disease) have cholesterol levels that exceed 300 mg/dL. Homozygous presentations of the disease include cholesterol levels that are approximately twice this value. The heterozygous form occurs at a frequency of about 1 in 500 in the general population and is a major cause of early-onset coronary artery disease. In addition, homozygous and some other severe forms of LDL receptor deficiency are associated with aortic valve calcification and stenosis.¹²⁸

For unknown reasons, elevated LDL cholesterol leads to cholesterol deposition on tendons. Tendon xanthomas like those seen in Figure 37-17C and D occur in approximately 75% of FH patients. It is most common on the Achilles tendon. On inspection, a loss of the usual bow-like shape of the tendon occurs, or a bump or generalized thickening of the tendon is apparent. The irregularity of the tendon can also be detected by palpation. This physical finding is sometimes similar to scarring that results from tendon rupture. If the tendon is abnormal, a history of athletic injury should be sought. Xanthomas also occur on extensor tendons of the hands, but less frequently, and are best appreciated on the knuckles of a clenched fist. Xanthomas of the Achilles tendon can cause recurrent episodes of Achilles tendinitis. Some xanthomas are subtle and are apparent only as a thickening of the tendon or a small bump at the insertion of the tendon into muscle. Patients with FH also have xanthelasma (Fig. 37-17A) and premature corneal arcus (i.e., in persons younger than 40 years of age), but these findings can also occur in patients without FH. Many affected subjects have no physical findings. Premature coronary artery disease is common but variable. Some FH patients develop coronary disease in the third or fourth decade of life, especially if they also have reduced HDL cholesterol levels or associated risk due to cigarette smoking. Even before the introduction of statin therapy, some patients (especially women) never developed clinical vascular disease.

Homozygosity for FH is rare, occurring at a frequency of about 1 in 10⁶ in the general population. These subjects come to clinical attention early in life because of the appearance of tendon and planar xanthomas as well as tuberous xanthomas (Fig. 37-17E), marked hypercholesterolemia apparent at birth, premature coronary disease, or aortic valve disease. Typical plasma cholesterol concentrations range from 15.5 mmol/L (600 mg/dL) to 25.9 mmol/L (1000 mg/dL), and LDL-C concentrations range from 550 to 950 mg/dL. Symptomatic coronary disease can occur before age 10 years. If not treated, these homozygous

persons usually die from myocardial infarction by age 20 years. Aortic valve disease in homozygotes can be valvular or supravalvular.¹²⁸ The diagnosis of homozygous FH should be suspected in any child with extremely high plasma cholesterol (typically >500 mg/dL) or the xanthomas characteristic of FH. Both parents are obligate heterozygotes and should manifest the phenotype of heterozygous FH. However, recent understanding of the biology of the LDL receptor and the role of PCSK9 (see earlier discussion) in its degradation have shown that individuals with defects in both LDL receptors and PCSK9 can have normal plasma LDL levels.¹²⁹

Familial Defective Apolipoprotein B100

Defects in LDL binding to normal LDL receptors also lead to elevated plasma cholesterol. The ligands for the LDL receptor are apoB100 and apoE. Familial defective apoB100 increases LDL and has a phenotype that is indistinguishable from that of FH, including increased susceptibility to CHD.¹³⁰ The substitution of glutamine for arginine at amino acid 3500, which reduces LDL binding to the LDL receptor, accounts for most cases of familial defective apoB100, although other defects have also been reported. Often the LDL elevations are less severe, a reflection of a partial defect in receptor binding attributed to the mutation or the continued ability of apoE to mediate lipoprotein uptake.

Rare Mutations Associated with Elevated LDL Levels

Several rare, isolated causes of hypercholesterolemia have been reported. Mutations in *LDLRAP1*, the gene encoding a putative adaptor protein (ARH) that is required for internalization of LDL bound by the LDL receptor on the surface of hepatocytes, cause autosomal recessive hypercholesterolemia. Mutations in ARH associated with autosomal recessive hypercholesterolemia have been reported mostly in Italians (Sardinia) and Lebanese.¹³¹

Autosomal dominant hypercholesterolemia caused by a mutation in the gene encoding cholesterol 7 α -hydroxylase has been reported in a single kindred.¹³² The hypercholesterolemia is caused by defective cholesterol conversion to cholic acid.

Mutation of PCSK9 (see earlier discussion) leads to alterations in LDL receptor expression because this enzyme is responsible for intracellular LDL degradation.¹³³ Gain-of-function mutations reduce LDL receptor numbers and lead to defective LDL clearance by the liver. Because plasma PCSK9 causes LDL receptor degradation,¹³⁴ inhibitors of this protein are being studied as a therapy for hypercholesterolemia. Loss-of-function mutations in PCSK9 are associated with low levels of total cholesterol and LDL-C and an apparent reduction in coronary artery disease.¹³⁵

Elevated Plasma Lipoprotein(a)

Apo(a), a protein of unknown function that shares high sequence homology with plasminogen, associates with apoB to produce an LDL termed Lp(a). Some but not all studies suggest that elevated plasma Lp(a) concentrations are associated with an increased risk of coronary disease in Caucasian populations.¹³⁶ Lp(a) is not a cardiovascular risk factor in Africans or African Americans.¹³⁷ In addition, patients with high levels of Lp(a) are more likely to clot bypass grafts and stents.¹³⁸ Unlike LDL, which confers risk

as a continuous function of plasma level, risk is found only in individuals with the highest levels of Lp(a).

Plasma Lp(a) levels are to a great extent determined genetically. Lp(a) particles contain a variable number of a protein repeat known as a kringle. Smaller Lp(a) particles, with fewer kringle repeats, are usually produced at higher levels. For this reason, some have suggested that it is Lp(a) size, rather than plasma level, that confers vascular risk. Renal failure leads to elevations of Lp(a) levels.

Polygenic Hypercholesterolemia

Most patients with elevated LDL cholesterol do not have FH, and even cholesterol levels above 300 mg/dL are not usually associated with xanthomas or defects in the LDL receptor. If, as is conventional for other laboratory values, hypercholesterolemia is defined as a cholesterol value that exceeds the 95th percentile for the population, only 1 in 25 of these patients should have FH. Although diet and lifestyle influence LDL, the genetic and environmental factors associated with most elevated LDL cholesterol levels are unknown, and therefore this type of hypercholesterolemia is referred to as polygenic. Nonetheless, the increased cholesterol levels are associated with more coronary artery disease.

Increased LDL levels can be a result of defective LDL clearance with normal LDL receptors, a more subtle regulation of the receptor, or increased LDL production. This last type occurs in the setting of familial combined hyperlipoproteinemia (see later discussion), which can manifest as primary elevations of LDL. Greater LDL production due to greater absorption of gut cholesterol, abnormalities in the regulation of lipid-regulated nuclear transcription factors, or gain-of-function abnormalities in cholesterol and apoB-lipoprotein assembly pathways are all possible but poorly defined.

Lp(X)

Obstructive liver disease sometimes leads to a marked increase in plasma cholesterol. In part, this is the result of increased LDL, presumably due to a defect in LDL receptors. In addition, free cholesterol circulates associated with albumin, a particle referred to as Lp(X).¹³⁹ This is caused by a deficiency in the cholesterol esterifying enzyme, LCAT. The clinical setting suggests the diagnosis. In addition, an abnormal ratio of free to total cholesterol (or cholesteryl ester) can be determined by the laboratory. The relationship of Lp(X) to vascular disease is unclear.¹⁴⁰

Sitosterolemia

In this rare disorder, dietary sitosterol and other plant sterols, which are not normally absorbed in significant quantities in the intestine, are absorbed in large amounts, resulting in their accumulation in the plasma and in peripheral tissues, causing premature atherosclerosis.¹⁴¹ The molecular cause is a mutation in the genes encoding ABCG8 and ABCG5, which are responsible for re-secretion of absorbed plant sterols.³⁰ Patients develop tendon xanthomas in childhood and have normal to high plasma levels of LDL; the differential diagnosis includes FH and cerebrotendinous xanthomatosis. The diagnosis can be confirmed by gas-liquid chromatography of plasma lipids, which demonstrates the high levels of plant sterols. Therapy consists of restriction of plant sterols in the diet and treatment with ezetimibe, a drug that inhibits absorption of dietary sterols.¹⁴²

Cerebrotendinous Xanthomatosis

Cerebrotendinous xanthomatosis is a rare disorder of sterol metabolism that is associated with neurologic disease, tendon xanthomas, and cataracts in young adults.¹⁴³ Neurologic manifestations include cerebellar ataxia, dementia, spinal cord paresis, and subnormal intelligence. Premature atherosclerosis is common. Osteoporosis has been reported and is presumably caused by alterations in vitamin D metabolism.¹⁴⁴ The disorder results from mutations that cause deficiencies of 27-hydroxylase, a key enzyme in cholesterol oxidation and bile acid synthesis, leading to high plasma levels of cholesterol and cholestanol, with subsequent accumulation of these sterols in tendons and in tissues of the nervous system. Chenodeoxycholic acid is indicated for treatment.

Hypothyroidism and Elevated Cholesterol

All patients with significant hyperlipidemia should be screened for hypothyroidism, because thyroid hormone deficiency causes hypercholesterolemia, and low levels of thyroid hormone predispose to statin-induced myositis.¹⁴⁵ Although hypothyroidism usually increases LDL-C due to reduced LDL clearance, it can also be associated with high plasma triglyceride levels. Levels of HDL-C are usually unchanged or slightly lower in hypothyroidism and may be reduced in hyperthyroidism. Subclinical hypothyroidism is a cause of hypercholesterolemia that sometimes responds to thyroid hormone replacement.¹⁴⁶

Diagnostic Evaluation of Isolated Hypercholesterolemia

A lipoprotein assessment is appropriate and, if the cholesterol level is higher than 300 mg/dL, a search for signs of FH is needed. The diagnosis of heterozygous FH is suggested by the presence of high plasma levels of total cholesterol and LDL-C, normal plasma triglycerides, tendon xanthomas, and a family history of premature coronary disease. Heterozygous FH should be suspected in any person with premature heart disease. In one study, heterozygous FH accounted for 4% of men who survived myocardial infarction before 60 years of age.¹⁴⁷ The diagnosis of FH is primarily a clinical diagnosis, because tests to detect one of the many LDL receptor gene mutations or to demonstrate diminished LDL receptor function are performed only in specialized research laboratories. The clinical diagnosis of FH is important not only for proper treatment of the affected patient but also for identification of other family members who may be at high risk for developing coronary disease. In addition, diagnosis of FH can be useful in genetic counseling.

Increased High-Density Lipoprotein

Occasionally, patients with hypercholesterolemia have elevations primarily of HDL, with normal levels of LDL. Usually, this pattern is found in families with little cardiovascular disease, and high HDL syndromes are associated with longevity.¹⁴⁸ The usual risk factor analysis and ratios of total cholesterol to HDL suggest that patients with high HDL have reduced risk of cardiovascular disease.

Newer information suggests that there are subgroups of these patients with a less sanguine prognosis. These relatively unusual patients are insufficiently represented in population studies to assess coronary risk. Isolation of HDL from patients with cardiovascular disease and high levels

of HDL led to the observation that these HDL do not have anti-inflammatory properties.¹⁴⁹ Atherogenic HDL has been detected in patients with systemic lupus erythematosus.¹⁵⁰ Therefore, there are clinical circumstances in which HDL may be dysfunctional (see earlier discussion).

Genetic Disorders Causing Increased High-Density Lipoprotein

CETP deficiency is a hereditary syndrome in which plasma HDL-C levels are increased because of diminished activity of plasma CETP. The disorder is not uncommon in the Japanese population. Its features include marked elevations of plasma HDL-C in homozygotes (usually >100 mg/dL). Despite the elevated HDL-C levels, the effect on coronary disease risk of CETP gene mutations is unclear.¹⁴⁹ Heterozygotes have moderately elevated HDL-C levels. The lower activity of CETP results in diminished transfer of cholesteryl esters from HDL to apoB-containing lipoproteins. As a result, more cholesteryl esters are found in HDL, and the ratio of total cholesterol to HDL-C is markedly reduced. CETP is most active in the setting of hypertriglyceridemia,¹⁵¹ so, in addition to reducing HDL cholesterol, it provides a mechanism for reduction of triglyceride through HDL metabolism. Perhaps for this reason, studies in mice, which normally do not have significant plasma CETP activity, have shown reduced apoB-containing lipoproteins and reduced atherosclerosis with addition of a CETP transgene. Therefore, the effect of CETP on vascular disease varies as a function of the underlying plasma lipid profile. CETP inhibition as a means to increase HDL and reduce vascular disease in humans is currently an active area of pharmaceutical research. The first CETP inhibitor tested clinically resulted in a colossal clinical trial failure, because the drug increased cardiovascular events despite elevating HDL.¹⁵² This result was ascribed by some to an off-target effect of the drug that increased aldosterone production, leading to hypertension. Other drugs without this side effect are currently in clinical trials.

Several pharmacologic agents are associated with increased plasma HDL. The antiatherogenic capacity of HDL produced in these circumstances is unknown. HDL induction occurs with the use of oral estrogens, alcohol intake, dilantin, phenobarbital, and insulin therapy in some patients with type 1 diabetes.

Endothelial lipase deficiency is caused by defects in the third member of the lipase gene family, endothelial lipase. As described earlier, endothelial lipase is responsible in part for HDL catabolism. Mutations in endothelial lipase are associated with increased plasma HDL levels.⁸⁷ Such patients may be protected from vascular disease.

ELEVATED TRIGLYCERIDES AND CHOLESTEROL

Elevated triglyceride and cholesterol levels can be caused by increased VLDL and LDL, combined hyperlipidemia, or the presence of increased circulating remnant lipoproteins (dysbetalipoproteinemia). These are indistinguishable by routine laboratory examination, but treatment approaches differ somewhat.

Combined Hyperlipidemia

Combined hyperlipidemia is a common disorder associated with elevations of plasma cholesterol and triglyceride levels

and increased susceptibility to coronary disease. Lipoprotein isolation reveals increased LDL and VLDL. Kinetic analysis has associated this pattern primarily with overproduction, rather than defective clearance, of apoB lipoproteins. When it occurs within families, it is termed *familial combined hyperlipidemia*. These individuals, who do not necessarily have other causes for lipid abnormalities, characteristically come from families with various hyperlipidemias that include increased isolated triglycerides or increased isolated LDL. Moreover, the abnormal lipoprotein pattern (increased triglycerides, cholesterol, or both) can vary over time in an individual.

Regulation of apoB production involves a number of steps (see earlier discussion), and understanding of this physiology explains some of the association of combined hyperlipidemia with other diseases. Increased fatty acid return to the liver and reduced insulin action prevent degradation of newly synthesized apoB. Therefore, it is not surprising that both dysmetabolic syndrome and type 2 diabetes are commonly found along with combined hyperlipidemias. Although the genetics of this disorder have been investigated, the coexistence of this lipoprotein pattern with insulin resistance and obesity syndromes has been a confounder. Therefore, although alterations in a number of genes associated with lipid metabolism, such as LPL and apoCIII, have been observed, a firm genetic marker is not currently available.

Familial Dysbetalipoproteinemia (Type III Hyperlipoproteinemia)

Familial dysbetalipoproteinemia (formerly known as type III hyperlipoproteinemia) is an uncommon disorder of lipoprotein metabolism that is characterized by moderate to severe hypertriglyceridemia and hypercholesterolemia caused by the accumulation of cholesterol-rich remnant particles in the plasma. Premature peripheral vascular disease and coronary artery disease are common. The cause is mutations in the apoE gene that result in defective binding of apoE to lipoprotein receptors. The disorder is associated with the apoE2 isoform and in most instances is inherited as an autosomal recessive trait. Because the phenotypic expression of the disorder is limited to approximately 1% of the patients with the apoE2/E2 phenotype, other genetic or environmental factors must also be operative. The hyperlipidemia is caused by a defect in clearance of remnant lipoproteins whose liver uptake requires apoE interaction with the LDL receptor, LRP1, and HSPG (see earlier discussion). The remnants that accumulate have lost much of their triglyceride through LPL-mediated triglyceride hydrolysis and therefore are cholesterol rich. The predominant remnant particles, termed β -VLDL, can be identified by abnormal migration on gel electrophoresis or by abnormal lipid content.

Dysbetalipoproteinemia is usually diagnosed in adulthood and is rarely detected in persons younger than 20 years of age, with the exception of those with rare autosomal dominant apoE mutations.¹⁵³ The disorder is more common in men than in women. It is characterized by moderately severe elevations in plasma triglyceride and cholesterol levels; typically, these values both range from 300 to 400 mg/dL. Concentrations of HDL-C are normal. Xanthomas are present in more than half of affected subjects. Palmar xanthomas, which are planar xanthomas in the palmar creases (see Fig. 37-17F), are pathognomonic for this disorder. Tuberos or tuberous xanthomas (see Fig. 37-17E) are also common but are less specific for this

disorder. Tendon xanthomas and xanthelasma occur in some patients. Unlike FH, in which peripheral vascular disease is uncommon, premature peripheral vascular disease occurs in addition to premature coronary artery disease in patients with dysbetalipoproteinemia. Coexisting metabolic conditions that exacerbate the phenotype of dysbetalipoproteinemia, such as obesity, alcohol consumption, diabetes mellitus, and hypothyroidism, are often present.

In addition to homozygosity for the apoE2 isoform, six mutations in the apoE gene are known to lead to the dysbetalipoproteinemia phenotype in an autosomal dominant fashion.¹⁵³ The phenotype manifests at an early age without exacerbating factors.

Hepatic Lipase Deficiency

Hepatic lipase deficiency is a rare disorder associated with lack of heparin-releasable hepatic lipase activity in the plasma.¹⁵⁴ Because this enzyme mediates the final step of conversion of IDL to LDL and is involved in chylomicron remnant clearance, its deficiency causes a phenotype that is similar to that found with dysbetalipoproteinemia—namely, elevated levels of plasma cholesterol (250 to 1500 mg/dL) and triglycerides (395 to 8200 mg/dL). Patients also have palmar and tuberoeruptive xanthomas, premature arcus corneae, and premature coronary artery disease. Because hepatic lipase also mediates HDL metabolism, HDL levels are not decreased. The demonstration of hepatic lipase deficiency requires in vitro assays of hepatic lipase activity in postheparin plasma or DNA analysis to identify mutations.

Nephrotic Syndrome

Hyperlipidemia almost always accompanies the nephrotic syndrome. Total cholesterol, VLDL, LDL-C, total triglycerides, and plasma apoB may all be elevated. Nephrotic syndrome increases liver production of apoB-containing lipoproteins, leading to increased plasma LDL or VLDL, or both. This may be a response to hypoalbuminemia and an associated generalized increase in liver protein secretion.

Protease Inhibitor Use in Human Immunodeficiency Virus Infection

Treatments for human immunodeficiency virus (HIV) infection often cause hyperlipidemia, lipodystrophy, and insulin resistance.¹⁵⁵ Hypertriglyceridemia is the most common lipid abnormality, although increases in LDL are also found. These effects were initially thought to result from the use of protease inhibitors, but other agents, such as reverse transcriptase inhibitors, can cause dyslipidemia. The dysmetabolic syndrome is not uniformly induced by all drugs; older agents such as zidovudine are more likely to have metabolic side effects. The cause of this syndrome is unclear but may be related to greater liver production of apoB-lipoproteins and triglycerides.

Immunosuppressive Regimens

Patients undergoing transplantation who require a number of medications commonly present with hypertriglyceridemia and/or hypertriglyceridemia and hypercholesterolemia. Glucocorticoids more often raise triglycerides, cyclosporine raises cholesterol, and rapamycin increases both cholesterol and triglycerides.¹⁵⁶

Diagnostic Evaluation of Elevated Triglycerides and Cholesterol

Appropriate assessment usually requires that clinicians determine whether the hyperlipidemia is primarily a genetic disorder or is secondary to another systemic disease. The clinical setting and accompanying drug therapies must be considered. In some situations, an evaluation for dysbetalipoproteinemia is useful. In other cases, empiric treatment is reasonable (see later discussion). The presence of cholesterol-enriched β -VLDL is determined by a direct measurement of the VLDL-C level to detect cholesterol-rich remnant particles. The directly measured ratio of VLDL-C to plasma triglycerides (in milligrams per deciliter) is a useful screen. In dysbetalipoproteinemia, this ratio is usually greater than 0.3 (when hyperlipidemia is present), whereas the normal ratio is typically about 0.2 (i.e., the VLDL-C concentration is about 20% of the plasma triglyceride level). Electrophoresis of plasma samples on agarose gels typically demonstrates a broad band in the β -migrating lipoprotein region. Patients with suspected dysbetalipoproteinemia can be evaluated for apoE2 homozygosity by apoE genotyping of DNA obtained from leukocytes, a procedure that is available in many clinical laboratories. The other rare dominant mutations in apoE can be diagnosed only in specialized laboratories.

HYPOCHOLESTEROLEMIA

Secondary causes that can lead to very low levels of apoB-containing lipoproteins and low cholesterol levels include malabsorption, sepsis, liver failure, and malnutrition. There are also genetic conditions that cause low cholesterol.

Familial Hypobetalipoproteinemia

Familial hypobetalipoproteinemia is defined as apoB and LDL-C levels below the 5th percentile. Hypobetalipoproteinemia is not associated with a phenotype and leads to a reduced risk for cardiovascular disease. Possible causes of this syndrome include mutations leading to truncation of apoB and mutations in PCSK9 presumably leading to increased numbers of LDL receptors. PCSK9 loss-of-function mutations occur in as many as 2% of African Americans but are rare in persons of European descent.

Abetalipoproteinemia

Abetalipoproteinemia is a rare autosomal recessive disorder caused by a deficiency in MTP, which results in a virtual absence of apoB-containing lipoproteins in the plasma.⁶² Abetalipoproteinemia occurs in fewer than 1 in 10⁶ persons and has the same phenotype as homozygous hypobetalipoproteinemia, including malabsorption of fat and fat-soluble vitamins from the intestine, which can lead to neurologic disease related to vitamin E deficiency. The disorder is usually detected in infancy because of fat malabsorption associated with marked decreases in plasma cholesterol and triglyceride levels.

Chylomicron Retention Syndrome

Anderson's disease, or chylomicron retention syndrome, is a rare condition that is phenotypically similar to abetalipoproteinemia. Subjects with Anderson's disease cannot secrete chylomicrons from the intestine. Eight mutations

in the *SAR1B* gene (formerly *SARA2*) have been linked to Anderson's disease. This gene encodes SAR1B, a protein that is important in the transport of chylomicrons through the secretory pathway in enterocytes.¹⁵⁷

Familial Hypoalphalipoproteinemia

Although low HDL in the general population is correlated with greater coronary artery disease, genetic disorders leading to very low plasma levels of HDL have variable and sometimes undefined coronary risk. In part, this might result from the rarity of some of these diseases. For this reason, the approach to the disorders is often unclear.

Apolipoprotein AI Mutations

Mutations in the apoAI gene can decrease HDL formation and result in low plasma HDL-C levels. ApoAI deficiency can be caused by point mutations in the apoAI gene or by deletions or gene rearrangements at the apoAI/CIII/AIV/AV gene locus.¹⁵⁸ ApoAI deficiency typically results in plasma HDL-C levels lower than 0.3 mmol/L (10 mg/dL). Some apoAI variants activate LCAT poorly (see later discussion). The molecular diagnosis is made by protein analysis showing an altered apoAI size or by genetic sequencing. Some apoAI variants are associated with amyloidosis.

The apoAI Milano variant (apoAI_{Milano}) is caused by a substitution of cysteine for arginine at amino acid 173. This results in low plasma HDL-C levels without premature CHD. Therefore, this HDL is hypothesized to be antiatherogenic and has been used in a human clinical trial.¹⁵⁹

Lecithin:Cholesterol Acyltransferase Deficiency

LCAT deficiency leads to low HDL as a consequence of defective conversion of cholesterol to cholesteryl ester. In a phenotypically appropriate patient, measurement of the ratio of free cholesterol to cholesteryl ester is diagnostic; normally free cholesterol is approximately 30% of the total, but this increases to more than 90% in LCAT deficiency. LCAT activity measurements and sequencing can also be performed. LCAT deficiency leads to striking corneal arcus, normochromic anemia, and, occasionally, renal failure in young adults.¹⁶⁰ Renal biopsies show characteristic foam cells. Despite their very low HDL levels, the risk of coronary disease in patients with LCAT deficiency is not pronounced; this may reflect the low levels of LDL that are also found in many of these patients.

A variant of LCAT deficiency, called fish-eye disease, is also caused by mutations of the LCAT gene. The phenotype is less severe than that seen in complete LCAT deficiency.¹⁶¹ Fish-eye disease is characterized by low plasma HDL-C levels and corneal opacities; anemia and renal disease do not occur. The phenotypic differences between LCAT deficiency and fish-eye disease have been attributed to whether mutations in the LCAT gene encode variants that fail to esterify cholesterol of both HDL and apoB-containing lipoproteins (LCAT deficiency) or of HDL only (fish-eye disease).

Adenosine Triphosphate–Binding Cassette Transporter AI Deficiency

The ABCA1 transporter is essential to complete synthesis of mature HDL by the liver and the small intestine. A number of mutations in this receptor are associated with hypoalphalipoproteinemia.¹⁶² Because the number of genetic mutations is great, assays often study fibroblast “unloading” of cholesterol to apoAI to show the defect.

Tangier disease is the most flagrant example of a defect in ABCA1. These patients, originally from Tangier Island in

the Chesapeake Bay, had hypocholesterolemia resulting from a marked decrease in plasma HDL as well as low LDL and the striking physical finding of orange tonsils. The orange tonsils are thought to result from defective reverse cholesterol transport from macrophages of the reticuloendothelial system, with the color probably caused by carotenoids. The risk of cardiovascular disease with this syndrome is uncertain.

OVERVIEW OF ATHEROGENESIS

Atherosclerosis and its clinical presentation as coronary artery disease, stroke, and peripheral vascular disease is likely to be the product of several pathophysiologies. Depending on the patient and setting, arterial disease results from a varying reaction to lipid infiltration, arterial damage, and macrophage inflammation. Population, genetic, and therapeutic data suggest that atherosclerosis is frequently caused by cholesterol deposition within the arterial wall. Those data include studies that correlated plasma cholesterol and coronary artery disease both within and between populations. As described earlier, a number of genetic hyperlipidemic disorders are associated with premature atherosclerosis. Reductions of blood cholesterol by diet, surgical ileal bypass, statins, and other cholesterol-lowering therapies have convincingly shown the impact of blood cholesterol on arteries. This cholesterol hypothesis is further supported by a wealth of animal data: Altering blood lipid levels by diet or genetic modification causes atherosclerosis-free animals to develop disease. However, both in animals and in humans, vascular disease is not universal, even among those individuals with marked hypercholesterolemia. Similarly, patients with low cholesterol are not assured of being protected from the disease. It is estimated that about 50% of all atherosclerosis is attributable to hyperlipidemia and other known cardiac risk factors.¹⁶³

In contrast, other approaches to atherosclerosis treatment directed toward theoretical etiologies have not been supported by human clinical intervention trials. Use of vitamin E and antibiotics has not altered CHD. Although low-dose aspirin has some anti-inflammatory properties, its reduction of cardiovascular events is most likely secondary to effects on coagulation rather than direct effects on atherosclerosis.

There are a number of clinical situations in which cholesterol reduction has failed to alter vascular disease. Most notably, statin-mediated cholesterol reduction appears to be ineffective in end-stage renal disease.¹⁶⁴ A similar situation may exist in other inflammatory diseases (e.g., collagen-vascular diseases) that are associated with cardiac events but have not yet been shown to respond to cholesterol-lowering therapies.¹⁶⁵ These diseases are more likely to have a primary inflammatory etiology,¹⁶⁶ the causes of which include hypertension, cigarette smoking, infections, and immune reactions.

Cholesterol-Induced Atherosclerosis

More than 100 years ago, pathologists identified cholesterol as a major component of atherosclerosis. This poorly metabolized lipid is found both associated with matrix and within arterial cells. Macrophages and smooth muscle cells are converted into foam cells, so called because of their intracellular foamy lipid. In addition, there are often acellular lipid-rich areas, a variable amount of overlying

collagen-rich connective tissue, and regions where the atherosclerotic plaque has ruptured. The process begins with lipid infiltration into the arterial wall.^{167,168}

Unresolved pathogenic issues include the following: (1) How does lipid enter the artery? (2) What pathways lead to excess lipid uptake by foam cells? and (3) What processes cause rupture and thrombosis?

Infiltration of lipoproteins into the artery wall is likely to be a normal and continuous process. Larger particles, such as chylomicrons, are more likely to be excluded by the endothelial barrier.¹⁶⁹ LDL can leave the circulation via channels between cells, along the continuous transendothelial movement of cell-free plasma, or via interaction with specific receptors. Once in the subendothelial space, lipoproteins must accumulate to cause disease. It is theorized that positive charges on apoB interact with negatively charged proteoglycans to promote lipoprotein retention. Both apoB100 in LDL and VLDL, apoB48 in chylomicron remnants, and apoE in several classes of lipoproteins have proteoglycan-binding sequences.¹⁷⁰ Another possibility is that, within the artery, lipoproteins fuse to form large aggregates that are unable to disassociate and re-enter the circulation.¹⁷¹ Lipoprotein uptake into cells is usually well controlled, because excess cellular cholesterol downregulates LDL receptors. Therefore, aberrant lipoprotein receptor regulation may be a factor, or LDL (and remnants) may enter cells by non-cholesterol-regulated pattern recognition receptors (see earlier discussion).

Cholesterol-containing lipoproteins can become inflammatory. Enzymes within the artery might induce alterations in the protein and lipid content of LDL that convert these particles into more-inflammatory oxidized LDL.¹⁷²

Unstable Plaque and Regression

The atherogenic process occurs within the artery wall. Initially, it was thought that the lumen was progressively narrowed by the accumulation of macrophages, the proliferation of smooth muscle cells, and the deposition of cholesterol. In fact, the truly dangerous lesion (the culprit lesion) may not cause marked luminal narrowing.¹⁷³ As atherosclerosis progresses, there is a compensatory expansion of the lumen that maintains an almost constant lumen size. As the lesion develops within the intima, the complication of rupture of the overlying intima or endothelial erosion leads to exposure of the lesional contents to platelets, initiating thrombosis. It is the acute thrombosis, not arterial lumen stenosis, that is responsible for infarctions in most patients. Rupture or erosion occurs where the fibrous cap covering the underlying thrombotic lipid is thin and where an active inflammatory process is occurring.

The surfaces of complicated lesions can become thrombogenic as endothelial cells are lost or the fibrous cap ruptures and the subendothelial space is exposed. Platelets can adhere to this exposed surface, promoting thrombus formation. In these unstable plaques, blood actually dissects into the artery wall, leading to the formation of a large thrombus. Calcification is also a feature of late lesions. Advanced lesions can weaken the elasticity and integrity of the artery wall, potentially creating an aneurysm of the vessel. As clinical trial data have shown, removal or reduction of the atherogenic stimulus can result in plaque regression and stabilization, leaving a remnant devoid of lipid that resembles a wound scar and is less likely to serve as a nidus for thrombus formation.

Atherosclerosis usually develops in the setting of hypercholesterolemia. Observations first made in animals and

now confirmed in humans indicate that this process can be reversed if plasma cholesterol reduction is intensive.¹⁷⁴

EVIDENCE SUPPORTING TREATMENT OF LIPID DISORDERS

Cholesterol and Cardiovascular Disease

Despite a very significant decrease in the incidence of vascular disease, cardiovascular diseases including CHD and cerebrovascular disease remain the major causes of death in the United States for both men and women. The major risk factors are age, elevated LDL-C, reduced HDL-C, smoking, hypertension, insulin resistance with or without overt diabetes mellitus, and a family history of premature CHD. Modifiable risk factors account for most of the excess CHD risk. Although a number of new risk factors have been proposed to increase the accuracy of predicting risk of CHD events, only four conditions—dyslipidemia, hypertension, cigarette smoking, and/or diabetes—account for increased CHD risk in 80% to 90% of patients.^{175,176}

Understanding of the relationship of cholesterol and lipids to atherosclerosis has evolved over the last century and especially over the last 60 years.¹⁷⁷ The “lipid hypothesis,” which postulates that increased plasma cholesterol concentrations increase the risk of CHD, that diets high in fat (especially saturated fat of animal origin) and cholesterol increase plasma cholesterol levels, and that lowering of cholesterol levels would decrease the risk of atherosclerotic vascular disease, was not accepted for many years.^{177,178} Data from population studies, animal studies, cell culture experiments, and, eventually, clinical trials of lipid-lowering interventions have made the treatment of hyperlipidemia an accepted strategy for decreasing cardiovascular risk.¹⁷⁸⁻¹⁸⁰

Epidemiologic Evidence

A number of studies have demonstrated a relationship between plasma cholesterol levels and the risk of CHD. Analysis of cholesterol levels of men who were screened for the Multiple Risk Factor Intervention Trial (see Fig. 37-16) showed that there is increased risk at total cholesterol levels greater than 5.2 mmol/L (200 mg/dL).¹⁸¹ Multiple studies have demonstrated the relationship between cardiovascular risk factors, dietary cholesterol and saturated fats, and the incidence of CHD, providing solid epidemiologic data for the lipid hypothesis.¹⁷⁹ Epidemiologic and clinical studies involving lifestyle changes have led to a variety of recommendations for diet and exercise approaches to decreasing cardiovascular risk.^{97,182-184}

Clinical Trials

Lowering cholesterol decreases the risk of CHD, as has been shown in many human clinical trials. In all groups examined, including patients with and without preexisting CHD over a range of initial plasma cholesterol levels, the results have demonstrated that sufficient lowering of plasma cholesterol levels reduces the risk of CHD regardless of the baseline cholesterol level.

Clinical trial data of lipid-modifying therapies include trials of both primary and secondary prevention, with measurements of clinical events and surrogate measurements such as carotid intima media thickness, quantitative coronary angiography, and intravascular ultrasound and a variety of therapies including diet, partial ileal bypass,

nicotinic acid, fibric acid derivatives, BAS, HMG-CoA reductase inhibitors, ω -3 fatty acids, LDL apheresis, and combinations of drugs. The most rigorous evidence is that of randomized controlled trials with cardiovascular events as the end point, but studies using vascular imaging techniques provide supporting evidence of benefit.

Before 1984, a number of clinical trials demonstrated the benefits of cholesterol lowering in both primary and secondary prevention settings using several medications, but they did not convince the medical profession that lowering of cholesterol was beneficial.¹⁷⁸ In 1984, the large, randomized, placebo-controlled, Coronary Primary Prevention Trial demonstrated that cholesterol lowering with the BAS cholestyramine decreased the risk of nonfatal myocardial infarction and cardiac death in men with high cholesterol levels.¹⁸⁵ However, the study did not have adequate statistical power to show an effect on mortality, and there remained concerns that cholesterol lowering did not decrease overall mortality. Other studies in the 1980s showed that use of cholesterol-lowering medications could decrease the progression of coronary atherosclerosis as demonstrated by coronary angiography. Two notable studies were the Cholesterol Lowering Atherosclerosis Study (CLAS)¹⁸⁶ and the Familial Atherosclerosis Treatment Study (FATS).¹⁸⁷

The Scandinavian Simvastatin Survival Study (4S),¹⁸⁸ a randomized, placebo-controlled trial using simvastatin in men and women with preexisting coronary artery disease and high LDL-C levels (190 mg/dL), evaluated total and cardiovascular mortality. It demonstrated a decrease in both cardiovascular and total mortality and provided compelling evidence of the benefit of cholesterol reduction. The 4S study finally convinced many researchers and practitioners of the value of lipid lowering, at least for secondary prevention. Cholesterol and Recurrent Events (CARE), another secondary prevention event trial done in patients with a history of myocardial infarction and baseline LDL-C levels of 115 to 175 mg/dL, showed a decrease in event rate with pravastatin treatment.¹⁸⁹ This benefit also extends to patients with a relatively low baseline LDL-C. In the Heart Protection Study, simvastatin decreased the first major vascular event by 24% in high-risk patients, even when LDL-C cholesterol was lower than 3.0 mmol/L (116 mg/dL).¹⁹⁰ Evidence for even lower LDL-C targets came from the Pravastatin or Atorvastatin Evaluation and Infection Therapy (PROVE-IT) study, which showed a benefit of atorvastatin (80 mg/day) compared with pravastatin (40 mg/day) in patients with acute coronary syndromes,¹⁹¹ and from the Treating to New Target (TNT) study comparing atorvastatin (80 mg/day) with atorvastatin (10 mg/day) in patients with stable coronary disease.¹⁹²

Clinical trials of primary prevention such as the West of Scotland study,¹⁹³ the Air Force/Texas Coronary Atherosclerosis Protection (AFCAPS/TexCAPS) study,¹⁹⁴ and the Collaborative Atorvastatin Diabetes Study (CARDS)¹⁹⁵ demonstrated the benefits of lowering LDL-C to reduce coronary artery disease events in patients without a history of CHD who had, respectively, high LDL-C levels, low HDL-C levels, and type 2 diabetes. The West of Scotland study confirmed a decrease in risk of coronary events in men with elevated cholesterol levels and no previous history of myocardial infarction.¹⁹³ The AFCAPS study showed the benefits of LDL-C lowering for primary prevention in both men and women with HDL-C levels lower than 50 mg/dL.¹⁹⁴ More recent evidence for the use of statins in primary prevention of cardiovascular events came from the Justification for the Use of Statins in Prevention: an Intervention Trial Evaluating Rosuvastatin

(JUPITER) study, in which men and women with LDL-C levels of 108 mg/dL at baseline were randomly assigned to receive either rosuvastatin or placebo. The trial was terminated early when there was a highly significant decrease in cardiovascular events in the statin-treated group.¹⁹⁶

Although the beneficial effect of cholesterol lowering through LDL-C reduction is well established, evidence for the benefit of lowering triglycerides or raising HDL-C levels, or both, is less robust. Data are most significant in studies of the fibric acid gemfibrozil and of niacin; niacin also lowers LDL-C levels at high doses. The Helsinki Heart Study¹⁹⁷ and the Veterans Affairs–High-Density Lipoprotein Cholesterol Intervention Trial (VA-HIT)¹⁹⁸ both used gemfibrozil, the former for primary prevention and the latter for secondary prevention, and in both studies the greatest benefit was in men with high triglyceride and low HDL-C levels. Studies with other fibrates, such as fenofibrate, have yielded results without unequivocal statistical significance.¹⁹⁹ The niacin arm of the Coronary Drug Project showed a decrease in nonfatal myocardial infarctions in men with coronary artery disease during the 6-year trial and a decrease in total mortality in the 9 years after the study.²⁰⁰

Although event trials provide the best evidence, studies using carotid intima medial thickness, coronary artery angiography, or coronary intravascular ultrasound have provided useful information. Trials with statins have shown an effect on the progression of atherosclerosis. In an uncontrolled study, rosuvastatin was associated with a reduction of total atheroma volume by 6.8% as determined by intravascular ultrasound (A Study to Evaluate the Effect of Rosuvastatin on Intravascular Ultrasound-Derived Coronary Atheroma Burden: ASTEROID).¹⁷⁴ In the Reversal of Atherosclerosis with Aggressive Lipid Lowering (REVERSAL) study, treatment with atorvastatin 80 mg/day (treatment LDL-C, 79 mg/dL) was associated with no progression of coronary artery disease compared with pravastatin 40 mg/day (treatment LDL-C, 110 mg/dL), which led to progression of disease.²⁰¹

Clinical event trial data for combination therapy of hyperlipidemia are minimal, but surrogate end point studies using coronary angiography have suggested benefit of combination therapy. Studies using a BAS and niacin, a statin and niacin, or triple therapy with a statin, niacin, and BAS have shown decreased progression of atherosclerosis.^{186,187,202,203} One of these studies, the FATS trial, showed decreases in end points as well as angiographic benefit of therapy.¹⁸⁷ Combinations including niacin have also shown benefit in studies measuring carotid intima medial thickness.^{204,205}

The large beneficial effect of cholesterol lowering, particularly with statins, on rates of cardiovascular events for both primary and secondary prevention and in a wide variety of patients² has continued to inform committees writing guidelines for the treatment of hyperlipidemia.^{97,206,207} Committees are still grappling with unanswered questions. Although decreasing LDL-C reduces CHD risk by 30% to 50% in statin studies, there is still significant residual risk, especially in patients with established vascular disease, many of whom have events despite achieving LDL-C levels of 70 to 80 mg/dL, as was shown in the Treating to New Targets study.¹⁹² Other questions include the following: How early in life should therapy be started for primary prevention? Will longer duration of therapy lead to better outcomes? What is the benefit of lowering triglycerides or raising HDL-C? What biomarkers are best to screen and monitor in at-risk patients? Can other mediators of atherosclerosis be manipulated? How

can lifestyle changes be accomplished? Additional clinical trials are underway to answer some of these questions.

TREATMENT OF LIPID DISORDERS

Rationale for Treating Hyperlipidemia

Clinical trials have clearly demonstrated the benefit of LDL-C reduction² and that reduction of triglycerides and increases in HDL-C may also be beneficial.^{197,198,208} Treatment of severe hypertriglyceridemia is indicated to reduce the risk of pancreatitis. Optimal management of risk factors reduces the risk of atherosclerotic clinical events. However, the 5-year incidence of myocardial infarction or cardiac death from a first heart attack remains high, with rates of 14% to 32% depending on age, race, and gender.²⁰⁹

Data from the INTERHEART study, a case-control study spanning 52 countries, suggest that optimization of nine easily measured and potentially modifiable risk factors could result in a 90% reduction in the risk of an initial acute myocardial infarction. The effect of these risk factors is consistent in men and women across different geographic regions and ethnic groups. The nine risk factors are cigarette smoking, abnormal blood lipid levels, hypertension, diabetes, abdominal obesity, lack of physical activity, low daily fruit and vegetable consumption, alcohol overconsumption, and a psychosocial index (reflecting depression, interpersonal stress at work or home, financial stress, major life events, and lack of control).²¹⁰

Approach to the Hyperlipidemic Patient

The initial evaluation consists of a history and physical examination, including assessment of CHD risk factors (Table 37-6) and measurement of plasma lipids (Table 37-7). Exclusion of secondary causes of lipid disorders (see earlier discussion) is important. Obesity is an independent risk factor for CHD not included in the formal list of NCEP

TABLE 37-6

Major Risk Factors for Coronary Heart Disease

Positive Factors

Age	Men, ≥45 yr; women, ≥55 yr
Current cigarette smoking	
Diabetes mellitus*	
Family history of premature CHD	Definite myocardial infarction or sudden death before age 55 yr in father or other male first-degree relative (or before age 65 yr in mother or other female first-degree relative)
Hypertension	Blood pressure ≥140 mm Hg systolic or ≥90 mm Hg diastolic, or on antihypertensive medication
Low HDL-C	<1.0 mmol/L (<40 mg/dL)

Negative Factors

High HDL-C	>1.6 mmol/L (≥60 mg/dL)
------------	-------------------------

*Diabetes mellitus or any clinical manifestation of atherosclerosis (claudication, stroke, abdominal aortic aneurysm) is regarded as a CHD-equivalent; that is, >20% risk of a CHD event within 10 years.

CHD, coronary heart disease; HDL-C, high-density lipoprotein cholesterol.

Adapted from The Expert Panel. Third Report of the National Cholesterol Education Program (NCEP) Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults (Adult Treatment Panel III): Final report. *Circulation*. 2002;106:3143-3421.

TABLE 37-7

Classification of Plasma Lipid Levels

Level	Classification
Total Cholesterol (mg/dL)	
<200	Desirable
200-239	Borderline high
>240	High
High-Density Lipoprotein Cholesterol (mg/dL)	
<40	Low (consider <50 mg/dL low for women)
>60	High
Low-Density Lipoprotein Cholesterol (mg/dL)	
<70	Optional treatment goal in very-high-risk patients
<100	Optimal
100-129	Near optimal
130-159	Borderline high
160-189	High
>190	Very high
Triglycerides (mg/dL)	
<150	Normal
150-199	Borderline high
200-499	High
>500	Very high

Adapted from The Expert Panel. Third Report of the National Cholesterol Education Program (NCEP) Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults (Adult Treatment Panel III): Final report. *Circulation*. 2002;106:3143-3421; and Grundy SM, Cleeman JJ, Merz CNB, et al. Implications of recent clinical trials for the National Cholesterol Education Program Adult Treatment Panel III guidelines. *Circulation*. 2004;110:227-239.

risk factors, although it is reflected in the waist circumference measurement that is used to define the dysmetabolic syndrome (see Table 37-5). Obesity aggravates dyslipidemia, hypertension, and insulin resistance and is a target of therapy regardless of the severity of traditional CHD risk factors. Particular emphasis should be placed on obtaining a detailed history of all first-degree relatives to identify cholesterol disorders or premature CHD.

Physical Examination

The examination should emphasize the cardiovascular system, manifestations of hyperlipidemia, and disorders causing secondary lipid abnormalities. Several unique clinical findings are illustrated in Figure 37-17.

Xanthelasmas (see Fig. 37-17A), a type of xanthoma, are raised, yellowish macules that typically appear around the medial canthus. Involvement can extend to the eyelids or skin immediately below the eye. They occur in patients with FH, familial defective apoB100, or dysbetalipoproteinemia. They occasionally occur in patients with normal cholesterol levels. Xanthelasmas typically regress with cholesterol lowering and may be treated effectively in the setting of normal cholesterol levels with cholesterol-lowering drugs.

Lipemia retinalis (see Fig. 37-17B), a condition in which lipemic blood causes opalescence of retinal arterioles, can be observed during fundoscopic examination. It is typically seen only when the triglyceride levels are 22.6 mmol/L (2000 mg/dL) or higher.

Tendon xanthomas (see Fig. 37-17C and D) are nodular deposits of cholesterol that accumulate in tissue macrophages in the Achilles and other tendons, including the extensor tendons in the hands, knees, and elbows. Tendon

xanthomas are often present in patients with FH or familial defective apo-B100 and sometimes in those with dysbetalipoproteinemia. As discussed earlier, the Achilles tendon should be palpated for assessment of thickness and contour.

Tuberous or tuberoeruptive xanthomas (see Fig. 37-17E) develop in areas that are susceptible to trauma, such as the elbows and knees. They range from pea-sized to lemon-sized and are seen in dysbetalipoproteinemia and FH.

Palmar xanthomas (see Fig. 37-17F) are found in the palmar and digital creases of the hands. This type of xanthoma is almost pathognomonic for high plasma levels of β -VLDL and dysbetalipoproteinemia.

Eruptive xanthomas (see Fig. 37-17G) appear as small, yellowish, round papules that contain a pale center and an erythematous base. Their distribution includes the abdominal wall, back, buttocks, and other pressure contact areas. They are caused by accumulation of triglyceride in dermal histiocytes and typically occur when the plasma triglyceride level is 11.3 to 22.6 mmol/L (1000 to 2000 mg/dL) or higher. They can disappear rapidly with lowering of the plasma triglyceride concentration.

Screening for Secondary Disorders

The history and physical examination should be directed toward uncovering secondary disorders of lipid metabolism and identifying agents that could cause hyperlipidemia. Minimal studies should include fasting blood glucose, glycosylated hemoglobin, renal and hepatic function tests, urinary protein, and thyroid-stimulating hormone.

Measurement of Plasma Lipids

Ideally, plasma lipids should be measured at least twice under fasting steady-state conditions before therapeutic decisions are made (see Table 37-7). Plasma lipids are usually measured after a 12-hour fast to preclude detection of significant elevations in atherogenic remnant lipoproteins. Because cholesterol is a minor component of chylomicrons, total plasma cholesterol can be measured in either a fasting or a nonfasting state. Plasma lipid measurements are usually reliable if done within the first 24 hours after an acute myocardial infarction.^{211,212}

Most clinical laboratories measure plasma levels of total triglycerides, total cholesterol, and HDL-C; the last analysis is performed after apoB-containing lipoproteins are removed from the plasma. The plasma LDL-C concentration is then calculated from these measurements by the Friedewald formula:

$$\text{LDL cholesterol} = \text{total cholesterol} - \text{HDL} - \text{VLDL}$$

where VLDL is calculated as triglycerides divided by 5. This formula assumes that cholesterol content of VLDL is about 20% of the plasma triglyceride level. It is reliable only when triglycerides are 4.5 mmol/L (400 mg/dL) or less. LDL-C concentrations calculated by this formula may be inaccurate in the presence of severe hypertriglyceridemia or when the triglyceride-to-cholesterol ratio of VLDL differs from the usual 4:1 ratio (as occurs in dysbetalipoproteinemia). Specialized laboratories can directly assay different lipoproteins by ultracentrifugation or nuclear magnetic resonance techniques. Direct measurement of LDL-C is also available in many clinical laboratories.

A triglyceride level higher than 11.3 mmol/L (1000 mg/dL) usually signifies the presence of two or more abnormalities of lipid metabolism (e.g., estrogen therapy in the presence of underlying familial hypertriglyceridemia). Elevated plasma triglyceride levels can fluctuate markedly in a single person over short periods. The fluctuation occurs because the LPL-mediated clearance mechanisms for

triglyceride-rich particles become saturated at plasma triglyceride concentrations of approximately 5.6 mmol/L (500 mg/dL), and above this level plasma triglyceride concentrations largely reflect dietary fat intake. Therefore, triglyceride levels can rise precipitously as dietary fat intake increases and can fall rapidly with dietary fat restriction.

As noted earlier, visual inspection of plasma after it has been refrigerated overnight can be helpful. A cream-like layer on the top signifies chylomicrons. A turbid infranant signifies high levels of VLDL. A cream-like top layer and turbid plasma indicates the presence of both chylomicrons and VLDL.

A complete plasma lipid profile (total cholesterol, LDL-C, HDL-C, and triglycerides) should be measured in all adults 20 years of age and older at least once every 5 years.⁹⁷ Triglycerides should be measured in all patients with pancreatitis.

Patient Selection and Treatment Goals

The presence of CHD or a CHD-equivalent (e.g., diabetes mellitus, cerebrovascular disease, peripheral arterial disease, abdominal aortic aneurysm) confers more than 20% risk of a subsequent CHD event within 10 years, and these patients require therapy. Others, especially those with two or more risk factors (see Table 37-6), should calculate the 10-year risk of a future CHD event. A calculator is available on the NCEP web site (<http://hp2010.nhlbi.nih.net/atpiiii/calculator.asp?>). Those whose 10-year risk is greater than 20% are also classified as high-risk, CHD-equivalent patients and should be treated.

Hyperlipidemia treatment in patients with established CHD is considered secondary prevention, whereas treatment in those who do not have known disease is primary prevention. When lipid-lowering therapy for primary prevention should be initiated is an unresolved question. There are no reliable biomarkers or imaging techniques that predict first events in people with dyslipidemia. Studies of high-risk groups for primary prevention have provided some guidance.^{2,207} The JUPITER trial showed a statistically significant reduction in total mortality ($P < .02$) in men aged 50 years and older and women 60 years and older, many of whom would not have fit the NCEP Adult Treatment Panel III guidelines for therapy.¹⁹⁶ The upcoming Adult Treatment Panel IV guidelines may address some of these issues involving drug therapy in primary prevention.

Treatment of hypercholesterolemia in persons older than 85 years is of unclear benefit, but CHD accounts for a high percentage of deaths in this age group, and there are survival benefits of treatment in elderly patients up to the age of 85 years who have known CHD.^{2,207}

Guidelines for treatment of patients with type 2 diabetes mellitus take into account their increased risk of cardiovascular events. The NCEP guidelines define diabetes mellitus as a CHD-equivalent, and treatment goals for lipids in diabetic patients are the same as for patients with established CHD, irrespective of whether the diabetic patient has a history of a prior CHD event.⁹⁷ Patients with established vascular disease and diabetes mellitus are considered to be at very high risk.²⁰⁷

Severe hypertriglyceridemia (>11.3 mmol/L [1000 mg/dL]) should be treated aggressively because pancreatitis associated with these levels can be fatal.

NCEP treatment goals based on LDL-C (and non-HDL-C) and risk assessment are summarized in Table 37-8.^{97,207} Non-HDL-C (total cholesterol minus HDL-C) is a useful measure in those with hypertriglyceridemia because it provides an assessment of potentially atherogenic VLDL particles. Although these guidelines are helpful, many experts

TABLE 37-8

NCEP Adult Treatment Panel III Guidelines for LDL-C Reduction

Risk	Target LDL-C (mg/dL)	Target Non-HDL-C (mg/dL)	LDL-C Threshold for Therapeutic Lifestyle Changes (mg/dL)	LDL-C Threshold for Medical Intervention (mg/dL)
CHD or CHD-equivalent (10-yr risk >20%)	<100 or <70 if at very high risk	<130	≥100	≥100 (<100 optional)
≥2 risk factors (10-yr risk ≤20%)	<130	<160	≥130	10-yr risk score 10-20%: ≥130 (100-129 optional) 10-yr risk <10%: ≥160
0-1 risk factor	<160	<190	≥160	≥190 (160-189 optional)

CHD, coronary heart disease; HDL-C, high-density lipoprotein cholesterol; LDL-C, low-density lipoprotein cholesterol; NCEP, National Cholesterol Education Program.

Adapted from The Expert Panel. Third Report of the National Cholesterol Education Program (NCEP) Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults (Adult Treatment Panel III): Final report. *Circulation*. 2002;106:3143-3421; and Grundy SM, Cleeman JJ, Merz CNB, et al. Implications of recent clinical trials for the National Cholesterol Education Program Adult Treatment Panel III guidelines. *Circulation*. 2004;110:227-239.

recommend that LDL-C be maintained at less than 130 mg/dL regardless of calculated risk.

Lowering triglycerides to less than 4.5 mmol/L (400 mg/dL) reduces the risk of developing pancreatitis. Moderate hypertriglyceridemia (in excess of 150 mg/dL) can be associated with CHD risk in certain circumstances (e.g., dysmetabolic syndrome).

Specific Therapies

Specific therapies include lifestyle changes (diet, weight management, and exercise recommendations) and drug therapy.⁹⁷

Lifestyle Treatment

Therapeutic lifestyle changes including dietary intervention, moderate exercise, and weight loss are first-line therapies for hyperlipidemia and may be sufficient for mild dyslipidemias in low-risk patients. All other treatments should build on therapeutic lifestyle changes. In patients with established CHD, drug therapy should be instituted with diet therapy. Most patients will have a 10% to 15% decrease in LDL-C levels with diet; this may be enough to reach goal levels in some patients and is important in patients for whom the ultimate drop in LDL-C needs to be 30% to 60%. Hypertriglyceridemia often responds to decreased intake of fat, simple sugars, alcohol, and calories. Response to lipid-lowering drugs may be disappointing in patients who do not follow dietary recommendations.

Dietary changes are best when individualized and instituted gradually. Involvement of family members is important, especially if the patient does not purchase or prepare food. The therapeutic diet is shown in Table 37-9. Patients with elevated triglycerides also need to restrict simple sugars and alcohol. The response to very-low-fat diets (i.e., 10% of calories from fat) may be disappointing in patients with impaired glucose tolerance unless the diet is hypocaloric. Nonfat desserts commonly increase calorie intake. Very-high-carbohydrate diets, unless composed of primarily complex carbohydrate, may lead to poor glycemic control and increased triglyceride levels. Patients with the chylomicronemia syndrome may initially require a diet with less than 10% of calories from fat to decrease chylomicron production.

Daily moderate exercise, such as walking, may help reduce triglyceride levels. Exercise may be particularly useful in obese, insulin-resistant patients with high triglyceride levels, low HDL-C, and moderately elevated LDL-C. Weight loss is beneficial, and an exercise program combined with a moderately hypocaloric diet may lead to

significant improvements in lipid levels as well as glucose tolerance. Modest weight loss may improve dyslipidemia as well as glucose tolerance and blood pressure in patients with the dysmetabolic syndrome.

The effects of various types of dietary fat have been studied extensively.¹⁸² Current recommendations are to restrict intake of saturated fats and trans fats and to substitute complex carbohydrates, polyunsaturated fats, and monounsaturated fats.^{97,184,213} Saturated fats elevate plasma cholesterol levels by decreasing receptor-mediated clearance of LDL. High levels of cholesterol intake raise plasma cholesterol by reducing receptor-mediated catabolism of LDL and by increasing LDL synthesis.^{182,183} Trans fats are unsaturated fatty acids with at least one *trans* double bond; they are produced when liquid vegetable oils are partially hydrogenated to produce semisolid fats used in margarines and shortening. Trans fats raise LDL-C and reduce HDL-C and have been implicated in cardiovascular disease.²¹⁴

Fish oils are enriched in eicosapentaenoic (EPA) or docosahexaenoic acid (DHA) (see Table 37-1). Daily doses of 4 g of EPA plus DHA lower VLDL and treat hypertriglyceridemia. Based on the results of both primary- and secondary-prevention studies, persons without known CHD should eat two fish meals weekly, and those with known CHD should take fish oil capsules that provide 1 g/day of EPA plus DHA.²¹⁵

TABLE 37-9

Therapeutic Lifestyle Changes for Reducing Coronary Heart Disease Risk

Therapeutic lifestyle changes diet:

- Saturated fat <7% of total calories
- Polyunsaturated fat ≤10% of total calories
- Monounsaturated fat ≤20% of total calories
- Total fat 25%-35% of total calories
- Carbohydrates (predominantly complex) 50%-60% of total calories
- Fiber 20-30 g/d
- Protein approximately 15% of total calories
- Cholesterol <200 mg/d
- Consider plant stanols/sterols (2 g/d) to enhance LDL-C lowering*

Total calories: Adjust total caloric intake to maintain desirable body weight or prevent weight gain

Physical activity: Include enough moderate exercise to expend at least 200 kcal/d

LDL-C, low-density lipoprotein cholesterol.

*Adapted from Third Report of the National Cholesterol Education Program (NCEP) Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults (Adult Treatment Panel III): Final report. *Circulation*. 2002;106:3143-421.

Other dietary components can influence plasma lipid levels. For example, soluble fibers such as psyllium or oat bran, which can bind bile acids in the gut and promote net cholesterol excretion, decrease LDL-C to a modest extent (about 5% to 10%).^{183,216} Margarines made with sitostanol or sitosterol, plant sterols that inhibit cholesterol absorption, reduce serum cholesterol by about 10%.¹⁸³ The combination of plant sterols, soluble fiber, and restriction of saturated fat and cholesterol can reduce LDL-C levels by about 30%.²¹⁷

Recommendations for management have been developed that use teams including experienced nutritionists and dietitians.²¹⁸

Drug Treatment

Table 37-10 lists drugs that interfere with bile acid absorption from the gut (BAS), inhibit cholesterol synthesis in cells (HMG-CoA reductase inhibitors), or block cholesterol absorption from the gut (ezetimibe). These agents work mainly by inducing LDL-receptor expression in hepatocytes. Niacin, fibrates, and ω -3 fatty acids either inhibit VLDL production or enhance clearance of triglyceride-rich particles.

TABLE 37-10

Drugs Used to Treat Hyperlipidemia

Class and Drugs Available	Dosage	Major Lipoprotein Decreased	Mechanism
Bile Acid Sequestrants			
Cholestyramine	4-12 g bid	LDL	Increase sterol excretion and LDL clearance
Colestipol	5-15 g bid		
Colesevelam	3.75-4.375 g qd		
Nicotinic Acid			
Niacin (crystalline)	1-3 g qd	VLDL (LDL)	Decrease VLDL production
Niaspan	500-2000 mg qd		
Fibric Acid Derivatives			
Gemfibrozil	600 mg bid	VLDL (LDL)	Decrease VLDL production; enhance LPL action
Fenofibrate*	34-200 mg qd		
HMG-CoA Reductase Inhibitors			
Lovastatin	10-80 mg qd	LDL	Decrease cholesterol synthesis; increase LDL receptor-mediated removal of LDL
Pravastatin	10-40 mg qd		
Simvastatin	5-80 mg qd		
Fluvastatin	20-80 mg qd		
Atorvastatin	10-80 mg qd		
Rosuvastatin	5-40 mg qd		
Intestinal Cholesterol Absorption Inhibitor			
Ezetimibe	10 mg qd	LDL	Inhibits cholesterol absorption
Omega-3 Fatty Acids			
Lovaza (1-g capsule contains EPA and DHA)	4 g qd	VLDL	Inhibits VLDL production

*There are several different preparations of fenofibrate with different doses. EPA, highly concentrated ethyl esters of eicosapentaenoic acid; DHA, docosahexaenoic acid; HMG-CoA, 3-hydroxy-3-methylglutaryl coenzyme A; LDL, low-density lipoproteins; VLDL, very-low-density lipoproteins.

The best drugs for lowering LDL-C are the HMG-CoA reductase inhibitors lovastatin, pravastatin, simvastatin, fluvastatin, atorvastatin, and rosuvastatin; the BAS resins cholestyramine, colestipol, and colesevelam; the cholesterol absorption inhibitor ezetimibe; and nicotinic acid (also called niacin). Nicotinic acid, gemfibrozil, and fenofibrate are useful for hypertriglyceridemia. For elevated LDL-C combined with mild to moderate (<500 mg/dL) elevations of triglycerides, the statins, nicotinic acid, fenofibrate, or gemfibrozil may provide acceptable results. Omega-3 fatty acids can also lower triglycerides. In cases of severe hypercholesterolemia (e.g., FH) or when the goal is to attain very low LDL-C (<1.8 mmol/L [70 mg/dL]), combinations of agents may be required.

HMG-CoA Reductase Inhibitors (Statins). Before the introduction of the HMG-CoA reductase inhibitors in 1987, lowering LDL-C was often difficult because of the poor tolerability or insufficient efficacy of available therapies. Large clinical trials using statins in a variety of patients for both primary and secondary prevention of cardiovascular events contributed to evidence-based clinical guidelines.^{2,97}

Inhibition of cholesterol biosynthesis by statins upregulates LDL receptors and enhances clearance of LDL.²¹⁹ Statins also reduce the release of lipoproteins from the liver.^{220,221} At high doses, statins decrease triglyceride levels by enhancing the clearance of VLDL and by decreasing the production of lipoproteins.^{222,223}

Statins are useful in all types of hyperlipidemia in which LDL-C is elevated, but they are less effective in homozygous LDL-receptor deficiency. They are particularly useful for patients with vascular disease and those with very high levels of LDL-C (e.g., FH, combined hyperlipidemia), and they are the drugs of choice for lowering LDL-C as secondary prevention. Several statins are approved for use in children and adolescents who have high or very high LDL-C levels and/or a significant family history of premature coronary artery disease.

Table 37-11 lists expected effects of various statins on LDL-C. They reduce LDL-C by 20% to 60%, increase HDL-C by 2% to 16%, and reduce triglycerides by 7% to 37%, depending on the drug, the dosage, and, in the case of triglycerides, baseline levels.²²⁴ Effects also vary among patients, with greater or lesser degrees of LDL-C reduction even at the same dose. For each statin, doubling of the dose typically produces an additional 6% reduction of LDL-C.²²⁵ LDL-C lowering is seen within 1 to 2 weeks after the start of therapy and is stable in about 4 to 6 weeks. Atorvastatin and rosuvastatin have long half-lives, about 14 hours and 21 hours, respectively. The other statins have half-lives of about 2 to 3 hours. Fluvastatin and lovastatin are available in extended-release preparations. Atorvastatin and fluvastatin have minimal renal clearance and may be more suitable for patients with significant renal insufficiency.

Lovastatin is best given with food, usually with the evening meal, but pravastatin, simvastatin, and fluvastatin can be given without food, preferably in the evening. Atorvastatin, rosuvastatin, and extended-release formulations of statins can be given at any time during the day. Several of the statins are available as generic drugs in the United States. Table 37-12 shows specific features of available statins.

The reductase inhibitors are well tolerated and cause few side effects. The most common side effects include abdominal pain, constipation, flatulence, nausea, headache, fatigue, diarrhea, and muscle complaints. Except for musculoskeletal symptoms, most side effects are infrequent

TABLE 37-11

Typical LDL-C Reductions (% Change from Baseline) by Statin Dose

Treatment	5 mg	10 mg	20 mg	40 mg	80 mg
Rosuvastatin	−40	−46	−52	−55	—
Atorvastatin	—	−37	−43	−48	−51
Simvastatin	−26	−30	−38	−41	−47
Lovastatin	—	−21	−27	−31	−40
Pravastatin	—	−20	−24	−30	−36
Fluvastatin	—	—	−22	−25	−35
Ezetimibe 10 mg plus variable simvastatin	—	−45	−52	−55	−60

LDL-C, low-density lipoprotein cholesterol; —, data not available.

From Hou R, Goldberg AC. Lowering low-density lipoprotein cholesterol: statins, ezetimibe, bile acid sequestrants, and combinations—comparative efficacy and safety. *Endocrinol Metab Clin North Am.* 2009;38:79-97.

and occur in only about 5% of patients. The adverse effects associated with statin use correlate with drug dose.^{192,226,227}

Although liver toxicity is frequently a concern for patients and physicians, it is not common with statin use, and serious hepatotoxicity is extremely rare. Hepatic aminotransferase elevation is usually mild and does not require discontinuation of the statin. It may be dose dependent, as demonstrated in clinical trials that showed rates of persistent elevations of liver aminotransferase greater than 3 times the upper limit of normal occurring in 0.1% to 1.9% of patients, depending on the statin and the dose.²²⁸

Only about 1% of patients have aminotransferase increases to greater than 3 times the upper limit of normal, and the elevation often decreases even if patients continue on the statin.²²⁹ A common cause is hepatic steatosis, which responds to weight loss. Statins should be used cautiously in the presence of liver disease, although

nonalcoholic hepatic steatosis is not a contraindication.²³⁰ Hepatic function tests should be obtained at baseline and at 6 and 12 weeks. If aminotransferases remain greater than 3 times the upper limit of normal, consider changing to a different statin and identify other contributing conditions or drugs. Irreversible liver damage resulting from statins is extremely rare, with a liver failure rate of 1 case per 1 million person-years of use.²³⁰

Muscle-related complaints occur in about 10% of people taking statins. Other disorders must be excluded, such as hypothyroidism, vitamin D deficiency, rheumatologic conditions, and perhaps depression. Inhibition of statin catabolism is associated with increased myopathy risk. Drugs metabolized through the cytochrome P450 (CYP) system, such as ketoconazole, itraconazole, clarithromycin, and erythromycin,²³¹ increase statin plasma levels. Other drugs that increase the risk of statin myopathy include gemfibrozil, cyclosporine, digoxin, verapamil, diltiazem, amiodarone, colchicine, and protease inhibitors.²³² The most serious potential side effect is rhabdomyolysis leading to myoglobinuria and renal failure. Rhabdomyolysis is rare and is more likely in patients with renal insufficiency, advanced age, other comorbidities, or polypharmacy and during perioperative periods.²³³ Routine surveillance of creatine kinase levels is not useful in most patients. Management of dyslipidemia in patients with muscle-related complaints is challenging and may include using a different statin, decreasing the dosing frequency, or resorting to other LDL-lowering drugs.²³²

There is no evidence that statins cause direct adverse effects on renal function beyond that due to rhabdomyolysis.²³⁴ Statins are contraindicated in pregnancy and nursing and in patients with significant hepatic dysfunction.

Bile Acid Sequestrants. The BAS drugs have been used since the 1970s. Cholestyramine, colestipol, and colesvelam are available in the United States. BAS have been shown to reduce cardiovascular events in clinical trials.^{185,235,236}

They work by binding negatively charged bile acids and bile salts in the small intestine to interrupt the enterohepatic circulation of bile acids and increase the conversion of cholesterol into bile.^{237,238} Decreased hepatocyte cholesterol content increases LDL receptors.²³⁹ Cholesterol synthesis also increases, which promotes VLDL secretion. This limits the LDL-lowering effect and raises triglyceride levels.²⁴⁰

BAS reduce LDL-C and total cholesterol; HDL-C may increase modestly.²⁴¹ As monotherapy, BAS lower LDL-C by 5% to 30% in a dose-dependent manner.^{185,242-246} Colesevelam has greater bile acid-binding capacity and affinity than cholestyramine or colestipol and can be used at lower doses.^{241,243} LDL-C reduction is typically 15% at 3.8 g/day (six 625-mg tablets) and 18% at 4.3 g/day (seven 625-mg tablets).^{242,245,247}

BAS are most useful in patients with elevated LDL-C levels as their major lipid abnormality. They can be combined with statins or niacin to achieve greater LDL-C reduction in patients with severe LDL-C elevations, or they can be used alone for initial therapy in low-risk patients and in patients who cannot tolerate statins. BAS have been reported to lower fasting blood glucose and hemoglobin A_{1c} levels in patients with diabetes.²⁴⁸

The BAS are neither absorbed nor metabolized and therefore have essentially no systemic exposure. They are extremely safe and can be used in women not using contraception. Gastrointestinal disturbances are common and include constipation, nausea, bloating, abdominal pain,

TABLE 37-12

Features of Individual Statins

Drug	Pharmacologic Considerations	Safety Issues
Fluvastatin	Synthetic drug; minimal renal excretion	Can interact with warfarin, phenytoin, glyburide, diclofenac, fluconazole, ketoconazole
Pravastatin	Derived from fermentation product of <i>Aspergillus terreus</i> ; dose reduction in renal insufficiency	Drug interaction with cyclosporine
Lovastatin	First statin marketed in U.S.; isolated from a strain of <i>A. terreus</i> ; food intake increases absorption	Interactions with CYP3A4 substrates
Simvastatin	Synthetic derivative of fermentation product of <i>A. terreus</i> ; dose reduction in severe renal insufficiency	Interactions with CYP3A4 substrates
Atorvastatin	Synthetic drug; <2% excreted in urine; half-life 14 hr	Interacts with CYP3A4 substrates; increases digoxin levels
Rosuvastatin	Synthetic compound; active metabolite is formed by CYP2C9	Can increase INR when used with warfarin—monitor INR

CYP2C9 and CYP3A4, cytochrome P450 isoenzymes 2C9 and 3A4; INR, international normalized ratio.

From Hou R, Goldberg AC. Lowering low-density lipoprotein cholesterol: statins, ezetimibe, bile acid sequestrants, and combinations—comparative efficacy and safety. *Endocrinol Metab Clin North Am.* 2009;38:79-97.

flatulence, and aggravation of hemorrhoids. Initiation with low doses, patient education, and use of stool softeners or psyllium can increase compliance. Cholestyramine and colestipol can affect the absorption of a wide variety of drugs. When used with these agents, other drugs should be taken either 1 to 2 hours before or 4 to 6 hours after the BAS. Colesevelam is better tolerated and does not bind most drugs, with the exceptions of verapamil and thyroxine.^{247,249}

These drugs should not be used in patients with severe constipation or bowel or biliary obstruction, nor those taking complicated medical regimens. They worsen hypertriglyceridemia and therefore should not be used in patients with severe hypertriglyceridemia or dysbetalipoproteinemia. Despite a theoretical concern about absorption of fat-soluble vitamins, vitamin K deficiency and bleeding are rare.²⁵⁰

Niacin. Nicotinic acid, or niacin, is a B-complex vitamin that was found to lower plasma cholesterol in humans in 1955. Niacin, either alone or in combination regimens, decreases the rates of cardiovascular events and atherosclerosis.^{186,187,200,204} Its mechanism of action is not completely understood, but it decreases triglyceride synthesis, leading to decreased VLDL secretion.²⁵¹ How niacin elevates HDL is unclear.

Niacin affects multiple lipoproteins and is the most effective drug currently available to raise HDL-C. At doses of 500 to 2000 mg/day, niacin lowers triglycerides by 10% to 30% and increases HDL-C by 10% to 40%. Doses of 1500 to 2000 mg/day decrease LDL-C by 10% to 20%. Niacin also lowers Lp(a) by up to 25%. It is useful for patients with combined hyperlipidemia and low HDL. It is not the best LDL-lowering drug, but it may be helpful when cost is limiting, because crystalline niacin is inexpensive.

Cutaneous flushing, which is most notable with the first doses, is the most common side effect. It occurs 15 to 60 minutes after ingestion, lasts 15 to 30 minutes, and may be related to release of dermal prostaglandin D₂. Ingestion with food and taking aspirin (preferably 325 mg) 30 to 60 minutes in advance of niacin minimizes flushing. Starting low and gradually increasing the dose improves tolerability. Repeated and consistent dosing is associated with tolerance to the flushing syndrome. A severe flush can sometimes be stopped by the ingestion of an 81-mg aspirin tablet dissolved in water.²⁵² Crystalline niacin should always be given with meals. Extended-release niacin (Niaspan) may be better tolerated than crystalline niacin. It is usually initiated with 500 mg at bedtime for 1 month, then titrated over 8 to 12 weeks to the maximum dose of 2000 mg/day. Niaspan can be given with meals if patients awaken with flushing in the middle of the night.²⁵² Alcoholic beverages potentiate flushing.

Liver function tests should be monitored, because hepatotoxicity is the most serious side effect. Because some over-the-counter sustained-release preparations have been associated with liver toxicity, crystalline (non-timed-release) nonprescription preparations should be used, and patients should not change brands after being titrated to high doses.²⁵³ Niaspan, available by prescription, was not associated with significant liver toxicity in clinical trials. Nausea, fatigue, and malaise may be signs of hepatotoxicity.

Worsening of glucose tolerance and hyperuricemia may also occur. Niacin can be used safely in patients with glucose intolerance or diabetes mellitus, and especially in those already being treated with glucose-lowering agents. Initiation of niacin may increase glucose, but glycemic

control usually returns to pretreatment levels.²⁵⁴ Niacin should be used with caution in patients who have a history of gout. It is contraindicated in those with active peptic ulcer disease. Rare side effects include blurred vision and a reversible condition known as cystoid macular edema. Myopathy is rare with niacin alone or in combination with statins.²⁵³

It is useful to check transaminases, glucose, and uric acid at baseline and during dose titration. Patients taking niacin should be monitored at 4- to 6-month intervals for signs of hepatic toxicity. Niacin can be discontinued temporarily if transaminases rise significantly. Retitration is possible once enzyme levels return to normal.

Niacin is contraindicated during pregnancy.

Fibrates. In the Helsinki Heart Study (primary prevention) and the VA HIT (secondary prevention), the use of the fibrate gemfibrozil reduced fatal and nonfatal CHD events and did not increase mortality from noncardiac causes.^{197,198} In the Fenofibrate Intervention and Event Lowering in Diabetes (FIELD) study, fenofibrate (another drug in the same class) decreased cardiac events but not cardiovascular or total mortality in patients with type 2 diabetes.¹⁹⁹

These drugs activate PPAR α (see earlier discussion), which increases fatty acid oxidation, increases LPL, decreases apoCIII, and increases apoAI as well as apoAII, lowering triglycerides (by 30% to 50%) and raising HDL (by 10% to 20% in those with elevated triglycerides).²⁵⁵ Fibrates may lower LDL-C modestly, but they are most commonly used for severe hypertriglyceridemia and combined hyperlipidemia. Fenofibrate may be taken once daily. Gemfibrozil is given twice a day with meals.

Side effects may include gastrointestinal discomfort, rash, and pruritus. The risk of gallstones may be increased. Liver transaminases may increase, particularly with fenofibrate. Their use should be avoided in patients with renal insufficiency, which predisposes to myopathy. The combination of gemfibrozil and most statins is associated with an increased risk of myopathy due to increased statin blood levels.²⁵⁶ Fenofibrate does not interfere with statin metabolism and is preferred in fibrate/statin combination regimens.²⁵⁷ Because of the effects on protein binding, warfarin doses may need to be adjusted when fibrate therapy is started. Fibrates are contraindicated in patients with liver or gallbladder disease. Gemfibrozil may be used beginning in the second trimester in pregnant women with severely elevated triglycerides who are at risk for pancreatitis.

Ezetimibe. Ezetimibe inhibits cholesterol absorption (see earlier discussion). It is mostly used in combination with statins to further lower LDL-C and is being studied for clinical outcomes.

The drug interacts with the NPC1L1 transporter²⁹ to decrease intestinal cholesterol absorption, leading to decreased hepatic cholesterol and increased LDL receptors, clearance of LDL-C from the plasma, and consequent reduction of plasma LDL-C. Ezetimibe undergoes glucuronidation, leading to extensive enterohepatic circulation.

Ezetimibe lowers LDL-C by 14% to 25%,²⁵⁸⁻²⁶⁰ and it is used alone or in combination with statins or other lipid-modifying drugs. It lowers LDL-C by an additional 15% to 20% when combined with any statin at any dose. Ezetimibe can be useful in patients who are intolerant of statins. Absorption is not affected by food.

Side effects include diarrhea and possibly myalgias. Myopathy is rare and is not clearly related to the medication.²⁶¹ Ezetimibe can increase cyclosporine levels. Fibrates

can increase the levels of ezetimibe, a finding with unknown clinical significance.²⁶² Ezetimibe monotherapy does not significantly increase hepatic aminotransferases, but elevations may occur when ezetimibe is combined with a statin. This effect has not been related to any clinical significance.²⁶¹

Ezetimibe is contraindicated in pregnancy and in severe liver dysfunction.

Omega-3 Fatty Acids. Fish-derived ω -3 fatty acids (EPA and DHA) improve plasma lipids and decrease the risk of sudden death through antiarrhythmic effects.²¹⁵ The Japan EPA Lipid Intervention Study (JELIS) showed that combined treatment with a statin plus EPA (1.8 g/day) in patients with CHD significantly reduced major coronary events by 19% compared with a statin alone.²⁶³

Omega-3 fatty acids decrease triglyceride secretion from the liver, through unclear mechanisms.²⁶⁴ EPA and DHA lower triglycerides by 20% to 50% depending on the baseline levels. There is minimal effect on HDL-C. LDL-C may increase as VLDL is converted to LDL. Approximately 3 to 4 g/day of EPA plus DHA is required to lower triglycerides.

Over-the-counter preparations have variable quantities of EPA and DHA. A prescription formulation, Lovaza, contains about 465 mg of EPA and 375 mg of DHA per capsule. As with fibrates, fish oils shift the distribution of LDL toward more buoyant particles and away from small dense particles. Unlike fibrates, EPA and DHA do not affect statin metabolism, and they do not increase the risk of myopathy. Side effects with ω -3 fatty acids include eructation, diarrhea, and abdominal discomfort. There is potential for increased bleeding, but this has not been seen in clinical trials.²⁶⁵

There are probably fewer contaminants such as mercury in fish oils than in some types of fish, and contamination concerns are unwarranted for purified prescription formulations.²⁶⁵

Combination Therapies

Combination therapy is indicated for patients with severe lipid elevations and those who have not reached goals with monotherapy.^{266,267} Patients with FH or familial combined hyperlipidemia are at particularly increased risk and may require LDL-C reductions that cannot be achieved with a single agent. Target LDL-C levels lower than 70 mg/dL can be difficult to achieve with a single drug. Higher statin doses may be associated with increased side effects, particularly myopathy. If the highest tolerated statin dose does not achieve the target LDL-C, adding an agent from a different class may produce the desired result. Statins, ezetimibe, and BAS work through different mechanisms and can be more effective in combination than when used alone. Data on clinical outcomes with combination therapy are limited.

Combination Therapy for Reduction of Low-Density Lipoprotein Cholesterol

Statin Plus Bile Acid Sequestrants. All three BAS drugs have been studied in combination with statins. The decreases in LDL-C range from 24% to 60%.^{241,242,268-271} For example, colesvelam 3.8 g/day plus atorvastatin 10 mg/day lowered LDL by 48%, compared with 53% reduction with atorvastatin 80 mg alone²⁷²; such data are relevant for those who cannot tolerate higher statin doses. Drugs from both classes decrease CHD event rates. Cholestyramine and

colestipol can interfere with the absorption of statins.²⁷¹ Colesevelam does not affect statin absorption.

This combination may not be ideal for patients with high triglycerides but may be useful in type 2 diabetes mellitus because of the reduction in glycemia.²⁴⁸

Statin Plus Ezetimibe. Ezetimibe added to a statin may further reduce LDL-C, by 20% or more,²⁷³⁻²⁷⁵ and reduce triglycerides by 7% to 13%. The combination of rosuvastatin 40 mg plus ezetimibe 10 mg daily lowered LDL-C by 69.8%, allowing 79.6% of a very-high-risk population to reach an LDL-C goal of less than 70 mg/dL.²⁷⁴ Ezetimibe added to a low-dose statin given two to three times per week can improve tolerance. A combination pill containing simvastatin and ezetimibe is available. The most common side effects reflect those of the individual drugs: myalgias, gastrointestinal complaints, and transaminase elevation.

Benefits of ezetimibe and statin-ezetimibe combinations are unproven. Combining ezetimibe with a statin is less effective than combining extended-release niacin with a statin at decreasing carotid intima medial thickness and lowering the incidence of cardiovascular events in patients with coronary disease or a coronary risk equivalent.²⁷⁶

Statin Plus Niacin. Adding niacin to a statin can lower LDL-C by 10% to 20%. This combination decreases LDL-C and triglycerides but also increases HDL-C more than the statin alone.^{203,277,278} The HDL-Atherosclerosis Treatment Study (HATS) showed regression of atherosclerosis by coronary angiography and decreased cardiovascular events in patients treated with simvastatin plus niacin 2000 mg/day.²⁰³ There was a 42% reduction in LDL-C, a 36% decrease in triglycerides, and a 26% increase in HDL-C in patients treated with this combination.

When used in combination with a statin, the maximum dose of niacin should be 2000 mg/day. Fixed-dose combinations of extended-release niacin with lovastatin (Advicor) and simvastatin (Simcor) are available.

Side effects of the combination of niacin with a statin are the same as those with niacin alone. Flushing is the most common reason for drug discontinuation. Myopathy is infrequent when niacin is used at 2000 mg/day or less. Liver enzymes should be monitored periodically. Other common side effects include pruritus (16%), rash (9%), and gastrointestinal side effects (24%).²⁷⁷

Bile Acid Sequestrants Plus Niacin. Before the availability of statins, BAS plus niacin was used to lower LDL-C in high-risk patients. The Cholesterol Lowering Atherosclerosis Study (CLAS) used a combination of colestipol 30 g/day and niacin 4.3 g/day to demonstrate decreased progression and increased regression of coronary artery atherosclerosis.¹⁸⁶ In the Familial Atherosclerosis Treatment Study (FATS), niacin 4 g/day plus colestipol 30 g/day produced greater regression and decreased progression of atherosclerosis as well as fewer clinical events, compared with diet and colestipol.¹⁸⁷ The availability of colesvelam and extended-release niacin has made this combination tolerable and useful for many patients who are unable to use statins.

Ezetimibe Plus Bile Acid Sequestrants. Ezetimibe inhibits cholesterol absorption, and BAS resins enhance cholesterol excretion through conversion to bile acids, so the combination can have additive effects. Colesevelam 3.8 g/day with ezetimibe 10 mg lowered LDL-C by 32%, compared with 21% reduction with ezetimibe monotherapy.²⁷⁹

This combination is useful for those patients who cannot take statins.

Three-Drug Combinations. Three medications can be useful in high-risk patients who have very high levels of LDL-C, such as patients with FH who have baseline LDL-C levels greater than 250 mg/dL. Combinations of a statin plus niacin plus BAS or ezetimibe have been used.

Combination therapy with lovastatin, niacin, and colestipol was compared with diet alone in patients with FH; regression of atherosclerotic lesions occurred in the drug combination group compared with progression in the diet-only group.²⁰²

In a study evaluating the safety and lipid-altering efficacy of the combination of ezetimibe 10 mg, simvastatin 20 mg, and extended-release niacin 2 g per day, LDL-C was reduced by 58% and HDL-C was increased by 30%, with a 42% decrease in triglycerides.²⁸⁰

Four-Drug Combinations. Four drugs may be necessary in patients with FH. Various combinations of a statin, BAS, niacin, and ezetimibe have been used in practice, but clinical studies are lacking.

Combination Therapy for Other Hyperlipidemias

Statin Plus Niacin. Combining a statin and niacin can be particularly effective for lowering LDL-C, raising HDL-C, and lowering triglyceride levels. This combination is useful for patients with combined hyperlipidemia and is becoming a common practice for secondary prevention based on several angiographic and other surrogate end point studies. Clinical outcomes trials with this combination are under way.

Statin plus Fibrate. The combination of a statin plus a fibrate decreases triglycerides and increases HDL-C more than either agent alone and is useful for patients with dysmetabolic syndrome, diabetes, or other forms of mixed dyslipidemia. However, LDL-C levels may not be lower on combination therapy compared with statin alone when patients with high triglyceride levels are treated with the combination.²⁸¹

Risk of myopathy, including rhabdomyolysis, is increased with the combination of most statins with gemfibrozil, because the latter drug interferes with the glucuronidation of statins, leading to higher serum levels of the statin drug.²³¹ Rhabdomyolysis is about 15 times less likely with fenofibrate combined with statins (0.58 per 1 million prescriptions) than with gemfibrozil plus statins (8.6 per 1 million prescriptions).²⁵⁷

Statin-fibrate combinations should be avoided in patients with renal insufficiency, congestive heart failure, severe debility, or other conditions that affect medication clearance. Side effects include mild gastrointestinal discomfort, rash, and pruritus. Mild aminotransferase elevations occur in 5% of the patients and return to normal after drug discontinuation.

Other Combinations. Triple-drug therapy with a statin, ezetimibe, and fenofibrate may be helpful to obtain adequate reductions of both triglyceride levels and LDL-C without using very high statin doses. When triglyceride levels are decreased with a fibrate, LDL-C may be above goal. If triglycerides are well-controlled, BAS could be added. Ezetimibe may lower LDL-C in combination with a fibrate when triglyceride levels are not optimal. Adding ω -3 fatty acids can be helpful if triglycerides are not well controlled. For markedly elevated triglyceride levels, it may be

necessary to combine a fibrate with niacin or with ω -3 fatty acids, or both.

Surgical Treatment and Other Modalities

Partial ileal bypass surgery has been used to reduce lipid levels in patients with severe hypercholesterolemia who cannot tolerate lipid-lowering drugs. This surgical therapy reduces total cholesterol by 20% to 25% and causes regression of atherosclerotic lesions.²⁸² Liver transplantation and portacaval shunting have been used as experimental therapies for homozygous FH. LDL apheresis can be used to lower atherogenic lipids in patients who cannot achieve appropriate lipid lowering despite combination therapy.

Specific Disorders and Therapy

Treatment for Chylomicronemia Syndrome. Patients with chylomicronemia syndrome usually present with acute pancreatitis and severe hypertriglyceridemia. They should be treated with total fat restriction until the triglycerides fall to less than 11.3 mmol/L (1000 mg/dL), after which a fat-restricted diet (e.g., <10% of calories) can be instituted. The goal is to maintain triglycerides lower than 11.3 mmol/L (1000 mg/dL) and preferably lower than 4.5 mmol/L (400 mg/dL). Diet and modification of glycemia, alcohol consumption, or offending medications are useful. A fibrate or niacin is usually required to control triglycerides. Therapy with orlistat may be beneficial.²⁸³

Treatment for Familial Hypercholesterolemia. For patients with FH, additional risk factors, such as smoking, should be addressed. Treatment of heterozygous FH includes a diet low in total and saturated fats and cholesterol, but effects on cholesterol are modest (5% to 15%). Adequate cholesterol lowering can occasionally be achieved with a single potent statin. However, combinations of two or three drugs are often needed. The usual approach includes a potent statin plus either a BAS or ezetimibe or both. The addition of niacin is also helpful. Ileal bypass surgery and LDL apheresis may be considered in patients who cannot tolerate lipid-lowering drugs.

The age at which drug treatment should begin in heterozygous FH is controversial. Many lipidologists tend to start treatment early, during the early stages of lesion development. Statins are approved for the treatment of children with heterozygous FH who are 8 years of age or older. Factors such as the age at onset of coronary disease in parents and grandparents and the presence of other risk factors should be considered.

High doses of atorvastatin or rosuvastatin combined with ezetimibe have been useful in homozygotes but do not provide sufficient lowering of LDL-C. The therapy of choice is LDL apheresis, the selective removal of LDL from the plasma or blood by extracorporeal apheresis combined with LDL adsorption, which is performed every 1 to 3 weeks. Liver transplantation, which provides functional LDL receptors, has also been used. Gene therapy involving delivery of an LDL receptor transgene to liver cells has not been successful.²⁸⁴

Treatment of familial defective apoB100 is similar to that of heterozygous FH and consists of a low-fat, low-cholesterol diet and a combination drug regimen. Family members at risk should also be screened for the dominant mutation.

