Despite the use of GH therapy, long-term studies still show that most patients fail to reach their genetic target heights. Evaluation of adult heights in 121 patients with childhood GHD treated in the Genentech GH research trials indicated a mean adult height in both male and female patients of -0.7 SDS, with 106 patients being within 2 SDS for normal adult Americans.¹⁴²⁵ Even in these closely monitored patients, however, a difference of -0.4 to -0.6 SDS from midparental target height still occurred. The achievement of the genetic target is possible, however: a Swedish subgroup (in the Kabi International Growth Study [KIGS] database) of consistently treated patients reached a median final height SDS of -0.32, which was equivalent to the midparental target height.¹⁴²⁹ A more recent study of the Swedish subgroup actually found a final height SDS greater than midparental target height by +0.2 (see Table 24-12).¹⁴²⁰

Factors that have been found to correlate with enhanced adult height in GH-treated, GH-deficient children include baseline height, younger age at onset of treatment, longer treatment duration (especially during prepubertal years), and a greater growth velocity during the first year of treatment (Figs. 24-48 and 24-49).¹⁴²⁸ Increased height velocity and subsequent superior adult height outcome, although with considerable overlap, were demonstrated in children with GHD who carried one or both *GHRd3* alleles (i.e., with an exon 3 deletion).^{783,1430,1431} Data from National Cooperative Growth Study (NCGS) and KIGS showed that the height gained during puberty in patients with GHD was generally comparable to that in healthy children with delayed bone age.^{1427,1432} As might be expected based on that observation, final height correlates with height at the onset of puberty in GHD patients.^{1404,1424,1433-1435} Therefore, every effort should be made to enhance growth before puberty, and delays in diagnosis and initiation of therapy

probably contribute to the compromised adult heights still reported in many studies.

GH treatment of children who develop GHD as a result of cranial irradiation represents a special case when evaluating final height outcomes. In these children, who have received cranial irradiation for the treatment of malignancy, GH treatment is not initiated until there is no evidence of active tumor; this results in a delay between the diagnosis of GHD and the initiation of treatment. Final height is negatively correlated with the length of that lag time.¹⁴³⁶ In addition, those who have received spinal irradiation in addition to the cranial irradiation have a lower final height due to impairment of spinal growth after irradiation.^{1436,1437}

Figure 24-48 Relationship between first-year change in height standard deviation score (SDS) and total change in height SDS between start of growth hormone (GH) treatment and near-final height in children with idiopathic isolated GH deficiency. KIGS, Kabi International Growth Study database. (Modified with permission from Reiter EO, Price DA, Wilton P, et al. Effect of growth hormone [GH] treatment on the final height of 1258 patients with idiopathic GH deficiency: analysis of a large international database. *J Clin Endocrinol Metab*. 2006;91:2047-2054.)

Figure 24-49 Relationship between prepubertal change in height standard deviation score (SDS) and total change in height SDS between start of growth hormone (GH) treatment and near-final height in children with idiopathic isolated GH deficiency. KIGS, Kabi International Growth Study database. (Modified with permission from Reiter EO, Price DA, Wilton P, et al. Effect of growth hormone [GH] treatment on the final height of 1258 patients with idiopathic GH deficiency: analysis of a large international database. *J Clin Endocrinol Metab.* 2006;91:2047-2054.)

In an effort to increase final height in GHD patients, the use of high-dose GH during puberty has been studied, based on the rationale that GH secretion normally rises twofold to fourfold during the pubertal growth spurt, with dramatic concomitant increases in serum IGF1 levels, and the pubertal growth spurt normally accounts for approximately 17% of adult male height and 12% of adult female height. Earlier studies by Stanhope and associates^{1438,1439} indicated that little difference in height gain could be observed when adolescent patients were treated with 30 versus 15 IU/m² per week of GH (approximately 0.04 versus 0.02 mg/kg per day). Mauras and colleagues¹⁴⁴⁰ evaluated higher pubertal GH doses (0.1 versus 0.043 mg/kg per day) and found that the higher dosage resulted in a 4.6-cm increase in near-final height. Mean height SDS achieved in the group receiving 0.043 mg/kg per day of GH (as in the earlier report¹⁴²⁵) was -0.7 ± 0.9 , but in the group receiving 0.1 mg/kg per day it was 0.0 ± 1.2 . The higher GH dosage did not result in more rapid acceleration of skeletal maturation.