Treatment for Familial Combined Hyperlipidemia. Weight reduction and dietary treatment can help correct

metabolic abnormalities, such as obesity and insulin resistance, that contribute to the hyperlipidemia. Drug therapy should be directed at the predominant lipid abnormality. Statins are most appropriate for most patients. Fibrates can lower triglycerides and raise HDL-C levels, and they reduce the incidence of coronary events in insulin-resistant hypertriglyceridemic patients with low HDL-C levels. Patients with low HDL-C should be treated with statins. Addition of niacin, ezetimibe, and fibrates can further improve lipid profiles and reduce CHD risk. Because familial combined hyperlipidemia is associated with premature CHD, affected family members should be identified.

Treatment for Dysmetabolic Syndrome. All patients with a diagnosis of the dysmetabolic syndrome should be informed of their increased risk of developing cardiovascular disease and type 2 diabetes mellitus. Weight loss and increased physical activity are the best therapy and may be the only therapy that many of these patients require. All patients should be assessed according to existing guidelines for treatment of high triglyceride levels, low HDL, hypertension, and hyperglycemia. Aspirin therapy is indicated because of the prothrombotic state.²⁸¹

Treatment for Dysbetalipoproteinemia. Because dysbetalipoproteinemia is influenced by coexisting metabolic conditions, a vigorous effort should be made to identify and treat obesity, diabetes mellitus, and hypothyroidism and to reduce alcohol consumption. Lipid abnormalities can often be resolved without the use of drug therapies. Dysbetalipoproteinemia is associated with hypothyroidism in particular and responds dramatically to thyroid hormone replacement therapy. Diet therapy should be aimed at restricting total fat, saturated fat, cholesterol, and, if appropriate, calories. If diet and treatment of coexisting metabolic conditions are unsatisfactory, drug therapy should be initiated using niacin, fibric acid derivatives, or statins, all of which are effective for this disorder. Combination therapy may be required. Because the disorder is associated with premature vascular disease, first-degree relatives should be screened for the presence of apoE2 (see earlier discussion).

Treatment for Elevated Plasma Lipoprotein(a). Only niacin appears to lower plasma Lp(a) levels. However, LDL-C should also be treated appropriately, and risk factors for CHD should be addressed.

Treatment for Low Levels of High-Density Lipoproteins. Patients with familial hypoalphalipoproteinemia can have normal or modestly increased plasma cholesterol but very low HDL-C, resulting in a predisposition to CHD. Such patients can have high ratios of total cholesterol to HDL-C (e.g., >10) despite having a normal plasma cholesterol level. Of the available drugs, niacin results in the largest increase in HDL-C. Fibrates do not increase HDL-C in patients with normal triglycerides. Statins lower total cholesterol and represent the most efficacious way to lower the ratio of total cholesterol to HDL-C. Statins decrease clinical events in patients with low HDL-C.^{97,194}

Management of low HDL levels is best accomplished by employing treatment goals for both LDL-C and non-HDL-C. The NCEP Adult Treatment Panel III guidelines advise additional treatment of low HDL-C in patients who are at their goal for LDL-C and have triglyceride levels greater than 2.25 mmol/L (200 mg/dL). In such patients, a secondary goal is set for non-HDL-C (total cholesterol minus HDL-C). The non-HDL-C goal is the same as the patient's LDL-C goal plus 0.8 mmol/L (30 mg/dL).⁹⁷

Drugs in Development

Drugs in development have the potential for additive effects with statins or other lipid-lowering medications to achieve further reduction of LDL-C or increases in HDL-C.^{285,286}

One interesting class of drugs to lower LDL-C is MTP inhibitors. MTP (see earlier discussion) is required for VLDL assembly. One study of MTP inhibition demonstrated LDL-C reduction of 50% in patients with homozygous FH.²⁸⁷ This drug class increases fat storage in the liver. The extent to which fatty liver develops compared with its cholesterol-lowering effect will likely be the major hurdle in the approval of drugs in this class. Studies in hypercholesterolemic patients are in progress.

Mipomersen is an apoB antisense oligonucleotide agent that is in development for treatment of severe hypercholesterolemia. It binds to the apoB messenger RNA, preventing translation and thereby decreasing apoB levels and LDL-C.²⁸⁸ Human studies in FH are under way.²⁸⁵ Reactions at the injection site are the most common side effect.

CETP inhibitors increase the amount of cholesterol carried in HDL and raise HDL-C by more than 60%.^{289,290} It is uncertain whether this method of raising HDL will translate into a clinical benefit, especially after the use of one such agent, torcetrapib, was found to increase mortality in a clinical trial (see earlier discussion). Whether similar problems will be encountered with other CETP inhibitors is unknown.²⁰⁸

Endocrinology of HIV/AIDS

STEVEN K. GRINSPOON

Human immunodeficiency virus (HIV) disease affects more than 33 million patients worldwide and more than 1 million in the United States. In many parts of the world, for example in sub-Saharan Africa, HIV remains epidemic, with an estimated 22 million people infected and an adult infection rate of 5.0% (data for early 2009 from <http://www.avert.org/worldstats.htm>). In addition, the number of HIV-infected patients is growing rapidly in Asia and other parts of the world.

Endocrine dysfunction is common among HIV-infected patients and patients with acquired immunodeficiency syndrome (AIDS). Adrenal, gonadal, thyroid, bone, and metabolic abnormalities have all been reported. HIV itself, related infectious organisms, cytokines, and antiretroviral medications may all affect endocrine function. Endocrine disorders in HIV disease, such as hypogonadism, adrenal insufficiency, diabetes, and bone loss, can cause significant morbidity and are important to diagnose. Furthermore, treatment of these disorders may improve quality of life and long-term mortality through effects on critical metabolic and body composition parameters, including loss of muscle mass (sarcopenia) in AIDS wasting and fat redistribution (loss of peripheral and abdominal subcutaneous fat with relative or absolute gains in central (visceral) adiposity in some patients). However, diagnosis and treatment can be difficult because of varying nutritional

conditions and effects of the varied medications used to treat HIV disease.

Because the success of antiretroviral medications has allowed HIV-infected patients to live longer, adverse effects of these very medications have resulted in increased cardiovascular risk and metabolic changes that require intervention and long-term management by the endocrine specialist. This chapter reviews the prevalence, mechanisms, and optimal treatment strategies for endocrine abnormalities in HIV-infected patients.

ADRENAL FUNCTION

Adrenal dysfunction may be suspected in the patient with advanced HIV disease because of fatigue, hyponatremia, and other features of adrenal insufficiency. Although clinical adrenal dysfunction is relatively rare among patients with AIDS, subtle impairments in adrenal reserve may be seen in this population. Adrenal dysfunction most often is caused by destruction of adrenal tissue by cytomegalovirus (CMV) in patients with advanced HIV disease, but it may also be caused by medications, hypothalamic/pituitary disease due to opportunistic infection, idiopathic inflammation or tissue destruction, and, in rare cases, cortisol resistance. In addition, some features of Cushing's

syndrome may be seen among HIV-infected patients with fat redistribution, although true Cushing's disease is rare.

Adrenal Insufficiency

Biochemical evidence of adrenal insufficiency is relatively common among hospitalized AIDS patients: 17% of 74 hospitalized AIDS patients screened by cosyntropin testing demonstrated inadequate adrenal stimulation (cortisol level at 1 hour $<18 \mu\text{g/dL}$) in an early study. In contrast, fewer patients (4%) demonstrated clinical symptoms of adrenal insufficiency.¹ Among those patients with clinical symptoms and signs of adrenal insufficiency, including hyponatremia, a higher percentage (up to 30%) may demonstrate inadequate testing with cosyntropin.²

Adrenal insufficiency occurring in the context of advanced HIV disease is most often caused by tissue destruction of the adrenal glands from opportunistic infections. CMV adrenalitis is the most common etiology and is seen in approximately 40% to 90% of patients with CMV infection at autopsy. However, adrenocortical destruction caused by CMV is usually less than 50% in extent and therefore is unlikely to cause adrenal insufficiency.³ CMV disease is rare in patients with well-preserved immune function who are receiving newer, potent antiretroviral therapies (ART).

Other organisms and processes that have been associated with adrenal destruction in HIV disease include *Mycobacterium tuberculosis*, *Mycobacterium avium-intracellulare* (MAI), *Cryptococcus*, and hemorrhage. Additionally, pituitary/hypothalamic destruction resulting in secondary adrenal insufficiency may be caused in rare instances by opportunistic infection (e.g., toxoplasmosis, *Cryptococcus*, CMV). Idiopathic adenohypophyseal necrosis is also observed in a minority of patients, approximately 10% at autopsy, and may be related to a direct effect of HIV.⁴

Impaired Adrenal Reserve

Longitudinal evaluation of adrenal function in HIV-infected patients suggests that impaired adrenal reserve may be common. One study found normal cortisol but reduced aldosterone and dehydroepiandrosterone (DHEA) responses to adrenocorticotrophic hormone (ACTH), particularly among patients with advanced HIV disease. Over time, ACTH levels increased, suggesting impaired adrenal reserve and subclinical adrenal dysfunction.⁵ However, the utility of glucocorticoid treatment in patients with slightly increased ACTH levels but normal cortisol response to cosyntropin testing has not been demonstrated.

Glucocorticoid Excess: Adrenal Shunting and Cortisol Resistance

Increased cortisol levels may also be seen in HIV-infected patients. More commonly, increased cortisol levels are seen as a stress response, in association with low weight or increasing degree of illness. Intra-adrenal shunting toward cortisol synthesis, potentially as a result of 17,20-lyase dysfunction, has been suggested by studies demonstrating a reduced DHEA-to-cortisol ratio on cosyntropin testing.⁶

Cytokine modulation of the hypothalamic-pituitary-adrenal (HPA) axis may also contribute to increased cortisol levels. Interleukin-1 (IL-1), which is produced in the median eminence, has been shown to increase corticotropin-releasing hormone (CRH) and ACTH secretion in vitro and in animal studies. Increased IL-1 secretion from infected monocytes in the median eminence is another possible

cause of increased cortisol secretion in HIV-infected patients. Glucocorticoid resistance has also been shown in rare patients with advanced HIV disease who demonstrate Addisonian symptoms, including hyperpigmentation, in the setting of hypercortisolism and increased ACTH.

Medication Effects

Medications may contribute to adrenal insufficiency in HIV patients (Table 38-1). Ketoconazole, an antifungal agent, inhibits the cytochrome P450 (CYP) side-chain cleavage enzyme and 11-hydroxylase. These effects are not generally seen with fluconazole, itraconazole, or more recently introduced imidazole derivatives. Phenytoin, opiates, and rifampin, among other drugs, affect cortisol metabolism. Adrenal insufficiency may be precipitated by the use of rifampin for treatment of tuberculosis in patients with reduced adrenal reserve.

Megestrol acetate, a potent synthetic progestational derivative, has glucocorticoid properties and decreases ACTH. Abrupt withdrawal of megestrol acetate may precipitate adrenal insufficiency, and patients should be tested for adrenal insufficiency and receive physiologic glucocorticoid administration as needed after megestrol withdrawal. In addition, megestrol acetate can decrease gonadal function, which should also be monitored during and after therapy.

Cases of Cushing's syndrome have been described with the concomitant use of fluticasone and ritonavir, via inhibition of CYP3A4, resulting in symptoms of severe cortisol excess and also severe adrenal insufficiency with discontinuation of fluticasone.⁷ Such patients may have very low measured cortisol and ACTH levels, despite symptoms of hypercortisolemia, during fluticasone treatment. Long-term physiologic steroid replacement is necessary until the HPA axis recovers. Rare case reports of interactions between ritonavir and budesonide⁷ or ritonavir and intra-articular triamcinolone have also been reported.^{7a}

Clinical Assessment

HIV-infected patients with symptoms of adrenal insufficiency, particularly those with hyponatremia and risk factors for adrenal insufficiency (e.g., known disseminated CMV infection, recent use of megestrol acetate), should be evaluated. Evaluation of the cortisol axis should proceed as in other patients with suspected adrenal dysfunction.

Cosyntropin testing is usually an adequate first step, except in those patients with suspected hypothalamic or pituitary insufficiency of recent onset. In such patients, use of morning cortisol levels, metyrapone, or insulin tolerance testing may be necessary, if there are no contraindications. After adrenal insufficiency is documented, determination of ACTH concentrations and appropriate imaging are used to localize the defect. In patients with clinical symptoms of adrenal insufficiency and elevated cortisol levels, cortisol resistance may be present and the diagnosis may be made by glucocorticoid receptor studies in blood monocytes.

GONADAL FUNCTION

Male

Gonadal dysfunction is common among HIV-infected men. Initial studies indicated biochemical hypogonadism in approximately 50% of men with AIDS in association with increased disease severity. More recent studies,

TABLE 38-1

Endocrine Effects and Metabolism of Approved Antiretroviral Agents and Other Medications Used in Care of HIV-Infected Patients*

Medication	Relevant Endocrine Effects	Site of Metabolism	Method of Metabolism
Protease Inhibitors			
Amprenavir	Hyperglycemia, fat redistribution, hypertriglyceridemia, hypercholesterolemia	Liver	CYP3A4
Atazanavir	Lactic acidosis in combination with didanosine; only minimal effects on glucose and lipid levels	Liver	CYP3A
Darunavir	Hypercholesterolemia, hyperglycemia, hypertriglyceridemia, increased amylase and lipase levels	Liver	CYP3A
Fosamprenavir	Diabetes mellitus, hyperglycemia, fat redistribution, increased serum lipase, hypertriglyceridemia	Liver	CYP3A4
Indinavir	Hyperlipidemia, fat redistribution, diabetes mellitus, hyperglycemia	Liver	CYP3A4
Lopinavir/ Ritonavir	Diabetes mellitus, fat redistribution, hypercholesterolemia, hypertriglyceridemia	Liver	CYP3A4
Nelfinavir	Hyperlipidemia, hyperglycemia, diabetes mellitus, fat redistribution, metabolic acidosis	Liver	CYP3A4, CYP2C19, CYP2C9, CYP2D6
Ritonavir	Diabetes mellitus, fat redistribution, hypercholesterolemia, hypertriglyceridemia, symptoms of cortisol excess when used with fluticasone	Liver	CYP3A4, CYP2D6
Saquinavir	Diabetes mellitus, hyperlipidemia, gynecomastia	Liver	CYP3A4
Tipranavir	Hyperglycemia, hypercholesterolemia, hypertriglyceridemia	Liver	CYP3A4
Nucleoside Reverse Transcriptase Inhibitors			
Abacavir	Hyperglycemia, fat redistribution, lactic acidosis	Liver	Alcohol dehydrogenase, glucuronyl transferase
Didanosine	Lactic acidosis, hyperglycemia, hypocalcemia, hypomagnesemia, hypokalemia, hyperuricemia, gynecomastia, fat redistribution, hypertriglyceridemia		Purine metabolism pathway
Emtricitabine	Lactic acidosis, fat redistribution	Liver	Sulfoxide and glucuronide metabolites
Lamivudine	Fat redistribution, hyperglycemia, lactic acidosis	Kidney	Trans-sulfoxide metabolite
Stavudine	Diabetes mellitus, fat redistribution (particularly associated with subcutaneous fat loss), lactic acidosis, mtDNA depletion, possibly gynecomastia	Liver; kidney	Unknown
Zidovudine	Lactic acidosis, fat redistribution, mtDNA depletion, gynecomastia	Liver	Metabolized to G-ZDV
Nucleotide Reverse Transcriptase Inhibitors			
Tenofovir, disoproxil, fumarate	Fat redistribution, hypophosphatemia	Plasma	Esterases
Non-Nucleoside Reverse Transcriptase Inhibitors			
Delavirdine	Fat redistribution	Liver	CYP3A, CYP2D6, CYP2C9, CYP2C19
Efavirenz	Fat redistribution, increased cholesterol and HDL, hypertriglyceridemia, hyperglycemia, vitamin D deficiency	Liver	CYP3A4, CYP2B6
Etravirine	Possible hyperglycemia, possible hyperlipidemia	Liver	CYP3A4, CYP2C9, CYP2C19
Nevirapine	Increased cholesterol and HDL, fat redistribution	Liver	CYP3A4, CYP2B6
Entry Inhibitors			
Enfuvirtide	No significant effects on glucose and lipid levels	Liver	Hydrolysis
Maraviroc	None known	Liver	CYP450
Integrase Inhibitor			
Raltegravir	Hyperglycemia	Liver	Uridine diphosphate glucuronosyltransferase-mediated glucuronidation
Additional Medications			
Foscarnet	Hyperphosphatemia and hypophosphatemia; hypocalcemia, hypokalemia, hypomagnesemia	None	None
Ketoconazole	Acute intermittent porphyria, gynecomastia, hypogonadism, adrenal insufficiency, reduced 1,25-dihydroxyvitamin D	Liver	Oxidation, dealkylation, hydroxylation
Megestrol acetate	Cushing's syndrome, hypercalcemia, hyperglycemia, adrenal insufficiency, weight gain, hypogonadism	Liver	Inactivation
Pentamidine	Ketoacidosis, hypocalcemia, hyperkalemia, hypomagnesemia, hyperglycemia	None	None
Phenytoin	Acute intermittent porphyria, vitamin D deficiency, gynecomastia, hyperglycemia, hyperprolactinemia, hypoproteinemia, hyperlipidemia, reduced T ₄	Liver	Hydroxylation
Rifampicin	Acute intermittent porphyria, hyperglycemia, reduced T ₄ , adrenal insufficiency	Liver	Deacetylation
Trimethoprim	Acute intermittent porphyria, decreased uric acid, hyperkalemia, hyponatremia	Liver	Oxidation, hydroxylation, demethylation, carbonylation, conjugation

*For a complete list of side effects and method of metabolism, consult the *Physician's Desk Reference*.

CYP, cytochrome P450 isoenzyme; G-ZDV, zidovudine glucuronide; HDL, high-density lipoprotein cholesterol; mtDNA, mitochondrial DNA; T₄, thyroxine.

performed in the current era of potent antiretroviral treatment, suggested a wide prevalence range, from 6% to 70%,^{8,9} most likely due to differences in assays used and timing of testing during the day. Among HIV-infected men with low weight, hypogonadism was seen in 20%.¹⁰ The mechanisms of hypogonadism in HIV-infected patients may relate to severe illness or to effects of undernutrition on gonadotropin secretion, medication effects, or, more rarely, tissue destruction from opportunistic infections.

Most often, hypogonadism is secondary in nature, with low or inappropriately normal gonadotropin levels; this was the case in 91% of patients with reduced free testosterone levels during initiation of highly active antiretroviral therapy (HAART) in the Swiss HIV Cohort study.⁹ Primary hypogonadism is seen less often and may be caused by cytokine effects on the testes, including effects of tumor necrosis factor (TNF), which inhibits steroidogenesis via effects on the side-chain cleavage enzyme, and of IL-1, which inhibits Leydig cell steroidogenesis and binding of luteinizing hormone to the Leydig cell. Opportunistic infections of the testes have rarely been reported, but up to 25% of HIV-infected patients with AIDS will demonstrate testicular involvement in the setting of widespread opportunistic infection or systemic neoplasms, including CMV, toxoplasmosis, Kaposi's sarcoma, and testicular lymphoma.

In addition, a number of medications can affect the hypothalamic-pituitary-gonadal (HPG) axis. Ketoconazole inhibits side-chain cleavage enzyme and other critical enzymes in testicular steroidogenesis. Megestrol acetate is used to increase appetite, but as a synthetic progestational agent it suppresses gonadotropin secretion and results in hypogonadism. Opiate therapy affects secretion of gonadotropin-releasing hormone and may result in hypogonadotropic hypogonadism (see Table 38-1).

More recently, increased prolactin levels and gynecomastia were demonstrated among HIV-infected patients. In a case-control study, gynecomastia was seen in 1.8% of 2275 consecutively screened HIV-infected patients and was associated with hypogonadism, hepatitis C infection, and the degree of lipotrophy (subcutaneous fat loss associated with potent ART). Levels of thyroid-stimulating hormone (TSH) were increased, although the proportion of patients with hypothyroidism was not different from normal.¹¹ Hyperprolactinemia was reported in 21% of HIV-infected men with stable HIV disease and was significantly associated with opioid use and increased CD4 count, but not with changes in body composition or gynecomastia.¹² Increased prolactin levels in association with galactorrhea have also been described among patients treated with protease inhibitors (PIs). The mechanism of this effect is unclear and may relate to a direct stimulation of prolactin secretion by specific PIs or effects on the P450 system to potentiate the dopamine antagonistic effect of other drugs.¹³ Dopamine agonists should be used cautiously in HIV-infected men who are receiving PIs because of the potential for interactions.

Levels of sex hormone-binding globulin are increased in 25% of HIV-infected patients.¹⁰ Therefore, use of bioavailable or free testosterone assays is recommended to diagnose hypogonadism, because total testosterone assays may underestimate the prevalence of true hypogonadism in this population. For example, hypogonadism was diagnosed by measurement of low levels of free testosterone in 49% of patients but in only 26% by measurement of low levels of total testosterone in an early study of HIV-infected men with weight loss.¹⁴

Decreased gonadal function is associated with sarcopenia and reduced strength in HIV-infected men. Treatment with

physiologic testosterone replacement results in increased lean body mass, improved quality of life, and reduction in indices of depression in HIV-infected men with hypogonadism and AIDS wasting (see "[The AIDS Wasting Syndrome](#)"). Sustained increases in lean body mass of almost 8% (or 3.7 kg) were demonstrated with 1 year of intramuscular testosterone treatment.¹⁵ Less severe fluctuations and more consistent improvement in quality of life were shown with transdermal gel preparations than with intramuscular dosing in hypogonadal HIV-infected men.¹⁶ Safety assessment should include monitoring of prostate-specific antigen, as is generally recommended for older men receiving testosterone administration. In patients with resolution of acute or chronic illness, retesting of gonadal function by measurement of an early-morning bioavailable testosterone level is recommended, because endogenous function may return with improved health.

No clear benefit has been demonstrated for combined use of testosterone and anabolic steroids for the treatment of hypogonadism in HIV-infected men. DHEA may be useful to improve mood and depression among HIV-infected patients with subsyndromal depression and dysthymia,¹⁷ but the use of DHEA has not been standardized, particularly with respect to dose, duration of treatment, and clinical end points, and remains investigational.

Female

Amenorrhea is seen in approximately 25% of HIV-infected women and may be caused by reduction of gonadotropin production associated with the stress of illness. In contrast, anovulation is seen in up to 50% of HIV-infected women in association with reduced CD4 counts. Changes in menstrual function are three times as likely in anovulatory HIV-infected women compared with normally ovulating patients. Early menopause has been reported in up to 8% of HIV-infected women.¹⁸

Androgen levels are often reduced in HIV-infected women. In one study, more than 50% of HIV-infected women with significant weight loss, and more than one third of those without weight loss, had androgen levels (assessed with the use of a free testosterone assay) that were reduced below those in age-matched healthy women.¹⁹ The mechanisms of androgen deficiency in HIV disease may be related in part to intra-adrenal shunting toward cortisol production and away from androgen production, particularly in women with significant weight loss (see "[Adrenal Function](#)").⁶

A number of studies have examined androgen administration in HIV-infected women. These studies have investigated the use of a transdermal testosterone patch designed to deliver low, physiologic doses of 150 to 300 µg/day. Among studies using the 150 µg/day dose, functional capacity and strength significantly improved over 6 months, with a trend toward increased lean body mass. Hirsutism was not seen, and virilization did not occur. A 6-month study using a larger dose of 300 µg/day by transdermal administration in normal-weight HIV-infected women did not show an increase in weight or lean body mass over 6 months, but the drug was well tolerated.²⁰ In contrast, in an 18-month randomized, placebo-controlled study conducted among relatively androgen-deficient HIV-infected women 300 µg/day of testosterone increased lean body mass, increased bone density at the hip, and improved depression indices without aggravation of lipid or glucose parameters (Fig. 38-1).²¹

Studies using nandrolone and other anabolic steroids demonstrated significant increases in lean body mass but

Figure 38-1 Change in hip bone mineral density (BMD) over 18 months in response to testosterone versus placebo ($P = .02$ for change between groups). (Data from Dolan Looby SE, Collins M, Lee H, et al. Effects of long-term testosterone administration in HIV-infected women: a randomized, placebo-controlled trial. *AIDS*. 2009; 23:951-959, with permission.)

reductions in high-density lipoprotein (HDL) and other side effects. Preliminary studies have investigated the effects of DHEA on androgen levels in HIV-infected premenopausal women, but the clinical utility of this strategy remains unknown.

THYROID FUNCTION

Altered thyroid function test results are common in HIV-infected patients. Levels of thyroid-binding globulin (TBG) are increased in HIV-infected patients and correlate inversely with CD4 counts.²² Abnormal thyroid function test results may be caused by the stress of illness in patients with advanced disease or concomitant morbidities, as in other patients with “euthyroid sick syndrome.” However, among adults, some studies have shown that levels of reverse triiodothyronine (rT₃) do not rise in association with decreasing T₃ levels, as would be expected in nonthyroidal illness.² Patients with progressive HIV disease therefore exhibit decreased T₃ levels, increased TBG, and decreased rT₃ levels with increasing illness.

In addition to the euthyroid sick syndrome, large screening studies have demonstrated an increased prevalence of primary hypothyroidism in HIV-infected patients. Among 350 patients studied in France, 2.6% had clinically evident hypothyroidism, 6.6% had subclinical hypothyroidism based on increased TSH levels but normal levels of free thyroxine (T₄), and 6.8% demonstrated low free T₄ levels. The prevalence of subclinical hypothyroidism was higher in men than in women. Use of stavudine and low CD4 counts were predictive of thyroid disease in multivariate modeling.²³ In a Spanish cohort, free T₄ was found to be below normal in only 1.3% of patients, and low free T₄ was shown to correlate with low CD4 counts. Increased TSH with a normal level of free T₄ was found in 3.5% of patients, but no relationship with specific antiviral drugs was found.²⁴ Subclinical hypothyroidism is therefore not uncommon among adult HIV-infected patients and is seen most often in the context of low CD4 counts.

Hypothyroidism in HIV-infected patients is not often seen in association with anti-thyroid antibodies, and the etiology remains unclear.^{25,26} Studies have investigated the prevalence of thyroid dysfunction in the current era of HAART. In one study of 1565 HIV-infected patients, the prevalence of overt hypothyroidism was 2.5% and that of overt hyperthyroidism was 1%. Higher percentages of

patients demonstrated subclinical hypothyroidism (4%) or nonthyroidal illness (17%). Conversely, 76% of patients had normal thyroid function tests. HIV therapy and specific antiretroviral medications were not associated with thyroid dysfunction.²⁷ Among 2437 HIV-infected patients, Nelson and associates demonstrated that the prevalence rates of hyperthyroidism and hypothyroidism were each 1%.²⁸ Use of specific antiretroviral agents, including PIs and efavirenz, were associated with thyroid dysfunction.

Increased TSH was demonstrated in young children with an average age of 1.5 years and failure to thrive. T₄ levels were normal, but thyrotropin-releasing hormone testing showed exaggerated TSH responses, and growth rates increased in response to thyroid hormone.²⁹ Fundaro and colleagues demonstrated increased anti-thyroglobulin antibodies in 34% of symptomatic HIV-infected children.³⁰ Increased TSH levels were found in 28% of HIV-infected children, particularly those with severe immunosuppression. In contrast, a larger study of perinatally infected children demonstrated reduced levels of total T₃, total T₄, and free T₄ and increased rT₃, TBG, and TSH, with negative autoantibodies, suggesting a euthyroid sick pattern, particularly in those with severe immunosuppression. HIV-infected children with failure to thrive should be screened for true hypothyroidism, but more often the thyroid function tests will reflect nonthyroidal illness and the severity of immune compromise.³¹

Thyroid dysfunction with an immune reconstitution syndrome has been described. The autoimmune thyroid disease occurred in association with use of potent ART and improved immune function, typically 12 to 36 months after ART was initiated.³² Graves' disease was most often reported in this context. The estimated prevalence for immune reconstitution thyroid disease with initiation of HAART was 3% for women and 0.2% for men.³³ Graves' disease has also been described after IL-2 therapy in HIV-infected patients.³⁴

In addition to autoimmune etiologies, thyroid disease related to anatomic replacement and infection of the thyroid has been reported in HIV-infected patients. *Pneumocystis* thyroiditis was reported to cause a painful thyroiditis-like picture, with hyperthyroidism followed by hypothyroidism, decreased uptake on scanning, and a firm, tender gland. *Pneumocystis* thyroiditis may result from the increased use of inhaled pentamidine, which is associated with extrapulmonary *Pneumocystis* infections.

CMV, MAI, *Cryptococcus*, and Kaposi's sarcoma have been demonstrated in the thyroid on autopsy but have not been related to clinical thyroid disease in patients with AIDS. Clinically apparent thyroidal abscesses caused by *Aspergillus* and *Rhodococcus equi* have been reported. Hypothalamic/pituitary replacement by opportunistic infections such as toxoplasmosis and CMV has also been reported to cause secondary hypothyroidism.

Medications may affect thyroid function. Rifampin influences hepatic clearance of T₄, and interferon is associated with an increased incidence of autoimmune hypothyroidism.

FLUID BALANCE AND ELECTROLYTES

Disorders of fluid balance and electrolytes are common among patients with AIDS. Hyponatremia may be seen in more than 50% of patients and is most often related to the syndrome of inappropriate secretion of antidiuretic hormone (SIADH). Hyperkalemia is also frequently reported and may be seen in association with various drugs, such as

trimethoprim. More rarely, hyperkalemia may be associated with adrenal insufficiency.

Sodium

Hyponatremia (<130 mmol/L) is seen in 40% to 60% of hospitalized patients with AIDS and in 20% of outpatients. SIADH (i.e., euvolemic with low levels of serum sodium and inappropriately elevated urine osmolality) is seen in 23% to 47% of hyponatremic patients. SIADH may be caused by various infections and tumors; if severe, it is treated with fluid restriction and hypertonic saline.

Adrenal insufficiency is documented in 30% of volume-depleted, hyponatremic HIV-infected patients.³⁵ Volume depletion (diarrhea, vomiting) with excessive free water and impaired water clearance (HIV nephropathy) may cause hyponatremia among ill HIV-infected patients, especially those who are hospitalized. Volume repletion is the treatment.

Hyporeninemic hypoaldosteronism,³⁶ more typically associated with hyperkalemia, may be another cause of hyponatremia. Treatment is with mineralocorticoids. The use of medications such as vidarabine, miconazole, and pentamidine is associated with hyponatremia of unknown etiology. Hypernatremia may be caused by foscarnet-induced nephrogenic diabetes insipidus.

Potassium

Hyperkalemia occurs in 20% to 53% of AIDS patients taking trimethoprim because of structural similarities to amiloride and inhibition of tubular potassium excretion.³⁷ Other potential etiologies include pentamidine-associated tubular nephropathy, HIV nephropathy (glomerular sclerosis), primary adrenal insufficiency, and, rarely, hyporeninemic hypoaldosteronism. Physiologic studies investigating potassium balance in HIV-infected patients also suggest an inadequate aldosterone response to hyperkalemia.

A Fanconi-like syndrome with tubular dysfunction, phosphate wasting, and hypokalemia has been described in patients receiving tenofovir and, more rarely, in those using adefovir, cidofovir, or didanosine.³⁸

BONE

Bone Loss: Prevalence, Etiologic Factors, and Treatment Strategies

Reduced bone density is common among HIV-infected patients. Fairfield and colleagues demonstrated reduced bone density at the hip and spine in men with AIDS and weight loss.³⁹ Studies during the HAART era in patients without significant weight loss also demonstrated reduced bone density. Tebas and associates demonstrated a significant reduction in lumbar spine bone density among HIV-infected men receiving combined ART as determined by dual-energy X-ray absorptiometry (DEXA).⁴⁰ Osteoporosis, osteopenia, or both were seen in 73% of HIV-infected patients but only 30% of HIV-negative patients of similar age. The study suggested that use of PI therapy was associated with reduced bone density. In contrast, Mondy and coworkers showed a 46% prevalence of osteopenia or osteoporosis in a primarily (86%) male population in whom traditional risk factors including low weight, smoking, and steroid use were associated with bone loss.⁴¹ Duration of HAART, but not use of specific PIs, was associated with bone loss.⁴¹ In a meta-analysis including 884 HIV-infected patients, HIV-infected patients demonstrated a 3.7-fold increased risk for osteoporosis (Fig. 38-2).⁴² Patients receiving ART had a 2.5-fold increased risk of osteopenia and a 2.4-fold increased risk of osteoporosis, compared with patients naïve to ART. Use of a PI was associated with increased relative risk of 1.5 for osteopenia and 1.6 for osteoporosis relative to non-PI-treated patients.⁴²

Among studies performed specifically in women, osteopenia of the hip or spine was demonstrated in more than 50% of consecutively screened outpatients and was 2.4 times as likely in HIV-infected women compared with control subjects matched for age and body mass index (BMI). Low bone density was associated with low weight and other nutritional factors.⁴³ Markers of bone resorption were increased, but there was no association with specific PI use. Reduced lumbar spine bone density was associated with increased follicle-stimulating hormone

Figure 38-2 Odds of osteoporosis (T-score ≤ -2.5) in HIV-infected patients receiving antiretroviral therapy compared with antiretroviral-naïve patients. CI, confidence interval. (Data from Brown TT, Qaqish RB. Antiretroviral therapy and the prevalence of osteopenia and osteoporosis: a meta-analytic review. *AIDS*. 2006;20:2165-2174, with permission.)

levels, suggesting that relative estrogen deficiency may be contributing to bone loss among premenopausal HIV-infected women. Relative androgen deficiency was also associated with bone loss.⁴⁴ Significant bone loss has also been shown among postmenopausal HIV-infected women, with time since menopause and traditional risk factors most significantly associated with bone loss.

Studies in HIV-infected patients receiving HAART have investigated markers of bone resorption and formation and found evidence of increased bone turnover.⁴⁵ Tebas and colleagues evaluated serum and urine bone markers in 73 HIV-positive patients receiving PI therapy.⁴⁰ Increased serum bone alkaline phosphatase and urine N-telopeptides were found to be inversely correlated with bone mineral density T- and Z-scores as measured by DEXA, suggesting an increased rate of bone turnover among HIV-infected patients receiving PI therapy.⁴⁰ In contrast, histomorphometric studies performed before the current era of potent

ART showed reduced bone turnover in association with increased disease severity.^{46,47}

A number of studies have examined fracture rates among HIV-infected patients. In a large data registry study, fracture rates were increased at the spine and wrist among HIV-infected women and at the spine, hip, and wrist among HIV-infected men compared with non-HIV-infected men. The overall fracture prevalence was 2.87 per 100 persons among HIV-infected patients and 1.77 per 100 among HIV-negative patients, and the difference appeared to increase with age (Fig. 38-3).⁴⁸ In a study limited to women, lifetime fragility fractures were significantly more common in HIV-infected versus non-HIV-infected women (odds ratio, 1.7; 95% confidence interval [CI], 1.1 to 2.6).⁴⁹ Among men, Arnsten and coworkers demonstrated that incident fracture rates increased among those with normal bone density, osteopenia, and osteoporosis, from 1.4 to 3.6 to 6.5 per 100 person-years, respectively ($P < .001$).⁵⁰

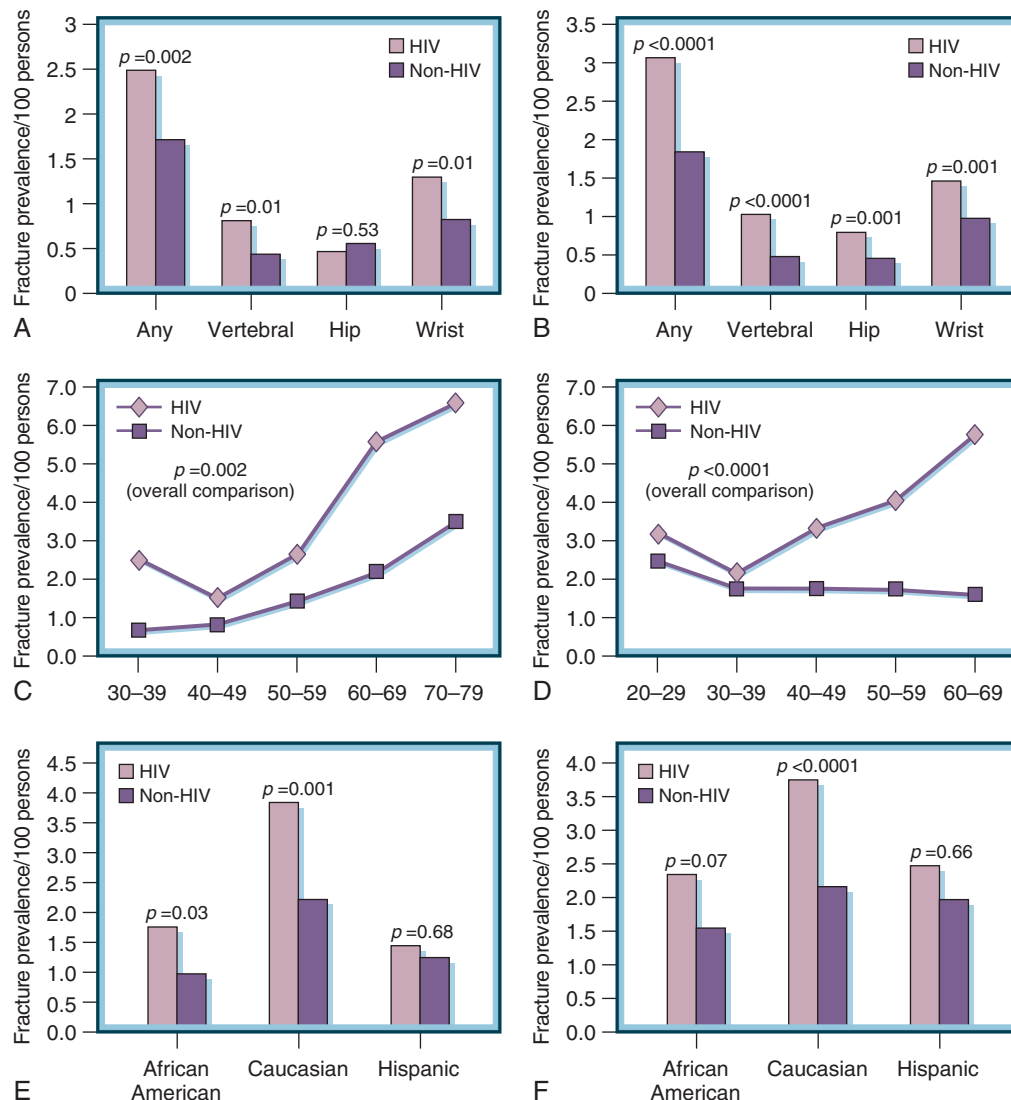

Figure 38-3 Fracture prevalence in HIV-infected and non-HIV-infected patients by gender, site of fracture, age group, and race. Data for female patients are shown in panels A, C, and E, and data for male patients in panels B, D, and F. A and B, Fracture prevalence and P values according to gender and site of fracture. C and D, Fracture prevalence according to gender and age group. The P values are for the comparison of overall fracture prevalence between HIV-infected and non-HIV-infected patients. E and F, Fracture prevalence and P values according to gender and race. Light bars and lines represent HIV-infected patients; dark bars and lines represent non-HIV-infected patients. (Data from Triant VA, Brown TT, Lee H, et al. Fracture prevalence among human immunodeficiency virus [HIV]-infected versus non-HIV-infected patients in a large U.S. healthcare system. *J Clin Endocrinol Metab*. 2008;93:3499-3504, with permission.)

Reduced bone density has also been reported in HIV-infected children. O'Brien and colleagues demonstrated reduced total body bone density in perinatally infected girls at age 9 years in association with increased levels of N-telopeptide and parathyroid hormone.⁵¹ Bone density is reduced among children receiving HAART, with the most significant reductions in those with lipodystrophy.⁵² Arpadi and associates demonstrated reduced bone density among prepubertal HIV-infected compared with non-HIV-infected children after controlling for height and weight.⁵³ In contrast to increased markers of resorption, reduced osteocalcin levels were reported in HIV-infected children, suggesting reduced bone formation and a relative discrepancy between increased resorption and reduced formation in this group.⁵⁴ Similar to the data in adults, bone density is related to levels of insulin-like growth factor 1 (IGF1) in HIV-infected children, suggesting a potential effect of low growth hormone (GH) on bone.⁵⁵ Mora and colleagues monitored bone density longitudinally over 1 year to compare changes in HIV-infected children versus control subjects and demonstrated relative reductions in total body, but not spinal, bone density accrual and relative increases in bone turnover.⁵²

Endocrine factors may contribute to reduced bone density in HIV-infected patients, including hypogonadism and relative GH deficiency associated with excess visceral adiposity. GH pulse area, determined from overnight frequent sampling, was reduced in patients with central fat accumulation and correlated significantly with vertebral bone density.⁴⁷ This relationship may explain, in part, the inverse association between increased visceral fat and reduced bone density in HIV-infected patients.⁵⁶ PIs may also inhibit 1 α -hydroxylase, resulting in 25-hydroxyvitamin D deficiency.⁵⁷ In a study of ambulatory clinic patients without known hypocalcemia, the prevalence of moderate 25-hydroxyvitamin D deficiency (>10 and <20 ng/mL) was 36.8%, and that of severe deficiency (<10 ng/mL) was 10.5%.⁵⁸

Limited data are available on treatment strategies for bone loss in AIDS patients. Among HIV-infected patients with idiopathic bone loss and high bone turnover, studies suggest that alendronate is effective in increasing bone density, with increases in lumbar spine bone density from 3.4% to 5.2% over 42 weeks and good safety tolerability, albeit in relatively small numbers of patients (Fig. 38-4).^{59,60} Longer-acting bisphosphonates (e.g., zoledronate) led to even greater changes in spinal bone density, 8.9% over 2 years, in a randomized, placebo-controlled study.⁶¹ Among men with AIDS wasting, testosterone at high doses (200 mg/week) has been shown to increase bone density,³⁹ and transdermal testosterone administration has been shown to increase bone density at the hip in relatively androgen deficient HIV-infected women.²¹

Avascular Necrosis of Bone

Miller and colleagues demonstrated a 4.4% prevalence of avascular necrosis among 339 asymptomatic HIV-infected individuals.⁶² A significant relationship was reported between avascular necrosis and prior use of systemic corticosteroids ($P = .02$). Other potential factors significantly associated with an increased risk of avascular necrosis included the presence of anti-cardiolipin antibodies and a history of routine bodybuilding with its associated mechanical stress. Alcohol use may also be a factor associated with avascular necrosis among HIV-infected patients.⁶³

The relationship between avascular necrosis and HAART is unclear. Gutierrez and associates demonstrated an

increased prevalence of avascular necrosis, from 1.6 per 1000 patients during the early 1990s to 14 per 1000 patients in the late 1990s.⁶⁴ Ninety-one percent of patients had prior exposure to HAART, and 70% had been given HAART before developing avascular necrosis.⁶⁴

Calcium Homeostasis

Hypocalcemia is common in HIV-infected patients. Hypocalcemia, based on albumin-adjusted total calcium levels, was demonstrated in 6.5% of a large cohort of HIV-infected patients with AIDS. Calcium decreased progressively with stage of disease. Among patients with hypocalcemia, 48% were vitamin D deficient, and in most subjects the expected increase in PTH levels was lacking.⁶⁵ Jaeger and coworkers also demonstrated decreased PTH secretion in severely immunocompromised patients with AIDS, but the mechanism is unknown.⁶⁶ In addition, decreased PTH may occur in the setting of hypomagnesemia during severe illness or in association with renal magnesium wasting. Vitamin D deficiency may be caused by malabsorption due to AIDS enteropathy or specific effects of antiretroviral drugs (e.g., inhibition of 1 α -hydroxylation of 25-hydroxyvitamin D by PIs).⁵⁷ Severe vitamin D deficiency of nutritional origin has also been described in HIV-infected children.

Earle and colleagues described three cases of Fanconi's syndrome in HIV-infected adults, characterized by excess phosphate excretion and osteomalacia in the context of tenofovir and cidofovir administration.⁶⁷ Osteomalacia was also associated with use of rifabutin for MAI in an HIV-infected patient. Rifabutin induces cytochrome P450, which may affect vitamin D metabolism. Other drugs that induce P450 could have a similar effect. A number of drugs may affect calcium homeostasis (see Table 38-1). Foscarnet complexes with calcium to decrease ionized calcium levels and may also induce severe hypomagnesemia. Pentamidine therapy has been associated with renal magnesium wasting and severe hypomagnesemia, which can cause hypocalcemia through decreased PTH release and resistance to circulating PTH. Ketoconazole inhibits synthesis of 1,25-dihydroxyvitamin D (calcitriol).

Among patients with HIV disease, hypercalcemia can be caused by excessive production of calcitriol in the setting of granulomatous disease (tuberculosis) or lymphoma; by local osteoclastic bone resorption caused by disseminated CMV infection; or by activation of parathyroid hormone-releasing hormone (PTHrP) related to human T-cell lymphotropic virus 1 (HTLV-1) infection.

GROWTH HORMONE

Significant abnormalities in the GH-IGF1 axis occur in HIV-infected patients. Among patients with AIDS wasting and significant weight loss, GH levels are increased in association with reduced levels of IGF1, a pattern typical of GH resistance seen with malnutrition. In contrast, in the setting of visceral fat accumulation, frequent sampling of GH levels over 24 hours suggested a different pattern.⁶⁸ Mean overnight GH and GH pulse amplitude were decreased in this setting, whereas pulse frequency was not different compared with the frequency in nonlipodystrophic HIV patients and non-HIV-infected patients matched for age and BMI. Reduced GH levels were strongly predicted by increased visceral fat in these patients. In subsequent studies, the percentage of patients failing a growth hormone-releasing hormone (GHRH) plus arginine stimulation test using a highly stringent cutoff of 3.3 ng/mL was

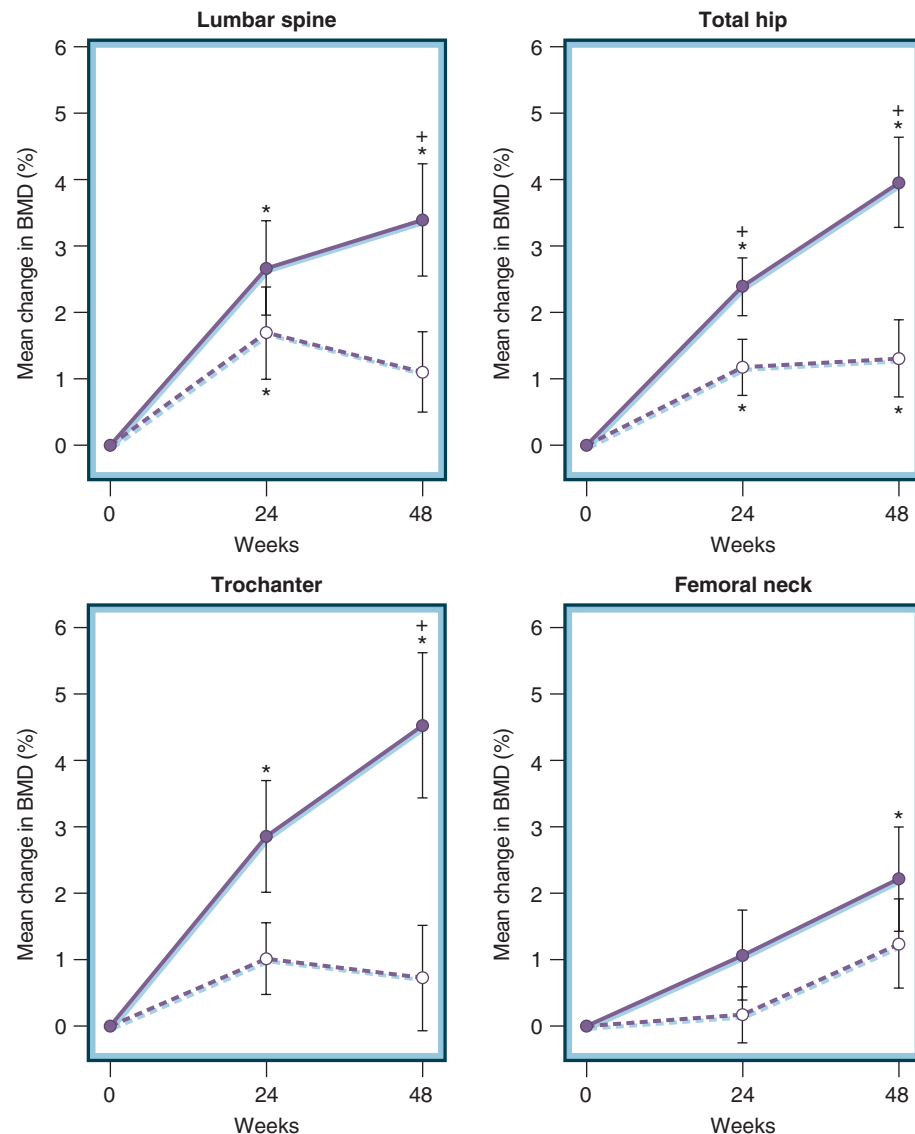

Figure 38-4 Mean percentage changes from baseline in the bone mineral density (BMD) of the lumbar spine, total hip, trochanter, and femoral neck in HIV-infected patients after treatment with alendronate plus calcium/vitamin D (solid lines) or calcium/vitamin D only (dashed lines). T bars denote the standard error of the mean. *Significant within arm; +significant between arms. (Data from McComsey GA, Kendall MA, Tebas P, et al. Alendronate with calcium and vitamin D supplementation is safe and effective for the treatment of decreased bone mineral density in HIV. *AIDS*. 2007;21:2473-2482, with permission.)

18% in patients with lipodystrophy but 0% in age- and BMI-matched healthy control subjects. The prevalence of GH deficiency increased to 30% with a cutoff of 5 ng/mL.

A role for suppression of GH release by free fatty acids (FFA) was suggested by experiments in which acipimox, a nicotinic acid derivative that blocks peripheral tissue lipolysis and lowers FFA levels, was administered. Peak GH response to GHRH was increased in response to acipimox, in inverse association to the change in FFA.⁶⁹ In contrast to patients with AIDS wasting, in whom GH levels are increased in association with GH resistance, physiologic studies of GH in HIV-infected patients suggest that increased somatostatin tone, reduced ghrelin, and increased lipolysis contribute to reduced GH secretion in viscerally obese HIV-infected patients with lipodystrophic changes in fat distribution.⁶⁹

GH and GH secretagogues have been used in HIV-infected patients both to increase lean body mass in sarcopenic patients with AIDS wasting and to reduce visceral

adiposity in HIV-infected patients with the lipodystrophy syndrome (Table 38-2). Among patients with AIDS wasting, high-dose, supraphysiologic GH (0.1 mg/kg per day) has been investigated. Relatively small but significant effects on weight (1.6 kg) were seen over 3 months in a placebo-controlled study.⁷⁰ Larger effects on lean body mass (3.0 kg) were achieved over 3 months, but a portion of this gain was attributed to increased total body water.⁷⁰ GH administration at 0.1 mg/kg has been shown to increase work output during treadmill exercise⁷⁰ and quality of life, as well as peripheral muscle oxygen extraction and utilization, in patients with AIDS wasting.⁷¹ These studies suggest that large doses of GH may be necessary to significantly increase lean mass in patients with AIDS wasting and nutritionally mediated resistance to GH. Short-term high-dose GH (6 mg/day) has also been used successfully to increase lean body mass at the time of acute opportunistic infection. However, high-dose GH is associated with side effects including hyperglycemia and fluid retention⁷² and is not

Randomized, Double-Blind, Placebo-Controlled Studies of GH and GHRH in HIV-Infected Patients

Study	N	Population	Duration	Dose	Primary End Point	Result
Growth Hormone						
Esposito et al. ¹⁷⁹	27	Wasting	3 mo	6 mg/day	Functional impact as observed by submaximal measures of physical performance	LBM increased and functionally relevant as determined by effort-independent submaximal measures or cardiopulmonary exercise testing
Esposito et al. ⁷¹	12	Wasting	3 mo	6 mg/day	Peripheral muscle oxygen extraction-utilization	Improvement in peripheral muscle oxygen extraction-utilization and in the cardiac output–oxygen consumption relationship during exercise
Grunfeld et al. ¹⁸⁰	325	Fat redistribution	12 wk	4 mg/day	VAT	Decrease in VAT
Herasimtschuk et al. ¹⁸¹	12	Lipodystrophy	Phase I, 12 wk; phase II, 12 wk	Phase I, 4 mg/day; phase II, 4 mg qod or biw	Virus-specific T-cell responses	Dose-dependent increases in CD4+ and CD8+ HIV-1–specific T-cell responses
Kotler et al. ^{74,75}	245	Excess VAT	12 wk	4 mg/day or 4 mg qod	Fat distribution	Decrease in VAT, trunk fat, dorsocervical fat, and non-HDL cholesterol concentrations
Lee et al. ¹⁸²	142	Wasting	12 wk	0.34 mg bid with 5.0 mg rhIGFI bid	Anabolic effects	No significant anabolic effect
Lo et al. ⁷⁶	55	Increased abdominal fat and reduced GH secretion	18 mo	2–6 µg/kg per day titrated to upper quartile range of age-adjusted normal IGFI range	Body composition	Reduced visceral fat and truncal obesity; improved triglyceride levels
Moyle et al. ⁷²	757	Wasting	12 wk	0.1 mg/kg per day or qod (6 mg max)	Lean body mass, physical performance, QoL	Lean body mass increased, increased maximum work output, QoL improved
Mulligan et al. ¹⁸³	17	Wasting	3 mo	0.1 mg/kg per day	Components of energy balance	Increases in weight and LBM accompanied by sustained increases in REE and lipid oxidation and decreases in protein oxidation
Schambelan et al. ⁷⁰	178	Wasting	12 wk	0.1 mg/kg/day	Weight, body composition, functional performance, QoL	Increased weight and lean body mass, decreased body fat, greater increase in work output, no significant change in QoL
Growth Hormone–Releasing Hormone						
Falutz et al. (initial study and follow-up study) ^{77,78}	412	Increased abdominal fat	Initial, 26 wk; follow-up, 52 wk	2 mg/day	Change in VAT; long-term safety and effects	VAT decreased by 15–18% (VAT was regained during withdrawal period); improved triglycerides and body image
Falutz et al. ¹⁸⁴	61	Increased abdominal fat	12 wk	1 mg/day or 2 mg/day	Change in abdominal fat	Decreased trunk fat in 2-mg group without significant change in limb fat; VAT decreased most in 2-mg group but not significant compared with placebo; LBM and VAT:SAT ratio significantly improved in both treatment groups
Koutkia et al. ^{47,185}	31	Increased abdominal fat	12 wk	1 mg bid	Change in IGFI concentration, markers of bone turnover	Increased IGFI concentration; improved bone metabolism

bid, twice daily; biw, biweekly; GH, growth hormone; GHRH, growth hormone–releasing hormone; HDL, high-density lipoprotein; LBM, lean body mass; qod, every other day; QoL, quality of life; REE, resting energy expenditure; rhIGFI, recombinant human insulin-like growth factor I; SAT, subcutaneous adipose tissue; VAT, visceral adipose tissue.

well tolerated in the long term. Use of GH has not been shown to worsen viral load in patients with HIV disease, and at high doses it was shown to increase thymic mass and circulating CD4 cells in one study.⁷³

GH has also been used to reduce visceral fat in HIV-infected patients with central fat accumulation. In a large randomized, placebo-controlled study, Kotler and associates found that GH, 4 mg/day, was associated with an 18.8% reduction in visceral adipose tissue (VAT) over 12 weeks and reduced total and non-HDL cholesterol levels

but also with increased glucose levels.^{74,75} Lo and colleagues investigated low-dose GH given for 18 months to HIV-infected patients with central fat accumulation and deficient responses to GHRH-arginine testing; VAT was reduced by 9% (Fig. 38-5), and blood pressure and triglyceride levels were improved. Even with low-dose GH, however, the 2-hour glucose level increased, demonstrating that GH is potentially useful to decrease central fat accumulation but hard to titrate in a population with significant insulin resistance.⁷⁶

Figure 38-5 Effects of growth hormone (GH) versus placebo treatment on visceral adipose tissue area and insulin-like growth factor I (IGF1) levels over 18 months ($P < .05$ and $P < .001$, respectively). Vertical bars indicate standard error of the mean. IGF1 data are presented for safety population receiving at least one dose of GH. The same number of patients were assessed at 2 weeks as at 1 month. (Data from Lo J, You SM, Canavan B, et al. Low-dose physiological growth hormone in patients with HIV and abdominal fat accumulation: a randomized controlled trial. *JAMA*. 2008;300:509-519, with permission.)

In contrast, GH secretagogues have been used to successfully increase lean body mass and reduce visceral and truncal fat without significant effects on fasting or 2-hour glucose levels. In a large, randomized, placebo-controlled study, GHRH(1-44) (TH9507, tesamorelin) reduced VAT by 20% relative to placebo in HIV-infected patients with central fat accumulation. Improvements were noted in triglycerides (equal to 59 mg/dL), total cholesterol, HDL-cholesterol, and total cholesterol-to-HDL ratio, as well as adiponectin and patient self-assessment of distress associated with central fat accumulation (Fig. 38-6).⁷⁷ No clinically significant effect to reduce subcutaneous adipose tissue was seen, indicating that tesamorelin was selective for VAT. Use of tesamorelin was associated with generally physiologic increases in IGF1 levels and was not associated with increased glucose or insulin levels, in contrast to low-dose GH. In addition, GHRH(1-29) was shown to increase bone turnover in HIV-infected patients.⁴⁷ Discontinuation

Figure 38-6 Changes in visceral adipose tissue from baseline to 26 weeks with 2 mg/day tesamorelin therapy. Figure shows the mean difference in visceral adipose tissue according to study group; T bars denote the standard error. The P value for the between-group comparison was calculated by analysis of covariance. (Data from Falutz J, Allas S, Blot K, et al. Metabolic effects of a growth hormone-releasing factor in patients with HIV. *N Engl J Med*. 2007;357:2359-2370, with permission.)

of both GH and GHRH resulted in reaccumulation of visceral fat back to baseline levels, demonstrating that the effects of these agents do not outlast the treatment period.^{74,75,78} In November 2010, tesamorelin was approved by the U.S. Food and Drug Administration (FDA) as the first treatment for central fat accumulation in HIV-infected patients. GH is approved by the FDA to treat severe loss of muscle mass in patients with the AIDS wasting syndrome.

GH deficiency is a potential cause of growth failure in HIV-infected children, and treatment with GH results in improved auxologic parameters.⁷⁹ Increased IGF-binding protein 3 (IGFBP3) proteolysis and reduced levels of IGF1, IGFBP3, and the acid-labile subunit of the IGFBP3 ternary complex are demonstrated among HIV-infected children with failure to thrive.⁸⁰ IGF1 and IGFBP3 responses to GH may be impaired in HIV-infected children, suggesting a degree of GH insensitivity in this population, which may improve with weight and improved immune function in response to HAART.⁸¹ GH deficiency may also disrupt the normal thymic development in HIV-infected children. GH has been used to increase height in HIV-infected children with normal GH responses to stimulatory testing.⁷⁹ Among HIV-infected children, reduced GH secretion is associated with excess visceral adiposity.

GLUCOSE HOMEOSTASIS AND PANCREATIC FUNCTION

Disorders of glucose homeostasis were relatively infrequent before the institution of potent ART but may result from the use of specific antiretroviral agents and are commonly seen in association with dyslipidemia and fat redistribution in the current era of HAART (see “Metabolic and Body Composition Changes”). The pancreas is a frequent target of opportunistic infections and malignancies in patients with HIV disease. However, clinical endocrine dysfunction rarely results, except in cases of massive pancreatic replacement due to lymphoma or Kaposi's syndrome. Opportunistic infections of the pancreas are seen on postmortem examination but are rarely clinically relevant.

More commonly, pancreatitis and hypoglycemia occur with the use of certain drugs, such as pentamidine, didanosine, or zalcitabine. Hypoglycemia can result from pentamidine administration secondary to islet cell inflammation

and insulin release, especially in the context of high-dose therapy and azotemia. Subsequently, chronic hyperglycemia from pancreatic B cell destruction may follow pentamidine use. Megestrol acetate use has been associated with new-onset diabetes mellitus because of its potent glucocorticoid action. Pancreatitis is common among patients with HIV and is most often related to a drug effect (i.e., pentamidine, trimethoprim-sulfamethoxazole [Bactrim], didanosine, and zalcitabine).

In a large study of almost 6000 patients observed for 23,460 person-years at the Johns Hopkins HIV Clinic between 2001 and 2006, the incidence of acute pancreatitis was 5.1 per 1000 person-years. Low CD4 count, aerosolized pentamidine, and female gender were associated with pancreatitis. In contrast, specific antiretroviral medications were not associated with pancreatitis.⁸² In the EuroSIDA study performed after 2001, the incidence of pancreatitis was 1.27 per 1000 person-years, and again low CD4 count was predictive. Similar to the data from the Hopkins cohort, no association was seen with cumulative exposure to ART nor with exposure to didanosine or stavudine, nucleoside reverse transcriptase inhibitors (NRTIs) that have been associated with pancreatitis.⁸³

Amylase levels may also be elevated in HIV-infected patients secondary to macroamylasemia and salivary amylase.

THE AIDS WASTING SYNDROME

Wasting is a common feature of progressive HIV disease, known originally as "slim disease." The AIDS wasting syndrome is currently defined by weight less than 90% ideal body weight or weight loss greater than 10% over 3 months. It is characterized by a disproportionate loss of lean body mass, with a relative sparing of body fat, particularly in men. In women, fat mass may be lost disproportionately with disease progression. The loss of lean body mass occurs early and may antedate weight loss. Muscle wasting, weakness, increased resting energy expenditure (8% to 9% at baseline), and increased triglyceride levels are also features of this disease. Macallan and associates demonstrated that energy expenditure falls during periods of rapid weight loss but less than the decrease in caloric intake.⁸⁴ Cytokines associated with severe illness may increase energy expenditure and decrease appetite. In addition, chronic weight loss may be associated with gastrointestinal disease, including malabsorption. Weight loss is a significant predictor of mortality in HIV infection, with BMI less than 18.4 kg/m² associated with a 2.2-fold increase in mortality and BMI less than 16.0 kg/m² associated with a 4.4-fold increase in mortality.⁸⁵ Wasting remains common in the era of HAART and was estimated at 34% in a longitudinal cohort study.⁸⁶

One potential endocrine mechanism that may predispose to a disproportionate loss of lean body mass is hypogonadism. Hypogonadism, usually central in etiology, is observed in 30% to 50% of men with AIDS wasting and is associated with decreased lean body mass, decreased muscle mass, and decreased exercise functional capacity.¹⁴ Testosterone has been successfully used to increase lean body mass in men with AIDS wasting. The route of administration can be intramuscular (testosterone enanthate or testosterone cypionate) or transdermal (scrotal, nonscrotal, and newer gel preparations). Skin reaction is reported in up to 30% with the nonscrotal skin patches. Randomized studies of intramuscular testosterone for hypogonadal men with AIDS wasting suggested a beneficial effect of testosterone administration on lean body mass (2.0 kg over 6

months) and improved quality of life.⁸⁷ Testosterone in women with AIDS wasting has also been shown to be safe and well tolerated and to increase physical function over 6 months and lean body mass over 18 months (see earlier discussion).^{21,88}

Although a limited number of studies have shown a benefit of anabolic steroids in HIV-infected patients with wasting, these agents potentially suppress endogenous gonadal function and may cause hypogonadism. Methyltestosterone and anabolic steroids can cause problems with the liver, including peliosis hepatitis, worsening liver function, and, potentially, malignancy. Oxandrolone, an oral anabolic steroid, was shown to be safe but ineffective for AIDS wasting at low doses. Doses higher than 20 mg/day may be associated with liver dysfunction. In a placebo-controlled, randomized, dose-ranging study, only doses of 40 or 80 mg/day of oxandrolone were associated with increased body cell mass. In addition, high-dose oxandrolone suppressed endogenous testosterone levels, significantly increased transaminase levels, and increased low-density lipoprotein (LDL).⁸⁹ Nandrolone (100 mg intramuscularly every other week) was shown to be effective in increasing weight and lean body mass in HIV-infected women with weight loss.⁹⁰ Anabolic steroids are associated with decreased HDL and other side effects and hold no advantage over natural testosterone in the treatment of hypogonadism associated with AIDS-related weight loss. Short-term use of anabolic steroids may be considered in eugonadal patients with severe wasting, but they may be associated with adverse effects and should generally be avoided.

Megestrol acetate (Megace) is a synthetic progestational agent with glucocorticoid-like properties. Randomized studies in the literature show that megestrol acetate increases weight by 3 to 4 kg over 12 weeks with an increase in caloric intake (+688 kcal/day).^{91,92} However, the change in weight is almost entirely fat mass without an increase in lean body mass. In addition, because of its glucocorticoid-like properties, megestrol acetate is associated with a number of side effects, including hypogonadism and hyperglycemia, and abrupt withdrawal can precipitate adrenal crisis. Testosterone has been investigated in combination with megestrol acetate and was shown to reduce the degree of associated hypogonadism, but it did not increase accrual of lean body mass among HIV-infected patients receiving megestrol acetate.⁹³ In children, megestrol acetate promotes weight gain without improving linear growth.⁹⁴

A number of other agents have been used in the setting of AIDS wasting. Thalidomide blocks the action of TNF- α and decreases esophageal ulcers in AIDS patients. Clinical studies demonstrate a modest beneficial short-term effect of thalidomide on weight indices but with significant associated adverse effects, including rash and fever. Administration of human chorionic gonadotropin results in increased testosterone levels and may have independent effects that inhibit Kaposi's sarcoma. No data are available from randomized, controlled studies to determine effects on wasting in humans. Small, short-term studies have shown benefits of an amino acid mixture of glutamine and arginine in increasing lean body mass.⁹⁵

Progressive resistance training has been shown to increase lean body mass by 2.3 kg over 12 weeks in men with AIDS wasting, but it may be even more effective when combined with anabolic therapies such as testosterone,⁹⁶ oxandrolone,⁹⁷ or nandrolone.⁹⁸

Patients with AIDS wasting may demonstrate a typical pattern of nutrition-related GH resistance. These patients

exhibit elevated GH levels but decreased levels of IGF1, the primary hormone mediating the action of GH on muscle, suggesting GH resistance.^{99,100} GH resistance is likely a secondary phenomenon in AIDS wasting, but the HIV envelope protein gp120 has been shown to decrease GH release in vitro and in animal studies,¹⁰¹ potentially leading to a relative reduction in GH secretion. GH at supraphysiologic doses has been shown to increase lean body mass in AIDS wasting and is approved by the FDA for this purpose at a dose of 6 mg/day. However, caution should be used with long-term treatment at this dose because it can cause acute and chronic side effects of GH excess.

Taken together, the data suggest a systematic multidisciplinary approach to the AIDS wasting syndrome. Optimization of ART is paramount in conjunction with provision of adequate nutrition and protein intake. However, weight and muscle loss may occur even in this context because of the highly catabolic nature of the disease. In such cases, endocrine evaluation should include assessment of gonadal function, which is often reduced. Testosterone administration may prove useful to increase lean body mass in these patients, and it may be used in conjunction with resistance training in appropriate patients to optimally increase muscle mass. GH levels are increased in AIDS wasting, but supraphysiologic administration, as approved by the FDA, can further increase lean body mass. This strategy is best reserved for severe wasting refractory to other treatments. Other therapeutic strategies that increase weight by stimulating appetite, including megestrol acetate, are not

associated with gain in lean body mass and may be associated with side effects.

In the current era of HAART, lipoatrophy, usually associated with antiretroviral drug use, should be distinguished from traditional wasting. Whereas AIDS wasting involves sarcopenia and requires anabolic strategies to increase muscle mass, the presence of severe lipoatrophy suggests that strategies to spare fat loss would be optimal.

METABOLIC AND BODY COMPOSITION CHANGES IN HIV-INFECTED PATIENTS

HIV-infected patients demonstrate a number of body composition and metabolic changes. These changes are present to varying degrees among HIV-infected patients and are multifactorial in nature, related in part to HIV virus itself, inflammation, specific antiretroviral drugs, and the interplay of these factors (Fig. 38-7).^{102,103} Some of these changes may contribute to increased cardiovascular disease (CVD) and respond to changes in ART, lifestyle modifications, and specific pharmacologic strategies (e.g., to improve lipid levels or insulin sensitivity).

Body Composition Changes

The most commonly seen change in body composition among HIV-infected patients is loss of abdominal and

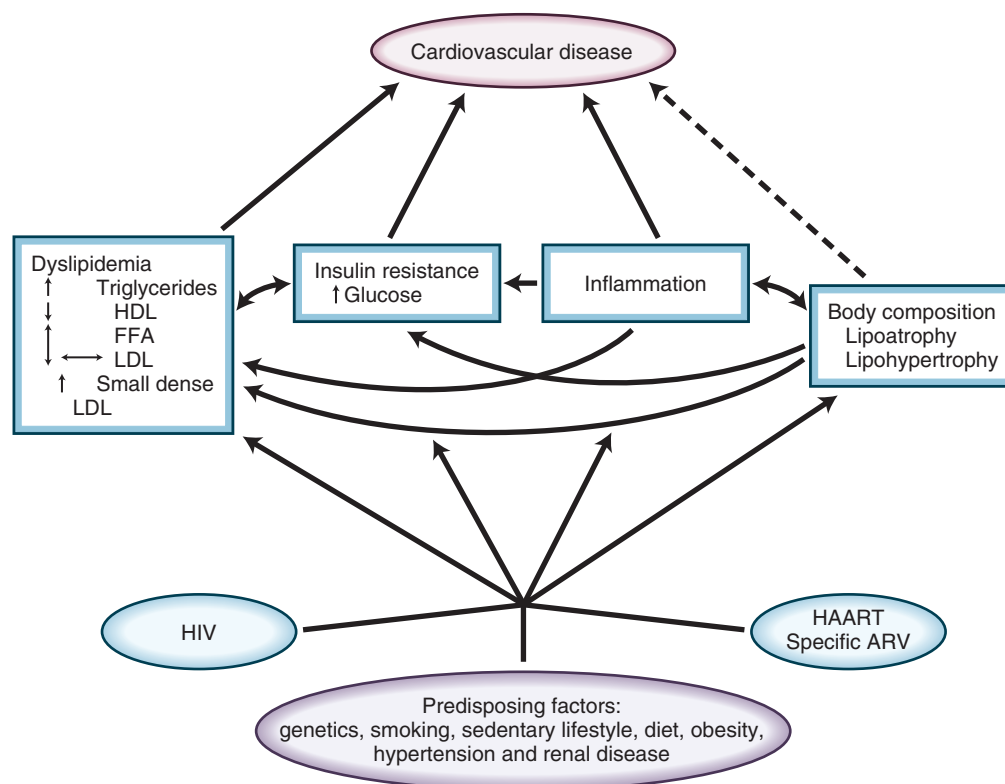

Figure 38-7 Overview of the effects of human immunodeficiency virus (HIV) infection and its therapies on risk of cardiovascular disease (CVD). The contribution of traditional risk factors (e.g., smoking) may occur with increased prevalence in people with HIV infection. HIV itself, most likely through the inflammatory response, and antiretroviral therapies independently affect many of the mediators of CVD risk. The effects on lipids are a prominent but complex example: HIV infection lowers low-density lipoprotein (LDL) levels, but antiretroviral therapy raises LDL back up to normal levels. The *bidirectional arrows* indicate associations for which there is not yet adequate proof of causality. The dotted arrow between body composition and CVD indicates that body fat is known to affect the mediators such as dyslipidemia and insulin resistance but may also have a direct effect. ARV, antiretroviral; FFA, free fatty acids; HAART, highly active antiretroviral therapy; HDL, high-density lipoprotein. (Schema from Grunfeld C, Kotler DP, Arnett DK, et al. Contribution of metabolic and anthropometric abnormalities to cardiovascular disease risk factors. *Circulation*. 2008;118:e20-e28, with permission.)

peripheral subcutaneous fat, including loss of subcutaneous fat in the face.¹⁰⁴ Other changes include relative preservation of central fat, with relative and absolute accumulation of excess visceral fat and excess upper trunk fat.^{104,105} In addition, ectopic fat collection can be seen, including in the dorsocervical area. Increased fat deposition in the liver and muscle is also seen and is likewise associated with insulin resistance. In prospective studies of antiretroviral-naïve patients beginning treatment that included an NRTI and a PI, initial gains in peripheral subcutaneous and central fat depots were seen, with reversal of the catabolic wasting state associated with severe viral infection; this was followed by decreases in peripheral fat and relative preservation and small absolute gains in central fat.

The mechanisms by which these changes in fat occur are only partially understood. NRTIs can inhibit mitochondrial DNA polymerase- γ and contribute to mitochondrial dysfunction. Use of specific NRTIs has been associated with apoptosis of fat and reduced mitochondrial DNA in vitro and in vivo, reduced expression of lipid metabolism genes and, clinically, reduced subcutaneous fat and lipodystrophy.^{106,107} Reduced mitochondrial DNA and clinically significant fat atrophy is most often associated with the use of specific NRTIs including stavudine. In contrast, PIs may have direct effects on adipogenesis via inhibition of nuclear localization of sterol regulatory element-binding protein 1 (SREBP1) and reduction in expression of peroxisome proliferator-activated receptor- γ (PPAR γ).¹⁰⁸ NRTIs and PIs have been associated with increased lipolysis in vivo and in vitro. An important question remains as to whether the changes in fat distribution seen in patients are caused by the use of specific antiretroviral agents that may selectively effect different fat depots. In particular, the etiology of relative and absolute central fat accumulation is not known. It remains unknown whether this is a direct effect of specific antiretroviral drugs and whether abnormal nutrient partitioning to relatively preserved central adipose stores less affected by NRTI administration and mitochondrial toxicity may contribute. Alternatively, fat redistribution may result in part from altered cytokines, including increased IL-6 and TNF,¹⁰⁹ or altered steroid milieu.

Recent evidence suggests a potential role for a number of genetic polymorphisms, which may predispose to changes in body composition and metabolic alterations in HIV-infected patients receiving ART. Such findings could indicate a gene-environment interaction contributing to these changes. For example, single-nucleotide polymorphisms in the resistin gene were found to predict the development of dyslipidemia, insulin resistance, and limb fat loss in response to a specific HAART regimen.¹¹⁰ In the same study, polymorphisms in the hemochromatosis gene and specific mitochondrial gene haplotypes were also associated with increased limb fat loss.¹¹¹ Specific haplotypes of the Fas gene (*APOC3*), the PPAR gene, and the adrenergic receptor have also been associated with the development of lipodystrophy.¹¹² Kratz and associates showed that reduced expression of SREBP1, PPAR γ , LPL, and the CCAAT/enhancer binding protein C/EBP α in thigh subcutaneous fat was associated with the loss of fat before it became evident clinically, whereas increased 11 β -hydroxysteroid dehydrogenase 1 (HSD11B1) and C/EBP β were associated with preservation of subcutaneous fat mass.¹¹³ Changes in fat distribution have been most widely recognized since the introduction of HAART, but abnormal fat distribution can be seen in antiretroviral-naïve patients, suggesting that viral factors also may contribute.

The changes in fat distribution seen among HIV-infected patients bear some similarities to Cushing's syndrome, with dorsocervical fat accumulation and centripetal fat distribution. However, more specific stigmata of true Cushing's syndrome, including proximal muscle weakness, facial plethora, thin skin, and bruising or violaceous striae, have not been seen, so these changes constitute a pseudo-Cushing's syndrome.¹¹⁴ Miller and colleagues observed normal cortisol levels and adequate suppression in response to dexamethasone among HIV-infected patients with cushingoid features.¹¹⁴ Yanovski and coworkers compared HIV-infected patients who had PI-associated lipodystrophic changes in fat to control patients and to subjects with true Cushing's syndrome.¹¹⁵ In contrast to patients with true Cushing's syndrome, patients with PI-associated lipodystrophy demonstrated normal diurnal variation in cortisol levels. The 24-hour urine free cortisol levels were reduced and 17-hydroxysteroid levels were increased, compared with controls. ACTH levels were somewhat increased after CRH testing, but these changes did not appear to be related to changes in abdominal adiposity and did not suggest pathologic activation of the cortisol axis as an etiology of lipodystrophic changes in fat distribution. However, stress activation of the adrenal axis may contribute to increased cortisol production. Evidence of shunting toward cortisol production and away from androgen production in the adrenal glands has been demonstrated in association with weight loss, disease severity, and immune compromise in HIV-infected patients.^{6,116} Among HIV-infected patients with changes in fat distribution, increased HSD11B expression in subcutaneous adipose tissue was demonstrated in association with an increased ratio of urinary cortisol to cortisone metabolites and may also contribute to increased cortisol production.¹¹⁷

Other abnormalities of steroid metabolism have been noted in association with changes in fat distribution. In a longitudinal evaluation, the development of lipodystrophy was associated with reduced DHEA, an increased ratio of cortisol to DHEA, and increased interferon- α .¹¹⁸ Increased cortisol regeneration from affected fat depots may contribute to insulin resistance and further fat redistribution.

Lipid Abnormalities

Lipid abnormalities are highly prevalent among HIV-infected patients, particularly those with changes in fat distribution and increased visceral fat and upper trunk fat. Hypertriglyceridemia has long been associated with HIV infection and was observed before the introduction of potent ART; it is related in part to increased secretion and decreased clearance of very-low-density lipoprotein (VLDL).¹¹⁹ The etiology of these changes is not known but may relate to the effects of viral infection itself, altered cytokines (including interferon- α ¹²⁰), or increased apolipoprotein E.¹²¹ In longitudinal studies, reduction in HDL, total cholesterol, and LDL cholesterol were observed with seroconversion. With ART, cholesterol and LDL rise to pre-infection levels, but low HDL levels persist.¹²²

Among HIV-infected patients receiving combination ART including a PI, hypercholesterolemia (>240 mg/dL), hypertriglyceridemia (>200 mg/dL) and low HDL (<35 mg/dL) were reported in 27%, 40%, and 27% of patients, respectively, compared with corresponding percentages of 8%, 15%, and 26% in previously untreated patients.¹²³ Among patients with changes in fat distribution, 57% demonstrated hypertriglyceridemia and 46% had low HDL, compared with an age- and BMI-matched cohort from the Framingham Offspring Study.¹²⁴ Severe dyslipidemia

among HIV-infected patients may result from the effects of antiretroviral drugs, including specific PIs, such as ritonavir, that have been shown to increase triglyceride levels. Use of PIs may also be associated with an atherogenic dyslipidemia and an increase in small dense LDL,¹²⁵ increased apolipoprotein CIII and apolipoprotein E, and decreased proteosomal degradation of apolipoprotein B.^{126,127}

Hyperglycemia and Insulin Resistance

Insulin resistance and diabetes mellitus are increasingly common among HIV-infected patients. In a longitudinal study, diabetes mellitus was 3.1 times more likely to develop in HIV-infected patients receiving combination ART than in control subjects.¹²⁸ Among HIV-infected patients with changes in fat distribution, including visceral adiposity and loss of subcutaneous fat, impaired glucose tolerance is seen in approximately 35% of patients (Fig. 38-8).¹²⁴ Hyperinsulinemia in such patients is consistent with insulin resistance as the primary mechanism for impaired glucose tolerance and diabetes mellitus. Insulin resistance among HIV-infected women may not be associated with typical features of polycystic ovary syndrome.

The mechanisms of insulin resistance among HIV-infected patients may be caused by the abnormal fat distribution itself (e.g., increased central adiposity, loss of peripheral subcutaneous fat), by altered cytokines (e.g., low adiponectin, elevated TNF), or by other factors, such as increased lipolysis, increased proteolysis, increased expression of suppressor of cytokine signaling 1 (SOCS1),¹²⁹ and increased accumulation of fat in the muscle and liver. In addition, significant evidence suggests direct effects of specific antiretroviral agents to reduce insulin sensitivity. PIs have been shown to decrease glucose uptake by inhibiting the glucose transport function of GLUT4 in vitro¹³⁰ and to reduce insulin sensitivity in vivo.¹³¹ NRTIs are associated with insulin resistance, which may occur through a direct effect, potentially related to mitochondrial toxicity,¹³² or through effects on subcutaneous fat.¹⁰⁷

Figure 38-8 Metabolic profile in HIV-infected subjects with lipodystrophy (dark purple bars) compared with controls matched for age and body mass index (light purple bars) from the Framingham cohort. The percentages of subjects with glucose levels greater than 140 or greater than 200 mg/dL on oral glucose tolerance testing, with cholesterol levels greater than 200 mg/dL, with triglyceride levels greater than 200 mg/dL, and with high-density lipoprotein levels lower than 35 mg/dL are shown. * $P \leq .05$. (Data modified from Hadigan C, Meigs JB, Corcoran C, et al. Metabolic abnormalities and cardiovascular disease risk factors in adults with human immunodeficiency virus infection and lipodystrophy. *Clin Infect Dis*. 2001;32:130-139, with permission.)

CARDIOVASCULAR RISK IN HIV-INFECTED PATIENTS

CVD is increased among HIV-infected patients treated with HAART. The Framingham equation predicts increased myocardial infarction rates among HIV-infected patients with fat redistribution.¹³³ More than 40% of such subjects meet the definition of the metabolic syndrome, and predicted myocardial infarction rates are most increased in this subgroup.¹³³ Risk factors for CVD include insulin resistance, atherogenic dyslipidemia, truncal adiposity, hypertension, impaired fibrinolysis, and increased levels of plasminogen activator inhibitor 1 (PAI-1) and tissue plasminogen activator (tPA), as well as reduced adiponectin and increased C-reactive protein (CRP).

Surrogate markers, including carotid intima-medial thickness and endothelial function, suggest increased CVD in HIV-infected patients. Hsue and colleagues demonstrated increased carotid intima-medial thickness in HIV-infected patients, in association with cigarette smoking, increased LDL, and hypertension.¹³⁴ Progression rates were also greater in HIV-infected patients during longitudinal follow-up. Endothelial dysfunction, as determined by impaired flow-mediated dilation, is seen among HIV-infected adults receiving PIs.¹³⁵ Abnormal endothelial function correlated with dyslipidemia, including increased chylomicrons, VLDL, and intermediate-density lipoprotein and reduced HDL. PIs may also directly affect endothelial function through an effect on epithelial nitric oxide synthase (eNOS).¹³⁶ Pravastatin improves lipid parameters and tends to improve endothelial function in HIV-infected patients receiving a PI.¹³⁷ In addition, evidence suggests increased carotid intimal-medial thickness and reduced flow-mediated dilation in children receiving PIs.¹³⁸

Mary-Krause and coworkers demonstrated a relative hazard ratio of 2.6 for increased myocardial infarctions in HIV-infected patients receiving a PI for 18 months or longer in a French cohort.¹³⁹ In contrast, data from a U.S. retrospective cohort study demonstrated an increased rate of myocardial infarction among HIV-infected patients but did not suggest an independent effect of PIs.¹⁴⁰ In retrospective studies, the risk of coronary heart disease related to ART use may be most pronounced among younger HIV-infected patients.¹⁴¹ In a large prospective study of 23,468 patients, the covariate-adjusted risk was 1.26 per each additional year of antiretroviral exposure. Other risk factors included male gender, diabetes, age, previous myocardial infarction, hypertension, and dyslipidemia.¹⁴² Controlling for dyslipidemia significantly reduced the effects of HAART exposure, suggesting that dyslipidemia is a significant mechanism by which HAART contributes to excess coronary artery disease in HIV-infected patients.

In a large study of patients in a major U.S. health care center, Triant and colleagues demonstrated a relative risk of 1.75 (95% CI, 1.51 to 2.02, $P < .0001$) for increased myocardial infarction in HIV-infected versus non-HIV-infected patients in a model accounting for age, gender, and race (Fig. 38-9).¹⁴³ Increased rates of traditional risk factors, including diabetes mellitus (11.5% for HIV-infected patients versus 6.6% for non-HIV-infected patients), hypertension (21.2% versus 15.9%, respectively), and dyslipidemia (23.3% versus 17.6%, respectively) were seen, and each contributed to the increase in myocardial infarction rates (relative risks, 1.62, 1.98, and 3.03, respectively, for each risk factor). In a recent prospective cohort study, Worm and coworkers demonstrated that the presence of diabetes mellitus was associated with a 2.41 times higher

Figure 38-9 **A**, Rates of acute myocardial infarction (AMI) and corresponding adjusted relative risk (RR) in patients with and without human immunodeficiency virus (HIV) infection. Bars indicate crude rates of AMI events per 1000 person-years (PYs) as determined by *International Classification of Diseases* (ICD) coding. The RR and associated probability (*P*) value are shown above the bars. RR was determined from Poisson regression analysis adjusting for age, gender, race, hypertension, diabetes, and dyslipidemia; the associated 95% confidence interval is 1.51 to 2.02. **B**, AMI rates by age group in patients diagnosed (squares) or not diagnosed (diamonds) with HIV disease. Data shown include both genders. Rates represent number of events per 1000 PYs as determined by ICD coding. (Data from Triant VA, Lee H, Hadigan C, et al. Increased acute myocardial infarction rates and cardiovascular risk factors among patients with human immunodeficiency virus disease. *J Clin Endocrinol Metab*. 2007;92:2506-2512, with permission.)

risk (95% CI, 1.91 to 3.05, $P = .0001$) of mortality among HIV-infected patients.¹⁴⁴ However, in Triant's study, regression modeling, accounting for hypertension, diabetes mellitus, and dyslipidemia, demonstrated that these three risk factors contributed to only 25% of the excess risk in HIV-infected versus non-HIV-infected patients, suggesting that other factors might contribute. Smoking rates are increased and may contribute to increased CVD risk in HIV patients.

Recent studies also suggest that inflammation may contribute significantly to increased CVD risk among HIV-infected patients. Increased CRP levels observed among HIV-infected patients predicted increased myocardial infarction rates.¹⁴⁵ In the SMART study, HIV-infected patients randomized to continuous viral suppression with antiretroviral medications demonstrated a reduced rate of cardiovascular events compared with patients randomized to interrupted therapy with less strict goals for control of immune function.¹⁴⁶ It has been hypothesized that intermittent treatment may have adverse effects on inflammation or lipid profiles that may contribute to the observed differences in myocardial infarction rates.

HIV-infected women are also at risk for increased CVD. Increased waist-to-hip ratio, visceral adiposity, increased levels of triglycerides and LDL, and reduced HDL were found in HIV-infected women compared with age- and BMI-matched control subjects. In addition to traditional risk factors, CRP and IL-6 are increased, and adiponectin is reduced. Central adiposity, more than other factors, was significantly predictive of abnormal CVD risk indices, including newer inflammatory indices.¹⁴⁷ In contrast, HIV status and viral load were not predictive, suggesting that central adiposity and changes in fat distribution may be responsible, in part, for the increased CVD risk in HIV-infected women.

Treatment of Metabolic and Body Composition Changes in HIV-Infected Patients

A number of options are available for the treatment of body composition and metabolic abnormalities in HIV-infected patients. Antiretroviral switching to less toxic NRTIs or PIs may be useful for improving changes in fat distribution and hyperlipidemia.¹⁴⁸ For example, a recent study demonstrated that changing from lopinavir/ritonavir to atazanavir/ritonavir improved glucose trafficking into

muscle, triglyceride levels (by 182 mg/dL on average), and visceral fat by 25%.¹⁴⁹ Traditional lifestyle modifications, with a focus on limiting saturated fats and increasing fiber and physical activity, may be adequate to improve glucose levels and blood pressure but inadequate to significantly improve dyslipidemia or markedly change fat redistribution. Large studies are needed to determine whether such programs can definitively improve CVD risk in HIV-infected patients and prevent the development of diabetes in those with impaired glucose intolerance. Lifestyle modifications, in combination with exercise, may improve lipid levels and visceral adiposity among HIV-infected patients.¹⁵⁰ Progressive resistance training may also confer significant benefits on glucose homeostasis in HIV-infected patients through a reduction in muscle adiposity.¹⁵¹ However, resistance training is unlikely to reverse the loss of subcutaneous fat often seen in HIV-infected patients receiving ART.

Testosterone, Growth Hormone, and Growth Hormone-Releasing Analogues

Testosterone reduces fat and builds muscle mass in hypogonadal HIV-infected men,⁸⁷ as in non-HIV-infected men, and limited data are now available on the use of testosterone in relatively androgen-deficient HIV-infected men with abdominal fat accumulation (waist-to-hip ratio >0.95 or waist circumference >100 cm).¹⁵² Testosterone gel, 10 g daily, did not improve visceral fat mass but reduced overall trunk fat by 15% relative to placebo over 24 weeks. Significant effects on glucose and insulin were not seen. Effects of high-dose testosterone and anabolic steroids on lipid parameters may limit the utility of this class of drugs in reducing visceral fat in HIV-infected patients. GH and GHRH can significantly reduce visceral fat (see earlier discussion) and improve lipid levels in HIV-infected patients with central fat accumulation. Supraphysiologic and even more physiologic doses of GH may also worsen glucose homeostasis. In contrast, GHRH significantly reduces visceral fat, improves lipids, and has not been shown to aggravate fasting glucose or glucose tolerance in large randomized trials performed to date.⁷⁴⁻⁷⁷

Insulin-Sensitizing Agents

Significant insulin resistance occurs among HIV-infected patients, in association with use of specific antiretroviral

agents, changes in fat distribution, and other factors. Among HIV-negative individuals, numerous studies have documented that hyperinsulinemia and truncal obesity are strong independent risk factors contributing to coronary artery disease with significant associated morbidity and mortality. Metformin is particularly appropriate for use in patients with significant truncal adiposity and increased FFA concentrations, in whom insulin resistance is in part attributable to increased hepatic glucose production. In addition, metformin has a modest favorable effect on lipids. In patients with hyperlipidemia, metformin decreases triglyceride and LDL levels without adversely affecting other parameters. The modest 10% to 20% reduction in plasma triglyceride levels is thought to be caused by decreased hepatic VLDL production.

The effects of metformin have been investigated in HIV-infected patients with central fat accumulation and insulin resistance in a number of studies. Using a dose of 500 mg orally twice daily in a randomized, placebo-controlled week study,¹⁵³ Hadigan and associates demonstrated that low-dose metformin used significantly reduced insulin resistance, abdominal visceral fat, diastolic blood pressure, and tPA and PAI concentrations over 12 weeks, thus improving the CVD risk profile of such patients.^{153,154} The effects of metformin were sustained over 9 months.¹⁵⁵ Other studies of metformin in HIV-infected patients also demonstrated general improvements in markers of insulin sensitivity, but with less consistent effects on abdominal fat.¹⁵⁶ These data suggest the need for further studies to assess the long-term efficacy of metformin in terms of fat redistribution and cardiovascular risk. In a randomized trial, the effects of metformin and progressive resistance training were compared with those of metformin alone, and the addition of resistance training further significantly improved central adiposity, blood pressure, and insulin resistance.¹⁵⁷

The loss of subcutaneous fat in HIV-infected patients may further contribute to insulin resistance by limiting peripheral glucose and triglyceride uptake. Therefore, attention has focused on insulin-sensitizing strategies that may act to increase subcutaneous adipogenesis. Metformin, although a potent insulin-sensitizing agent, is not expected to restore peripheral adipogenesis but rather to act primarily via a reduction of hepatic insulin resistance. In contrast, a novel class of therapeutic agents, the thiazolidinediones (TZDs), have been shown to promote adipogenesis, primarily through activation of PPAR γ . Although TZDs have effects on both hepatic and peripheral insulin resistance, the dominant effect is to improve peripheral glucose uptake.

The therapeutic efficacy of the TZDs has been well established among patients with type 2 diabetes mellitus. Short-term studies have demonstrated an effect on glycosylated hemoglobin (HbA_{1c}) and fasting glucose after 12 weeks. The TZDs also reduce plasma triglyceride levels by 10% to 20% and increase HDL by 5% to 10% in diabetic patients. Weight has reported to increase in response to TZDs, in contrast to metformin, which is associated with weight loss. Based on the known effects of TZDs in stimulating insulin sensitivity through PPAR γ and promoting adipogenesis, this strategy might be appropriate to reverse insulin resistance and promote adipogenesis in HIV-infected patients with subcutaneous fat loss and insulin resistance.

In a 3-month randomized, placebo-controlled study involving 28 patients selected based on insulin resistance, rosiglitazone was shown to improve insulin sensitivity, adiponectin, FFA levels, and subcutaneous fat mass.¹⁵⁸ In

contrast, an effect of rosiglitazone on subcutaneous fat was not shown during a 48-week study in patients with lipoatrophy who were selected for fat loss but not for insulin resistance.¹⁵⁹ Adiponectin levels were significantly increased and resistin levels decreased in response to rosiglitazone in HIV-infected patients, changes that may contribute to improved insulin sensitivity.^{158,160} TZDs may be effective to increase subcutaneous fat in selected subpopulations of HIV-infected patients, particularly those with insulin resistance,¹⁶¹ but significant adverse effects on lipid levels suggest that pioglitazone may be better than rosiglitazone in this regard. Indeed, Slama and colleagues investigated the effects of pioglitazone in HIV-infected patients with confirmed lipoatrophy in a large, randomized placebo-controlled trial.¹⁶² Pioglitazone was shown to increase peripheral fat and to improve HDL, suggesting potential utility for HIV-infected patients with insulin resistance and fat atrophy.

The TZDs are not appropriate for severely overweight patients, because they may be associated with weight gain; they are best reserved for patients with lipoatrophy and insulin resistance. Moreover, recent data have called into question the actual cardiovascular benefit produced by rosiglitazone in non-HIV-infected diabetics, in whom increased CVD rates were seen in association with rosiglitazone use.¹⁶³ Although such effects have not been shown among HIV-infected patients, the studies to date have been small, and rosiglitazone should be used with caution in the HIV population. In addition, Mallon and colleagues showed that simultaneous use of NRTIs may reduce the effects of TZD agents in promoting subcutaneous adipogenesis in HIV-infected patients with lipoatrophy by limiting the rosiglitazone-related increase in adipose expression of PPAR γ .¹⁶⁴

Lipid Management

Lipid abnormalities are common among HIV-infected patients. Hypertriglyceridemia is more common than hypercholesterolemia and is associated with HIV infection and increased VLDL secretion. In addition to effects of HIV itself, specific antiviral drugs contribute significantly to hypertriglyceridemia. Mulligan and associates demonstrated that changes in lipid levels occur within 3 months after initiation of PI therapy,¹⁶⁵ and Purnell and colleagues confirmed significant increases in triglyceride levels among HIV-negative patients receiving a short course of ritonavir after 2 weeks.¹⁶⁶ Hypertriglyceridemia is most severe among patients treated with ritonavir or a ritonavir/saquinavir combination. Nelfinavir and indinavir are less often associated with abnormalities in triglyceride levels. Among the currently approved PIs, atazanavir is least often associated with hyperlipidemia.¹⁶⁷ Lipid changes appear to be less and to improve with use of atazanavir, in contrast to other PIs.¹⁴⁹

Treatment for hyperlipidemia among HIV-infected patients is indicated to reduce CVD risk and should proceed according to standard National Cholesterol Education Program (NCEP) guidelines. Severe hypertriglyceridemia should be treated to reduce the risk of pancreatitis. Triglyceride levels higher than 1000 mg/dL are associated with pancreatitis, but lesser elevations are often asymptomatic and of unknown risk. If triglyceride levels increase substantially, lipid-lowering therapy should be considered. An initial option in patients with severe elevations in triglyceride levels is to switch treatment to a PI that is less likely to cause dyslipidemia. Triglyceride levels are reduced approximately 21% by diet¹⁶⁸ and 30% by exercise¹⁶⁹ in

HIV-infected patients. Neither diet nor exercise is likely to normalize triglyceride levels in the HIV-infected population with severe dyslipidemia.

Fenofibrate resulted in a 40% reduction in triglyceride levels and a 14% reduction in total cholesterol levels over 3 months in HIV-infected patients with hypertriglyceridemia.¹⁷⁰ Lesser but nonetheless beneficial effects may be seen with gemfibrozil or other fibrate derivatives. Niacin also significantly reduces triglyceride level, but it may aggravate glucose tolerance in HIV-infected patients, although such changes in glucose may only be transient.¹⁷¹ In addition, niacin can be difficult to use because of the associated flushing and potential liver abnormalities. Studies have also suggested the efficacy of omega-3 polyunsaturated fatty acids, which were shown in a randomized, placebo-controlled study to reduce triglyceride levels by 25.5% and to be well tolerated.¹⁷² In a study investigating combined therapy, triglyceride levels were reduced by 65.5% among hypertriglyceridemic HIV-infected patients receiving simultaneous fenofibrate and fish oil.¹⁷³

The 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitors are most useful for lowering cholesterol levels in HIV-infected patients, but they are less effective in lowering triglyceride levels. For example, pravastatin combined with dietary advice reduced total cholesterol levels by 17% over 24 weeks without effects on

triglyceride levels.¹⁷⁴ In addition, pravastatin reduced the number of small LDL particles by 27%.¹³⁷ The combination of gemfibrozil and atorvastatin resulted in a 30% reduction in cholesterol and a 60% reduction in triglycerides in HIV-infected patients,¹⁶⁸ and this combination may be useful in HIV-infected patients with combined hyperlipidemia. The risk of rhabdomyolysis increases when HMG-CoA reductase inhibitors are used in combination with fibric acid derivatives.

Data suggest that the PIs can themselves affect metabolism of the HMG-CoA reductase inhibitors. In this regard, ritonavir was shown to increase levels of simvastatin by 2600% and those of atorvastatin by 74%.¹⁷⁵ Use of simvastatin should be avoided in patients receiving PI therapy. In an analysis of almost 900 HIV-infected patients in the Kaiser Permanente system, use of statins was shown to lower LDL by 25.6% in HIV-positive patients, compared with 28.3% in HIV-negative patients; use of gemfibrozil lowered triglyceride by 44.2% versus 59.3%, respectively, in these two groups (Fig. 38-10). Effects of statins on LDL did not vary by antiretroviral treatment class, whereas effects of gemfibrozil were less in HIV-infected patients receiving PIs and best in those patients receiving therapy with non-NRTIs. Safety of the statins, including atorvastatin, pravastatin, and lovastatin, was good, with few cases of myositis. The relative potency of each statin on LDL was

Figure 38-10 Adjusted percentage changes in low-density lipoprotein (LDL) cholesterol and triglyceride levels within 12 months after initiation of lipid-lowering therapy in human immunodeficiency virus (HIV)-positive and -negative patients. Results are based on linear regression with adjustment for age, gender, year, lipid-lowering therapy class, months of follow-up, baseline LDL cholesterol and triglyceride levels, number of coronary disease risk factors, past coronary disease or diabetes diagnoses, and hepatitis B or C infection. The model for any statin use is also adjusted for dose-equivalents of different individual statins and concomitant use of other lipid-lowering therapy classes. The model for gemfibrozil is also adjusted for medication dose and concomitant use of other lipid-lowering therapy classes. Ator, atorvastatin; Lova, lovastatin; Prav, pravastatin; Simv, simvastatin. (Data from Silverberg MJ, Leyden WJ, Hurley L, et al. Response to newly prescribed lipid-lowering therapy in patients with and without HIV infection. *Ann Intern Med.* 2009;150:301-313, with permission.)

similar, with reductions ranging from 26.4% with atorvastatin to 23.6% with pravastatin.¹⁷⁶

Leptin

Leptin levels are low in association with fat loss and lipoatrophy in HIV-infected patients. Administration of leptin to HIV-infected patients with lipoatrophy and reduced leptin levels resulted in significant improvements in insulin sensitivity, HDL, triglycerides, and reduced truncal and visceral fat.^{177,178} Because leptin reduces appetite, administration is associated with weight loss, and the small studies to date do not permit the direct effects of leptin to be distinguished from those associated with weight loss.

CHAPTER 39

Gastrointestinal Hormones and Gut Endocrine Tumors

ADRIAN VELLA • DANIEL J. DRUCKER

Endocrine tumors originating from islet or enteroendocrine cells may manifest with unique clinical symptoms that reflect the biologic actions of secreted peptide hormones. In this chapter, we discuss how endocrine cell lineages develop during organogenesis in the endocrine pancreas and intestine, and we review the biologic actions of peptide hormones produced in pancreatic and intestinal endocrine cells and enteric nerves. Numerous physiologic actions of these peptides are still poorly understood and are being actively investigated. However, excessive production of one or more of these peptides frequently accounts for the clinical symptoms attributable to endocrine tumors arising from the gastrointestinal tract and pancreas.

ENDOCRINE CELL DEVELOPMENT IN THE PANCREAS

The endocrine and exocrine pancreas develops from the primitive foregut endoderm. Pancreatic morphogenesis is a complex process that begins with the evagination of the

embryonic foregut into ventral and dorsal buds at 28 days' gestation in humans and at embryonic day 8 (E8) in mice. Rotation of the stomach and duodenum during development results in simultaneous rotation of the ventral bud, which undergoes fusion with the dorsal bud to give rise to the primitive pancreas. The ventral bud develops into the posterior portion of the pancreatic head, including the uncinate process; the remaining pancreas is derived from the dorsal bud. In mice, a complex, treelike, epithelium-lined ductal system develops within the pancreatic diverticula, with glucagon-immunoreactive cells detected as early as E9.5, followed by detection of cells containing insulin at E10.5. Stem cells that give rise to terminally differentiated endocrine and exocrine acinar cells are thought to reside within the ductal epithelium.

In humans, islet formation begins at gestational week 12 with the aggregation of polyclonal endocrine cells. Between weeks 13 and 16, small aggregates of endocrine cells arise from the pancreatic duct and develop their own blood supply. By weeks 17 to 20, fewer islets are observed in contact with the ducts, and a mantle of non-beta endocrine cells forms around the beta cells. Between gestational

weeks 21 and 26, a continual increase in the proportion of islet tissue and in the average size of the islets is observed, with occasional non-beta cells in the center of the islet, a morphologic appearance that is characteristic of the post-natal islet. At birth, the endocrine pancreas accounts for 1% to 2% of the entire pancreatic cell mass.

Although genetic studies in mice have yielded valuable insights into the ontogeny of islet development, the relative order of appearance of unique populations of hormone-producing islet endocrine cells is different in humans and mice. Somatostatin- and pancreatic polypeptide (PP)-positive cells are detected at 7 weeks' gestation in the human pancreas, scattered among ductal cells. One week later, glucagon cells appear, and by 9 to 10 weeks' gestation, insulin-producing cells are detectable. In mice, both insulin- and glucagon-expressing cells are first detected between days E9.5 and E10.5, and somatostatin and PP are expressed by E15.5. Although cells coexpressing insulin and glucagon are detected during early islet development, cell lineage studies employing specific transgenes that mark or ablate islet cell precursors suggest that the alpha and beta cell lineages arise independently during ontogeny in the mouse.¹ Peptide YY (PYY) co-localizes with each of the four main islet hormones in the developing pancreas, but genetic evidence for an essential role of a PYY-producing precursor cell in pancreatic endocrine development has not been developed.

Delineation of the genetic determinants that regulate the developmental formation and organization of pancreatic endocrine cell populations has been facilitated by studies of mice with disruption of candidate regulatory genes, principally islet transcription factors (Table 39-1). The homeobox transcription factor Pdx1 is required for transcription of multiple beta-cell genes, including those for insulin and glucokinase in the adult beta cell, and for developmental formation of the entire pancreas.² Similarly, the homeodomain transcription factor Prox1 controls pancreatic morphogenesis and formation of islet cell precursors after E13.5. Mice homozygous for a null mutation in Pdx1 fail to develop a pancreas, whereas restricted inactivation of Pdx1 in the murine beta cell produces insulin deficiency and diabetes. Pancreatic agenesis has also been

reported in human subjects homozygous for a loss-of-function PDX1 mutation,³ and subjects heterozygous for PDX1 develop a form of maturity-onset diabetes of the young (MODY4).

Targeted disruption of the LIM domain *Isl1* gene in mice results in abnormal development of the dorsal pancreatic mesenchyme and abnormal differentiation of islet cells. A heterozygous human *ISL1* mutation has been reported in a single patient with type 2 diabetes. Mutations in the *Pax4* and *Pax6* genes produce profound abnormalities in developmental formation of murine pancreatic endocrine cells.⁴ Binding sites for the MODY genes *PDX1*, *HNF1A*, and *HNF4A* have been identified in the *PAX4* promoter, suggesting that MODY genes may be upstream regulators of genes critical for islet cell formation and islet function in the pancreas. Single-nucleotide polymorphisms in *PAX4* occur more commonly in some subjects with MODY, and a human kindred with aniridia and a *PAX6* mutation exhibited impaired glucose tolerance associated with evidence for impaired processing of proinsulin.⁵ Nevertheless, islet function has not been extensively studied in human subjects with *PAX* mutations.

Genes encoding members of the Notch receptor family, their ligands, and downstream targets are essential for developmental formation of the endocrine pancreas (see Table 39-1). Targeted inactivation of genes in the Notch signaling pathway markedly perturbs the normal development and differentiation of pancreatic endocrine cells. Mice lacking neurogenin 3 (*Ngn3*, also designated *Neurog3*), a basic helix-loop-helix (bHLH) transcription factor, fail to develop pancreatic endocrine cells and die from diabetes postnatally, whereas overexpression of *Ngn3* produces accelerated differentiation of pancreatic endocrine cells. These findings, taken together with the loss of *Isl1*, *Pax4*, *Pax6*, and *NeuroD* expression in *Ngn3*^{-/-} mice, implicate *Ngn3* as a key upstream regulator of pancreatic endocrine cell development.

The transcription factor *Arx* is expressed in an *Ngn3*-dependent manner, and targeted inactivation of the *Arx* gene results in hypoglycemia and neonatal lethality, with a failure to develop islet alpha cells.⁶ Similarly, the *Nkx* transcription factor family appears to be essential for the formation of beta and alpha cell lineages in the mouse.⁷ Targeted deletion of the *Nkx2.2* gene produced murine islets expressing ghrelin,⁸ and subsequent studies demonstrated that ghrelin is produced within a subset of normal islet alpha cells and in a small proportion of newly identified ghrelin-producing epsilon cells.⁸ Research into the identification of upstream control mechanisms and downstream targets that promote islet cell formation, growth, and differentiation is proceeding rapidly and informing scientists and clinicians about the genetic determinants regulating the growth of normal and neoplastic endocrine cells.⁹ Table 39-1 summarizes the genetic mutations associated with abnormal formation of pancreatic endocrine cells in the mouse.

TABLE 39-1

Effects of Disruption of Genes Important for Development of Pancreatic Endocrine Cells

Gene	Phenotype in Homozygous (-/-) Mutant Mice
<i>Arx</i>	Failure to develop glucagon-positive alpha cells
<i>FoxM1</i>	Impaired beta-cell replication
<i>Glis3</i>	Impaired islet and beta-cell development
<i>Hes1</i>	Increased glucagon-positive alpha cells, pancreatic hypoplasia
<i>Hlxb9</i>	Dorsal lobe agenesis, small islets, reduced beta cells
<i>Isl1</i>	Loss of differentiated islet cells
<i>Myt1</i>	Abnormal islet cell development
<i>Nkx2.2</i>	Absent mature beta cells, reduced alpha and PP cells
<i>Nkx6.1</i>	Reduced beta cell precursors
<i>NeuroD</i>	Reduced beta cells, arrested islet morphogenesis
<i>Ngn3</i>	Absent islet cells and defective enteroendocrine cell formation
<i>Nkx6</i>	Impaired alpha-cell development
<i>Pax4</i>	Absent islet beta and delta cells
<i>Pax6</i>	Absent islet alpha cells
<i>Pbx1</i>	Marked reduction in islet alpha and beta cells
<i>Pdx1</i>	Pancreatic agenesis
<i>Sox4</i>	Defective islet development

ENDOCRINE CELL DEVELOPMENT IN THE INTESTINE

Stem cells associated with the intestinal epithelium differentiate into four cell lineages: enterocytes, Paneth cells, goblet cells, and enteroendocrine cells. In mice, the bHLH gene *Atoh1* (formerly designated *Math1*) is a critical regulator of intestinal secretory cell lineages. Deletion of *Atoh1* results in failure to develop goblet, Paneth, or

enteroendocrine cell lineages.¹⁰ The enteroendocrine cell population comprises less than 1% of all intestinal epithelial cells but represents the largest mass of endocrine cells in the body. Compared with pancreatic endocrine cell development, much less is known about the molecular control of enteroendocrine cell formation and differentiation. Numerous enteroendocrine cell types have been identified that can be classified based on morphologic criteria and expression of one or more secretory products. In the stomach, gastrin cells first appear in the duodenum; they localize to the antrum and pylorus in adult gastric mucosa. In the small bowel, a secretin-precursor cell appears to be important for enteroendocrine cell lineage formation. In the murine colon, PYY is the first detectable hormone marking the appearance of enteroendocrine cells; it is coexpressed in most endocrine cells in the large intestine as they first differentiate.

The Notch signaling pathway is essential for developmental formation of enteroendocrine cells. Activation of the Notch pathway in mice results in increased expression of the bHLH transcriptional repressor Hes1, which functionally antagonizes bHLH genes that regulate cellular differentiation. Mice deficient in Hes1 demonstrate premature cellular differentiation and severe pancreatic hypoplasia due to depletion of pancreatic epithelial precursors.¹¹ These mice also demonstrate excessive differentiation of multiple endocrine cell types in the developing stomach and gut, suggesting that Hes1 is a negative regulator of endodermal endocrine differentiation. Ngn3 is expressed at early time points during gut development and is essential for development of enteroendocrine cells in the small intestine¹² and in the stomach.¹³ In mice, Notch1 and Ngn3 act upstream of BETA2/NeuroD, a bHLH protein that is important for differentiation of endocrine cells in the pancreas and intestine (Table 39-2).¹⁴

Mice homozygous for a null mutation in the *Pdx1* gene demonstrate poorly differentiated duodenal intestinal epithelium with absence of Brunner's glands and a deficiency of gastrin cells in the stomach. Just distal to the abnormal epithelium, the number of enteroendocrine cells is reduced. In contrast, expression of *Pdx1* in gut epithelial cells redirects cell lineage toward an enteroendocrine phenotype. Inactivation of BETA2/NeuroD in mice results in absence of secretin- and cholecystokinin (CCK)-producing enteroendocrine cells.¹⁴ The complexity of lineage relationships between gut endocrine cell populations is further illustrated by studies in mice with targeted ablation of secretin-producing cells. These mice exhibit almost complete

TABLE 39-2

Consequences of Disruption of Genes Important for Development of Enteroendocrine Cells

Gene	Phenotype in Homozygous (–/–) Mutant Mice
Hes1	Enhanced numbers of enteroendocrine cells
Insm1	Defective enteroendocrine cell differentiation
NeuroD	Absent secretin and CCK lineages
Ngn3	Absent enteroendocrine cell development in the small intestine
Nkx2.2	Abnormal allocation of gut endocrine cell lineages
Pax4	Reduced endocrine cell lineages in duodenum and stomach
Pax6	Reduced number of GIP+ K cells, antral gastrin and somatostatin cells, and L cells
Pdx1	Reduced enteroendocrine cells in stomach and duodenum
lhh	Reduced enteroendocrine cells in duodenum

CCK, cholecystokinin; GIP, gastric inhibitory polypeptide.

elimination of enteroendocrine cell populations producing CCK, PYY, and glucagon and a reduction in cells producing gastric inhibitory polypeptide (GIP), somatostatin, and serotonin.¹⁵ Similarly, combined deletion of *Foxa1* and *Foxa2* from the gut results in reduction of selected endocrine cell lineages.

Members of the *Pax* gene family are also essential for the formation of enteroendocrine cells (see Table 39-2). In mice, targeted disruption of *Pax4* markedly reduces the number of murine duodenal cells immunopositive for serotonin, secretin, GIP, PYY, and CCK and decreases the number of somatostatin- and serotonin-positive cells in the stomach. Complete disruption of the *Pax6* locus more selectively reduces the number of duodenal cells expressing GIP and CCK¹⁶ and decreases the number of gastrin- and somatostatin-immunopositive cells in the stomach, whereas *Sey-Neu* mice that express a dominant negative mutant *Pax6* allele demonstrate markedly reduced levels of proglucagon messenger RNA (mRNA) transcripts in the small and large intestines, with almost complete depletion of enteroendocrine cells exhibiting glucagon-like peptide 1 (GLP1) and glucagon-like peptide 2 (GLP2) immunoreactivity (Fig. 39-1).¹⁷ *Nkx2.2* appears to control the expression of *Pax6*, and *Nkx2*-null mice exhibit significant reductions in expression of CCK, gastrin, glucagon, GIP, neurotensin, and somatostatin.¹⁸ The classification of enteroendocrine cells is currently based principally on the

Figure 39-1 **A**, *Pax6* is an essential requirement for glucagon-immunopositive enteroendocrine cell formation in the murine intestine. **B**, *Pax6* *Sey-Neu* mutant mice (–/–) exhibit markedly reduced numbers of glucagon-immunopositive cells in the small and large intestine.

phenotype ascribed to the production of one or more peptide hormones, but it seems likely that additional enteroendocrine cell subpopulations will be described in different regions of the gut that exhibit considerable biologic complexity beyond what is currently appreciated.

PANCREATIC AND GUT HORMONES

Amylin

Amylin, also known as islet amyloid-associated peptide, is a 37-amino-acid hormone produced in islet beta cells and in scattered endocrine cells in the stomach and the proximal small intestine. Exogenous administration of amylin inhibits gastric emptying and glucagon secretion in rodents and humans. Excess amylin secretion and deposition in the endocrine pancreas has been implicated as a potential pathogenic feature in some subjects with type 2 diabetes, and transgenic mice engineered to overexpress human amylin develop islet amyloid and impaired insulin secretion after a high-fat feeding.¹⁹ Amylin exerts its physiologic actions through interaction with the calcitonin receptor in the presence of a receptor activity-modifying protein (RAMP). Mice deficient in amylin display modest perturbations in islet function and enhanced glucose clearance after a glucose challenge. The role of gut-derived amylin in human physiology has not been clearly established, but the amylin analogue pramlintide is approved for the adjunctive treatment of type 1 and type 2 diabetes with concomitant insulin administration.²⁰ It delays gastric emptying in a dose-dependent manner through vagally mediated mechanisms. Although amylin expression has been detected in pancreatic and gut endocrine tumors, a specific syndrome attributable to amylin overexpression has not been delineated.

Apelin

Apelin is a 36-amino-acid peptide originally purified from bovine stomach extracts that was determined to be the endogenous ligand for the orphan G protein-coupled receptor APJ (now designated APLNR).²¹ Apelin and its receptor are widely expressed in peripheral tissues, such as the lung, heart, and mammary gland, and in the central nervous system (CNS); in the gastrointestinal tract, apelin is most abundant in the stomach.²² Apelin promotes cardiomyogenesis during development and produces vasodilator and inotropic actions in the adult cardiovascular system.²³ The apelin system shares significant similarities with the renin-angiotensin system, and the two systems may have antagonistic and overlapping roles. Apelin is downregulated in left ventricular dysfunction, is an adipokine, and enhances insulin action in mouse models of insulin resistance.²⁴ The apelin receptor functions as a coreceptor for human immunodeficiency virus (HIV) in vitro, and apelin-related peptides act as antagonists of HIV infection.²³

Calcitonin Gene-Related Peptide

Calcitonin gene-related peptide (CGRP) is a member of a larger family of peptides that includes calcitonin, amylin, and adrenomedullin. In humans, distinct genes *CALCA* and *CALCB* encode calcitonin and CGRP and give rise to two 37-amino-acid, carboxy terminal-amidated neuropeptides designated α -CGRP and β -CGRP. These neuropeptides share considerable amino acid sequence homology, with a

difference of only three amino acids in humans. α -CGRP is expressed predominantly in primary afferent sensory neurons arising from the spinal cord, whereas β -CGRP is expressed in enteric neurons. Two calcitonin/CGRP seven-transmembrane domain, G protein-coupled receptors²⁵ interact with a family of RAMPs; coexpression of calcitonin receptor-like receptor with RAMP1 results in ligand specificity for CGRP, whereas expression of the same receptor with RAMP2 results in specificity for adrenomedullin.²⁶

CGRP immunoreactivity has been localized to enteroendocrine cells in the human rectum and to endocrine cells and neurons in the small intestine. Intestinal CGRP is released in response to glucose and by gastric acid secretion. CGRP produces marked vasodilatation in the stomach, splanchnic, and peripheral circulation through stimulation of nitric oxide release. CGRP also inhibits gastric acid and pancreatic exocrine secretion, probably through stimulation of somatostatin release. Although focal CGRP positivity has been detected in some human carcinoid and pancreatic endocrine tumors, its utility as a tumor marker has not been firmly established.

Cholecystokinin

CCK was first characterized as a factor that stimulates gallbladder contraction. The CCK gene is expressed in open-type enteroendocrine cells in the proximal small intestine (Table 39-3) and in nerve fibers branching to the gastric and colonic myenteric plexus and submucosal plexus, where CCK acts as a neurotransmitter. CCK-immunoreactive peptides are found in the cerebral cortex and in the limbic system, as well as in pituitary corticotrophs, C cells of the thyroid, adrenal medulla, and the acrosome of the developing and mature spermatozoa. The CCK gene encodes a 94-amino-acid prohormone that is post-translationally processed in a tissue-specific fashion into multiple molecular forms, including CCK-83, CCK-58, CCK-39, CCK-33, CCK-22, CCK-8, and CCK-5, all sharing a common C-terminus. The major active form, CCK-8, is an octapeptide containing a sulfated tyrosine residue and an amidated C-terminal phenylalanine residue. CCK-33 appears to be the predominant circular form in human plasma.²⁷

CCK binds with high affinity to CCKAR, a seven-transmembrane domain, G protein-coupled receptor expressed in pancreatic acinar cells, gallbladder, smooth muscle, chief and D cells of the gastric mucosa, and the

TABLE 39-3

Location of Enteroendocrine Cells and Their Associated Peptide Hormones in the Gastrointestinal Tract

Hormones	Enteroendocrine Cell	Location
Somatostatin	D cells	Stomach, duodenum, small intestine, colon
Gastrin, TRH	G cells	Stomach and duodenum
CCK	I cells	Duodenum and jejunum
GIP	K cells	Duodenum and proximal jejunum
GLP I, GLP2, PYY	L cells	Ileum, colon, and rectum
Motilin	M cells	Duodenum and proximal jejunum
Neurotensin	N cells	Small intestine especially ileum
Secretin	S cells	Duodenum and proximal jejunum

CCK, cholecystokinin; GIP, gastric inhibitory polypeptide; GLP, glucagon-like peptide; PYY, peptide YY; TRH, thyrotropin-releasing hormone.

central and peripheral nervous systems. In the stomach, CCK inhibits proximal gastric motility while increasing the force of antral and pyloric contractions. CCK also regulates meal-stimulated pancreatic enzyme secretion and gallbladder contraction.

CCK exhibits trophic effects on pancreatic acini in rats. Experimental manipulations that increase levels of circulating CCK, such as treatment with soybean trypsin inhibitor or long-term pancreatobiliary diversion, result in pancreatic growth and premalignant changes. Elevated circulating levels of CCK also enhanced the development of preneoplastic acinar lesions induced by azaserine, a pancreatic carcinogen in rats. In contrast, the Otsuka Long-Evans Tokushima Fatty (OLETF) rat fails to express a functional CCKAR and exhibits reduced pancreatic size.²⁸ The CCKB receptor (CCKBR) mediates the trophic actions of progastrin in murine normal and neoplastic gut.²⁹

Exogenous administration of CCK decreases the size of spontaneously ingested meals, whereas CCKAR antagonists increase appetite and delay gastric emptying in humans. A human subject with autoimmune polyglandular syndrome type 1 exhibited severe diarrhea and malabsorption associated with reduced numbers of enteroendocrine cells and CCK deficiency.³⁰ CCK secretion in response to oral nutrient ingestion probably regulates nutrient absorption and postprandial satiety, and CCK-8 regulates hepatic glucose production through a CNS-dependent CCKAR mechanism that may be defective in the setting of obesity-induced insulin resistance.³¹ Nevertheless, CCK receptors do not appear to be essential for weight regulation in vivo because mice with targeted disruption of CCKAR and CCKBR exhibit normal food intake and weight gain well into adult life. Emerging evidence suggests that CCK may represent an important growth factor for adaptive islet growth in rodents.

Galanin

Galanin was initially isolated from porcine intestine as a 29-amino-acid, C-terminally amidated neuropeptide. In humans, the two molecular forms of galanin are 19 and 30 amino acids long. Galanin is expressed in the central and peripheral nervous systems, in the pituitary, and in neural structures of the gut, pancreas, thyroid, and adrenal gland. In the intestine, galanin immunoreactivity is detected predominantly within enteric neurons located in the myenteric and submucosal plexus that innervate the mucosa and the circular and longitudinal smooth muscle layers. Galanin is released by enteric neurons in response to intestinal distention, chemical stimulation of the mucosa, and electrical stimulation of periaxonal nerves and extrinsic sympathetic neurons.

At least three galanin receptor subtypes have been identified: GALR1, GALR2, and GALR3; they are widely expressed in gastric and intestinal smooth muscle cells, in the pancreas, and in the CNS.³² The actions of galanin include regulation of food intake, memory and cognition, and anti-nociception, and it modulates multiple neuroendocrine systems in the pituitary, pancreas, and gut. Galanin exhibits potent anticonvulsant activity in experimental rodent models of seizure disorders,³³ and it likely acts through modulation of glutamate release. Galanin may also act as a neuroprotective factor, and galanin knockout mice exhibit enhanced sensitivity to neuronal injury.³⁴ Although GalR1^{-/-} mice exhibit increased anxiety and abnormal nociceptive sensitivity, mice with inactivation of GalR2 are normal and do not exhibit defects in classic phenotypes ascribed to galanin.

Galanin knockout mice that have reduced levels of prolactin and complete failure of lactation exemplify the importance of galanin in pituitary lactotroph biology. Although galanin can inhibit GIP- and GLP1-induced proinsulin gene transcription and insulin secretion, infusion of galanin in humans has no effect on levels of plasma insulin. Galanin also inhibits pancreatic exocrine secretion and intestinal ion transport, and it induces contraction and relaxation of intestinal smooth muscle. In humans, intravenous administration of galanin delays gastric emptying and prolongs colonic transit times. Although galanin expression has been detected in hypothalamic, pituitary, and adrenal tumors, galanin immunopositivity in pancreatic or gut endocrine tumor cells is rare.

Gastric Inhibitory Polypeptide

GIP, also called glucose-dependent insulinotropic polypeptide, is a 42-amino-acid peptide secreted by enteroendocrine K cells located in the duodenum and proximal jejunum. GIP levels rise immediately after nutrient ingestion, leading to modest inhibitory effects on gastric acid secretion and gastrointestinal motility. The precise role of GIP as an enterogastrone remains controversial, because supraphysiologic concentrations of GIP are required to inhibit gastric acid secretion and gastric emptying in humans.

The actions of GIP on the pancreatic beta cell are primarily those of an incretin, a gut-derived peptide that stimulates insulin secretion in the setting of raised plasma glucose levels after oral nutrient ingestion. GIP receptor knockout mice are viable but exhibit impaired oral glucose tolerance and enhanced susceptibility to diabetes after high-fat feeding.³⁵ GIP receptors are expressed on adipocytes, where they modulate lipid accumulation. Transient blockade of GIP receptor signaling with GIP antagonists or genetic elimination of the GIP receptor in mice reduces fat storage in adipocytes and may contribute to improved insulin sensitivity through reduction of adipokine expression.³⁶

GIP is an essential determinant of bone resorption in rodents, but the role of GIP in the control of bone turnover in human subjects remains uncertain. Although GIP is a potent stimulator of glucose-dependent insulin secretion in normal rodents and human subjects, experimental or clinical diabetes is associated with defective GIP action and reduced insulinotropic activity of exogenous GIP. The reduced insulinotropic activity of GIP in diabetic subjects can be partially reversed by a brief period of insulin administration.³⁷ GIP-secreting endocrine tumors are rare, but gut-derived GIP may contribute to the development of food-induced Cushing's syndrome in a subset of patients with adrenal adenomas that express the GIP receptor.³⁸

Gastrin

A single mRNA transcript encodes a pre-progastrin precursor of 101 amino acids that undergoes post-translational processing into many biologically active molecular forms of circulating gastrin, including G-34, G-17, and G-14. Gastrin is produced predominantly in G cells located in the gastric antrum and duodenal bulb, but gastrin immunoreactivity has also been detected in the central and peripheral nervous systems, pituitary, adrenal gland, genital tract, respiratory tract, and tumors. The fetal endocrine pancreas produces large amounts of amidated gastrin, suggesting a possible role of gastrin in pancreatic development. However, gastrin-deficient mice do not demonstrate overt abnormalities in pancreatic islet morphology.

G cells are open-type endocrine cells that are subject to regulation by luminal contents in addition to humoral and neural influences. The effects of gastrin on acid secretion are mediated by the fully processed amidated forms of gastrin (G-17 and G-34) at CCKBRs (formerly known as gastrin/CCK2 receptors) located on the enterochromaffin-like (ECL) cells of the oxyntic mucosa. Gastrin stimulates histamine synthesis and release from ECL cells; histamine then induces acid secretion by binding to the histamine H₂ receptor located on the basolateral aspect of the parietal cell. Gastrin also stimulates acid secretion from parietal cells through the CCKBR.

The actions of progastrin and glycine-extended gastrin are less completely defined but involve regulation of the growth and differentiation of the gastrointestinal tract. Amidated gastrin has trophic effects on the oxyntic mucosa of the stomach, where it stimulates proliferation of gastric stem cells and ECL cells, resulting in increased parietal and ECL mass. Glycine-extended gastrin exerts trophic effects on the colonic mucosa and stimulates growth of a diverse number of human cancers. Transgenic mice expressing progastrin or glycine-extended gastrin exhibit increased colonic proliferation and mucosal thickness and are more prone to formation of aberrant crypt foci after treatment with azoxymethane, whereas inactivation of the gastrin gene results in reduced basal rates of colonic proliferation.³⁹ The proliferative actions of progastrin in the normal gut and in colonic neoplasms requires a functional CCKBR.²⁹

Gastrin induces proliferation of colon cancer cell lines expressing the CCKBR, but most colon cancers and normal colonic epithelium do not normally express this receptor. A truncated gastrin-binding receptor has been described in some colon cancer cell lines, and a constitutively active CCKBR mutant, called CCK2i4svR, that confers ligand-independent growth to transfected cells has been identified in human colorectal and pancreatic cancers.^{40,41} CCKAR and CCKBR are capable of forming homodimers and heterodimers, and heterodimerization appears to modulate the sensitivity to agonist-induced cell growth.⁴²

The trophic effects of gastrin have led to studies of gastrin-neutralizing antisera for the potential treatment of intestinal neoplasia.⁴³ Conversely, G-17 has been shown to reduce cell proliferation and induce apoptosis in human colon cancer cells expressing the CCKBR.⁴⁴ Gastrin is mitogenic for rodent and human pancreatic islet and ductal cells that have been cultured in vitro or propagated in immunodeficient, nonobese diabetic (NOD), severe combined immunodeficient (SCID) mice.⁴⁵ Treatment of mice with gastrin and epidermal growth factor or gastrin plus GLP1 ameliorates type 1 diabetes in NOD mice. These findings implicate a role for gastrin or epidermal growth factor, or both, in modulation of the immune response that initiates development of type 1 diabetes in NOD mice.

Gastrin-Releasing Peptide and Related Peptides

The bombesin family of peptides was originally isolated from frog skin and includes bombesin, gastrin-releasing peptide (GRP, the mammalian homolog of bombesin), neuromedin B, and neuromedin C. GRP is a 27-amino-acid peptide; neuromedin B and neuromedin C are decapeptides. These peptides share an identical C-terminal α -amidated heptapeptide sequence that is essential for biologic activity. GRP is expressed in the central, peripheral, and enteric nervous systems; the reproductive tract; and the lung, where it acts as a neurotransmitter. Neuromedin

B is expressed predominantly in the brain and the gastrointestinal tract. Within the intestine, GRP and neuromedin B are localized to neurons in the submucosal and myenteric plexus of the stomach, small intestine, and colon. GRP-containing neurons are also distributed throughout the human pancreas. Bombesin and GRP stimulate smooth muscle cell contraction in the stomach, intestine, and gallbladder. GRP stimulates the release of CCK, gastrin, GIP, glucagon, GLP1, GLP2, motilin, PP, PYY, and somatostatin in some species.

Three GRP receptor subtypes that are seven-transmembrane domain, G protein-coupled receptors that bind bombesin-like peptides have been cloned. They include a GRP-preferring subtype (expressed throughout the intestine), a neuromedin B-preferring subtype (expressed in the esophageal and intestinal muscularis), and a third subtype designated bombesin receptor subtype 3, which preferentially binds GRP over neuromedin B and is expressed in testes and small-cell lung cancer. GRP regulates appetite, memory, and thermoregulation and suppresses appetite after intracerebroventricular or systemic administration. Mice with knockout of the GRP-preferring receptor exhibit defective control of food intake and increased body weight gain.⁴⁶ GRP stimulates pancreatic growth in part through a CCK-dependent mechanism. The expression of GRP in human tumors with neuroendocrine properties (e.g., small-cell carcinoma, medullary thyroid carcinoma) and its autocrine and endocrine effects on cell growth suggest that GRP may contribute to regulation of tumor cell growth.⁴⁷ GRP exhibits angiogenic properties, and GRP antagonists reduce tumor growth and angiogenesis in vivo.⁴⁸

Ghrelin

Ghrelin, a motilin-related peptide, is a 28-amino-acid growth hormone-releasing factor that originally was purified from rat stomach. It stimulates growth hormone release through the growth hormone secretagogue receptor (GHSR). Fasting increases gastric ghrelin gene expression, and ghrelin exhibits gastric prokinetic activity and orexigenic activity after intracerebroventricular or peripheral administration through the ghrelin receptor expressed in hypothalamic nuclei. Control of ghrelin acylation is regulated by ghrelin O-acyl transferase (GOAT), which is regulated by nutrient availability, requires specific dietary lipids as acylation substrates, and links the availability of medium-chain fatty acids to control of energy expenditure and body fat mass.⁴⁹ Ghrelin expression is induced by stressors, and ghrelin may play a role in the murine anxiogenic stress response in a corticotropin-releasing factor-dependent manner. Most rat and human gut endocrine cells that express ghrelin are localized to the stomach, with a small number of ghrelin-positive cells identified in the small and large intestine.⁵⁰ The GHSR also is expressed in the gut, but the function of the intestinal ghrelin-GHSR axis remains poorly understood. Bioactive ghrelin is acylated, and circulating immunoreactive ghrelin represents a mixture of the free acylated form and molecules bound to higher-molecular-weight proteins.⁵⁰

Circulating levels of ghrelin in human subjects increase and fall before and after food ingestion, respectively, consistent with a role for ghrelin in appetite regulation. The effects of ghrelin on stimulation of appetite, but not on growth hormone secretion, require an intact vagus nerve.⁵¹ Many hormonal mediators regulate plasma levels of ghrelin, including PYY(3-36), which suppresses appetite in association with a reduction in circulating ghrelin.

Diet-induced weight loss is associated with a compensatory increase in circulating ghrelin, but some patients with weight loss after gastric bypass surgery fail to upregulate plasma levels of ghrelin.⁵²

Ghrelin exhibits several actions beyond control of appetite, including regulation of insulin sensitivity and hepatic glucose output and regulation of immature Leydig cell proliferation. Ghrelin action in the CNS increases food intake, most likely through activation of neurons containing neuropeptide Y (NPY)/agouti-related peptide. Central ghrelin infusion also enhances glucose uptake in peripheral adipose tissue. Ghrelin is expressed in pancreatic islet alpha cells and may regulate glucose-induced insulin secretion. Ghrelin exhibits effects on cardiovascular function, including vasodilation, inhibition of a proinflammatory response in endothelial cells, and improvement of left ventricular contractility and exercise capacity in human subjects with left ventricular failure.⁵³

Glucagon, Glucagon-Like Peptide 1, and Glucagon-Like Peptide 2

The proglucagon gene is expressed in the pancreatic alpha cell, the intestinal L cell, and specialized regions of the brain, primarily neurons in the brainstem and, to a lesser extent, in the hypothalamus. In mammals, a single proglucagon precursor is differentially processed to yield multiple proglucagon-derived peptides, including glucagon in the islet alpha cell and glicentin, oxyntomodulin, GLP1, GLP2, and several spacer or intervening peptides in the gut enteroendocrine L cell.

Pancreatic glucagon is a 29-amino-acid peptide that regulates plasma glucose levels through effects on gluconeogenesis and glycogenolysis. Glucagon excess represents one of the hallmark metabolic derangements that contribute to hyperglycemia in type 1 and type 2 diabetes. Conversely, appropriately increased glucagon secretion functions as the primary counterregulatory mechanism to restore normal levels of plasma glucose in the setting of hypoglycemia, and individuals who are prone to frequent episodes of hypoglycemia may use glucagon injections for emergency management of severe hypoglycemia. The physiologic importance of glucagon action has been examined after genetic or transient interruption of glucagon receptor expression. Glucagon receptor knockout mice exhibit modest fasting hypoglycemia, pancreatic alpha cell hyperplasia, and markedly elevated levels of circulating glucagon and GLP1.⁵⁴ Similarly, transient reduction of glucagon receptor mRNA transcripts in rodents markedly lowers blood glucose, improves insulin secretion, and increases levels of circulating GLP1 in rodents with experimental diabetes.

GLP1 secreted from the gut endocrine cell enhances glucose disposal after nutrient ingestion by stimulation of insulin and inhibition of glucagon secretion.⁵⁵ Pharmacologic levels of GLP1 inhibit food intake, stimulate pancreatic islet neogenesis and proliferation, and inhibit beta cell apoptosis, biologic actions that facilitate long-term control of nutrient homeostasis (Fig. 39-2). The physiologic importance of endogenous GLP1 has been studied using the GLP1 receptor antagonist exendin(9-39) and *Glp1R*^{-/-} mice. Exendin(9-39) deteriorates glycemic control, increases insulin and decreases glucagon levels, and increases gastric emptying in rodents and humans. Similarly, *Glp1R*^{-/-} mice exhibit defective glucose-stimulated insulin secretion, glucose intolerance, and enhanced susceptibility to islet injury. These findings illustrate the essential importance of endogenous GLP1 in the control of islet hormone secretion and gut motility.

Figure 39-2 Molecular mechanisms of glucagon-like peptide (GLP) action. The GLP1 receptor expressed on islet beta cells promotes growth and cytoprotection, leading to expansion of beta cell mass. The GLP2 receptor, expressed on human gut endocrine cells, enteric neurons, and myofibroblasts, indirectly activates pathways coupled to control of mucosal permeability, cell proliferation, and apoptosis, leading to expansion of the surface area of the small bowel mucosal epithelium.

Several GLP1 receptor agonists have been approved for the treatment of type 2 diabetes. Exendin-4 (exenatide), administered twice daily, reduced hemoglobin A_{1c} values and prevented weight gain in 6-month, randomized clinical trials enrolling subjects with type 2 diabetes not well controlled on one or two oral antidiabetic agents.⁵⁶ The principal side effects associated with exenatide use were gastrointestinal, predominantly nausea. Antibodies against exenatide were detected in about 40% of treated patients, but they did not seem to correlate with therapeutic outcome. Similarly, liraglutide, a human GLP1 receptor agonist, is used as monotherapy or, more commonly, in combination with other oral agents. Liraglutide appears to be slightly more effective in controlling blood glucose, compared with twice-daily exenatide.⁵⁷ Many once-weekly GLP1 receptor agonists are being developed and appear to be more potent antidiabetic agents than the shorter-acting agonists.⁵⁶

GLP2 is a 33-amino-acid peptide that is cosecreted with GLP1, oxyntomodulin, and glicentin from enteroendocrine cells in a nutrient-dependent manner. GLP2 inhibits both centrally induced antral motility and meal-stimulated gastric acid secretion. GLP2 exhibits trophic actions in the small intestine and colon (see Fig. 39-2) through stimulation of crypt cell proliferation and reduction of apoptosis within the crypt and villus compartments.⁵⁸ GLP2 also exerts actions independent of intestinal growth, including enhancement of intestinal epithelial barrier function and stimulation of blood flow and of intestinal hexose and lipid transport.⁵⁹ The beneficial actions of GLP2 in experimental models of intestinal injury and in human subjects with short-bowel syndrome suggest that GLP2 may be useful for preventing injury and enhancing repair, regeneration, and function in the gastrointestinal epithelium.^{59,60}

The actions of GLP1 and GLP2 are transduced through distinct receptors, and both peptides are rapidly cleaved at the position 2 alanine by dipeptidyl peptidase 4 (DPP4). Genetic elimination of DPP4 action in rodents increased the levels of GIP and GLP1, enhanced glucose-stimulated insulin secretion, and lowered blood glucose levels.⁶¹ Conversely, chemical inhibitors of DPP4 lowered glucose and hemoglobin A_{1c} values in preclinical models and in humans with type 2 diabetes.⁵⁶ Several DPP4 inhibitors

(e.g., sitagliptin, saxagliptin, vildagliptin) are approved for the treatment of type 2 diabetes. They increase insulin and suppress postprandial glucagon secretion but do not produce changes in gastrointestinal motility, satiety, or body weight.^{56,62}

In contrast to GLP1 and GLP2, the biologic actions of the proglucagon-derived peptides glicentin and oxyntomodulin are less well established. Glicentin appears to be trophic for the gut mucosal epithelium, whereas oxyntomodulin inhibits short-term food intake and pentagastrin-stimulated gastric acid secretion *in vitro* and *in vivo*. Oxyntomodulin administered three times daily for 4 weeks reduced body weight in overweight and obese human subjects.⁶³ Although distinct G protein-coupled receptors for glucagon, GLP1, and GLP2 have been characterized, separate receptors that mediate the actions of glicentin and oxyntomodulin have not been identified, and the anorectic action of oxyntomodulin requires a functional GLP1 receptor.⁶⁴ Oxyntomodulin simultaneously activates both glucagon and GLP1 receptors, and oxyntomodulin mimetics resulted in enhanced weight loss in preclinical models compared with the actions of GLP1 receptor agonists alone.⁶⁵

Motilin

Motilin is a 22-amino-acid peptide originally isolated from porcine intestine. Motilin immunoreactivity has been detected in open-type enteroendocrine epithelial M cells located predominantly in the duodenum and proximal jejunum. Secretion of motilin occurs in a cyclic manner during the interdigestive state between meals. The presence of nutrients in the duodenum suppresses the endogenous release of motilin in dogs and humans. Duodenal alkalization, sham feeding, gastric distention, and administration of opioid agonists promote motilin secretion. A putative motilin receptor has been cloned that exhibits 52% amino acid identity with the human receptor for growth hormone secretagogues. The motilin receptor is expressed in many regions of the gastrointestinal tract, predominantly in smooth muscle and enteric neurons, and it binds the macrolide antibiotic erythromycin.⁶⁶

Motilin induces phase III contractions in the stomach, an effect that can be abolished by food ingestion, duodenal acidification, somatostatin, pentagastrin, and CCK. Atropine and 5-hydroxytryptamine antagonists also abolish phase III contractions, emphasizing the importance of the cholinergic and serotonergic neuronal pathways. Motilin stimulates gastric and pancreatic enzyme secretion and induces contraction of the gallbladder, sphincter of Oddi, and lower esophageal sphincter. Administration of motilin induces nausea and inhibits gastric emptying in human subjects.

Neuropeptide Y

NPY is primarily synthesized and secreted by neurons in the central and peripheral nervous systems. In the brain, NPY is expressed in the hypothalamus, where it exhibits extremely potent effects on nutrient intake, and in the cortex, hippocampus, basal forebrain striation, limbic structures, amygdala, and brainstem. In the peripheral nervous system, NPY expression occurs predominantly in sympathetic neurons and in the myenteric and submucosal plexuses of the enteric nervous system. NPY and vasoactive intestinal peptide (VIP) are often coexpressed in enteric neurons. NPY is synthesized in and released from pancreatic islet cells, and it inhibits glucose-stimulated insulin secretion through the Y1 receptor. Elevated circulating NPY

levels are observed after sympathetic nervous system activation and in patients with pancreatic endocrine tumors and carcinoid tumors or neurogenic tumors, including neuroblastomas and pheochromocytomas.

NPY exerts its actions through at least four receptor subtypes, including the Y1 and Y2 receptors, which bind NPY and PYY with similar affinities, and the Y3 receptor, which exhibits a preference for NPY over PYY. Increased hypothalamic NPY is a potent stimulator of food intake in rodents, but NPY antagonists have not proved useful for the treatment of human obesity. NPY is also produced in adipocytes, where it promotes adipogenesis. NPY actions in the cardiovascular system include stimulation of vascular smooth muscle cell growth and neointima formation through Y1 and Y2 receptors, and its angiogenic effects are mediated through Y2 and Y5 receptor activation.⁶⁷ NPY and PYY are targets for amino-terminal degradation by the enzyme DPP4, leading to the generation of NPY(3-36) and PYY(3-36), peptides that exhibit preferential binding to the Y2 receptor. In the gastrointestinal tract, NPY reduces fluid and electrolyte secretion and inhibits gastric and small-intestinal motility. Intravascular administration of NPY is associated with marked vasoconstriction of the splanchnic circulation, an effect that is not effected by α - or β -adrenergic blockade.

Neurotensin

Neurotensin is a 13-amino-acid peptide originally detected in bovine hypothalamus. Neurotensin-related peptides include neuromedin N (a 6-amino-acid, neurotensin-like peptide coencoded in proneurotensin), xenin, and xenopsin. In the gastrointestinal tract, processing favors the generation of neurotensin in N cells of the ileum and in enteric neurons. Neurotensin also is produced in the central and peripheral nervous systems, heart, adrenals, pancreas, and respiratory tract. Neurotensin secretion is stimulated by luminal nutrients, especially lipids, but not by amino acids or carbohydrates. GRP also stimulates neurotensin release, and somatostatin exerts an inhibitory effect.

At least three neurotensin receptors or neurotensin-binding proteins have been identified. NTS1 and NTS2 belong to the G protein-coupled receptor family, whereas NTS3 represents a structurally unrelated protein with neurotensin-binding properties.⁶⁸ NTS1 is expressed in the brain and intestine, whereas NTS2 and NTS3 are expressed exclusively in the brain. Neurotensin administration to rats augments the adaptive response to small-bowel resection in the intestinal remnant, and neurotensin stimulates growth of the colonic epithelium *in vivo*. Neurotensin also inhibits postprandial gastric acid secretion and pancreatic exocrine secretion, stimulates colonic motility, and inhibits gastric and small intestinal motility. Neurotensin facilitates fatty acid uptake in the proximal small intestine and induces histamine release from mast cells. Neurotensin receptor expression has been detected in a subset of human colon and pancreatic ductal cancers, and neurotensin is trophic for some pancreatic and colon cancer cells *in vitro*. Experiments using neurotensin antagonists or knockout mice have suggested a role for neurotensin in pain perception or nociception, and reduction of neurotensin action improves survival in preclinical models of sepsis.⁶⁹

Pituitary Adenylate Cyclase-Activating Peptide

Pituitary adenylate cyclase-activating peptide (PACAP), VIP, and growth hormone-releasing factor (GHRH, somatocrinin)

are structurally related members of the glucagon/secretin superfamily.⁷⁰ PACAP-immunoreactive nerve fibers are distributed along the gastrointestinal tract from the esophagus to the colon. Both bioactive forms, PACAP-38 and PACAP-27, are detected in many tissues, and PACAP-38 usually is the predominant peptide. PACAP stimulates histamine release from the stomach; increases the secretion of pancreatic fluid, protein, and bicarbonate; and stimulates insulin and glucagon secretion and catecholamine release. It reduces blood pressure and causes vasodilation, which may limit its therapeutic utility. PACAP-deficient mice exhibit defective glucagon responses to insulin-induced hypoglycemia. PACAP signaling in gastric ECL cells may also constitute an important component of the neural regulation of gastric acid secretion.

PACAP exerts neuroprotective actions in the CNS and peripheral nervous system, likely related to stimulation of cyclic adenosine monophosphate (cAMP) accumulation. PACAP may also play a role in the central control of ventilation, because PACAP-deficient mice experience prolonged apneas, atrioventricular block, and an increased incidence of sudden death. PACAP modulates platelet function, and PACAP overexpression may be associated with increased platelet cAMP accumulation and defective platelet aggregation.⁷¹ Three PACAP receptors (designated PAC1, VPAC1, and VPAC2) have been cloned, and they bind PACAP and VIP with different affinities. Consistent with the putative importance of PACAP for islet function, PAC1 receptor knockout mice exhibit defective glucose-stimulated insulin secretion. PACAP exhibits vasodilatory effects in the pulmonary vasculature, whereas PAC1 receptor-deficient mice exhibit pulmonary artery hypertension and right ventricular failure. PACAP also regulates normal megakaryopoiesis through the VPAC1 receptor. Whether DPP4 inhibition modulates the actions of PACAP(1-38) *in vivo* remains uncertain.

Peptide YY

PYY, NPY, and PP are members of the pancreatic polypeptide family. These peptides consist of 36 amino acids, contain several tyrosine residues, and share considerable amino acid identity with amidated C-terminal ends. Although these peptides likely share a common ancestry, they exhibit unique actions and patterns of tissue-specific expression, with PYY and PP acting as hormones and NPY acting primarily as a neurotransmitter.

PYY is expressed in the fetal and adult gastrointestinal tract in enteroendocrine cells. Distinct enteroendocrine subpopulations have been identified that express PYY alone or express both PYY and GLP1 in the ileum, colon, and rectum. Immunoreactive PYY has been detected in the developing endocrine pancreas and in a subpopulation of glucagon-producing alpha cells in mature islets. PYY is secreted as a 36-amino-acid peptide, and it circulates as two molecular forms, PYY(1-36) and PYY(3-36), an N-terminally truncated form. Luminal nutrients, CCK, GRP, and vagal tone regulate PYY secretion.

PYY exerts its actions in part through the NPY Y1 and Y2 receptors. Whereas PYY(1-36) binds both Y1 and Y2 receptors, PYY(3-36) is selective for the Y2 receptor. PYY demonstrates inhibitory effects on gastrointestinal secretion, motility, and blood flow. In the stomach, PYY functions an enterogastrone, inhibiting gastric acid secretion and gastric emptying. PYY also increases intestinal transit times by inhibiting motility of the small and large intestine. The role of PYY as an intestinal epithelial growth factor remains unclear, but some studies have

demonstrated an intestinotrophic effect of PYY in rodents. In the pancreas, PYY(1-36) and PYY(3-36) inhibit pancreatic exocrine secretion.

Administration of PYY(3-36) to rodents and to normal and obese humans potentially inhibited food intake in short-term studies, and PYY(3-36) produced a conditioned taste aversion in some but not all studies in rodents. Functional magnetic resonance imaging (MRI) studies demonstrated that infusion of PYY(3-36) in humans produces changes in neural activity within corticolimbic and higher cortical areas and in homeostatic brain regions that mimic neuronal activity pursuant to meal ingestion.⁷² Obese humans exhibit attenuated release of PYY(3-36), and alterations in these signals may lead to increased hunger or reduced satiety in response to meal ingestion. Whether prolonged PYY(3-36) administration can produce weight loss in obese humans has not been determined.

Pancreatic Polypeptide

PP was isolated from chicken pancreatic extracts as a byproduct of insulin purification. Most PP is expressed in pancreatic endocrine cells located predominantly in the periphery of islets in the pancreatic head and uncinate process. Elevated plasma levels of PP have been detected in patients with gastrointestinal endocrine tumors, and PP may be used as a tumor marker in appropriate clinical scenarios. Nutrients, hormones, neurotransmitters, gastric distention, insulin-induced hypoglycemia, and direct vagal nerve stimulation regulate PP secretion, whereas hyperglycemia, bombesin, and somatostatin inhibit PP secretion.

The actions of PP are mediated by the Y4 receptor, a G protein-coupled receptor linked to inhibition of cAMP accumulation.⁷³ The human Y4 receptor is expressed in the stomach, small intestine, colon, pancreas, prostate, enteric nervous system, and certain CNS neurons. Exogenous administration of PP reduces CCK-induced gastric acid secretion and increases intestinal transit times by reducing gastric emptying and upper intestinal motility. PP also inhibits postprandial exocrine pancreas secretion through a vagus-dependent pathway. Transgenic mice that overexpress PP exhibit reduced weight gain, reduced rate of gastric emptying, and decreased fat mass. The biologic actions of PP in the gastrointestinal tract and pancreas are in part centrally mediated, and intracisternal injections of PP cause increased gastric acid secretion, increased gastric motility, and reduced pancreatic secretion. Administration of PP was found to inhibit gastric emptying and reduces food intake in human subjects over a 24-hour study period.⁷⁴

Secretin

Secretin is a 27-amino-acid peptide that is synthesized predominantly in the brain and gastrointestinal tract. In the gut, secretin is produced by the enteroendocrine S cell in the duodenum and proximal jejunum. Gastric acid, bile salts, and luminal nutrients stimulate secretin, and somatostatin inhibits its release. Secretin stimulates pancreatic and biliary bicarbonate and water secretion, and it may regulate pancreatic enzyme secretion. Secretin also stimulates the gastric secretion of pepsinogen and inhibits lower esophageal sphincter tone, postprandial gastric emptying, gastrin release, and gastric acid secretion. Although secretin is expressed in the fetal endocrine pancreas, its function in islet biology remains uncertain. Only a single secretin receptor has been isolated and characterized. Secretin has been proposed as a treatment for autism, but clinical trial results examining this issue have not been consistently positive.⁷⁵

Somatostatin

Somatostatin, originally isolated as a hypothalamic growth hormone release-inhibiting factor, is also expressed in the intestine and pancreas. Post-translational processing of prosomatostatin results in the generation of somatostatin-14 and somatostatin-28, biologically active peptides corresponding to the C-terminal 14 and 28 amino acids of prosomatostatin. Somatostatin-28 is the predominant molecular form liberated by enteroendocrine D cells, whereas somatostatin-14 is the predominant species liberated by D cells in the stomach and pancreas.

Five somatostatin receptor subtypes (SSTR1 through SSTR5) have been identified and are expressed in a tissue-specific manner.⁷⁶ SSTR2 modulates islet hormone secretion, whereas SSTR4 regulates inflammatory responses.⁷⁷ Variants in the *SSTR2* gene have been linked to increased risk of glucose intolerance. Somatostatin actions usually are inhibitory; somatostatin inhibits the secretion of growth hormone and thyrotropin in the pituitary and inhibits secretion of insulin, glucagon, and PP in the endocrine pancreas. In the gastrointestinal tract, somatostatin inhibits the secretion of a broad range of gut peptides. Somatostatin inhibits pancreatic exocrine secretion and acts in a paracrine manner on G cells, ECL cells, and parietal cells to inhibit gastric acid secretion. In the brain, somatostatin regulates metabolism of amyloid- β peptide, a primary pathogenic agent of Alzheimer's disease, by modulating proteolytic degradation catalyzed by neprilysin.⁷⁸

The inhibitory properties of somatostatin make it suitable for the treatment of conditions characterized by excess hormone secretion. Although the circulating half-life of native somatostatin is short, longer-acting synthetic somatostatin analogues such as octreotide and lanreotide are useful in the treatment of neuroendocrine tumors, acromegaly, and portal hypertension.⁷⁹ Octreotide and lanreotide are octapeptides that bind the SSTR2 and SSTR5 receptors, which are commonly expressed in neuroendocrine tumors. A meta-analysis of clinical trials using these analogues for treatment of acromegaly demonstrated that the efficacy of long-acting release (LAR) octreotide is greater than that of sustained-release (SR) lanreotide among subjects unselected for prior somatostatin analogue responsiveness.⁸⁰ Somatostatin analogues are also employed for the treatment of portal hypertension and gastrointestinal bleeding. Tumor-associated somatostatin receptor expression forms the basis for the radiolabeled octreotide scan, a test used for the detection of a broad spectrum of human neoplasms. Somatostatin-deficient mice exhibit normal growth but have defects in sexually dimorphic hepatic gene expression.

Tachykinins

The family of tachykinins includes substance P, neurokinin A, and neurokinin B, all of which share a common C-terminal pentapeptide sequence essential for biologic action. Two genes encode these tachykinins, a tachykinin precursor 1 gene (*TAC1*) that encodes substance P and neurokinin A and a tachykinin 3 gene (*TAC3*) that encodes neurokinin B. Tachykinins are synthesized within neurons localized to the submucous and myenteric plexuses, extrinsic sensory fibers, and enterochromaffin cells in the gut epithelium. Tachykinins are also widely distributed throughout the central and peripheral nervous systems, respiratory tract, skin, sensory organs, and urogenital tract. Four tachykinin receptors have been cloned: NK1 (*TACR1*), NK2 (*TACR2*), NK3 (*TACR3*), and a putative NK4 that

appears to be a variant of the NK3 receptor rather than a distinct tachykinin receptor subtype. These receptors bind tachykinin peptides with different affinities. NK1 receptors preferentially bind substance P, NK2 receptors preferentially bind neurokinin A, and NK3 and NK4 receptors preferentially bind neurokinin B.⁸¹

Tachykinins produce a broad range of biologic actions, including regulation of inflammation and vasomotor and gastrointestinal motor activity. Germline mutations in neurokinin B (*TAC3*) or its receptor (*TACR3*) have been identified in families with hypogonadotropic hypogonadism, implicating the neurokinin B axis as a critical regulator of human reproduction.⁸² The ability of tachykinins to induce vasodilatation or vasoconstriction appears to be species specific and vascular bed specific. Tachykinins exhibit direct and indirect effects on intestinal smooth muscle contractile activity. Activation of NK1 receptors on the interstitial cells of Cajal and NK2 receptors on intestinal smooth muscle cells directly promotes peristalsis, whereas activation of NK3 receptors on enteric neurons exerts a prokinetic effect that is indirectly mediated through cholinergic stimulation of enteric smooth muscle cells.

The NK1 and NK3 receptors can inhibit intestinal motility by inducing the release of inhibitory molecules such as nitric oxide and VIP from inhibitory neurons. NK2 receptors can inhibit intestinal motility by stimulation of sympathetic ganglia or activation of nonadrenergic inhibitory mechanisms. NK2 receptor antagonists reduce or prevent trinitrobenzenesulfonic acid (TNBS)-induced weight loss and intestinal injury, and an NK1 receptor antagonist exhibits protective effects in acetic acid-induced colitis and in colitis induced by the *Clostridium difficile* toxin. Tachykinins are commonly produced by gut carcinoids and may be responsible for mediating some of the clinical manifestations associated with these tumors. There is considerable interest in determining whether blockade of NK1 and NK2 receptors may represent a therapeutic approach for the treatment of asthma. Similarly, the NK1 and NK3 receptors are targets for development of therapeutic agents that modulate gut motility and pain, potentially in the setting of irritable bowel syndrome.^{82a}

Thyrotropin-Releasing Hormone

Originally isolated as a hypothalamic regulatory peptide, thyrotropin-releasing hormone (TRH) is expressed throughout the gastrointestinal tract, including the stomach, colon, and pancreas. In the pancreas, TRH is most abundantly expressed during perinatal development. Prepro-TRH is synthesized by islet beta cells, G cells in the stomach, and neurons comprising the myenteric plexus of the esophagus, stomach, and intestine. In the stomach, histamine and serotonin stimulate and endogenous opioids inhibit TRH release. TRH acts through two related G protein-coupled receptors, TRHR1 and TRHR2. TRH suppresses pentagastrin-stimulated gastric acid secretion, and chronic administration of TRH induces pancreatic hyperplasia and inhibits amylase release. Centrally administered TRH modulates pancreatic blood flow and gastric mucosal permeability. TRH also attenuates CCK-induced gallbladder smooth muscle contraction and inhibits cholesterol synthesis within the intestinal mucosa.

Vasoactive Intestinal Peptide

VIP is a 28-amino-acid member of a peptide superfamily that includes PACAP, peptide histidine isoleucine, and peptide histidine methionine, which are neurotransmitters

and neuromodulators of the enteric nervous system. The *VIP* gene is widely expressed in the central and peripheral nervous systems. Receptors for VIP and PACAP belong to the same family of G protein-coupled receptors. The adenylate cyclase-activating polypeptide 1 (pituitary) receptor type 1 (ADCYAP1R1) binds PACAP(1-27) and PACAP(1-38) with the same affinity, but it is unable to bind VIP. Vasoactive intestinal peptide receptor 1 (VIPR1) and VIPR2 recognize both VIP and PACAP.⁷⁰

In the digestive tract, VIP functions as an inhibitory neurotransmitter that induces relaxation of vascular and nonvascular smooth muscle. VIP mediates relaxation of the lower esophageal sphincter, sphincter of Oddi, and anal sphincter. VIPergic innervation along the intestine plays an important role in the nonadrenergic, noncholinergic inhibition of smooth muscle contraction leading to the relaxation phase of peristalsis, in part through a nitric oxide-dependent mechanism. VIP-deficient mice exhibit anatomic abnormalities of the intestine, with thickening of the muscularis propria, focal loss of the myenteric plexus, and impaired gastrointestinal transit.⁸³ In humans, VIP and PACAP may be co-localized to some neuronal subpopulations, and they are coreleased as neurotransmitters, leading to nitric oxide regeneration. VIP inhibits gastric acid secretion but stimulates biliary water and bicarbonate, pancreatic enzyme, and intestinal chloride secretion. VIP may also regulate pancreatic release of insulin and glucagon, and it exerts either trophic or growth inhibitory effects on both normal and neoplastic cells.⁸⁴ In the lung, VIP functions as a bronchodilator through the VIPR2 receptor. Consistent with the importance of the ADCYAP1R1 receptor for control of pulmonary artery pressure,⁸⁵ VIP reduced mean pulmonary artery pressure, increased cardiac output, and increased mixed venous oxygen saturation in eight human subjects with pulmonary hypertension.⁸⁶

Miscellaneous Gut Endocrine Peptides

In addition to the peptide hormones outlined previously and summarized in Table 39-4, several other gut endocrine peptides exist. Chromogranins and secretogranins are a family of secretory proteins that are found in secretory vesicles of endocrine cells and neurons. Chromogranin A (CgA), a protein belonging to this family of peptides, induces the formation of mobile secretory granules and is secreted into the circulation by several neuroendocrine tumors, especially small gastrinomas and pheochromocytomas. Circulating levels of CgA directly correlate with tumor burden, making this a well-suited marker for assessing treatment response. CgA likely helps to regulate blood pressure, because elimination of CgA expression in a knockout mouse led to decreased size and number of chromaffin granules and hypertension, whereas transgenic expression of human CgA or exogenous injection of human catestatin, a CgA-derived cholinergic antagonist, restored normal blood pressure in CgA knockout mice.⁸⁷

Opioid peptides regulate intestinal motility and inhibit gastric acid secretion. Neuromedin B and its receptor are expressed in the gut, where they activate pathways coupled to epithelial mitogenesis. Neuromedin U is a neurotransmitter that is expressed in the enteric nervous system, where it regulates intestinal motility and ion secretion. Several hormones are secreted by the gastrointestinal tract directly into the lumen, where they modulate the secretion and release of other hormones. Guanylin and uroguanylin stimulate water, bicarbonate, and chloride secretion by the intestine and kidney while inhibiting

sodium reabsorption.⁸⁸ Guanylin may also regulate cell proliferation in the colon; guanylin^{-/-} mice have increased epithelial cell migration and colonocyte proliferation. Other lumenally secreted peptides include sorbin, a 153-amino-acid peptide involved with monitoring fluid and sodium fluxes in the duodenum, and monitor peptide, which is a 61-amino-acid peptide that stimulates CCK release.

PANCREATIC AND GUT ENDOCRINE TUMORS

The ontogeny of pancreatic and gut endocrine cells provides some insight into the molecular pathophysiology of pancreatic endocrine tumors. Although gastrin is not normally produced in human adult islets of Langerhans, the finding of gastrinomas arising from adult endocrine pancreas may reflect the dedifferentiation of neoplastic endocrine tumor cells that recapitulates, in part, patterns of islet gene expression observed during embryonic development. Similarly, the observation that pancreatic and gut endocrine tumors are frequently plurihormonal is consistent with studies demonstrating co-localization of peptide hormones in fetal and adult endocrine cells in the pancreas and gut.

Although pancreatic endocrine tumors frequently manifest as sporadic, isolated lesions, genetic alterations detected in tumors from patients with familial syndromes may also be detected in sporadic tumors. Multiple endocrine neoplasia type 1 (MEN1); phakomatoses such as von Hippel-Lindau disease, von Recklinghausen's disease, or neurofibromatosis type 1; and tuberous sclerosis represent the common familial syndromes associated with pancreatic endocrine tumors. Defects in distinct tumor suppressor genes account for the phenotypic manifestations and development of tumors in these syndromes (Table 39-5). Loss of heterozygosity at 10q has been detected in sporadic pancreatic endocrine tumors, with cellular rather than nuclear localization of PTEN (phosphatase and tensin homolog, deleted on chromosome 10) detected in a substantial proportion of malignant pancreatic endocrine tumors.⁸⁹ Similarly, loss of heterozygosity at the 11q13 *MEN1* locus has been detected in sporadic pancreatic endocrine tumors, and alterations in loci of the *CDKN2A* (formerly called p16 or MTS1), *SMAD4* (formerly DP64), and *ERBB2* (also called HER2 or Neu) genes have also been reported.

Mutations in *MEN1*, the gene encoding menin, give rise to the MEN1 syndrome, which is associated with an increased incidence of endocrine tumors in the pancreas, pituitary, parathyroid, and gut and carcinoids in the stomach.⁹⁰ The *MEN1* gene encodes a 610-amino-acid nuclear protein that interacts with the N-terminus of the JunD transcription factor, presumably resulting in de-repressed cell growth. Menin regulates cell growth through control of histone methylation and regulation of cyclin-dependent kinase (CDK) inhibitors. Menin functions as a molecular adaptor linking the mixed-lineage leukemia (MLL) histone methyltransferase with lens epithelium-derived growth factor (LEDGF). LEDGF is a chromatin-associated protein that is required for both MLL-dependent transcription and leukemic transformation; menin mutations in MEN1 patients abrogate interaction with LEDGF, thereby compromising MLL- or menin-dependent functions.⁹¹ About 10% of all MEN1 germline mutations arise de novo. The utility of genetic testing for patients with possible MEN1 syndrome remains

TABLE 39-4

Summary of Gastrointestinal-Derived Hormones

Hormone	Cell or Tissue of Origin	Related Peptides	Actions	Secretory Stimuli
Amylin	Pancreatic beta cell, endocrine cells of stomach and small intestine	Calcitonin, CGRP, adrenomedullin	Inhibits gastric emptying Inhibits arginine-stimulated and postprandial glucagon secretion Inhibits insulin secretion Satiety factor	Cosecreted with insulin in response to oral nutrient ingestion
CGRP	α -CGRP is expressed predominantly in afferent sensory nerves from the spinal cord β -CGRP is expressed in enteric neurons and enteroendocrine cells of the rectum	Calcitonin, amylin, adrenomedullin	Produces marked vasodilation in the splanchnic and peripheral circulation by stimulating nitric oxide release Inhibits gastric acid and pancreatic exocrine secretion Induces intestinal smooth muscle relaxation	Glucose and gastric acid secretion
CCK	Enteroendocrine I cells and enteric nerves, CNS, pituitary corticotrophs, C cells of the thyroid, adrenal medulla, and the acrosome of developing and mature spermatozoa		Inhibits proximal gastric motility while increasing antral and pyloric contractions Regulates meal-stimulated pancreatic enzyme secretion and gallbladder contraction Trophic effects on pancreatic acini in rats Postprandial satiety In the brain, CCK affects memory, sleep, sexual behavior, and anxiety	Oral nutrient ingestion Several intestine-derived hormones, including GRP and bombesin Activation of β -adrenergic receptors
Galanin	CNS and PNS, pituitary, neural structures of the gut, pancreas, thyroid, and adrenal gland		In the brain, regulation of food intake, memory and cognition, and anti-nociception Inhibits pancreatic exocrine secretion and intestinal ion transport Induces both contraction and relaxation of intestinal smooth muscle, depending on the species examined Delays gastric emptying and prolongs colonic transit times Inhibits secretion of insulin, PYY, gastrin, somatostatin, enteroglucagon, neurotensin, and PP	Intestinal distention Chemical stimulation of the intestinal mucosa Electrical stimulation of periaxillary nerves Extrinsic sympathetic neurons
GIP	Neuroendocrine K cells in the duodenum and proximal jejunum		Inhibits gastric acid secretion and GI motility Increases insulin release and regulates glucose and lipid metabolism Exerts anabolic actions in bone	Oral nutrient ingestion, especially long-chain fatty acids
Gastrin	Predominantly enteroendocrine G cells of the stomach and duodenal bulb, CNS and PNS, pituitary, adrenal gland, genital tract, respiratory tract, fetal pancreas		Induces gastric acid secretion Amidated gastrins are trophic to the oxyntic mucosa of the stomach Progastrin and glycine-extended gastrin induce colonic epithelial proliferation	Luminal contents, especially partially digested aromatic amino acids, small peptides, calcium, coffee, and ethanol Humoral and neural influences, including the vagus nerve, β -adrenergic and GABA neurons, and GRP
GRP and related peptides	CNS, enteric nervous system, reproductive tract, and the lungs, where it acts as a neurotransmitter; GRP neurons are also distributed throughout the human pancreas	Bombesin, neuromedin B, neuromedin C	Stimulates smooth muscle contraction in the stomach, intestine, and gallbladder Stimulates release of CCK, gastrin, GIP, glucagon, GLP I, GLP2, motilin, PP, PYY, and somatostatin Stimulates gastric acid secretion via direct effect on G cells In the brain, regulates appetite, memory, thermogenesis, and cardiac function Stimulates pancreatic growth In the lungs, growth factor for normal and neoplastic tissue	Cholinergic stimulation
Ghrelin	CNS, stomach, small intestine, colon	Motilin	Stimulates GH release Stimulates gastric kinetic activity Orexigenic activity Stimulates energy production and signals hypothalamic regulatory nuclei that control energy homeostasis	Fasting
Glucagon	Pancreatic alpha cell, CNS		Primary counterregulatory mechanism to restore plasma glucose levels in hypoglycemia by increasing gluconeogenesis, glycogenolysis, and protein-lipid flux in the liver and periphery GI smooth muscle relaxation	Neural and humoral factors released in response to hypoglycemia

TABLE 39-4

Summary of Gastrointestinal-Derived Hormones (Continued)

Hormone	Cell or Tissue of Origin	Related Peptides	Actions	Secretory Stimuli
GLP1	Enteroendocrine L cells located in the ileum and colon, CNS		Enhances glucose disposal after nutrient ingestion by inhibiting gastric emptying, stimulating insulin secretion, and inhibiting glucagon secretion Inhibits food intake Stimulates pancreatic islet neogenesis and proliferation Inhibits sham feeding-induced gastric acid secretion	Oral nutrient ingestion, especially carbohydrates and fat-rich meals Vagal nerve, GRP, and GIP ACh and neuromedin C Somatostatin inhibits secretion
GLP2	Enteroendocrine L cells located in the ileum and colon, CNS		Induces small-intestinal and colonic mucosal growth by stimulating crypt cell proliferation and inhibiting apoptosis Inhibits centrally induced antral motility and meal-stimulated gastric acid secretion Enhances intestinal epithelial barrier function Stimulates intestinal hexose transport Inhibits short-term control of food intake	Oral nutrient ingestion, especially carbohydrates and fat-rich meals Vagus nerve, GRP, and GIP ACh and neuromedin C Somatostatin inhibits secretion
Motilin	Brain, bronchoepithelial cells, and enteroendocrine M cells located in the duodenum and proximal jejunum	Ghrelin	Induces phase III contractions in the stomach Stimulates gastric and pancreatic enzyme secretion Induces contraction of the gallbladder, sphincter of Oddi, and LES	Duodenal alkalinization, sham feeding, gastric distention; opioid agonists promote secretion Unlike most GI hormones, motilin is suppressed in the presence of duodenal nutrients
NPY	CNS and PNS, pancreatic islet cells	PYY and PP	Potent stimulator of oral nutrient intake Inhibits glucose-stimulated insulin secretion Reduces GI fluid and electrolyte secretion Inhibits gastric and small-intestinal motility Induces mesenteric vasoconstriction of the splanchnic circulation	Oral nutrient ingestion Activation of the sympathetic nervous system
NT	N cells located in the small-intestinal mucosa, especially the ileum; CNS and PNS, including the enteric nervous system; heart, adrenal gland, pancreas, and respiratory tract	Neuromedin N, xenin, and xenopsin	Stimulates growth of the colonic epithelium Inhibits postprandial gastric acid secretion and pancreatic exocrine secretion Stimulates colonic motility but inhibits gastric and small-intestinal motility Facilitates fatty acid uptake in the proximal and small intestine and induces histamine release from mast cells Trophic in some pancreatic and colon cancer cell lines in vitro	Luminal nutrients, especially lipids, but not amino acids or carbohydrates GRP and bombesin Somatostatin inhibits secretion
PP	Major site of expression is pancreatic endocrine cells located in periphery of islets in pancreatic head and uncinate process	NPY and PYY	Reduces CCK-induced gastric acid secretion Increases intestinal transit times by reducing gastric emptying and upper intestinal motility Inhibits postprandial exocrine pancreas secretion via vagal-dependent pathway	Stimulated by nutrients, hormones, neurotransmitters, gastric distention, insulin-induced hypoglycemia, and direct vagal nerve stimulation Hyperglycemia, bombesin, and somatostatin inhibit secretion
PYY	Enteroendocrine cells, developing endocrine pancreas, subpopulation of pancreatic alpha cells in mature islets	NPY and PP	Enterogastrone inhibits gastric acid secretion and gastric motility Increases intestinal transit time by reducing intestinal motility Inhibits pancreatic exocrine secretion Role as an intestinal epithelial growth factor remains controversial Peripheral vasoconstriction and reduced mesenteric and pancreatic vascular blood flow	After oral nutrient ingestion, early secretion is mediated by the vagus nerve and hormonal influences; later, secretion occurs as a result of direct L-cell stimulation Bile acids and fatty acids Amino acids administered intracolonicallly
PACAP	Brain, respiratory tract, and enteric nervous system	VIP, PHI, and PHM	Stimulates histamine release from the stomach Increases secretion of pancreatic fluid, protein, and bicarbonate Stimulates insulin and catecholamine release Neural regulation of gastric acid secretion	Activation of CNS
Secretin	CNS, fetal endocrine pancreas, and enteroendocrine S cells located in the duodenum and proximal jejunum		Principal hormonal stimulant of pancreatic and biliary bicarbonate and water excretion Regulates pancreatic enzyme secretion Stimulates gastric secretion of pepsinogen Inhibits LES tone, postprandial gastric emptying, gastrin release, and gastric acid secretion	Gastric acid, bile salts, and luminal nutrients, especially fatty acids, peptides, and ethanol Somatostatin inhibits secretion

Table continued on following page

TABLE 39-4

Summary of Gastrointestinal-Derived Hormones (Continued)

Hormone	Cell or Tissue of Origin	Related Peptides	Actions	Secretory Stimuli
Somatostatin	CNS, pancreatic delta cells, enteroendocrine D cells		Inhibits secretion of islet hormones, including insulin, glucagon, and PP Inhibits secretion of gut peptides, including gastrin, secretin, VIP, CCK, GLP1 and GLP2 Inhibits pancreatic exocrine secretion Acts in a paracrine manner on G cells, enterochromaffin-like cells, and parietal cells to inhibit gastric acid secretion Reduces splanchnic blood flow, intestinal motility, and carbohydrate absorption while increasing water and electrolyte absorption	Luminal nutrients Gastrin, CCK, bombesin, GLP1, and GIP Neural influences, including PACAP, VIP, and β -adrenergic agonists stimulate while ACh inhibits secretion
Tachykinins	Throughout the CNS and PNS, including the respiratory tract, skin, sensory organs, and urogenital tract; in the GI tract, neurons localized in the submucous and myenteric plexuses, extrinsic sensory fibers, and enterochromaffin cells in the gut epithelium	Substance P, neurokinin A, and neurokinin B	Regulate vasomotor and GI smooth muscle contractility Chemotaxis and activation of immune cells, mucus secretion, water absorption and secretion Role in visceral inflammation, hyperreflexia, and hyperalgesia	Direct or indirect activation of neurons
TRH	CNS and enteric nervous system, colon, G cells of the stomach, pancreatic islet beta cells		Suppresses pentagastrin-stimulated gastric acid secretion Chronic administration induces pancreatic hyperplasia and inhibits amylase release Attenuates CCK-induced gallbladder smooth muscle contraction Inhibits cholesterol synthesis within the intestinal mucosa	In the stomach, histamine and serotonin stimulate and endogenous opioids inhibit secretion
VIP	Widely expressed in the CNS and PNS including the enteric nervous system	PACAP, PHI, and PHM	Induces relaxation of vascular and nonvascular smooth muscle Mediates relaxation of the LES, sphincter of Oddi, and anal sphincter Regulates relaxation-associated gut contraction and may be involved with reflex vasodilation in the small intestine Inhibits gastric acid secretion Stimulates biliary water, bicarbonate, pancreatic enzyme, and intestinal chloride secretion	Mechanical stimulation Activation of the CNS and PNS

ACh, acetylcholine; CCK, cholecystokinin; CGRP, calcitonin gene-related peptide; CNS, central nervous system; GABA, γ -aminobutyric acid; GH, growth hormone; GI, gastrointestinal; GIP, gastric inhibitory polypeptide; GLP, glucagon-like peptide; GRP, gastrin-releasing peptide; LES, lower esophageal sphincter; NPY, neuropeptide Y; NT, neurotensin; PACAP, pituitary adenylate cyclase-activating peptide; PHI, peptide histidine isoleucine; PHM, peptide histidine methionine; PNS, peripheral nervous system; PP, pancreatic polypeptide; PYY, peptide YY; TRH, thyrotropin-releasing hormone; VIP, vasoactive intestinal peptide.

TABLE 39-5

Genetic Diseases Associated with the Development of Pancreatic or Gut Endocrine Tumors

Gene	Disease	Phenotype
Menin	MEN1	Parathyroid, pituitary, and pancreatic endocrine tumors
VHL	von Hippel-Lindau syndrome	Pancreatic endocrine tumors, hemangiomas and multiple neoplasms
NF1	Neurofibromatosis	Neurofibromas, pheochromocytomas
TSC1/2	Tuberous sclerosis	Pancreatic endocrine tumors, hamartomas

MEN1, multiple endocrine neoplasia type 1; NF1, neurofibromin 1; TSC1/2, tuberous sclerosis genes 1 and 2; VHL, von Hippel-Lindau tumor suppressor gene.

unclear because of the large number of heterogeneous mutations identified in the menin gene. The likelihood of detecting *MEN1* mutations correlates directly with the number of MEN1-related tumors in the index case at presentation.⁹²

A search for clinical manifestations of diseases associated with these genetic syndromes is an important component in the initial diagnosis and ongoing management of patients with pancreatic endocrine tumors. Careful phenotype-genotype analyses have ascertained that facial angiofibromas, collagenomas, lipomas, leiomyomas, and adrenocortical tumors may be seen with increased frequency in patients with MEN1.⁹³ Moreover, somatic mutations of the menin gene have been described in isolated cases of gastrinomas, insulinomas, and gut endocrine tumors.⁹³

The secretion of one or more peptide hormones resulting in the production of symptoms attributable to hormone excess, such as hypoglycemia, gastric ulceration, or profuse watery diarrhea in patients with insulinoma, gastrinoma, or VIPoma, respectively, facilitates the diagnosis of a hormone-secreting endocrine tumor. In some instances, pancreatic or gut endocrine tumors may not be associated with clinically or biochemically detectable hormone excess and development of a recognizable syndrome. Because nonfunctioning pancreatic endocrine tumors may escape clinical detection, they often are larger and more frequently are malignant at the time of diagnosis. The term *nonfunctioning* may be a misnomer, because these tumors frequently produce peptide hormones (Fig. 39-3) whose biologic actions are less clinically apparent. In some instances, tumor-associated defects in post-translational processing may preclude the efficient synthesis and secretion of peptide hormones. Factors affecting prognosis include liver metastases, incomplete resection of the primary tumor, and poorly differentiated tumor cells.

The use of somatostatin receptor scintigraphy and measurement of gene products commonly expressed in endocrine cells, such as chromogranin, PP, neuron-specific enolase, or glycoprotein hormone subunits, may be useful as an adjunct for monitoring the tumor response to therapy. Widespread expression of receptors for somatostatin and multiple peptide hormone G protein-coupled receptors, including the GLP1 receptor,⁹⁴ has stimulated efforts to develop novel radiolabeled peptide ligands for the localization and treatment of endocrine and non-endocrine neoplasms.