Another approach that has been taken to attempt to increase final height in GH-treated patients has been to adjust the dose of GH to reach a target IGF1 level rather than treating with a fixed, weight-based dose.^{1441,1442} A study reported by Cohen and colleagues found that targeting a high IGF1 level (reaching a mean IGF1 SDS of approximately +1.5) resulted in an increase in growth compared with the two comparator groups, which had mean IGF1 SDS of approximately +1.¹⁴⁴¹ It required a GH dose approximately three times higher to reach this IGF1 level (0.11 mg/kg per day versus 0.041 and 0.033 mg/kg per day for the comparator groups).¹⁴¹ In the study reported by Marchisotti and colleagues,¹⁴⁴² the difference in IGF1 levels between groups (+0.8 SDS versus -0.3 SDS) was even greater than that in the report by Cohen and colleagues,¹⁴⁴¹ but the Marchisotti study did not find a difference in growth rate between the two groups. The difference in GH dose was much smaller, however (0.038 versus 0.30 mg/kg per day). Therefore, as would be expected, a higher GH dose results in a higher growth rate, but it is not yet known whether

targeting a specific IGF1 level results in an increased final height; nor is it known whether these higher doses have adverse effects not seen with the more usual doses currently used. An interesting finding was the wide range of doses required to reach a given IGF1 level: the high-IGF1 targeted group required GH doses ranging from less than 0.025 mg/kg per day to greater than 0.25 mg/kg per day, whereas the low-IGF1 targeted group required doses ranging from less than 0.025 to 0.15 mg/kg per day.¹⁴⁴¹

The impact of treatments to alter sex hormone levels (e.g., GnRH agonists, aromatase inhibitors) with the aim of improving final height in GHD and other conditions is discussed later.

Combined Pituitary Hormone Deficiencies. If GHD is part of a combined pituitary insufficiency syndrome, it is necessary to address each endocrine deficiency, both for general medical reasons and to ensure maximal effect of GH therapy. TSH deficiency is often “unmasked” during the initial phase of therapy, and thyroid function should be assessed before the onset of therapy, during the first 3 months of GH treatment,¹⁴⁴³ and at least on an annual basis thereafter. The pituitary-adrenal axis can be evaluated during the insulin stimulation test in the workup for GHD or separately if GHD is identified with the use of a different provocative test. If ACTH secretion is impaired, patients should be placed on the lowest safe maintenance dose of glucocorticoids, certainly no more than 10 mg/m² per day of hydrocortisone, and less if possible. Higher doses impair the growth response to GH therapy but should be given during times of stress. It is critical to monitor the long-term evolution of glucocorticoid deficiency, especially in those with PROP1 mutations (discussed earlier). However, Lange and colleagues studied 24 adults with a prior history of idiopathic isolated childhood GHD and identified adrenal insufficiency in 10 of them, half of whom did not have evidence of ongoing GHD¹⁴⁴⁴; this suggests a need to consider monitoring for impaired ACTH secretion even in those patients with presumed IGHD.

Gonadotropin deficiency may be evident in the infant with microphallus. This can be treated with three or four monthly injections of 25 mg of testosterone enanthate in the first months of life.¹⁴⁴⁵ Management at puberty can be more complicated, in that the physical and psychological benefits of promoting sexual maturation must be balanced against the effects of epiphyseal fusion. When GH therapy is initiated in childhood and growth is normal before adolescence, it is appropriate to begin gonadal steroid replacement at a normal age (11 to 12 years of age in girls, 12 to 13 years of age in boys). In boys, this can be done by beginning with monthly injections of 50 to 100 mg of testosterone enanthate, gradually increasing to 200 mg per month, and eventually moving to the appropriate adult replacement regimen as determined by monitoring of plasma testosterone levels. In girls, therapy involves the use of conjugated estrogens or ethinyl estradiol and eventual cycling with estrogen and progesterone.

Monitoring Growth Hormone Therapy. Patients treated with GH should be seen every 3 to 6 months to monitor their response to treatment (Table 24-13). An increase in linear growth velocity should be seen within the first 6 months. Height SDS should increase at least 0.25 SDS in the first year.¹⁴⁴⁶ Treatment models have been developed that predict the expected growth rate in response to GH treatment.^{1399,1408,1447-1449} A model¹³⁹⁹ explaining 61% of growth response variability in the first year of therapy includes inverse relationships with maximum GH response

TABLE 24-13

Elements of Monitoring Growth Hormone Therapy

Close follow-up with a pediatric endocrinologist every 3-6 mo
Determination of growth response (change in height SDS)
Evaluation of compliance
Screening for potential adverse effects
Interval measurements of serum IGF1 and IGFBP3
Annual assessment of thyroid function
Consideration of dose adjustment based on IGF values, growth response, and comparison with growth prediction models
Periodic reevaluation of adrenal function