Despite the large number and complexity of endocrine cell populations in the human small bowel, gut endocrine tumors, including ileal carcinoids, are uncommon. Similarly, peptide hormone-secreting carcinoid tumors arising from the colon are much less common than colonic adenocarcinomas. The molecular basis for the infrequent malignant transformation of human gut endocrine cells remains incompletely understood. Mutations in the regenerating islet-derived 1 α gene (*REG1A*) have been identified in a subset of patients with ECL cell tumors and associated hypergastrinemia, but the contribution of this genetic mutation to transformation of these cells remains unclear. The clinical presentation, diagnosis, and treatment of several more common pancreatic and gut endocrine tumors are discussed later, and medical and surgical perspectives about treatment have been reviewed elsewhere.⁹⁵⁻⁹⁷ Surgical resection remains the principal goal and therapeutic strategy, because chemotherapeutic regimens have had only modest success in patients with malignant tumors.

Insulinomas

Insulinomas are the most common functioning islet cell tumors, and they are characterized by hypoglycemia that often is precipitated by exercise or fasting. A subset of insulinomas are characterized by postprandial hypoglycemia.⁹⁸ More than 80% are solitary, benign tumors with an indolent course. Patients may tolerate symptoms of hypoglycemia for years before seeking medical attention. Surgical enucleation is the treatment of choice, and cure should be expected in patients without the MEN1 syndrome. In these patients, the recurrence rate is low, often less than 10%. Insulinomas that accompany MEN1 tend to occur at an earlier age. Although they comprise about one third of pancreatic islet cell tumors seen in MEN1 patients, they occur more often before 40 years of age and are the most

Figure 39-3 Clinically nonfunctioning tumors often are found to express one or more peptide hormones after immunocytochemical analyses. Histologic sections from the identical “nonfunctioning” human pancreatic endocrine tumor exhibit immunopositivity for glucagon (A) and pancreatic polypeptide (B).

common tumor seen before age 20. Insulinomas may be the first manifestation of MEN1.

In contrast to the single adenoma found in most patients with sporadic insulinoma, many patients with MEN1 have multicentric, benign disease and a higher incidence of

recurrence (21%). When possible, distal subtotal pancreatic resection to the level of the portal vein combined with enucleation of tumors in the head of the pancreas (guided by intraoperative ultrasonography for safe removal) is thought to be optimal treatment. Preservation of endocrine and exocrine pancreatic function may not be possible in these situations. Insulinomas may be malignant (about 5%), defined by the presence of local invasion or liver or lymph node metastases.⁹⁸ Resection of hepatic metastases may provide effective palliation and probably prolonged survival, depending on the extent of resectable tumor burden. Palliative resection should be considered only when at least 90% of the tumor bulk can be excised. The success rate for identification of insulin-secreting pancreatic endocrine tumors with noninvasive testing such as computed tomography (CT) and transabdominal ultrasound has remained constant at about 75%. However, with the implementation of endoscopic ultrasound and selective arterial calcium stimulation testing, preoperative localization rates have significantly improved.⁹⁸

Gastrinoma

In 1955, Zollinger and Ellison described two patients with intractable peptic ulcer disease and pancreatic islet cell tumors.⁹⁹ Subsequent studies demonstrated elevated levels of circulating gastrin associated with gastric acid hypersecretion in patients with Zollinger-Elison syndrome.

Although the gastrin gene is not normally expressed in the adult pancreas, gastrinomas commonly arise from within the pancreas and manifest as endocrine carcinomas, solitary adenomas, microadenomas, or endocrine cell hyperplasia. Gastrinomas and insulinomas represent the two most common pancreatic endocrine tumors. Between 20% and 40% of gastrin-secreting tumors arise from the duodenum. Most gastrinomas (75%) occur sporadically, but about 25% are associated with the MEN1 syndrome. Duodenal gastrinomas in patients with sporadic Zollinger-Elison syndrome are frequently small, most commonly located in the proximal duodenum, and associated with regional lymph node metastases in 60% of patients.¹⁰⁰ Patients presenting with gastrinoma as a component of the MEN1 syndrome may develop pituitary disease (60%), adrenal disease (45%), and carcinoid tumors (30%).¹⁰¹ A substantial proportion of MEN1 patients also present with benign skin lesions, such as angiofibromas and collagenomas.¹⁰² Patients with MEN1-related duodenal gastrinomas frequently exhibit hyperplastic foci of gastrin-immunopositive cells in the adjacent nontumorous duodenal tissue. Sporadic gastrinomas may contain menin gene mutations. MEN1 patients tend to be younger at the time of tumor diagnosis than those without MEN1. Sporadic tumors are most often solitary and malignant; MEN1-associated tumors are usually multiple but may be more localized at the time of diagnosis.

Based on the presence of metastases at the time of diagnosis, about 50% to 60% of gastrinomas are malignant, perhaps because of the long delay between initial clinical presentation and diagnosis of Zollinger-Elison syndrome. Nevertheless, gastrin-secreting tumors are often slow growing and associated with prolonged survival despite complications arising from intestinal ulceration. Loss of heterozygosity at 1q or on the X chromosome may be associated with a more aggressive clinical presentation.

Clinical manifestations of gastrinomas are usually related to excessive gastric acid secretion resulting in severe refractory peptic ulceration complicated by hemorrhage, perforation, and stricture. Many patients report symptoms

for 5 to 6 years before the diagnosis of Zollinger-Elison syndrome is established.¹⁰¹ Abdominal pain, diarrhea, and heartburn are common presenting symptoms, with diarrhea and pain observed in more than 70% of patients with Zollinger-Elison syndrome. The diarrhea results in part from fat malabsorption due to pancreatic lipase degradation by excess gastric acid. Small-bowel inflammation and impaired nutrient absorption may also arise from excess gastric acid. Antisecretory therapy usually abolishes the diarrhea and diminishes many clinical features of Zollinger-Elison syndrome.

The diagnosis of gastrinoma is based on the detection of elevated fasting circulating gastrin levels (>200 pg/mL) and gastric acid hypersecretion (basal acid output >15 mEq/hour with an intact stomach or >5 mEq/hour after ulcer surgery) in patients off all acid antisecretory medication (14 days for proton pump [H⁺,K⁺-ATPase] inhibitors and 3 days for H₂-receptor antagonists). Although many patients with Zollinger-Elison syndrome have serum gastrin values that exceed 500 pg/mL, a secretin stimulation test may be performed when the serum gastrin levels are in the range of 200 to 500 pg/mL to confirm the diagnosis. Provocative testing requires overnight fasting and the intravenous administration of secretin 0.4 mcg/kg over 1 minute (2 units/kg bolus) followed by serial measurement of circulating gastrin levels at 2, 5, 10, 15, and 20 minutes. A rise in the serum gastrin level of more than 200 pg/mL within 15 minutes or a doubling of the fasting gastrin level strongly suggests the presence of a gastrinoma. Secretin receptor expression in tumors correlates with the gastrin response to secretin infusion, and calcium infusion testing may be useful in patients with an equivocal secretin test result.¹⁰³ Provocative testing may be useful in distinguishing gastrinomas from other causes of ulcerogenic hypergastrinemia, such as gastric outlet obstruction, retained antrum after a Billroth II gastrectomy, antral G-cell hyperplasia, and *Helicobacter pylori* infection, which demonstrate a flat gastrin response to secretin. Difficulty in obtaining clinical supplies of secretin may preclude routine use of the secretin test, and intravenous calcium administration has been successfully used to stimulate gastrin secretion in several cases. More than 90% of patients have prominent gastric folds at the time of endoscopy, consistent with the trophic effect of gastrin on the stomach mucosa. Assays of serum calcium and parathyroid hormone levels, baseline pituitary function tests and imaging studies, should be considered to rule out the MEN1 syndrome.

Localization of small primary tumors or endocrine hyperplasia can be difficult. Conventional endoscopy or an upper gastrointestinal series occasionally can be used to directly visualize duodenal lesions, but tumors are often confined to the submucosa, making detection and biopsy challenging. Radiolabeled octreotide scanning can be useful for detecting the primary tumor and metastases. MRI or CT can be informative, but the primary tumor may not be detected with these modalities alone. Endoscopic ultrasonography has been used for tumor localization with increasing success; less commonly, angiography with selective venous sampling may be helpful in localizing occult tumors. Primary tumors may be localized to lymph nodes, and ectopic gastrinomas have been found in sites such as the ovary.

Initial treatment of patients with gastrinoma is directed at pharmacologic reduction of gastric acid secretion. Although H₂-blockers have been used with some success, H⁺,K⁺-ATPase inhibitors such as omeprazole have become the treatment of choice because of their longer duration of action. Doses should be titrated to keep the H⁺ ion output

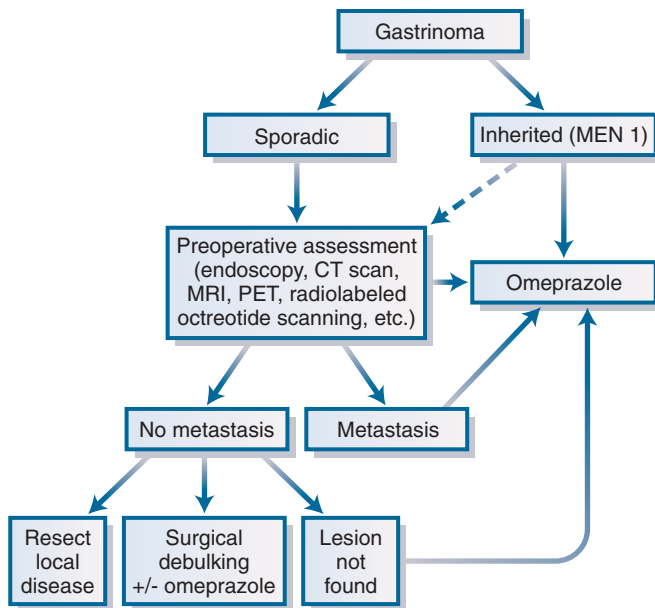

Figure 39-4 Treatment algorithm for the management of a patient with gastrinoma. In some circumstances, patients with familial gastrinoma may also be candidates for surgical resection if disease is highly limited (dotted line). CT, computed tomography; MEN 1, multiple endocrine neoplasia type 1; MRI, magnetic resonance imaging; PET, positron emission tomography.

to less than 10 mEq/hour (5 mEq/hour in patients with prior acid-reducing surgery) for the hour before the next dose of the drug is received.

As outlined in Figure 39-4, in the absence of unresectable disease, all patients with sporadic gastrinoma should undergo surgical exploration with the intent of curative surgical resection. Exploration should include a combination of duodenal palpation, endoscopic transillumination, intraoperative ultrasonography, and duodenotomy. In up to 20% of patients undergoing surgical exploration, the primary tumor remains undetected at laparotomy despite meticulous exploration of the abdominal cavity. Total gastrectomy should be performed only rarely in patients with severe ulcer disease refractory to medical therapy in which the primary tumor cannot be resected. Surgery usually is not indicated in patients with gastrinoma and MEN1 syndrome because they often have multiple, small pancreatic tumors that are not amenable to surgical resection.

Glucagonomas

Most glucagonomas are pancreatic in origin. Approximately 80% of tumors occur sporadically, with the remainder associated with the MEN1 syndrome. About 75% of glucagonomas are malignant and have metastasized by the time of diagnosis. The clinical presentation reflects the various actions of the proglucagon-derived peptides and depends on the profile of the peptides liberated due to tumor-specific differences in the post-translational processing of proglucagon. A hallmark of this syndrome is necrolytic migratory erythema, a rash that usually begins in the groin and perineum as a raised, erythematous patch with occasional bullae that may also involve the lower extremities and perioral area. The exact cause of the rash remains unknown, but elevated plasma glucagon levels and deficiencies of zinc, amino acids, and fatty acids may represent contributing factors.

Patients with glucagonomas may exhibit weight loss, abdominal pain, diabetes, stomatitis, glossitis, cheilitis, nail dystrophy, thromboembolic events, anemia, hypoaminoacidemia, and neuropsychiatric symptoms. The triad of hyperglucagonemia, necrolytic migratory erythema, and a pancreatic tumor is seen in a few cases. Intestinal obstructive symptoms and increased intestinal transit times have been reported and may reflect tumor-specific liberation of GLP1 and GLP2, peptides with antimotility and intestinotrophic properties, respectively.¹⁰⁴

The diagnosis may be confirmed by measurement of significantly elevated levels of plasma glucagon in association with a pancreatic mass. Extremely high levels of glucagon are more often seen with the classic glucagonoma syndrome, whereas more modest elevations of glucagon are detected in the setting of plurihormonal tumors. In contrast to insulinomas, glucagonomas are often large and more easily localized with imaging modalities. Somatostatin receptor scintigraphy is effective in detecting metastatic disease that most commonly involves the liver, lymph nodes, adrenal glands, or vertebrae. Therapy with a somatostatin analogue may be useful in the setting of metastatic disease by reducing levels of circulating glucagon through action at the SSTR2 receptor, improving the rash and promoting weight gain. The rash may also respond to selective nutrient supplementation. Somatostatin analogues may reduce glucagon secretion and tumor-associated symptoms, but effects on tumor growth are often modest. Patients with nonresectable or recurrent disease may be treated with chemotherapeutic agents such as streptozotocin and dacarbazine (DTIC), with interferon, or with the selective use of arterial embolization.

Somatostatinomas

Somatostatinomas are rare tumors that arise in the pancreas and the duodenum. Most clinical symptoms observed in the originally described somatostatinoma syndrome reflect the inhibitory properties of somatostatin on digestive organs. A classic triad involving mild diabetes mellitus, steatorrhea, and cholelithiasis is observed in a minority of patients and is caused by reduced insulin secretion, reduced biliary and pancreatic secretions, and inhibition of gallbladder motility. More prominent symptoms seen with duodenal tumors include weight loss, postprandial fullness and abdominal pain, cholelithiasis anemia, and hypochlorhydria. Many patients do not present with the classic triad and exhibit only nonspecific symptoms. As a result, somatostatinomas are frequently later-stage malignancies with extensive metastases to the liver by the time of diagnosis.

Duodenal tumors often are associated with neurofibromatosis type 1 or, less commonly, with von Hippel-Lindau syndrome, and they may be associated with pheochromocytomas. Most duodenal tumors are not associated with symptoms of classic somatostatinoma syndrome, and they may manifest with local obstruction and abdominal pain. Pancreatic tumors usually occur sporadically or as part of the MEN1 syndrome and are most commonly located in the head of the pancreas. The diagnosis is confirmed by the presence of markedly elevated levels of plasma somatostatin. Conventional and endoscopic ultrasonography and CT may be used to localize the duodenal tumors (Fig. 39-5). In the small proportion of patients with localized disease, surgical resection can be curative. Patients with incurable or recurrent disease can be treated with the chemotherapeutic agents streptozotocin and dacarbazine.

Figure 39-5 Somatostatin immunoreactivity in a human duodenal D-cell tumor. The low-power micrograph illustrates the diffuse somatostatin immunoreactivity. Brunner's glands and the partly eroded mucosa are seen to the lower right and upper right, respectively, of the immunopositive endocrine tumor.

VIP-Secreting Tumors

The VIPoma syndrome is also known as pancreatic cholera, Verner-Morrison syndrome, or the watery diarrhea, hypokalemia, and achlorhydria (WDHA) syndrome. Approximately 90% of individuals with a VIPoma present with a pancreatic endocrine tumor that secretes VIP and, often, prostaglandins. The remaining tumors are extrapancreatic, usually involving the sympathetic chain or adrenal medulla. VIPomas may manifest as sporadic tumors or as part of the MEN1 syndrome.

Clinical manifestations include intermittent, severe watery diarrhea that contains large quantities of potassium, bicarbonate, and chloride. Patients may exhibit signs and symptoms of hypokalemia, metabolic acidosis, and dehydration. Hypotension may result from dehydration and the vasodilator effects of VIP. The secretory diarrhea does not respond to antidiarrheal medications. Gastric analysis usually reveals hypochlorhydria or achlorhydria, although an appropriate increase in acid secretion is observed in response to a pentagastrin challenge. Glucose intolerance may reflect hypokalemia and altered insulin sensitivity. Cutaneous flushing of the head and trunk, usually during a bout of diarrhea, may be observed in 15% of patients and may be associated with a patchy, erythematous rash.

The diagnosis of VIPoma may be challenging due to the intermittent nature of the symptoms. A history of recurrent, severe diarrhea and elevated fasting levels of plasma VIP (>200 pg/mL) should prompt a search for a pancreatic tumor. Increased circulating levels of peptide histidine methionine, PP, neurotensin, and prostaglandins have also been detected in patients with VIP-producing tumors. VIPomas can be localized by ultrasonography, CT, somatostatin receptor scintigraphy, or exploratory laparotomy with intraoperative ultrasound.

Initial treatment of patients with the VIPoma syndrome involves aggressive fluid and electrolyte replacement. Somatostatin analogues may be used preoperatively to control the diarrhea by lowering circulating VIP levels and directly inhibiting intestinal secretion. Definitive treatment requires surgical resection of the tumor, which is commonly located in the body or tail of the pancreas. Although tumors are usually solitary, 60% are malignant at the time of diagnosis; 75% metastasize to the liver and regional lymph nodes, and metastases to the lungs, mediastinum, stomach, and kidney also occur. If a pancreatic tumor cannot be identified, exploration of the retroperitoneum, including the adrenal glands and sympathetic chains, is indicated. If no pancreatic tumor is identified, some patients may elect to be closely monitored, but others opt for an 80% distal pancreatectomy. The latter strategy may be beneficial for the 10% to 20% of symptomatic patients with diffuse islet cell hyperplasia. In patients with inoperable or metastatic tumor, a combination 5-fluorouracil and streptozotocin may be effective.

Miscellaneous Gut Hormone-Producing Tumors

Pancreatic endocrine tumors are rare but may secrete parathyroid hormone, growth hormone-releasing hormone, and adrenocorticotrophic hormone, leading to development of hypercalcemia, acromegaly, and Cushing's syndrome, respectively. A large number of peptide hormones may be produced by pancreatic endocrine tumor cells, including PYY, calcitonin, neurotensin, melanocyte-stimulating hormone, corticotropin-releasing hormone, NPY, neurokinin B, CGRP, GRP, and motilin. In some cases, the hormone precursors are produced but the correctly processed intact hormone is not secreted by the tumor. Accordingly, excessive production of many of these hormones may not always be associated with characteristic signs and symptoms. Similarly, carcinoid tumors of the gastrointestinal tract often exhibit immunopositivity for multiple peptide hormones in the absence of a recognizable clinical syndrome.

A large number of peptides are synthesized in and secreted by endocrine cells of the pancreas and gastrointestinal tract. Many of these peptides circulate as hormones, but they also function as paracrine modulators or neurotransmitters in the gut and in the central and peripheral nervous systems. Although some biologic actions have been delineated for many of these peptides, it seems likely that new peptides, receptors, and biologic functions will continue to be characterized. These discoveries may provide opportunities for better understanding the pathophysiology, diagnosis, and treatment of endocrine disease.

CHAPTER

40

Pathogenesis of Endocrine Tumors

ANDREW ARNOLD

A great deal is now known about the mechanisms underlying human tumorigenesis in general and about neoplasia of the endocrine glands in particular. The application of general principles of neoplasia to endocrine tumors has been a productive area of research and is now being translated into clinical applications. Endocrine tumorigenesis also involves some special, if not unique, features that must be considered in understanding the pathogenesis of endocrine tumors. The aim of this chapter is to present the general principles of neoplasia as a framework through which current knowledge about and future advances in endocrine tumorigenesis can be understood.

MOLECULAR TUMOR BIOLOGY

Both inherited tumor predisposition syndromes and the more common noninherited (*sporadic*) forms of neoplasia are genetic diseases in the sense that tumors develop when specific damage to genes leads to deregulated cell growth. As a general rule, damage to one such gene controlling cell growth is not sufficient to confer a neoplastic phenotype on a cell; instead, mutations in multiple genes accumulate over time. Inherited tumor syndromes constitute a special

case in which mutation of one key gene is already present in each somatic cell at birth.

Clonality

Concepts of Clonality and Clonal Evolution

All cancers and many benign hypercellular expansions are *monoclonal*; that is, they are composed of cells that are the descendants of a single clonal progenitor cell in which the accumulation of a sufficient number of DNA alterations (and, perhaps, other epigenetic damage that does not actually change the nucleotide sequence) caused a selective advantage. Over time, this selective advantage—manifested as an increase in proliferative capacity, a decrease in the normal cell death rate, or both—leads to the development of a neoplasm.

The monoclonality of tumors implies that the necessary accumulation of mutations occurs only rarely in the large population of cells in a tissue. Viewed in another way, the identification of a specific monoclonal (also called *clonal*) change in DNA, found in all or most of the cells of a neoplasm but not in that person's constitutional DNA (i.e., DNA obtained from adjacent normal tissue or leukocytes),

indicates that this DNA alteration was advantageous in the accelerated evolutionary process that is oncogenesis. Such a DNA lesion, especially if it recurs in other tumors of the same type, is therefore highly likely to contribute to tumor development.¹ However, this conclusion must be drawn more cautiously in rare circumstances, such as an inherited DNA mismatch repair deficiency, in which the underlying global mutation rate is exceedingly high. One of the strongest types of evidence to implicate a given gene as a driving force in tumorigenesis is the recurrent demonstration of clonal DNA changes in or near that gene.

This situation contrasts with the one in which an increase or decrease in the expression of a particular gene (RNA or protein levels) occurs in a tumor; such changes can be secondary consequences of tumor-related processes and may or may not themselves drive or contribute to the neoplastic phenotype. This caveat is especially important to bear in mind, given that the Human Genome Project and modern microarray technology have made it possible to examine expression changes in a huge number of genes in a tissue or tumor simultaneously.

An original clonal progenitor or transformed cell does not necessarily contain all the genetic lesions that are ultimately present in the mature, clinically apparent tumor. A continuing process of *clonal evolution* can result in the development of additional DNA damage that provides an incremental selective advantage to the single tumor cell in which it occurs. Over time, the progeny of this cell may become the dominant clonal population. The percentage of neoplastic cells in the final tumor that contain such a later mutation can vary markedly and depends on factors such as the duration of the mutation's existence and the relative rates of proliferation and death of the various cell populations.

Endocrine tumor cells are often sufficiently differentiated to express the hormonal activity that is characteristic of the corresponding normal cell type, but the hormonal function of the tumor is typically regulated in an abnormal fashion. The genes that cause tumors of endocrine tissues do so only because of their effects on cell proliferation and accumulation; such genes need not influence hormonal function. Moreover, a mutant gene that alters hormonal function but confers no selective growth advantage is not tumorigenic. Nevertheless, the frequent coexistence of growth deregulation and hormonal hyperfunction in endocrine tumors does indicate that tumor-causing genes can often, directly or indirectly, alter hormone control pathways.

In certain instances, such as a mutation affecting the α -subunit of stimulatory G protein ($G_s\alpha$) in growth hormone-producing and thyroid adenomas, a single mutant gene can directly contribute to both cell proliferation and hormonal hyperfunction. In general, however, the relation between hypercellularity caused by clonally selected mutant genes and hormonal hyperfunction is poorly understood.

Hyperplasia versus Neoplasia

Not all hypercellular expansions are monoclonal. For instance, the generalized proliferative response of all cells of a tissue to an extrinsic stimulus yields a polyclonal expansion. Examples include the hyperthyroidism of Graves' disease and the early, reversible secondary hyperparathyroidism that occurs in states of chronic hypocalcemia. Such polyclonal expansions represent biologic hyperplasia, whereas any monoclonal growth (benign or malignant) is a true neoplasm. Analyses of tumor clonality have been used to distinguish between these types of

tumorigenic mechanisms. However, the genesis of some tumors can involve both types of processes. For example, a generalized stimulus to polyclonal hyperplasia can, by increasing the chances of mitosis-related DNA damage in one cell, foster the emergence of a monoclonal population capable of eventually overwhelming or replacing its hyperplastic neighbors.

The clinical and histopathologic use of the term *hyperplasia* does not necessarily correspond to the biologic meaning just described, a situation that has engendered much confusion. For example, the usual tumors responsible for primary hyperparathyroidism have been clinicopathologically classified as adenomas when a single gland is abnormal and as hyperplasia when the individual patient has multiple hypercellular glands. No histopathologic criteria can reliably predict whether a single or multiple glands are involved on the basis of analysis of only one such gland. Not only are clinical adenomas monoclonal neoplasms,² but many parathyroid glands from patients with multigland "hyperplasia" are also monoclonal.³ It is therefore important to ensure that the terms used in the description of endocrine tumorigenesis are clearly defined.

Insights into Tumor Pathogenesis

Because the clonal status of a cellular proliferation is of fundamental importance in deciphering its pathogenesis, endocrine tumors are studied to determine whether the expansion is monoclonal or polyclonal. One way of determining that a tumor is monoclonal is to identify a DNA or chromosomal lesion that, because of its tumor specificity and presence in all or most of the neoplastic cells, directly defines the expansion as monoclonal. Examples of cytogenetically defined clonal abnormalities are chromosome translocations such as the t(9;22) Philadelphia translocation in chronic myelogenous leukemia and the t(14;18) translocation in follicular lymphoma.

The use of classic cytogenetics is technically more difficult in solid tumors than in hematopoietic tumors because hematopoietic cells divide in culture much more readily and yield excellent metaphase chromosomal spreads. Specimens of endocrine tumors are difficult to obtain for culture and to analyze cytogenetically.

Improved methods for the cytogenetic and molecular cytogenetic study of tumors, including fluorescence in situ hybridization (FISH), comparative genomic hybridization, and chromosome painting, have opened up new avenues for detection of clonal chromosomal lesions in endocrine tumors.^{4,5} New, large-scale methodologies for obtaining the DNA sequence of a sample's entire genome carry the potential to generate a virtually complete catalog of acquired, clonal mutations in a series of human tumors. This catalog would include the full spectrum of structural changes from point mutations to rearrangements and copy number changes. The sensitivity of these methods will also allow for detection of mutations that are present only in subclones or subpopulations of a tumor's cells. Cost and throughput limitations of these technologies are still significant but have been improving rapidly, increasing accessibility for investigators.⁶

Examples of monoclonal abnormalities defined by molecular methods in endocrine neoplasia include $G_s\alpha$ gene mutations in growth hormone-producing pituitary tumors,⁷ thyrotropin (TSH) receptor gene mutations in thyroid tumors,⁸ and cyclin D1 or *CCND1* (also called *PRAD1*) gene rearrangements in parathyroid adenomas.^{9,10} Identification of tumor-specific changes, such as deletions of DNA markers in particular regions of the tumor genome,

also serves as evidence of monoclonality, even if the specific genes affected by such deletions are not known.^{4,11}

Indirect methods can determine the clonal status of tumors without the necessity of identifying the specific genes or chromosomal regions that are clonally mutated and involved in tumorigenesis. These methods have generally exploited the phenomenon of random X-chromosome inactivation (the *Lyon phenomenon*) in women.¹² Random X-chromosome inactivation occurs early in female embryonic development in all somatic cells. In any given cell, the choice of which X chromosome is inactivated is random; however, once that choice is made the decision is faithfully transmitted to all progeny of that cell. Usually, the maternally derived X chromosome is inactive in about 50% of the cells in a normal tissue, and the paternally derived X chromosome is inactive in about 50%.

Polyclonal growth, representing a generalized expansion of many or all original cells within a tissue, maintains the relatively even mix of active maternal and paternal X chromosomes characteristic of the normal tissue. In contrast, the neoplastic cells in a monoclonal tumor are derived from a single progenitor and therefore should all have an identical X chromosome pattern, with either the maternal or the paternal X chromosome uniformly inactivated.

A unifying feature of methods based on the analysis of X-chromosome inactivation to determine the clonal status of a tumor is the use of a normally occurring variant, or *polymorphism*, at the genetic or protein level to distinguish between a woman's two X chromosomes. The other step involves assaying some property that reflects the state of X-chromosome inactivation imposed on the tumor cell chromosomes at the polymorphic site. Assays to reflect X-chromosome inactivation status include assessments of gene expression (RNA or protein levels) or regional DNA methylation.

A polymorphism in glucose-6-phosphate dehydrogenase (G6PD) was the first to be used in X-chromosome inactivation analyses of tumor clonality.¹³ A disadvantage of the G6PD system is that only a small minority of women are heterozygous for electrophoretically distinguishable isoforms of this X chromosome-encoded enzyme. Therefore, most tumors have been unsuitable for G6PD-based clonal analysis. Furthermore, the method fails to detect the monoclonality of certain tumors,^{2,14,15} perhaps because of differences in the level of G6PD expression in tumor cells compared with contaminating admixed normal cells within the analyzed samples.

DNA polymorphisms are now preferred for clonal analyses to distinguish between the two X chromosomes. High rates of heterozygosity make it possible to analyze most tumors. Some multiallelic polymorphisms, based on differences in the number of highly repeated sequence units in a genomic location, are heterozygous in more than 90% of women, and a large number of DNA polymorphisms have been described on the X chromosome (and on all chromosomes). However, most of these polymorphisms cannot be used in clonality studies because they have not been characterized for detectable changes that correlate with the state of activity of the X chromosome on which an allele resides. Some of the X-linked polymorphisms that have been valuable in clonal analyses of human tumors include restriction fragment length polymorphisms in the *HPRT* and *PGK* (now called encoding hypoxanthine phosphoribosyltransferase 1 [*PGKI*]) gene regions,¹⁶ a minisatellite repeat (>10 nucleotide core repeated unit) region called M27 or DXS255,³ and a microsatellite repeat (<10 nucleotide core repeated unit) locus in the androgen receptor gene.¹⁷

Changes in DNA methylation in the vicinity of certain polymorphic sites on the X chromosome correlate with the activity of that X chromosome and are useful in clonal analyses. Methylation of specific cytosine nucleotides is an epigenetic process that is faithfully replicated from a given cell to its progeny, and this process may have a role in maintaining the activity status of the particular X chromosome. Methylation at certain specific sites may be easily detected through the action of methylation-sensitive restriction endonucleases, which cleave when their target sites are unmethylated but cannot do so when a methyl group is present.

One cannot predict how or whether X-chromosome inactivation will affect the methylation of a particular nucleotide in or near a gene; correlations must be established separately for individual genomic sites. For example, a useful restriction site in the *HPRT* region is consistently methylated when on the active X chromosome and unmethylated when on the inactive X chromosome; the opposite pattern is observed for an informative site in the *PGK* region. Despite the need for such empiric validation, the use of DNA methylation as a surrogate marker for the status of X chromosome activity has major advantages in clonality studies and eliminates the vulnerability of the assay to the vagaries of gene expression in tumor cells.

The analysis of clonality in endocrine tumors has yielded important insights. For example, most corticotropin-producing pituitary tumors are monoclonal, which shows that Cushing's disease is not explained solely by a generalized hypothalamic stimulation of corticotrophs.^{18,19} Typical parathyroid adenomas are also monoclonal outgrowths^{2,11} and are not, as previously suggested, asymmetric forms of multiglandular hyperplasia.^{14,15} In patients with multifocal papillary thyroid cancer, clonal analysis of physically distinct individual tumors showed that these foci are often clonally unrelated and, therefore, of independent origins,¹⁷ suggesting an underlying predisposition to thyroid tumorigenesis in such patients (Fig. 40-1).

In severe secondary (or tertiary) hyperparathyroidism in patients with uremia, the typical finding of multigland involvement had led to the assumption that this disease predominantly involves polyclonal (non-neoplastic) cellular proliferations. However, examination of clonality using X inactivation showed that 64% of informative patients with renal failure undergoing hemodialysis who had refractory hyperparathyroidism harbored at least one monoclonal parathyroid tumor, and 63% of all tumors examined had monoclonal X-inactivation patterns.³

One often overlooked pitfall in the interpretation of any X inactivation analysis must be emphasized: Polyclonal patterns cannot be interpreted definitively. For example, admixed normal cells or tumor-specific aberrations in DNA methylation can obscure the detection of a monoclonal cell population. Therefore, the true extent of monoclonality in severe secondary or tertiary hyperparathyroidism might be even higher (but not lower) than demonstrated. These unexpected results indicate that monoclonal parathyroid neoplasms are common in uremic refractory hyperparathyroidism and suggest that autonomous parathyroid function in this disorder is caused by the outgrowth of true neoplasms, presumably on a background of preexisting (and more reversible) polyclonal parathyroid hyperplasia.

Predisposing Influences

Both environmental and genetic factors can contribute to the risk of a particular type of tumor development over a

Figure 40-1 Example of discordant X-inactivation clonality patterns in distinct tumor foci from one patient with multifocal papillary thyroid carcinomas. Shown in the left panels are photomicrographs (stained with hematoxylin and eosin, $\times 40$) of a single patient's three tumor foci, labeled A, B, and C. Even though the three discrete carcinomas have a similar microscopic appearance, they do not share an identical X-inactivation pattern. For each tumor, the corresponding plot to the right shows the size and amount of fluorescent polymerase chain reaction (PCR) products amplified from tumor DNA as analyzed on an automated sequencer. Products are plotted from left to right, from smaller to larger alleles differing at a polymorphic site in the androgen-receptor gene on the X chromosome. The height of the peaks corresponds to the amount of product present. Methylation-sensitive PCR analysis of tumor foci A and B shows that, in each focus, the smaller allele is methylated and therefore inactivated, and the larger allele is unmethylated. Tumor focus C, from the same patient, shows the opposite pattern, with the larger allele methylated and the smaller allele unmethylated. The number in the box under each peak indicates the estimated allele size in base pairs. The discordant X-inactivation patterns indicate that tumor focus C originated independently from A and from B. Foci A and B could have originated separately, sharing an X-inactivation pattern by chance (such concordance is expected in 50% of independently originating tumors), or they could be clonally related. (Modified from Shattuck TM, Shattuck TM, Vestra WH, et al. Independent clonal origins of distinct tumor foci in multifocal papillary thyroid carcinoma. *N Engl J Med*. 2005;352:2406-2412. Copyright © Massachusetts Medical Society.)

lifetime. In highly penetrant inherited syndromes, the genetic predisposition is overriding. In most instances, however, the intimate relation between environmental and (often multiple) genetic factors of lower penetrance makes the traditional "nature versus nurture" question difficult to assess.

A commonly overlooked genetic component of tumor predisposition is gender; however, the specific mechanisms by which gender influences the risk of endocrine tumors such as thyroid cancer and parathyroid adenoma are not well understood. Additional genetic variables, which may be common or rare in the population, also influence the chance of tumor development. It has been notoriously difficult to isolate these specific genetic variations, each of

which might confer only a small degree of risk, might be rare, or might increase risk only when present in particular combinations with other DNA polymorphisms.

An important environmental factor in endocrine tumorigenesis is ionizing radiation. Both thyroid and parathyroid tumors have been linked to prior head and neck irradiation in a dose-dependent fashion.^{20,21} The latency period for tumor development after radiation exposure in the United States is quite long. However, childhood thyroid cancer was observed with markedly increased frequency in the aftermath of the 1986 Chernobyl nuclear accident.²² This heightened susceptibility may not be solely a function of age and amount of exposure; it may be modified by other factors such as iodine deficiency in the region,²² highlighting the point that tumor predisposition and development can be influenced by complex interacting factors.

Oncogenes and Tumor Suppressor Genes

Two broad categories of genes are implicated in the excessive cell proliferation and other properties that result in the outgrowth and evolution of a neoplastic clone. An *oncogene* carries a gain-of-function mutation in its regulatory or coding region that results in dysregulation of its normal product or in the formation of an abnormal protein product. Typically, only one mutated allele need be present for an oncogene to exert its tumorigenic action. The normal, unmutated version of an oncogene is called a *proto-oncogene*. Proto-oncogenes may be converted to oncogenes by various molecular genetic mechanisms, such as fusion of part of its coding region with that of another gene, chromosomal translocations or inversions that alter its regulatory environment, or point mutations.

A *tumor suppressor gene*, in contrast, normally acts to restrain cell proliferation or other potential aspects of the malignant phenotype. This restraint can directly control proliferation (e.g., by regulating the cell cycle), or it can affect proliferation indirectly (e.g., by maintaining genomic stability). Therefore, the definition of a tumor suppressor gene is not restrictive concerning its specific cellular function.²³ Tumors are provoked or fostered by inactivating or loss-of-function mutations in such genes; common inactivating mechanisms are gene deletion, point mutations, and microdeletions or small base insertions that cause a frameshift. Both alleles of a classic tumor suppressor gene must be inactivated to eliminate the functional protein product and to contribute to tumorigenesis.

The existence of a critical tumor suppressor gene is often inferred from the finding that a particular subchromosomal stretch of DNA is recurrently and nonrandomly lost in a particular tumor type. The loss typically involves only one of a gene's two alleles. Because these regions of loss of heterozygosity are often large and can encompass many innocent bystander genes, the case that the correct tumor suppressor gene has been found can be made most convincingly when the remaining allele of the gene is shown to harbor another, more specific, clonal inactivating lesion, such as an intragenic coding region mutation or microdeletion. It is also possible (albeit unproved in human neoplasia) that certain nonclassic tumor suppressors exist, contributing to neoplasia through acquired haploinsufficiency, in which somatic inactivation of only one allele provides the relevant selective advantage.²⁴

Although there has been some evolution in, and even controversy about, the best definition of a tumor suppressor gene, the "simplest, most inclusive, and cleanest genetic definition" is that favored by Haber and Harlow,²³ namely, "genes that sustain loss-of-function mutations in the

development of neoplasia.” This definition, although unrestricted concerning the function of the tumor suppressor, “does have an essential component—the unequivocal demonstration of inactivating mutations.”²³ Therefore, evidence for reduced or absent expression of a gene in a particular tumor, or even the ability of a gene to inhibit cell proliferation, should not be accepted as sufficient to designate it as a tumor suppressor if it is not accompanied by clear and recurrent evidence of clonal mutation.

Some oncogenes or tumor suppressor genes contribute to tumors of only one or a few cell types, whereas other genes are involved in many different types of tumors. It is rare for any one particular gene to be invariably involved in the development of a given type of tumor, and different combinations of mutated genes can have similar cellular and clinical consequences (genetic heterogeneity).

Finally, genetic hits affecting multiple oncogenes and tumor suppressor genes in a single cell appear to be required if that cell is to become neoplastic. In most instances, no single activated oncogene or inactivated tumor suppressor gene is sufficient for the development of a tumor.

Mutational Mechanisms and the Primary Role of Selection in Tumorigenesis

Tumors can acquire mutations that in themselves increase the rate at which new mutations develop at other sites in the genome. Many tumor biologists have commented on the apparently excessive number of genetic changes observed in individual cancers compared with measured rates of mutation in normal cells. Genetic changes are usually considered to occur or to be fixed during DNA replication or mitosis.^{25,26} However, some mutations may be time dependent rather than replication dependent, meaning that they can arise even in the absence of cell proliferation.^{25,27}

One mechanism by which somatic mutations might occur is through a defect in postreplication mismatch repair, the pathway responsible for removing and correcting mismatched base pairs in DNA.²⁷ At least one form of inherited genetic instability can result from inactivation of mutator genes (*MSH2* or *MLH1*) in the mismatch repair system.²⁸ Although such mutational mechanisms may in theory be quite important in benign or slow-growing endocrine tumors that derive from slowly proliferating normal tissues, little direct evidence has supported this hypothesis. Some investigators have drawn conclusions about the extent of genomic instability in endocrine tumors based on the number of observed chromosomal abnormalities, and such conclusions may cloud the distinction between state and rate.²⁹ The presence of genetic alterations in a tumor, even in large numbers, does not necessarily imply that the tumor is genetically unstable. True instability is defined as an abnormal mutation rate, and the snapshot of a mature tumor's complement of mutations (i.e., its state) does not provide information about their rate of occurrence.

As noted by Lengauer and colleagues,²⁹ several factors in addition to true instability may explain the greater frequency of observed mutations in tumors compared with non-neoplastic tissues. These include potentially crucial differences in the selective conditions of the tumor compared with the normal cell context, differences that involve humoral and intercellular interactions.³⁰ For example, a given mutation may confer an important selective advantage and lead to clonal expansion only when it occurs in a tumor cell environment, whereas the same mutation (occurring at the same rate) in a normal cell environment

would not lead to clonal expansion and might even cause apoptosis, thus avoiding detection. In most instances, it does not appear to be necessary to invoke an increased mutation rate to explain the evolutionary process of tumor outgrowth, and an increased mutation rate often may confer a disadvantage on the cell.^{1,31}

In summary, selection is the driving force for tumor growth. This key principle is as applicable to slow-growing and benign endocrine tumors as it is to aggressive cancers.

GENETIC ALTERATIONS IN ENDOCRINE TUMORS: EXAMPLES

Neoplasia is, in large part, a genetic disease in which most of the critical DNA damage occurs somatically rather than through inheritance (germline mutations). Somatic alterations of proto-oncogenes and tumor suppressor genes are implicated in endocrine tumorigenesis; in other words, such mutations can be of either the gain-of-function or the loss-of-function type. Germline mutations that predispose to endocrine neoplasia can also occur in either proto-oncogenes or tumor suppressor genes. Germline mutations in *RET*, causing multiple endocrine neoplasia types 2A (MEN2A) and 2B (MEN2B), and familial medullary thyroid cancer (FMT), are prominent examples of the former and are discussed in Chapter 41. However, most germline mutations identified to date are inactivating mutations, thus identifying the affected genes as tumor suppressors by definition.

Patients in whom a particular tumor develops on the basis of a strong inherited predisposition typically constitute only a minority of patients with that tumor. Nonetheless, the lessons learned from identifying the molecular basis of inherited tumor predisposition are important, both clinically and from a fundamental biologic perspective. In addition, some genes identified as the cause of a rare genetic syndrome through germline mutations have subsequently been found to be somatically mutated in the more common, sporadic occurrences of the same tumors. Two examples, *MEN1* and *HRPT2*, illustrate this point.

Thyrotropin Receptor and G_{α} in Toxic Thyroid Adenomas

The fact that solitary toxic thyroid adenomas often contain somatic mutations in different genes whose products are functionally interrelated highlights the point that heterogeneous genetic lesions can converge on common pathways to predispose to neoplasia. Solitary toxic thyroid adenomas are characterized by autonomous (*TSH-independent*) hyperfunction and growth. Because TSH is normally a stimulus to both functional activity and growth of thyroid cells, toxic adenomas chronically and inappropriately behave as though they are stimulated by TSH. Somatic mutations in the TSH receptor itself can lead to TSH-independent (*constitutive*) activation of the receptor and cause both clonal expansion and hyperthyroidism in a subset of toxic adenomas.³² Therefore, the TSH receptor is a proto-oncogene that can be activated by a variety of point mutations. Analysis of how these point mutations mimic the effects of TSH binding has provided insight into the mechanism of activation of G protein-coupled receptors.

The TSH receptor is a member of the large family of G protein-coupled receptors, and its major actions on thyroid proliferation and differentiated function are mediated

through the cyclic adenosine monophosphate (cAMP) signaling pathway. The predominant G protein involved in transduction of the stimulatory effect of the receptor on adenylyl cyclase is G_s . The α -subunit of G_s is also a proto-oncogene and has undergone clonally selected activating point mutation in a subset of toxic thyroid adenomas.³³ $G_s\alpha$ genes bearing such gain-of-function mutations have been termed *GSP* oncogenes and are also present in some growth hormone-secreting pituitary tumors. These pituitary tumors demonstrate constitutive activation of the cAMP pathway, a prime mediator of proliferation and hormonal function in the somatotroph.

In this context, it is instructive to raise the example of McCune-Albright syndrome (see Chapters 25 and 28), in which activating $G_s\alpha$ mutations are present in multiple tissues of a given patient owing to mutation early in embryonic development and subsequent genetic mosaicism. Hyperthyroidism and acromegaly are among the characteristic components of this syndrome. Another gene encoding an element in the cAMP signaling pathway, the protein kinase A type 1 α regulatory subunit gene *PRKARIA*, has been implicated in the familial syndrome termed *Carney's complex*, which includes corticotropin-independent Cushing's syndrome related to autonomously functioning adrenocortical nodules, growth hormone-secreting pituitary tumors, and male precocious puberty caused by hormonally active testicular tumors.^{34,35}

Cyclin D1 in Hyperparathyroidism and General Oncology

Another illustrative example is that of the *CCND1* oncogene. Unlike many endocrine tumor-associated oncogenes, cyclin D1 is also commonly involved in nonendocrine tumors. This gene, which is now appreciated to be of central importance to molecular oncology and to normal cellular physiology, was discovered in the molecular dissection of an endocrine tumor.

Many human oncogenes were discovered because they are adjacent to nonrandom chromosome breakpoints in tumors. Chromosome breaks and rearrangements probably occur often in normal cells but are recognized only when they result in deregulation of the expression of a growth-related gene (or create a new fusion gene) and confer a selective advantage on the cell. *CCND1* was identified as the putative oncogene adjacent to one such breakpoint PARD1 on chromosome 11 in a subset of parathyroid adenomas (Fig. 40-2).^{9,36,37} On the 11q13 side of the inversion breakpoint, the promoter and coding exons of the cyclin D1 gene remain in contiguity with each other. Across the breakpoint are regulatory sequences from the upstream region of the parathyroid hormone gene (*PTH*) on 11p15 that normally function to enhance *PTH* gene transcription in the presence of parathyroid tissue-specific signals (likely to be DNA-binding proteins found in the nucleus). Such transcriptional enhancer sequences can act over distances of many kilobases to enhance transcription, and cyclin D1 transcription is increased in these tumors. Collectively, such rearrangements along with other activating mechanisms result in elevated cyclin D1 protein levels, which are present in 20% to 40% of parathyroid adenomas.¹⁰ Cyclin D1 overexpression has also been demonstrated to cause hyperparathyroidism in transgenic mice.³⁸

In a broader context, the tissue-specific enhancer-driven expression of cyclin D1 in parathyroid tumors is analogous to the activation of oncogenes such as *BCL2* or *MYC* in B-cell lymphomas. In these tumors, chromosomal rearrangements lead to a juxtaposition of immunoglobulin

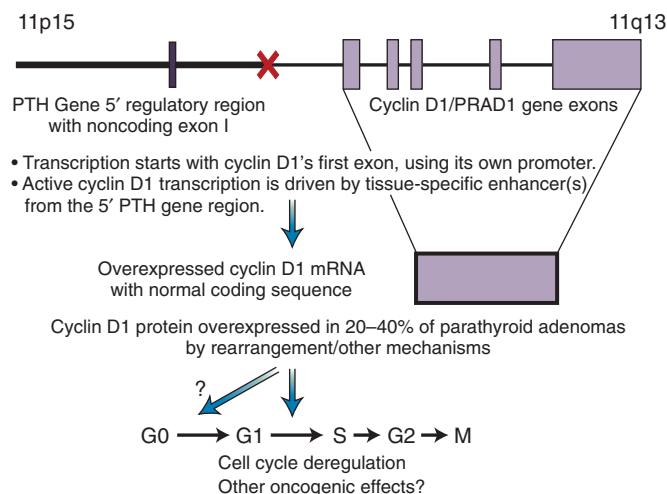

Figure 40-2 Diagram of the molecular structure of the parathyroid hormone–cyclin D1 DNA rearrangement in a subset of parathyroid adenomas and its functional consequences. The dark X represents the chromosome breakpoint between the parathyroid hormone gene (*PTH*) regulatory region plus *PTH* noncoding exon I (solid light vertical bar) and part of its first intron, from 11p15 (left), and the intact promoter and five exons of the cyclin D1 gene from 11q13. Cyclin D1 gene transcription proceeds in a left-to-right direction, as drawn. (Modified from Arnold A. Genetic basis of endocrine disease 5: molecular genetics of parathyroid gland neoplasia. *J Clin Endocrinol Metab.* 1993;77:1108-1112. Copyright © 1993, The Endocrine Society.)

gene enhancer elements and the oncogene, which is thereby inappropriately activated.

The *CCND1* gene product (cyclin D1) was initially recognized as a cyclin by virtue of its structural relation to the cyclin family of proteins, which were known to be involved in controlling the cell cycle. However, before the discovery of cyclin D1, no mammalian cyclins were known to participate in the control of the critical transition from G_1 to S phase of the cell cycle. This checkpoint would be an appropriate site for attack by an oncogenic protein, because movement into S phase commits a cell to the remainder of the cycle and another mitosis. It is now widely accepted that cyclin D1 is a G_1 cyclin that functions to push the cell toward or through this key juncture.³⁹

On a cautionary note, this functional assignment for cyclin D1 as a G_1 cyclin is primarily derived from cultured cell systems, which might not fully reflect the true in vivo roles of this key oncoprotein. The detailed mechanism of action of cyclin D1, both normally and especially when dysregulated in tumorigenesis, deserves further exploration.³⁷

Cyclins are regulatory subunits of holoenzymes whose catalytic subunits are cyclin-dependent kinases (CDKs). The major kinase partner for cyclin D1 appears to be CDK4 or, in some cell types, CDK6. The protein product of the retinoblastoma tumor suppressor gene, *RBI*, has been recognized as one substrate for phosphorylation by cyclin D–CDK complexes. Natural inhibitors of CDK function also exist, and p16^{INK4a} (*CDKN2A*) is recognized as a key inhibitor of cyclin D–CDK4/6 complexes. Inactivation of *CDKN2A* might be expected to be as oncogenic as cyclin D1 overexpression, and *CDKN2A* is, indeed, a tumor suppressor gene in familial melanoma and several types of sporadic human tumors. Inactivating mutations of *CDKN2A* are uncommon, if they occur at all, in parathyroid adenomas.⁴⁰ Therefore, the cellular consequences of *CDKN2A* loss and cyclin D1 activation might not precisely

overlap. Consistent with this observation, increasing evidence exists for possible non-CDK-dependent actions of cyclin D1.³⁷ That being said, the involvement of other CDK inhibitors in endocrine neoplasia does suggest that disruption of these molecules' cell-cycle functions may be a key component of their tumorigenic mechanisms in endocrine cells.⁴¹

The significance of cyclin D1 in human neoplasia extends far beyond its involvement in endocrine tumors. For example, it is the long-sought *BCL1* oncogene that is deregulated by the characteristic t(11;14) translocation in mantle cell or centrocytic B-cell lymphomas. Assessment of cyclin D1 gene rearrangement or expression is clinically useful in the molecular diagnosis of B-cell neoplasia. In addition, cyclin D1 is a key oncogene in breast cancer, myeloma, squamous cell cancers of the head and neck, esophageal cancer, and a variety of other tumors.³⁷ Cyclin D1 and other members of its oncogenic pathway or pathways might serve as targets for development of antineoplastic therapies.

MEN1 Tumor Suppressor Gene

Multiple endocrine neoplasia type 1 (MEN1) is a familial predisposition to tumors of the parathyroid glands, anterior pituitary, pancreatic islets, and duodenum. Other tumors, including carcinoid tumors, lipomas, and angiofibromas, also occur with increased frequency in this disorder (see Chapter 41).

Familial MEN1 is inherited in an autosomal dominant pattern with high penetrance, indicating that in an affected family a single mutant gene is responsible for transmitting the tumor predisposition. *MEN1*, the normal gene whose mutant form causes most cases of MEN1, was identified by positional cloning.⁴² *MEN1* germline mutations have been detected in most MEN1 families and in many individuals with clinically sporadic MEN1 (i.e., patients with a negative family history). Many of these mutations would clearly be expected to truncate the translated product severely and can safely be categorized as *inactivating* mutations. It can be reasonably anticipated that when definitive functional testing is available, other reported mutations, especially in the missense category, will prove to be inactivating lesions as well.

The identification of *MEN1* opened up the potential for direct presymptomatic molecular diagnosis in established or suspected MEN1 kindreds or individual patients. However, the benefits of such DNA testing with respect to prophylactic interventions are more restricted, and improvements in morbidity or mortality are less well established, than, for example, in *RET* testing for MEN2.⁴³ Furthermore, in part because inactivating *MEN1* mutations can occur throughout or even near the gene and are not restricted to its coding region, a substantial fraction of pathologic mutations would be expected to elude identification in MEN1 patients when exons are sequenced in research or commercial laboratories. Therefore, a negative genetic test, which is known to occur in about 30% of kindreds with classic MEN1 features, does not eliminate the diagnosis of MEN1 in a new patient or family. Moreover, a degree of genetic heterogeneity exists in that a subset of "MEN1-like" individuals or kindreds who test negative for *MEN1* mutations have mutations in other genes, including the p27 CDK inhibitor gene, *CDKN1B*.^{41,44}

The *MEN1* gene encodes a 610-amino-acid protein termed *menin*. The structure of menin has yielded few clues to menin's normal function except for its nuclear localization signals. Menin may play an important role in

regulation of gene transcription, related to its partnership with MLL, the mixed lineage leukemia protein, in a multiprotein complex that regulates chromatin structure and expression of target genes.⁴⁵ Menin has been reported to influence various cellular systems, including cell-cycle control, apoptosis, and DNA repair, but exactly how its inactivation leads to endocrine cell neoplasia requires further investigation.⁴⁵ Tissue surveys have shown *MEN1* expression to be almost ubiquitous.

The molecular pathology of MEN1 strongly suggests that *MEN1* functions as a classic tumor suppressor gene, requiring biallelic inactivation to drive the emergence of a clinically significant tumor. For example, somatic deletion on 11q13 in a particular parathyroid or islet cell of a patient with MEN1 results in a cell that is devoid of the normal tumor suppressor function of the *MEN1* gene product and thereby confers an actual or potential selective advantage over neighboring cells. The high incidence of endocrine tumors in MEN1 (which demonstrates almost 100% penetrance) implies that this somatic inactivation of the remaining normal gene copy ("second hit") is a common development in the context of the patient's entire endocrine tissue complement. Cells in tissues not affected in MEN1 probably sustain second hits as well but are able to tolerate the menin loss without fostering tumorigenesis,⁴⁶ indicating the crucial importance of cell and tissue context in endocrine tumor specificity in this disorder and others. Also, one should not assume that loss of function in both *MEN1* alleles is *sufficient* for tumorigenesis in susceptible tissues; additional cooperating oncogenic lesions are probably needed.⁴⁷

Allelic losses of DNA markers on 11q13, including the *MEN1* region, are found in some of the more common, sporadically occurring versions of the tumors associated with familial MEN1. They include, for example, a frequency of 25% to 40% for 11q13 allelic loss in sporadic parathyroid adenomas. However, most studies have found putatively inactivating mutations of the nondeleted *MEN1* allele in only 12% to 17% of parathyroid adenomas. This gap, which is larger than expected from comparisons with other established tumor suppressors, suggests that another tumor suppressor on 11q may exist and may serve as the target for specific acquired mutation in many of the tumors with 11q allelic loss but an apparently intact remaining *MEN1* allele. However, the possibility remains that *MEN1* is the only 11q tumor suppressor that is relevant in these tumors and that epigenetic or noncoding alterations are disproportionately frequent mechanisms of somatic inactivation of *MEN1*.

HRPT2 Tumor Suppressor Gene

The hereditary hyperparathyroidism–jaw tumor syndrome (HPT-JT) is a rare autosomal dominant predisposition to parathyroid gland neoplasms, ossifying fibromas of the mandible and maxilla, renal abnormalities including cystic lesions and hamartomas, and uterine tumors.^{48,49} Based on genetic linkage and positional cloning approaches, the *HRPT2* gene was identified as the source of predisposing germline mutations in the majority of HPT-JT kindreds examined.⁵⁰ The remaining 30% to 40% of kindreds most likely also have *HRPT2* mutations that are located outside the sequenced coding region and therefore evade detection. Similar germline mutations occur in a subset of kindreds with familial isolated hyperparathyroidism (FIHP).⁵¹ Mutations of *HRPT2* are predicted to inactivate or eliminate its protein product, parafibromin, again consistent with a tumor suppressor mechanism. Parafibromin's

normal cellular function appears to involve regulation of gene expression and chromatin modification as part of the human Paf complex,⁵² and its regulatory targets may include cyclin D1.⁵³

Hyperparathyroidism is the most penetrant component of HPT-JT, and it can develop as early as the first or second decade of life. Although the inherited mutation puts all of the parathyroid glands at increased risk for tumor development over a patient's lifetime, the tumors can develop asynchronously, and only a solitary parathyroid tumor may be present at the time of initial diagnosis and surgical exploration. Although most such parathyroid tumors are classified as adenomas, parathyroid carcinoma is found in an impressively high proportion (15%) relative to its less than 1% incidence among parathyroid tumors in the general population. This observation led investigators to consider *HRPT2* as a possible target for somatic mutations in nonfamilial sporadic cases of parathyroid carcinoma and, indeed, somatic inactivating *HRPT2* mutations were discovered in the majority of sporadic parathyroid carcinomas.⁵⁴ Even the impressive combined prevalence of more than 75% in this and subsequent studies is likely to underestimate the true role of *HRPT2* mutation in sporadic parathyroid cancer, because noncoding mutations that are equally capable of inactivating the gene would have escaped detection. Therefore, *HRPT2* mutation is central to the pathogenesis of most, and perhaps all, sporadic parathyroid carcinomas. In contrast, although *HRPT2* was an equally plausible candidate for involvement in benign parathyroid neoplasia, somatic *HRPT2* mutations are rarely, if ever, present in unselected series of typical sporadic parathyroid adenomas.⁵⁵

Importantly and unexpectedly, Shattuck and colleagues also found that some patients with sporadic presentations of parathyroid carcinoma harbor germline mutations in *HRPT2*.⁵⁴ Whether such patients represent newly recognized classic HPT-JT or have a distinct syndrome (akin to MEN2A and familial isolated medullary thyroid cancer as alternative expressions of the same *RET* mutation) is unknown, but in any case this molecular genetic insight has yielded a new clinical indication for DNA-based carrier identification in family members of patients with parathyroid cancer, aimed at preventing parathyroid malignancy.

Genetic paradigms that have originated in the study of malignant neoplasia are useful in the molecular dissection of endocrine tumors, including common benign endocrine tumors. Identification of clonally selected mutations in oncogenes and tumor suppressor genes has opened the door to understanding the control of growth in endocrine tissues and has already resulted in important advances in clinical diagnosis and management. Emerging large-scale sequencing technologies will enable the rapid acceleration of this discovery process. The fact that these genetic alterations can affect endocrine cell function as well as cell number may be exploited in devising medical therapies in the future.

Multiple Endocrine Neoplasia

STEPHEN J. MARX • SAMUEL A. WELLS, JR.

INTRODUCTION TO MULTIPLE ENDOCRINE NEOPLASIA SYNDROMES

The multiple endocrine neoplasia (MEN) syndromes offer special chances for gene discovery and for insights into the broader topics relevant to all endocrine tumors. These possibilities have drawn disproportionate attention to them since their first recognition. The MENs were described in the early 1900s¹ and subsequently classified into two principal categories, MEN type 1 (MEN1) and MEN type 2 (MEN2). They were named *multiple endocrine neoplasia* or *multiple endocrine adenomatosis* syndromes because they cause tumors in two or more types of hormone-secreting tissues and consequently produce multiple syndromes of hormone excess.

From 1950 to 1980, parallel advances in steroid and peptide hormone assays, imaging and histopathology, and connections of genes to cancers led to a fuller delineation of these syndromes. These technologies assisted the recognition that a recurring spectrum of endocrine tumors occurs in certain sporadic cases and in certain families. Furthermore, unique sets of hormones were associated with specific tumors, cell types, and clinical syndromes.

Hormone measurements were used to identify specific neoplasms with the hope that earlier management would improve the course. Prominent among these hormones were prolactin to identify adenomas of the pituitary, gastrin and insulin to identify pancreaticoduodenal tumors, catecholamines or their metabolites to identify adrenal medullary tumors, and calcitonin to identify C-cell hyperplasia or C-cell neoplasia.

During this same period, at least six multiple endocrine neoplasia syndromes with several subvariants were described: MEN1, MEN2, von Hippel-Lindau disease (VHL), neurofibromatosis type 1 (NF1), Carney complex (CNC), and McCune-Albright syndrome (MAS).²⁻⁸ The first five of these are present in the germline with autosomal dominant transmission; MAS develops as a result of very early embryonic somatic mutation leading to tumors in multiple cell types. Each of these syndromes meets the definition of multiple endocrine neoplasia with potential for excess production of multiple hormones. What was not completely recognized at the time of their early description is that each of these syndromes also causes nonendocrine neoplasias, and in some cases, the nonendocrine manifestations cause the most morbidity.

This chapter will not provide an in-depth review of the management of nonendocrine manifestations. Since the 1980s, understanding of these syndromes has focused on the main gene associated with each of them. The main genes whose mutations are responsible for each of the six MEN syndromes have been identified, and this has clarified some important questions. Gene identification led rapidly to gene sequencing to detect germline mutations in patients and in their relatives. Mutation testing for *RET* has had a large impact on management in young members of MEN2 families; but identification of the tumors and precursor cells associated with the other genes at very early stages does not easily lead to beneficial treatments.

Gene sequencing has provided molecular evidence that most of the clinical variants of each syndrome are in fact initiated by mutations of a single gene. The only exceptions at present are MEN1 and CNC, in which a second or even more genes at different chromosomal loci remain to be identified. In two other syndromes, *VHL* and MEN2, specific mutations of the causative genes define unique clinical variants, making genetic information useful for predicting the phenotype. For most of these disorders, mutations of the same gene have been found in sporadic tumors of the same type, indicating a broader importance for these genes in common endocrine and nonendocrine neoplasias. Examples include the identification of somatic mutations of *MEN1* in a high percentage of common pancreatic islet tumors, *VHL* mutations in sporadic renal cell carcinomas, and somatic mutations of *RET* in sporadic medullary thyroid carcinomas (MTCs).

The genetic and molecular abnormalities in these tumor syndromes are representative of the abnormalities found in all human neoplasia: MEN1, *VHL*, CNC, and NF1 are caused by inactivating mutations of a growth suppressor gene, whereas MAS and MEN2 are caused by activating mutations of a growth promoter gene. In at least one of these syndromes, MEN2, the identification of the molecular defect has led to the development of pharmacologic agents that may blunt the molecular abnormalities and to clinical trials to reverse malignant tumor growth.

This chapter describes tumor expression, tumor management, and genetics of MEN1. Data on the molecular pathway from the *MEN1* gene are not yet sufficient to apply to management. In contrast, data on genetics, and molecular pathway are covered early in the section on MEN2, because both the *RET* gene and its molecular pathway have achieved a central role in management.

Progress has been extremely rapid during the current era of gene discovery, and further exciting discoveries are expected shortly. Still, a number of important questions remain: How do the molecular defects cause transformation? What is the mechanism of cell or tissue specificity? Are there molecular events that can be used as therapeutic targets?

MULTIPLE ENDOCRINE NEOPLASIA TYPE I SYNDROME

MEN1 is defined by the presence of two of the following three tumors: parathyroid, duodeno-pancreatic endocrine, and pituitary. Although there were earlier descriptions,¹ MEN1 was recognized as a clinical and familial syndrome by Moldawer³ and by Wermer⁴ in 1954 (hence, the eponym *Wermer syndrome*). MEN2 was recognized as distinct from

MEN1 in 1968.⁷ In previous years, MEN1 patients presented with advanced manifestations of parathyroid, pancreatic islet, or pituitary neoplasia (or some combination of these) in the third and fourth decades of life. However, improved carrier ascertainment and improved tumor surveillance have now resulted in earlier identification and earlier treatment of its hormonal expressions.

The most common mode of presentation for MEN1 is in a previously identified kindred; less often, a patient with newly diagnosed disease may be the proband of a new kindred or a sporadic case. The fact that many tissues are affected causes morbidity and complexity and increases expense in diagnosis and treatment. It is important for the clinician to recognize the high probability of recurrent or new neoplasms in many affected organ systems and to balance this likelihood against the potential effects of a deficiency syndrome resulting from complete organ removal. Furthermore, even with satisfactory control of symptoms from hormone excess, patients have a high likelihood of eventual MEN1-related cancer.

Tumor Expression and Management

Parathyroid Tumors in MEN1

MEN1 is uncommon. The population prevalence is about 1 in 30,000, and MEN1 accounts for only about 1% to 3% of cases of primary hyperparathyroidism (HPT).⁹ HPT is the most common hormonal manifestation of MEN1 (Table 41-1).^{6,9,10-13} Prospective tumor surveillance in members of MEN1 families has shown manifestation of HPT as early as age 8 years^{10-12,14-18}; by age 40 years, about 95% of MEN1 carriers have been hyperparathyroid.^{10,12,19}

Expressions of Parathyroid Tumors. HPT in MEN1 is most commonly asymptomatic; expressions include hypercalcemia, urolithiasis, parathyroid hormone (PTH)-induced bone abnormalities, musculoskeletal complaints, weakness, and alterations of mental status. These features are similar to those associated with other forms of HPT (see Chapter 28).

HPT in MEN1 differs in some ways from that caused by a sporadic adenoma. First, there is a different epidemiology. HPT in MEN1 has an earlier age of onset (typically age 25 years), compared with sporadic parathyroid adenoma (55 years)^{12,13} (Fig. 41-1), and there is a lack of the female preponderance seen in sporadic cases (1:1 versus 3:1 female-to-male ratio, respectively). Earlier onset implies that the disease can last longer. In particular, bone undermineralization among women with MEN1-related HPT seems increased already during their 20s and 30s.²⁰

Second, there is a different parathyroid pathology. Enlargement, albeit highly asymmetric, of three or four parathyroid glands is usually present at the time of parathyroid exploration in patients with MEN1 (Fig. 41-2).^{21,22}

Third, the distribution of outcomes after parathyroid surgery differs in MEN1 and in sporadic HPT. The presence of multiglandular disease and the resulting need to examine each gland during an initial operation result in a higher postoperative rate of hypoparathyroidism and a higher rate of postoperative hyperparathyroidism.^{21,22} Successful subtotal parathyroidectomy is followed within 10 years by recurrent HPT in half of MEN1 cases.^{21,23} True recurrence in common HPT is unusual, and recurrence should suggest the possibility of unrecognized MEN1. As with other tumor recurrences in MEN1, true recurrent HPT could arise theoretically from a small remnant of

TABLE 41-1	
Features of Multiple Endocrine Neoplasia Type I in Adults	
Tumor Type	Estimated Average Penetrance

Meningioma	5

Italics indicate tumor type with substantial (>20% of cases) malignant potential.
 *Many nonfunctioning MEN1 tumors synthesize a peptide hormone or other factors (e.g., small amine) but do not oversecrete enough to produce a hormonal expression.
 ACTH, adrenocorticotrophic hormone; MEN, multiple endocrine neoplasia; VIP, vasoactive intestinal peptide.

tumor tissue or from a new tumor clone in residual normal tissue.

Fourth, HPT in MEN1 almost never progresses to parathyroid cancer, even though untreated HPT lasts longer in MEN1 than in sporadic cases.²⁴

Several characteristics of hyperfunctioning parathyroid cells in MEN1 can have mechanistic implications. First, all or almost all parathyroid glands have been overgrown by one or a few neoplastic clones by the time of parathyroid surgery in MEN1 (Fig. 41-3, top).²⁵ Second, a circulating growth factor is specific to the plasma of MEN1 patients and is mitogenic toward normal parathyroid cells in vitro²⁶ (see later discussion).

Figure 41-1 Age at onset for endocrine tumor expressions in multiple endocrine neoplasia type I (MEN1). Data from retrospective analysis of multiple tumor expressions in 130 inpatients with MEN1 during 15 years. Age at tumor onset was defined as the age at first symptom or at first abnormal test result, whichever was earlier. (Modified from Marx S, Spiegel AM, Skarulis MC, et al. Multiple endocrine neoplasia type I: clinical and genetic topics. *Ann Intern Med.* 1998;129:484-494.)

Management of Parathyroid Tumors

Decision for Surgery. Surgery is the treatment of choice for HPT in MEN1, although the timing and the type of operation remain variable. Parathyroid surgery is definitely indicated in an MEN1 patient with a moderately elevated PTH and other moderately advanced features, such as an albumin-adjusted serum calcium level higher than

Figure 41-2 Parathyroid gland size at initial parathyroidectomy for 18 cases with familial multiple endocrine neoplasia type I. The mean ratio of largest versus smallest tumor at one operation was 9:1. Volumes of all glands at one operation are connected by a vertical line. Adjacent circles are highlighted by being open. The dashed horizontal line represents the upper limit of normal gland volume (0.075 cm³, equivalent to a mass of 75 mg). (Modified from Marx SJ, Menczel J, Campbell G, et al. Heterogeneous size of the parathyroid glands in familial multiple endocrine neoplasia type I. *Clin Endocrinol [Oxf].* 1991; 35:521-526.)

Figure 41-3 Tumor multiplicity within a tissue in multiple endocrine neoplasia type I (MEN1). *Top*, Hypercellular parathyroid gland from a patient with MEN1. The gland section is totally replaced by diffuse sheets of chief cells and two discrete nodules of chief cells. It suggests three or more abnormal parathyroid clones. This image could reflect three or more second hits to the normal copy of the *MEN1* gene in three different clone precursor cells, followed by growth of three or more independent clones. Alternatively, stepwise evolution from one clone could occur (i.e., third hits to genes other than *MEN1*). *Bottom*, Duodenal mucosa from a second MEN1 patient, showing two large submucosal microgastrinomas. Each tumor was positive for gastrin immunostain and negative for other peptide hormones. Possible development of these two adjacent tumors could have followed the same mechanisms suggested for the two parathyroid nodules at the top. (Microphotographs from I. Lubensky, National Institutes of Health, Bethesda, MD.)

3.0 mmol/L (12.0 mg/dL), kidney stones, or PTH-induced bone disease.

Prospective surveillance for HPT in MEN1 families has led to systematic identification of affected members with minimal elevations of serum calcium and PTH, including some as young as 8 to 15 years of age. The optimal management of such patients is not clear. The surgical indication of age younger than 50 years for common HPT cannot be applied to all cases of HPT in MEN1.²⁷

Early parathyroid surgery in MEN1 has been advocated by some, who believe that HPT should always be treated as early as possible for several reasons such as that normalization of the serum calcium concentration might lead to a reduction of gastrin secretion and, possibly, lowered pancreatic islet cell growth or transformation, or both.⁹ An opposite approach is to delay surgery awaiting more severe indications, and thereby assuring an easier parathyroidectomy.

Although parathyroidectomy can decrease gastrin secretion by gastrinomas in MEN1 (Fig. 41-4), there is no evidence that this intervention prevents or slows gastrin-cell growth transformation.²⁸ For this reason, and because drug

control of gastric acid oversecretion is usually excellent, the coexistence of a gastrinoma is not a sufficient indication for parathyroidectomy in MEN1, except in the rare case in which medical control of Zollinger-Ellison syndrome (ZES) is too difficult.

Preoperative and Intraoperative Assessment of Parathyroid Tumors. Noninvasive imaging (ultrasonography, technetium 99m sestamibi, computed tomography, magnetic resonance imaging, or combinations) is being performed with increasing frequency before parathyroid surgery.²⁹ The major justification for the added costs of these procedures in sporadic HPT is the ability to perform a unilateral or even more limited neck exploration, thereby reducing operative morbidity, time, and cost.³⁰ In MEN1 the likely presence of multiple parathyroid tumors makes it necessary to perform an exploration for four or more tumors at initial surgery, thereby eliminating one major rationale for preoperative imaging.⁹ Furthermore, imaging rarely shows all of the overactive parathyroid glands in MEN1. A separate, and less frequent, concern is that if four glands are overactive, as in MEN1, then there is a fourfold greater possibility that one tumor has an abnormal location. A much stronger case can be made for the use of noninvasive and carefully selected invasive procedures (e.g., guided fine-needle aspiration for PTH assay, computed tomography, selective arteriography, selective venous sampling for PTH) in MEN1 patients before reoperation.^{31,32}

Several intraoperative tools can increase the likelihood of successful parathyroid surgery. Rapid on-line assay of PTH can be done at 5-minute intervals, with a turnaround time of 10 minutes for each result.³³⁻³⁵ A substantial PTH fall from baseline predicts that no hyperfunctioning parathyroid tissue remains (Fig. 41-5). This is useful information particularly if multiple tumors are likely. Multiple tumors are almost always present at initial surgery in MEN1, and they are even common at many reoperations for MEN1. These tests are even more likely to be helpful

Figure 41-4 Effect of parathyroidectomy in patients with both multiple endocrine neoplasia type I and Zollinger-Ellison syndrome. Basal acid output and fasting serum gastrin are shown. All patients became normocalcemic except for one (case 4), who remained hypercalcemic. (From Jensen RT. Management of the Zollinger-Ellison syndrome in patients with multiple endocrine neoplasia type I. *J Intern Med.* 1998;243:477-488.)

Figure 41-5 Intact parathyroid hormone (PTH) by rapid assay during parathyroid surgery. Normal range is indicated by the shaded area. The patient had multiple endocrine neoplasia type 1 and primary hyperparathyroidism without prior parathyroidectomy. Three and one half similarly enlarged parathyroid glands (0.8 to 1.6 g; normal, <0.08 g) and the accessible portions of the thymus (THYM) were removed at the times indicated; the thymus contained no identified parathyroid tumor. A rapid fall of PTH below a cutoff criterion indicates that little or no hyperfunctioning parathyroid tumor remains. Removal of the first two parathyroid tumors was not followed by a fall in PTH. The PTH assay result for each time point was available within several minutes to help establish the time at which no hyperfunctioning parathyroid tumor remained and thereby contribute to serial decisions about extending or ending the operation. I, inferior; L, left; R, right; S, superior. (From S.K. Libutti, H.R. Alexander, and A. Remaley, National Institutes of Health, Bethesda, MD.)

during parathyroid reoperations in MEN1, because the number and locations of tumors during a second operation are particularly hard to predict. Sensitive ultrasound transducers routinely provide intraoperative imaging of parathyroid tumors in difficult locations, such as within the thyroid gland or within scar from prior surgery.²⁹ Intraoperative PTH assay and ultrasonography may be useful as backup options at initial parathyroid surgery, particularly in any patient who is expected to have multiple parathyroid tumors (as in MEN1).

Removal of Parathyroid Tumors. The standard surgical approach for initial parathyroidectomy in MEN1 is removal of 3.5 glands and conservation of approximately 50 mg of the most normal-appearing gland, attached to its vascular pedicle in the neck. Because eventual parathyroid reoperation in MEN1 is likely, the recording of careful operative notes and diagrams and the marking of remaining tissue with nonresorbable materials enhance the likelihood of success in subsequent operations.

An alternative is attempted complete removal of all parathyroid tissue from the neck and immediate autotransplantation of small fragments to pockets in the nondominant forearm.³⁶ This strategy is dependent on the likelihood of achieving a high rate of graft success. This technique does not prevent recurrent HPT but can simplify its management. A PTH concentration in the venous effluent of the graft that is greater than in the effluent from the contralateral arm confirms graft function. However, this does not prove graft hyperfunction, and it does not exclude other parathyroid tissue in the neck or chest. Surgical removal of parathyroid tissue from the forearm graft bed during the likely second or third operation is technically easier than a neck reexploration. Cryopreservation of

parathyroid tumor fragments is a useful option at any operation in MEN1, given the high rate of postoperative hypoparathyroidism. Cryopreservation permits a late parathyroid autograft.³⁶ Parathyroid cryopreservation in the United States is discouraged by regulatory considerations.

Partial thymectomy can be performed through the cervical incision. This procedure not only results in removal of intrathymic parathyroid tissue but also can remove thymic carcinoid tissue, an issue discussed later in this chapter. The best time for this is during the initial neck operation, because scar tissue can prevent a simple transcervical thymectomy at reoperation.

Parathyroid surgery in patients with MEN1 requires judgment, familiarity with neck anatomy, and experience. An excellent outcome is more likely when initial or reoperative procedures are performed by an experienced endocrine surgery team.

Pancreatico-Duodenal Neuroendocrine Tumors

Neoplasia of the pancreatico-duodenal neuroendocrine cells is the second most common endocrine manifestation of MEN1 and eventually is expressed in about 60% of MEN1 patients (see Table 41-1). Also, multiple clinically silent pancreatico-duodenal macroadenomas may be recognized at abdominal surgery or autopsy in almost 100% of MEN1 patients older than 40 years.^{37,38} Gastric carcinoid tumors are described later (see "Foregut Carcinoid Tumors"). The pancreatico-duodenal tumors are multiple, can over-secrete various hormones, and can become malignant. Approximately one third of MEN1 patients die from a MEN1-related cancer, particularly gastrinoma; among these fatal cancers, the ratio of hormonal cancer to malignant carcinoid is 2:1.^{39,40} In this era of excellent pharmacotherapy for gastric hyperacidity, about one sixth of MEN1 patients with gastrinoma die from metastatic gastrinoma, but deaths from hypergastrinemia-induced metabolic complications have become rare.⁴¹

Although MEN1 patients can show symptoms or signs caused by one pancreatico-duodenal hormone, there are often several associated and asymptomatic near by tumors with production of the same or other hormones or no hormone.^{42,43} The frequency of peptide immunostaining in MEN1 pancreatic islet tumors is as follows: glucagon, 35%; insulin, 25%; pancreatic polypeptide, 25%; and no hormone, 10%. There are no data on the comparable frequency in duodenal gastrinomas.⁴²⁻⁴⁴

Interpretation of pancreatic islet histology in MEN1 has changed over the decades. Early studies emphasized hyperplastic processes and budding of islet cells from ducts (nesidioblastosis).⁴⁵ Such features have now been reinterpreted as nonspecific in MEN1. The overriding and important islet lesion in MEN1, now termed *multifocal microadenoma*,⁴² is a monoclonal or oligoclonal process (see Fig. 41-3).^{46,47} Molecular evidence is also accumulating for a hyperplastic precursor stage to tumor. Hyperplastic foci of gastrin cells are seen by light microscopy in the duodenum of gastrinoma specimens from MEN1 but not from sporadic gastrinoma.⁴⁸ Furthermore, heterozygous knock-out of the *MEN1* gene in the mouse provides a good model of human MEN1; multiple giant hyperplastic islets composed of beta cells are striking and precede insulinoma in this model, suggesting that unrecognized islet hyperplasia is an undetected islet tumor precursor lesion also in MEN1 of humans.⁴⁹ Because MEN1 cases often have multiple islet macroadenomas and some with differing hormonal properties, tumor imaging has roles different from those in sporadic islet tumor. Sensitive new imaging methods such as endoscopic ultrasound and fluorine

18-labeled L-dihydroxyphenylalanine positron emission tomography (^{18}F -DOPA PET) may achieve roles that remain to be defined.

Rarely, pancreatico-duodenal neuroendocrine tumors occur in several members of a family without other features of MEN1; these have been insulinomas.⁵⁰ Nonfunctioning pancreatic islet tumors and pheochromocytoma can also appear uncommonly in a familial setting as expressions of VHL syndrome.⁵¹

Gastrinoma

Expressions of Gastrinoma. Gastrinoma is the second most common endocrine tumor and the most common cause of severe symptoms and signs in MEN1. The symptoms and signs reflect two processes, malignancy and gastrin induction of excessive acid secretion by the stomach. Gastrinomas are found in about 40% of adults with MEN1 (see Table 41-1).^{9,12,28} ZES is defined here as symptoms or signs of gastric acid hypersecretion caused by a gastrin-secreting pancreatico-duodenal neuroendocrine tumor or tumors. Among all patients with ZES, MEN1 is found often, on the order of 25% in large series.⁵² MEN1 in most of these patients is readily recognizable from personal and family history. In contrast, among carefully defined sporadic ZES cases without obvious MEN1, occult MEN1 is much less frequent; this conclusion is based on family history, long-term follow-up, and mutational analysis of the *MEN1* gene.⁵³

Symptoms of ZES include diarrhea, esophageal reflux, and those symptoms associated with peptic ulceration. Symptoms can antedate recognition of fasting hypergastrinemia. At one extreme, ulcer perforation can be caused infrequently by hypergastrinemia, even without prior symptoms.⁵⁴ The laboratory diagnosis of gastrinoma is mainly made by finding an elevated serum gastrin level. Other causes of elevated gastrin (false-positive results) that must be differentiated from gastrinoma include hypochlorhydria resulting from autoimmunity or from pharmacologic agents that inhibit peptic acid secretion.⁵⁵ HPT in MEN1 often exacerbates hypergastrinemia (see earlier discussion and Fig. 41-4).

The first recognition of elevated gastrin or acid-related symptoms should be followed by assessment of the gastric acid secretion rate without acid-blocking drugs; the normal rate is less than 15 mEq/hour (or <5 mEq/hour after acid-reducing surgery).⁵⁵ The diagnosis of gastrinoma may also be confirmed by measuring the serum gastrin response to intravenous synthetic secretin. A gastrin increase of more than 114 pmol/L (200 pg/mL) diagnoses gastrinoma. This test differentiates gastrinoma from other hypergastrinemic states, such as retained gastric antrum, massive small bowel resection, or gastric outlet obstruction. Gastric endoscopy and ultrasonography are advisable at the initial evaluation for ZES in MEN1 to allow assessment of associated peptic ulcerations, gastric carcinoids, duodenal gastrinomas, and Barrett esophagus. Other imaging modalities should also be used to search for gastric carcinoids, which are common in MEN1 (see later discussion).⁵⁶

Like parathyroid adenomas, gastrinomas have two features that are relatively specific for MEN1. One is earlier age at onset than in sporadic tumors. On average, gastrinoma begins 10 years earlier in patients with MEN1 than in those without it—a lesser age differential than the 30 years difference for HPT.⁵⁷ The second feature is multifocal tumor. The gastrinomas in MEN1 are often small, multiple, and intraduodenal (see Fig. 41-3, bottom).⁴⁴ The duodenal predominance is only modestly greater than that in sporadic gastrinoma.^{31,58}

Gastrinomas in MEN1 have a high propensity to metastasize to local nodes.²⁸ High-grade aggressive behavior, including distant spread to the liver and occasionally to other tissues, also occurs in about 20% of cases. Diffuse hepatic metastases are particularly ominous, predicting a 5-year survival rate of only 50%.⁴¹ The prognosis of gastrinoma in MEN1 is similar to that in sporadic cases.⁴¹ No early features have allowed reliable prediction of which gastrinomas will behave aggressively.⁵⁹

Therapy for Gastrinoma. Most centers have reported almost zero success with attempted surgical cure of gastrinoma in MEN1, even though one third of gastrinoma patients without MEN1 are cured by surgery.^{58,60} Unique characteristics of gastrinoma in MEN1 that contribute to the low rate of curative resection are the multiplicity of small tumors and the frequency of local metastases. The largest tumor was not a gastrinoma in 40% of operations for gastrinoma in MEN1. Extreme approaches, mainly pancreatico-duodenectomy, have been suggested,⁶¹ but long-term benefit is unproven, and the associated potential for surgically induced morbidity seems unacceptable. Only three groups have reported frequent surgical cure of gastrinoma by pancreatico-duodenectomy in MEN1.⁶²⁻⁶⁴ Other groups have not reported similar success rates despite the use of similar approaches.⁵⁸ Differences in the criteria for cure and in the selection of patients (e.g., patient age) can contribute to the differences in outcome.

The development of histamine H_2 receptor antagonists (cimetidine and ranitidine) and subsequently of proton pump inhibitors (PPIs; omeprazole and other members of this class) has made it possible to perform a pharmacologic gastrectomy for ZES.^{55,65} The PPIs are even more effective than the H_2 receptor antagonists. If compliance is good, the need for surgical total gastrectomy is eliminated.^{66,67} Side effects, including those from achlorhydria, are mild. Gastric carcinoids develop in rats given large doses of PPIs.⁶⁸ Gastric carcinoids are also seen in MEN1,⁶⁹ but the PPIs do not seem to exacerbate them in MEN1. There remains disagreement about whether the PPIs worsen enterochromaffin-like cell hyperplasia in sporadic ZES.^{63,70,71} The somatostatin analogue octreotide partially inhibits the secretion of both gastrin and gastric acid⁷² and is under evaluation for a role in malignant gastrinoma.⁷³ In addition, the gastrin-lowering effect of somatostatin analogues might contribute to their effective suppression of gastric carcinoid mass in MEN1.⁷⁴

Although medical therapy for ZES in MEN1 is effective and preferred, the need for lifetime medical therapy, the recognition that small duodenal gastrinomas cause a high percentage of cases, and the poor outcome (50% 5-year survival rate) in patients with hepatic metastasis require frequent reexamination of treatment choices.

Insulinoma. Insulinoma is the second most common hormone-secreting pancreatico-duodenal neuroendocrine tumor in MEN1, with lifetime prevalence of 10% among adults with MEN1 (see Table 41-1).^{12,13} MEN1 accounts for approximately 10% of all patients with insulinoma.¹⁴ The clinical features and diagnostic criteria are the same in MEN1 and in sporadic cases: glucopenic symptoms and fasting hypoglycemia with high insulin, C peptide, or proinsulin (see Chapter 34). Insulinoma syndrome in MEN1 is usually caused by a single dominant and benign pancreatic islet tumor, although simultaneous nonhypersecreting islet tumors that stain for insulin or another gut hormone are common in MEN1. The main insulinoma is typically 2 to 3 cm in diameter and located anywhere in the pancreas. Removal of the largest islet tumor is usually curative.¹³

Rarely, insulinoma syndrome in MEN1 is caused by more than one tumor, either at one time or sequentially. The postoperative recurrence rate of insulinoma may be higher in MEN1 than in sporadic cases. In theory, recurrent insulinoma in MEN1 may arise after 10% of operations; this is from residual tumor or from a new clone.

The preferred treatment is surgical removal of the insulinoma. Other incidental pancreatic islet macroadenomas should also be removed because of the possibility that one may be a hypersecreting insulinoma that could become malignant. Somatostatin receptor scintigraphy (SRS) can provide 30% to 60% true-positive images.⁷⁵ When surgery is performed with guidance only by intraoperative ultrasonography,^{76,77} the success rate should be satisfactory, although no large series has yet documented this outcome in insulinoma of MEN1. In some centers, routine distal pancreatectomy is performed as an adjunct procedure in MEN1 patients for prevention of other tumors.

Several techniques, based on insulin radioimmunoassay, can be useful for localization of an insulinoma in patients with MEN1. These include infusion of calcium into selectively catheterized pancreatic arteries with measurement of insulin in right or left hepatic venous effluent.⁷⁸ Identification of an insulin peak after an intra-arterial calcium infusion localizes the insulinoma to the distribution of the infused artery. Other tests that have been useful include intraoperative rapid measurement of insulin and glucose levels in serum⁷⁹ or intraoperative insulin levels in fine-needle aspirates of a pancreatic tumor (S.K. Libutti, et al., National Institutes of Health, Bethesda, MD, unpublished observation).

Metastatic insulinoma causing hypoglycemia should be treated surgically for palliation, but operative strategies are not likely to be curative.^{80,81} Hypoglycemia caused by unlocated or metastatic insulinoma can be controlled with diazoxide⁸¹; somatostatin analogues are less effective.⁸²

Tumors Secreting Glucagon, Vasoactive Intestinal Peptide, or Other Hormones

Glucagonoma. The glucagonoma syndrome consists of hyperglycemia, anorexia, glossitis, anemia, diarrhea, venous thrombosis, and a characteristic skin rash termed *necrolytic migratory erythema* (see Chapter 39). Glucagonoma syndrome is rare in MEN1,⁸³ although one third of MEN1 pancreaticoduodenal neuroendocrine tumors immunostain for glucagon.⁴³ Glucagonoma is in MEN1 usually large and metastatic at presentation. Palliation is often possible with surgery or another ablative procedure (see later discussion). Some patients have responded partially to the somatostatin analogue octreotide, although an initial response has not predicted a long-term response.⁸⁴

VIPoma. Although the most common cause of diarrhea in MEN1 is gastrinoma, a separate syndrome is caused by oversecretion of vasoactive intestinal peptide (VIP) and is termed WDHA (watery diarrhea, hypokalemia, and achlorhydria) or VIPoma syndrome⁸⁵ (see Chapter 29). In MEN1, it is rare and can occur with pancreaticoduodenal neuroendocrine tumor.⁸³ Half of such tumors also cause hypercalcemia, perhaps by cosecreting PTH-related peptide⁸⁶; of course, coexistent primary HPT is common in patients with MEN1. The tumor is usually malignant, large, and metastatic at presentation. Treatment considerations are the same as for glucagonoma (see later discussion).

Growth Hormone-Releasing Hormone Oversecretion. Oversecretion of growth hormone-releasing hormone (GHRH) is a rare manifestation of a pancreaticoduodenal neuroendocrine tumor; however, half of such cases are found in patients with MEN1 (see later discussion).⁸⁷ GHRH

oversecretion can also occur with bronchial carcinoid in MEN1.⁸⁸

Other Ectopic Hormones. Other peptides that may rarely be oversecreted by pancreaticoduodenal neuroendocrine tumors in MEN1 include ACTH, PTH-related peptide,⁸⁶ somatostatin,⁸⁹ and calcitonin.⁹⁰ Calcitonin oversecretion can cause confusion with thyroidal C-cell cancer, but serum calcitonin levels are usually higher in C-cell cancer than in MEN1 cancers.

Pancreatic Polypeptide-Secreting and Other Nonfunctional Tumors. One third of pancreaticoduodenal neuroendocrine tumors in MEN1 immunostain mainly for pancreatic polypeptide; similar percentages immunostain mainly for insulin or for glucagon.^{42,43} Pancreaticoduodenal neuroendocrine tumors in MEN1 commonly also oversecrete pancreatic polypeptide.^{91,92} Oversecretion of pancreatic polypeptide is not associated with any identifiable hormonal syndrome. Like other nonfunctional pancreaticoduodenal neuroendocrine tumors in MEN1, these are often large, malignant, and metastatic at presentation.⁸³

Nonfunctional tumor is an abused but convenient term. In the context of MEN1, it is applied to pancreaticoduodenal neuroendocrine tumors, anterior pituitary tumors, or foregut carcinoids that do not immunostain for the common hormones of that tissue or that immunostain for one or more hormones but do not hypersecrete the hormone. Most pancreaticoduodenal tumors in MEN1 fit this definition,³⁸ are only microscopic and most never become a clinical problem. Of course, one oversecreting tumor is sufficient to dominate the clinical features. If a nonfunctioning tumor becomes malignant, its lack of symptomatic hormone hypersecretion can allow progression to an advanced stage before recognition. About 5% of islet or duodenal tumors in MEN1 immunostain for somatostatin without clinical expression; these tumors rarely metastasize.⁸⁹

Staging of Pancreaticoduodenal Neuroendocrine Tumors. Appropriate management of pancreaticoduodenal neuroendocrine tumors in MEN1 is challenging because of the multicentric nature of the tumors and the need to decide between surgical and other approaches. A pancreaticoduodenal tumor causing a hormone excess state in MEN1 is likely to be accompanied by one or more nonfunctional tumors. Much of the experience acquired with imaging of sporadic tumors of the same types cannot be generalized to MEN1 tumors. Accurate localization of tumor and, in particular, identification of metastatic disease is critical for preoperative decision making. The multicentricity and variable size of these tumors stretch the limitations of radiologic techniques that have difficulty imaging tumors smaller than 1 cm in diameter, and their rarity has prevented organization of controlled trials.

SRS imaging (¹¹¹In-octreotide scan) enhanced by single-photon emission computed tomography (SPECT) is a useful method for imaging pancreaticoduodenal neuroendocrine and foregut neuroendocrine tumors.^{58,93,94} It can image primary tumors and local or distant metastases.^{95,96} It is particularly useful for multiple gastrinomas in MEN1,^{97,98} and it has replaced most angiographic procedures in MEN1-associated gastrinoma.^{58,99,100} SRS fails to image one third of lesions identified at surgery even in sporadic gastrinoma.¹⁰⁰ The yield of SRS with sporadic insulinoma is somewhat lower than with other pancreatic islet tumors, with 30% to 60% true-positives.⁷⁶ Abdominal imaging by computed tomography (particularly helical),^{101,102} combined with early-phase images after contrast injection or magnetic

resonance imaging, provides enhanced sensitivity for detection of small lesions and is complementary to SRS.^{58,103} Carbon 11-labeled 5-hydroxytryptophan PET scanning is a relatively new method; it and ¹⁸F-DOPA PET are generally more sensitive than SRS, but neither has been explored in MEN1.^{104,105}

No imaging technique used for evaluation of MEN1 pancreatico-duodenal tumors is completely satisfactory. Endoscopic ultrasonography with or without needle aspiration of a pancreatic mass is useful for characterizing very small pancreatico-duodenal abnormalities but is a technically demanding and expensive option for the foreseeable future.^{106,107} With the exception of endoscopic ultrasonography, the current preoperative imaging methods are not able to image tumors that are confined to the pancreas and smaller than 1.5 cm in diameter. They also fail to identify metastases in 25% of cases and the extent of tumor multiplicity in MEN1 cases.⁹⁴ In contrast, intraoperative ultrasonography is a useful tool for localizing small tumors that are not detectable by the eye or fingers of the surgeon. This technique has become the primary approach for diagnosis of small insulinomas in most medical centers, although reports have been limited to sporadic tumors.^{76,108}

Functional (i.e., insulin-specific) testing can be useful to assess insulinoma because, unlike other pancreatico-duodenal neuroendocrine tumors in MEN1, insulinoma may be symptomatic when it is small and solitary (see earlier discussion).

Serum markers in MEN1, mainly chromogranin-A, provide useful diagnostic tools for monitoring the mass of an pancreatico-duodenal tumor.¹⁰⁹ Chromogranin-A has not been helpful in insulinoma, perhaps because of the small tumor mass.¹¹⁰ Chromogranin-A and gastrin as possible tumor markers also have not been reliable indices of gastrinoma extent or progression.¹¹¹

Treatment of Pancreatico-Duodenal Neuroendocrine Tumors. Aspects of treatment specific to gastrinomas and insulinomas in MEN1 have already been described. Treatment of these and other pancreatico-duodenal neuroendocrine tumors in MEN1 is controversial and is guided in part by staging procedures and local preferences. Some of the controversies are highlighted in the following paragraphs.

Is Tumor Size Important? Metastasis has been associated with gastrinomas larger than 3 cm in diameter. This association has led some to recommend resection for all pancreatico-duodenal tumors larger than 2.5 cm.¹¹² However, another analysis of this strategy suggested a failure to prevent later emergence of hepatic metastases.¹¹³ Some others have not found a relation between tumor size and metastasis and do not use a size criterion for surgery.¹¹⁴

Should All Pancreatico-Duodenal Neuroendocrine Tumors in MEN1 Be Removed? There is no consensus on whether all pancreatico-duodenal neuroendocrine tumors in patients with MEN1 should be removed. In MEN1, for every identifiable pancreatic tumor, there are likely to be several smaller, unidentified tumors that coexist or emerge at a later date. Improvements in pancreatic surgical technique have made it possible to excise smaller lesions surgically, although the rationale for doing this is less clear. Certainly, there is no compelling evidence to suggest that surgical removal of small tumors, unless they produce a hormonal syndrome, improves overall outcome. Some urge removal of all detectable macroadenomas if removal would not be dangerous.¹¹⁵ Others urge a large size cutoff (2.5 to 3 cm in diameter) for removal.

Should Metastatic Pancreatico-Duodenal Cancer Be Debulked? Total pancreatectomy with a high rate of complications has been used for very large tumors.¹¹⁶ Many methods are under exploration for resecting or otherwise ablating pancreatico-duodenal neuroendocrine cancer.^{117,118} Results are too preliminary to justify endorsing any of these.

Should Medications Be Used to Control Tumor Progression? Pancreatico-duodenal neuroendocrine tumors are usually differentiated and quite resistant to chemotherapy. Several regimens have been tried, including streptozotocin, doxorubicin, or interferon, but there is no proof of long-term efficacy.^{119-122,6} Octreotide has been effective in inhibiting hormone secretion by benign and malignant pancreatico-duodenal neuroendocrine tumors^{82,123-125}; however, it has not been effective by itself in blocking growth of these tumors except to a small degree for malignant gastrinoma.^{73,126} Its use in multidrug regimens needs further evaluation.

Somatostatin Analogue Linked to a Radioisotope. Because of their selectivity for certain tumors, somatostatin analogues have been explored as vehicles to deliver a radioactive isotope to the tumor. These drugs had not been approved by the U.S. Food and Drug Administration (FDA) in 2010 and are currently under investigation in the United States. The best results seem to be from Lutetium 177 bound to octreotate.¹²⁷ However, controlled studies have not yet been done.

Pituitary Tumor or Adrenal Cortical Tumor

Anterior pituitary tumor occurs in about one third of MEN1 patients.^{12,13,128} The frequency of MEN1 in cases of apparently sporadic pituitary tumor is probably less than 5%, although estimates vary widely to as high as 15% with prolactinoma.^{129,130} The overall frequency of hormones hypersecreted is similar to that observed in non-MEN1 pituitary tumors: prolactin, 60%; growth hormone with or without prolactin, 15%; nonsecreting, 25%; and ACTH, 5%; thyrotropin and gonadotropins are rare.^{12,13,128} Pituitary mass effects can be the principal problem.¹³¹ In fact, pituitary tumors in patients with MEN1 have been larger and less responsive to treatment than without MEN1.¹²⁸ Pituitary tumor can occur early in MEN1 and is occasionally the first recognized feature.^{128,131,132} Rarely, two independent pituitary tumors have been suggested.^{133,134}

Prolactinoma. Prolactinoma is the most common pituitary tumor in MEN1 and the third most common endocrine tumor in MEN1 after parathyroid tumors and gastrinomas (see Table 41-1). The general properties are similar to those of sporadic prolactinoma (see Chapter 9); MEN1 prolactinomas are even larger and harder to treat.^{128,135} Dopamine agonists (e.g., cabergoline, bromocriptine, quinagolide) are the preferred treatment.^{136,137} A reduction in side effects and greater potency make cabergoline the current treatment of choice and have improved patients' compliance. In patients who escape the growth-inhibitory effects of these dopamine agonists or who are noncompliant, transsphenoidal surgery combined with radiation therapy is usually effective.

Tumors that Produce Growth Hormone or Growth Hormone-Releasing Hormone. The clinical features of growth hormone excess are similar in patients with and without MEN1.¹³⁸ There are two different etiologic mechanisms with different treatment implications. The majority of MEN1 pituitary adenomas arise clonally from inactivation of both alleles of the *MEN1* gene in a tumor precursor

cell.¹³⁹ Additional genes such as *AIP* or *GNAS* (which encodes the α -subunit of the stimulatory G protein) may be implicated outside of MEN1.¹⁴⁰ The second mechanism of pituitary growth hormone tumorigenesis begins with the over secretion of GHRH by pancreatic islet or carcinoid tumor.^{88,141-143} The resulting secondary pituitary tumor is a polyclonal or hyperplastic process that responds poorly to therapy directed only at the pituitary; removal of the primary GHRH-producing tumor is essential. Although acromegaly secondary to GHRH is rare in sporadic or MEN1 cases,¹⁴¹ a disproportionate fraction of patients with GHRH tumors have had MEN1. Therefore, measurement of serum GHRH in MEN1 acromegalic patients is sometimes worthwhile. Growth hormone-producing pituitary tumors also produce GHRH locally, but this has not interfered with the interpretation of serum GHRH levels.^{142,144}

Treatment for acromegaly with MEN1 is the same as in acromegalic patients without MEN1 (see Chapter 9). Surgery is usually the first choice, but pharmacologic therapies, including long-acting somatostatin receptor antagonists and growth hormone receptor antagonists, can provide effective, albeit expensive, control.^{145,146} In patients with large tumors causing mass effects and those in whom growth hormone effects are not controlled by surgery or pharmacologic therapy, radiation using an external beam, gamma knife, or proton beam is an alternative (see Chapter 9).

Corticotropin Hypersecretion. Hypercortisolism in MEN1 can be caused by a pituitary tumor producing ACTH, uncommonly by ectopic production of ACTH from a carcinoid or an islet tumor, by ectopic production of ACTH-releasing hormone (CRH), or by adrenal tumor. Therapy should be directed initially to treat the ACTH- or CRH-producing primary tumor. If therapy directed toward the primary source is not successful, corticosteroid production can be controlled by bilateral adrenalectomy or medical therapy (see Chapters 10 and 16).

Primary Adrenocortical Hyperfunction. One or both adrenal glands are enlarged in about 40% of MEN1 patients.^{147,148} This enlargement, most often discovered during pancreatic imaging, is usually clinically silent and rarely requires treatment. The silent enlargement represents a presumably polyclonal or hyperplastic process of unknown etiology,¹⁴⁷ and it rarely behaves as a neoplasm. Rare MEN1 cases have been identified with primary hypercortisolism, hyperaldosteronism, or adrenocortical cancer^{147,149}; none of these have been proved to be intrinsic features of MEN1.

Foregut Carcinoid Tumors

Carcinoid tumor is recognized in 5% to 15% of MEN1 patients.^{13,128} Although sporadic carcinoid is derived mainly from midgut and hindgut, MEN1 carcinoid is almost always found in derivatives of the foregut (e.g., thymus, bronchus, stomach). Certain carcinoid tumors, unlike any other manifestation of MEN1, have a strong sex-specific distribution. In MEN1, thymic carcinoid is mainly in males and with some familial clustering, and bronchial carcinoid is mainly in females.¹⁵⁰⁻¹⁵² The average age of carcinoid recognition in MEN1 is 45 years,¹⁵³ later than that of other MEN1 tumors. This later age may reflect the lack of compression-induced symptoms and the lack of a hormone oversecretion syndrome with most MEN1 carcinoids.

Thymic carcinoid in MEN1 is usually found at an already advanced stage as a large invasive mass. Much less commonly, it is recognized during chest imaging or during

thymectomy adjunctive to parathyroidectomy. Thymic carcinoid is more often malignant (about 70% of cases) than bronchial carcinoid (about 20%) in MEN1.^{151,152,154,155} MEN1 thymic or bronchial carcinoids rarely oversecrete ACTH, calcitonin, or GHRH; similarly, they rarely oversecrete serotonin or histamine and rarely cause the carcinoid syndrome. Most can therefore be considered clinically nonfunctioning. Mediastinal or bronchial carcinoids are best imaged by computed tomography; however, SRS and new PET ligands sometimes give positive results.¹⁵⁶

Gastric carcinoid has been recognized more recently but is less well characterized in MEN1. It is a tumor of enterochromaffin-like cells. Large gastric carcinoids can cause a hormonal syndrome from serotonin and histamine secretion in patients with MEN1.¹⁵⁷ In up to 15% of MEN1 patients, they have been recognized incidentally during endoscopy.⁵⁶ The overall malignancy rate seems low, but there are exceptions.^{157,158} At early stages, they can regress after treatment with somatostatin analogues.⁷⁴

Occasionally, carcinoid occurs in several members of a small family without other manifestations of MEN1.^{159,160} The etiology of such clustered carcinoids is not known.¹⁶¹⁻¹⁶³

Miscellaneous Tumors of MEN1

Miscellaneous Endocrine Tumors in MEN1

Pheochromocytoma. Pheochromocytoma is a rare feature in MEN1; there have been fewer than 10 reported cases.^{9,148} Most have been unilateral and chemically silent; one was malignant.¹³¹ In two tumors, 11q13 loss of heterozygosity (LOH) was documented,¹⁶⁴ making it likely that all or most of these rare pheochromocytomas in MEN1 are true clonal expressions from biallelic *MEN1* gene inactivation. This cause is supported by the fact that pheochromocytoma is even more frequent in mouse than in human MEN1.⁴⁹

Thyroid Follicular Neoplasm. Thyroid follicular neoplasm has been associated with MEN1 since the earliest reviews. This association is likely related to the high incidence of thyroid follicular neoplasms in the general population (unrelated to MEN1) and to their incidental discovery during the inevitable neck exploration for parathyroid disease in MEN1.⁶ Further support for a coincidental association is the failure to identify *MEN1* gene mutations in sporadic thyroid follicular tumors.¹⁶⁵

Miscellaneous Nonendocrine Tumors. MEN1 is associated with nonendocrine tumors that vary from rare to common, with some offering possible use in the diagnosis of MEN1.

Lipoma. The association of lipomas with MEN1 has been known since the 1960s.⁶ MEN1 lipomas are usually dermal, small, and sometimes multiple. Their frequency in MEN1 is about 30%, compared with 5% in control subjects without MEN1.¹⁶⁶ This frequency in normal subjects has limited their use for MEN1 carrier ascertainment.

Angiofibroma. Angiofibromas have been found in 85% of MEN1 patients but not in control subjects.^{166,167} Half of MEN1 patients have five or more. They are acneiform papules on the face that do not regress and can extend across the vermilion border of the lips (Fig. 41-6).

Collagenoma. Collagenomas were also observed in 70% of MEN1 patients but not in control subjects.^{166,167} Collagenomas are whitish, macular or, rarely, pedunculated lesions about the trunk that spare the face and neck. The MEN1 lipomas, angiofibromas, and collagenomas show loss of one copy of 11q13.¹⁶⁸ Therefore, it is likely that

Figure 41-6 Facial angiofibroma in patients with multiple endocrine neoplasia type I. A small, light pink lesion on the vermilion border of the lip (top) and a large, reddish angiofibroma on the nose (bottom) are shown. Typical lesions are smaller than these and multiple and may require biopsy for confirmation. (From T. Darling and M. Turner; National Institutes of Health, Bethesda, MD.)

these are clonal neoplasms and caused by inactivation of both copies of the *MEN1* gene.

Spinal Cerebellar Ependymoma. Spinal cerebellar ependymoma has been seen in four *MEN1* patients.^{9,169} There are no studies to determine whether 11q13 LOH or other *MEN1* gene abnormalities are causative.

Malignant Melanoma. Malignant melanoma has occurred in at least seven *MEN1* patients, but direct involvement of the *MEN1* gene has not been tested.¹⁷⁰

Leiomyoma (of Esophagus, Lung, Rectum, or Uterus). Leiomyoma has been reported in several *MEN1* patients.^{6,171,172} Analyses of 11q13 LOH established that esophageal and uterine leiomyomas are specific to *MEN1* patients.¹⁷³ In contrast, *MEN1* inactivation was not implicated in sporadic uterine leiomyoma.¹⁷³ It is not known whether uterine leiomyoma differs clinically in patients with or without *MEN1*.

Meningioma (Cranial). A large prospective series reported meningioma in 8% of *MEN1* patients. These tumors are mostly small and incidental and would not be recognized without imaging.¹⁷⁴ No intervention is warranted for these. A large and locally aggressive meningioma was seen in one *MEN1* patient who had prior irradiation to a pituitary tumor (SJM, personal observation). This tumor showed biallelic inactivation of *MEN1*.¹⁷⁴

Barrett Esophagus. The frequency of the presumably premalignant Barrett esophagus was increased fivefold in patients with *MEN1* and ZES compared to those with ZES alone.¹⁷⁵ This may relate to a longer interval with uncontrolled excess of stomach acid.

MEN1-Like Phenotypes

Varying Penetrance of Tumors by Tissue or by Age

MEN1 is the most heterogeneous of all neoplasia syndromes. The many tumors of *MEN1* have a wide range of penetrance (see Table 41-1). If the organ is paired and the penetrance is high, the tumors are usually bilateral (e.g., parathyroid adenomas); if the tumor is rare in *MEN1*, its random occurrence is typically unilateral even in a paired organ (e.g., pheochromocytoma). Naturally, the apparent penetrance of any tumor type is heavily dependent on the scrutiny that the organ is given. For example, the frequent facial angiofibromas of *MEN1* were not recognized until 1997.¹⁶⁶ When symptoms alone are the main basis for disease recognition, the first feature of *MEN1* in adolescents is not HPT but rather prolactinoma or insulinoma.¹⁷⁶

For each tumor type, penetrance necessarily increases with age (see Fig. 41-1). Overall, the penetrance for *MEN1* reaches almost 100% by age 50 years,¹² but occasional obligate *MEN1* mutation carriers have not shown any tumor development beyond age 70 years.¹⁶⁹ Earliest penetrance and earliest preventable morbidity must be considered in decisions about when to begin tumor surveillance in a known carrier. The earliest ages for identification of specific tumor expression in *MEN1* have been as follows: prolactinoma, 5 years¹³²; insulinoma, 6 years¹⁷⁷; non-functioning islet, 12 years.^{177,5} HPT, 8 years¹²; and gastrinoma, 12 years (R. Jensen, personal communication). The information about tumor morbidity for most of these young patients is incomplete; more information is needed to improve the recommendations about age at which carrier ascertainment, tumor surveillance, and possibly intervention should begin.

Differential Diagnosis of MEN1

When *MEN1* occurs in its typical and full forms, it is easily diagnosed. Presentation as a single, apparently sporadic tumor; as familial isolated hyperparathyroidism (FIH); or as atypical combinations presents the clinician with challenges to diagnosis and understanding.

Familial Variation in Phenotype or in Penetrance of Tumors

Clustering of clinical subvariants of *MEN1*, similar to that seen for *MEN2* (discussed later), has been evaluated. Preliminary analyses in small *MEN1* families suggested clusters of ACTH-producing pituitary tumors, insulinomas^{178,179} intestinal carcinoids,¹⁵² thymic carcinoids,^{152,180} and aggressive gastrinomas.¹⁵⁴ Identification of a specific *MEN1* mutation or a modifier locus that correlates with a specific clinical variant in multiple kindreds would be most meaningful. However, subsequent analyses have failed to identify such a relationship (see later discussion), increasing the likelihood that tumor clustering is random in most of these families.

Prolactinoma Variant of MEN1

The prolactinoma variant of *MEN1* is defined in a family with high penetrance for HPT and prolactinoma but low penetrance for gastrinoma (typically 90%, 50%, and 5%, respectively, among adults). Three large families have been reported, each with thirteen or more affected members.¹⁸¹ The largest has more than 100 affected members. Because their ancestors colonized the Burin Peninsula of Newfoundland, Canada, their trait has been

termed MEN1_{Burin}. Several other families seem similar but cannot be categorized because of their small size. Foregut carcinoid tumors seemed prominent (10% to 15% of cases) in MEN1_{Burin}.

Isolated Hyperparathyroidism Variant of MEN1

HPT is the most common clinical feature of MEN1 and often begins at a relatively young age. It would therefore not be surprising to identify isolated HPT in small families with occult MEN1, particularly in those families with a disproportionate number of young members. Larger families (four or more affected members) have been identified with FIH and an identifiable *MEN1* mutation but still could represent a random part of the normal spectrum of *MEN1* expression.¹⁸² Eventually, most patients would probably develop other clinical features of MEN1.¹⁸³ Two FIH families with *MEN1* mutation have been particularly large, with 11 and 14 hyperparathyroid members, raising the likelihood that isolated HPT can exist and continue in some families as the only manifestation of *MEN1* mutation.^{182,184} Although these families by definition have *MEN1* mutation, *MEN1* mutation is rare among all families with FIH (see later discussion).¹⁸⁵

Sporadic Tumor or Tumors

MEN1 can occur without a recognized or even a recognizable family history of MEN1. Some sporadic patients who present with two or more typical tumors meet the definition criteria for MEN1¹⁸⁶; for others, the suspicion of MEN1 is high. The prevalence of *MEN1* mutation is 7% to 70%, depending on the specific tumors (see later discussion).¹⁸⁷ When the sporadic case manifests with tumor in only one tissue, the suspicion and the true frequency of *MEN1* mutation are low. The frequency of occult MEN1 with sporadic tumor can be estimated as follows: HPT, 2%^{9,188}; gastrinoma, 5%⁵³; prolactinoma, 5%.^{129,130,189} Factors that increase the likelihood of MEN1 in these settings are suggestive features in the family, earlier onset, and tumor multiplicity in the same tissue. Diffuse or multifocal hyperplasia of the islets or nesidioblastosis is rare and is sometimes seen as a consequence of gastric bypass surgery.¹⁹⁰ Isolated alpha cell disease of the islets with glucagon cell hyperplasia and multiple glucagonomas is sporadic and very rare.¹⁹¹

Familial Isolated Endocrine Tumors Not from the *MEN1* Gene

Familial Isolated Hyperparathyroidism. When HPT is familial and isolated to this tissue, the main possibilities include occult MEN1 (discussed earlier), familial hypocalciuric hypercalcemia (FHH), hyperparathyroidism–jaw tumor syndrome (HPT-JT), MEN2A, and so-called true FIH¹⁸⁵ (see Chapter 28). FHH, with a frequency similar to that of MEN1, is an autosomal dominant disorder characterized by lifelong hypercalcemia with normal urine calcium excretion.^{192,193} PTH levels and parathyroid gland mass are normal or minimally increased.^{194,195} After subtotal parathyroidectomy, the residual parathyroid tissue directs persistent hypercalcemia. The parathyroid dysfunction is probably not monoclonal but polyclonal.¹⁹⁶ A remarkably high rate of persistence after subtotal parathyroidectomy and a low morbidity without surgery justify efforts to avoid parathyroid surgery in FHH. Useful diagnostic features of FHH are the low urine calcium (in the presence of hypercalcemia), the normal PTH level despite hypercalcemia, and the onset of hypercalcemia in young relatives, even before age 1.

Two thirds of FHH index cases have an identifiable inactivating mutation of the calcium-sensing receptor gene (*CASR*).¹⁹⁷ Most of the rest are believed to have an undetected mutation of *CASR*, suggested by genetic linkage to chromosome 3q; occasional families have the FHH syndrome with mutation in unknown genes at 19p or 19q.^{198–200}

One family with a missense mutation of *CASR* had features more like typical HPT.²⁰¹ Two large, prospective studies of FIH found unexpected germline mutation of *CASR* in 15% of families. These families were small (mainly with two or three affected members), and no family had typical clinical features of FHH.^{185,202}

HPT-JT is a syndrome of HPT, jaw tumors, and renal lesions.²⁰³ Transmission is autosomal dominant. The most common and sometimes the only feature is HPT.²⁰⁴ The HPT typically involves one parathyroid gland at a time, and there is a uniquely high malignant potential in the parathyroid tumor; 15% of patients have parathyroid cancer.^{185,205} Germline mutation of *HRPT2* is found in most seemingly sporadic parathyroid cancers, suggesting an occult familial process.²⁰⁶ The associated jaw tumors (in 25%) are ossifying or cementifying fibromas.²⁰⁷ Unlike the jaw tumors of HPT, they are not influenced by the parathyroid status. The associated renal lesions (in 5%) are multiple renal cysts, hamartomas, or Wilms' tumor.²⁰⁸ Uterine tumors are common and can impair fertility.²⁰⁹ *HRPT2* mutation has been found in 5% to 10% of kindreds with FIH.^{185,202,210} Occult MEN2A, theoretically another cause of FIH, has not been identified in the form of FIH.^{211,212}

Many small kindreds with two or three affected members receive a diagnosis of FIH.^{184,213,214} For years, FIH was not pursued as a syndrome because of its bland features and the belief that most kindreds had occult MEN1. Gene tests of many kindreds with FIH have found occult MEN1, FHH, or HPT-JT in about one third.¹⁸⁴ Probably, mutation in undiscovered genes will account for most kindreds with FIH. One such gene seems to be on chromosome 2 by genetic linkage analysis.²⁰⁰

Familial Isolated Pituitary Tumor. Familial isolated tumor of the anterior pituitary has been recognized in several small and a few large families.²¹⁵ The tumors are usually somatotropinomas or prolactinomas. In some families, somatotropinoma is the main expression. In theory, familial isolated tumor of the anterior pituitary could be an expression of occult MEN1. However, no family with familial isolated somatotropinoma has had a *MEN1* mutation (see later discussion). About 15% of these families harbor mutations of the *AIP* gene, which coincidentally is very near the *MEN1* gene at 11q13.²¹⁶

Other Familial Endocrine Tumors.

Isolated Chromaffin Tumor. Chromaffin tumor refers to adrenal pheochromocytoma and to extra-adrenal paraganglioma. Isolated chromaffin tumor occurs in some families. Most family clusters are caused by one of six genes that encode proteins in the mitochondrial succinate dehydrogenase complex (*SDHA*, *SDHB*, *SDHC*, *SDHD*, *SDH5* and *TMEM127*). This topic is covered in more detail in Chapter 16.

Isolated Carcinoid Tumor. Carcinoid tumor clustering in families is statistically significant. However, few families have been described, and most have had fewer than five affected members. The tumors seem to be distributed between foregut and hindgut. None has been associated with *MEN1* mutation. In fact, no single gene or gene locus has been implicated.

The Normal *MEN1* Gene and Normal Menin

Larsson and colleagues²¹⁷ showed in 1988 that the *MEN1* gene mapped to chromosome band 11q13 and that it probably caused tumor by a loss of function.^{218,219} However, almost a full decade passed before the *MEN1* gene was identified by positional cloning.²²⁰ This strategy involved a progressive narrowing of the candidate gene interval,²²¹ cloning of all the DNA in the narrowed interval,²²² and identification of all or most genes therein.²²² The final step required sequence analysis of each of these genes in a panel of DNA from familial *MEN1* index cases, a systematic process that led to the identification of the one candidate gene that carried the defining mutations.^{217,223,224}

The *MEN1* gene is 10 kb long and encodes transcripts of 2.7 and 3.1 kb.²²⁵ The transcripts are expressed in all or most tissues and with little cell-cycle dependence.²²⁶ They encode a 610-amino-acid protein termed *menin*. Rat, mouse, zebrafish, snail, *Drosophila*, and human menins are highly homologous.²²⁷

Menin has two nuclear localization signals near the carboxyl terminus that are likely to be responsible for its predominantly nuclear compartmentalization.²²⁶

Molecular Pathways for Menin's Normal Actions

Because menin has an amino acid sequence without any homologies in the genome, its sequence alone is not informative about its mechanism of action. The principal method applied to search for its molecular pathway has been that of menin partnering to proteins or chromatin. Approximately 25 protein partners for menin have been identified, but only a few have been reproduced in other laboratories.

The first interacting protein partner identified for menin was selectively JunD but not other members of the activator protein-1 (AP1) transcription factor family that includes Fos, Fra, and other Jun proteins.^{228,229} The menin-JunD interaction can confer upon JunD unique effects by which JunD differs from other members of the AP1 transcription family. For example, JunD has several actions opposite to those of c-Jun, and in the absence of menin binding to it, JunD behaves more like c-Jun.²³⁰

The importance of the menin-JunD interaction for the development of *MEN1* is unclear. Homozygous knockout of JunD in the mouse resulted in no identifiable abnormality of tissues involved in *MEN1*.²³¹ Other partnering studies have identified a mixed-lineage leukemia protein (MLL)-containing complex, or SMAD3, PEM, NM23, nuclear factor-κB, and several other proteins that potentially interact with menin. Each interacting partner has unknown importance.²³² Hundreds of chromatin binding sites for menin have been identified but no specific DNA recognition element. At present, none of the menin partners has been convincingly shown to be critical in *MEN1* tumorigenesis. The largest attention has been given to JunD and MLL, and these studies can be explored elsewhere.²³²

Tumorigenesis Roles of the *MEN1* Gene

The first DNA-based discoveries in *MEN1* suggested that the *MEN1* gene was a tumor suppressor²¹⁷⁻²¹⁹ (see Chapter 40), and these observations were supported by subsequent studies (see later discussion).

Two-Step Inactivation of the *MEN1* Gene. Complete inactivation of the *MEN1* gene's function requires, in addition to the inherited or somatically acquired first hit (inactivating mutation), a second hit at the same genetic locus

that finishes the inactivation of both copies of the *MEN1* gene. Inactivation of the second allele can be by mutation or by other (epigenetic) means such as promoter methylation.²³³ A two-hit model for tumorigenesis was developed by Alfred Knudson^{218,219} in 1971 to account for epidemiologic observations in retinoblastoma: In comparison with sporadic cases, some hereditary tumors occurred earlier and in multiple sites. This can now be generalized to say that, in a hereditary tumor, the germline mutation is obligatorily present in every cell. Therefore, the earliest step seen in sporadic tumorigenesis is bypassed in the hereditary form. Multiple independent cells in susceptible organs are thus primed for somatic mutations at the second or normal copy of the tumorigenic gene, to cause early and multiple tumors. This model can also be extended to stepwise tumorigenesis by an oncogene such as *RET* (see later discussion).

Somatic Point Mutations of the *MEN1* Gene in Sporadic Tumors.

MEN1 is one of the most commonly mutated genes in sporadic endocrine tumors. The mutations are typically seen as a first hit represented by a small mutation in the *MEN1* gene and a second hit represented by a large zone of loss of heterozygosity about the *MEN1* locus (see following explanation). Among sporadic tumors, the frequency of *MEN1* mutation is 10% to 20% in parathyroid adenomas,²³⁴⁻²³⁷ 25% in gastrinomas,²³⁸⁻²⁴⁰ 10% to 20% in insulinomas,^{238,241} 50% in VIPomas,^{238,241} and 25% to 35% in bronchial carcinoids.^{238,241,242} Some other sporadic endocrine tumors show a lower frequency of *MEN1* somatic mutation: 0% to 5% in anterior pituitary tumor,²⁴³⁻²⁴⁷ 0% in non-C-cell thyroid tumor,¹⁶⁵ 0% in benign or malignant adrenocortical neoplasm,^{248,249} 0% in uremic secondary HPT,^{248,250} and 0% in parathyroid cancer.²⁵¹ Sporadic non-endocrine tumors have undergone little evaluation; the *MEN1* mutation frequency was 2 in 19 angiofibromas,²⁵² 1 in 6 lipomas,²⁵³ 0% in lung cancer other than carcinoid,²⁵⁴ 1% in malignant melanoma,^{170,255} and 0% in leukemia.²⁵⁶

The First Step (First Hit) Can Be in the Germline or in Somatic Tissue. Virtually all germline or somatic first hits at the *MEN1* gene have been small mutations, involving only one or several bases.^{257,258} The mutations are broadly distributed across the *MEN1* open reading frame, so much so that half of newly ascertained index cases are still found to have a novel mutation. At the same time, the other half show recurring mutations. These are equally distributed in the germline between cause by common ancestry (founder effect)^{257,259-263} and cause by a hot spot for new mutation.²⁵⁷

Accumulated patterns of germline and somatic first-hit *MEN1* mutations have further supported the two-hit gene inactivation hypothesis for the *MEN1* gene (Fig. 41-7). Three fourths of *MEN1* first-hit mutations predict premature truncation of the menin protein. Although the biologic functions of menin are not established, such truncation mutations would probably cause menin inactivation or even absence. For example, all truncation-type *MEN1* mutations cause loss of the most C-terminal nuclear localization signal (see Fig. 41-7) and therefore could compromise the nuclear localization of menin.²²⁶ The remainder predict missense or replacement of one to three amino acids. The functional consequences of any one missense mutation are uncertain and even hard to distinguish from a rare benign polymorphism; however, their frequent occurrence specifically in *MEN1* and their absence in normal subjects has suggested that all or most are deleterious mutations.

Figure 41-7 Germline and somatic mutations of the *MEN1* gene. Unique germline *MEN1* mutations in families, and sporadic cases, and somatic mutations in nonhereditary tumors. The figure shows 670 unique mutations identified by 2006. Repeating mutations within the germline or somatic category (common ancestry versus hot spots for mutation) are shown only once, with a small number in parentheses to indicate total occurrences. Germline mutations are shown as black lollipops or as code about the messenger RNA (mRNA). Somatic *MEN1* mutations in diverse tumors are shown separately as flags along the upper and lower border and as code. *MEN1* mRNA is diagrammed with exons numbered; untranslated regions are crosshatched. Truncating mutations (frame-shift mutations, splice errors, and nonsense [stop codon] mutations) are shown above the mRNA; they account for 75% of all mutations. Codon change mutations (missense mutations or small in-frame deletions) are shown below the mRNA with their three-letter amino acid code. Gray mRNA about exon 3 represents the main zone of menin interaction with JunD. Several large deletions, probably of the entire *MEN1* gene, are not shown.²⁵³ NLS, nuclear localization sequence.

The Second Hit in *MEN1* Tumorigenesis. The second hit is usually a large chromosomal or subchromosomal rearrangement (mutation) causing a deletion of sequence that includes the remaining normal *MEN1* gene. Another potential mechanism for creating a mutant second copy is deletion of DNA that spans all or part of the normal copy and then duplication of the DNA from the mutant chromosome 11, called *gene conversion*. In either case, the result is that neither copy of the *MEN1* gene remains normal. LOH or loss of alleles (heterozygosity) at the affected locus is usually a necessary marker for this process and can provide evidence that gene inactivation has occurred in that chromosomal segment. Other rare mechanisms for the second hit are small mutations (one to three bases) and promoter methylation.²³³ The second hit is delayed after the first hit. It is always in somatic tissue and almost always occurs postnatally.

Loss of Heterozygosity about the Locus of the *MEN1* Gene. LOH about 11q13 has been used mainly to deduce loss of the normal copy of the *MEN1* gene (i.e., the second hit in tumorigenesis). In *MEN1*, 11q13 LOH was found for almost 100% of parathyroid tumors,^{26,264} gastrinomas and other pancreatic islet tumors,^{46,47} gastric carcinoid,^{260,265} anterior pituitary tumors,¹³⁹ and mesenchymal tumors (lipoma, angiofibroma, collagenoma, and leiomyoma).^{168,171,173} These prevalences are higher than those for small mutations of *MEN1* in the same tumors (see earlier discussion). Therefore, mutation of other genes on chromosome 11 may account

for some first hits, and undetected mutations of *MEN1* may account for some. Surprisingly, thymic carcinoid tumor and adrenocortical tumor in *MEN1* have not shown 11q13 LOH.^{147,153,266} This has led to speculation that the normal *MEN1* copy can be inactivated by other mechanisms, such as promoter methylation, that would not cause LOH.

Among sporadic endocrine tumors of the type found in *MEN1*, some but not all have frequent 11q13 LOH. The frequencies of 11q13 LOH in these tumors have been as follows: sporadic primary hyperparathyroid, 30% to 40%;^{234,236,267} uremic parathyroid, 0% to 5%;^{242,268-271} parathyroid cancer, 0%;²⁴⁶ gastrinoma, 25% to 70%;^{47,238} insulinoma, 30%;⁴⁷ bronchial and other foregut carcinoid, 40% to 70%;^{242,272} and anterior pituitary, 5% to 10%.^{140,242-247} In the adrenal cortex, 11q13 LOH was less common in benign than in malignant tumors (20% and 80%, respectively).^{248,249} Assessment of 11q13 LOH is not useful in clinical practice because it does not help in staging or in germline diagnosis; however, it has been used in research as an indicator of an underlying first hit in a tumor suppressor gene at that locus. Of unknown significance, most sporadic hibernomas have deletions of both *MEN1* & mean by *A1P* genes at 11q13.^{272,5}

11q13 LOH has also been used as an indicator of tissue monoclonality or oligoclonality. Because 11q13 LOH is a DNA rearrangement, it can be detected only if it is present in the DNA of most or a substantial minority of cells in a specimen. The nuclei are deduced to be monoclonal or oligoclonal descendants from one or a few precursor cells

with that rearrangement or mutation. Early studies of MEN1 parathyroid glands by light microscopy suggested oncogenesis through a polyclonal hyperplastic process, an observation that was supported by the finding in MEN1 plasma of a factor mitogenic for parathyroid cells.²⁷ The subsequent finding of almost universal 11q13 LOH in MEN1 parathyroids,^{221,228,264} established that monoclonal or oligoclonal growth was predominant and that tumorigenesis in MEN1 occurred by loss of function.

Hyperplasia and DNA Repair. The earliest tissue-level effects toward tumorigenesis in MEN1 are not well defined, nor are many intermediate steps. Although a widespread role for hyperplasia prior to neoplasia has been seen in MEN2 and many hereditary neoplasias, hyperplasia has been subtle or unrecognized as a tumor precursor in MEN1 tissues. A related progression has been identified, from gastrin cell hyperplasia to microtumor as a precursor to gastrinoma, in MEN1 but not in sporadic gastrinoma.⁴⁸ The mouse *MEN1* knockout model for MEN1 exhibits striking giant hyperplasia of beta cells in pancreatic islets as a precursor for insulinoma,⁴² suggesting that more subtle hyperplasia may have gone unrecognized in human MEN1. If there is a role for hyperplasia, it would be uncertain whether this is an expression of inactivation of one *MEN1* allele or further processes. MEN1 plasma contains a growth factor that promotes mitogenesis in normal parathyroid cells and could contribute to hyperplasia.^{26,272} Considering the overriding roles of *MEN1* gene inactivation and of clonal growth, it is not certain whether the growth factor is a contributor to or a consequence of oncogenesis in MEN1.

Clonal cell proliferation has been identified in mesenchymal perivascular tissues about MEN1 angiofibromas²⁷³; this could represent a precursor stage of that tumor.²⁷⁴

Other unknown genes can be implicated in MEN1 tumor evolution through gene loss of function (tumor suppressor gene) or gene gain of function (oncogene).²⁷³⁻²⁸³ Genome instability has been suggested in studies of MEN1 lymphocytes and fibroblasts.^{280,281} Also, MEN1 leukocytes show a subtle deficiency in repair of DNA damage.²⁸² Menin null cells of the mouse show a defect in repair of DNA damaged selectively by ionizing radiation.²⁸³

MEN1 Mutations and Tumor Phenotypes

MEN1 genotype has not been clearly related with phenotype, unlike the situation in MEN2 (discussed later). The truncating *MEN1* mutations cause the same diverse types of tumor expression as the missense mutations, and tumor expression does not differ between amino-terminal and C-terminal mutations. The distribution of somatic mutations about the open reading frame is similar to that of germline mutations (see Fig. 41-7) and seems almost random. There appears to be a deficiency of missense mutations near the C-terminus and a cluster of missense mutations between amino acids 100 and 200. Otherwise, there is no clear clustering of missense mutations that could point to a zone of menin protein susceptible to change of function.

The prolactinoma variant of MEN1, one of the clinical variants described previously in three unrelated kindreds, was associated with no specific genotype or rather with three different *MEN1* mutations.²⁸⁴ *MEN1* mutation has been found in up to 20% of tested families with isolated hyperparathyroidism (FIH).^{181,184} Two of the largest *MEN1* mutation-positive families with isolated HPT had similarly located missense mutations (E255K and Q260P).^{181,285} However, *MEN1* mutations in 14 other kindreds with FIH showed no patterns of similarity.¹⁸⁴

A *MEN1* mutation has not been found with familial isolated anterior pituitary tumor, although more than 100 such families have been evaluated.^{177,246,259,260,286} Therefore, most kindreds with isolated pituitary tumor, like most of those with FIH, represent MEN1 phenocopies; that is, they are probably caused by mutation in genes (e.g., *AIP*²⁸⁶) other than *MEN1*. There has also been no relationship between a specific somatic *MEN1* mutation and tumor type. Tumor testing for somatic *MEN1* mutation has not shown prognostic or staging value when evaluated in sporadic gastrinomas of varying aggressiveness.²⁴⁰

Mutation of a CDKI Gene as a Rare Cause of MEN1-Like State

Inactivation of certain other tumor suppressor genes, alone or in combination, can cause specific endocrine tumors in mice. In particular, mice with homozygous knockout of both *p18INK4c* (*CDKN2C*) and *p27KIP1* (*CDKN1B*) develop neoplasia in at least eight types of tissue, including tumors of parathyroid, pituitary, pancreas islet, and duodenum (as in MEN1); they also develop C-cell cancers and pheochromocytoma (as in MEN2).²⁷⁶ The knocked out genes encode members of the two cyclin-dependent kinase inhibitor (CDKI) families that participate in the cell-cycling pathway and also include retinoblastoma and cyclin D1.²⁷⁷

Rats with homozygous inactivation of *p27* show a spectrum of tumors similar to those comprising MEN1 and MEN2.²⁷² Seven human index cases and several of their relatives exhibited MEN1-like tumors after inactivation of one copy of *p27*.^{287,288} This has been termed *MEN4*. Based on this limited number of cases, the spectrum of *MEN4* is indistinguishable from that of MEN1, and it has not been found to include its rodent counterparts of C-cell neoplasia or pheochromocytoma.

Similar mutations in three other CDKI genes (*p15*, *p18*, and *p21*) and similar clinical features have also been seen in rare MEN1-like cases and families.²⁸⁸ The similar features resulting from mutation of *MEN1* or several of the CDKI genes suggest that they share an overlapping pathway. For example, menin might activate the promoter of a CDKI gene and thereby function as a growth suppressor.

Testing for Carrier State or for Tumor Emergence in MEN1

Screening and Counseling for MEN1. A screening program for MEN1 patients should routinely meet three main objectives: identification of MEN1 carriers;

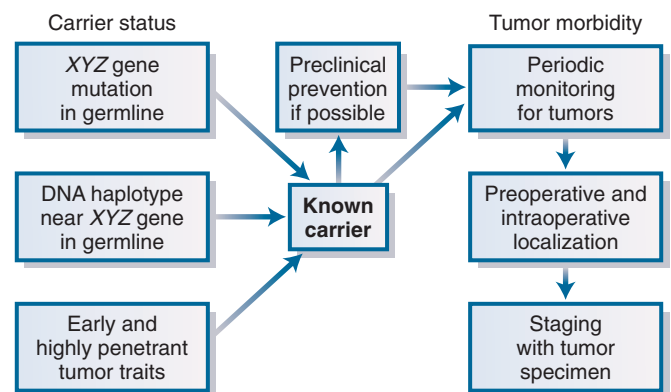

Figure 41-8 Test categories and test methods in a hereditary tumor syndrome. Tests of the germline carrier status (left) are largely distinguished from tests of tumor status (right). When DNA testing is not informative, carrier status can be tested by streamlined surveillance of tumors (lower left).

TABLE 41-2

Representative Protocol of Tests and Schedules to Survey for Tumor Emergence in a Carrier of Multiple Endocrine Neoplasia Type I

Tumor	Age to Begin Testing (Yr)	Biochemical Tests Annually	Imaging Tests Every 3-5 Yr
Parathyroid adenoma	8	Calcium, PTH	None
Gastrinoma	20	Gastrin	None
Insulinoma	5	Fasting glucose	None
Other pancreaticoduodenal	15	NA	¹¹¹ In-DTPA octreotide [‡] ; CT or MRI
Anterior pituitary	5	Prolactin; IGF I	MRI
Foregut carcinoid*	20	NA [‡]	CT

*Stomach is best evaluated for carcinoids (ECLomas) incidental to gastric endoscopy. Thymus is removed partially at parathyroidectomy in MEN1.

[‡]Not available.

[‡]A robust test with serum is not available. Chromogranin-A is not proven as a screen for small tumors.

CT, computed tomography; DTPA, diethylenetriaminepentaacetic acid; ECL, enterochromaffin-like; IGF I, insulin-like growth factor I; MRI, magnetic resonance imaging; PTH, parathyroid hormone.

(Modified from Brandi ML, Gagel RF, Angeli A, et al. Guidelines for diagnosis and therapy of MEN type 1 and type 2. *J Clin Endocrinol Metab*. 2001;86:5658-5671.)

identification of MEN1 tumors, particularly at a treatable stage; and cost-effectiveness (Fig. 41-8).^{218,289} The term *screening* has been applied to several processes in the setting of MEN1. Herein, a distinction is made between testing for carrier ascertainment and testing for periodic surveillance of tumors in a known carrier. When carrier testing with DNA (mutation or haplotype test) is not possible, streamlined and periodic tumor surveillance becomes the preferred method for carrier ascertainment.

Encounters for carrier ascertainment often involve counseling for the patient. In addition to standard genetics topics, counseling in MEN1 addresses two different faces of MEN1: an endocrinopathy with good but complex management options and a cancer syndrome with limited management options. A MEN1 information web page can help in orientation.²⁹⁰

Benefits and Limitations of Carrier Ascertainment. The benefits of this type of analysis are several. First is the secure proof of the MEN1 carrier state in a person with a mutation and, equally important, the potential to exclude the MEN1 carrier state by a normal sequence analysis when another affected member of the kindred has an identified mutant *MEN1* gene sequence.¹⁸² This type of information can assist in decisions about such issues as family planning and future medical needs. Second, the information from an index case, if shared, can be helpful to relatives who are unaware of their status. In particular, after a germline *MEN1* mutation is first identified, the information may be shared with a laboratory and with relatives, and DNA-based information may be used to develop an accurate shortcut test for that mutation in relatives (see later discussion). Third, the information is useful to the physician. It assists in further planning about counseling and tumor surveillance. Occasionally, it is important in a decision about surgery, such as in a case of apparently sporadic gastrinoma.

What the MEN1 carrier ascertainment test does not do is also important. MEN1 carrier ascertainment, unlike similar testing for MEN2, does not routinely lead to a

recommendation for medical or surgical intervention. MEN1 cancers, in contrast to MTC in the thyroid, arise in tissues that cannot easily be ablated. This lack of mutation-guided intervention makes mutation testing at early ages in MEN1 less urgent than in MEN2. We recommend DNA testing in children of gene carriers at age 5 years, the youngest age at which a morbid and possibly treatable MEN1-related tumor (prolactinoma) has been identified.¹³² An alternative approach, based on the fact that MEN1 morbidity is rare before the age of 20 years, is to delay carrier ascertainment until the child can make a mature decision about a test that could affect availability of insurance or job opportunities.

No identifiable *MEN1* mutation is found in 0% to 40%^{187,292,293} of typical MEN1 kindreds, although most are believed to harbor *MEN1* mutations not detected by the most common DNA sequencing strategies. Carrier ascertainment in such kindreds can be established by 11q13 haplotype analysis or by streamlined tumor surveillance (discussed later) (see Fig. 41-8). In practice, this is rarely done. Overall, the potential for benefit from the *MEN1* mutation test is proportional to the likelihood of finding a *MEN1* mutation. Obvious benefit is possible for a proband with familial or sporadic MEN1 or with a state that resembles MEN1 but does not quite meet the usual definitions. For example, a *MEN1* germline mutation was found in each of four patients with sporadic HPT and carcinoid tumor.¹⁸⁶ The likelihood of benefit in a case of atypical MEN1 is typically much lower and varies greatly with the specific tumor identified. For example, the likelihood of finding a *MEN1* germline mutation in a case of sporadic HPT (without special features such as youth or multigland disease) is probably less than 1%.¹⁸⁶

Germline DNA: Mutation or Haplotype Ascertainment. The following sections cover carrier ascertainment by mutation testing, haplotype testing, and tumor surveillance. The general principles of alternative ascertainment methods, with slight modification, are applicable to MEN2 and to many hereditary syndromes (see Fig. 41-8).

Germline DNA mutation analysis can identify or rule out most *MEN1* mutation carriers by a test applied only once during the life span. This test is available through several commercial and academic laboratories.²⁸⁹ The usual tissue surrogate for germline DNA is blood leukocytes; MEN1-associated tumor is less satisfactory because any identified mutation could have occurred somatically. The *MEN1* mutation test is based on polymerase chain reaction (PCR) amplification of their nine translated exons (the open reading frame) and the intron-exon boundaries. Laboratories use modestly differing protocols. The germline mutation test or carrier test in DNA has two different roles (see also below). First the carrier state can be evaluated in an affected proband with MEN1-like features. This test, if positive, confirms MEN1, begins tumor screening, and promotes carrier testing in relatives; this test in the same family can be based on an exon-specific short-cut sequence test. Second the carrier state can be evaluated in asymptomatic relatives of a carrier. The positive test can begin tumor screening and testing for additional relatives.

MEN1 germline mutations have been detected in 60% to 100% of well-defined MEN1 families.^{283,290-292} The wide variability in mutation detection rate is explained partly by family selection but more likely by differences in laboratory detection methods. Genetic linkage analysis previously mapped all well-characterized MEN1 kindreds to 11q13, making it likely that mutation of the *MEN1* gene causes almost all familial MEN1.²⁹³ Three atypical MEN1

families have not been linked to 11q13.^{177,286,294} Failure to identify a *MEN1* mutation could be explained by the presence of mutations involving 5' or 3' untranslated or central intronic regions, sequences that are not normally examined, or by a large *MEN1* deletion that results in no abnormal PCR reaction product.²⁵⁸ Mutation at another gene, such as a member of the CDK1 gene family, is also possible. An error in sample processing is a related possibility.

The *MEN1* mutation detection rate has been lower (10% to 80%) in sporadic than in familial *MEN1*.^{172,177,259,260,284,289} The *MEN1* germline mutation rate has been high (about 75%) in sporadic cases with HPT and ZES,²⁸⁴ but it is far lower (about 7%) in sporadic cases with HPT and acromegaly.²⁹⁵ For the same reason, the *MEN1* mutation detection rate has also been low (0% to 30%) in sporadic cases with atypical *MEN1*, a truly broad category without a consensus definition.^{172,177,284,296} Most *MEN1* mutations are familial, but about 10% may arise de novo.²⁹⁶

When *MEN1* mutation cannot be detected in the germline DNA of a *MEN1* index case, ascertainment of the carrier state in relatives is more difficult. Carrier ascertainment can still be based on streamlined periodic tumor surveillance in a relative (discussed later) or on haplotype analysis (similar to genetic linkage analysis) in a kindred (see Fig. 41-8). With three or more affected relatives, haplotype or linkage analysis for the *MEN1* trait may be done with high degrees of confidence²⁹⁷; however, few laboratories are doing these analyses.

Carrier Ascertainment for *MEN1* by Streamlined Surveillance for Tumors: An Alternative to DNA Testing. In kindreds with no identifiable *MEN1* mutation and no possibility of 11q13 haplotype analysis, it is necessary to base assignment of carrier status on the clinical identification of a frequent tumor of *MEN1* (see Fig. 41-8). Streamlined periodic surveillance for tumors by biochemical tests should be offered to asymptomatic offspring of known carriers every 3 to 5 years. HPT is the most common and usually the earliest manifestation of *MEN1*, and its recognition is central to this carrier-ascertainment strategy. The preferred parathyroid tumor surveillance test is the ionized calcium test, beginning at age 8 years or later. A serum PTH assay should be performed at the same time. If the ionized calcium test is unavailable, an albumin-adjusted calcium test is suitable and is also preferable to measurement of total serum calcium.¹⁰

Five years is a suggested starting age for prolactinoma surveillance, based on the occurrence of a morbid macroprolactinoma in a child of that age with *MEN1*.¹³⁰ Because serum prolactin rises with stress, avoidance of phlebotomy stress in a child can require an indwelling venous catheter and three blood samples obtained at 20-minute intervals.²⁹⁸ Gastrinoma surveillance can be introduced during adulthood because of the typically later age at onset of ZES in *MEN1* (see Fig. 41-1). Occasionally gastrinoma is the first clinical tumor to occur in *MEN1*.²⁹⁹

Surveillance for cutaneous manifestations of *MEN1*, collagenomas or facial angiofibromas, may be promising but has not yet been explored in children.¹⁶⁶ False-positive test results are often found in *MEN1* tumor surveillance through assays of PTH (caused mainly by vitamin D deficiency) prolactin (caused by stress, pregnancy, or psychotropic medications) or gastrin (caused mainly by hypochlorhydria, including that resulting from inhibitors of gastric acid secretion). Rarely can one be misled by a sporadic but common endocrine tumor (such as parathyroid adenoma or pituitary tumor) that could occur in a family member who is not a *MEN1* carrier.³⁰⁰

Periodic Surveillance for Tumors after Proof of the *MEN1* Carrier State. After the *MEN1* carrier status has been identified by any method, it is appropriate to focus continued and increased attention on the carrier with the goal of identifying and treating neoplastic manifestations at an appropriate stage (see Table 41-2). Surveillance for parathyroid tumor, prolactinoma, and insulinoma can begin in proven carriers at age 5 to 8 years; surveillance for gastrinoma, other islet tumors, and foregut carcinoids should be delayed until after the age of 20 years. Cost-effective surveillance combines a carefully obtained history focused on clinical symptoms associated with these tumors, limited hormonal and serum chemistry analysis, and carefully defined (i.e., selective and less frequent) use of imaging (see Table 41-2).¹⁸⁵

Some have recommended more extensive surveillance measures that include measurement such as pancreatic polypeptide,^{92,94} chromogranin-A, proinsulin, or cortisol.²⁹⁴ A meal-stimulated test was developed in the hope of increasing *MEN1*-related diagnostic information from pancreatic polypeptide and other markers.^{91,109,301} It is unclear whether these methods lead to earlier detection and whether benefit to the patient may result.

MULTIPLE ENDOCRINE NEOPLASIA TYPE 2

Beginning about 50 years ago, a series of independent, seemingly unrelated clinical and basic science discoveries provided the basis for the characterization of the type 2 multiple endocrine neoplasia syndromes: *MEN2A*, *MEN2B*, and familial medullary thyroid carcinoma (FMTC). In 1959, Hazard, Hawk, and Crile identified MTC as a specific clinicopathologic entity, but it was not until 7 years later that Williams described the histogenesis of MTC from the neural crest-derived C cells in the thyroid gland.^{302,303} In 1968, Steiner and associates described a kindred with MTC, pheochromocytomas, HPT, and Cushing's syndrome.⁶ They named the disease complex *MEN2*, and we now know it as *MEN2A*. In 1966, Williams and Pollack described a syndrome of multiple mucosal neuromata with endocrine tumors, similar to von Recklinghausen's disease, and 2 years later Shimke and colleagues described a similar entity of bilateral pheochromocytomas, MTC, and multiple mucosal neuromas—a disorder we now know as *MEN2B*.^{304,305} In 1986, Farndon and associates described a large family with MTC without other endocrine tumors. This endocrinopathy is termed familial MTC (FMTC), and it appears to be closely related to *MEN2A*.³⁰⁶ In 1962, Copp and colleagues discovered the hormone calcitonin, which was thought to lower blood calcium.³⁰⁷ Although they hypothesized that the parathyroid cells secreted the substance, Hirsch and associates subsequently demonstrated that the hormone was produced by the thyroid gland.³⁰⁸ In 1985, Takahashi and colleagues reported a novel human transforming gene, which they named *RET* (Rearranged during Transfection)³⁰⁹.

The *MEN* type 2 and related syndromes occur in 1 of every 30,000 individuals with the following frequencies: *MEN2A*, 80%; *MEN2B*, 5%; and FMTC, 15%. Each syndrome is inherited in an autosomal dominant fashion with near-complete penetrance and, in the case of *MEN2A* and *MEN2B*, with variable expressivity. Virtually all individuals with these syndromes develop MTC, and it is the most common cause of death in affected patients. Approximately 50% of patients with *MEN2A*

Figure 41-9 A, B, and E, Typical facial appearance of three patients with multiple endocrine neoplasia type 2B (MEN2B). C and D, Characteristic mucosal neuromas on the tongues of the mother and daughter shown in A and B, respectively.

and MEN2B develop pheochromocytomas, and 30% of patients with MEN2A develop parathyroid tumors. Rarely, patients with MEN2A develop two associated disorders, cutaneous lichen amyloidosis and Hirschsprung's disease.

Patients with FMTC only develop MTC. Patients with MEN2B manifest developmental abnormalities of the musculoskeletal system, medullated corneal nerves, mucosal neuromas, hypotonia, ganglioneuromatosis of the aerodigestive tract, and a typical physical appearance (Fig. 41-9). Because of motor dysfunction resulting from ganglioneuromatosis of the large bowel (Fig. 41-10), most patients with MEN2B develop colonic symptoms, characterized by constipation, abdominal bloating, and abdominal pain. A distended colon is evident on radiographic studies of the abdomen, and some patients require surgery for intestinal obstruction.

It is estimated that the disease arises *de novo* in 50% of patients with MEN2B and 10% of patients with MEN2A or FMTC. In all founder cases studied thus far, the *de novo* mutation has arisen from the paternal allele.^{310,311} Also, of the 43 founder cases with MEN2B, 28 were female and 15 were male, a finding that appears unlikely due to chance.³¹⁰ The reason for this distorted sex ratio is unknown.

Few hereditary cancer syndromes have such a close relationship between genotype and phenotype. For that reason, the molecular biology and genetics of the MEN2 syndromes and FMTC, and their clinical relevance, are addressed early in this part of the chapter.

The Molecular Basis for MEN2A, MEN2B, and FMTC

Structure and Function of the Normal *RET* Proto-Oncogene

The *RET* proto-oncogene was identified as a novel hybrid oncogene with transforming activity in NIH 3T3 cells. The proto-oncogene, derived from a recombination event involving two unrelated DNA sequences from human lymphoma, encodes a fusion protein comprising an N-terminal region linked to a tyrosine kinase. *RET* is located in the pericentromeric region of chromosome 10q11.2 and spans 21 exons, including more than 60 kb of genomic DNA.³⁰⁹ *RET* is highly conserved, and homologues have been found in lower vertebrates and in the fruit fly.^{312,313}

The *RET* protein structure consists of three domains: an extracellular ligand-binding segment containing four cadherin-like repeats, a calcium binding site, and a cysteine-rich region that is important for receptor dimerization; a hydrophobic transmembrane domain; and an internal catalytic core containing two tyrosine kinase subdomains (TK1 and TK2) that are involved in the activation of several intracellular signal transduction pathways. Alternative 3' splicing of *RET* produces three isoforms with 9, 43, or 51 amino acids at the C terminus, referred to as RET9, RET43, and RET51, respectively.³¹⁴ The two major isoforms, RET9 and RET51, have markedly different signaling complexes, suggesting different physiologic functions.^{315,316}

Figure 41-10 Pathologic specimens of the colon in patients with multiple endocrine neoplasia type 2B (MEN2B). **A**, Masses of hypertrophied ganglia cells in the wall of the large bowel (arrows). **B**, Mucosal neuroma of the tongue (hematoxylin-eosin stain; original magnification, $\times 10$). **C**, Cross-section of large bowel wall shown in **A** with mass of subserosal ganglia cells (arrow) (Masson's trichrome stain; original magnification, $\times 2$). **D**, Section of bowel wall showing enlarged myenteric plexus (arrows) (hematoxylin-eosin stain; original magnification, $\times 40$).

RET plays a central role in various intracellular signaling cascades that regulate cellular differentiation, proliferation, migration, and survival. A tripartite cell-surface complex is needed for RET signaling. One of four glial cell line-derived neurotrophic factor (GDNF) family ligands (GFLs)—GDNF, neurturin, artemin, or persephin—binds RET in conjunction with one of four glycosylphosphatidylinositol-anchored coreceptors designated GDNF-family α -receptors (GFR α s) termed GFR α 1, GFR α 2, GFR α 3, and GFR α 4.³¹⁷⁻³²¹ GDNF primarily associates with GFR α 1, whereas neurturin, artemin, and persephin preferentially bind GFR α 2, GFR α 3, and GFR α 4, respectively. All GDNF-family members have similar downstream signaling pathways, because all GFR α s bind and activate the same tyrosine kinase and induce phosphorylation of the same four key RET receptors (Y905, Y1015, Y1062, and Y1096).^{322,323}

Ligand stimulation leads to activation of the RET receptor with dimerization and subsequent autophosphorylation of intracellular tyrosine residues, which serve as docking sites for various adaptor proteins. At least 18 specific phosphorylation sites have been identified, some of which are shown in Figure 41-11.

The normal RET extracellular cysteine residues are involved in the formation of intramolecular disulfide bonds, which are necessary for maintaining the tertiary structure of the extracellular domain. RET cysteine mutants induce constitutive disulfide-linked dimerization of RET molecules.³²⁴⁻³²⁶

RET is expressed in developing neuroendocrine cells, including thyroid C cells, adrenal medullary cells, parathyroid cells, neural cells (including parasympathetic and sympathetic ganglion cells), and cells of the testis and urogenital tract.³²⁷⁻³³⁰ RET plays a central role in the development of the kidney and the enteric nervous system, as evidenced by the similar phenotype of renal and neural abnormalities in mouse embryos and newborns with

deficiencies of RET.³³¹ In adults, RET is expressed in several tissues including brain, thymus, peripheral enteric sympathetic and sensory neurons, and testis.^{322,327,332}

Structure and Function of the Mutated RET Proto-oncogene

The first step in cloning the mutated RET proto-oncogene was the demonstration through linkage analysis that a putative genetic marker for MEN2A maps to a small region on chromosome 10q11.2.^{333,334} Subsequently, it was shown that germline, missense, and point mutations on chromosome 10 are associated with MEN2A, MEN2B, and FMTC.³³⁵⁻³³⁸ The findings that dominant negative activating mutations of the RET proto-oncogene cause these hereditary diseases was unexpected, because most tumor syndromes previously described were associated with tumor suppressor genes or mismatch repair genes. To date, approximately 76 RET mutations have been reported in association with MEN2A, MEN2B, and FMTC, and 98% of reported MEN2 families have demonstrated RET mutations. Additional information regarding specific molecular changes in the RET proto-oncogene can be found on the web sites of The Human Gene Mutation Database at the Institute of Medical Genetics in Cardiff, U.K. (<http://www.hgmd.cf.ac.uk/ac/index.php>), and Online Mendelian Inheritance in Man (OMIM) from Johns Hopkins University (<http://www.ncbi.nlm.nih.gov/sites/entrez?db=omim>).

Almost all of the germline point mutations causing the MEN2A, MEN2B, and FMTC occur in a confined segment, either in the extracellular domain of RET (exons 10 and 11) or in the tyrosine kinase domain (exons 13 through 16). The mutations for MEN2A are mostly located in the extracellular, cysteine-rich region of exon 10 (including codons 609, 611, 618, and 620) and exon 11 (including codons 630 and 634). Approximately 85% of the mutations associated

Figure 41-11 Molecular pathways activated by the *RET* proto-oncogene. (Reprinted with permission from Wells SA, Santoro M. Targeting the *RET* pathway in thyroid cancer. *Clin Cancer Res*. 2009;15:7119-7123.) These abbreviations are well known molecular terms. I am not sure that an explanation is necessary, as they are rarely spelled out in text figures. However, here they are: DOK-docking protein, FRS2-fibroblast growth factor receptor substrate 2, GRB-granzyme B, IRS1/2-internal resolution sites 1/2, PLCγ-phospholipase C gamma, Shc-sarc homology, Src-sarc, STAT-signal transducer and activator of transcription, Y752-Y1096-tyrosine docking sites.

with MEN2A involve *RET* codon 634, and approximately half of those are C634R *RET* mutations.³³⁹ The reason for the prevalence of codon 634 mutations in MEN2A is unknown. Base-pair duplications in the cysteine-rich extracellular domain of *RET* and dual de novo mutations on the same *RET* allele have been reported in MEN2A.^{340,341}

The mutations characteristic of FMTC also occur in exons 10 and 11, however, noncysteine point mutations have also been found in exon 8 (codons 532 and 533), exon 13 (codons 768, 790, and 791), exon 14 (codons 804 and 844), exon 15 (codon 891), and exon 16 (codon 912). Pigny and associates reported a family with FMTC who did not have a usual *RET* mutation; rather, a 9-base-pair duplication in exon 8 was present in all affected family members.³⁴²

Mutations associated with FMTC result in less potent transformations in vitro than those associated with MEN2A.³⁴³

Unlike the mechanism in MEN2A, the MEN2B mutations in the kinase domain cause constitutive *RET* activation in a monomeric form of *RET*, thereby altering substrate specificity, presumably as a result of a conformational change in the binding pocket of the kinase.^{325,344} Approximately 95% of mutations causing MEN2B are in codon 918 (exon 16), and 5% are located in codon 883 (exon 15). There have been two reports of patients with an atypical MEN2B syndrome who were found to have two *RET* mutations on the same allele, neither involving codons 918 or 883. One patient had a germline Y806C mutation (also present in the asymptomatic father) in association with a de novo V804M

mutation.³⁴⁵ The second patient and affected family members had MTC and mucosal neurilemmomas, and one family member had HPT, which is not a component of MEN2B.³⁴⁶ Mutational analysis showed double germline mutations of V804M and S904C. Both amino acid changes are located within the split kinase domain, the V804 mutation within an area of unknown function and the S904C mutation within the highly conserved distal half containing the activation loop of the RET receptor tyrosine kinase. Similarly located mutations, such as c-Kit (KIT) and fibroblast growth factor receptor 3 (*FGFR3*), have been demonstrated to cause ligand-independent activation.³⁴⁶ There has also been a report of a double mutation, V804M and R844L, in a patient with FMTC.³⁴⁷

It appears that the pattern of expression of the MEN2 and related syndromes may vary, and may be more or less restrictive, in different parts of the world. For example, studies of patients in two Asian countries found that almost all patients with MEN2A have *RET* 634 codon mutations, whereas patients with MEN2B have *RET* 918 codon mutations.^{348,349}

Genetic Testing for Hereditary Medullary Thyroid Carcinoma. The role of direct DNA analysis in the detection of family members who have inherited a mutated *RET* allele cannot be overemphasized. According to the Gene Tests Laboratory Directory, 38 laboratories currently perform DNA analyses for *RET* in MEN2A, MEN2B, FMTC, and sporadic MTC. Information can be found at the National Center for Biotechnology Information (<http://www.genetests.org>). All listed laboratories use direct sequence analysis to identify *RET* mutations. Almost all of the laboratories evaluate mutations in exons 10, 11, 13, 14, 15, and 16, and some laboratories include exon 8. If no mutations are found in these exons, the entire coding region of *RET* can be sequenced. *RET* mutations in exons 10 or 11 are identified in more than 95% of families demonstrating a germline transmission of MEN2A or FMTC.³⁵⁰

Genetic Counseling. Genetic counselors have a significant role in the management of patients with hereditary cancer syndromes and their families. Whereas formerly the physician alone gave advice and recommended treatment decisions based on available data, contemporary programs involving predictive genetic testing require a broader explanatory interface between medical personnel and the patient. Genetic counselors provide information to patients regarding the genetic aspects of their disease, the methods of genetic testing, and the interpretation of genetic test results. They are helpful in meeting with family members to discuss the patterns of inheritance and their potential risks of developing the disease.

It is important to explain the implications of a given genetic test to the patient and to tell the patient that family members may be at risk for developing the disease. In most cases, the patient will inform family members of their risk, but there are situations in which they might not, and this presents a problem for the doctor and the "duty to warn" those who are at risk of foreseeable harm. This issue is complex and has been debated in the courts, which emphasizes the importance of providing genetic information to patients in the setting of genetic counseling. If there is uncertainty about the correct course of action, physicians should seek advice from their institution's ethics committee or from legal counsel. The issues related to informed consent in the new age of personalized genetic medicine have been addressed by Rosenthal and Pierce.³⁵¹

Relationship between *RET* Genotype and Phenotype in MEN2A, MEN2B, and FMTC

The various *RET* mutations characteristic of MEN2A, MEN2B, and FMTC relate not only to the clinical expression of the disease phenotypes but also to the clinical aggressiveness of the MTC. In MEN2A, specific genotypes are associated with the expression of pheochromocytoma or HPT, whereas in patients with MEN2B, the expression of pheochromocytoma is not associated with a specific genotype, except for the 918 codon mutation.

Medullary Thyroid Carcinoma

Shortly after discovery of the genetic basis of MEN2A, MEN2B, and FMTC clinicians realized that the clinical aggressiveness of the MTC (age at onset, tumor size, timing and frequency of local and distant metastases) in these syndromes was highly variable. For example, the MTC associated with MEN2B is much more aggressive than the MTC occurring in MEN2A or FMTC. The primary basis for the difference appears to be that certain *RET* mutations are more highly activating than others. *RET* mutations associated with MEN2A have greater activating and transforming abilities than *RET* mutations associated with FMTC.³⁴³ Also, MEN2B mutations are associated with greater basal kinase activity, compared to mutations occurring with MEN2A or FMTC.³²⁵ These observations were subsequently confirmed and extended.³⁵² The molecular data are useful for predicting the clinical course of the MTC in a given setting and especially for determining the timing of prophylactic thyroidectomy in members of kindreds with these syndromes who are shown by genetic testing to have inherited a mutated *RET* allele.

Pheochromocytomas

Pheochromocytomas are most common in patients with *RET* mutations in exon 11 (particularly codon 634) and are less common, or occur infrequently, in patients with mutations in exon 8 (codon 533), exon 10 (codons 609, 611, 618, and 620), exon 13 (codons 768, 790, 791, and 804), and exon 15 (codon 891). A study of 477 MEN2A families conducted by the International RET Consortium found that 169 (91%) of 186 families with MEN2A and pheochromocytoma had a mutation in the *RET* 634 codon.³³⁹

Hyperparathyroidism

In MEN2A families, there is a strong association between the presence of HPT and codon 634 mutations. Of 104 patients with MTC and HPT, 93 (89%) had a mutation in *RET* 634 and in 57 patients (62%) the mutation was a C634R *RET*.³³⁹

Similar findings correlating *RET* codon mutations with the presence of pheochromocytoma or HPT have been reported by other investigators.³⁵³⁻³⁵⁵ The recognition that a certain *RET* mutation signals that a patient is at increased risk for developing pheochromocytoma or HPT is useful in patient management.

Cutaneous Lichen Amyloidosis

Cutaneous lichen amyloidosis associated with MEN2A occurs in the intrascapular region of the back corresponding to dermatomes T2-T6.^{356,357} Pruritus, the dominant symptom, leads to repetitive scratching and secondary skin changes characterized by deposition of amyloid. The initiating lesion is thought to be notalgia paraesthetica, a sensory neuropathy involving the dorsal spinal nerves.³⁵⁸ Although it was once thought rare, the abnormality was found in 9 (36%) of 25 patients in 10 families with

MEN2A.³⁵⁸ The lesion may be evident in infancy, thus serving as a precursor marker of MEN2A.

Cutaneous lichen amyloidosis is associated with a *RET* 634 codon mutation; the sole exception has been an apparent case in a patient with FMTC and an associated *RET* 804 codon mutation.^{358,359} The entity may also occur as an isolated sporadic or familial entity in which the skin lesions are generalized rather than intrascapular and patients have no *RET* mutations nor MTC.³⁶⁰

Hirschsprung's Disease

Hirschsprung's disease, manifested by the absence of intrinsic ganglion cells in the distal gastrointestinal tract, is a common cause of intestinal obstruction in the neonate. To date, more than 100 *RET* mutations have been identified in patients with Hirschsprung's disease, occurring in 50% of familial cases and 35% of sporadic cases.³⁶¹⁻³⁶³ The mutations are inactivating and occur throughout the proto-oncogene. Most are point mutations, but there are also nonsense mutations, frameshift mutations, microdeletions, insertions, and splicing mutations. In rare cases, large deletions encompass the entire proto-oncogene.³⁶⁴

Hirschsprung's disease has been reported in at least 30 families with MEN2A or FMTC, and the disease has been associated with mutations in exon 10 of *RET* involving codons 609 (15%), 611 (4%), 618 (30% to 35%), and 620 (50%).³⁶⁵⁻³⁶⁸ In functional studies, the cell surface expression of *RET* of mutations in these codons is lower than that found with the *RET* 634 codon mutations.³⁶⁹ These data provide a molecular basis for the range of phenotypes engendered by alterations of *RET* cysteines and suggest a novel mechanism whereby these *RET* codon mutations have a dual effect, on the one hand causing transformation of C cells leading to MTC while on the other hand interfering with transportation of the protein to the plasma membrane, resulting in absence of ganglion cells and the development of Hirschsprung's disease.^{343,352}

Sporadic Medullary Thyroid Carcinoma and *RET* Mutations

Approximately 75% of MTCs are sporadic, and the incidence peaks during the fifth decade of life. Patients present with a palpable solitary thyroid nodule, and cervical lymph node metastases are present in most patients. Approximately 50% of patients with sporadic MTC have somatic M918T *RET* mutations; however, point mutations and in-frame deletions in exons 10, 11, 13, and 14 have been reported also.^{338,370,371} In one study of 51 sporadic MTCs confirmed by family history and direct DNA analysis, somatic *RET* mutations were identified in 33 (64.7%) of the tumors, with exon 16 being affected most frequently (60.6%, compared with exon 10 (9.1%), exon 11 (21.2%), and exon 15 (9.1%).³⁷²

It was initially reported that the presence of a somatic *RET* mutation in sporadic MTC, compared with its absence, was associated with a less favorable clinical outcome.³⁷³ This issue has been controversial, however. Some investigators have confirmed the original observation, whereas others have reported no relationship between clinical prognosis and the presence or absence of somatic *RET* mutations.^{371,374-379}

Relationship of *RET*/PTC Translocations to Papillary Thyroid Carcinoma

The clinical relevance of *RET* was first shown in 1987 when Fusco and associates transfected NIH 3T3 cells with DNA

obtained from a series of individual papillary thyroid carcinomas (PTCs) and found a new oncogene resulting from the relocation of an unknown N-terminal sequence to the tyrosine kinase domain of the *RET* proto-oncogene.³⁷⁷ The gene was subsequently cloned and sequenced. This genetic rearrangement was found in all transfectants and in the original PTC DNAs but not in autologous DNA from normal cells.³⁷⁸

These hybrid oncogenes in PTC, the paradigm for chimeric oncoproteins in solid tumors, occur with wide variations in clinical frequency, ranging from 5% to 70%, partly depending on the geographic region.^{379,380} *RET* is not mutated; rather, the chromosomal rearrangements activate the transforming potential of *RET* by replacing its transcriptional promoter with those of the fusion partners, thereby allowing its expression in the follicular cells, where it is usually transcriptionally silent.³²² The incidence of *RET*/PTC translocations is significantly higher in patients exposed to radiation, such as the children who developed PTC after the Chernobyl nuclear accident and patients subjected to therapeutic x-ray treatment for benign or malignant conditions.³⁸¹⁻³⁸⁴ Virtually all of the breakpoints in *RET* occur at sites throughout intron 11, resulting in proteins with no transmembrane domain. At least 12 different fusion partner genes have been reported, the most common being *RET*/PTC1 (60% to 70%) and *RET*/PTC3 (20% to 30%)³⁸⁵ (Fig. 41-12).

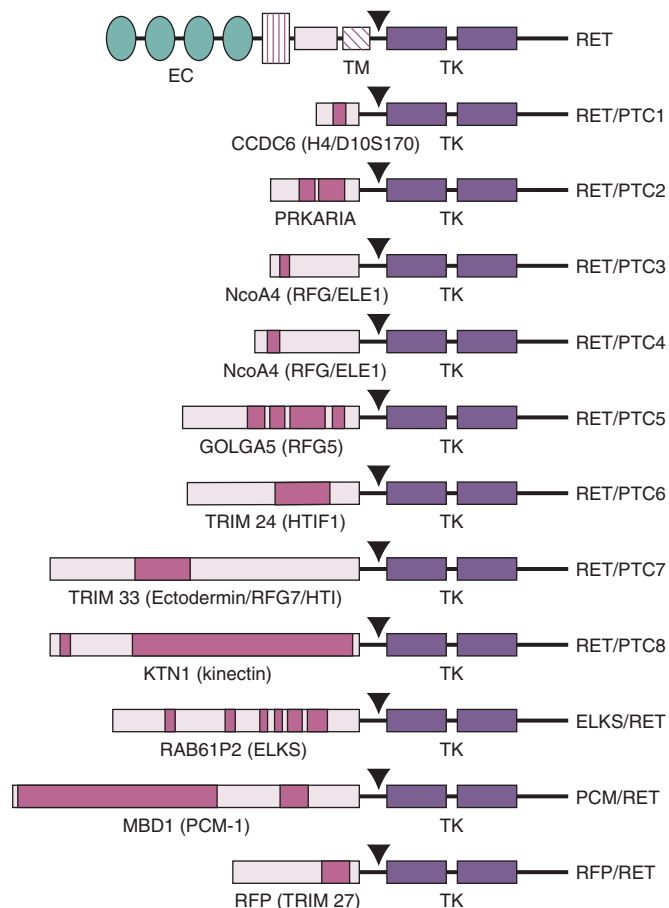

Figure 41-12 *RET*/PTC translocations associated with papillary thyroid carcinoma. EC, extracellular; TK, tyrosine kinase domain; TM, transmembrane. (Reprinted with permission from Santoro M, Melillo RM, Fusco A. *RET*/PTC activation in papillary thyroid carcinoma: European Journal of Endocrinology Prize Lecture Eur J Endocrinol. 2006;155:645-653.)

There is an association between the *RET/PTC* genotype and the pathology and clinical behavior of the associated PTCs. *RET/PTC3* is associated with the solid-follicular variant, and almost all of the tall-cell variant PTCs have the *RET/PTC3* isoform. Also, *RET/PTC1* tumors seem to be associated with a more indolent behavior, compared with the more aggressive *RET/PTC3* tumors.^{386,387}

It has also been shown that most Hürthle cell adenomas as well as Hürthle cell carcinomas have *RET/PTC1* translocations, raising the question of whether all Hürthle cell tumors should be considered malignant, regardless of their histologic appearance.^{388,389}

The receptor tyrosine kinase NTRK1 is also activated in PTCs but with a much lower frequency compared to *RET*.³⁹⁰ The activation of NTRK results from rearrangements with three different genes forming four chimeric variants: TRK, TRK-T1, TRK-T2, and TRK-T3. All except TRK-T1 have a transmembrane domain.

The most common genetic abnormality in PTC is not a *RET/PTC* translocation but a V600E mutation in *BRAF*. Compared to tumors with *RET/PTC* translocations, PTCs with this *BRAF* mutation have a more aggressive clinical course characterized by larger tumors, a higher incidence of extrathyroidal invasion, metastases to regional lymph nodes and distant sites, and poorer survival.³⁹¹

Diagnosis and Management of Tumors Associated with MEN2 and Related Syndromes

Medullary Thyroid Carcinoma

Expression and Diagnosis of C-Cell Disorders. MTC is actually not a thyroid tumor in that the MTC cells arise from the parafollicular C cells and not the follicular cells from which all other histologic types of thyroid cancers originate. Very early in embryologic life, the C cells stream from the neural crest to populate the adrenal medulla, the sympathetic and parasympathetic ganglia, and the superior aspects of the thyroid lobes. In birds and fishes, the C cells are located in the ultimobranchial body.^{392,393}

In patients with MEN2A, MEN2B, or FMTC, the first evident histologic abnormality in the thyroid gland is C-cell hyperplasia, a premalignant entity that is also found in the thyroid tissue surrounding macroscopic tumor foci in hereditary MTC but not in sporadic MTC. C-cell hyperplasia appears to represent carcinoma in situ, which is rarely if ever seen in other endocrine tissues and is the first step in a progression to early microinvasive carcinoma and, finally, invasive macroscopic carcinoma (Fig. 41-13).³⁹⁴ Many thyroid glands removed prophylactically from young children with hereditary MTC appear normal to the naked eye; however, on microscopic examination, C-cell hyperplasia is often the only evident abnormality.

The histologic diagnosis of C-cell hyperplasia has much more validity in members of families with MEN2A, MEN2B, or FMTC, because the lesion can occur in the thyroid glands of patients with other disease states, such as HPT, hypergastrinemia, and chronic lymphocytic thyroiditis. This so-called secondary C-cell hyperplasia is not a premalignant condition.³⁹⁵ Up to 50 C cells per low-power field can be seen in the thyroid glands of normal adults.³⁹⁶ Using this criterion, in a study of 47 normal human subjects, 33% (15% women and 41% men) met the criteria for C-cell hyperplasia.³⁹⁷ This is of interest not only because of the surprisingly high frequency of this histologic condition in normal subjects but because of the known higher normal range of serum calcitonin for men compared to women.^{398,399}

In hereditary MTC, the tumor is bilateral and multicentric, although there may be discordance in the size of tumor foci in one thyroid lobe compared with the other (see Fig. 41-13). The MTC is primarily located in the superior-medial aspect of each thyroid lobe. Histologically, the tumor cells are spindle shaped and on immunohistochemical staining are positive for calcitonin and carcinoembryonic antigen (CEA). When the cells are stained with Congo Red and viewed under polarized light, a substance with staining properties of amyloid is evident; however, the substance represents full-length calcitonin fibrils (see Fig. 41-13).⁴⁰⁰ As the MTC ages, certain portions become fibrotic and calcific, which is often evident on radiologic imaging of the neck and metastatic sites.^{401,402} MTC first spreads to the regional lymph nodes in the neck and mediastinum and subsequently to the liver, lungs, bone, brain, and, rarely, skin.

Patients with sporadic MTC present with a thyroid mass and palpable cervical lymph nodes. Patients with hereditary MTC not detected by genetic or biochemical screening also present with a thyroid mass and are indistinguishable from patients with sporadic MTC, with the exception of those with MEN2B, who should be recognizable because of their characteristic physical appearance.

Tumor Markers and Medullary Thyroid Carcinoma. MTC cells have great biosynthetic activity and secrete calcitonin, CEA, chromogranin-A, dopa-carboxylase, histaminase, somatostatin, gastrin-releasing peptide, thyrotropin-releasing hormone, and ACTH.⁴⁰³⁻⁴⁰⁸ Of these markers, calcitonin and CEA are the most useful clinically.

Tashjian and associates demonstrated that the thyroid C cells secrete the hormone, calcitonin, and that the intravenous infusion of calcium gluconate stimulates calcitonin secretion.⁴⁰⁹ The polypeptide, pentagastrin, is also a calcitonin secretagogue, and the combined infusion of calcium and pentagastrin is a more potent secretagogue than either agent administered alone.⁴¹⁰ Initially, the infusion of these provocative agents, either alone or in combination, was the standard method of establishing the diagnosis of MTC in family members at direct risk for MEN2A, MEN2B, or FMTC. An abnormally elevated calcitonin level indicated the presence of MTC even if it was not evident clinically, and this screening methodology set the stage for early thyroidectomy in kindred members at risk for hereditary MTC, the goal being to remove the thyroid gland before MTC develops or while it is still confined to the thyroid gland.

Although CEA is also elevated in patients with MTC, it is a less sensitive biomarker than calcitonin; furthermore, serum levels of CEA do not increase after the administration of intravenous calcium or pentagastrin.

Clinical and Biochemical Diagnosis of Familial Medullary Thyroid Carcinoma. Once it was discovered that mutations in the *RET* proto-oncogene caused MEN2A, MEN2B, and FMTC, direct DNA analysis for *RET* mutations became the method of choice for screening of family members at risk for these diseases. The test could be performed at any age, and the designation of a positive or negative test was definitive. Nowadays, measurement of serum calcitonin and CEA are seldom used to establish the early diagnosis of hereditary MTC in a family member. However, these markers are extremely useful for detection of persistent or recurrent MTC after thyroidectomy and for measuring the response to various therapies in patients with advanced disease.

With the advent of biochemical testing and the subsequent development of direct DNA analysis, there

has been improvement in the early diagnosis and treatment of hereditary MTC. With time, this is highly likely to result in improved survival. Over the last 30 years, however, there has been no change in stage at diagnosis, and survival has not improved, in patients with sporadic MTC and in patients with unsuspected hereditary MTC. For that reason, early detection and treatment are of great importance.⁴¹¹ Thus, the clinicians have concentrated on fine-needle aspiration cytology and determination of serum calcitonin to diagnose MTC in patients with nodular thyroid disease.

Fine-needle aspiration cytology is widely employed as a diagnostic tool in patients with nodular thyroid disease. In a review of 91 patients with a histologic diagnosis of MTC, fine-needle aspiration cytology had a sensitivity of 89%, a false-negative rate of 11%, and a positive predictive value of 85.3%.⁴¹² Other investigators found that fine-needle aspiration cytology is less sensitive than measurement of basal calcitonin levels in screening for MTC. However, the addition of immunocytochemistry of the aspirated cells for calcitonin and the measurement of calcitonin levels in aspirate fluid may increase the sensitivity of the technique.⁴¹³⁻⁴¹⁵

In the United States, the place of serum calcitonin measurements in screening for MTC is controversial. The American Thyroid Association guidelines do not recommend for or against calcitonin screening in patients with thyroid nodules, citing concerns of sensitivity, specificity, assay methodology, and cost-effectiveness.⁴¹⁶ The view is somewhat different in Europe, where results of several clinical studies have led to the routine practice of measuring serum calcitonin in patients with nodular thyroid disease. MTC was detected in 0.4% to 0.6% of more than 12,000 patients in two Italian studies of calcitonin screening for nodular thyroid disease.^{417,418} Calcitonin screening was superior to fine-needle aspiration cytology. Furthermore, compared with patients diagnosed by physical examination only, patients detected by calcitonin screening had an earlier stage of disease and a better prognosis. The French Medullary Study Group detected MTC in 1.2% of 1167 patients evaluated by calcitonin screening for nodular thyroid disease.⁴¹⁹ They also found calcitonin screening to be superior to fine-needle aspiration cytology. A German evidence-based consensus recommended basal serum calcitonin screening for patients with nodular thyroid disease.⁴²⁰ They recommended a pentagastrin stimulation test if basal

calcitonin values exceed 10 pg/mL. They also recommended thyroidectomy if stimulated calcitonin values exceed 100 pg/mL, and lymphadenectomy if stimulated values exceed 200 pg/mL.

In a genetic screening series of 481 patients with presumed sporadic MTC, *RET* mutations were detected in 35 patients (7.5%), all of whom had a negative family history. Of the 35 newly diagnosed cases of hereditary MTC, 18 were the index case of families in which several presumably normal family members had MTC.⁴²¹ This is an important matter, because such screening provides the opportunity for diagnosis and treatment of patients at an early disease stage.

Management of Medullary Thyroid Carcinoma

The Primary Operation. The management of patients with newly diagnosed MTC involves two different strategies, depending on the clinical setting at diagnosis. Virtually all patients with sporadic MTC and the majority with hereditary MTC present with a palpable thyroid nodule and lymph nodes metastases. A minority of patients are members of kindreds with hereditary MTC who on genetic screening are found to have inherited a mutated *RET* allele.^{335,336} Regardless of the method of diagnosis, thyroidectomy is the treatment for all patients, although for those diagnosed through genetic screening, the timing of the procedure depends on the patient's age and the specific *RET* mutation.