IGF, insulin-like growth factor; IGFBP, insulin-like growth factor-binding protein; SDS, standard deviation score.

during provocative testing, age, and height SDS minus midparental height SDS and positive correlation with body weight SDS, GH dose, and birth weight SDS.^{1450,1451} The single most important predictive factor for growth in years 2 through 4 is the first-year height velocity. These models can be used to quantify whether the individual patient is responding appropriately to GH treatment. If a patient's initial growth response is lower than predicted, the clinician should consider whether the diagnosis of GHD was correct, whether additional growth disorders (e.g., hypothyroidism) are present, and whether there is lack of compliance with the treatment.¹⁴⁴⁸

It is appropriate to monitor the IGF1 and IGFBP3 levels after initiation of GH treatment and perhaps yearly thereafter.^{1446,1452} A failure of IGF1 and IGFBP3 levels to increase into the normal range with treatment, together with an inadequate growth response, suggests compliance failure or the presence of GH insensitivity. Because of the association of elevated IGF1 levels with certain cancers (see later discussion), a reduction in GH dose should be considered for patients with serum IGF1 levels substantially above the normal range after the first 2 years of therapy.¹⁴⁴⁶ Whether the IGF1 level should be used to guide GH dosing awaits additional studies (see earlier discussion).

CPHD may evolve over several years, so children who are initially diagnosed with IGHD may develop CPHD. Thyroxine levels should be assessed after GH treatment has been initiated, and annually thereafter, to identify the development of central hypothyroidism during treatment. Periodic reevaluation for ACTH deficiency should be performed. It is not necessary to routinely monitor fasting insulin and glucose levels, but if impaired glucose control is suspected, a fasting glucose level and glycosylated hemoglobin (HbA_{1c}) should be measured.

The growth response to GH typically attenuates after several years but should continue to be equal to or greater than the normal height velocity for age throughout treatment. Use of statistical growth treatment models can prove valuable in judging therapeutic efficacy.^{1399,1408,1448} A suboptimal response to GH can result from several causes: (1) poor compliance, (2) improper preparation of GH for administration or incorrect injection techniques, (3) subclinical hypothyroidism, (4) coexisting systemic disease, (5) excessive glucocorticoid therapy, (6) prior irradiation of the spine, (7) epiphyseal fusion, (8) anti-GH antibodies, or (9) incorrect diagnosis of GHD as the explanation for growth retardation (particularly in a patient with idiopathic IGHD and normal findings on MRI). Although 10% to 20% of recipients of recombinant GH develop anti-GH antibodies, growth failure is rarely caused by such

antibodies, except in the case of individuals who have GHD as a result of GH gene deletion.^{1376,1377,1453}

Treatment during the Transition to Adulthood and in Adulthood. A growing challenge in the management of patients with GHD has been the issues surrounding their care after the growth process has ceased.¹⁴⁵⁴ This period, from the middle to late teenage years until the mid-20s, is a normal physiologic phase during which peak bone and muscle mass is achieved and the independence and self-sufficiency characteristic of adulthood are attained. It is also a time during which care of pediatric patients is transferred to endocrinologists who treat adults.

Clinical consequences of GHD in adults and the potential benefits of GH therapy in such patients have already been described.¹⁴⁵⁵⁻¹⁴⁵⁸ Signs and symptoms of adult GHD include reduced lean body mass and musculature, increased body fat, reduced BMD, reduced exercise performance, and increased plasma cholesterol. Adults with GHD have a significantly increased risk of death from cardiovascular causes, a finding potentially linked to increased visceral adiposity and other cardiovascular risk factors.^{1459,1460} Adults with GHD have been found to have "impaired psychological well-being and quality of life," characterized by depression, anxiety, reduced energy and vitality, and social isolation.¹⁴⁶¹ Several placebo-controlled studies have demonstrated that GH therapy for adult GHD results in marked alterations in body composition, fat distribution, bone density, and sense of well-being.^{1456,1457,1462,1463}