The first step is an ultrasound examination of the thyroid gland, the central and lateral lymph node compartments, and the superior mediastinum. Computed tomographic imaging of the chest and abdomen and bone scintigraphy are indicated only for patients with evidence of palpable cervical lymph nodes or a serum calcitonin level greater than 150 pg/mL.

The operation of choice in patients with primary MTC and no evidence of distant metastases is total thyroidectomy and resection of lymph nodes in the central compartment of the neck, an area bounded by the hyoid bone superiorly, the thoracic inlet inferiorly, and laterally to the carotid sheaths (levels I through VI). Total thyroidectomy is indicated because the incidence of intrathyroidal lymphatic spread is 10% to 20%, and even if the disease appears to be sporadic, the hereditary status of the patient is usually unknown at the time of thyroidectomy. If lymph nodes are palpable in the ipsilateral or contralateral neck or are evident on ultrasound examination preoperatively, the respective lymph node compartments (II through V) are cleared. During the procedure, great care must be taken to preserve the parathyroid glands, the recurrent laryngeal nerve, and the external branch of the superior laryngeal nerve.

The prognosis is excellent in patients who have a tumor smaller than 1 cm in diameter that is confined to the thyroid gland, a preoperative basal serum calcitonin level lower than 150 pg/mL, and no lymph node metastases. Rarely, lymph node metastases and distant metastases occur with primary tumors smaller than 1 cm in diameter.⁴²²

Several studies have demonstrated a correlation between preoperative, intraoperative, and postoperative findings and surgical outcome. In a study of 224 consecutive patients with MTC treated surgically over a 10-year period, the serum calcitonin normalized in 62% of 45 patients with node-negative disease and in 10% of patients with node positive disease. Nodal metastases increased in proportion to the preoperative serum calcitonin level ranging from an incidence of 50% of patients with calcitonin levels

of 3000 pg/mL and tumors larger than 20 mm in diameter to 100% of patients with levels of 100,000 pg/mL or tumors larger than 60 mm.⁴²²

There is a correlation between preoperative serum CEA levels and lymph node and distant metastases. In a study of 150 patients, an increase in preoperative serum CEA (from a level of 4.7 to 10 ng/mL to >100 ng/mL) was associated with an increased incidence of metastases in the central lymph node compartment (from 33% to 93%), in the ipsilateral compartment (from 20% to 88%), in the contralateral compartment (from 22% to 73%), and at distant sites (from 0% to 75%). Therefore, an elevated preoperative serum CEA heralds advanced disease, and surgical cure is exceptional when the CEA level exceeds 30 ng/mL.⁴²³

Several authors have correlated patient outcome with findings at thyroidectomy, the most important factors being multifocality of the MTC within the thyroid gland and the presence of metastases to lymph nodes in the central compartment.⁴²⁴⁻⁴²⁷ In a study of 232 consecutive patients undergoing thyroidectomy for MTC, the incidence of lymph node metastases in patients with sporadic MTC increased from 41% with unifocal tumors to 90% with multifocal tumors. In patients with hereditary MTC, the comparable numbers were 14% and 48%.⁴²⁴ Another study evaluated patterns of lymph node metastases. In 195 patients, the incidence of ipsilateral lymph node metastases increased from 10% when no central compartment nodes were involved, to 77% with one to three lymph nodes involved, and to 98% with four or more lymph nodes involved. Regarding the contralateral neck, lymph node involvement was less frequent, occurring in 5% of patients with a single central compartment nodal metastasis and increasing to 38% when 9 central nodes were involved and to 77% when more than 10 central compartment nodes were involved. In almost all cases, metastases to the contralateral lymph node compartment occurred only when the central and ipsilateral compartments were involved.⁴²⁵

The prognosis of patients who have undetectable basal calcitonin levels after initial thyroidectomy is excellent. In a study of 863 patients 371 (43%) had serum calcitonin levels that were either normal or failed to respond to pentagastrin stimulation after total thyroidectomy. They were considered cured because their 5- and 10-year survival rates exceeded 98%.⁴²⁸ In a study of 1430 patients, the French Calcitonin Tumour Study Group identified 453 patients who were considered "not cured" at their last follow-up visit. Only 15 (3.3%) of these patients had been considered cured 6 months after thyroidectomy (basal and pentagastrin-stimulated serum calcitonin <10 ng/L).⁴²⁹

One must be careful in equating normalization of postoperative basal serum calcitonin levels with cure of MTC. If the basal serum calcitonin is undetectable but increases after pentagastrin or calcium provocation, C cells are present (which they should not be if all were removed at thyroidectomy). Often, the basal or stimulated calcitonin concentration becomes elevated at some time after thyroidectomy but the values are within the normal range. Almost certainly, these patients have persistent or recurrent MTC, whether or not it is evident clinically. This poses a dilemma unique to many endocrine tumors in which the increased level of a hormone marker is a more sensitive indicator of persistent or recurrent disease than the results of physical examination or radiographic imaging studies. A progressively increasing serum calcitonin level after thyroidectomy is troubling, both for the patient and the physician because, although this indicates an increasing

tumor burden, there is currently no effective therapy for this disease state.

Even though surgical resection infrequently cures patients with regional lymph node metastases, many have a good prognosis, with 5- and 10- year survival rates of 80% and 70%, respectively. Although the outcome for most patients is favorable, there are significant differences in survival times between patients who achieve complete remission, patients with persistently elevated serum calcitonin levels, and patients with distant metastases.⁴³⁰

Sternotomy with mediastinal lymph node dissection is indicated only if there is radiologic evidence of progressively enlarging or symptomatic mediastinal lymph node metastases and in patients undergoing initial or repeat operation for node-positive, extrathyroidal MTC.⁴³¹ In patients with palpable thyroid tumors, total thyroidectomy and clearance of lymph node metastases in the neck by systemic compartment-oriented dissection may afford local control and prevent invasion of the trachea, esophagus, and mediastinum.

Prophylactic Thyroidectomy. There are several hereditary cancer syndromes, and in many of them removal of the organ at risk for malignancy is a preventative strategy. When considering such a procedure, certain criteria need to be met:

1. From the genetic standpoint, the cancer should be associated with near-complete penetrance.
2. There should be a reliable test to detect family members who will develop the malignancy.
3. The organ at risk should be easily removable with minimal morbidity and virtually no mortality.
4. There should be suitable replacement for the organ's function.
5. There should be a reliable serologic test to determine whether the patient is cured.

The hereditary cancer syndromes MEN2A, MEN2B, and FMTC fulfill each of these criteria.

Many young family members found to have a mutated *RET* allele on genetic screening have no evidence of thyroid disease, and such patients have the greatest likelihood of being cured by prophylactic thyroidectomy.^{432,433} Since the original reports of prophylactic thyroidectomy for MEN2A and FMTC in asymptomatic patients detected by genetic screening programs, investigators from several countries have reported successful results with this operative procedure.⁴³³⁻⁴⁶⁰ There is little doubt that prophylactic thyroidectomy is indicated for patients who are certain to develop MTC; however, the specific operative procedure and when it should be performed are somewhat controversial.

The Consensus Committee of the 7th International Workshop on MEN, the EUROMEN group, and an International Guideline Committee of the American Thyroid Association have proposed guidelines regarding the timing of prophylactic thyroidectomy in patients with MEN2A, MEN2B, or FMTC.^{186,461,462} The recommendations of these three groups are similar in that children with MEN2B (or with mutations in codons 918 or 883) should have thyroidectomy performed at the time of diagnosis, preferably during the first months of life. In children with mutations in codons 611, 618, 620, or 634, thyroidectomy should be performed at or before 5 years of age. In children with mutations in other *RET* codons, the recommended timing of thyroidectomy is less clear but usually between 5 and 10 years of age. Some clinicians use measurements of basal or stimulated calcitonin levels to determine the indication and timing of thyroidectomy in the latter group of patients, including patients with FMTC.⁴⁶³

Particularly instructive is the EUROMEN study of 145 families with 207 patients (≤ 20 years of age) who had a total thyroidectomy after confirmation of a germline *RET* mutation. Comparing patients with mutations in extracellular-domain codons (609, 611, 618, 620, 630, and 634) to those with mutations in intracellular-domain codons (768, 790, 791, 804, and 891), the mean age at diagnosis of C-cell hyperplasia was 8 versus 11 years, respectively; the mean age of patients with node-negative MTC was 10 versus 17 years, respectively, and the mean age of those with node-positive MTC was 17 versus more than 20 years. A 634 *RET* codon mutation was present in 63% of patients, and a further analysis of this group found that malignant transformation was present as early as 1 year of age but there was no spread to lymph nodes until 14 years of age. By 20 years of age 42% of patients had lymph node metastases. The average interval from tumor development to nodal metastases was 6.6 years.⁴⁶²

In a more recent study, 50 children with MEN2A (*RET* codon mutations, 609, 611, 618, 620, and 634) treated by prophylactic thyroidectomy, central zone lymph node resection, and parathyroid transplantation were evaluated 5 years postoperatively. The operation was curative in 44 patients (88%), meaning that serum calcitonin was undetectable both in the basal state and after stimulation with calcium and pentagastrin.⁴⁶⁴ All 22 children who were 7 years of age or younger at the time of operation were cured. Metastases to central zone lymph nodes were present in three patients (ages 10, 11, and 11 years), and 3 patients (ages 4, 4, and 6 years) developed permanent hypoparathyroidism. The incidence of permanent hypoparathyroidism in series from experienced surgeons has ranged from 5% to 29%, and this represents a significant problem requiring lifelong calcium and vitamin D replacement.^{445,451,455,459,460,464}

Patients with MEN2A rarely develop lymph node metastases before 10 years of age, and it is unusual for hypoparathyroidism to complicate total thyroidectomy in patients older than 5 years of age, although it is recognized that identification of parathyroid glands in children (compared with adults) is difficult.⁴⁶⁴ Removal of the thyroid gland at about 5 years of age seems reasonable in phenotypically normal children who are found to have a mutated *RET* allele by genetic screening. Also, considering that lymph node metastases are unlikely at this age, there seems to be little need for resection of the central compartment, which also decreases the risk of hypoparathyroidism.

Monitoring for Persistent or Recurrent Medullary Thyroid Carcinoma. Patients should have a physical examination and measurement of serum levels of calcitonin and CEA within 6 months after thyroidectomy. If the tumor is small and confined to the thyroid gland and on pathologic examination there is no extraglandular extension or lymph node metastases, the patient can be monitored at 6-month intervals with measurements of serum calcitonin and CEA. The serum calcitonin level usually drops precipitously after thyroidectomy, although the time to nadir may be several weeks.⁴⁶⁵ In patients who have lymph node metastases, extrathyroidal extension of the MTC, or postoperative serum calcitonin levels greater than 150 pg/mL, radiographic imaging studies should be done to determine whether there are metastases to regional lymph nodes, liver, lung, or bone. If these studies are normal, they need not be repeated until the serum calcitonin concentration increases to more than 150 pg/mL.

Miyauchi and associates first demonstrated a strong relationship between the doubling time of serum calcitonin and MTC recurrence and survival.⁴⁶⁶ It was subsequently

shown in patients with MTC that serum levels of calcitonin and CEA are strongly correlated. The median doubling time of each marker was 12 months or less in patients with progressive disease and 48 months or longer in patients with stable disease.⁴⁶⁷ In a study of 65 patients with elevated serum calcitonin levels after total thyroidectomy, calcitonin doubling times between 6 months and 2 years were associated with 5- and 10-year survival rates of 92% and 37%, respectively. With doubling times of less than 6 months the 5- and 10-year survival rates decreased to 25% and 8%, respectively. Also, tumor-node-metastasis (TNM) stage, European Organization for Research and Treatment of Cancer (EORTC) score, and serum calcitonin doubling time were significant predictors of survival by univariate analysis, but only calcitonin doubling time remained an independent predictor of survival by multivariate analysis. Calcitonin doubling time is superior to CEA doubling time as a predictor of survival.⁴⁶⁸

On the other hand, serum CEA levels are an excellent tumor marker and usually increase in parallel with serum calcitonin levels as an index of tumor progression. In some patients, the serum CEA increases progressively but the serum calcitonin does not; this is thought to be a sign of tumor dedifferentiation.⁴⁶⁹ This hypothesis was supported by immunohistochemistry studies of MTC specimens from patients with various stages of disease. It was found that the concentrations of CEA and calcitonin are expressed to a similar degree in patients with C-cell hyperplasia or with MTC confined to the thyroid gland; however, compared with calcitonin, there was more intense staining of CEA in the MTC cells of patients with metastatic disease.⁴⁷⁰

Operations for Persistent or Recurrent Medullary Thyroid Carcinoma after the Primary Operation. There are indications for repeat operation after the initial thyroidectomy if patients develop serious complications from recurrent tumor compressing or invading vital structures such as the spinal cord, airway, or esophagus. Often, relief follows tumor excision or debulking.⁴⁷¹ Also, patients who have intractable diarrhea due to markedly elevated tumor hormone secretions, presumably calcitonin, may have symptomatic relief from tumor ablation.⁴³⁰

Rarely, patients with MTC develop Cushing's syndrome due to the inappropriate secretion of ACTH or CRH.^{472,473} Complete surgical resection of the MTC is the preferred treatment, but this is difficult to accomplish because patients usually have advanced disease. Bilateral adrenalectomy may be required if steroidogenesis inhibitors are ineffective. This poor prognostic sign is associated with an average survival time of 2 years.⁴⁷³

The less clear indication for repeat operation for persistent or recurrent MTC concerns patients who only have elevated serum calcitonin levels after primary thyroidectomy. The strategy of re-exploration of the neck in patients with elevated serum calcitonin levels after initial total thyroidectomy is understandable if one considers that lymph node metastases are the first step in spread of the primary tumor and the first manifestation of metastatic disease. However, some have argued that in most cases MTC is relatively indolent, and patients should be managed by watchful waiting.⁴⁷⁴⁻⁴⁷⁶

Initially, repeat neck surgery with lymphadenectomy was performed with the hopes of cure; however, few, if any, patients were rendered disease free, as indicated by normalization of serum calcitonin levels.^{477,478} Early reports of repeat operation were discouraging until Tisell and associates reported that a significant proportion of patients could be cured by repeat neck operations and extensive lymph node resection.⁴⁷⁷⁻⁴⁸⁰ Based on these encouraging results,

stricter criteria for patient selection, and the refinement of operative techniques (e.g., introduction of compartmentalized lymphadenectomy), surgical results improved.^{471,481-484}

The optimal management of patients with persistent or recurrent MTC after primary surgery remains controversial, primarily for three reasons.⁴⁸⁴ The operation is difficult and is associated with higher complication rates than with first surgeries for MTC. The extent of lymph node dissection required for biochemical cure, as defined by normalization of postoperative serum calcitonin levels, remains to be determined. Finally, it is unknown whether "biochemical cure" after reoperation is long lasting and adds years of quality to a patient's life. In one study of 56 patients evaluated 8 years after repeat operation for persistent or recurrent MTC, basal calcitonin levels were lower than 10 pm/mL in 14 patients (26%), and 11 additional patients (20%) had basal serum calcitonin levels lower than 100 pg/mL. None of these 25 patients had radiologic evidence of metastatic MTC.⁴⁸⁴ Therefore, it appears that repeat operations have merit in selected patients with locally advanced or recurrent MTC; however, prolonged follow-up is needed.

Chemotherapy and Radiation Therapy for Metastatic Medullary Thyroid Carcinoma. For patients with locally advanced or metastatic MTC, single-agent or combined chemotherapeutic regimens have been of modest effectiveness, and currently chemotherapy does not play a major role in patients with advanced disease.⁴⁸⁵⁻⁴⁸⁹ The most effective agent has been doxorubicin, although in recent trials fewer than 20% of patients experienced partial remission as determined by RECIST (Response Evaluation Criteria in Solid Tumors).⁴⁹⁰

Similarly, external-beam radiotherapy has shown minimal effectiveness in patients with MTC. Most of the studies have been retrospective and have reported improved local control of disease.^{491,492} There have been no randomized, controlled trials comparing radiation therapy to watchful waiting in patients at high risk for local tumor recurrence after initial thyroidectomy. Currently, external-beam radiotherapy is indicated for patients with metastases to the central nervous system. Percutaneous image-guided radiofrequency ablation has been effective in the treatment of bone metastases.^{493,494}

Pheochromocytoma

Expression and Diagnosis of Pheochromocytoma. Approximately 50% of patients with MEN2A or MEN2B develop pheochromocytomas. These tumors occur between 30 and 40 years of age, compared with a mean age of 47 years in patients with sporadic pheochromocytomas.⁴⁹⁵ In genetic screening programs in which MTC is diagnosed at a young age, pheochromocytomas are also diagnosed earlier compared to patients with sporadic pheochromocytomas, at ages as young as 23 years in one series of 87 patients.⁴⁹⁶ The diagnosis is made concurrently with MTC in 35% to 73% of cases of MEN2A, and it may be the first manifestation of this syndrome in 9% to 27% of cases.⁴⁹⁵ Many patients have no signs or symptoms of a pheochromocytoma at the time MTC is diagnosed, although on careful questioning they may report episodes of headache, sweating, or rapid heartbeat.

Pheochromocytomas in MEN2A and MEN2B are almost always confined to the adrenal gland and are rarely malignant. The pheochromocytomas tend to be multiple and bilateral, although only a single adrenal gland may be involved when the diagnosis is first made. On examining the adrenal glands from patients with MEN2A or MEN2B, one finds adrenal medullary hyperplasia, either alone or adjacent to frank pheochromocytomas (Fig. 41-14). The

Figure 41-14 Pheochromocytomas. **A**, Bilateral and multiple pheochromocytomas in the left adrenal gland (top) and the right adrenal gland (bottom). **B**, Foci of adrenal medullary hyperplasia in adrenal glands (arrow) and pheochromocytoma (arrow).

hyperplasia is often manifested by a thickening of the adrenal glands on radiographic imaging studies. Adrenal medullary hyperplasia is the counterpart of C-cell hyperplasia in the thyroid gland and is not associated with hypertension or increased excretion rates of catecholamines or metabolites.

An undiagnosed pheochromocytoma that makes itself known during induction of anesthesia for thyroidectomy or during childbirth can be catastrophic and often lethal. Therefore, all patients with a confirmed or presumptive diagnosis of hereditary MTC should have biochemical and radiographic studies to exclude the presence of a pheochromocytoma. Pheochromocytomas in patients with MEN2A and MEN2B secrete epinephrine and, usually, norepinephrine. Palpitations, anxiety, tremor, dyspnea, hyperglycemia, and paroxysmal hypertension are more commonly associated with tumors that secrete epinephrine. Even though pheochromocytomas secrete catecholamines in an intermittent fashion, they metabolize catecholamines to metanephrines continuously. Concentrations of plasma free metanephrines and 24-hour urinary free metanephrines have sensitivities ranging from 90% to 100%, although the specificities are appreciably less.⁴⁹⁷

Computed tomography and magnetic resonance imaging are highly accurate in localizing intra-abdominal pheochromocytomas, with 95% to 100% sensitivity for intra-adrenal tumors larger than 0.5 cm. Also, T2-weighted magnetic resonance images of pheochromocytomas may show characteristic high-intensity signals.⁴⁹⁸ Although there have been relatively few clinical studies using PET to localize pheochromocytomas, [¹⁸F]-fluorodopamine ([¹⁸F] DA) PET is thought to be the best overall imaging modality in the localization of pheochromocytomas.⁴⁹⁹

Management of Pheochromocytoma

Preoperative Preparation. Before resection of a pheochromocytoma, it is critical that patients be adequately prepared with the α -adrenergic blocker, phenoxybenzamine, which is usually given in a dose of 10 mg orally twice a day for 10 to 14 days preoperatively. Higher doses may be needed to ensure blood pressure control. Patients with pheochromocytomas are volume constricted and should be warned that they may develop postural hypotension during phenoxybenzamine treatment. Most patients can be prepared on an outpatient basis; however, if blood pressure proves to be labile, hospitalization may be required.

β -Adrenergic blockade is usually unnecessary unless there is difficulty controlling the hypertension or the patient develops a tachyarrhythmia. If β -blockade is administered, it should be undertaken only after α -blockade; otherwise, patients may develop severe hypertension due to unopposed vasoconstriction.

Before anesthetic induction, a radial artery catheter is placed and a urinary bladder catheter is inserted. A pulmonary artery catheter for central monitoring is usually unnecessary unless the patient has cardiac disease or another indication. During manipulation of the pheochromocytoma intraoperatively, there may be episodes of hypertension; these are best controlled with sodium nitroprusside or esmolol. The patient may experience hypotension after resection of the pheochromocytoma, but this is usually easily managed pharmacologically.

Operation for Pheochromocytoma. Whether to perform a unilateral or a bilateral adrenalectomy depends on the extent of disease at the time of diagnosis. Bilateral adrenalectomy is obviously indicated in patients with bilateral pheochromocytomas; however, there has been controversy regarding the management of patients with a single pheochromocytoma. Because there may be years between the development of a pheochromocytoma in one adrenal gland and a pheochromocytoma in the contralateral gland (and in some patients a second pheochromocytoma may never develop), most surgeons favor performing a unilateral adrenalectomy for solitary pheochromocytomas. Iatrogenic bilateral adrenocortical ablation has a high rate of morbidity, including death from the Addison state.⁵⁰⁰ The argument for bilateral adrenalectomy relates to the propensity for bilateral and multicentric development of pheochromocytoma, the decreased morbidity associated with a single operative procedure, and the reduced risk of hypertensive crisis developing in patients who are not compliant with continued evaluation after resection of the first pheochromocytoma. In a 2006 report of adrenal-sparing surgery (unilateral adrenalectomy and contralateral subtotal adrenalectomy) in 13 patients with MEN2A and pheochromocytoma, 12 of whom had unilateral disease, the mean risk of developing recurrent pheochromocytoma was 38% at both 5 and 10 years.⁵⁰¹ The long-term follow-up of patients treated with this procedure bears observation, because it may offer an alternative to total adrenalectomy. The operative approach of choice for resection of an intra-abdominal pheochromocytoma is laparoscopic adrenalectomy. The

Figure 41-15 Parathyroid glands: right upper (A), right lower (B), left upper (C), and left lower (D).

results are excellent, with minimal morbidity and virtually no mortality.^{502,503}

Parathyroid Tumors: Expression, Diagnosis, and Management

HPT occurs in approximately 30% of patients with MEN2A and is characterized by generalized parathyroid hypertrophy and a histologic picture of nodular hyperplasia (Fig. 41-15). Usually, the symptoms of HPT are milder in patients with MEN2A, compared to patients with MEN1. The diagnosis depends on the demonstration of elevated serum levels of calcium and PTH. In hypercalcemic patients with MEN2A, the surgeon will find one or more enlarged parathyroid glands at the time of thyroidectomy. Regardless of the number of enlarged glands, the patient should be treated either by resection of 3½ glands or by total parathyroidectomy and heterotopic autograft of a small portion of one gland.⁵⁰⁴ The preferred operative procedure depends on the experience, the expertise, and the preference of the operating surgeon.

There has been little clarity on how normal-appearing parathyroid glands should be managed at the time of thyroidectomy in patients with MEN2A who have an *RET* mutation associated with a high incidence of HPT. The more prudent course would be to treat the MTC without concern for future HPT, because only 25% of patients develop this disease. Some surgeons, however, consider it reasonable to treat the parathyroid glands as if there were generalized parathyroid enlargement, because repeat operations for persistent or recurrent HPT, should they occur, are much more difficult than the primary operation and are associated with a higher incidence of complications.

In patients who develop recurrent or persistent HPT after thyroidectomy for MTC, the initial step is a sestamibi scan and ultrasonography in an attempt to identify the hyperfunctioning parathyroid glands.

In a properly performed total thyroidectomy, it is difficult to preserve the normal parathyroid glands. If the vascular supply to the parathyroids cannot be preserved or

if there is a question of parathyroid gland viability, the gland or glands should be autografted to a muscle bed. In patients with sporadic MTC, MEN2B, or FMTC, where there is no risk of HPT, the removed parathyroid tissue can be sliced into small slivers and grafted into the sternocleidomastoid muscle. There is a very high success rate with this technique.⁵⁰⁵ In patients with MEN2A who are at high risk for developing HPT, the removed parathyroid tissue should be grafted to a heterotopic site such as the brachioradialis muscle of the forearm, so that a portion of the graft can be removed if the patient develops graft-dependent HPT.

Recent Advances in the Management of Patients with Locally Advanced or Metastatic Medullary Thyroid Carcinoma

There has been no effective treatment for locally advanced or metastatic MTC, and the management of patients with advanced disease has been very challenging. With the demonstration that the tyrosine kinase inhibitor, imatinib, induced remissions in patients with chronic myelogenous leukemias, there was hope that similar small-molecule therapeutics might be developed for patients with MTC and also for patients with the other histologic types of thyroid tumors.^{506,507} Subsequently, it was shown that the orally administered tyrosine kinase inhibitor, ZD6474, inhibits vascular endothelial growth factor signaling, angiogenesis, and KDR tyrosine kinase activity and blocks oncogenic RET kinases.^{508,509} In a phase 2 single-arm study of ZD6474 (vandetanib), 6 (20%) of 30 patients with locally advanced or metastatic MTC experienced a partial remission and another 60% experienced stable disease, for a disease control rate of 80% (Fig. 41-16).⁵¹⁰ Phase II clinical trials of other molecular targeted therapeutics in patients with advanced MTC have shown partial responses in the range of 15-25%.^{511a-511h} Also, a clinical study of vandetanib in children with MEN2B and advanced MTC showed a partial response rate of 67%.⁵¹¹ⁱ Recently, a phase III, double-blind,

Figure 41-16 Waterfall plot of patients with hereditary medullary thyroid carcinoma who were treated with the tyrosine kinase inhibitor, vandetanib, by RECIST (Response Evaluation Criteria in Solid Tumors). (Reprinted with permission from Wells SA, Gosnell JE, Gagel RF, et al. Vandetanib for the treatment of patients with locally advanced or metastatic hereditary medullary thyroid cancer. *J Clin Oncol.* 2010; 28:767-772.

randomized clinical trial comparing vandetanib to placebo in 331 patients with locally advanced, or metastatic MTC, showed that compared to placebo the progression free survival was greater in the vandetanib arm (hazard ratio 0.46; $p = 0.0001$).^{511j} Therefore, there is promise that there will be effective therapies for patients with advanced disease, and perhaps for patients with minimal disease that is evident after primary thyroidectomy for MTC.

MULTIPLE ENDOCRINE NEOPLASIA OF MIXED OR OTHER TYPE

Overlap and Nonendocrine Syndromes

Overlap syndromes reported in single patients include gastrinoma in a MEN2 patient,⁵¹² adenomatous polyposis coli with MEN1 or MEN2B,^{513,514} prolactinoma in a patient with MEN2A,⁵¹⁵ pheochromocytomas in MEN1 (see earlier discussion), and an ovarian stromal carcinoid tumor in a patient with MEN2A.⁵¹⁶

Most cases of overlap of MEN1 and MEN2 were published before the syndrome-causing genes were discovered. Currently and in retrospect, most can be understood as follows:

- Unusual expressions of a syndrome: VHL can cause pheochromocytoma and islet tumor (see later discussion), CNC can cause somatotropinoma and primary adrenal hypercortisolism (see Chapter 15), and MEN1 can cause its rare pheochromocytoma with any other feature of MEN1 (see earlier discussion).
- Coexistence of two rare disorders: Several families carry mutations for both MEN1 and MEN2.⁵¹⁷ Their expressions seem to be independent.
- Rare syndromes that have not yet been characterized sufficiently. The Carney triad comprises paragangliomas, gastrointestinal stromal tumors, and pulmonary chondromas with occasional adrenocortical tumors. No inherited cases have been identified.⁵¹⁸
- Cases of unexplained overlap: These are few.

MEN1 and MEN2 are the only multiple neoplasia syndromes in which the two most prominent features are hormone-secreting tumors. In other MEN syndromes, non-hormonal tumors are more urgent. For example, MAS (which is not hereditary) features fibrous dysplasia of bone and café-au-lait spots of skin (see Chapter 25), and VHL syndrome features papillary renal cancer and central nervous system hemangioblastomas. CNC is the main

cause of myxomas of the cardiac atria. Still, these are forms of MEN, and they sometimes manifest through their endocrinopathies.

Von Hippel-Lindau Disease

VHL is an autosomal dominant neoplastic syndrome characterized by hemangioblastomas of the central nervous system, retinal angiomas, renal cell carcinomas, visceral cysts, pheochromocytoma, and islet cell tumors.^{519,520} More than 90% of gene carriers express one or more of the manifestations of this disorder by the age of 60 years. More than 70% of gene carriers have one or more central nervous system tumors.⁵²¹ Of particular relevance to endocrinologists is the observation that 25% to 35% of these patients have unilateral or bilateral pheochromocytomas, and 15% to 20% have islet cell tumors.^{518,522} Although the islet cell tumors may immunostain weakly for insulin, they almost never hypersecrete it.

The *VHL* gene was mapped to chromosome 3p25.3⁵²³ and identified by positional cloning.⁵²⁴ This is a tumor suppressor gene, implying that loss of function or inactivating mutations of both alleles or copies of this gene are associated with tumor formation. The action of the VHL protein to facilitate the proteasome-mediated degradation of the hypoxia-inducible factor 1 (HIF-1) protein and other proteins can prove central to many manifestations of *VHL* gene alteration.⁵²⁵ Mutation of codon 238 was identified in more than 40% of VHL families with pheochromocytoma, suggesting that families with a mutation in this codon should be surveyed routinely for pheochromocytoma.⁵²⁶

Clinical management of VHL syndrome is often focused on the presence of renal or central nervous system tumors. Pheochromocytomas or islet cell tumors associated with hypertension, cardiac arrhythmias, hypoglycemia, watery diarrhea, carcinoid, or a glucagonoma-like picture should be surgically excised. Judgment is required in the management of other malignant features associated with VHL. For example, a less aggressive approach to the management of pheochromocytoma or islet cell tumor may be indicated in a patient who has VHL and a renal cell carcinoma with metastasis. An adrenal cortical-sparing operation may be appropriate for pheochromocytoma in such a patient.

The association of pheochromocytoma and islet cell tumors can occur in familial⁵²⁷⁻⁵²⁹ or nonfamilial⁵³⁰⁻⁵³² patterns. There is little information about the molecular genetics of these rare disorders, although it is possible that abnormalities of the *VHL* gene are involved.

Neurofibromatosis Type I

The main features of NF1 or von Recklinghausen's neurofibromatosis are neurofibromas and dermal café-au-lait spots. NF2 causes acoustic neuromas and arises from a different but related gene. NF1 has been associated with a variety of endocrine neoplasms, including pheochromocytoma,⁵³³ HPT,⁵³⁴ somatostatin-producing carcinoid tumors of the duodenal wall,^{535,536} MTC,⁵³⁷ and hypothalamic or optic nerve tumors that cause precocious puberty.⁵³⁸ The causative gene for NF1 encodes a Ras guanosine triphosphatase (GTPase)-activating protein (RasGAP) of 2818 amino acids, named *neurofibromin*, which accelerates GTP hydrolysis on p21 Ras. Loss of the GTPase-activating function of neurofibromin (through mutation or allelic loss) leads to p21 Ras activation.⁵³⁹ More specific evidence for a role of this protein in endocrine tumors is suggested by allelic loss of this gene in NF1-associated⁵⁴⁰ or sporadic⁵⁴¹ pheochromocytomas.

Carney Complex

CNC includes myxomas of the heart, skin, and breast; spotty skin pigmentation; testicular, adrenal cortical, and pituitary tumors; and peripheral nerve schwannomas.⁵⁴²⁻⁵⁴⁴ Linkage analysis has identified a locus at 2p in half of the families and another locus at 17q in most others.⁵⁴⁵ The gene at 17q encodes the regulatory subunit (type IA) of protein kinase A (*PRKA1A*), and it has tumor suppressor properties.⁵⁴⁶ Several small kindreds with only bilateral adrenal hyperplasia have mutation of a phosphodiesterase (PDE11A) at chromosome 2p.⁵⁴⁷ The activating *GNAS* mutations in MAS and the inactivating *PRKA1A* mutations in CNC cause tumors in selected tissues with a similar tissue spectrum, perhaps because either gene can raise cyclic adenosine monophosphate.

CHAPTER

42

The Immunoendocrinopathy Syndromes

JENNIFER M. BARKER • PETER A. GOTTLIEB • GEORGE S. EISENBARTH

Since Addison's initial description of primary adrenal insufficiency in which a patient with two autoimmune disorders (vitiligo and the hyperpigmentation of Addison's disease) was depicted, the immunoendocrinopathy syndromes have contributed to the understanding of both endocrinology and immunology (Fig. 42-1). Understanding of the pathogenesis of the polyendocrine syndromes continues to expand. In particular, shared genetic loci underlying disease susceptibility, potential environmental factors, and organ-specific autoantigens targeted by the immune system are being defined. Recent advances include the development of more reliable T-cell assays, further refinement in predictive models of disease, and continued unraveling of the genetic factors underlying disease susceptibility.

Most autoimmune endocrine disorders (e.g., type 1 diabetes, autoimmune thyroid disease) occur in isolation. Two distinct autoimmune polyendocrine syndromes with characteristic groupings of manifestations are readily recognized. *Autoimmune polyendocrine syndrome type I* (APS-I) is a rare disorder with autosomal recessive inheritance that is caused by defects in the autoimmune regulator gene. In contrast, *autoimmune polyendocrine syndrome type II* (APS-II)

is more common but less well defined and includes overlapping groups of disorders. A unifying characteristic within APS-II is the strong association with polymorphic genes of the human leukocyte antigen (HLA) region located on the short arm of chromosome 6 (band 6p21.3). In addition to HLA, many other genetic loci are likely to contribute to susceptibility to APS-II. For purposes of simplicity in this chapter, *APS-II* encompasses what some clinicians divide into APS-II (Addison's disease plus type 1 diabetes or thyroid autoimmunity), APS-III (thyroid autoimmunity plus other autoimmune diseases, not Addison's or type 1 diabetes), and APS-IV (two or more other organ-specific autoimmune disorders).

APS-II has also been known by various other names, including Schmidt's syndrome, polyglandular autoimmune disease, polyglandular failure syndrome, organ-specific autoimmune disease, and polyendocrinopathy diabetes. Such diverse names reflect the large number of studies and case reports of this syndrome and its historical importance. Studies of patients with APS-II were instrumental in identifying the autoimmune bases of several diseases and developing autoantibody assays such as those

Figure 42-1 Reproduction of an illustration from Addison's initial description of primary adrenal insufficiency (Addison's disease). (From Addison T. *On the Constitutional and Local Effects of Disease of the Supra-renal Capsules*. London, UK: Samuel Highley, 1855.)

for type 1 diabetes and cytoplasmic islet cell antibodies. Each of these other names has some shortcomings, such as failure to include the fact that both hyperfunction and hypofunction of endocrine glands can occur or failure to recognize that nonendocrine disorders such as pernicious anemia and celiac disease are parts of the syndrome.

Other rare autoimmune endocrine disorders have contributed to understanding of the development of autoimmunity. For example, the rare disorder immunodysregulation polyendocrinopathy enteropathy X-linked syndrome (IPEX) is caused by a mutation of the forkhead box P3 (FOXP3) gene. FOXP3 plays a central role in the development of regulatory CD4⁺/CD25⁺ T cells that function to maintain tolerance to self. It has become increasingly recognized that these and other regulatory T cells play a key role in the pathogenesis of many autoimmune diseases, and therapies targeting these regulator cells will likely be developed and tested. A thorough understanding of these rare and often genetically simple disorders provides insight into the development of syndromes that are characterized by polygenic inheritance and that affect a larger group of patients.

AUTOIMMUNITY PRIMER

An understanding of the pathophysiology of autoimmune disease requires a basic knowledge of the immunologic mechanisms that underlie tolerance (the ability to differentiate self from non-self). Autoimmunity develops when the mechanisms of immune tolerance break down. This can occur centrally at the level of the thymus or peripherally in the target organs. T lymphocytes and autoantibodies produced by B cells are two arms of the immune system that differ fundamentally in their recognition of target antigens. Autoantibodies react with intact molecules

(including both soluble and cell surface molecules) and usually interact with conformational determinants of the autoantigen. In contrast, T lymphocytes recognize peptide fragments of autoantigens, often 8 to 12 amino acids in length, that are presented on the surface of another cell by molecules of the major histocompatibility complex (MHC).

Histocompatibility molecules interact with T-cell receptors when bound with an antigenic peptide. These molecules resemble a hot dog in a bun, with the antigenic peptide (the hot dog) bound in the groove of the histocompatibility molecule (the bun). Histocompatibility molecules are extremely polymorphic, with different amino acids lining the peptide-binding groove. These variable amino acids determine which peptides are bound and presented to T lymphocytes.

T cells differ based on multiple cell surface molecules, and these molecules determine their function in the immune system. T cells interact with other cells within and outside the immune system. CD4⁺ T cells typically react with peptides that are derived from the extracellular fluid and are bound by class II histocompatibility molecules (HLA-DP, HLA-DQ, or HLA-DR in humans), which are typically expressed on antigen-presenting cells (APCs) such as macrophages, dendritic cells, and B lymphocytes. CD8⁺ T cells react with peptides bound by class I histocompatibility molecules (HLA-A, HLA-B, and HLA-C). Class I molecules are present on the surface of almost all nucleated cells. The antigen peptide in this case is derived from and presented by the target cell itself. Recognition of the antigenic peptide by CD8⁺ T cells typically leads to the release of cytotoxic chemicals that kill the cell.

The T-cell response depends on the context in which the antigen is presented. The simple expression of histocompatibility molecules and recognition of antigen by a T cell are not sufficient for T-cell activation. This context is at least partially determined by the interaction of cell surface molecules on both the T cell and the APC. Interaction among the MHC, the peptide, and the T-cell receptor (*signal one*) is critical to the activation process; other molecules then help to define the nature of the immune response (*signal two*). The context in which the antigens are presented is critical for the determination of this response. Cell surface molecules and receptors, cytokines, and chemokines form the context in which the antigen is presented. Based on this context, the cell can become activated, tolerized, or anergic (immune unresponsive). For example, the cell surface molecule B7 engages the CD80 receptor on the T cell and amplifies signal one, which leads to T-cell activation. When a T cell recognizes an antigen in the context of the MHC and does not receive the appropriate second signal, anergy results.

Tolerance induction is a staged process that begins in the thymus during T-cell maturation. This process depends in part on the presence of *peripheral antigens* in the thymus. Peripheral antigens are antigens (e.g., insulin) normally expressed in tissues outside the immune system that are expressed at low levels in the thymus. T cells that react strongly to these peripheral molecules in the context of the MHC are deleted in the thymus. T cells that react with peripheral antigens that are not expressed in the thymus have a greater opportunity to escape tolerance. Study of *AIRE* gene knockout mice has supported the importance of these phenomena in the development of autoimmunity. These mice have low levels of expression of peripheral antigens in the thymus and develop lymphocytic infiltrates in multiple organs.^{1,2}

Peripheral tolerance is an important mechanism for tolerance induction after T cells have matured in the thymus.

Figure 42-2 Model of the pathogenesis of autoimmunity in polyendocrine disorders. The development of autoimmune disease is determined by a group of T cells that recognize one or more organ-specific epitopes. Peptides are presented in the human leukocyte antigen (HLA) molecule and are recognized by the T-cell receptor. Recognition of self molecules depends on the maturation of the T cell, a process that begins in the thymus and continues in the periphery. The transcription factor FOXP3 stimulates the development of CD4⁺/CD25⁺ regulatory T cells. B cells produce autoantibodies under the stimulation of T cells. AIRE, autoimmune regulator; APS-I, autoimmune polyendocrine syndrome I; IPEX, immune dysregulation, polyendocrinopathy, enteropathy, X-linked; PAE, peripheral antigen-expressing cell; Th1, type 1 helper T cell; Th2, type 2 helper T cell. (Reproduced from Eisenbarth GS, Gottlieb PA. Autoimmune polyendocrine syndromes. *N Engl J Med*. 2004;350:2068-2079.)

Anergic and regulatory T cells are integral in the development of tolerance for naïve T cells. A major population of T-regulatory cells carry the cell surface markers CD4 and CD25 and express FOXP3. The function of the population of CD4⁺/CD25⁺ cells continues to be elucidated. Maturation of these cells in the thymus depends on the transcription factor FOXP3. Deletion of this transcription factor leads to fulminant autoimmunity in neonates (e.g., neonatal type 1 diabetes and enteropathy), often resulting in death within the first year of life (the IPEX syndrome).

Linked recognition is the process by which B cells are activated by CD4⁺ T cells that are responding to the same antigen. CD4⁺ T cells activate B cells to produce the humoral immune response. This occurs after the CD4⁺ T cell engages an antigen in the context of the MHC on the cell surface of a B cell. The cytokines (interleukin 4 [IL-4], IL-5, and IL-6) produced by the CD4⁺ T cells induce the maturation of a B cell. Depending on the cytokine milieu, the B cell will switch from producing immunoglobulin M (IgM) to IgG, IgE, or IgA. The development of B-cell tolerance is partially dependent on this linked recognition: autoreactive B-cell clones that do not have a CD4⁺ T cell that can bind with the antigen in its MHC groove will not normally be activated.

NATURAL HISTORY OF AUTOIMMUNE DISORDERS

The natural history of autoimmune disorders can be divided into a series of stages beginning with genetic susceptibility, followed by triggering of autoimmunity (e.g., dietary gliadin exposure in celiac disease), active autoimmunity preceding clinical manifestations (e.g., progressive glandular destruction), and, finally, overt disease. This is a theoretical construct that may be useful for understanding factors involved with the development of autoimmunity and disease, but of necessity it is simplified and does not

reflect the potential relapsing-remitting nature of autoimmunity (Fig. 42-2).

Genetic Associations

Although there is familial aggregation of APS-II and its component disorders, there is no simple pattern of inheritance (Table 42-1). Susceptibility is probably determined by multiple genetic loci (with HLA having the strongest effect) interacting with environmental factors. Autoimmune diseases share common genetic risk factors, including HLA, the MHC class I-related gene A (*MICA*), the gene for lymphoid tyrosine phosphatase (*PTPN22*), the cytotoxic T lymphocyte-associated antigen 4 (*CTLA4*), and the gene for NACHT leucine-rich repeat protein 1 (*NALP1*). In addition, genetic susceptibility for some autoimmune diseases has been linked to polymorphisms that are organ specific; for example, polymorphisms in the variable nucleotide tandem repeat (VNTR) upstream from the insulin gene have been associated with risk for type 1 diabetes.³

Genes located on the MHC found on chromosome 6 have been implicated in the pathogenesis of organ-specific autoimmune diseases. These genes are in strong linkage disequilibrium with each other and encode proteins that are important in the function of the immune system. Foremost in importance for the genetics of organ-specific autoimmune diseases are class I and class II HLA genes. Molecular HLA genotyping has revealed many subtypes of the older, serologically defined alleles, and the unique genetic sequence encoding each polymorphic chain of the histocompatibility molecules is now given a unique identifying number. A case in point is the DQ molecule, which is the histocompatibility molecule most strongly associated with endocrine autoimmunity. A number is assigned for each unique α - and β -chain sequence. Examples are DQA1*0501 for the α chain and DQB1*0201 for the β chain of the DQ molecule (also termed DQ2) commonly encoded on DR3 (DRB1*0301) haplotypes. A haplotype consists of a series of alleles of different genes on a contiguous region

TABLE 42-1

Genetic Associations with Autoimmune Disease

Gene	Proposed Mechanism of Action	Polymorphism/Mutation	Disease	Inheritance
HLA	Antigen presentation	DR3-DQ2/DR4-DQ8 DR3-DQ2 DR3-DQ2/DRB1*0404-DQ8 DR3-DQ2/DR4-DQ8 DR3 DR5	Type 1 diabetes Celiac disease Addison's disease Graves' disease Hypothyroidism	Multigenic
MICA	Priming of naïve T cells	5, 5.1 4, 5.1 5.1	Type 1 diabetes Celiac disease Addison's disease	Multigenic
PTPN22	T-cell receptor signaling pathway through interaction with regulatory kinases	Tryptophan substitution for arginine at position 620	Type 1 diabetes SLE RA Graves' disease Hypothyroidism Vitiligo	Multigenic
CTLA4	Receptor on activated CD4 ⁺ and CD8 ⁺ T cells; decreases T-cell activation	CT60 CT60; +49A/G CT60; +49A/G ++49A/G ++49A/G	Type 1 diabetes Graves' disease Hypothyroidism Celiac disease Addison's disease	Multigenic
AIRE	"Peripheral" antigen presentation in the thymus	Multiple reported mutations	APS-I	Autosomal recessive
FOXP3	Transcription factor important for maturation of CD4 ⁺ /CD25 ⁺ regulatory T cells	Multiple reported mutations	IPEX	X-linked

APS, autoimmune polyendocrine syndrome; IPEX, immunodysregulation polyendocrinopathy enteropathy X-linked syndrome; RA, rheumatoid arthritis; SLE, systemic lupus erythematosus.

of a chromosome (e.g., DQA1 and DQB1 alleles) that are inherited together. A genotype is the combination of the haplotypes of both chromosomes. Fine mapping of the HLA has shown remarkable conservation of the HLA-A1/B8/DR3 haplotype such that a region of approximately 2.9 megabases is invariable. Conservation of large areas suggests that these areas of the genome have been inherited without recombination and are in very tight linkage disequilibrium. This greatly complicates the ability to identify which, if any, of the genes within the area of conservation are associated with disease and must be accounted for when assessing susceptibility to disease in this region.

Part of the overlapping risk for autoimmune disease is related to shared genetic susceptibility, especially within the HLA. For example, the highest-risk HLA genotype for type 1 diabetes is DR3-DQ2, DR4-DQ8 (DQ8 = DQA1*0301-DQB1*0302). The importance of this HLA genotype in the development of type 1 diabetes is highlighted by the observation that children who inherited the same DR3-DQ2, DR4-DQ8 as a sibling with type 1 diabetes are at risk for development of autoimmunity of greater than 75% by age 12 years, and of diabetes of greater than 50% by 12 years.⁴ A specific DR4 subtype of this gene, DRB1*0404, shows a strong association with Addison's disease.^{5,6} The DR3-DQ2 haplotype is associated with celiac disease both in the presence⁷ and in the absence⁸ of type 1 diabetes. This haplotype has been associated with autoimmune thyroid disease,⁹ although conflicting reports exist.¹⁰

Whereas some HLA alleles increase disease risk, others are associated with protection from disease. For example, the DQ alleles DQA1*0102-DQB1*0602 (usually associated with DR2) confer strong protection from type 1A diabetes in a dominant fashion¹¹ but also confer susceptibility to another autoimmune disorder, multiple sclerosis.

Furthermore, this protection is not general to endocrine autoimmunity, because no protection from Addison's disease is afforded by DQB1*0602. DP is another gene within the MHC, and its 0402 polymorphism has been shown to be associated with a decreased risk for type 1 diabetes in subjects with the highest-risk HLA genotype for type 1 diabetes (DR3/DR4).¹² Observations such as these suggest that, as more is learned about the genetic influence of disease, researchers will be able to combine different genotypes and refine prediction of autoimmune disease.

MICA produces a gene that is expressed in the thymus and in naïve CD8⁺ T cells. Polymorphisms of *MICA* have been associated with type 1 diabetes,¹³ celiac disease,¹⁴ and Addison's disease.¹⁵ A particular polymorphism of *MICA*, denoted 5.1, results from the insertion of a single base pair. This insertion produces a premature stop codon and a truncated protein. This particular polymorphism has been shown to influence the risk for Addison's disease in subjects with autoimmunity associated with Addison's disease.

Genes outside the MHC have also been implicated in the pathogenesis of autoimmune disease. For example, the *PTPN22* gene encodes lymphoid tyrosine phosphatase (LYP) protein. LYP, through interactions with regulatory kinases such as CSK, appears to act as an inhibitor of the signal cascade downstream from the T-cell receptor. A specific polymorphism associated with a tryptophan substitution for arginine at position 620 (R620W) blocks LYP's interaction with CSK.¹⁶ This polymorphism has been associated with type 1 diabetes,¹⁶ rheumatoid arthritis,¹⁷ systemic lupus erythematosus (SLE),¹⁸ Graves' disease,¹⁹ and vitiligo²⁰ and is weakly associated with Addison's disease.¹⁹ This polymorphism has also been associated with SLE, rheumatoid arthritis, type 1 diabetes, and autoimmune hypothyroidism in families with several members affected by more than one autoimmune disease.²¹

CTLA4 is expressed on activated CD4⁺ and CD8⁺ T cells, where it is hypothesized to act as a negative regulator.²² Several polymorphisms within the CTLA4 gene have been associated with autoimmune diseases. One polymorphism associated with AT repeats has been shown to reduce the inhibitory function of CTLA4 in subjects with Graves' disease.²³ A single nucleotide polymorphism in the 3' untranslated region, denoted CT60, has been associated with Graves' disease²⁴ and autoimmune hypothyroidism.²⁵ An additional polymorphism, denoted *49A/G, has been associated with celiac disease in the Dutch population,²⁶ with autoimmune thyroid disease,²⁷ and with Addison's disease.²⁸

NALP1 regulates the innate immune system. After the initial observation that this gene was associated with the risk of vitiligo²⁹ and other related autoimmune diseases, it was associated with Addison's disease and type 1 diabetes.³⁰

Organ-specific genetic polymorphisms have been associated with the development of specific autoimmune diseases. For example, polymorphisms of the variable number of tandem repeats (VNTR) upstream of the insulin gene have been associated with the development of type 1 diabetes. Higher numbers of tandem repeats are associated with increased production of insulin in the thymus and protection from type 1 diabetes.³ Similarly, polymorphisms of the thyroglobulin gene are associated with autoimmune thyroid disease.³¹

Single-gene defects such as *AIRE* and *FOXP3* cause multiorgan autoimmunity and are discussed in sections devoted to those topics. Analysis of mutations of the *AIRE* gene indicates that it does not play a role in APS-II or sporadic Addison's disease, with 1 (1.1%) of 90 patients with Addison's disease (non-APS-I) and 1 (0.2%) of 576 control subjects having *AIRE* mutations.²⁸

Environmental Triggers

Although genetics is known to play an important role in the development of autoimmunity, it does not tell the whole story. For example, the highest-risk HLA genotype for type 1 diabetes (DR3-DQ2, DR4-DQ8) is associated with a risk of 1 in 20 for the development of diabetes.³² Although this is greater than the general population prevalence rate of 1 in 200 by the age of 20 years, it is certainly not a 100% risk. Therefore, other factors (genetic and environmental) must be involved in the initiation of autoimmunity. Some theorize that these factors may be environmental triggers.

For one disease, celiac disease, the underlying environmental trigger has been identified: gluten. Through studies such as the Diabetes Autoimmunity Study in the Young (DAISY), BabyDiab, and Celiac Disease Autoimmunity Research (CEDAR), the timing of first exposure to cereal has been identified as a risk factor for the development of diabetes and celiac disease autoimmunity. Infants exposed at a very young age to cereal developed diabetes and celiac-associated autoimmunity at a greater rate than those who had cereal introduced at a later date.³³⁻³⁵ In epidemiologic studies, cod liver oil consumption has been associated with a decreased risk for type 1 diabetes. Cod liver oil contains ω -3 polyunsaturated fats and vitamin D. In prospective studies, there is some suggestion that lower consumption of omega 3 polyunsaturated fats is associated with a increased risk for autoimmunity associated with type 1 diabetes.³⁶ Further investigation may identify additional environmental associations.

Immunologic therapies, especially in patients with an autoimmune disease, can induce autoimmunity. A remarkable example is the treatment of patients with multiple sclerosis with an anti-CD52 monoclonal antibody. One third of 27 patients given the monoclonal antibody developed antithyrotropin receptor autoantibodies and hyperthyroidism.³⁷ Interferon- α (IFN- α) therapy for hepatitis has been associated with thyroid autoimmunity³⁸ and type 1 diabetes.³⁹ Severe hypoglycemia associated with insulin autoantibodies in the absence of insulin administration, termed *Hirata's disease*, is associated with methimazole treatment of Graves' disease. The development of Hirata's disease in these patients is associated with HLA-Bw62/Cw4/DR4 with a specific DRB1 allele (DRB1*0406).⁴⁰

Development of Organ-Specific Autoimmunity

Autoantibodies highly specific for a given disorder are present before disease onset. Each specific autoantibody reacts with only a single autoantigen, although autoantigens may be present in multiple tissues. The targets of autoantibodies appear to be unrelated except that for organ-specific autoimmunity they are usually expressed in specific cells and cellular sites. Anti-islet antibodies include antibodies to glutamic acid decarboxylase (GAD), islet cell antibody (ICA) 512 (also termed *insulinoma antigen-2* [IA-2]), and insulin. Recently, an additional autoantigen, ZnT8, has been identified in association with type 1 diabetes. Antibodies against ZnT8 have been found at onset of diabetes, before the development of diabetes, and not in control sera.⁴¹ Celiac disease is associated with antibodies against tissue transglutaminase. Addison's disease is associated with antibodies against 21-hydroxylase.

Given that the antibodies can be identified before the development of organ dysfunction, they can be used to screen subjects who are at high risk for development of autoimmune disease to identify risk for additional autoimmune diseases. This approach has been employed in studies such as TrialNet for Type 1 Diabetes to screen first-degree relatives of patients with type 1 diabetes for diabetes-related autoantibodies. In this and other cohorts, risk for development of diabetes increases with the number of autoantibodies and their persistence.

Organ-specific autoantibodies (with appropriate assays) are rarely present (approximately 1 in 100) in the general population and identify a subset of people who are at greater risk for clinical disease. These autoantibodies may be expressed for years before the disease develops, and additional autoantibodies can develop over time. The pace at which disease develops is highly variable. For example, children as young as 1 year of age can present with type 1 diabetes. In contrast, a subset of subjects (5% to 10%) with type 2 diabetes diagnosed in adulthood have autoimmunity as the underlying cause. This may be in part due to genetics, because subjects who develop autoimmune diabetes at an older age have a higher proportion of the protective diabetes allele DQB1*0602, although even in adults DQB1*0602 provides dramatic protection.⁴²

In contrast, less is known concerning the specificity of pathogenic T cells. Given the observation that cross-reactive recognition by pathogenic T-cell clones may be determined by as few as four properly spaced amino acids of a nonapeptide and the estimate that each T-cell receptor might react with a million different peptides, there is considerable potential for patterns of autoimmunity to be determined by cross-reactive T cells. An important

development has been the discovery in the thymus and other lymphoid tissues of peripheral antigen-expressing cells that express autoantigens such as insulin. Minute quantities of such molecules in the thymus can contribute to tolerance. Insulin messenger RNA (mRNA) in the thymus is regulated by genetic polymorphisms of the insulin gene associated with diabetes risk.³ There is also evidence that stromal and lymphoid cells (CD11c⁺) in the spleen, lymph nodes, and circulation express multiple similar antigens.⁴³

Failure of Gland

Organ dysfunction develops over time and can include a period of intermediate function that may be characterized by increased levels of the stimulatory hormones (e.g., thyroid-stimulating hormone, corticotropin [ACTH]) with normal levels of the hormones (T₃, T₄, and cortisol). Once a significant portion of the gland has been destroyed, overt disease is then present.

AUTOIMMUNE POLYENDOCRINE SYNDROME TYPE I

Clinical Features

Table 42-2 compares the features of APS-I with those of APS-II. Table 42-3 shows the clinical features and recommended follow-up for patients with APS-I.

APS-I (Mendelian Inheritance in Man [MIM] 240300), also known as *autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy* (APECED), is characterized by the classic triad of mucocutaneous candidiasis, autoimmune hypoparathyroidism, and Addison's disease, which form three of the most common components of the disorder. Patients with APS-I are at risk for development of autoimmune diseases affecting almost every organ. More than 140 patients have been reported, including subjects in two large series from Finland⁴⁴⁻⁴⁶ and the United States.⁴⁷

In a series of 89 Finnish patients described by Perheentupa, all had chronic candidiasis at some time, 86% had hypoparathyroidism, and 79% had Addison's disease.

Figure 42-3 Incidence of disease development by age in patients with autoimmune polyendocrine syndrome type I (APS-I). (Reproduced from Perheentupa J. APS-I/APECED: the clinical disease and therapy. *Endocrinol Metab Clin North Am.* 2002;31:295-320.)

Gonadal failure (72% in women, 26% in men) and hypoplasia of the dental enamel (77% of patients) were also frequent findings. Other manifestations that occurred less often included alopecia (40%), vitiligo (26%), intestinal malabsorption (18%), type 1 diabetes (23%), pernicious anemia (31%), chronic active hepatitis (17%), and hypothyroidism (18%).⁴⁴ The incidence rates for many of these disorders peak in the first or second decade of life, and the disease continues to develop over decades (Fig. 42-3). Therefore, reported prevalence rates of component disorders are highly dependent on the age at which follow-up ended.

APS-I is characteristically recognized in early childhood. Infants can present with chronic or recurrent mucocutaneous candidiasis in the first year of life, followed by hypoparathyroidism and Addison's disease, but new components can develop at any age. Decades can elapse between the diagnosis of one disorder and the onset of another in the same patient. Consequently, lifelong follow-up is important to allow early detection of additional components.

Recurrent candidiasis commonly affects the mouth and nails and, less frequently, the skin and esophagus.⁴⁴ Chronic oral candidiasis can result in atrophic disease with areas suggestive of leukoplakia. If this develops, the patient is at significant risk for carcinoma of the oral mucosa (with its high mortality rate).

Ectodermal dystrophy is another component of the syndrome (manifested by pitted nails, keratopathy, and enamel hypoplasia) and cannot be attributed to hypoparathyroidism. Enamel hypoplasia can precede the onset of hypoparathyroidism and, despite adequate replacement therapy, can also affect teeth forming after the onset of hypoparathyroidism.⁴⁸

Friedman and colleagues⁴⁹ reported the frequent occurrence of asplenism and cholelithiasis as additional features of APS-I. Splenic atrophy may also cause immune deficiency. Although the etiology of this part of the disorder is unknown, it is relatively common: up to 15% of patients are asplenic.⁴⁴ The presence of Howell-Jolly bodies on peripheral blood smear is suggestive of asplenia. If asplenia is identified, immunization with polyvalent pneumococcal vaccine should be administered, and follow-up antibody titers should be obtained. If an adequate response is not produced, daily prophylactic antibiotics may be necessary.

Malabsorption with steatorrhea is of uncertain origin, is usually intermittent, and may be exacerbated by

TABLE 42-3

Clinical Features and Recommended Follow-Up for APS-I and APS-II

Component Disease	Frequency at Age 40 Yr (%)	Recommended Evaluation
Autoimmune Polyendocrine Syndrome Type I		
Addison's disease	79	Sodium, potassium, ACTH, cortisol, plasma renin activity, 21-hydroxylase autoantibodies
Diarrhea	18	History
Ectodermal dysplasia	50-75	Physical examination
Hypoparathyroidism	86	Serum calcium, phosphate, PTH
Hepatitis	17	Liver function test
Hypothyroidism	18	TSH; thyroid peroxidase and/or thyroglobulin autoantibodies
Male hypogonadism	26	FSH/LH
Mucocutaneous candidiasis	100	Physical examination
Obstipation	21	History
Ovarian failure	72	FSH/LH
Pernicious anemia	31	CBC, vitamin B ₁₂ levels
Splenic atrophy	15	Blood smear for Howell-Jolly bodies; platelet count; ultrasound if positive
Type I diabetes	23	Glucose, hemoglobin A _{1c} , diabetes-associated autoantibodies (insulin, GAD65, IA-2)
Autoimmune Polyendocrine Syndrome Type II*		
Addison's disease	0.5	21-Hydroxylase autoantibodies ACTH stimulation testing if positive
Alopecia		Physical examination
Autoimmune hypothyroidism	15-30	TSH; thyroid peroxidase and/or thyroglobulin autoantibodies
Celiac disease	5-10	Transglutaminase autoantibodies; small-intestine biopsy if positive
Cerebellar ataxia	Rare [†]	Dictated by signs and symptoms of disease
Chronic inflammatory demyelinating polyneuropathy	Rare [†]	Dictated by signs and symptoms of disease
Hypophysitis	Rare [†]	Dictated by signs and symptoms of disease
Idiopathic heart block	Rare [†]	Dictated by signs and symptoms of disease
IgA deficiency	0.5	IgA level
Myasthenia gravis	Rare [†]	Dictated by signs and symptoms of disease
Myocarditis	Rare [†]	Dictated by signs and symptoms of disease
Pernicious anemia	0.5-5	Anti-parietal cell autoantibodies CBC, vitamin B ₁₂ levels if positive
Serositis	Rare [†]	Dictated by signs and symptoms of disease
Stiff-man syndrome	Rare [†]	Dictated by signs and symptoms of disease
Vitiligo	1-9	Physical examination

*In the population with type I diabetes.

[†]Rare reported disorders in subjects with APS-II.

ACTH, adrenocorticotrophic hormone; APS, autoimmune polyendocrine syndrome; CBC, complete blood count; FSH, follicle-stimulating hormone; GAD, glutamic acid decarboxylase; IA-2, insulinoma antigen 2; IgA, immunoglobulin A; LH, luteinizing hormone; PTH, parathyroid hormone; TSH, thyroid-stimulating hormone.

hypocalcemia. Berek et al.⁵⁰ reported a case in which patchy intestinal lymphangiectasia was discovered by endoscopically directed biopsy. Pancreatic insufficiency has been treated with cyclosporine.⁵¹ Autoantibodies (e.g., tryptophan hydroxylase, histidine decarboxylase) reacting with intestinal endocrine cells (enterochromaffin, cholecystokinin, and enterochromaffin-like) occur and are associated with loss of endocrine cells on biopsy and with gastrointestinal dysfunction.^{52,53}

Genetics

Mutations of the autoimmune regulator gene, AIRE, located on the short arm of chromosome 21 (near markers D21s49 and D21s171 on 21p22.3), are associated with APS-I.⁵⁴ The gene encodes a putative DNA-binding protein of unknown function expressed in the thymus and in lymphoid and other tissues. It has been localized to the nucleus, and mutations have been demonstrated to be associated with decreased transcription of reporter products.^{55,56} AIRE

knockout mice have decreased production of peripheral antigens within the thymus.^{1,2} Researchers hypothesize that AIRE acts as a transcriptional factor in cells of the thymus and that it promotes the expression of peripheral antigens in these APCs. Mutations in AIRE are hypothesized to decrease central tolerance.

Multiple mutations of AIRE have been identified in subjects with APS-I. The frequency of specific mutations varies in different populations. For example, in Sardinia, a deletion of amino acid 257 is present in 90% of mutated alleles. A 136-base-pair deletion in exon 8 is present in 71% of British alleles and in 56% of alleles in the United States. Analysis of haplotypes indicates that this deletion has arisen on many occasions.

Most cases of APS-I are associated with autosomal recessive inheritance patterns. A rare kindred of patients from Italy have a mutation of the AIRE protein G228W that, when present in the heterozygous state, is associated with autoimmunity, thus fitting an autosomal dominant inheritance pattern.⁵⁷ In a mouse model of this mutation,

the expression of peripheral antigens in the thymus was decreased, compared with the control, suggesting a mechanism for this observed inheritance pattern.⁵⁸

Diagnosis

The diagnosis of APS-I is highly likely when two or more of the primary component disorders (i.e., mucocutaneous candidiasis, hypoparathyroidism, and Addison's disease) are present. Siblings of an affected patient should be considered affected even if only one of these disorders is present. Analysis of *AIRE* for the common mutations may be helpful in identifying subjects with APS-I. However, because multiple mutations have been discovered, the absence of a common mutation does not exclude APS-I. Any patient with any of the component disorders deserves careful follow-up to watch for development of additional disease.

Autoantibodies against interferon- α and interferon omega have been identified in almost 100% of subjects with APS-I, regardless of age at screening.⁵⁹ The autoantibody has been found in subjects with many different mutations of the *AIRE* gene; it is not present in other autoimmune diseases, and it has been proposed to use this autoantibody to screen subjects with multiple autoimmune diseases for APS-I.

Therapy and Follow-Up

The treatment of adrenal insufficiency and hypoparathyroidism is the same as that discussed in other chapters with the caveat that malabsorption can complicate treatment. The therapy for mucocutaneous candidiasis has been improved with the use of orally active antifungal drugs such as fluconazole and ketoconazole. Infection often recurs when the drug is discontinued or the dosage is decreased. Patients must be monitored carefully, because ketoconazole can inhibit adrenal and gonadal steroid synthesis and can precipitate adrenal failure. It is also associated with transient elevation of liver enzyme levels and, occasionally, with hepatitis. Fluconazole is associated with a lower frequency of hepatitis and does not inhibit steroidogenesis when given in the recommended doses.

Autoantibodies associated with multiple autoimmune diseases have been reported. Antiparathyroid and antiadrenal antibodies have been reported. Whereas 21-hydroxylase appears to be the major autoantigen in isolated Addison's disease and in Addison's disease associated with APS-II, autoantibodies against 17 α -hydroxylase and cytochrome P450 side-chain cleavage enzyme (CYP11A1) have also been reported in Addison's disease associated with APS-I.⁶⁰ Antibodies to tryptophan hydroxylase in intestinal disease, tyrosine hydroxylase in alopecia areata, L-amino acid decarboxylase in hepatitis and vitiligo, and phenylalanine hydroxylase^{61,62} and antibodies reacting with hair follicles have been reported.⁶³ Tuomi and coworkers originally observed that many more APS-I patients (41%) express anti-GAD65 autoantibodies than become diabetic, suggesting that reactivity to this single autoantigen has low predictive value in this population.⁶⁴ Recently, antibodies against NALP5 were identified in 49% of patients with APS-I and hypoparathyroidism, compared with none of those with APS-I but no hypoparathyroidism.⁶⁵ Screening for autoantibodies associated with additional autoimmune diseases may be useful in patients with APS-I.

Screening to allow the early detection of new disorders before overt symptoms and signs develop is recommended, including autoantibody studies, electrolytes, calcium and

phosphorus levels, thyroid and liver function tests, blood smear, and plasma vitamin B₁₂. Patients at risk for adrenal failure can be screened by measurement of basal ACTH and supine plasma renin activity (PRA), followed by dynamic testing as appropriate. Evaluation for asplenism⁴⁹ with abdominal ultrasonography and blood smear examination for Howell-Jolly bodies is warranted, with pneumococcal vaccination and appropriate antibiotic coverage for affected patients.

There are case reports of severely affected patients who have benefited from immunosuppressive therapy. For example, Ward and colleagues⁵¹ treated a 13-year-old patient who had keratoconjunctivitis, hepatitis, and severe pancreatic insufficiency. Treatment with cyclosporine was associated with normalization of stool fat (from 31.5 to 2.5 g/day).

AUTOIMMUNE POLYENDOCRINE SYNDROME TYPE II

Clinical Features

APS-II (MIM 269200) is more common than APS-I. It occurs more often in female than in male patients, often has its onset in adulthood, and exhibits familial aggregation (see Table 42-2). APS-II is usually defined by the occurrence in the same patient of two or more of the following: primary adrenal insufficiency (Addison's disease), Graves' disease, autoimmune thyroiditis, type 1A diabetes mellitus, primary hypogonadism, myasthenia gravis, and celiac disease. Vitiligo, alopecia, serositis, and pernicious anemia also occur with increased frequency in patients with this syndrome and their family members (see Table 42-3).

When one of the component disorders is present, an associated disorder occurs more commonly than in the general population. Furthermore, circulating organ-specific autoantibodies are often present even in the absence of overt clinical disease. For example, in subjects with type 1 diabetes, there is a 15% to 20% risk of hypothyroidism, a 5% to 10% risk of celiac-related autoimmunity, and a 1.5% risk of adrenal autoimmunity. The risk of autoimmunity is greater in relatives of patients with APS-II. In our assessment of APS-II families with Addison's disease, up to 15% of relatives were found to have 21-hydroxylase autoantibodies (Addison's disease-associated autoantibodies), anti-islet autoantibodies, or transglutaminase (tTG) autoantibodies (celiac disease-associated autoantibodies). The initial lesion and precipitating events that result in the syndrome are unknown, but immunogenetic and immunologic similarities are present with regard to both the time course and the pathogenesis of each of the component disorders.

Because of the chronic development of organ-specific autoimmunity, patients with the syndrome and their families should have repeated endocrinologic evaluations over time. In a family in which the syndrome has been documented, relatives should be advised of the early symptoms and signs of the principal component diseases (a list is available at www.barbaradaviscenter.org [accessed January 2011]). Relatives of patients with multiple disorders should have a medical history, physical examination, and screening every 3 to 5 years, with measurement of anti-islet autoantibodies, a sensitive thyrotropin assay, and measurement of serum vitamin B₁₂ levels. If there are any symptoms or signs or if 21-hydroxylase autoantibodies are present, the patient should have annual assays of basal

corticotropin and corticotropin-stimulated cortisol levels with Cortrosyn stimulation testing.

Among 224 patients with Addison's disease and APS-II reported by Neufeld and colleagues,⁴⁷ type 1 diabetes and autoimmune thyroid disease were the most common coexisting conditions (52% and 69% of patients, respectively). Other components were less common, including vitiligo (5%) and gonadal failure (4%).

Among patients with type 1A diabetes, thyroid autoimmunity and celiac disease coexist with sufficient frequency to justify screening. Thyroid peroxidase autoantibodies are present in 10% to 20% of children with type 1 diabetes; this incidence is higher in female patients and increases in all patients with age and with diabetes duration. A significant fraction of patients with type 1 diabetes and thyroid peroxidase autoantibodies develop thyroid disease. One study showed that after follow-up for more than 15 years, 80% of patients with thyroid peroxidase autoantibodies and type 1 diabetes became hypothyroid.⁶⁶ However, several studies have shown that a subset of patients with negative autoantibodies develop thyroid disease. Therefore, patients with type 1 diabetes should be screened annually for thyrotropin levels, which is a cost-effective approach.

With the identification of transglutaminase as the major endomysial autoantigen of celiac disease, radioimmunoassays were developed and demonstrated that 10% to 12% of patients with type 1 diabetes have tTG autoantibodies.⁷ The prevalence of tTG autoantibodies was higher in diabetic patients with HLA-DQ2; one third of DQ2-homozygous subjects were found to express anti-tTG antibody. Seventy percent of those with high-titer antibody who underwent biopsy were subsequently found to have the disease.⁶⁷ Therefore, screening with anti-tTG antibody can be carried out; if the results are positive and are confirmed on repeat assay, small-bowel biopsy to document celiac disease is warranted, with institution of a gluten-free diet if the disease is present. Many patients have asymptomatic celiac disease that is nevertheless associated with osteopenia and impaired growth. If left untreated, symptomatic celiac disease is also associated with an increased risk of gastrointestinal malignancy, especially lymphoma.

Down syndrome, or trisomy 21 (MIM 190685), is associated with the development of type 1 diabetes mellitus, thyroiditis, and celiac disease. Patients with Turner syndrome are at increased risk for the development of thyroid disease and celiac disease. It is recommended to screen patients with trisomy 21 and Turner syndrome for associated autoimmune diseases on a regular basis.

Diagnosis

Improved assays for several organ-specific autoantibodies have been developed since the cloning of specific autoantigens and the development of assays that use recombinant antigens. These radioimmunoassays are superior to assays based on immunofluorescence with tissue sections, such as ICA testing. The most notable finding is the identification of a large number of different autoantigens that are targeted even in single autoimmune disorders. Most of the endocrine autoantigens are hormones (e.g., insulin) or enzymes associated with differentiated endocrine function: thyroid peroxidase in thyroiditis; GAD, carboxypeptidase H, and ICA 512/IA-2 in type 1 diabetes; 17 α -hydroxylase and 21-hydroxylase in Addison's disease; and the parietal cell enzyme H⁺,K⁺-adenosine triphosphatase in pernicious anemia.

In type 1 diabetes, the four most informative assays currently available determine autoantibodies that react with insulin, GAD65, ICA512/IA-2, and ZnT8.⁴¹ In a similar manner, a radioassay format for the detection of autoantibodies that react with the enzyme 21-hydroxylase in Addison's disease has been developed and provides excellent disease specificity and sensitivity. Adrenal autoantibodies reacting with recombinant 21-hydroxylase usually precede the development of Addison's disease. However, as with thyroid autoantibodies, there may be patients who present with antibodies but have normal production of cortisol in response to ACTH. Continued endocrine testing every year initially and then every other year is indicated in this situation.

In contrast to the autoimmune polyendocrine disorders with T cell-mediated glandular destruction, autoantibodies may also be pathogenic. A hallmark of pathogenic autoantibodies is the existence of a neonatal form of the disorder, secondary to transplacental passage of the autoantibody. Examples include neonatal Graves' disease (anti-thyrotropin-receptor autoantibodies) and neonatal myasthenia gravis (anti-acetyl choline-receptor autoantibodies).

Therapy

Treatment of the individual diseases of the polyendocrine autoimmune syndrome is discussed in other chapters. Therapeutic considerations related specifically to APS-II are discussed here.

Many of the component disorders of the syndrome have a long prodromal phase and are associated with the expression of autoantibodies before the manifestation of overt disease. The way the disorders develop allows consideration of disease prediction and of clinical trials for prevention. This is particularly important for type 1A diabetes but is also likely to apply to Addison's disease and hypogonadism.

Because of the autoimmune nature of these disorders, several studies have evaluated the use of immunosuppressive drugs. Drugs such as cyclosporine have preserved some residual insulin secretion. However, because cyclosporine is nephrotoxic and potentially oncogenic, more generalized use is precluded. Newer immunosuppressive agents (e.g., sirolimus) are being studied, and biologics such as anti-CD20 antibody (rituximab) or nonmitogenic CD3 antibodies have been shown to prolong C-peptide production and to result in a decreased insulin dose through the first year of diabetes, compared with control subjects.⁶⁸

Mucosal administration of antigens is commonly associated with bystander immunosuppression, in which T cells specific to the antigen are apparently induced to produce suppressive Th2-like or Th3-like cytokines (e.g., IL-4, IL-10, and transforming growth factor- β). In addition, subcutaneous administration of insulin prevents diabetes and insulinitis in animal models, and subcutaneous administration of insulin peptides in adjuvants can prevent diabetes but not insulinitis. A large National Institutes of Health (NIH) trial, the Diabetes Prevention Trial—Type 1 (DPT-1), directly tested oral and parenteral insulin for prevention of diabetes. DPT-1 had two arms: intravenous-subcutaneous for those at high risk (risk of diabetes >50% within 5 years) and oral insulin for those at moderate risk (risk of diabetes 25% to 50% within 5 years). Neither parenteral⁶⁹ nor oral⁷⁰ insulin slowed progression to diabetes. However, in a subgroup analysis of subjects in the DPT-1 oral trial, a treatment effect was noted for those who had the higher insulin autoantibody levels at diagnosis,⁷⁰ and further trials are

under way. In preclinical Addison's disease, a short course of glucocorticoids appeared to suppress the expression of adrenal autoantibodies and prevent progressive adrenal destruction.⁷¹

Thyroxine therapy can precipitate a life-threatening Addisonian crisis in a patient with untreated adrenal insufficiency and hypothyroidism. Therefore, it is necessary to evaluate adrenal function in all hypothyroid patients in whom the syndrome is suspected before instituting such therapy. A decreasing insulin requirement in a patient with insulin-dependent diabetes mellitus can be one of the earliest indications of adrenal insufficiency, occurring before the development of hyperpigmentation or electrolyte abnormalities.

OTHER POLYENDOCRINE DEFICIENCY AUTOIMMUNE SYNDROMES

Rare polyendocrine syndromes are listed in Table 42-4.

Anti-Insulin Receptor Autoantibodies

In this rarely reported disorder (<25 patients), also known as type B insulin resistance or acanthosis nigricans, insulin resistance is caused by the presence of anti-insulin receptor antibodies.⁷² Approximately one third of patients with these antibodies have an associated autoimmune illness

such as SLE or Sjögren's syndrome. Arthralgia, vitiligo, alopecia, and secondary amenorrhea have also been reported. One patient had a daughter with hyperthyroidism and a granddaughter with SLE. Autoimmune thyroid disease has been described in two such patients, one with hypothyroidism and the other with antithyroid antibodies. Anti-nuclear antibodies, an elevated erythrocyte sedimentation rate, hyperglobulinemia, leukopenia, and hypocomplementemia are common.⁷³

The major clinical manifestations are related to the anti-insulin receptor antibodies. Insulin resistance is profound, and up to 175,000 U of insulin given intravenously per day may be ineffective in lowering the elevated glucose. Despite hyperglycemia and marked insulin resistance, ketoacidosis is uncommon. The course of the diabetes is variable, and several patients have had spontaneous remissions. Other patients have had severe hypoglycemia (perhaps related to the insulin-like effects of anti-insulin receptor antibodies demonstrable in vitro).⁷³ The acanthosis nigricans, which is caused by hypertrophy and folding of otherwise histologically normal skin, appears to be related to the insulin-resistant state. Other forms of marked insulin resistance in the absence of antireceptor antibodies are also associated with acanthosis nigricans.

POEMS Syndrome

The components of the multisystem disorder POEMS (plasma cell dyscrasia with polyneuropathy, organomegaly, endocrinopathy, M protein, and skin changes, also known as Crow-Fukase syndrome; MIM 192240) consist of diabetes mellitus (20% to 50% of patients), primary gonadal failure (55% to 70% of patients), plasma cell dyscrasia, sclerotic bone lesions, and neuropathy.⁷⁴ Patients usually present with severe progressive sensorimotor polyneuropathy, hepatosplenomegaly, lymphadenopathy, and hyperpigmentation. On evaluation, they are found to have plasma cell dyscrasia and sclerotic bone lesions. Patients present in the fifth to sixth decade of life and have a median survival after diagnosis of less than 3 years.⁷⁴

POEMS is assumed to be secondary to circulating immunoglobulins, but binding of antibody directly to involved tissues has not been demonstrated. There is evidence implicating cytokines such as IL-1A, IL-6, and TNF- α in addition to the M protein in the pathogenesis of this disorder. In several studies, elevated levels of vascular endothelial growth factor (VEGF) correlated with the disease state and treatment with immunosuppressive agents reduced the symptoms of the disease and the levels of VEGF, suggesting that this growth factor plays a role in the disease.^{75,76} A case report of the use of ticlopidine, which has been shown to decrease VEGF in experimental rats, has shown decrease of VEGF with resolution of ascites, edema, and pleural effusions and no change in the remainder of the clinical disease.⁷⁷ A therapeutic trial of an anti-VEGF antibody would provide more definitive evidence for this hypothesis.

The diabetes mellitus responds to small, subcutaneous doses of insulin. The hypogonadism is associated with elevated plasma levels of follicle-stimulating hormone and luteinizing hormone. Temporary resolution of disease, including a return of the blood glucose level to normal, may occur after radiotherapy for localized plasma cell lesions of bone. Peripheral blood stem cell transplantation has been performed and shows promise, producing stabilization or improvement of the components of POEMS. However, transplantation is not without risks, including death and respiratory failure.^{78,79}

TABLE 42-4

Rare Polyendocrine Disorders

Disorder	Clinical Features	Cause
Hirata's disease (insulin resistance syndrome)	Hypoglycemia	Insulin autoantibodies
IPEX	Type I diabetes Enteropathy	Associated with methimazole Mutations of <i>FOXP3</i>
Kearns-Sayre syndrome	Hypoparathyroidism Primary gonadal failure Nonautoimmune diabetes	Deletions of mitochondrial DNA
POEMS	Hypopituitarism Polyneuropathy Organomegaly Diabetes Primary gonadal failure	Plasma cell dyscrasia with production of M protein and cytokines
Thymic tumors	Myasthenia gravis Red blood cell hypoglobulinemia Autoimmune thyroid disease Adrenal insufficiency	Thymomas
Type B insulin resistance	Severe insulin resistance	Insulin receptor autoantibodies
Wolfram's syndrome	Diabetes insipidus Nonautoimmune diabetes Bilateral optic atrophy Sensorineural deafness	Mutations of <i>WSF1</i> , which encodes wolframin

IPEX, immunodysregulation polyendocrinopathy enteropathy X-linked syndrome; POEMS, plasma cell dyscrasia with polyneuropathy, organomegaly, endocrinopathy, M protein, and skin changes.

Kearns-Sayre Syndrome

The rare Kearns-Sayre syndrome (MIM 530000), also known as oculocraniosomatic disease or oculocraniosomatic neuromuscular disease with ragged red fibers, is characterized by myopathic abnormalities leading to ophthalmoplegia and progressive weakness in association with several endocrine abnormalities, including hypoparathyroidism, primary gonadal failure, diabetes mellitus, and hypopituitarism.⁸⁰ Crystalline mitochondrial inclusions are found in muscle biopsy specimens, and such inclusions have also been observed in the cerebellum. The relation between the mitochondrial disorders and endocrinologic abnormalities is not known. Antiparathyroid antibodies have not been described; however, antibodies to the anterior pituitary gland and striated muscle have been found, and the disease may have autoimmune components. Other abnormalities include retinitis pigmentosa and heart block. Deletions in mitochondrial DNA have been associated with Kearns-Sayre syndrome.⁸¹ These mutations usually occur sporadically and are not associated with a familial syndrome.

Thymic Tumors

The thymus is a complex tissue with a specialized endocrine epithelium that synthesizes a variety of biologically active peptides involved in the control of T-cell maturation. This epithelium is derived from the neural crest and contains complex gangliosides that react with monoclonal antibody (A2B5) and tetanus toxin in a manner similar to that of pancreatic islets.

The illnesses associated with thymomas are similar to those seen in APS-II,⁸² although the incidence of specific disorders is different. In one review of patients with thymoma, myasthenia gravis was found to occur in 44% of the patients, red blood cell aplasia in approximately 20%, hypoglobulinemia in 6%, autoimmune thyroid disease in 2%, and adrenal insufficiency in 1 of 423 patients (0.24%). The incidence of autoimmune thyroid disease reported in patients with thymoma is probably an underestimate, given the incidence of unsuspected thyroid disease in patients with myasthenia gravis. Mucocutaneous candidiasis in adults is also associated with thymomas. In most patients, the thymomas are malignant, although temporary remissions of the autoimmune disease can occur with resection of the tumor.

Congenital Rubella

Patients with congenital rubella have an almost 20% risk of acquiring diabetes mellitus and a higher than normal risk of acquiring thyroiditis and hypothyroidism.^{83,84} Those at highest risk for diabetes express diabetes-associated HLA-DR3 and HLA-DR4 alleles.⁸⁵ Rubella appears to be associated with diabetes primarily after fetal infection, and it is not known whether the virus increases the probability of subsequent autoimmunity due to permanent effects on the developing immune system.⁸⁶ Because of the intensive effort to immunize against the rubella virus, recent reports from the Centers for Disease Control and Prevention (CDC) indicate that rubella is no longer endemic in the United States.⁸⁷

Wolfram's Syndrome

Wolfram's syndrome (MIM 222300, chromosome 4; MIM 598500, mitochondrial) is a rare autosomal recessive disease that is also called DIDMOAD (*diabetes insipidus, diabetes*

mellitus, progressive bilateral optic atrophy, and sensorineural deafness). In addition, neurologic and psychiatric disturbances are prominent in most patients and can cause severe disability. Atrophic changes in the brain have been found on magnetic resonance imaging.⁸⁸ Segregation analysis of the mutations found in familial and sporadic cases of Wolfram's syndrome led to the identification of wolframin, a 100-kd transmembrane protein encoded by *WFS1*, a gene located at 4p16.1.116. Genotype and phenotype analyses have identified the severe phenotype (defined as the development of neurologic disease within the first decade) in patients with truncated proteins and mutations in the C-terminus of the protein.⁸⁹

Wolframin has been localized to the endoplasmic reticulum⁹⁰ and is found in neuronal and neuroendocrine tissue.⁹¹ Its expression induces ion channel activity with a resultant increase in intracellular calcium and may play an important role in intracellular calcium homeostasis.⁹² Functional studies have shown that reported *WFS1* mutations lead to decreased stability of the protein wolframin.⁹³ Linkage to other loci in addition to *WFS1* may explain the variability in phenotype seen in this disorder.

Wolfram's syndrome appears to be a slowly progressive neurodegenerative process, and there is also (nonautoimmune) selective destruction of the pancreatic beta cells. This association is probably a result of the expression pattern of *WFS1*. Diabetes mellitus with an onset in childhood is usually the first manifestation. Diabetes mellitus and optic atrophy are present in all reported cases, but expression of the other features is variable. Duration of diabetes is linked to the development of microvascular complications.⁹³ Additional endocrinologic diseases, such as ACTH deficiency and growth hormone deficiency, have been reported.⁹³ In one case report, two related children with Wolfram's syndrome had megaloblastic and sideroblastic anemia that responded to treatment with thiamine. Furthermore, thiamine treatment was associated with a marked decrease in insulin requirements.⁹⁴

Immunodysregulation Polyendocrinopathy Enteropathy X-Linked Syndrome

IPEX (MIM 340790, MIM 300292), first described in 1982, is a rare, X-linked recessive disorder that is characterized by immune dysregulation and results in multiple autoimmune diseases and early death (Fig. 42-4). Its clinical features include early type 1 diabetes and severe enteropathy resulting in failure to thrive. Other reported abnormalities include eczema or atopy, thrombocytopenia, hemolytic anemia, hypothyroidism, and lymphadenopathy.⁹⁵

Characteristics of the scurfy mouse gene (*sf*) bear a number of similarities to this syndrome, and abnormalities in the *sf* gene lead to abnormalities in the amount and function of scurfin, a DNA-binding protein in these mice.⁹⁶ Implantation of thymus from a scurfy mouse into immunoincompetent mice transfers the disease, but transplantation of thymus into immunocompetent mice does not transfer disease, and injections of normal T cells can rescue the phenotype. These observations suggest that a regulatory cell is involved in the pathogenesis of this disorder.

Linkage analysis demonstrated that a 17-centimorgan (cM) stretch of the X chromosome (Xp11.1-q13.3) is associated with IPEX, and mutations within the *FOXP3* gene have been identified in most of the families studied thus far.⁹⁷ *FOXP3* encodes a protein called scurfin and belongs to the forkhead class of winged helix transcription factors. It is hypothesized to function as a transcription factor. *FOXP3* has been shown to be expressed in CD4⁺/CD25⁺

Figure 42-4 The development of CD4⁺/CD25⁺ regulatory T cells in the thymus is dependent on FOXP3 expression. The lack of FOXP3 in immune dysregulation, polyendocrinopathy, enteropathy, X-linked syndrome (IPEX) prevents the development of these regulatory T cells and promotes the development of autoimmunity. (Reproduced from Sakaguchi S. The origin of FOXP3-expression regulatory T-cells: thymus or periphery. *J Clin Invest*. 2003;112:1310-1312.)

regulatory T cells.⁹⁸ These T cells can suppress activation of other T cells (see Fig. 42-4).⁹⁸ Therefore, mutations in *FOXP3* result in inability to generate regulatory T cells and the development of IPEX.

Therapy has been targeted to the component disorders. Bone marrow transplantation has been attempted with mixed success, and there is evidence for disease regression in most subjects.⁹⁹ Use of immunosuppressive therapy with sirolimus was reported to have beneficial effects in three patients with IPEX.¹⁰⁰

Omenn's Syndrome

Omenn's syndrome (MIM 603554) is a primary immunodeficiency syndrome with autoimmune manifestations affecting mainly the skin and gastrointestinal tract. Mutations associated with decreased recombination of the T-cell receptor have been described. One study showed that the levels of *AIRE* gene expression were decreased in the thymus of two affected patients and that this was associated with decreased expression of peripheral antigens compared with controls.¹⁰¹

CONCLUSION

Through the study of rare disorders such as APS-I and IPEX, the processes of thymic expression of peripheral antigens and development of regulatory T cells are beginning to be defined. This understanding provides invaluable insight into the development of the normal immune system and the mistakes that can occur and lead to autoimmunity. Lessons learned from these rare diseases will help to better define the pathophysiology of more common autoimmune

endocrine disorders, hopefully leading to the development of immunologic methods for prevention and treatment of these disorders.

Endocrine Management of the Cancer Survivor

ROBERT D. MURRAY

Over the last 4 decades, cure rates for childhood malignancies have improved at a remarkable pace. Overall 5-year survival rates have improved from less than 30% in 1960 to more than 70% in 1990.¹ Survival from adult cancers has lagged behind, but significant inroads have been made. For example, progress in the treatment of Hodgkin's disease, which affects predominantly a young adult population, has resulted in long-term survival rates of 70% to 90% using combination chemotherapy, radiotherapy, or both.^{2,3} With increasing survivorship from both childhood and adult cancers, the long-term detrimental effects of multimodality cancer therapy on multiple organ systems have been recognized.⁴ The long-term adverse sequelae are likely to gain increasing importance because of the significant demands on health service resources by these individuals. Within the United Kingdom, it is estimated that about 2 million people (3% of the population) have received a diagnosis of cancer. Of these, 1.2 million had their initial cancer diagnosis more than 5 years ago.⁵ It is predicted that the number of cancer survivors will increase by 3% per year, reflecting an increase in both cancer incidence and survival rates.⁵

Concentrating on the endocrine system alone, at least one long-term endocrine sequela is prevalent in 43% of unselected long-term childhood cancer survivors.⁶ Data from adult survivors have been less forthcoming because survival has, until recently, been of much shorter duration than that achieved in childhood cancers. Endocrine late effects include disturbances of growth and puberty, hypothalamo-pituitary dysfunction, primary hypogonadism, subfertility, thyroid dysfunction, benign and malignant thyroid nodules, hyperparathyroidism, and reduced bone mass.

GROWTH

Table 43-1 outlines the primary effects of multimodality cancer therapy on growth. The initial evidence for the impact of irradiation on growth velocity and final height was derived from animal studies and from growth data in children who received cranial irradiation for a variety of malignant and nonmalignant conditions. Cranial irradiation of 2-day-old rats led to a dose-dependent reduction in

TABLE 43-1

Overview of the Primary Effects of Multimodality Cancer Therapy on Growth and Hypothalamo-Pituitary Function in Cancer Survivors

Physiologic System	Insult	Pathology	Comments
Growth	Cranial XRT Spinal XRT	Impaired GH secretion Precocious puberty Impaired spinal growth Disproportion	All insults culminate in reduced height velocity and final height. There are no robust data supporting a direct action of chemotherapy on growth. The ultimate impact on height depends on age at XRT, dosage, and schedule. Puberty occurs earlier; spinal growth is more attenuated, and GH deficiency is more prevalent if XRT occurs at a younger age, in fewer fractions, and at higher dosage.
GH/IGF1 axis	Chemotherapy Cranial XRT	?Potentiation of XRT effects ?Direct effect on growth plate GH deficiency (GHD) (a) <i>Childhood</i> : reduced growth velocity (b) <i>Transition</i> : impaired somatic development (c) <i>Adult</i> : impaired quality of life, adverse body composition, and vascular risk profile	Cranial XRT doses as low as 18 Gy given during childhood result in GHD in about one third of individuals by 5 yr after treatment, whereas doses of 30-40 Gy result in GHD in 60-100% of patients by 5 yr. ⁴ Prevalence of GHD depends on age at irradiation, fractionation schedule, and dose.
Hypothalamo-pituitary axis	Cranial XRT	LH/FSH deficiency ACTH deficiency TSH deficiency Hyperprolactinemia	Additional anterior pituitary hormone deficits are usually seen with XRT doses >30 Gy and are dependent on dose, fractionation schedule, and time since XRT. ⁴ Progression of hormone loss usually follows the pattern GH → LH/FSH → ACTH → TSH. Other than GHD, additional deficits are unusual within the first 2 yr after XRT except with exposure to very high doses. Transient hyperprolactinemia is frequently seen after XRT and resolves with a few years.
Hypothalamo-pituitary axis	Cranial XRT	Early/precocious puberty	Early puberty is a consequence of disinhibition of cortical influences on the GnRH pulse generator. The earlier the age at XRT (25-50 Gy), the earlier puberty occurs. ⁸ Early puberty effectively foreshortens the time available for growth-promoting interventions when growth is impaired.

ACTH, adrenocorticotropic hormone; FSH, follicle-stimulating hormone; GH, growth hormone; GHD, growth hormone deficiency; GnRH, gonadotropin-releasing hormone; IGF1, insulin-like growth factor 1; LH, luteinizing hormone; TSH, thyroid-stimulating hormone; XRT, radiation therapy.

growth⁷ with reduction in the size of the pituitary gland. The mechanism of growth disturbance was, however, unclear, because levels of insulin-like growth factor 1 (IGF1) remained similar to those in control rats, and no increase in growth was observed after treatment with bovine growth hormone (GH). The severity of growth retardation was greatest in rats receiving cranial irradiation during the first few days of life, with a degree of tolerance developing by the end of the first postnatal week.⁸

Early observations in humans noted somatic growth to be retarded in children after irradiation for brain tumors^{9,10} or acute leukemia.^{11,12} The Childhood Cancer Survivors Study is a multicenter questionnaire-based study of individuals within the United States who have survived at least 5 years after childhood cancer. A subanalysis of survivors of brain tumors within this cohort reveals that 40% of patients had a final height below the 10th percentile.¹³ In these individuals who have undergone multimodality cancer therapy for childhood malignancy, the exact contribution of the endocrine perturbations to the growth failure is difficult to disentangle from the additional effects of chemotherapy, corticosteroid therapy, spinal irradiation, graft-versus-host disease, poor nutritional status, and the acute illness itself.^{14,15} Endocrine disturbances, including radiation-induced hypothyroidism, precocious puberty, and GH insufficiency, adversely affect growth. The importance of cranial or craniospinal irradiation on growth is

clear from studies of survivors of childhood acute leukemia and brain tumors.^{12,16} The degree of height loss correlates inversely to age at irradiation, the most profound reduction in final height occurring in those who were in the youngest age group at irradiation¹⁵ and to irradiation dosage, there being greater height loss even with small increases in overall dosage (e.g., 18 Gy versus 24 Gy).¹² Growth is frequently observed to be reduced during intensive therapy for acute lymphoblastic leukemia (ALL) but normal thereafter.^{16,17} The spontaneous improvement in growth rates emphasizes that GH insufficiency is not present in all patients with growth failure,¹¹ and for that reason GH replacement therapy may not always be indicated.

Spinal irradiation administered before puberty significantly impairs spinal growth.^{18,19} Leg length standard deviation scores (SDS) in patients who receive cranial and craniospinal irradiation are equivalent, whereas spinal growth is impaired primarily in the latter group.¹⁸ The impairment of spinal growth results in disproportion, reflected by an increase in the ratio of leg length to sitting height. The impact on the skeleton of spinal irradiation correlates with age: the younger the individual is at the time of irradiation, the greater is the impairment of spinal growth and the greater the degree of disproportion.^{18,19} This observation simply reflects the fact that there is a greater loss in growth potential when the insult to growth

occurs at a younger age. A degree of disproportion is observed to occur in children who receive a combination of cranial irradiation and chemotherapy for acute leukemia¹² and most likely relates to disturbance of puberty or a direct effect of the chemotherapy. The effect of cytotoxic chemotherapy on growth remains contentious, but there is a suggestion that subsequent growth may be attenuated.¹² Additionally, chemotherapy has been shown to potentiate the growth impairment resulting from cranio-spinal irradiation.^{14,15} Although the pathophysiologic mechanism by which chemotherapy adversely influences growth is unclear, a reduction in growth factors including IGF1, increased sensitivity of bone to irradiation damage, and a direct action on the growth plate are postulated.

Height loss correlates negatively with age at onset of puberty.²⁰ Radiation doses of less than 50 Gy during childhood may result in early or precocious puberty,²¹ whereas higher doses more frequently result in gonadotropin deficiency. The impact of early puberty in a child is to reduce the time available for growth. If the child is additionally GH insufficient, the available time for intervention with GH therapy is also foreshortened, restricting the therapeutic efficacy of this intervention. It is for this reason that children with early puberty are treated with gonadotropin-releasing hormone (GnRH) analogues with or without GH replacement. Studies examining the effect of GnRH analogues on final height in GH-insufficient children treated with cranial irradiation have generally reported improvements in auxologic outcome.²² Most of these were nonrandomized, open-label studies that compared patients treated with GnRH analogues with those who did not receive this intervention. The decision to initiate GnRH therapy is frequently based on the child's having a poorer final height prediction. Direct comparison of GnRH-treated and -untreated individuals have therefore almost certainly underestimated the beneficial impact of GnRH analogues on final height.

Despite the multiple insults on growth in cancer survivors, the importance of GH status is exemplified by the greater loss of final height in patients with impaired GH secretion compared to those with normal GH secretion who have undergone otherwise similar treatment regimens.²⁰ Normal growth and peak GH responses are frequently observed in long-term survivors of ALL who receive cranial irradiation doses of less than 24 Gy.^{23,24} Higher radiation doses result in progressive impairment of the GH axis with height loss correlating negatively with the peak GH response to stimulation.²⁰

GH replacement therapy can increase growth velocity in children with radiation-induced GH insufficiency.¹⁵ Most studies have shown improvements in height velocity, although the height data have been conflicting. Early studies showed disappointingly small differences in the height loss prevented by the use of GH replacement, much less than observed in children treated for idiopathic growth hormone deficiency (GHD).^{15,20,25-27} A number of factors contribute to the failure of GH to fully redeem the loss of height that results from multimodality cancer therapy, including chemotherapy, spinal irradiation, precocious puberty, a prolonged interval between irradiation and initiation of GH therapy, and inadequate GH treatment schedules.^{15,20} The predominant factor is probably the interval between hypothalamo-pituitary irradiation and initiation of GH therapy.

Because the risk of recurrence of childhood brain tumors is relatively low more than 2 years out from treatment and there is no evidence that GH increases the risk of recurrence of brain tumors,²⁸⁻³¹ it is reasonable to consider GH

replacement at that time. The approach of clinicians is variable, with some offering GH replacement only to children who demonstrate a reduced peak GH response to stimulation in association with a reduced height velocity and others offering GH replacement on the basis of the biochemistry alone, with the aim of preventing height loss which, once established, may not be fully remediable. If growth velocity and GH stimulation test results are normal at 2 years after treatment, growth should be monitored at least every 6 months, and the GH stimulation test should be repeated annually. Use of GH therapy to promote growth in GHD children who have received spinal irradiation can exacerbate disproportion.¹⁵ Whereas the long bones respond appropriately, the irradiated spine is relatively resistant to the growth-promoting effects of GH. In this scenario, growth should be monitored by measurements of leg length velocity, because spinal growth is abrogated.

THE HYPOTHALAMO-PITUITARY AXIS

Deficiency of one or more anterior pituitary hormones is a consequence of treatment with external-beam irradiation when the hypothalamo-pituitary axis falls within the field of irradiation³² (see Table 43-1). GH is almost exclusively the first axis to be affected.³³ Prospective studies from treatment of pituitary adenoma³⁴ and nasopharyngeal carcinoma³³ show that gonadotropin or adrenocorticotropin (ACTH) deficiency evolves next, with thyroid-stimulating hormone (TSH) deficiency being relatively infrequent. A similar temporal pattern is observed independent of whether radiation exposure occurs during childhood or adult life. To date, there are no reported cases of the development of diabetes insipidus as a consequence of cranial irradiation, in either children or adults, at any irradiation dosage used.^{33,35,36}

The site of radiation damage to the hypothalamo-pituitary axis remains a matter of conjecture. With radiation doses less than 50 Gy, hypothalamo-pituitary hormone deficits are attributable to the cumulative damage from delayed neurotoxic effects of irradiation on the hypothalamus and secondary pituitary atrophy. Higher irradiation doses are thought to cause concurrent damage directly at the level of the pituitary. There are a number of lines of support for this consensus. Patients treated for pituitary adenoma with insertion of yttrium-90 implants (500 to 1500 Gy) show a lower prevalence of combined ACTH and TSH deficits³⁷ compared with those receiving conventional external-beam irradiation (37.5 to 42.5 Gy).³⁴ The likely explanation for this observation is that the field of exposure during conventional irradiation includes the hypothalamus, which is relatively spared with beta emissions from yttrium 90. Evidence of hyperprolactinemia after irradiation is suggestive of a reduction in prolactin inhibitory factors from the hypothalamus with relative preservation of the lactotrophs.³⁸ A frequent observation after irradiation of the hypothalamo-pituitary axis is that of a delayed TSH response to thyrotropin-releasing hormone (TRH) in the absence of overt hypothyroidism, further suggesting hypothalamic dysfunction.³⁸

Greater impairment of GH response to the insulin tolerance test (ITT) in comparison with growth hormone-reducing hormone (GHRH) adds further weight to the notion of a hypothalamic site of damage.³⁹ Nonetheless, GH profiles in irradiated individuals show preservation of GH pulsatility despite a significant reduction in pulse amplitude.⁴⁰ GH pulse generation is dependent on GHRH, supporting a concept that irradiation-induced hypopituitarism

most likely results from combined hypothalamic and pituitary damage, with compensatory overdrive of the remaining pituitary cells by hypothalamic hormones in an attempt to maintain the normal hormonal milieu.

The pathophysiologic mechanism responsible for radiation-induced hypothalamic damage is unclear and may reflect either vascular or direct neuronal damage. Hypothalamic blood flow declines with time after irradiation; however, no change in the ratio of hypothalamic to occipital blood flow was found between 6 months and 5 years after irradiation.⁴¹ This finding is in contrast to the progressive endocrine dysfunction, suggesting that the nature of the damage is predominantly neuronal.

Although an association between the development of hypopituitarism and chemotherapy has been suggested,⁴² no robust relationship has been established.^{43,44} In particular, no individual class of chemotherapeutic agents has been implicated. It is possible that the poor reproducibility and variable potency of different secretagogues used in endocrine stimulation tests may provide a more appropriate explanation for occasional individuals falsely diagnosed with GHD.^{45,46} However, there is stronger evidence that cytotoxic drugs may increase the incidence of radiation-induced hypopituitarism.^{14,15,47} A number of chemotherapeutic agents modulate release of antidiuretic hormone (ADH) from the posterior pituitary, resulting in the syndrome of inappropriate secretion of ADH (SIADH). Cisplatin, cyclophosphamide, melphalan, vinblastine, and vincristine have all been implicated, but this is by no means a comprehensive list.

Growth Hormone Deficiency

Childhood Growth Hormone Deficiency

Isolated GHD is commonly the only hormonal sequela of neuroendocrine injury after irradiation of the hypothalamo-pituitary axis with doses less than 40 Gy. Studies of animal models have attributed this to selective radiosensitivity of the somatotrophic axis.^{48,49} Long-term data reveal that almost all children irradiated with doses in excess of 30 Gy develop blunted GH responses to provocation,^{50,51} whereas only about one third of patients treated with lower doses show impaired GH release. Isolated GHD in children has been described with irradiation doses as low as 10 Gy used in the setting of total-body irradiation (TBI); however, it is infrequent.⁵² The severity and speed of onset of GHD in childhood as a result of irradiation is dose dependent.^{53,54} Blunting of GH responses to provocative tests may occur as early as 12 months after high-dose irradiation (40 to 60 Gy) for brain tumors.^{55,56} Progressive impairment in GH production occurs with time since treatment,^{55,57} necessitating prolonged follow-up and regular assessment of hypothalamo-pituitary function. The prevalence of GHD is also influenced by how the dose is delivered. Among children treated for acute leukemia with a cranial irradiation dose of 25 Gy delivered in 10 fractions, a greater proportion developed GHD, compared with those who received 24 Gy in 20 fractions.⁵⁸ Abrogated GH responses are more likely to occur if irradiation is administered at a younger age, suggesting that the younger hypothalamo-pituitary axis is more susceptible to radiation-induced damage.⁵³

A threshold effect has been proposed for the hypothalamo-pituitary axis, with irradiation dosages greater than 24 to 25 Gy resulting in impaired GH secretion and lower doses having negligible effect on the axis.^{53,59} In keeping with this concept, normal growth is usually

observed in long-term survivors of ALL who received cranial irradiation doses of less than 24 Gy.^{23,24} In children, regimens used in treatment of acute leukemia involving cranial radiation doses of 24 Gy for central nervous system (CNS) prophylaxis result in impaired spontaneous and stimulated GH secretion.^{11,60} Within this population, a continuum between retention of normal GH secretion and severe GHD is observed. Spontaneous GH secretion involves a reduction in both daytime and nocturnal GH secretion, as well as a reduction in GH pulse amplitude (Fig. 43-1).^{11,40,60,61} However, normal pulsatile characteristics are maintained.⁴⁰ In those individuals showing the greatest reduction in spontaneous GH secretion, there is loss of the normal GH diurnal rhythm and a fall in IGF1 levels below the reference range.⁶⁰ At the other end of the continuum, a subgroup of children is described where the impact of irradiation on the hypothalamo-pituitary axis is minimal, leading to failure of the expected increase in GH secretion only at puberty, when demands are increased.^{62,63}

In these latter individuals, the reduction in spontaneous GH secretion is purported to occur before attenuation of the peak GH response to stimulation⁶⁰—a phenomenon termed *neurosecretory dysfunction*. Neurosecretory dysfunction of the GH axis is best understood in the context of growth data. Growth velocity is normal prepubertally, but an attenuated growth spurt is observed during puberty,⁶² when GH secretion is normally amplified twofold to threefold.^{64,65} This phenomenon probably represents inability of the hypothalamic GH control mechanisms to respond to the pubertal rise in endogenous sex steroids. Although individual stimulated GH values are found to be “normal” when defining GH neurosecretory dysfunction, group mean values are reduced compared with control data.⁶³ This suggests that neurosecretory dysfunction may more factually represent decompensation of a partially damaged hypothalamo-pituitary axis. It is likely, therefore, that the term neurosecretory dysfunction has in part been created by difficulties in defining a normal GH axis based on pharmacologic stimulation tests.

Prophylactic cranial irradiation in children with ALL has been undertaken on the premise of reducing the rates of CNS relapse. In an attempt to minimize the adverse effects on GH secretion and neuropsychological function, prophylactic cranial radiation dosage was reduced from 24 Gy to 18 Gy. This reduction in dosage does not result in a greater incidence of CNS relapse.⁶⁶ Cranial radiation doses of 18 Gy were subsequently introduced in the 1980s and then later abandoned completely in favor of high-dose intravenous methotrexate or intrathecal chemotherapy. Abrogated GH responses to stimulation are infrequently observed after 18-Gy cranial irradiation. In contrast, the pubertal increase in spontaneous GH secretion may be attenuated⁶⁷ and associated with with randomization of GH pulsatility.⁶⁷ The randomized bursts are explained by a reduction in somatostatin tone, as is similarly observed in rats with focused lesions in the median eminence that reduce somatostatin tone.⁶⁸

Adult Growth Hormone Deficiency

After cranial irradiation, the importance of GHD in adults is twofold. First, GHD almost exclusively occurs before deficits in the additional anterior pituitary hormone axes and therefore acts as a marker that damage to the additional hypothalamo-pituitary axes may ensue.³³ Second, with recognition of the beneficial effects of GH replacement in adults⁶⁹⁻⁷¹ consideration should be given to replacement therapy, particularly if quality of life is significantly impaired.^{72,73} The underlying cancer diagnosis and the

Figure 43-1 Spontaneous pulsatile secretion of growth hormone in a patient with acute lymphoblastic leukemia (ALL) who received prophylactic intrathecal methotrexate and cranial irradiation with 24 Gy (**A**) and in a representative normal child (**B**). (From Blatt J, Bercu BB, Gillin JC, et al. Reduced pulsatile growth hormone secretion in children after therapy for acute lymphoblastic leukemia. *J Pediatr*. 1984;104:182-186.)

duration of remission must be taken into account before embarking on this course of management.

Similar to observations in children, the occurrence of adult GHD after irradiation depends on a number of variables. After a dose of 37.5 to 45.0 Gy to the hypothalamo-pituitary axis, mean peak GH levels after insulin-induced hypoglycemia were observed to decrease over the first 5 to 6 years and to plateau thereafter.⁷⁴ Blunting of GH responses to stimulation have been reported as early as 12 months after high-dose (50 to 70 Gy) radiation therapy for nasopharyngeal carcinomas.⁷⁵ In addition to length of follow-up, the peak GH response to stimulation correlates inversely with the radiation dosage received by the hypothalamo-pituitary axis.⁵⁷ Development of GHD, defined by a peak GH response of less than 2 $\mu\text{g/L}$ (5 mU/L), will occur in patients with preirradiation peak GH responses of 12 $\mu\text{g/L}$ (30 mU/L), 8 $\mu\text{g/L}$ (20 mU/L), and 4 $\mu\text{g/L}$ (10 mU/L) at a mean of 4 years, 3 years, and 1 year, respectively.⁷⁴ Therefore, if the basal peak GH response is in excess of 20 $\mu\text{g/L}$ (50 mU/L) before radiotherapy, it is unlikely that severe GHD will occur within 5 years.⁷⁴

Adult Survivors of Childhood Cancer. Adult survivors of childhood cancer who have received irradiation to the hypothalamo-pituitary axis during their childhood cancer

treatment frequently exhibit impaired GH secretion. Assessment of GH status in young adult survivors of ALL who received cranial irradiation of 18 to 25 Gy revealed that one third of patients had severe GHD (peak GH response, <3 $\mu\text{g/L}$), and a further third had partial GHD (peak GH response, 3 to 7 $\mu\text{g/L}$).⁵⁹ Almost all patients with impaired GH secretion received 24 to 25 Gy, supporting a threshold effect of irradiation dosage on the GH axis.⁵⁹ Impaired GH secretion during adult life after childhood irradiation of the hypothalamo-pituitary axis is more likely to be observed in those who received radiation therapy early during childhood.⁵⁹ Late assessment of the GH status in childhood brain tumor survivors (who received dosages of 40 to 50 Gy) in adult or predominantly adult cohorts revealed that most patients had blunted GH responses to stimulation.⁵⁷

In adults who have received cranial irradiation but retain "normal" individual albeit attenuated mean stimulated GH responses, a similar phenomenon to the described GH neurosecretory dysfunction of puberty is not observed.⁷⁶ When the GH axis of these individuals is placed under stress during prolonged fasting, spontaneous GH secretion increases appropriately.^{76,77} A number of qualitative changes in the GH profiles of these adults are observed^{76,78} and reflect those observed in adults with severe GHD.⁴⁰ Profiles

show elevated nadir and interpeak GH levels, reduced peak GH, reduced pulsatile GH, and a decrease in the ratio of pulsatile area under the curve (AUC) to total AUC GH secretion.^{76,78} The diurnal rhythm, pulse frequency, pulse duration, and interpulse interval are unaffected. In those individuals with severe GHD, an increase in approximate entropy is observed, consistent with perturbation of the hypothalamic control of GH release.⁴⁰ Mechanistically, these changes are attributable to a reduction in somatostatin tone leading to higher nadir GH levels and reduced peak levels.

GHRH activity is essential to GH pulse generation,^{79,80} suggesting that irradiation damage is not purely the consequence of hypothalamic damage to GHRH neurons. The reduced GH secretion after low-dose (<40 Gy) irradiation of the hypothalamo-pituitary axis can, therefore, be postulated to occur as a combination of a mild hypothalamic insult and direct damage to the pituitary somatotrophs with compensatory overdrive of the remaining somatotrophs from the hypothalamic GHRH neurons.^{50,76}

Survivors of Cancer Treated in Adult Life. Radiation-induced GHD is recognized to occur after treatment of brain tumors and sinonasal carcinomas during adult life. Some of the most robust data comes from individuals who have received high-dose irradiation (45 to 60 Gy) for stage I (T1 N0 M0) or stage II (T1 N1 M0) nasopharyngeal carcinoma. These tumors receive most of their irradiation through opposing lateral facial fields that include the pituitary gland and, frequently, the basal hypothalamus (Fig. 43-2). When investigated for hypothalamo-pituitary dys-

function on the premise of putative symptoms of hormonal dysfunction after at least 5 years without recurrence, almost all of these individuals were found to have impaired GH responses to stimulation.^{38,81} If radiation therapy occurs during adult life, age and gender have no measurable effect on the risk of developing GHD.³³

Only limited data are available for GH status after irradiation of nonpituitary brain tumors. The prevalence of severe GHD at 5 years after treatment is reportedly about 30%.^{42,82} Prospective assessment of pituitary function after irradiation of nasopharyngeal carcinoma showed that mean stimulated GH levels fell beginning from as early as 1 year.³³ At 5 years after radiotherapy, 60% to 65% of individuals would be expected to show abrogated GH levels (<6.7 µg/L [<20 mU/L]).³³ Similar irradiation doses to the hypothalamo-pituitary axis administered during childhood would be expected to result in an earlier onset and greater prevalence of GHD.^{56,83,84}

The Diagnosis of Radiation-Induced Growth Hormone Deficiency

The diagnosis of irradiation-induced GHD in children is suspected when the height velocity SDS remains below normal after completion of cancer therapy. The diagnosis can then be confirmed or refuted biochemically with the use of appropriate GH stimulation tests. In the absence of a pathophysiologic marker equivalent to growth, the diagnosis of irradiation-induced adult GHD becomes dependent exclusively on the prevailing biochemistry. In general, biochemical evaluation of GH status in both children and adults is undertaken as it would be for other causes of GHD. Because radiation-induced GHD is frequently isolated, the diagnosis can robustly be achieved only through the use of two provocative tests of GH reserve.^{85,86} The ITT is considered to be the "gold standard" in the diagnosis of GHD in adults who are at risk for hypopituitarism.^{86,87} In children, profound hypoglycemia during the ITT has led to deaths and irreversible neurologic damage.⁸⁸ Therefore, this test should be performed only in centers experienced in use of this test in children.

In addition to cranial irradiation, individuals requiring assessment of their GH status may have received anthracycline therapy as part of their treatment regimen. Anthracycline therapy has been implicated in the development of cardiomyopathies, which can decompensate⁸⁹⁻⁹¹ during times of significant stress on the cardiovascular system. Although no data exist for decompensation occurring during assessment of the hypothalamo-pituitary axis using the ITT, an alternative stimulation test should be used if echocardiographic evidence for significant anthracycline cardiac damage exists.

Debate has arisen as to whether all GH stimulation tests, when abrogated, appropriately represent a state of GHD. After irradiation of the hypothalamo-pituitary axis, the peak GH response to the ITT is often more attenuated than that observed with the arginine,⁹² GHRH plus arginine,^{93,94} or GHRH test.³⁹ After radiotherapy, the peak GH response to the ITT falls significantly within the first 5 years with minimal change over the subsequent 10 years.⁹³ In contrast, the peak GH response to the GHRH plus arginine test shows little change in the first 5 years, with a more significant fall occurring over the following 10 years.^{93,95,96} Therefore, the evolution in GH responsiveness to provocative tests is stimulus dependent and suggests initial hypothalamic damage followed by later somatotroph dysfunction. The GHRH plus arginine test may be unreliable in

Figure 43-2 Lateral facial field used during radiotherapy for nasopharyngeal carcinoma. The shielded areas are shaded. Distances shown are 1.5 cm (a and c) and 0.75 cm (b). AT, atlantoid tubercle; LOM, lateral orbital margin; WTD, wax tongue depressor. (From Lam KS, Wang C, Yeung RT, et al. Hypothalamic hypopituitarism following cranial irradiation for nasopharyngeal carcinoma. *Clin Endocrinol (Oxf)*. 1986;24:643-651.)

characterizing GH status during the first 5 years after radiotherapy.

Among irradiated individuals who show discordant responses, characterized by a subnormal response to the ITT (peak GH secretion, $<5 \mu\text{g/L}$) but a normal or less attenuated response to the GHRH plus arginine test, spontaneous GH release is reliably reduced only in those patients who failed the GHRH test (peak GH secretion, $<16.5 \mu\text{g/L}$).⁷⁸ In contrast, if only the response to the ITT is impaired, spontaneous GH secretion is normal.⁷⁸ Among patients with impaired responses to the ITT, IGF1 levels are reduced to a similar extent in those with reduced and those with normal spontaneous GH secretion.⁷⁸ This observation questions the validity of defining GH status by a measurement of 24-hour GH secretion.⁹⁷ The diagnosis of GHD in these individuals remains complex, and it is not clear which test most accurately reflects a state of GHD.

Growth Hormone Replacement in Adult Cancer Survivors

Long-term survivors of cancer who have been rendered GH deficient by multimodality cancer therapy exhibit a clinical picture identical to that of GH-deficient adults with primary hypothalamo-pituitary pathology, including increased fat mass; reduced lean body mass, strength, exercise tolerance, and bone mass; an adverse lipid profile; and impaired quality of life.^{98,99} The pattern of impairment of quality of life in GH-deficient adult cancer survivors is identical to that in patients with primary pituitary disease, the domain relating to vitality showing the greatest impairment.¹⁰⁰ The extent to which GHD contributes to the abnormalities observed in adult cancer survivors is difficult to disentangle from the direct effects of the primary tumor, treatment modalities used to induce remission, limited exercise, and poor nutritional status.

There are no data specific to the use of GH replacement during transition with radiation-induced GHD; however, it is intuitive to surmise that the beneficial effects of GH replacement in these individuals would be similar to those in hypopituitary adults with GHD of other etiologies.^{101,102} Before committing an individual who received childhood GH replacement for radiation-induced GHD to transitional GH replacement, it is essential to reassess the GH axis. This necessity is derived from the fact that all degrees of GHD are treated during childhood but only those patients with severe GHD qualify for treatment as an adult. Furthermore, the reproducibility of GH stimulation tests is poor, and reassessment of GH status in childhood brain tumor survivors shows that only about 60% retest as severely GHD after reaching final height.¹⁰³ GH doses used to treat adults with GHD during transition should be aimed at normalizing the IGF1 level, in contrast to the weight-based regimens used during childhood.¹⁰⁴

Low-dose GH replacement in adult GH-deficient survivors of childhood cancer leads to small improvements in body composition and serum lipids, a significant improvement in quality of life, and increased spinal bone mineral density.^{99,105} No data are yet available on the effect of GH on fracture rates in these individuals. Previous spinal irradiation impairs the osteo-anabolic effects of low-dose GH replacement on bone accretion.¹⁰⁵ Improvements in quality of life occur in all domains; however, as in patients with primary pituitary pathologies, the greatest improvement occurs in the domain of vitality.¹⁰⁰ In adult survivors of childhood cancer, the minor changes in body composition, lipid profile, and bone mass after GH replacement suggest

that GHD may not be a major etiological factor in their pathogenesis. The converse appears to be true for quality-of-life status in these individuals, and this should be the primary indication for initiation of GH replacement therapy.

Several lines of evidence suggest a link between the GH axis and development of various cancers. Epidemiologic data indicate a link between circulating serum IGF1 levels and both prostate cancer and premenopausal breast cancer. Those individuals with IGF1 values in the upper reaches of the normal range have an increased relative risk compared with those in the lowest quartile.^{106,107} Patients with active acromegaly show an increased risk of colonic polyps and carcinoma.¹⁰⁸ In vitro data indicate that GH and IGF1 promote leukemic blast cell replication.¹⁰⁹ Given these data, concerns regarding the potential of GH replacement to induce recurrence or increase relapse rates of patients in remission from malignant disease have been raised. Reassuringly, no increase in recurrence rates of childhood brain tumors or acute leukemias are observed with GH replacement therapy;^{29,31,110} and analysis by brain tumor subtype has shown no diagnostic subgroup to be at increased risk of recurrence.^{31,110} No trend in the relative risk of recurrence with cumulative duration of GH treatment is observed, adding further support for the safety of GH replacement in these individuals.²⁹ Residual abnormalities seen on computed tomography are not a contraindication to treatment in childhood brain tumor survivors.³¹ However, continued neurosurveillance imaging is warranted in these individuals, consequent on the limited power of studies to date.

Cranial Irradiation and Additional Anterior Pituitary Hormone Deficits

Although low-dose radiation therapy most frequently results in isolated GHD, damage to additional anterior pituitary hormone axes as a consequence of hypothalamo-pituitary irradiation is well recognized.^{55,111,112} As with children who develop GHD, the vulnerability to more extensive hypothalamo-pituitary dysfunction after irradiation during childhood is dependent on the patient's age at irradiation;^{47,53,84,113} time since treatment;^{38,82,114} radiation dose, fractionation, time allowed between fractions for tissue repair;^{32,35,36,38,43,82} and the margins of the irradiation field.³⁸

During adult life, gender, age at irradiation, and adjuvant chemotherapy do not predict development of hypopituitarism.⁸² The greater the radiation dose, the more likely the patient is to develop deficits and the earlier these deficiencies will occur.³² For example, when tumors of the pituitary gland or anatomically related lesions are treated during adult life, the 5-year cumulative risk of TSH deficiency increases from 10% to 52% with dose escalation from 20 Gy delivered in 8 fractions to 42 to 45 Gy delivered in 15 fractions (Fig. 43-3).³⁵ Modern radiation schedules typically do not use more than 2 Gy per fraction and no more than five fractions per week. An increase in fractionation size leads to relatively more injury to late-responding (neuronal) compared with early-responding (tumoral) tissues.¹¹⁵ Notably, the presence of a pituitary lesion or previous surgery in the region of the hypothalamo-pituitary axis increases susceptibility to radiation-induced damage because the axis may already be compromised to some extent.^{34,42,116} Overall, however, the relative frequencies of deficiencies affecting the various anterior pituitary hormones is similar to those observed after irradiation of pituitary tumors,^{33,34} with GH, gonadotropins, ACTH, and

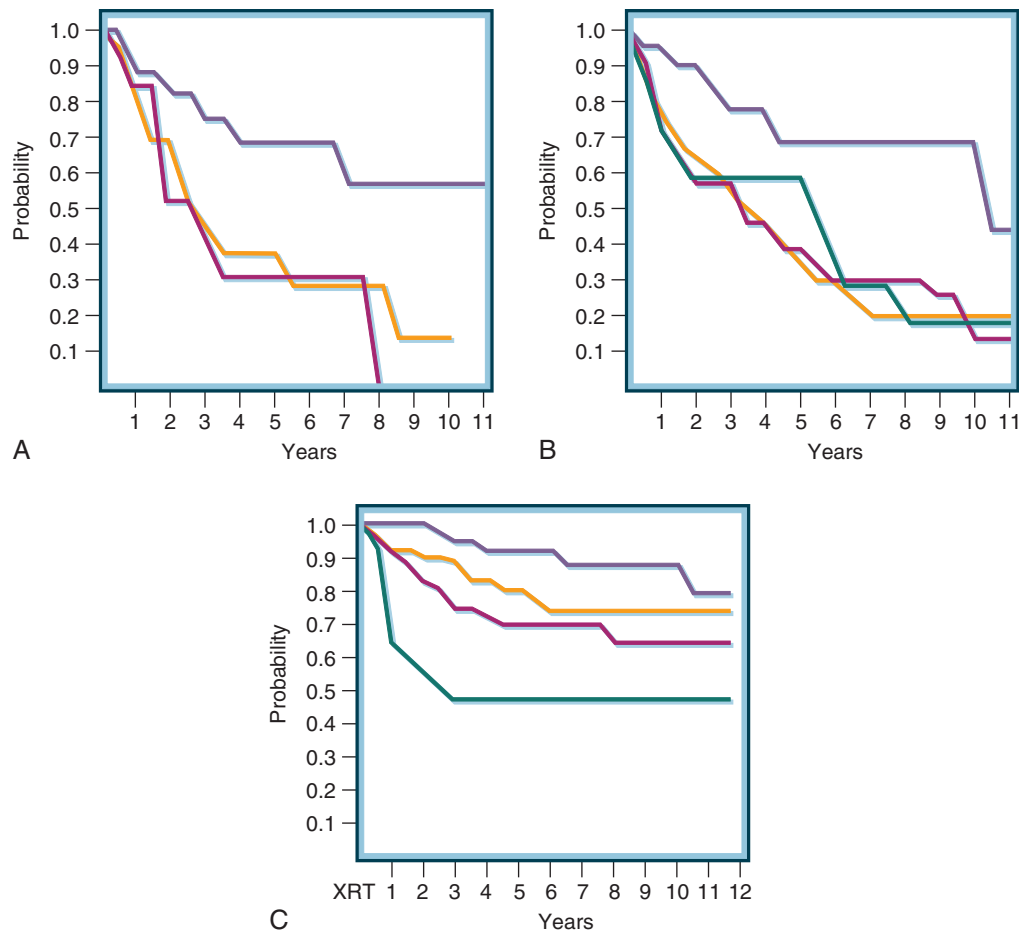

Figure 43-3 The probability that secretion of gonadotropin (A), adrenocorticotropin (ACTH) (B), and thyroid-stimulating hormone (TSH) (C) will remain normal up to 11 years after radiotherapy using three dosing regimens: 20 Gy in 8 fractions over 11 days, 35 to 37 Gy, or 40 Gy in 15 fractions over 21 days. Blue line = 20 Gy in 8 fractions; yellow line = 35-37 Gy in 15 fractions; pink line = 40 Gy in 15 fractions; and green line = 42-45 Gy in 15 fractions. (From Littley MD, Shalet SM, Beardwell CG, et al. Radiation-induced hypopituitarism is dose-dependent. *Clin Endocrinol (Oxf)*. 1989;31:363-373.)

TSH being affected in descending order of frequency (Fig. 43-4).

As with GHD, much of the data concerning irradiation-induced hypopituitarism characterized in adults results from the long-term sequelae of cranial irradiation administered during treatment of childhood cancers. Deficiency of the gonadotropins, ACTH, and TSH in adulthood after cranial irradiation of 18 to 25 Gy administered during treatment of childhood ALL occurs relatively infrequently. Radiation doses used in childhood for the treatment of CNS relapses of ALL, brain tumors, and soft tissue sarcomas of the head and neck (35 to 60 Gy) require closer observation for long-term pituitary hormone dysfunction.

Hypopituitarism resulting from irradiation used during adulthood to treat tumors anatomically distant from the pituitary gland is best exemplified by data derived from treatment of brain tumors⁸² and sinonasal carcinomas.^{33,117,118} Radiation doses used in treatment of these tumors are typically in excess of 40 to 50 Gy. After radiation therapy for sinonasal disease, deficiency of one or more pituitary hormones is reported to occur in 60% to 80% of individuals with long-term follow-up.^{33,38,43,117,119}

Gonadotropins

Gonadotropin deficiency after cranial irradiation occurs in a continuum from impaired LH or FSH responses to GnRH with maintenance of normal sex steroids to that of severe

deficiency of both gonadotropins and sex steroids. In the first year after irradiation of the hypothalamo-pituitary axis in men with nasopharyngeal carcinoma, a rise in basal and stimulated FSH is observed with no change in either LH or testosterone levels.^{33,75} After the first year, a progressive decline in both the FSH and LH occurs.^{33,75} Studies in humans and primates suggest that these changes reflect an initial decline in pulse frequency of hypothalamic GnRH, followed by a progressive reduction in GnRH pulse amplitude.^{120,121}

In the majority of cases where the gonadotropins have been affected by irradiation, levels continue to lie within the normal range. In men, this is usually accompanied by a testosterone level in the lower reaches of the normal range or only slightly below normal. In women, the failure of adequate pulsatile gonadotropin secretion leads to failure of egg development or ovulation, initially in intermittent cycles; oligomenorrhea ensues before the onset of amenorrhea and estrogen deficiency. Symptoms occurring as a consequence of gonadotropin deficiency frequently bring to attention the possibility of evolving hypopituitarism in individuals who are not undergoing regular endocrine screening.³⁸ In postmenopausal women, gonadotropin deficiency is asymptomatic and may be recognized only when biochemical studies show failure of physiologic elevation of these hormones. Care must be taken in assessing radiation-induced gonadotropin

Figure 43-4 Cumulative probability of retaining normal endocrine function after irradiation of the hypothalamo-pituitary axis during treatment of nasopharyngeal carcinoma. (From Lam KS, Tse VK, Wang C, et al. Effects of cranial irradiation on hypothalamic-pituitary function: a 5-year longitudinal study in patients with nasopharyngeal carcinoma. *Q J Med*. 1991;286:165-176.)

deficiency because of the not infrequent presence of concurrent hyperprolactinemia.^{33,38,81}

Gonadotropin deficiency is uncommon when radiation doses to the hypothalamo-pituitary axis are less than 40 Gy, but there is a remarkable increase in incidence after more intensive schedules. After irradiation for brain tumors^{42,44,82} (40 to 70 Gy) or nasopharyngeal carcinomas,^{33,36,119} gonadotropin deficiency is reported in approximately 30% of individuals 5 years after exposure. A similar proportion of women and men are affected.^{33,44} Repeated infusion of GnRH may induce LH and FSH pulsatility, suggesting predominantly hypothalamic damage and the prospect of restoring fecundity.¹²²

In addition to gonadotropin deficiency, cranial irradiation doses of less than 50 Gy can result in precocious or early puberty in children.^{21,123} Both genders are affected equally with radiation doses typically used in the treatment of brain tumors (25 to 50 Gy),²¹ whereas lower doses used for prophylaxis in the treatment of acute lymphocytic leukemia (18 to 25 Gy) result in a predominance of precocious puberty in girls.¹²⁴ A linear relationship between age at irradiation and age at onset of puberty is observed. The onset of puberty occurs at a mean of 8.51 years in girls and 9.21 years in boys plus 0.29 years for every year of age at irradiation.²¹ The mechanism responsible for early puberty is thought to result from disinhibition of cortical influences on the hypothalamus, which allows GnRH pulse frequency and amplitude to increase prematurely. It has been postulated that the cortical restraint on the onset of puberty is more easily disrupted in girls than in boys by any insult, including irradiation.

Adrenocorticotropin Hormone

Impaired cortisol reserve occurring as a consequence of ACTH deficiency is less common than either GH or

gonadotropin deficiency following irradiation of the hypothalamo-pituitary axis. When present, ACTH deficiency is a relatively late occurrence, and there is almost exclusively evidence of additional anterior pituitary hormone deficits.^{33,38,44} Occasionally, ACTH deficiency occurs before gonadotropin deficiency,³⁴ and in rare cases it is the first hormone deficiency to occur.³³ ACTH deficiency is uncommon with radiation doses less than 40 to 50 Gy¹²⁵ and virtually absent with doses of less than 24 Gy.^{52,126} After irradiation of brain tumors distant to the hypothalamo-pituitary axis in adult life, approximately 20% of patients are reported to be glucocorticoid deficient.^{42,82} The 5-year prevalence of biochemical ACTH deficiency after treatment of nasopharyngeal carcinomas occurs in up to 27% of patients, although many show borderline subnormal results.^{33,36,119}

Normal or slightly exaggerated cortisol responses to corticotropin-releasing hormone (CRH)⁴⁴ are also described after cranial irradiation for brain tumors. Individuals who retain normal cortisol response to stimulation show activation of the hypothalamo-pituitary-adrenal axis.¹²⁷ Integrated 24-hour cortisol levels and cortisol production rates are increased by 14% and 20%, respectively. Cortisol half-life, pulsatility, and diurnal rhythmicity are unchanged.¹²⁷ It is reasonable to assume that the increase in cortisol secretion reflects underlying activation of the CRH-ACTH axis. The pathophysiologic mechanism pertaining to these observations remains unclear, although it has been speculated that chronic stress or a local radiation-induced inflammatory response may play a role.

Thyroid-Stimulating Hormone

Central hypothyroidism is most classically represented by low free thyroid hormones in association with an inappropriately low TSH. In most cases, the TSH lies below or in the lower portion of the normal range. The infrequent contribution of immunoreactive but bioinactive TSH in irradiated individuals with central hypothyroidism can lead to TSH values that are in the upper reaches of normal or mildly elevated.¹²⁸

A delayed TSH response to TRH and a diminished nocturnal TSH surge are reported to occur in children, in adult survivors of childhood cancer, and in adults who have received cranial irradiation.^{38,75,81,129,130} These qualitative changes suggest dysfunction of the hypothalamic control of the thyroid axis. It has been proposed that they may represent a diagnosis of hidden central hypothyroidism and that TSH secretion may be compromised even before the somatotrophic axis.¹³⁰ Despite a relatively high proportion of individuals displaying these qualitatively abnormal TSH responses (approximately 30%) after cranial radiotherapy, levels of free thyroxine (T_4) are usually normal, and few individuals go on to develop overt secondary hypothyroidism.^{33,75} These latter observations suggest that the TSH anomalies are functional and do not represent hidden central hypothyroidism.¹²⁹ However, most patients who develop overt hypothyroidism do show a delayed or decreased TSH response to TRH. To date, there is no convincing evidence to support the routine use of the TRH test or assessment of the TSH surge to improve the diagnostic sensitivity and specificity of central hypothyroidism.

Deficiency of TSH occurs late, and infrequently within the first 2 to 3 years after radiotherapy, even when the hypothalamo-pituitary axis has been exposed to high-dose radiation.³³ The prevalence of central hypothyroidism in children undergoing cranial irradiation (35 to 45 Gy) for nonpituitary brain tumors is 3% to 6%,^{125,131} and it is

virtually zero after prophylactic cranial irradiation used to treat acute leukemia.¹³²⁻¹³⁴

In adults treated for sinonasal disease, the actuarial risk of clinical central hypothyroidism after irradiation (40 to 70 Gy) is approximately 3% at 5 years and 13% at 10 years¹³⁵; the risk of subclinical (biochemical) hypothyroidism is 9% at 5 years and 22% at 10 years.¹³⁵ Nine percent of adults irradiated with a median biologic effective dose (BED) of 54 Gy for nonpituitary brain tumors show biochemical evidence of central hypothyroidism 3 years after radiation therapy.⁸² A dose-dependent increase in the incidence of central hypothyroidism is observed over the dose range of 40 to 70 Gy.¹³⁵ There is no significant effect of dose fractionation, age, or gender on the development of TSH deficiency in irradiated adults.¹³⁵ Adjuvant chemotherapy does not predispose to development of radiation-induced central hypothyroidism.¹³⁵

Hyperprolactinemia

In adults, mild hyperprolactinemia is observed in a minority of patients after low-dose irradiation of the hypothalamo-pituitary axis.³⁵ When patients are exposed to the higher irradiation doses used in treatment of nasopharyngeal carcinoma and brain tumors, hyperprolactinemia is frequent.^{33,36,38,44,81,82} Prolactin levels are rarely elevated to more than three to four times the upper limit of the normal range.^{33,82} The pattern of development shows a gender dichotomy, being elevated in women but only infrequently in men,^{33,38,44} and it is more likely to occur after irradiation during adult cancer therapy than during childhood.^{44,50} The hyperprolactinemia not infrequently returns to baseline values over the next few years (Fig. 43-5). Symptomatic irradiation-induced hyperprolactinemia in women may lead to oligomenorrhea and galactorrhea.³³ Men are rarely symptomatic. Individuals with low serum prolactin levels, usually associated with panhypopituitarism, have also been described.⁸²

Figure 43-5 Mean serum prolactin concentration (mU/L) of adult men (●) and women (▲) with time after radiotherapy to the hypothalamo-pituitary axis. Error bars represent the standard error of the mean (\pm SEM). (Reproduced with permission from Little MD, Shalet SM, Beardwell CG, et al. Hypopituitarism following external radiotherapy for pituitary tumours in adults. *Q J Med.* 1989;70:145-160.)

GONADAL FUNCTION

Table 43-2 outlines the primary effects of multimodality cancer therapy on the reproductive system. Multimodality treatment regimens employed in the treatment of cancer damage the gonadal axis directly at the level of the gonad and centrally at the hypothalamus and pituitary, as previously discussed. Damage to the gonads and central structures are not mutually exclusive, and it is not uncommon for an individual who has received multimodality cancer therapy to have involvement at both levels. Damage to the gonads can occur from radiation exposure and cytotoxic chemotherapy. Irradiation of the gonads occurs during treatment of gonadal tumors, testicular relapses of hematologic malignancies, soft tissue sarcomas of the pelvis, TBI in preparation for bone marrow transplantation (BMT), and from scatter during spinal irradiation for certain brain and relapsed hematologic malignancies. Damage from cytotoxic chemotherapy is most frequently described after use of alkylating agents including cyclophosphamide, chlorambucil, and mustine; however, nitrosoureas, procarbazine, vinblastine, cytosine arabinoside, and cisplatin have also been incriminated.¹³⁶

In children, it has been suggested that the chances of maintaining or recovering gonadal function after multimodality cancer therapy are greater for girls than for boys.^{137,138} In unselected female childhood cancer survivors, 6% to 7% developed ovarian failure within 5 years after diagnosis. Of the patients with ovarian failure, more than 50% received ovarian irradiation in excess of 10 Gy.¹³⁹ Female 5-year childhood cancer survivors who continued to menstruate at age 21 years displayed a risk of entering the menopause fourfold greater than expected by age 21 to 25 years, and about 40% had entered the menopause by age 31 years (compared with 5% of the general population).¹⁴⁰ Independent risk factors for development of ovarian failure include increasing age, exposure to ovarian irradiation, and treatment with alkylating agents, particularly procarbazine or cyclophosphamide.^{139,140} The direct and synergistic effect of taxanes, tyrosine-kinase inhibitors, and monoclonal antibodies on gonadal function are not yet clear.

Male Gonadal Function and Cancer Therapy

Radiation and the Testis

The testis is one of the most radiosensitive tissues in the body. A dichotomy between damage to the germinal epithelium and damage to the Leydig cells is observed: very low doses of irradiation cause significant impairment of spermatogenesis, whereas sex hormone production is impaired only with high radiation doses. As a consequence, puberty typically progresses normally in children and secondary sexual characteristics are maintained in most adults who receive irradiation to the testis. Testicular volumes are small, reflecting damage to the germinal epithelium,¹²⁶ and should not be relied on for staging of puberty. In contrast to most other tissues, dose fractionation increases the degree of gonadal toxicity.

The effect of single-fraction low-dose radiotherapy on spermatogenesis is well documented (Fig. 43-6). The most immature cells, spermatogonia, are the most radiosensitive; doses as low as 0.1 Gy cause a significant reduction in sperm count and morphologic changes in the spermatozoa. Higher doses of 2 to 3 Gy are required to kill spermatocytes, resulting in a reduction in spermatid number. Doses of 4 to 6 Gy significantly reduce the number of

TABLE 43-2

Overview of the Effects of Multimodality Cancer Therapy on the Reproductive System of Cancer Survivors

Physiologic System	Insult	Pathology	Comments
Male reproductive system	Local XRT, spinal XRT, TBI	Oligospermia, azoospermia Subfertility, sterility Leydig cell insufficiency	Primary insult is to germ cells of testis—azoospermia occurring within 2 mo from doses as low as 2 Gy. Recovery occurs at mean of 30 mo after 2-3 Gy and >5yr after 4-6 Gy. ¹⁰ Impaired spermatogenesis leads to small testes, which should not be used to stage puberty. Leydig cell function is rarely compromised with doses <20 Gy. Puberty progresses normally, and secondary sexual characteristics are maintained despite subfertility.
Ovarian function	Local XRT, spinal XRT, TBI	Transient amenorrhea Premature ovarian failure Subfertility, sterility Estrogen deficiency	Insult reflects damage to a fixed pool of oocytes. Impact of XRT on ovarian function is age and dose dependent. ¹⁴ XRT doses >6 Gy result in premature menopause in women >40 yr of age; in younger women, a dose of 20 Gy leads to premature ovarian failure in only 50%. Recovery is infrequent, usually transient, and occurs almost exclusively in younger women. Concurrent estrogen deficiency results in failure of puberty to progress.
Uterine function	Pelvic XRT	Immature uterus Failure to carry a child	Irradiation (20-30 Gy) of the uterus during childhood results in impaired growth, reduced uterine blood flow, and failure of the endometrium to respond to estrogen and progesterone. The impact is greater with younger age at the time of XRT. With egg donation, the impaired uterine function reduces the likelihood of carrying a child through pregnancy.
Male reproductive system	Chemotherapy	Oligospermia, azoospermia Subfertility, sterility Leydig cell insufficiency	Gonadal toxic agents include the alkylating agents procarbazine, cisplatin, vinblastine, and cytosine. Damage depends on the cumulative dosage. Multiagent chemotherapy is usually more gonadotoxic than single-agent therapy. Primary insult is to the germ cells, with high-dose therapy additionally resulting in compensated hypogonadism. ¹⁸ Recovery frequently occurs, and its speed depends on the regimen administered.
Ovarian function	Chemotherapy	Transient amenorrhea Premature ovarian failure Subfertility, sterility Estrogen deficiency	Insult reflects damage to a fixed pool of oocytes. Ovarian toxicity occurs with agents similar to those that are toxic to testis. Impact of chemotherapy on ovarian function is dependent on age and cumulative dose. ²⁰ Recovery of ovarian function is frequently observed, but these individuals may undergo a premature menopause.

TBI, total-body irradiation; XRT, radiation therapy.

spermatozoa, implying direct damage to the spermatids.¹⁴¹ A fall in the number of spermatozoa is seen 60 to 70 days after damage to immature cells from radiation doses of up to 3Gy. At higher doses, the reduction in sperm count occurs earlier, reflecting damage to the spermatids. Doses of less than 0.8 Gy tend to result in transient oligospermia, and doses higher than 0.8 Gy cause azoospermia. At the doses discussed, recovery of spermatogenesis occurs with proliferation of surviving stem cells.

Complete recovery of the germinal epithelia and achievement of premorbid sperm counts occurs 9 to 18 months, 30 months, and 5 years or more after radiation doses of less than 1 Gy, 2 to 3 Gy, and more than 4 Gy, respectively.¹⁴¹⁻¹⁴³ The majority of testicular radiation exposure occurs as a consequence of fractionated irradiation, which is significantly more toxic to the germinal epithelium than single-dose irradiation. Fractionated radiotherapy doses of less than 0.2 Gy have no significant effect on

spermatogenesis. Doses of 0.2 to 0.7 Gy cause a dose-dependent increase in FSH and transient reduction in spermatogenesis that recovers within 12 to 24 months.¹⁴⁴ Doses of 2.0 to 3.0 Gy frequently result in azoospermia, with recovery of spermatogenesis often delayed for 10 years or longer.

At the radiation doses <10 Gy, Leydig cell function is relatively spared, and most patients have normal testosterone levels, albeit frequently at the cost of elevated LH levels. With time, the elevated LH level returns to normal. During adulthood, radiation doses of 20 to 30 Gy used to treat carcinoma in situ in the contralateral testis after unilateral orchidectomy result in overt Leydig cell insufficiency,¹⁴⁵ characterized by a fall in testosterone and a compensatory increase in LH levels. However, the fall in testosterone is not so great as to require replacement therapy in most adult patients. In contrast, there is a suggestion that individuals who undergo a similar treatment

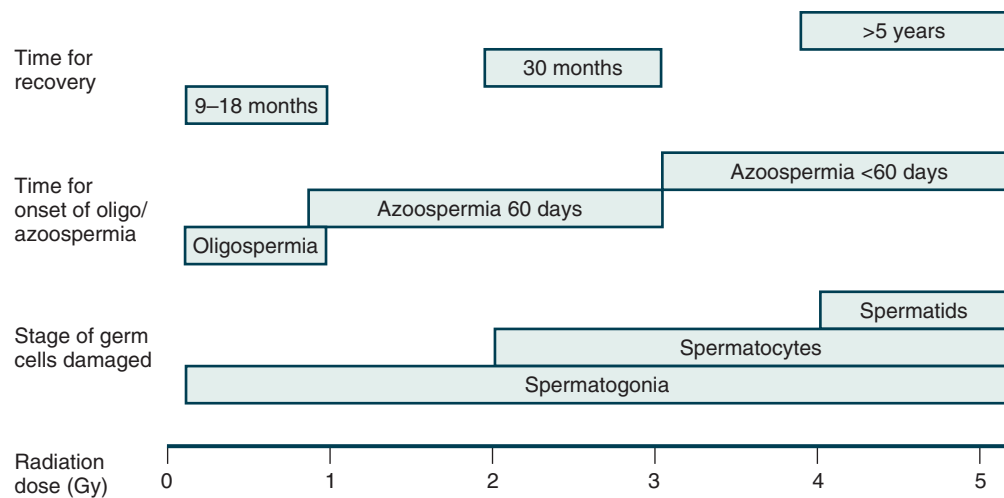

Figure 43-6 Impairment of spermatogenesis after single-dose radiation therapy: The effect of radiation dose on stage of germ cell damage and time to onset and recovery from germ cell damage. (Adapted from data of Rowley MJ, Leach DR, Warner GA, et al. Effect of graded doses of ionizing radiation on the human testis. *Radiat Res.* 1974;59:665-678; and Howell SJ, Shalet SM. Effect of cancer therapy on pituitary-testicular axis. *Int J Androl.* 2002;25:269-276.)

regimen for testicular cancer during childhood may be more vulnerable to Leydig cell damage and frequently require testosterone replacement as an adult. A radiation dose of 20 to 30 Gy completely ablates the germinal epithelium.

Chemotherapy and the Testis

The adverse impact of chemotherapeutic agents on the testis is directed primarily at the germinal epithelium, with evidence for Leydig cell dysfunction usually limited to a raised LH level with a normal or low-normal testosterone level.¹³⁶ The extent of damage and the potential for recovery of spermatogenesis depend on the chemotherapeutic agents used and the cumulative dosage.^{137,146} It has been suggested that the adult testis is more susceptible to damage than the prepubertal testis. However, few studies have suggested a relationship between age and risk of gonadal failure within adult patients.^{137,146} In general, combination chemotherapy is more toxic than treatment with single agents, and the induced azoospermia is less likely to recover.

Insight into testicular function after chemotherapy comes mainly from studies of cyclophosphamide and combination chemotherapy regimens used in the treatment of lymphoma and testicular tumors. Approximately 45% of men treated with cyclophosphamide as single-agent therapy show evidence of testicular dysfunction, with the incidence of gonadal dysfunction correlating with the cumulative dosage.¹³⁷ More than 80% of postpubertal men who received a total dose of more than 300 mg/kg showed evidence of testicular dysfunction.¹³⁷ The use of combination chemotherapy regimens incorporating alkylating agents such as MVPP (mustine, vinblastine, procarbazine, prednisolone) in the treatment of Hodgkin's disease renders almost all males azoospermic after the first cycle, and fewer than one quarter of them will have a normal sperm count 5 years after receiving six or more cycles.^{138,146-148} Alternate regimens consisting of nonalkylating chemotherapy (e.g., ABVD [doxorubicin, bleomycin, vinblastine, dacarbazine]) infrequently result in germinal epithelial failure, and if it does occur, recovery is relatively rapid.^{146,148} In the treatment of metastatic testicular cancer, despite the fact that most patients are rendered azoospermic after use of CVB (cisplatin, vinblastine, bleomycin), the outlook for fertility is relatively good, with 50% of men having a normal sperm

count 3 years later. In general, standard combination chemotherapy regimens used in the treatment of leukemia spare spermatogenesis in most individuals, with only 10% to 20% showing persistent gonadal damage.^{149,150} Newer regimens for the treatment of lymphoma and testicular tumors yield a better outlook for testicular function because of an absence of procarbazine and the lower doses of alkylating agents used.

Although subnormal testosterone levels (<7 nmol/L) are infrequent, there is irrefutable evidence for a more subtle impact of chemotherapy on Leydig cell function.¹⁵¹ The most frequent abnormalities of Leydig cell function are elevated basal and GnRH-stimulated LH levels in the setting of a normal or low-normal testosterone level. Physiologically, LH pulse amplitude is increased and pulse frequency remains unaltered. The compensatory increase in LH means that testosterone replacement is rarely necessary. Among men treated with high-dose chemotherapy for Hodgkin's disease, approximately 30% had an elevated LH level in association with a testosterone level in the lower half of the normal range or frankly subnormal, and a further 7% showed an isolated raised LH level.¹⁵¹ These biochemical abnormalities support the hypothesis that a significant proportion of men treated with cytotoxic chemotherapy have mild testosterone deficiency. Studies of testosterone replacement in these individuals with elevated LH and low-normal testosterone levels have failed to show significant benefits to date.¹⁵²

Preservation of Male Fertility and Sex Hormone Replacement

Discussions as to strategies for preservation of fertility need to be undertaken as early as possible before commencement of cancer therapy. At present, sperm banking is the only option for fertility preservation that is widely accepted and available for postpubertal men. All other techniques remain in the realm of research (Table 43-3).

Men who are at risk of azoospermia due to their impending treatment schedule can have sperm frozen for future use. This procedure is relatively simple and is part of standard practice, but it is of no value in prepubertal males. Sperm storage is most effective when the sperm concentration, motility, and morphology are not affected by the

TABLE 43-3

Methods of Preserving Fertility in Men and Women before Cancer Therapy.

	Current Clinical Practice	Experimental Procedures
Men	Sperm storage (ejaculation or electrical stimulation) Microsurgical aspiration Testicular biopsy	Germ cell cryopreservation Testicular tissue cryopreservation In vitro maturation of stem cells
Women	Embryo cryopreservation Oophoropexy	Oocyte cryopreservation Ovarian cortex cryopreservation Ovarian cryopreservation In vitro maturation of primordial follicles In vitro maturation of immature oocytes Ovarian transplantation (from monozygotic twin)

primary disease process. A significant proportion of men with lymphoma, leukemia, or testicular tumors are oligospermic or have impaired semen quality at presentation.¹⁵³⁻¹⁵⁵ For prepubertal boys, there has been interest in harvesting spermatogonial stem cells that can be frozen and stored for future use. Reimplantation of this tissue into the testis after attainment of remission from cancer and completion of puberty could theoretically result in restoration of spermatogenesis.^{156,157} In vitro maturation of spermatogonial stem cells is a further investigational methodology that has been examined in animals. Suppression of the gonadal axis with GnRH analogues before cancer therapy has been shown to result in gonadal protection in animal models,¹⁵⁸ but there is no convincing evidence to date for benefit in human males or females. After chemotherapy, an increase in genetic abnormalities is observed in the spermatozoa, but concerns regarding the potential transmissibility of genetic anomalies have not been substantiated.^{159,160}

Men with overt hypogonadism should have testosterone replacement instituted to improve body composition, prevent osteoporosis, and maintain sexual function and well-being.^{161,162} In pubertal boys who fail to progress through puberty due to overt testosterone deficiency,

testosterone replacement needs to be titrated to bring the individual through puberty and maintain body composition and well-being thereafter. In men with compensated hypogonadism secondary to cytotoxic chemotherapy, sexual function has been found to be impaired,¹⁶³ along with slight reduction in bone mass and subtle body composition changes.¹⁶⁴ It is unclear whether these changes are secondary to the mild Leydig cell insufficiency or to the primary tumor and its treatment. Testosterone replacement in these individuals has not resulted in significant improvement in bone mass, body composition, serum lipids, sexual function, or quality of life, with the exception of a reduction in physical fatigue and low-density lipoprotein (LDL) cholesterol.¹⁵²

Female Gonadal Function and Cancer Therapy

Radiation and the Female Reproductive Tract

The ovaries are irradiated as part of the management of pelvic tumors and lymphoma, during the spinal component of craniospinal irradiation, and during TBI preconditioning before BMT. The effect of irradiation and chemotherapy on the ovary can best be explained by loss of oocytes from a fixed population, which, once destroyed, cannot be replaced. The natural history of the healthy ovary is for oocyte number to fall exponentially with aging. Ovaries of older women are therefore much more sensitive to radiation-induced damage, and a dose of 6 Gy is liable to result in permanent menopause in women age 40 years or older. In contrast, it is estimated that 20 Gy over a 6-week period will result in permanent sterility in approximately 50% of younger women (Fig. 43-7).¹⁶⁵ Higher doses inevitably result in ovarian failure irrespective of age. In childhood, the median lethal dose (LD50) of the oocyte has been estimated to be 4 Gy,^{166,167} and this may manifest as failure to enter or complete puberty or, later in life, as premature menopause. Ovarian recovery after childhood irradiation has been reported, but it is often temporary, with the onset of secondary amenorrhea usually ensuing within a few years.

Pelvic irradiation during childhood that involves the uterus within the irradiation field leads to changes that result in failure to carry a child. In those patients who do conceive, the risk of miscarriage or a low-birth-weight

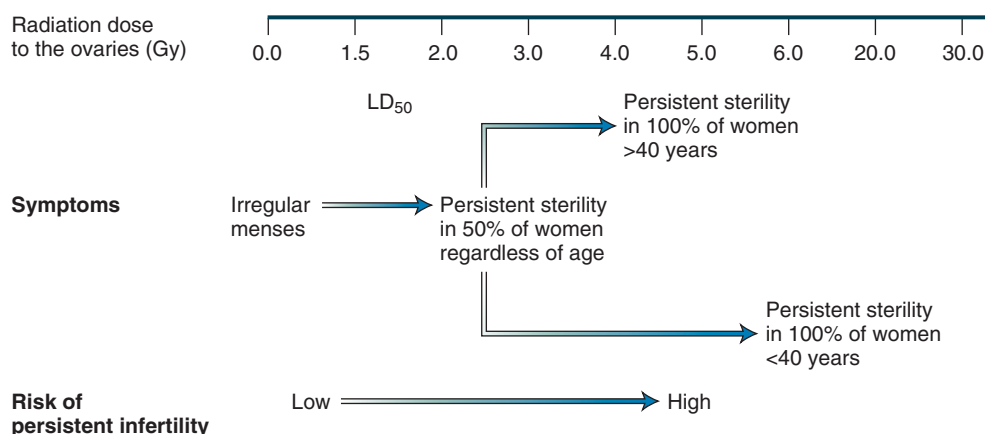

Figure 43-7 The relationship between radiation dosage to the ovaries and ovarian function. LD₅₀, lethal dose that will result in sterility in 50% of the tested group. (From Nakayama K, Milbourne A, Schover LR, et al. Gonadal failure after treatment of hematologic malignancies: from recognition to management for health-care providers. *Nat Clin Pract Oncol*. 2008;5:78-89.)

infant is greatly increased.¹⁶⁸ A radiation dose of 20 to 30 Gy during childhood leads to a reduction in adult uterine length and failure of the endometrium to respond to physiologic estrogen and progesterone therapy.¹⁶⁹ After irradiation, blood flow is reduced in the uterine arteries as assessed by Doppler ultrasound. An adequate blood flow is essential to uterine function, particularly endometrial proliferation, implantation, and successful continuation of pregnancy. It is unlikely that an adult woman who has received a significant radiation dose to the uterus during childhood would be able to carry a child to term. Uterine irradiation not only affects patients who retain normal ovarian function but also those who request in vitro fertilization with donor oocytes for concomitant ovarian failure.

Chemotherapy and the Ovary

Ovarian damage manifests clinically with amenorrhea with or without symptoms of estrogen deficiency or failure to progress through puberty. Hormonally, the gonadotropins may be grossly elevated with an unrecordable estradiol level, or there may be moderate elevation of the gonadotropins in association with a midfollicular estradiol level. As with radiation-induced ovarian damage, the susceptibility of the ovary to chemotherapeutic damage, the speed of onset of amenorrhea, and the potential for recovery depend on age and cumulative dosage.^{137,170} With increasing age, smaller doses of chemotherapy are required to induce ovarian failure.

In women with breast cancer treated with multiagent chemotherapy including cyclophosphamide, the average doses of cyclophosphamide that induce amenorrhea in women in their 20s, 30s, and 40s are 20.4, 9.3, and 5.2 g, respectively.¹⁷¹ Intuitively, prepubertal and pubertal girls would be assumed to be at lower risk of ovarian damage. However, clinical and morphologic studies reveal that they are not totally resistant to cytotoxic ovarian damage, although it occurs infrequently. After treatment of Hodgkin's disease with the alkylating combination chemotherapy regimens MVPP, MOPP (mustine, vincristine, procarbazine, prednisolone), or ChlVPP (chlorambucil, vinblastine, procarbazine, prednisolone), 15% to 62% of survivors developed amenorrhea.^{170,172,173} Among those older than 35 years, amenorrhea is almost invariable. In many, the onset is abrupt, but in others there is a progression to oligomenorrhea with later development of a premature menopause. In contrast, use of ABVD is much less gonadotoxic.¹⁷⁴ Treatment of acute leukemias with standard regimens results in persistent ovarian failure in fewer than 20% of survivors.^{139,175}

Assessment and Preservation of Female Fertility

Strategies aimed at prevention of gonadal damage have led to the use of chemotherapeutic regimens, such as ABVD for the treatment of Hodgkin's disease, that have equivalent cure rates but significantly less impact on gonadal function. However, there remains some risk to gonadal function with almost all cancer therapies, and discussions as to strategies for preservation of fertility need to be undertaken as early as possible in the management algorithm. At present, embryo cryopreservation provides the only option for fertility preservation in women that is widely accepted and available. All other techniques remain in the realm of research (see Table 43-3).

A large number of cytotoxic agents have been implicated as teratogenic to the fetus, and it is therefore important that during cancer therapy women use appropriate contraception until remission is achieved. No evidence of an increase in birth defects has been detected in women

who retain normal ovulatory cycles after having received cytotoxic chemotherapy and who spontaneously conceive. Recovery of ovarian function in amenorrheic women and the possibility of a premature menopause in women retaining a normal cycle are difficult to predict accurately after an insult to the gonads received during multimodality cancer therapy. The use of transvaginal ultrasound to accurately quantitate ovarian volume and antral follicle count, along with measurements of inhibin B and anti-müllerian hormone (AMH), have been proposed as guides to future reproductive potential after cancer therapy.^{176,177} Both inhibin B and AMH are secreted by granulosa cells, so their concentrations decline with the depletion of follicles. Further work is required to optimize the predictive models.

Preservation of fertility in women who are to undergo intense treatment that is likely to result in infertility is a significant growth area. Treatment of Hodgkin's disease frequently includes local irradiation of involved lymph nodes, including those along the iliac vessels. The ovaries lie adjacent to the iliac vessels and receive a dose of approximately 35 Gy, inevitably resulting in premature ovarian failure. Oophoropexy to remove the ovaries from the irradiation field, combined with shielding, can reduce the dose of radiation received by the ovaries to less than 6 Gy, thereby reducing the incidence of amenorrhea by approximately 50%.^{178,179} The exact reduction in risk of amenorrhea as a consequence of oophoropexy is controversial and needs to be assessed in the context of disease extent, patient age, and surgical expertise.

Both oocytes and embryos can be frozen. Embryo storage requires the patient to be in a stable relationship and to undergo controlled stimulation of the ovary for several weeks, along with regular ultrasonographic monitoring and aspiration of follicles. This technique is time-consuming when there is a pressing need to start treatment, is invasive, does not permit natural conception, and is not applicable to prepubertal girls. Pregnancy rates are approximately 15% to 30% per cycle with thawed embryos. Oocyte cryopreservation can be considered for patients without a partner; it requires stimulation of the ovaries for approximately 2 weeks before retrieval of the oocytes. It is associated with a success rate of less than 5% for thawed oocytes and therefore must be regarded as an experimental approach. Interest has been directed toward cryopreservation of ovarian cortical strips that are rich in primordial follicles; these are later thawed and grafted back into the patient at the original site (orthotopic) or elsewhere (heterotopic).^{180,181} This technique is available to both prepubertal and mature women. Several large centers are now storing ovarian strips, and to date there have been 13 live births in 10 women after orthotopicregrafting in women treated with cytotoxic therapy for cancer (n = 8) or benign disease (n = 2).^{182,183,183a} Concerns remain as to whether cancer cells may be transferred back to the recipient. Only time will tell if this technique improves the fertility prospects of women who undergo multimodality cancer therapy.

In women younger than 50 years of age who have developed gonadal failure, the impact is twofold: fertility and sex steroid production. Sex steroid replacement is recommended to alleviate symptoms of hot flashes, mood changes, and vaginal dryness and to prevent loss of bone mass.¹⁴⁵ The impact of sex steroid replacement on cardiovascular events remains controversial in patients younger than 50 years in light of recent data showing an increase in vascular events in postmenopausal women treated with hormone replacement therapy (HRT).^{184,185} Reassuringly, stratification of the Women's Health Initiative study data

by age revealed that the relative risk of cardiovascular disease was not increased in those aged 50 to 55 years.¹⁸⁶ The use of HRT in postmenopausal women has been associated with an increased risk of breast cancer.¹⁸⁴ It is probable that this latter risk equates to lifetime exposure to estrogens, so that continuing estrogen replacement until age 50 in these individuals should not convey an excess risk. Exposure of the breast to radiation scatter during mantle irradiation for Hodgkin's disease^{187,188} or TBI before BMT¹⁸⁹ is associated with an increased risk of breast cancer. Whether estrogen replacement further amplifies this risk is not known.

Radioiodine Therapy and the Gonadal Axis

Although the radioiodine doses used in treatment of hyperthyroidism have minimal, if any, effect on gonadal function, their effect on gonadal and reproductive function is an important consideration when treating differentiated thyroid carcinoma (DTC) because of the high-dose and often repeated administrations.

Transient absence of menstrual periods occurs in 8% to 27% of women during the first year after radioiodine therapy for DTC,^{190,191} particularly in women closer to the age of menopause. Several studies have reported increased rates of spontaneous and induced abortions during the first year after radioiodine therapy.¹⁹⁰ However, radioiodine treatment for DTC is not associated with a significantly increased risk of long-term infertility, miscarriage, induced abortions, stillbirths, neonatal mortality, or congenital defects.¹⁹⁰⁻¹⁹³ Women treated with radioiodine may experience their menopause at a slightly younger age than untreated women.^{190,193} There is otherwise little observational evidence to suggest important adverse effects of radioiodine treatment on gonadal function, fertility, or pregnancy outcomes beyond 12 months.

Doses of radioiodine used in the treatment of thyrotoxicosis in men result in only minimal and transient changes in the germinal epithelium and in Leydig cell function.¹⁹⁴ There is no significant variation in sperm concentration or percentage of normal forms. After therapy for DTC in men with single high-dose therapy, FSH levels frequently are increased at 6 months, after which a decline

is observed, with all subjects showing normal values by 18 months.¹⁹⁵⁻¹⁹⁸ Similarly, inhibin B levels fall significantly by 3 to 6 months after treatment but normalize by 18 months,¹⁹⁷ reflecting transient damage to spermatogenesis. Increases in LH are much less frequent and, when present, return to normal levels by 12 months.^{195,197} Testosterone levels remain normal. A greater proportion of patients experience elevated gonadotropins after cumulative radioiodine activities of greater than 14 GBq.¹⁹⁵ At these doses, short-term oligospermia is common,¹⁹⁵ but there is little evidence for long-term infertility.^{196,198}

PRIMARY THYROID DISEASE

The effects of multimodal cancer therapy on the thyroid are summarized in Table 43-4. Recognition of the adverse effects of head and neck irradiation, particularly secondary cancers, has led to the demise of radiation therapy in the treatment of benign diseases including acne vulgaris, goiter, tuberculous adenitis, thymic enlargement, and tonsillar hyperplasia. Use of low-dose (2 to 7 Gy) radiation therapy for benign disease was common in the United States from the 1930s through the 1950s. Since the 1960s, exposure of the thyroid and parathyroids to radiation has occurred almost exclusively during treatment of malignant disease, most commonly during neck irradiation for Hodgkin's disease and sinonasal carcinomas, craniospinal irradiation for certain brain tumors, TBI before BMT, and unavoidable scatter during treatment of primary brain tumors.

Thyroid tissue is among the most radiosensitive tissues in the body. After irradiation, the prevalence of both thyroid dysfunction and formation of thyroid nodules increases significantly.¹⁹⁹⁻²⁰¹ However, the absolute incidence of thyroid disorders after irradiation is not clearcut because of differences in radiation dose and schedules (duration and fractionation), previous thyroid surgery, volume of thyroid irradiated, duration of follow-up, definition of thyroid disorders ("clinical" versus "biochemical" hypothyroidism), and effects of adjuvant therapies.²⁰² This uncertainty was reflected in a survey of radiation oncologists, whose estimates of the risk of clinical

TABLE 43-4

Overview of the Effects of Multimodality Cancer Therapy on the Thyroid and Parathyroid Glands of Cancer Survivors

Physiologic System	Insult	Pathology	Comments
Thyroid nodules	Neck XRT or TBI	Malignant nodules	Risk is significantly increased after neck XRT (RR ~15). ²² Incidence increases from 5-10 yr after XRT. There is a possible "cell kill" effect at doses >30 Gy. ²³ Risk is significantly greater in children compared with adults and in females compared with males. ²³
		Benign nodules	There is increased prevalence of all benign thyroid disease. ²² Palpable nodules occur in 20-30% of patients who received neck XRT. Prevalence depends on time since XRT, female gender, and XRT dose.
Thyroid dysfunction	Neck XRT or TBI	Hypothyroidism	Frank or compensated hypothyroidism occurs in 20-30% of patients who received TBI and in 30-50% of those who received neck irradiation (30-50 Gy). ²² Hypothyroidism usually occurs within 5 yr after XRT. Thyroxine therapy should be instituted early because of the hypothesis that an elevated TSH may drive early thyroid cancers.
		Hyperthyroidism	Graves' disease is reported to occur at increased frequency (RR ~8). ²²
Parathyroid	Neck XRT	Late-onset hyperparathyroidism	Latency period is 25-47 yr. Dose dependency has been observed. ²⁴

RR, relative risk; TBI, total-body irradiation; TSH, thyroid-stimulating hormone; XRT, radiation therapy.

hypothyroidism after administration of 50 Gy to the whole thyroid ranged from 2% and 50%.²⁰³ Radiation damage to the thyroid is proposed to result from direct thyroid cell injury, immune-mediated damage, and damage to small thyroid arterioles.²⁰²

Thyroid Dysfunction

Hypothyroidism

The first reports of development of hypothyroidism as a consequence of irradiation for head and neck cancers were published in the 1960s.^{204,205} Hypothyroidism is the most common late sequela of irradiation of the thyroid, and it may be overt or subclinical. Neck irradiation for treatment of adult sinonasal disease results in a 5-year actuarial risk of 32% for clinical and 29% for subclinical primary hypothyroidism,¹³⁵ with little change in prevalence thereafter (Fig. 43-8).¹³⁵ In the long term, biochemical evidence for primary hypothyroidism is present in up to 60% of patients who received high-dose radiation (30-70 Gy) to the neck for sinonasal disease or Hodgkin's lymphoma.^{119,201,202,206-210} A similar incidence is observed after craniospinal irradiation for primary brain tumors during childhood.⁴⁴ Even though the thyroid does not lie directly within the field of irradiation administered during cranial irradiation for brain tumors, there is an increased incidence of subsequent hypothyroidism.²¹¹

At least half of the cases of hypothyroidism occur within the first 5 years after radiation,^{201,206,209,210,212,213} with a peak incidence between 2 and 3 years.^{206,209,210,212,213} However, the latency period may be prolonged.^{200,201} A dose-dependent increase is observed in the incidence of clinical primary hypothyroidism.^{135,201,210,212,214} Dose is inversely associated with the latency period to the development of thyroid dysfunction,²¹² and hypothyroidism can occur within the first 6 months after high-dose therapy.²⁰⁶ Fractionation of the dose has minimal impact on development of hypothyroidism, in contrast to its effect on other radiosensitive organs.²⁰⁶ Up to 20% of patients with subclinical hypothyroidism show improvement or resolution of elevated TSH levels.^{211,212}

Figure 43-8 Probability of remaining free from hypothyroidism after irradiation therapy during treatment of extracranial head and neck malignancies. Patients are divided according to the radiation dosage received to the neck. (Reprinted with permission from Bhandare N, Kennedy L, Malyapa RS, et al. Primary and central hypothyroidism after radiotherapy for head-and-neck tumors. *Int J Rad Onc Biol Phys*. 2007;68:1131-1139.)

Among adults exposed to neck irradiation, no effect of age^{135,207,209,215} or gender^{207,209,214,215} on the development of thyroid dysfunction is observed. A higher proportion of individuals irradiated in childhood develop thyroid dysfunction compared with those irradiated during adult life.^{208,214} Among those irradiated in childhood, an inverse relationship is observed between age at irradiation and the development of hypothyroidism.^{201,213,216} The risk of developing primary hypothyroidism is dependent on the proportion of the gland exposed to irradiation, with primary hypothyroidism occurring infrequently when less than 50% of the gland is irradiated.^{135,214} In keeping with this latter observation, hypothyroidism is more common in patients who have undergone a surgical hemithyroidectomy as part of their cancer therapy before irradiation.^{217,218}

Treatment of both subclinical and overt hypothyroidism should be undertaken early with levothyroxine to reduce TSH to the low-normal range. Most patients presenting with subclinical hypothyroidism progress to overt hypothyroidism with time, so early intervention is warranted. Furthermore, even mildly elevated TSH values may convey an elevated risk of both benign and malignant thyroid nodules in the irradiated thyroid,²¹⁹ and this risk can be abrogated by levothyroxine replacement. Use of levothyroxine to suppress TSH before irradiation has been proposed as a potential method to reduce thyroid cell turnover and thereby ameliorate irradiation-induced thyroid damage, but this strategy has not proved to be efficacious.²²⁰

Hyperthyroidism

In addition to hypothyroidism, Graves' disease,^{210,221} Graves' ophthalmopathy,^{199,210,221} and thyroiditis^{200,210} occur with increased prevalence after neck irradiation. The relative risk of hyperthyroidism after neck irradiation is increased 5- to 20-fold^{201,210,221} and shows a temporal distribution similar to that of radiation-induced hypothyroidism.^{201,210} The actuarial risk of Graves' disease equates to 2% to 3% at 10 years after irradiation.^{210,221} Radiation-induced hyperthyroidism is dose dependent,²⁰¹ with the prevalence increasing with time since treatment.²⁰¹ Age at irradiation and gender have no effect on development of Graves' disease.²¹⁰ Graves' ophthalmopathy occurring after head and neck irradiation is indistinguishable clinically from that occurring in nonirradiated individuals,²²¹ and it may occur both in the euthyroid and the hyperthyroid state.²¹⁰

Effects of Chemotherapy

Although adjuvant chemotherapy has been suggested to cause thyroid dysfunction or influence development of hypothyroidism after irradiation,^{210,211,213} this has not been conclusively demonstrated.^{135,201,207,209,211,215} Both interferon and interleukin-2 increase the risk of developing autoimmune hypothyroidism.^{222,223} This condition is usually transient, although a small proportion of patients remain hypothyroid in the long term. A number of chemotherapeutic agents affect thyroid function tests by modulating thyroid hormone binding. 5-Fluorouracil increases total triiodothyronine (T₃) and T₄, but patients remain euthyroid with normal TSH and free T₄ levels; asparaginase decreases production of hepatic thyroid-binding globulin (TBG) and total T₄ levels through its widespread effects on protein and DNA synthesis.

Thyroid Nodules

In 1950, Duffy and Fitzgerald raised the possibility that irradiation of the thymus gland during infancy was an

etiological factor in the future development of thyroid carcinoma. In their series, 9 of 28 children with thyroid carcinoma had been exposed to low-dose neck radiation.²²⁴ Since that time, a number of epidemiologic studies have conclusively established an association between exposure to external irradiation of the thyroid and development of both benign thyroid neoplasia and DTC.^{188,225-228} Occurrence of radiation-induced thyroid nodules is uncommon during the first 5 years after exposure, with the peak incidence of excess risk occurring 15 to 20 years after radiotherapy.^{201,225,227,229} Twenty years after exposure, the excess relative risk decreases, but the excess absolute risk continues to increase for at least 40 years.²²⁶

The dose-response relationship approximates linearity from 0.1 Gy to a few gray,²²⁵ with the relative risk per gray for both carcinoma and adenoma being about fourfold to eightfold.²²⁵ Risk increases with higher doses, but at a more gradual rate. Early data suggested that the risk of developing thyroid cancer was linearly associated with dose, but more recent data confirm this to be true only for radiation doses up to 20 to 29 Gy (Fig. 43-9).²³⁰ At doses greater than 30 Gy, a fall in the dose response is observed, consistent with a cell-killing effect of radiation at high doses.²³⁰ The cumulative risk in individuals receiving greater than 5 Gy is estimated to be 4% to 6% at 25 to 30 years,^{225,227} with the relative risk calculated to be 15- to 50-fold that of the nonirradiated population.^{188,202,227} In contrast to its impact in other radiosensitive endocrine glands, fractionation of the dose seems to have little effect on reducing the incidence of nodules.²²⁵ The use of adjuvant chemotherapy has yet to be shown to have an independent effect or demonstrable influence on the incidence of radiation-induced nodules.^{225,227,230} A gender dimorphism is observed and is similar to that for spontaneous tumors in nonirradiated individuals.

Tumor development is significantly greater when irradiation occurs at a younger age,^{227,230-232} reflecting the greater susceptibility of growing tissues to irradiation-induced damage. When exposure occurs during treatment of childhood malignancy, the risk of developing thyroid carcinoma is greater in those with a primary diagnosis of neuroblastoma or Wilms' tumor,²²⁷ suggesting an underlying predisposition to tumor development in these individuals.

Figure 43-9 Thyroid cancer risk by radiation dose according to age at diagnosis of first cancer. (From Sigurdson AJ, Ronckers CM, Mertens AC, et al. Primary thyroid cancer after a first tumour in childhood (the Childhood Cancer Survivor Study): a nested case-control study. *Lancet*. 2005;365:2014-2023.)

Approximately two thirds of thyroid nodules occurring after irradiation are benign, and one third are malignant. The distribution of thyroid carcinoma histologic subtypes after irradiation is not dissimilar to that observed in the general population, with the majority being papillary and a lesser proportion being follicular carcinomas.^{201,225-227,229} These radiation-induced tumors do not seem to act differently from spontaneous tumors,^{232,233} although regional lymph node metastasis is reported to occur at a higher frequency (up to 30%) than in nonirradiated individuals.^{226,229} A number of *RET/PTC* gene rearrangements have been shown to be more frequent in radiation-induced thyroid tumors.^{234,235}

The use of routine ultrasound scans to monitor the thyroid of patients who have received neck irradiation remains controversial. Thyroid ultrasonography may be an overly sensitive screening tool because of its low specificity, in that the clinical relevance of lesions detected is unclear.²³⁶ To place this in perspective, results of thyroid ultrasonography in children undergoing radiation therapy for Hodgkin's disease were reported to be abnormal in all cases, with focal lesions in more than 40% of the patients.²³⁷ Once palpable or ultrasound-characterized thyroid nodules are elucidated, fine-needle aspiration for cytology should be performed. However, cytologic evaluation may prove difficult because of the presence of radiation-induced cellular atypia.²³⁸ For that reason, there should be a low threshold for undertaking a diagnostic lobectomy.

HYPERPARATHYROIDISM

Early studies of the effects of irradiation in animal models revealed parathyroid tumors to occur in 8% of irradiated rats compared with 0% of nonirradiated control rats.²³⁹ A putative association between radiation and development of hyperparathyroidism in humans was first hypothesized in 1975 by Rosen and colleagues, who described the development of radiation dermatitis, a sublingual salivary gland pleomorphic adenoma, and hyperparathyroidism in a young woman treated with face and neck irradiation for hirsutism.²⁴⁰ A number of series followed in which low-dose radiation used in treatment of benign conditions was correlated with the occurrence of hyperparathyroidism. In studies from the late 1970s and early 1980s, the prevalence of previous low-dose (<8 Gy) head and neck radiation in patients diagnosed with surgically proven or biochemical hyperparathyroidism was found to be significantly higher (11% to 30%) than in control populations without hyperparathyroidism (0% to 8%).²⁴¹⁻²⁴⁵ Further studies are unlikely to be able to confirm this observation because of the reduced use of low-dose radiation therapy for treatment of benign disease since the 1950s.

In patients who have received low-dose neck irradiation, the prevalence of hyperparathyroidism is 1% to 11%, significantly greater than that in background population data and matched control groups.^{241,246-248} The relative risk of hyperparathyroidism increases by 0.11 per cGy.²⁴⁸ The presence of a relationship between radiation dose and development of hyperparathyroidism supports the previous observational data of a causal association. Radiation-induced hyperparathyroidism follows a benign and indolent course, with many patients remaining clinically asymptomatic.^{241,244}

The majority of studies have considered radiation therapy administered during childhood or adolescence. Middle-aged individuals who receive low-dose irradiation to the neck show a prevalence of hyperparathyroidism of

less than 5% when assessed 25 years later, and most do not require operative intervention.²⁴⁹ Few robust data are available regarding the occurrence of hyperparathyroidism after high-dose neck irradiation used in treatment of malignant diseases, although an association has been described.^{250,251} In those individuals who developed hyperparathyroidism, the estimated radiation dose at the thyroid was only 0.9 to 13.2 Gy. It has been hypothesized that a “cell kill” effect of higher radiation doses may prevent development of hyperparathyroidism. Monitoring of calcium and parathyroid hormone (PTH) levels during the first 36 months after high-dose neck irradiation showed increasing PTH levels in the setting of normal calcium levels²⁵² without development of hyperparathyroidism.

The latency period from low-dose irradiation to the development of hyperparathyroidism is prolonged, and although cases have been reported as early as 5 years after irradiation, most cases occur 24 to 45 years later.^{226,241-243,246,247,253} A longer latency period has been suggested to occur in younger individuals,^{243,250} although age at irradiation does not significantly affect the overall incidence of hyperparathyroidism.^{246,248} In nonirradiated populations, there is a gender dichotomy, with females showing a higher incidence of hyperparathyroidism. This dichotomy holds true for irradiated individuals, and a similar gender distribution²⁴¹ and relative risk of radiation-induced hyperparathyroidism is present in males and females.²⁴⁶

Irradiation-induced hyperparathyroidism may be the result of either adenoma or hyperplasia. Single adenomas are about two times as frequent as hyperplasia and multiple gland involvement.^{226,243,245,248} Histologic studies usually confirm a predominance of chief cells,^{244,245} but cases with a high proportion of oxyphil cells have been described in hyperfunctioning adenoma and hyperplasia.^{244,245} This latter observation is difficult to reconcile, because oxyphil cells are generally held to be nonfunctioning. Although cases of parathyroid carcinoma occurring after neck irradiation have been described,²⁵³ they are infrequent and were not observed in the larger series.^{241,242}

The frequency of synchronous benign nodules or non-medullary carcinoma of the thyroid is at least twofold to threefold increased in individuals with irradiation-induced hyperparathyroidism compared with nonirradiated patients.^{226,244,246,247,253-255} The association between radiation-induced thyroid damage and parathyroid disease is likely a consequence of the sensitivity of both endocrine organs to irradiation; however, a genetic predisposition to radiation-induced tumorigenesis cannot be excluded.

The effects of multimodal cancer therapy on the parathyroid glands are summarized in Table 43-4.

THE METABOLIC SYNDROME AND VASCULAR RISK

Epidemiologic data show childhood cancer survivors to have excess morbidity and mortality for at least 10 to 15 years, with those surviving longer than 5 years having an approximately 10-fold excess mortality.^{256,257} After exclusion of deaths relating to recurrence or progression of the primary tumor, mortality rates remain elevated, with a standardized mortality rate for cardiac and cerebrovascular disease increased fivefold to eightfold.^{256,257} An increased risk of late-occurring stroke is observed among childhood survivors of Hodgkin's disease, leukemia, and brain tumors, compared with sibling controls,^{258,259} with the relative risks estimated at 4.3, 6.4, and 29.0, respectively.^{258,259}

Examination of demographic and treatment variables reveals the excess vascular disease to be highest in patients who received chest and spinal irradiation²⁵⁶ or anthracycline therapy.²⁶⁰ The relative importance of these mechanisms in placing childhood survivors of cancer at increased risk of vascular disease is unclear. Abnormalities of left ventricular function are observed in individuals treated with anthracyclines,^{89,91,261,262} with total cumulative dose being the most significant risk factor for anthracycline late-onset cardiomyopathy.^{89,91,261} Anthracycline cardiac toxicity fails to explain the increased vascular morbidity in patients who do not receive this class of drug.

Derangements in both traditional and nontraditional cardiovascular risk factors, consistent with the metabolic syndrome, are prevalent in childhood cancer survivors and can be proposed to have a putative role in predisposition to atherothrombosis. Abnormalities of body composition in childhood survivors of cancer are well documented. The prevalence of obesity is significantly increased,²⁶³⁻²⁶⁸ with the excess fat mass located predominantly in the central compartment.²⁶⁹ During childhood, obesity is observed to develop between treatment and achievement of final height,^{264,270,271} and cranial irradiation has been implicated in its development.²⁷¹ The greatest degree of obesity is observed in those individuals who were treated at the youngest ages.²⁶⁴

Fasting glucose and insulin are elevated in long-term survivors of childhood cancer²⁶⁷ and in those who underwent BMT during childhood.²⁷² Prospective data concerning glucose tolerance showed the recorded frequency of hyperinsulinemia, impaired glucose tolerance, and diabetes to be significantly elevated at 18%.²⁷³ Dyslipidemia is an important determinant of vascular disease. Childhood cancer survivors show adverse lipid profiles characterized by increased LDL-cholesterol, apolipoprotein-B, and triglycerides; decreased high-density lipoprotein (HDL)-cholesterol; and increased ratio of total cholesterol to HDL-cholesterol.^{267,269,272} Blood pressure abnormalities have also been reported in survivors of childhood cancers (brain tumors) in some²⁶⁹ but not all studies.^{266,267,273} Insulin resistance in cancer survivors is associated with obesity, subnormal HDL levels, and hypertriglyceridemia, consistent with a diagnosis of metabolic syndrome.

Nontraditional risk factors, including von Willebrand factor (vWf), plasminogen activator inhibitor-1 (PAI-1), and C-reactive protein (CRP) plasma levels, are elevated in cancer survivors,²⁷⁴ but data in this area are limited and concrete conclusions cannot be made. Direct confirmation of premature vascular disease can be acquired from imaging of the great arteries. In studies of young adult survivors of Hodgkin's disease who received neck irradiation, the incidence of abnormal carotid scans (26% versus 3%), and specifically carotid intima medial thickness (IMT), were increased compared with control subjects.²⁷⁵ Long-term survivors of childhood brain tumors also show an increased IMT of the carotid bulb.²⁶⁹

BONE MARROW TRANSPLANTATION

Survival from childhood and adult hematologic malignancies has been improved by development of effective procedures for BMT, which is used primarily to treat poor-prognosis and relapsed leukemias, lymphoma, and myeloma. BMT encompasses allogeneic and autologous transplantation of stem cells from the bone marrow or peripheral blood. The complex treatment regimens employed before and during BMT to achieve such remarkable cure rates entails the use

of combination chemotherapy (frequently encompassing high-dose alkylating agents), TBI, and immunosuppressive agents. The relative frequency of occurrence of long-term adverse sequelae from these regimens is greater than might be predicted from the individual components, suggesting synergism between the toxic effects of these treatment modalities on normal tissues.

Growth and Growth Hormone

Children who received TBI as part of the preparative regimen showed significant impairment of height velocity and height SDS.²⁷⁶⁻²⁸¹ Interpretation of the effect of TBI on height velocity is complicated by the frequent concomitant use of cranial irradiation before progression to BMT.^{280,282} Both height and height velocity are impaired to a greater extent by the combination of cranial irradiation and TBI compared with TBI alone.^{277,279-281} Single-fraction TBI (sTBI) leads to greater impairment of growth than if TBI is fractionated (fTBI).^{277,278,283} The adverse effect of TBI on growth is demonstrable within the first year after BMT in patients who additionally received cranial irradiation, but in the absence of cranial irradiation it may be delayed by several years.²⁷⁹ Mean relative changes in height SDS between BMT and final height of children who received both cranial irradiation and sTBI, sTBI alone, fTBI, or no irradiation were -2.0, -1.4, -0.9, and -0.1, respectively.²⁸⁴ The degree of height loss caused by TBI is greater when the radiation is administered at a younger age.^{280,281}

TBI, in the absence of cranial radiation, results in GH insufficiency (peak stimulated GH level, <6.7 µg/L [<20 mU/L]) in 7% to 66% of recipients of childhood BMT; when only those children with growth failure are assessed, 60% to 95% are found to be GH insufficient.^{52,276-279,282,285,286} The wide range of prevalence of GH insufficiency results from significant differences in study designs and patient populations. Evidence from comparison of the effects of sTBI and fTBI suggests that fractionation of the radiation dose reduces the risk of developing GH insufficiency.²⁷⁸ In the setting of impaired GH secretion secondary to TBI, GH replacement therapy significantly improves height velocity.^{277,279,287} In contrast to observations in children, the radiation dosage employed during TBI (10 to 13.2 Gy) before BMT has not been shown to cause GHD when delivered during adult life.¹²⁶

There are a number of skeletal sequelae in addition to reduced final height that may be present in the adult survivor of childhood BMT. Spinal disproportion has been reported to occur as a consequence of TBI received during childhood,^{282,287} suggesting a greater inhibitory effect of TBI on the spine compared with the long bones. Spinal irradiation, corticosteroid therapy, sex steroid deficiency, and childhood GH insufficiency^{105,288} are associated with reduced bone acquisition during childhood. There are no data on peak bone mass in adult survivors of childhood BMT, although the impaired bone acquisition is likely to result in lower than genetic peak bone mass, in the long term placing these individuals at risk for osteoporosis and fragility fractures. In young adult recipients of BMT, bone mineral density is transiently reduced at the spine and hip, but this tends to improve over the subsequent 2 years.²⁸⁹

Hypopituitarism

Although there is a large amount of available data concerning the GH axis after childhood BMT, there are far fewer data on the other anterior pituitary axes. Abnormalities of the cortisol axis were reported in up to 24% of patients as

assessed by the metyrapone test; however, all of the patients were asymptomatic.²⁸³ This finding probably reflects the characteristics of the test employed, which is plagued by false-positive results even in normal, healthy individuals. When assessed by ITT, the cortisol axis is found to be normal in all^{276,278,279} or almost all patients.^{52,285} When cortisol responses were found to be subnormal, the patients either had been taking or had recently taken corticosteroids for graft-versus-host disease.²⁸⁵ If present, cortisol deficiency usually manifests late (5 to 10 years after irradiation).

The true prevalence of cortisol deficiency in adult long-term survivors of malignancy who underwent BMT during childhood is unclear. There are few data concerning prolactin levels in recipients of BMT, but elevated levels are usually infrequent, mild, and asymptomatic.^{52,126} TBI (10 to 13.2 Gy) before BMT delivered during adult life has not been shown to cause hypopituitarism.¹²⁶

Primary Thyroid Disorders

Thyroid function is abnormal in a significant percentage of childhood and adult survivors of BMT. As with GH insufficiency, there is a wide range of prevalence of thyroid dysfunction after childhood TBI (5% to 43%).^{52,276,278,279,282,283,286} Subclinical hypothyroidism is much more frequently observed than overt hypothyroidism.^{126,290} Thyroiditis and hyperthyroidism have also been described to occur after exposure of the thyroid to TBI.^{290,291} Thyroid dysfunction develops more frequently in patients who received sTBI than in those who received fTBI;^{52,282,285} and it is more frequent in patients who received BMT at a younger age.²⁹⁰ Although the frequency of abnormal thyroid function tests is relatively high, transient increases in TSH that resolve during follow-up are relatively common.^{282,285,290}

Where the thyroid has been exposed to radiation, it is at greater risk for development of both benign thyroid nodules and carcinoma.²²⁵⁻²²⁷ The standard incidence ratio (SIR) for development of thyroid carcinoma after BMT with TBI preconditioning is sevenfold to eightfold higher than in the general population, and the risk is significantly greater when irradiation occurs at a younger age (Fig. 43-10).^{292,293} The latency period from BMT to diagnosis of thyroid carcinoma is usually in excess of 5 years, but cases have been reported within the first few years after TBI.²⁹²⁻²⁹⁴ Almost all cases manifest subclinically.²⁹⁴ Histologically, most of these thyroid carcinomas are papillary, with the remainder being follicular.^{292,294}

TSH is a trophic factor for thyroid cell growth, and in established DTC suppression of TSH with levothyroxine reduces recurrence and mortality rates. In patients who have received TBI, the elevated TSH in subclinical hypothyroidism is thought to be an etiologic factor in the development of thyroid carcinoma; therefore, it is recommended that these patients receive levothyroxine replacement. Given the potential transient nature of subclinical hypothyroidism after BMT, a significant proportion of patients will be able to discontinue the levothyroxine at a later date. There are no data on the success of levothyroxine withdrawal after earlier treatment of subclinical hypothyroidism resulting from TBI.

Gonadal Failure

The ovaries are exquisitely sensitive to radiation damage. TBI (10 to 15 Gy) used in combination with gonadotoxic chemotherapy almost invariably results in ovarian failure (Fig. 43-11).^{52,126,295} Ovarian failure during childhood results

Figure 43-10 A, Cumulative incidence of thyroid cancer after hematopoietic stem cell transplantation (HSCT). **B,** Cumulative incidence of thyroid cancer by age at the time of HSCT. (From Cohen A, Rovelli A, Merlo DF, et al. Risk for secondary thyroid carcinoma after hematopoietic stem-cell transplantation: an EBMT Late Effects Working Party Study. *J Clin Oncol*. 2007;25:2449-2454.)

in either delayed or failed progression through puberty^{276,283} and renders almost all postpubertal women amenorrheic.^{283,295} Characteristically, gonadotropin levels are elevated and estradiol levels are low.^{52,276,282,283} Short-term ovarian recovery is recognized to occur during the first few years after regimens inclusive of TBI (see Fig. 43-11).²⁹⁵ Recovery occurs in at least 50% of prepubertal girls who receive high-dose chemotherapy and hyperfractionated TBI, allowing progression of puberty and spontaneous menstruation.^{296,297} With advancing age at treatment, recovery is increasingly infrequent.²⁹⁵ Rarely, ovarian recovery occurs after a significant period of amenorrhea. It has been suggested that fTBI may be less damaging to the ovaries than sTBI.²⁸⁵ Female survivors of BMT during adolescence or young adult life experience significant symptoms of estrogen deficiency including hot flashes, night sweats, and vaginal dryness.²⁹⁸ They additionally express concerns over infertility, amenorrhea, and femininity. Libido is impaired in most of these patients, and coitus becomes painful with orgasm difficult to achieve.^{298,299} The consequence of direct radiation damage to the uterus and estrogen deficiency results in poor development of the uterus, which may not enlarge appropriately in response to estrogen replacement therapy.²⁷⁶

Estrogen replacement therapy significantly improves the symptoms of estrogen deficiency in the majority of hypogonadal young women,²⁵ and it should also be considered to maintain bone mass and potentially improve long-term vascular outcomes. There are no comparative data on sexual health in survivors of childhood BMT taking estrogen replacement therapy compared with normal individuals. Breast cancer risk is elevated in survivors of BMT (SIR, 2.2), the risk increasing with duration of survival, younger age at transplantation, and TBI.¹⁸⁹ There are no data on whether estrogen replacement further elevates the risk of breast cancer. Intuitively, it is appropriate to replace estrogen to physiologic levels, which would be unlikely to increase the risk beyond that observed in women who retain normal ovarian function. All women who have received TBI during BMT, regardless of estrogen replacement status, should be enrolled in a breast cancer screening program.

In boys, the germinal epithelium is significantly more sensitive to radiation than the Leydig cells. As a consequence, testosterone production is usually maintained, and puberty progresses normally.^{52,280,297} Testicular volumes are small, reflecting the damage to the germinal epithelium.⁵² Biochemically, FSH is elevated in most peripubertal and pubertal boys (68% to 90%),^{52,283} and LH is elevated in 40% to 50%,^{52,283} whereas testosterone levels are infrequently low (0% to 16%).^{52,126,283} There are no robust data documenting sperm counts during adult life to determine what

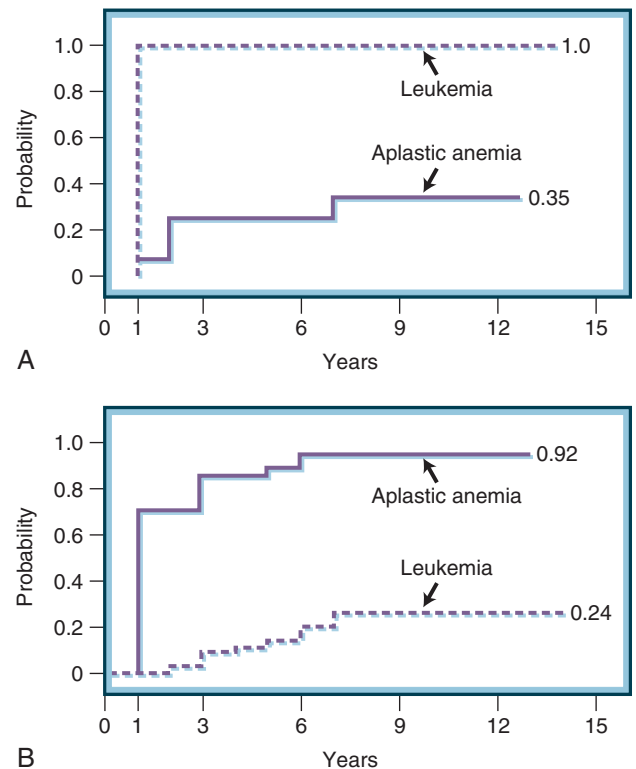

Figure 43-11 A, The probability of developing ovarian failure as determined by the first elevated LH/FSH levels beginning at 1 year after hematopoietic stem cell transplantation. **B,** The probability of recovery of normal ovarian function as determined by first normal LH/FSH levels beginning at 1 year after transplantation. FSH, follicle-stimulating hormone; LH, luteinizing hormone. (From Sanders JE, Buckner CD, Amos D, et al. Ovarian function following marrow transplantation for aplastic anemia or leukemia. *J Clin Oncol*. 1988;6:813-818.)

proportion of boys receiving BMT are spontaneously fertile or fertile with the help of assisted fertility techniques.

Severe oligospermia or azospermia, associated with testicular volumes below the normal range and normal testosterone levels, is expected after TBI during adult life.¹²⁶ Sterility is not universal,¹²⁶ and patients should be advised with respect to contraception. Adult men commonly report an adverse impact on long-term sexual functioning after BMT, although to a lesser degree than women.²⁹⁹

Effects of Chemotherapy-Only Preparatory Regimens

Children who undergo BMT having received only chemotherapy during their preparative regimen, without preceding irradiation, experience no adverse effects on height or height velocity SDS.^{276,279,284} In fact, catch-up growth after BMT is a frequent observation in these individuals.^{276,278} and final height is not significantly affected.²⁸⁴ GH stimulation tests in children who were growing normally after preconditioning with chemotherapy alone showed appropriate responses.^{278,300} Impaired stimulated GH responses have been reported occasionally after chemotherapy-alone preparatory regimens administered during childhood.^{279,301} The class of drugs involved and the mechanisms for this result remain unclear. Whether the abrogated GH responses relate to inadequate or inappropriate assessment of the GH axis is unclear. The cortisol axis and thyroid function are unaffected in children receiving chemotherapy alone for preconditioning.^{276,278,279,290,300} The relative risk for development of thyroid cancer with BMT regimens that do not include TBI is not significantly elevated.^{292,294}

Permanent gonadal damage is uncommon in children, with most patients progressing through puberty spontaneously.²⁷⁶ Gonadotoxic agents including cyclophosphamide, busulfan, and ARA-C have a dose-dependent toxic effect on the male germinal epithelium, with a high incidence of transient or permanent oligospermia or azospermia.²⁹⁶ Mild Leydig cell dysfunction, characterized by compensated hypergonadotropic hypogonadism, is frequently observed, but puberty is usually completed without the need for testosterone replacement therapy.²⁹⁶

Most adult women who undergo cyclophosphamide-based preparatory regimens are rendered amenorrheic with elevated gonadotropins.^{291,295,302} Return of menses and normalization of the gonadotropins occurs in most cases, with a median duration of 6 months (see Fig. 43-11).²⁹⁵ The likelihood of ovarian recovery is age related, with younger individuals having the more promising outlook.^{295,302} However, many individuals will have received gonadotoxic treatments prior to going forward with BMT, and the cumulative effect of these therapies has a significant impact on recovery rates.³⁰² Recovery of reproductive function in older individuals (>25 years) is more likely to be transient, although frequently menses can be present for several years before the onset of a premature menopause.²⁹⁵

Neuroendocrine Gastrointestinal and Lung Tumors (Carcinoid Tumors), Carcinoid Syndrome, and Related Disorders

KJELL ÖBERG

The first clinical and histopathologic description of carcinoid tumor was made by Otto Lubarsch in 1888.¹ He was impressed by the multicentric origin of carcinoid tumors of the gastrointestinal (GI) tract, their lack of gland formation, and their lack of similarity with the usual adenocarcinoma of the alimentary system.

The term *Karziinoide* was introduced in 1907 by the pathologist Oberndorffer² as a descriptive name for what he considered to be a benign type of neoplasm of the ileum but one that could behave like a carcinoma. It was subsequently accepted that the carcinoid tumor was a very slow growing and benign neoplasm with no potential for invasiveness or tendency to metastasize. This myth of benignity has survived to the present, even though in 1949 Pearson and Fitzgerald³ described a large series of metastasizing carcinoid tumors.

Carcinoid tumors have subsequently been reported in a wide range of organs, but they most commonly involve the lungs and GI tract. Carcinoid tumors of the thymus, ovaries, testes, heart, and middle ear have also been described. The clinically well-known *carcinoid syndrome* was described by Thorson and associates⁴ in 1954; 1 year earlier, Lembeck⁵ had extracted serotonin from a carcinoid tumor.

PHYLOGENESIS AND EMBRYOLOGY

Carcinoid tumors are derived from neuroendocrine cells, and in 1914, Gosset and Masson⁶ were the first to point out the neuroendocrine properties of carcinoid tumors. Masson⁷ later described the remarkable affinity for silver salts displayed by intracytoplasmic granules in tumor cells

Figure 44-1 Normal human intestine stained with chromogranin A (Chrom. A) to delineate neuroendocrine cells. The cells are scattered in the intestinal mucosa.

and observed that carcinoid tumors originated from enterochromaffin cells, the Kulchitsky cells in the crypts of Lieberkühn in the intestinal epithelium. He also suggested that the tumors were of endocrine origin (Fig. 44-1).

The mammalian GI tract and pancreas contain 14 endocrine cell types, which initially were believed to originate from the neuroectoderm. This observation gave rise to the *APUD concept* (amine precursor uptake and decarboxylation) because of the ability of these cells to take up and decarboxylate amino acid precursors of biogenic amines such as serotonin and catecholamines.⁸ The APUD concept was later revised by others, who postulated that these endocrine cells might also be derived from mesoderm and endoderm.⁹ The neuronal phenotype is clearly seen when culturing carcinoid tumor cells in vitro. The enterochromaffin cells, from which many carcinoid tumors derive, have the property of producing and secreting amines (e.g., serotonin) and polypeptides (e.g., neurokinin A, substance P).

Carcinoid tumors also may originate from other neuroendocrine cells, such as the enterochromaffin-like (ECL) cells of the gut and endocrine cells in the bronchi. Tumors derived from these cells can produce a wide range of hormones, such as gastrin, gastrin-releasing peptide (GRP), ghrelin, calcitonin, pancreatic polypeptide, adrenocorticotrophic hormone (ACTH), corticotropin-releasing hormone (CRH), and growth hormone-releasing hormone (GHRH), as well as somatostatin, glucagon, and calcitonin gene-related peptide (CGRP).¹⁰ A common secretory product from all types of carcinoid tumors is the glycoprotein chromogranin A (CgA), the most important general tumor marker in these patients (see later discussion).

MOLECULAR GENETICS

Despite advances in the diagnosis, localization, and treatment of carcinoid tumors, no etiologic factor associated with the development of these tumors has been identified. Little is known about molecular genetic changes underlying tumorigenesis. Sporadic foregut carcinoids and the familial-type multiple endocrine neoplasia type 1 (MEN1) often display allelic losses at chromosome 11q13, and somatic *MEN1* gene mutations have been reported in one third of sporadic foregut tumors.¹¹ In contrast to foregut carcinoids, molecular and cytogenetic data for midgut carcinoids are quite limited, and these tumors are not included in MEN1 syndrome. Deletions of chromosomes 18q and 18p have been reported in 38% and 33%, respectively, of GI carcinoids.¹²

In one publication, deletions on chromosome 18 were found in 88% of midgut carcinoid tumors, but the *SMAD4/DPC4* locus was not deleted.¹³ In addition to the consistent finding of deletions on chromosome 18, multiple deletions on other chromosomes (e.g., 4, 5, 7, 9, 14, 20) were noticed in single tumors. The region telomeric to the *SMAD4/DPC4/DCC* loci must be further explored for possible losses of a tumor suppressor gene in this area. Gene expression arrays for carcinoid tumors have demonstrated upregulation of the *RET* proto-oncogene, but no mutations have been detected. Data indicate that the Notch signaling pathway is a significant regulator of neuroendocrine differentiation and serotonin production in GI carcinoid tumors.^{14,15}

CLASSIFICATION

In 1963, Williams and Sandler reported a relationship between the embryonic origin of carcinoid tumors and the histologic, biochemical, and to some extent, clinical features of the tumors.¹⁶ Three distinct groups were formed (Table 44-1): foregut carcinoids (i.e., intrathoracic, gastric,

TABLE 44-1

Classification of Carcinoid Tumors

Foregut	Midgut	Hindgut
Histopathology		
Argyrophilic CgA positive NSE positive	Argentaffin positive CgA positive NSE positive	Argyrophilic SVP-2 positive CgA positive, NSE positive
Molecular Genetics		
Chromosome 11q13 deletion	Chromosome 18q, 18p deletion	Unknown
Secretory Products		
CgA, 5-HT, 5-HTP, histamine, ACTH, GHRH, CGRP, somatostatin, AVP, glucagon, gastrin, NKA, substance P, neurotensin, GRP	CgA, 5-HT, NKA, substance P, prostaglandins E ₁ and F ₂ , bradykinin	PP, YY, somatostatin
Carcinoid Syndrome		
Present (30%)	Present (70%)	Absent

ACTH, adrenocorticotrophic hormone; AVP, arginine vasopressin; CgA, chromogranin A; CGRP, calcitonin gene-related hormone; GRP, gastrin-releasing peptide; 5-HT, 5-hydroxytryptamine; 5-HTP, 5-hydroxytryptophan; NKA, neurokinin; NSE, neuron-specific enolase; PP, pancreatic peptide; YY, peptide YY; SVP-2, synaptic vesicle protein 2.

Figure 44-2 Histopathology of classic, well-differentiated midgut carcinoid tumor.

and duodenal carcinoids), midgut carcinoids (i.e., carcinoids of the small intestine, appendix, and proximal colon), and hindgut carcinoids (i.e., carcinoid tumors of the distal colon and rectum).

Although this original classification has been useful in the clinical assessment of patients with carcinoid tumors, its significant shortcomings prompted development of a new classification system that takes into account both the site of origin and variations in the histopathologic characteristics of carcinoid tumors: the World Health Organization (WHO) classification.¹⁷ In this revised system, typical tumors are classified as *well-differentiated* neuroendocrine tumors (WHO I), with their characteristic growth pattern (Fig. 44-2). These tumors are usually slow growing, with low proliferation capacity (proliferation index <2%). They are usually confined to the mucosa and submucosa and are less than 1 to 2 cm in diameter (i.e., classic midgut carcinoid). Well-differentiated endocrine carcinomas (WHO II) are larger than 2 cm and show widely invasive growth and a high proliferation index (2% to 15%). Poorly differentiated carcinomas (WHO III) are large tumors with metastases and a proliferation index of greater than 15% (Table 44-2).^{17a} The European Neuroendocrine Tumor Network Society (ENETS) has proposed a new tumor-node-metastasis (TNM) classification and grading system, but it has not been widely accepted.

Neuroendocrine lung tumors are classified as typical carcinoids, atypical carcinoids, large cell neuroendocrine carcinomas, and small cell lung carcinomas. The difference between the typical and atypical carcinoid is based on histopathology, with higher amounts of proliferation and necrosis found in the atypical carcinoid.¹⁸ The incidence of carcinoid tumors is similar in Western countries and is estimated to be 2.8 to 4.5 cases per 100,000 people.^{19,20}

Because many carcinoid tumors are indolent, the true incidence may be higher. In particular, appendiceal carcinoids have not been included in many studies, but a higher incidence of 8.2 cases per 100,000 people was found in an autopsy study when appendiceal carcinoids were included.²¹ The incidence of patients with a carcinoid syndrome is about 0.5 case per 100,000 people.²² Data from the United States, based on results from the End Results Group and the Third National Cancer Survey for 1950 to 1969 and for 1969 to 1971, respectively, found that the appendix was the most common site of carcinoid tumors, followed by the rectum, ileum, lungs, and bronchi.²³

An analysis done in the Surveillance, Epidemiology, and End Results (SEER) program of the National Cancer Institute between 1973 and 1999 reported an increase in the percentage of pulmonary and gastric carcinoids and a decrease in the percentage of appendiceal carcinoids.²⁰ Age-specific incidence rates showed a peak between 65 and 75 years (7.5 to 9.5 per 100,000), with a male predominance. Among persons younger than 50 years, a female predominance has been observed for appendiceal and lung carcinoids.²⁴ The most recent analysis of the SEER database showed an incidence of 5.2 per 100,000 people and a prevalence of 35 per 100,000 people,²⁵ indicating a real increase over the past decade.²⁶

BIOCHEMISTRY

The production of hormones appears to be a highly organized function of carcinoid cells. In 1953, Lembeck isolated serotonin from a carcinoid tumor; since then, carcinoid syndrome has been associated with serotonin overproduction.⁵ The biosynthesis of serotonin and its metabolic degradation are outlined in Figure 44-3.

Carcinoid tumors of the midgut and foregut region with metastatic disease secrete serotonin and produce elevated urinary excretion of 5-hydroxyindoleacetic acid (5-HIAA)

in 76% and 30% of these tumors, respectively.²⁵ Carcinoid tumors arising from the foregut, however, commonly have low levels of L-amino acid decarboxylase, which converts 5-hydroxytryptophan (5-HTP) to serotonin, and these tumors secrete primarily 5-HTP.^{27,28}

For many years, it was believed that the carcinoid syndrome could be explained by the secretion of these biologically active amines. However, further studies found that serotonin was mainly involved in the pathogenesis of diarrhea and that other biologically active substances played a more important role in the carcinoid flush and bronchoconstriction.

Oates and associates²⁹ hypothesized that *kallikrein*, an enzyme found in carcinoid tumors, is released in association with flush and stimulates plasma kininogen to liberate lysyl-bradykinin and bradykinin. These biologically active substances cause vasodilation, hypotension, tachycardia, and edema.²⁹⁻³¹ Prostaglandins (E₁, E₂, F₁, F₂) may also play a role in carcinoid syndrome.³² Gastric carcinoids and lung carcinoids contain and secrete histamine, which may be responsible for the characteristic bright red flush seen in these patients.³³⁻³⁵ Metabolites of histamine are often present in high concentration in the urine of patients. Dopamine and norepinephrine also have been found in carcinoid tumors.³⁶

The occurrence of *substance P* in carcinoid tumors was first demonstrated by Håkansson and coworkers in 1977.³⁷ Substance P belongs to a family of polypeptides, called *tachykinins*, that share the same carboxy terminus (Fig. 44-4). Several tachykinin-related peptides, such as neurokinin A, neuropeptide K, and eledoisin, have been isolated from carcinoid tumors. During stimulation of flush in patients with midgut carcinoids, multiple forms of tachykinins are released into the circulation (Fig. 44-5).³⁸⁻⁴⁰

Many different polypeptides (e.g., insulin, gastrin, somatostatin, S100 protein, polypeptide YY, pancreatic

polypeptide, human chorionic gonadotropin α -subunit [hCG- α], motilin, calcitonin, vasoactive intestinal polypeptide [VIP], endorphins) have been demonstrated in carcinoid tumors by immunohistochemical staining and sometimes identified in tumor extracts.¹⁰ Ectopic ACTH or CRH production may be found in foregut carcinoids, and

patients with bronchial carcinoids seem particularly susceptible to Cushing's syndrome.⁴¹ Patients with carcinoid tumors of the foregut may present with acromegaly due to ectopic secretion of GHRH from the tumor.⁴² Duodenal carcinoids as part of von Recklinghausen's disease can secrete somatostatin.⁴³

The *chromogranin/secretogranin* family consists of CgA, CgB (sometimes called *secretogranin I*), secretogranin II (sometimes called CgC), and some other members. CgA was first isolated in 1965 as a water-soluble protein in chromaffin cells from bovine adrenal medulla.⁴⁴ Its immunoreactivity has been found in all parts of the GI tract and pancreas, and it has been isolated from all endocrine glands.⁴⁵

CgA is an acidic glycoprotein of 439 amino acids with a molecular weight of 48 kd. It can be spliced into smaller fragments at dibasic cleavage sites, generating multiple bioactive fragments such as vasostatins, chromostatin, and pancreastatin (Fig. 44-6).⁴⁵⁻⁴⁹

Amines and hormones are stored intracellularly in two types of vesicles: large, dense-core vesicles and small, synapse-like vesicles. These vesicles release amines and hormones on stimulation. Large, dense-core vesicles contain the hormones and one or more members of the chromogranin/secretogranin family of proteins.^{46,50} Amines and peptides are coreleased (Fig. 44-7).

The physiologic function of CgA is not fully elucidated. Its ubiquitous presence in neuroendocrine tissues and its cosecretion with peptide hormones and amines indicate a storage role of the peptide within the secretory granule.^{45,46,50} It also acts as a prohormone that can generate bioactive smaller fragments. CgA is an important tissue and serum marker for different types of carcinoid tumors, including those of the foregut, midgut, and hindgut (see Table 44-1 and later discussion).

CLINICAL PRESENTATION

The clinical presentation of carcinoid tumors depends on location, hormone production, and extent of the disease. Usually, a lung carcinoid is diagnosed incidentally on routine pulmonary radiography, whereas a midgut carcinoid may be identified as a bowel obstruction or as a cause of abdominal discomfort or pain. Rectal carcinoids may cause bleeding or obstruction. Lung carcinoids can manifest clinically as Cushing's syndrome, due to CRH or ACTH secretion or as carcinoid syndrome, due to production of serotonin, 5-HTP, or histamine.⁵¹ A midgut carcinoid often manifests as carcinoid syndrome due to production of serotonin and tachykinins.

The clinical manifestations at referral depend on the type of referral center. At my institution, which cares for patients with malignant tumors, 74% of the patients present with carcinoid syndrome, 13% with abdominal

pain, 12% with carcinoid heart disease, and 2% with bronchial constriction.²⁵ When unbiased material is analyzed, bowel obstruction is the most common problem leading to the diagnosis of ileal carcinoid tumor. The second most common symptom is abdominal pain. Flushing and diarrhea, which are components of carcinoid syndrome,

Figure 44-7 Schematic drawing of an enterochromaffin cell. The initial step in 5-hydroxytryptamine (5-HT) synthesis is carrier transport of the amino acid tryptophan from blood into the cell across the cell membrane. Intracellular tryptophan is first converted to 5-hydroxytryptophan (5-HTP), which is converted to 5-HT and stored in secretory granules. The transport of 5-HT into granules requires vesicular monoamine transporters (VMATs). Through the basal lateral membrane, 5-HT can be released into the circulation. A membrane pump mechanism in the cell membrane is responsible for amine reuptake. A minor part of 5-HT can also be released into the gut lumen. Monoamine oxidase (MAO) degrades 5-HT to 5-hydroxyindoleacetic acid (5-HIAA). Peptide prohormones are synthesized in the rough endoplasmic reticulum (RER) together with chromogranin A (CgA) and other granule proteins. The products are transported to the Golgi apparatus (GA) for packaging into prosecretory granules. On stimulation, the secretory products are released from the granules by exocytosis.

constitute the third most common presentation.^{19,52-54} Because many patients have vague symptoms, diagnosis of the tumor may be delayed by approximately 2 to 3 years.²²

Carcinoid Syndrome

In 1954, Thorson and coworkers for the first time described carcinoid syndrome as having the following features: malignant carcinoid of the small intestine with metastasis to the liver; valvular disease of the right side of the heart (i.e., pulmonary stenosis and tricuspid insufficiency without septal defect); peripheral vasomotor symptoms; bronchial constriction; and an unusual type of cyanosis.⁴ One year later, Dr. William Bean⁵⁵ gave this colorful description of carcinoid syndrome: "This witch's brew of unlikely signs and symptoms, intriguing to the most fastidious connoisseur of clinical esoterica—the skin underwent rapid and extreme changes—resembling in clinical miniature the fecal phantasmagoria of the aurora borealis."

The well-characterized syndrome includes flushing, diarrhea, right-sided heart failure, and sometimes, bronchial constriction and increased urinary levels of 5-HIAA.^{56,57} This is the classic carcinoid syndrome, but some patients display only one or two of the features. Other symptoms related to the syndrome are weight loss, sweating, and pellagra-like skin lesions.

Development of carcinoid syndrome is a function of tumor mass, extent and location of metastases, and location of the primary tumor. The syndrome is most common in tumors originating in the small intestine and proximal colon; 40% to 60% of patients with these tumors experience the syndrome.^{25,53,56,57} The disorders are less common in patients with bronchial carcinoids and do not occur in patients with rectal carcinoids.^{51,58,59} The syndrome rarely occurs in patients with midgut carcinoids and a small tumor burden, such as those with only regional lymph node metastases.⁵⁴ Patients with the full syndrome usually have multiple liver metastases. The association with hepatic metastases reflects efficient inactivation by the liver of amines and peptides released into the portal circulation. The venous drainage of liver metastases runs directly

into the systemic circulation and bypasses hepatic inactivation.⁶⁰

Other carcinoid tumors likely to be associated with carcinoid syndrome in the absence of liver metastases are ovarian carcinoids and bronchial carcinoids, which release mediators directly into the systemic rather than the portal circulation. Retroperitoneal metastases from classic midgut carcinoids also release mediators directly into the circulation and may cause carcinoid syndrome without any liver metastases.^{56,57}

Flushing

Four types of flushing have been described in the literature: erythematous, violaceous, prolonged, and bright red.^{56,57}

The best-known type is the sudden, diffuse, erythematous flush, which usually affects the face, neck, and upper chest (i.e., normal flushing area) (Fig. 44-8). This type of flush commonly has a short duration, lasting 1 to 5 minutes, and is related to early-stage midgut carcinoids. Patients usually experience a sensation of warmth during flushing and sometimes have heart palpitations. This type of flushing is reported in 20% to 70% of patients with midgut carcinoid at manifestation of the disease.^{22,56-58}

The second type, violaceous flush, affects the same area of the body. It has roughly the same time course or sometimes lasts a little longer. Patients may also have facial telangiectasia. This flush is related to the later stages of midgut carcinoid (Fig. 44-9) and is normally not felt by patients because they have become accustomed to the flushing reaction.

The third type is prolonged flushing that usually lasts a couple of hours but can last up to several days. This flush sometimes involves the whole body and is associated with profuse lacrimation, swelling of the salivary glands, hypotension, and facial edema (Fig. 44-10). These symptoms are usually associated with malignant bronchial carcinoids.

The fourth type of flushing is a bright red, patchy flush, which is seen in patients with chronic atrophic gastritis and ECL cell hyperplasia or ECLoma (derived from ECL cells). This type of flushing is related to increased release of histamine and histamine metabolites.

Figure 44-8 A, Patient with carcinoid syndrome before flush provocation. B, The same patient after pentagastrin-stimulated flush.

Figure 44-9 Long-lasting, chronic flushing in a patient with long-standing carcinoid disease. Note the telangiectases.

Figure 44-10 A patient with lung carcinoid and carcinoid syndrome with severe, long-standing flushing, lacrimation, and a swollen face.

Flushes may be spontaneous, or they may be precipitated by physical or mental stress, infection, alcohol, spicy foods, or drugs such as injections of catecholamines, calcium, or pentagastrin (see later discussion). The pathophysiology of flushing in carcinoid syndrome has not been elucidated.⁶¹⁻⁶³ It was previously linked to excess production of serotonin or serotonin metabolites.⁶² However, several patients with high levels of plasma serotonin did not have flushing, nor did serotonin antagonists (e.g., methysergide, cyproheptadine, ketanserin) have any effect on the flushing.^{61,64}

In a study in which my own group measured the release of tachykinins, neuropeptide K, and substance P during flushing provoked by pentagastrin or alcohol, the onset and intensity of the flushing reaction was clearly correlated with the release of tachykinins (see Fig. 44-5).³⁸ When the release of tachykinins was blocked by prestimulatory administration of octreotide, little or no flushing was observed in the same patient (Fig. 44-11).³⁸⁻⁴⁰ Other mediators of the flushing reaction may be kallikrein and bradykinins, which are released during provoked flushing.²⁹⁻³¹

Histamine may be a mediator of the flushes seen in patients with lung carcinoids or gastric carcinoids (ECLomas).³³⁻³⁵ Tachykinins, bradykinins, and histamines are well-known vasodilators, and somatostatin analogues may alleviate flushing by reducing circulating levels of these agents (see later discussion).^{38-40,63-68} Furschgott and Zawadski suggested that flushing is caused by indirect vasodilation mediated by endothelium-derived relaxing factor (EDRF) or by nitric oxide released by 5-HTP during platelet activation.⁶⁹

Facial flushing associated with carcinoid tumors should be distinguished from idiopathic flushing and menopausal hot flushes. Patients with idiopathic flushes usually have a long history of flushing starting early in life and sometimes with a family history without occurrence of a tumor. Menopausal hot flushes usually involve the whole body and are accompanied by intense sweating. Postmenopausal

Figure 44-11 Tachykinin (TKLI) levels after stimulation with pentagastrin in patients with classic midgut carcinoids. Pretreatment for 15 minutes with somatostatin (SMS) causes inhibition of tachykinin release and inhibition of the flush reaction (open circles). P, placebo.

women in whom true carcinoid syndrome is developing can tell the difference between the two types of flushes.

Diarrhea

Diarrhea occurs in 30% to 80% of patients with carcinoid syndrome.^{22,25,56,57} Its pathophysiology is poorly understood but is probably multifactorial. Diarrhea is often accompanied by abdominal cramping, and endocrine, paracrine, and mechanical factors contribute to this condition. A variety of tumor products, including serotonin, tachykinins, histamines, kallikrein, and prostaglandins, can stimulate peristalsis, electromechanical activity, and tone in the intestine.^{63,70-72} Secretory diarrhea can occur with fluid and electrolyte imbalance. Malabsorption can result from intestinal resections, lymphangiectasia, mesenteric fibrosis, bacterial overgrowth, tumor partially obstructing the small bowel, or rapid intestinal transit. Increased secretion by the small bowel, malabsorption, or accelerated transit can overwhelm the normal storage and absorptive capacity of proximal colon and result in diarrhea, which may be aggravated if the reabsorptive function of the colon is impaired.

In a study of patients with elevated serotonin levels and carcinoid syndrome, transit time in the small bowel and colon was significantly decreased compared with that of normal subjects.⁷³ The volume of the ascending colon was significantly smaller than in normal subjects, and the postprandial colonic tone was markedly increased. This indicates that in patients in whom carcinoid syndrome is associated with diarrhea, major alterations in gut motor function affect the small intestine and the colon. Many patients with carcinoid tumors have undergone wide resection of the small intestine, and they may be affected by the symptoms of short-bowel syndrome.

Serotonin is thought to cause diarrhea in patients with carcinoid syndrome through its effects on gut motility and intestinal electrolyte and fluid secretion.^{57,70-72} Serotonin receptor antagonists, such as ondansetron and ketanserin, relieve the diarrhea to a certain degree.^{70,74-76}

Carcinoid Heart Disease

A unique endocrine effect of carcinoid tumors is the development of plaque-like thickenings of the endocardium, valve leaflets, atria, and ventricles in 10% to 20% of patients.^{77,78} This fibrotic involvement causes stenosis and regurgitation of the blood flow. Finding new collagen beneath the endothelium of the endocardium is almost pathognomonic for carcinoid heart disease.⁷⁷⁻⁷⁹ The incidence of these lesions depends on the diagnostic methodology. Echocardiography can demonstrate early lesions in about 70% of patients with carcinoid syndrome, whereas routine clinical examinations detect them in only 30% to 40%.^{77,78,80} These figures have significantly dropped to 10% to 15%, probably because of earlier diagnosis and the use of biologic antitumor treatments, such as somatostatin analogues and α -interferons. Both agents control the hormonal release and excess that may be involved in the fibrotic process.

In a study performed 15 years ago,²² 40% of patients with carcinoid tumors died of cardiac complications related to the carcinoid disease. Later data reveal that this complication is a rare event, and patients usually die of the effects of a progressive tumor.²⁵

The precise mechanism behind the fibrosis in the right heart is unknown, but it occurs mainly in patients with liver metastases who usually also have carcinoid syndrome.^{77,78} Substances inducing fibrosis are thought to be released directly into the right heart and are then neutralized or degraded through the lung circulation, because few

patients present with similar lesions of the left heart.^{77,78} However, patients with lung carcinoids occasionally display the same fibrotic changes in the left heart. Histologically, the plaque-like thickenings in the endocardium consist of myofibroblasts and fibroblasts embedded in a stroma that is rich in mucopolysaccharides and collagen.⁷⁷

We previously showed that the transforming growth factor- β (TGF- β) family of growth factors is upregulated in carcinoid fibrous plaques on the right heart.⁸¹ The TGF- β family of growth factors stimulates matrix formation and collagen deposition. The substances that induce TGF- β locally in the heart have not been identified, but serotonin, tachykinins, and insulin-like growth factor 1 (IGF1) may be mediators.^{77,82}

Circulating levels of serotonin and tachykinins correlate with the degree and frequency of carcinoid heart lesions. The weight-reducing drugs fenfluramine and dexfenfluramine appear to interfere with normal serotonin metabolism and have been associated with valvular lesions identical to those seen in carcinoid heart disease.^{83,84} However, treatment resulting in decreased urinary 5-HIAA excretion does not lead to regression of cardiac lesions in carcinoid patients.⁸⁵ Two animal studies indicated that serotonin may play a significant role in the development of carcinoid heart disease. Serotonin also has induced TGF- β_1 in *in vitro* experiments.⁸⁶⁻⁸⁸ Connective tissue growth factor (CTGF) is produced by carcinoid tumor cells, and increased expression is found in patients with advanced fibrosis. CTGF stimulates TGF- β .⁸⁹

Bronchial Constriction

A true asthma episode is rare in patients with carcinoid syndrome.^{22,56,57} The causative agents of bronchial constriction are unknown, but tachykinins and bradykinins have been suggested as mediators.^{90,91} These agents can constrict smooth muscle in the respiratory tract and can cause local edema in the airways.

Other Manifestations of Carcinoid Syndrome

Fibrotic complications other than heart lesions may be found in patients with carcinoid tumors. They include intra-abdominal and retroperitoneal fibroses, occlusion of the mesenteric arteries and veins, Peyronie's disease, and carcinoid arthropathy.^{56,57}

Intra-abdominal fibrosis can lead to intestinal adhesions and bowel obstruction, and it is a more common cause of bowel obstruction than is the primary carcinoid tumor itself.^{54,92,93} Retroperitoneal fibrosis can result in urethral obstruction that impairs kidney function, which sometimes requires treatment with urethral stents.

Narrowing and occlusion of arteries and veins by fibrosis are potentially life threatening. Ischemic loops of the bowel may require removal, and this procedure ultimately causes short-bowel syndrome.^{54,93} Other rare features of the syndrome are pellagra-like skin lesions with hyperkeratosis and pigmentation, myopathy, and sexual dysfunction.⁵⁷

Carcinoid Crisis

Carcinoid crisis has become rare since the introduction of treatment with somatostatin analogues.⁹⁴ It may occur spontaneously or during induction of anesthesia, embolization procedures, chemotherapy, or infection. Carcinoid crisis is a clinical condition characterized by severe flushing, diarrhea, hypotension, hyperthermia, and tachycardia. Without treatment, patients may die during the crisis.⁹⁴⁻⁹⁶

Intravenous or subcutaneous somatostatin analogues, or both, are given before, during, and after surgery to prevent

the development of carcinoid crisis.^{94,96-98} Patients with metastatic lung carcinoids are particularly difficult to treat during crisis. Intravenous infusions of octreotide at doses of 50 to 100 µg/hour, supplemented with histamine H₁-receptor and H₂-receptor blockers and intravenous sodium chloride, are recommended.⁹⁹

Other Clinical Manifestations of Carcinoid Tumors

Ectopic secretion of CRH and ACTH from pulmonary carcinoid tumors and thymic carcinoids accounts for 1% of all cases of Cushing's syndrome.^{41,100} Acromegaly due to ectopic secretion of GHRH has been reported in foregut carcinoids.^{42,101} Gastric carcinoid tumors make up fewer than 1% of gastric neoplasms.²⁰ They originate from gastric ECL cells¹⁰² and can be separated into three distinct groups based on clinical and histologic characteristics. Type 1 (80%) is associated with chronic atrophic gastritis type A. Type 2 (6%) is associated with Zollinger-Ellison syndrome as part of MEN1 syndrome. Type 3 represents sporadic gastric carcinoids occurring without hypergastrinemia and pursues a more malignant course, with 50% to 60% of patients developing metastases.^{102,103}

About 80% of gastric carcinoids are associated with chronic atrophic gastritis type A, and more than 50% of patients with these carcinoids also have pernicious anemia. These tumors are more common in women than in men and are usually identified endoscopically during diagnostic evaluation for anemia or abdominal pain.^{102,104} They are often multifocal and localized in the gastric fundus area, and they are derived from ECL cells. Patients have hypochlorhydria and hypergastrinemia. Gastrin hypersecretion is thought to result in hyperplasia of the ECL cells, which may later develop into carcinoid tumors.^{105,106} Hyperplasia of ECL cells has been noticed in patients on long-standing proton-pump inhibitor therapy.^{107,108}

DIAGNOSIS

The diagnosis of a suspected carcinoid tumor must take into consideration molecular genetics, tumor biology, histopathology, biochemistry, and localization. The diagnosis may be suspected from clinical symptoms suggesting carcinoid syndrome or from the presence of other clinical symptoms, or it can be made in relatively asymptomatic patients from the histopathology at surgery or after liver biopsy for unknown hepatic lesions.

In one study involving 154 consecutive patients with GI carcinoids found at surgery, 60% were asymptomatic.¹⁰⁹ In patients with symptomatic tumors, the time from onset of symptoms until diagnosis is often delayed 1 to 2 years.^{19,22} The current tumor biology program includes growth factors (e.g., platelet-derived growth factor [PDGF], epidermal growth factor [EGF], IGF1, TGF-β)¹¹⁰ and proliferation factors (e.g., measurements of the nuclear antigen Ki-67) as a proliferation index. The index correlates with tumor aggressiveness and survival.^{111,112} The presence of adhesion molecules such as CD44, particularly variant exons v6 and v9, is associated with improved survival.¹¹³ Determination of the expression of angiogenic factors basic fibroblast growth factor (bFGF) and vascular endothelial growth factor (VEGF) should also be included in a tumor biology program. Somatostatin analogues are cornerstones in the treatment of carcinoid syndrome, and determination of the subtypes of somatostatin receptors (i.e., SSTR1 to SSTR5) with specific antibodies is warranted.^{114,115} Rare cases of familial

carcinoids should be analyzed with respect to loss of heterozygosity on chromosome 11q13 and chromosome 18.

The histopathologic diagnosis of carcinoids is based on immunohistochemistry using antibodies against CgA, synaptophysin, and neuron-specific enolase. These immunohistochemical stains have replaced the old silver stains, the argyrophil stains by Grimelius and Sevier-Munger. The argentaffin stain used by Masson to demonstrate the content of serotonin has been replaced by immunocytochemistry with serotonin antibodies.¹⁰ These neuroendocrine markers can be supplemented by specific immunocytochemistry to different hormones, such as substance P, gastrin, and ACTH. The WHO classification forms the basis for therapeutic decisions.

Biochemical Diagnosis

In patients with flushing and other manifestations of carcinoid syndrome, the diagnosis can be established by measuring the urinary excretion of 5-HIAA, because levels are invariably elevated under these circumstances.¹¹⁶ Patients with carcinoid tumors usually have a 24-hour urinary 5-HIAA output of 100 to 3000 µmol/L (15 to 60 mg), compared with the reference range of less than 50 µmol/L (10 mg) in 24 hours. Assays for urinary 5-HIAA include high-performance liquid chromatography (HPLC) with electrochemical detection and colorimetric and fluorescence methods.¹¹⁷ Various foods and drugs can interfere with the measurement of urinary 5-HIAA, and patients should avoid these agents during the 24-hour sampling (Table 44-3).¹¹⁸ Normally, two 24-hour urine collections are

TABLE 44-3

Factors That Interfere with Determination of Urinary 5-HIAA

Foods	Drugs
Factors That Produce False-Positive Results	
Avocado	Acetaminophen
Banana	Acetanilid
Chocolate	Caffeine

5-HIAA, 5-hydroxyindoleacetic acid.

recommended. In a study of patients with malignant midgut carcinoid tumors, 60% to 73% presented with increased urinary 5-HIAA levels,^{25,56,57} with a specificity of almost 100%.

Measurement of urinary 5-HIAA is the predominant biochemical analytic procedure used for diagnosis of carcinoid tumor. However, urinary and platelet measurements of serotonin can give additional information. In some studies, platelet serotonin levels were more sensitive than urinary 5-HIAA and urinary serotonin levels and were not affected by the patient's diet, as are 5-HIAA levels.

In a comparative study of 44 consecutive patients with carcinoid tumor, the platelet serotonin, urinary 5-HIAA, and urinary serotonin levels were measured. In foregut carcinoids, the sensitivities were 50%, 29%, and 55%, respectively. For midgut carcinoids, the sensitivities were 100%, 92%, and 82%, respectively, and for hindgut carcinoids, they were 20%, 0%, and 60%, respectively.¹¹⁹

Elevations of 5-HIAA can occur in malabsorption states and several other conditions. Foregut carcinoids tend to produce an atypical carcinoid syndrome with increased plasma 5-HTP levels, but not serotonin, because they lack the appropriate decarboxylase.^{27,36} That results in normal urinary 5-HIAA levels. However, some of the 5-HTP is decarboxylated in the intestine and other tissues, and many of these patients have slightly elevated urinary 5-HT or 5-HIAA levels.

Attempts have been made to identify more specific and sensitive serum markers for carcinoid tumors that may allow earlier diagnosis. One such marker is CgA. CgA and CgB are more abundant than CgC in human neuroendocrine tissues.^{45,46,120} In 44 patients with carcinoid tumors, CgA was increased in 99%, CgB in 88%, and CgC in only 6% (Fig. 44-12).¹²⁰ CgA levels in plasma may reflect tumor size. In a study of 75 patients with midgut carcinoids and carcinoid syndrome, CgA was elevated in 87% of carcinoid patients, and levels of plasma chromogranin correlated with extent of disease ($P < .0001$).²⁵ In the same study, the level of urinary 5-HIAA was elevated in 76% of midgut carcinoids, and there were no correlations with tumor size or extent of disease.

CgA is a more sensitive marker than urinary 5-HIAA in detecting carcinoid tumors, but because CgA is released and secreted from various types of neuroendocrine tumors, the specificity is lower.¹²⁰⁻¹²³ In a workup of patients with carcinoid syndrome, determination of plasma CgA should be combined with that of urinary 5-HIAA or serotonin. Plasma neuron-specific enolase shows a lower sensitivity and specificity than does plasma CgA.¹²² Serum hCG- α has been increased in 60% of patients with foregut carcinoid tumors and 50% of hindgut carcinoids but in only 11% of patients with midgut carcinoids and carcinoid syndrome. Plasma neuropeptide K levels have been elevated in 46% of patients with midgut carcinoids, whereas only 9% of patients with foregut carcinoids displayed elevated levels.^{121,124} Plasma substance P has a sensitivity of 32% and a specificity of 85%.^{25,38-40} Pancreatic polypeptide levels are also elevated in about one third of patients with midgut carcinoids and in as many with foregut carcinoids.^{125,126}

During therapy with somatostatin analogues, neither plasma CgA nor urinary 5-HIAA is a reliable marker of tumor size because somatostatin inhibits the synthesis and release of the hormones without changes in tumor size.

Localization Procedures

Numerous imaging techniques, including endoscopy, barium enema, chest radiography, ultrasonography, computed tomography (CT), magnetic resonance imaging (MRI), and angiography, have been used to determine the locations of the primary tumor and metastases in patients with carcinoid tumors. In more recent years, somatostatin receptor scintigraphy (SRS) and ¹³¹I-*meta*-iodobenzylguanidine (¹³¹I-MIBG) scanning have been used to localize and stage the disease.¹²⁷⁻¹³⁰ Bronchial carcinoids are usually detected by chest radiography, CT, or occasionally, by bronchoscopy.¹³¹ The primary midgut tumor is usually small and difficult to localize with traditional diagnostic methods such as barium enema, CT, or MRI. Some tumors can be localized by angiography, capsule endoscopy, or SRS. Liver metastases are usually detected by CT or MRI.

Figure 44-12 Plasma (p) levels of chromogranin A (CgA), CgB, and CgC in patients with various neuroendocrine tumors. EPTs, endocrine pancreatic tumors; MEN-1, multiple endocrine neoplasia type 1.

Figure 44-13 Bronchial carcinoid. **A**, Somatostatin-receptor scintigraphy in a patient with a bronchial carcinoid. **B**, Computed tomography scan in the same patient.

CT or MRI and SRS are the primary diagnostic modalities for tumor staging (Fig. 44-13).

A more sensitive method is positron emission tomography (PET) using ^{11}C -5-HTP, the precursor of serotonin synthesis (Fig. 44-14).^{132,133} This isotope accumulates in carcinoid tumors, and with the development of PET cameras, tumors as small as 0.5 cm in diameter can be detected.¹³² During treatment, correlations have been found among changes in the PET scan, transport rate constant, and urinary 5-HIAA, suggesting that PET scanning may be useful in monitoring the results of therapy. PET scanning using ^{18}F -fluorodeoxyglucose (FDG-PET) is not useful in detecting low-proliferating neuroendocrine tumors, but it can be beneficial in identifying poorly differentiated anaplastic tumors.

Carcinoid tumors contain high-affinity receptors for somatostatin in 80% to 100% of cases.^{114,115,134} The receptors

occur in both the primary tumor and metastases. Five subtypes of somatostatin receptors have been cloned, and SSTR2 is the predominant subtype expressed in carcinoid tumors.

The most commonly available somatostatin analogue, *octreotide*, binds with high affinity to SSTR2 and with lower affinity to SSTR3 and SSTR5.¹³⁵⁻¹³⁷ SRS with ^{111}In -DTPA-Phe-octreotide (Octreoscan) can detect carcinoids in patients with a sensitivity of 80% to 90%.^{137,138} Many studies have demonstrated that SRS has greater sensitivity for localizing carcinoids compared with conventional imaging studies.¹³⁸⁻¹⁴² False-positive scans can be obtained for patients with granulomas (e.g., sarcoidosis, tuberculosis), activated lymphocytes (e.g., lymphomas, chronic infection), thyroid diseases (e.g., goiter, thyroiditis), endocrine pancreatic tumors, and other endocrine tumors. Because of its high sensitivity and ability to image, whole-body SRS should be the initial imaging procedure to localize and establish the stage of the disease. Bone metastases, which are common with carcinoid tumors, are efficiently detected by SRS, which is as sensitive as traditional bone scanning with technetium.^{140,143} ^{68}Ga -DOTA-octreotate PET scanning has also been developed and has shown higher sensitivity than Octreoscan.¹⁴⁴

Scintigraphy with ^{123}I -MIBG has been applied in patients with midgut carcinoids with a sensitivity of about 50%, which is lower than that for SRS (80% to 90%). However, it can pick up carcinoids in patients that are sensitive to therapy with ^{123}I -MIBG.¹⁴⁵

A diagnostic algorithm is outlined in Figure 44-15.

Figure 44-14 Positron emission tomography (PET) scan with ^{11}C -5-hydroxytryptophan. Notice the metastasis in the liver.

TREATMENT

Treatment of carcinoid tumors with carcinoid syndrome requires a multimodal approach, including symptomatic control and tumor reduction. Most patients with carcinoid syndrome have metastatic disease. The therapeutic goals are to ameliorate and improve clinical symptoms, abrogate tumor growth, improve quality of life, and if possible, prolong overall survival.

Symptomatic control of carcinoid syndrome includes lifestyle changes, diet supplementation, and specific medical treatment that reduces the clinical symptoms

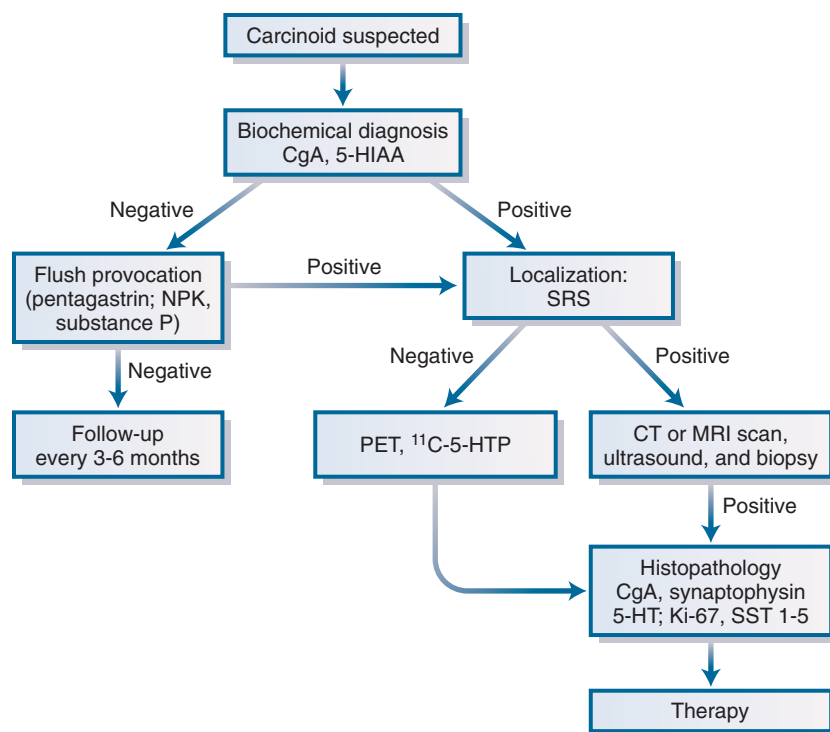

Figure 44-15 Diagnostic algorithm for patients with carcinoid tumors. CgA, chromogranin A; ¹¹C-5-HTP, ¹¹C-5-hydroxytryptophan; CT, computed tomography; 5-HIAA, 5-hydroxyindoleacetic acid; 5-HT, 5-hydroxytryptamine; MRI, magnetic resonance imaging; NPK, neuropeptide K; PET, positron emission tomography; SRS, somatostatin receptor scintigraphy; SST 1-5, somatostatin receptor subtypes 1 through 5.

related to the different components of carcinoid syndrome. Avoidance of psychological and physical stress and substances such as alcohol, spicy foods, and medications that precipitate a flushing reaction may be sufficient in early cases.⁵⁷

Production of serotonin by the tumor consumes tryptophan. Normally, about 1% of body tryptophan is used for production of serotonin, but in carcinoid tumors, as much as 60% of the available tryptophan may be consumed for the synthesis of serotonin, and this can result in tryptophan and niacin deficiencies. Therefore, supplemental niacin has been recommended to prevent the development of pellagra. Many patients have undergone resection of the terminal ileum, which can result in vitamin B₁₂ and folic acid deficiencies. Supplementation is needed in these patients.

Heart failure due to carcinoid heart disease can require diuretics or angiotensin-converting enzyme (ACE) inhibitors. A few patients need bronchodilators such as salbutamol, which interacts with β -adrenergic receptors and does not induce flushing. Diarrhea in patients with carcinoid syndrome may be controlled by loperamide or diphenoxylate.¹⁴⁶ If patients still have carcinoid syndrome, they receive somatostatin analogue treatment, which has replaced most of the earlier types of serotonin and serotonin receptor inhibitors. Serotonin inhibitors (e.g., parachlorophenylalanine, α -methyl dopa), which inhibit serotonin synthesis, and serotonin receptor antagonists (e.g., cyproheptadine, methysergide, ketanserin) are not routinely used clinically.

Earlier treatments had limited efficacy in inhibiting flushing and diarrhea, and they were accompanied by significant side effects. A combination of histamine H₁ and H₂ receptor antagonists is effective in carcinoid syndrome that is caused by foregut carcinoids due to concomitant secretion of histamine and serotonin. Prednisolone in doses of 15 to 30 mg/day gives occasional relief in some cases of severe flushing and diarrhea.¹⁴⁶

Somatostatin Analogues

Although natural somatostatin-14 reduces symptoms in patients with carcinoid syndrome,⁶⁷ its use is limited by its short half-life (approximately 2.5 minutes). During the past 2 decades, synthetic somatostatin analogues (i.e., octapeptides) have been developed for clinical use. Octreotide is the most commonly available drug; other analogues are lanreotide and vapreotide.¹⁴⁷⁻¹⁴⁹

The somatostatin analogues used in clinical practice (e.g., octreotide, lanreotide) (Fig. 44-16) bind to SSTR1, SSTR5, and, with lower affinity, SSTR3. They exert their cellular action through interaction with specific cell and transmembrane receptors belonging to the superfamily of G protein-coupled membrane receptors. They inhibit adenylate cyclase activity, activate phosphotyrosine phosphatases (PTPs), and modulate mitogen-activated protein kinases (MAPKs).^{135,150-152} Receptor subtypes 2 and 5 modulate K⁺ and Ca²⁺ fluxes in the cell.¹⁴⁷ Activation of all these pathways inhibits known growth factor production and release and has antiproliferative effects.¹⁵²⁻¹⁵⁵

SSTR3 mediates PTP-dependent apoptosis accompanied by activation of TP53 and the pro-apoptotic protein BAX.¹⁵⁶ Four of the five somatostatin receptor subtypes (SSTR2 to SSTR5) undergo rapid internalization after ligand binding, which has been explored by tumor-targeted radioactive somatostatin analogue therapy.^{150,152,157}

An antiproliferative effect has been reported to occur, probably through a combination of SSTR2 and SSTR5 activities, which inhibits MAPK and K⁺ and Ca²⁺ fluxes, leading to cell cycle arrest¹⁵³⁻¹⁵⁵; the precise antitumor mechanism, however, is unknown.

Different subtypes of somatostatin receptors form heterodimers with each other (e.g., SSTR1 and SSTR5) and with the D₂ dopamine receptor (DRD2). This cross-talk modulates the intracellular signal and fine-tunes the mediated effects.¹⁵⁸

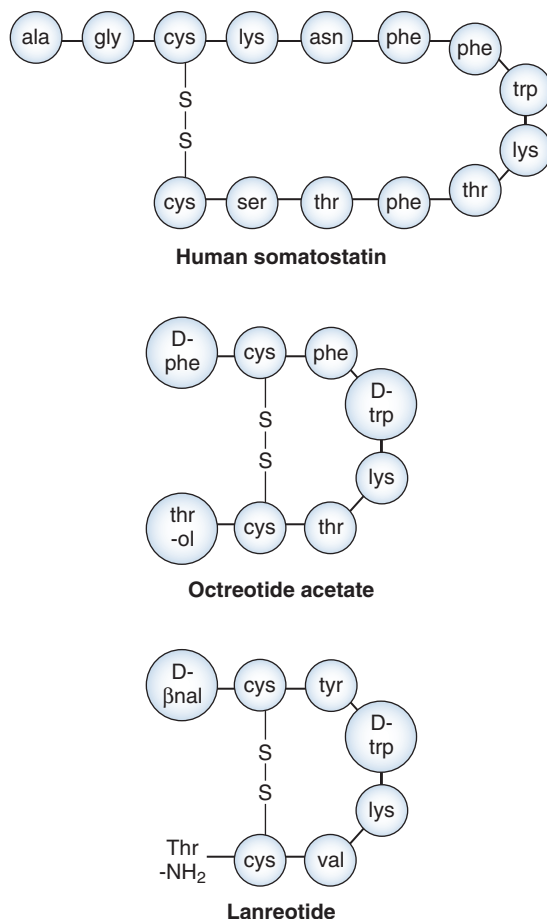

Figure 44-16 Molecular structures of human somatostatin-14, octreotide acetate, and lanreotide.

The five subtypes of somatostatin receptors are expressed in carcinoid tumors in various combinations, and some tumors express all five subtypes.^{115,150,159,160} The receptors are expressed on tumor cells and also in peritumoral veins.¹⁶¹ Antiangiogenesis may be another antitumor mechanism of somatostatin analogues.¹⁶²

Subcutaneous administration of octreotide and lanreotide every 8 to 12 hours can control clinical symptoms in about 60% to 70% of patients with carcinoid syndrome; these agents are considered the drugs of choice.^{97,163-167} Octreotide and lanreotide decrease serotonin and urinary 5-HIAA levels and plasma tachykinin and CgA levels. The recommended dose for octreotide is 100 to 150 μ g two or three times daily, a standard treatment for controlling clinical symptoms.⁹⁷ However, some patients require higher doses, up to a total of 3000 μ g/day, to control the clinical symptoms and tumor growth, particularly during long-term therapy.

Tachyphylaxis (i.e., reduced sensitivity) to somatostatin analogues can develop during long-term therapy.¹⁵² Long-acting, slow-release formulations of octreotide and lanreotide have been developed, and doses of Octreotide LAR of 20 to 30 mg given once per month or Somatuline Autogel of 90 to 120 mg once per month control clinical symptoms and hormone levels in 50% to 60% of patients with carcinoid syndrome.¹⁶⁸⁻¹⁷⁰ The long-acting formulations of somatostatin analogues have clearly improved the quality of life of patients by reducing the number of injections and provide more stable control of clinical symptoms.¹⁶⁹ A new somatostatin analogue (SOM230) that binds SSTR1, SSTR2,

SSTR3, and SSTR5 is being evaluated in clinical trials for the treatment of carcinoid tumors.

High-dose therapy with lanreotide (12 mg/day) and octreotide (3 mg/day) has increased the percentage of patients demonstrating a significant reduction in tumor size (12% versus 5% for the standard dose).¹⁷¹⁻¹⁷⁴ Induction of apoptosis has been achieved with high-dose therapy,¹⁷⁵ possibly mediated through activation of SSTR3. Ultra-high-dose octreotide has generated significant antitumor responses in patients resistant to standard-dose therapy.¹⁷⁶ A prospective, randomized study in midgut carcinoids (PROMID) demonstrated a significantly longer time to progression for Octreotide LAR compared with placebo.¹⁷⁷ These data have changed the U.S. National Comprehensive Cancer Network guidelines for the treatment of carcinoid tumors. All types of carcinoid tumors, irrespective of functionality, can be treated with octreotide.

For patients at risk for carcinoid crisis, somatostatin analogue therapy is the treatment of choice. Carcinoid crisis is a life-threatening complication of carcinoid syndrome. It can occur spontaneously or may be associated with stress and anesthesia, chemotherapy, and infections. Patients usually experience severe flushing, diarrhea, abdominal pain, and hypotension. Continuous infusion with somatostatin analogues, 50 to 100 μ g/hour, is recommended and usually alters the life-threatening condition. Patients should be given subcutaneous somatostatin analogues before surgery or other stressful situations.

Side effects of somatostatin analogue therapy usually have not been serious and occur in 20% to 40% of patients. They include pain at the injection site, gas formation, diarrhea, and abdominal cramping. Significant long-term side effects include gallstone formation, sludge in the gallbladder, steatorrhea, deterioration of glucose tolerance, and hypocalcemia.^{97,168,169} The incidence of gallstones in patients treated over the long term has varied from 5% to 70%, and the incidence of symptomatic gallstones requiring surgical treatment is less than 10%.¹⁷⁸

Interferons

Interferon- α (IFN- α)—alone or in combination with somatostatin analogue—is effective in the treatment of the carcinoid syndrome. Symptomatic and biochemical control is obtained in 40% to 50% of patients with the recommended doses of 3 to 5 million units of recombinant interferon alfa-2a or interferon alfa-2b given subcutaneously three to five times per week.¹⁷⁹⁻¹⁸⁵ Significant tumor reduction is reported in 10% to 20% of the patients.^{179,185}

IFN- α exerts a direct effect on the tumor cells by blocking cell division in the G₁/S phase of the cell cycle, by inhibiting protein and hormone synthesis, and by reducing angiogenesis through inhibition of angiogenic factors bFGF and VEGF. It has also an indirect effect through stimulation of the immune system, particularly T cells and natural killer cells.¹⁸⁶⁻¹⁸⁹ Response to IFN- α can be predicted by analyzing induction of 2',5'-oligoadenylate synthetase or protein kinase p68 (PKR), enzymes involved in cell cycle regulation and protein synthesis.^{190,191} Long-acting formulations of IFN- α (i.e., pegylated interferons) can be applied at doses of 80 to 150 μ g/week subcutaneously.

Treatment with IFN- α induces an intratumoral fibrosis that is not picked up by regular CT scanning or ultrasonography, and tumor size may therefore remain unchanged.¹⁹² The side effects of α -interferons are more pronounced than with somatostatin analogues and include chronic fatigue syndrome, anemia, leukopenia, and thrombocytopenia; 10% to 15% of patients may develop autoimmune

reactions.^{180,193} Most of the side effects are dose-dependent and can be managed by individualizing the dose.

Patients with carcinoid syndrome who have not responded to octreotide or IFN- α alone may be given both agents. Such combinations have generated symptomatic control in 70% of patients and stabilization of tumor growth in 40% to 50% of patients.^{194,195} The combination also offers better tolerance of α -interferons when somatostatin analogues are added. Moreover, somatostatin analogue treatment is hampered by the development of tachyphylaxis with time, which means less sensitivity to the somatostatin analogue, necessitating escalating doses and eventually withdrawal of the compound for several months, after which IFN- α therapy can continue. Conversely, IFN- α may be withdrawn and the somatostatin analogue continued if severe side effects of IFN- α (mainly chronic fatigue syndrome or mental depression) develop.¹⁹⁶

Chemotherapy

Most oncologists agree that patients with classic midgut carcinoids and carcinoid syndrome, in which tumors show low proliferation capacity, should not receive chemotherapy. The results of various studies have been disappointing; response rates are no more than 5% to 10%, are short lived, and are accompanied by considerable side effects.^{197,198} The combination of streptozotocin and 5-fluorouracil, which has demonstrated antitumor effects in endocrine pancreatic tumors, has not shown similar effects in classic midgut carcinoids.¹⁹⁹ In foregut carcinoids, which usually manifest a more malignant behavior, cytotoxic treatment may be attempted. Chemotherapeutic combinations include streptozotocin plus 5-fluorouracil, doxorubicin plus streptozotocin plus cisplatin plus etoposide, and dacarbazine plus 5-fluorouracil.²⁰⁰⁻²⁰² Temozolomide has significant efficacy in foregut carcinoids.²⁰³ All of these cytotoxic treatments can be combined with a somatostatin analogue.

Other Agents

Tyrosine kinase receptors such as platelet-derived growth factor receptor (PDGFR) α/β , epidermal growth factor receptor (EGFR), and vascular endothelial growth factor receptor (VEGFR) are expressed in carcinoid tumor cells and in the stroma cells. Therefore, tyrosine kinase receptor inhibitors have been used, with objective response rates of about 10% to 15%.²⁰⁴ Inhibitors of the mammalian target of rapamycin (mTOR) are drugs that block the mTOR signaling pathway, which is activated in many tumors. Everolimus alone or in combination with octreotide has generated objective response rates of 15% to 20%.²⁰⁵

Surgery

Because most tumors in patients with carcinoid syndrome are malignant at the time of clinical presentation, surgical cure is seldom obtained. Resection of local disease or regional nodular metastatic disease can cure some patients; however, even if radical surgery cannot be performed, debulking procedures and bypass should always be considered and can be performed at any time during the course of treatment.^{54,93,206}

In recent years, a more proactive attitude among surgeons has emerged, and wider resections and debulking procedures are being performed today than in the 1990s.^{54,207} In contrast to other metastatic tumors to the liver, for which liver transplantation has given poor results, liver transplantation can benefit patients with metastatic

carcinoids.^{208,209} In a review of 103 patients with malignant neuroendocrine tumors, including carcinoids and pancreatic endocrine tumors, 5- and 2-year survival rates were 16% and 47%, respectively; however, recurrence-free survival was less than 24%.²⁰⁸ Liver transplantation may be considered in younger patients (<50 years) who have a life-threatening, uncontrolled carcinoid syndrome during medical therapy or tumor-targeted radioactive treatment without known metastatic spread outside the liver.

Another means of tumor reduction is hepatic artery embolization, which not only improves the symptoms of carcinoid syndrome in about 50% of the patients but also reduces the tumor size in as many. The therapeutic effect may last for 9 to 12 months, and the procedure can be repeated.^{210,211} Chemoembolization—simultaneous embolization with surgical gel (i.e., Gelfoam) and chemotherapy (mitomycin C, cisplatin, 5-fluorouracil) or IFN- α —has resulted in symptomatic improvement in a significant number of patients with carcinoid syndrome.^{212,213} However, hepatic artery occlusion or embolization can result in serious side effects (e.g., nausea, vomiting, liver pain, fever) and major complications (e.g., hepatorenal syndrome, sepsis, gallbladder perforation, intestinal necrosis). Complications occur in 5% to 7% of patients.²¹¹⁻²¹³

Other cytoreductive treatments include cryotherapy and radiofrequency ablation.²¹⁴ However, these procedures are limited to patients with smaller tumor burden, tumors less than 5 cm in diameter, and a limited number of metastases.

Irradiation

External irradiation has demonstrated limited efficacy and is used mainly to palliate symptoms related to bone and brain metastases.^{215,216} MIBG is taken up by carcinoids and is concentrated. The possibility of radiolabeled MIBG therapy has been evaluated in a limited number of patients. The response rate has been about 30% with ¹²⁵I-MIBG or ¹³¹I-MIBG.^{217,218}

Somatostatin analogue-based, tumor-targeted radioactive treatment has been applied using ¹¹¹In-DTPA-octreotide. Symptomatic improvement has been reported for about 40% of patients, and tumor stabilization has occurred in about 30%.²¹⁹ Indium 111 is a weak irradiator (Auger electrons) and seems to be replaced by yttrium 90 (⁹⁰Y), a γ and β emitter.

Studies with ⁹⁰Y-DOTA-octreotide have shown promising results.²²⁰ The new isotope lutetium 177, a β emitter, has come into clinical use as Lu¹⁷⁷-DOTA-octreotate, with further improved results. Significant tumor reduction has occurred in 30% to 40% of patients with advanced disease. However, this agent is more effective for small tumors. It is an attractive mode of treatment because the radioactive ligand, after binding to the receptor, is internalized and transported to the cell nucleus, causing DNA damage.²²¹ Because tumor cells usually have higher-density somatostatin receptors (SSTR2 and SSTR5) than do surrounding normal tissues, the treatment may be better tolerated. The treatment algorithm for metastatic carcinoid tumor is provided in Figure 44-17.

PROGNOSIS

Carcinoid syndrome is a clinical manifestation of advanced disease. Carcinoids from various sites differ in the percentage developing carcinoid syndrome and in their aggressiveness. Survival rates for patients with carcinoids depend on the site and the extent of the tumor. In patients with

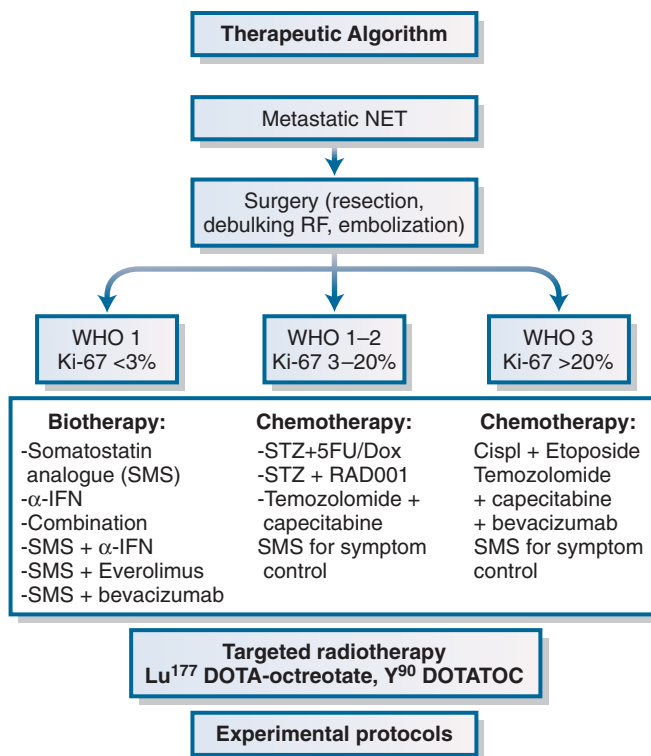

Figure 44-17 Therapeutic algorithm for treatment of metastatic carcinoid tumor. DOTATOC, DOTA-octreotide; Dox, doxorubicin; 5FU, 5-fluorouracil; IFN, interferon; NET, neuroendocrine tumor; RAD001, everolimus; STZ, streptozotocin; WHO, World Health Organization classification.

localized disease, the 5-year survival rate for those with midgut carcinoids is about 65%, not essentially higher than that for patients with regional metastases. In patients with distant metastases, the 5-year survival rate is reduced to 39%.^{10,19,20,23,25} The relative 5-, 10-, and 15-year survival rates for those with midgut carcinoids are 67%, 54%, and 44%, respectively.²²¹ The 5- and 10-year survival rates for patients with typical bronchial carcinoid are 95% and 80%, respectively. Patients with atypical lung carcinoids have only a 50% survival rate at 5 years.¹⁸

An important determinant of survival in carcinoid patients is the presence of metastases. Female gender and younger age are associated with a better prognosis. Other factors that correlate with impaired survival are high CgA level at diagnosis and high proliferation index (Ki-67).^{34,111} During the 1990s, there was a reduced incidence of death from carcinoid heart disease, possibly a result of earlier diagnosis, active surgery, and the introduction of somatostatin analogues and α -interferons. In a study performed by our group, 30% of the patients died of carcinoid heart complications.²² In a later study, this rate was reduced to less than 10%.²⁵ Clinically significant carcinoid heart disease is now rare. Between 5% and 10% of patients with carcinoids are at increased risk for simultaneous adenocarcinoma of the large intestine. Occurrence of a second malignancy is associated with a worse prognosis.^{20,23}

OTHER FLUSHING DISORDERS

Medullary Thyroid Carcinoma and VIPoma

Other neuroendocrine tumors, such as medullary thyroid carcinoma (MTC) and VIP-producing tumors (e.g., ganglioglioma, endocrine pancreatic tumors), can manifest with

flushing syndromes (Fig. 44-18).^{222,223} Patients also may have diarrhea, particularly those with VIP-producing tumors, which are accompanied by severe secretory diarrhea. In patients with MTC, flushing and diarrhea are infrequent symptoms and are seen mainly in patients with high circulating levels of calcitonin and CGRP.

The mechanism producing flushing and diarrhea is unknown, but it may be mediated through prostaglandins stimulated by calcitonin. The frequency of flushing and diarrhea is usually less than 5% in patients with advanced metastatic MTC.^{222,224} Treatment is directed against tumor growth and can consist of surgical resection, embolization of liver metastases, and cytotoxic treatment (i.e., doxorubicin-based combination therapies). Somatostatin analogue therapy can alleviate the diarrhea.

VIPoma or the watery diarrhea, hypokalemia, and achlorhydria (WDHA) syndrome (i.e., Verner-Morrison syndrome) is associated with severe secretory diarrhea (up to 15 L/day), and some patients also display continuous, whole-body, violaceous flushing and hypotension.^{223,225} The syndrome also includes achlorhydria, hypokalemia, and metabolic acidosis and is related to overproduction of VIP and a related peptide-peptide histidine methionine. These patients have tumors in the pancreas, lung, or sympathetic ganglia.^{223,224}

The diagnosis is confirmed by measuring plasma VIP, which usually exceeds 70 pmol/L.²²⁶ Treatment is directed against the tumor and hormone excess. Administration of somatostatin analogues by subcutaneous or intravenous infusion in the worst cases can control clinical symptoms.²²⁷ Cytotoxic treatment with streptozotocin-based combinations, 5-fluorouracil, or doxorubicin is recommended for malignant cases.¹⁹⁷

Mastocytosis and Related Disorders

Mastocytosis and other systemic mast cell activation are clinically related to flushing disorders. Most patients with mastocytosis have an indolent course, but some forms of mastocytosis are aggressive. Symptoms are attributed primarily to paroxysmal mast cell activation.^{228,229}

Most patients with mastocytosis have evidence of cutaneous involvement, most commonly multiple, small, pigmented lesions that produce urticaria on stroking with

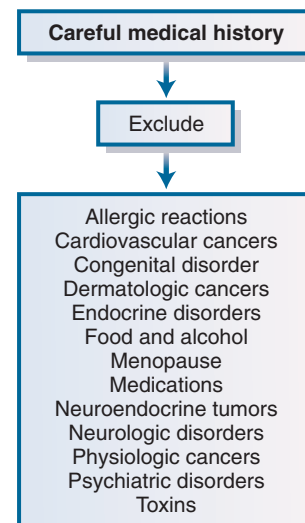

Figure 44-18 Flushing disorders. (From Yale SH, Vasudeva S, Mazza JJ, et al. Disorders of flushing. *Compr Ther*. 2005;31:59-71.)

a blunt object (Darier's sign); this condition is called *urticaria pigmentosa*.²³⁰ Another form of cutaneous mastocytosis is a more telangiectatic form called *telangiectasia macularis eruptiva perstans*. Hepatomegaly and splenomegaly can be caused by infiltration of mast cells, and hepatic fibrosis is also common.^{231,232}

Bone involvement may manifest as osteoporosis or osteosclerosis.²³³ Systemic mastocytosis can also involve the GI tract with mucosal nodules in the ileum, stomach, and large bowel.²³⁴

Hematologic abnormalities are nonspecific, with marked mast cell infiltration of the bone, anemia, leukocytosis, eosinophilia, and sometimes, lymphadenopathy.²³⁵ In a subgroup of patients, mastocytosis is secondary to primary hematologic disorders, usually myeloproliferative or myelodysplastic disease.^{236,237} Mast cell leukemia has been reported in rare cases.²³⁸ The primary eosinophilia seen in some patients with the FIP1-like 1/PDGFR- α (*FIP1L1-PDGFR α*) gene rearrangement represents a subset of chronic eosinophilic leukemia. These patients also have elevated serum tryptase levels.²³⁹ More than 80% of patients with systemic mastocytosis have activating mutations (D816V) in the tyrosine kinase domain of *KIT* that alter mast cell growth and differentiation.^{239,240}

Clinical signs of systemic mastocytosis include flushing, tachycardia, and hypotension and sometimes include nausea, vomiting, and diarrhea. This syndrome resembles carcinoid syndrome. Histamine is a potent vasodilator and is released from mast cells. Other mediators of the syndrome are the release of prostaglandin D₂, tryptase, and heparin.²⁴¹ Prostaglandin D₂ is a more potent mediator than histamine.

The diagnosis is made by measurement of histamine and histamine metabolites in the urine.^{241,242} Quantification of histamine metabolites (N-methylhistamine and methylimidazole acetic acid) appears to be more sensitive for overproduction of histamine in patients with mastocytosis.²⁴² Endogenous production of prostaglandin D₂ can be assessed by quantifying the major urinary metabolite (9 α -hydroxy-11,15-dioxo-2,3,18,19-tetranorprost-5-ene-1,20-dioic acid).²⁴³ However, these measurements can be done only in specialized laboratories. Measurement of the tryptase release is easier to perform, and increased quantities of this granule-associated enzyme tryptase can be detected by immunoassay.²⁴⁴ Bone marrow analysis of CD25⁺ cells may support the diagnosis of mast cell disease.²³⁹

Treatment depends on the severity of the disease. As in the treatment of allergic anaphylaxis, epinephrine is effective in reversing the hypotension associated with mast cell mediator release²⁴⁵; these patients should have constant access to epinephrine in the form of subcutaneous injection or inhalation. Chronic therapy to prevent acute attacks includes antihistamine therapy combined with inhibition of prostaglandin biosynthesis. Blockade of histamine H₁ and H₂ receptors is required to prevent the vasodilator effect of histamine.^{99,239}

Nonsteroidal anti-inflammatory drugs (NSAIDs) inhibit the cyclooxygenase enzyme that catalyzes the formation of prostaglandins. Aspirin has been used, but some patients cannot tolerate it because of side effects in the gut and allergic reactions.²⁴⁶ In patients resistant to antihistamines and NSAIDs, IFN- α has been attempted with a reduction in mast cell numbers and excretion of mast cell mediators. Treatment with IFN- α is still considered experimental.^{239,247} A subset of patients who carry the *FIP1L1-PDGFR α* oncogene achieve complete clinical, histologic, and molecular remission with imatinib mesylate therapy, in contrast to those with the *KIT* D816V mutation.²³⁹

DISCLOSURE INDEX

The following contributors have indicated that they have a relationship that, in the context of their participation in the writing of a chapter for the twelfth edition of *Williams Textbook of Endocrinology*, could be perceived by some people as a real or apparent conflict of interest. Codes for the disclosure information (institution[s] and nature of relationship[s]) are provided below.

RELATIONSHIP CODES

- A Stock, stock options, or bond holdings
- B Research grants
- C Employment (full- or part-time)
- D Ownership or partnership
- E Consulting fees or other remuneration received by the contributor or immediate family
- F Nonremunerative positions, such as board member, trustee, or public spokesperson
- G Receipt of royalties
- H Participation in a “speakers’ bureau”