Based on the adult data, which suggest profound metabolic derangements associated with untreated GHD, continuation of GH treatment in late adolescence in the patient who shows persistent GHD is an important issue. Documentation of persistent GHD is important. Among almost 500 patients with IGHD, 207 (44%) had normal GH levels on provocative retesting.¹⁴⁶⁴⁻¹⁴⁷¹ In contrast, approximately 96% of patients with CPHD, with or without structural abnormalities of the hypothalamic-pituitary area, had sustained GHD.^{1465,1466,1468-1472} The presence of multiple anterior pituitary hormone deficiencies or structural disease would seem to obviate the need for retesting. The data are not absolute, so clinical judgment is of paramount importance. The strict pharmacologic definition of GHD in this age group is difficult, as was shown by Maghnie and colleagues,¹⁴⁷³ who demonstrated that the much lower GH responses to testing that characterize older adults should not be used in this population. The issue of testing validity may have influenced the dichotomy observed between the IGD and CPHD patient populations in testing "positive" on the provocative tests. As in the childhood population, it seems reasonable not to rely solely on artificial cutoffs in pharmacologic provocative tests but to include broader clinical and laboratory data.

Many patients do not wish to continue the daily GH regimen, but the data do support strong consideration for sustained treatment. After 1 to 2 years off GH therapy, IGF1 and IGFBP3 levels decrease substantially below baseline levels.¹⁴⁷⁴⁻¹⁴⁷⁸ Resumption of GH normalizes these levels, although there is a strong suggestion of a gender-based difference in GH requirements, with females needing higher GH doses.¹⁴⁷⁶⁻¹⁴⁷⁸ Loss of energy and strength is a frequent finding,¹⁴⁷⁹ and some quality-of-life data suggest age-specific psychological issues in patients with untreated severe GHD during the transition to adulthood.^{1480,1481} Quality-of-life data with rigorous study designs are lacking in GH-treated childhood GHD.^{1482,1483} In untreated patients, total body fat and abdominal fat increase significantly and lean body mass is lost, compared with control subjects,

comparable GH-treated patients, or patients who have reinstituted therapy.^{1474,1475,1477,1484,1485}

Because bone mass accrual is not completed until the third decade, late adolescence is an important time for GH sufficiency, to prevent later osteopenia.^{849,1454} There have been numerous GH treatment studies carried out in the transition age group to assess the impact on bone mineralization.^{1476-1478,1486,1487} Differences in age at onset of retreatment, duration of therapy, GH dosage, and gender distribution have led to variations in results. In general, however, the data affirm the concept that reinstitution of treatment with GH enables progression of bone mineralization to appropriate adult levels. Bone density assessment in patients with childhood-onset IGHD who tested negative for GHD in adulthood showed lower bone mineralization than in controls and a correlation with IGF1 levels.¹⁴⁸⁸

The cardiovascular risk of stopping GH treatment has also been examined. Colao and associates showed modest left ventricular ejection fraction decrements that paralleled IGF levels when stopping and restarting GH therapy in a group of adolescents with GHD.¹⁴⁸⁹ The overall IGF levels were rather low, so cardiac changes were relatively modest. It should be recalled that GH treatment during childhood alters cardiac size but does not seem to change cardiac function.¹⁴⁹⁰ Mauras and associates used a wide array of functional studies in a similar transition-age group and were unable to demonstrate cardiac changes,¹⁴⁷⁸ but their patients had relatively high IGF1 levels (mean, 427 ng/mL) at GH discontinuation, suggesting a degree of “protectiveness” in the subsequent period off GH treatment. Nonetheless, abnormal cardiovascular risk factors, such as elevated concentrations of lipids, fibrinogen, inflammatory markers, and homocysteine, and platelet hyperactivation may occur in adolescents with untreated GHD.¹⁴⁹¹⁻¹⁴⁹³ In prepubertal children with GHD, normalization of homocysteine levels and of markers of oxidative stress is achieved with GH treatment,^{1494,1495} buttressing the notion of important effects of GH upon cardiovascular health. Therefore, cardiac function and those factors affecting vascular biology are targets in the spectrum of GH-mediated body compositional changes.

These studies support the continuation of GH treatment in late adolescence, albeit at lower doses than in childhood, to prevent the development of adverse cardiovascular risk, diminished bone mineralization, and an overall lowering of energy level. Whether the diversity of treatment and response data relates to the efficacy of the childhood GH therapeutic process is not clear, but the period of time off GH and the degree of persistent GHD would seem likely predictors of clinical status at the time of reinitiation of GH treatment.

After the adolescent with GHD has completed skeletal growth, the persistence of GHD is evaluated.^{1237,1454} If the patient has a high probability of persistent GHD (i.e., CPHD, IGHD with structural abnormalities, or confirmed genetic mutations), a presumption of persistent GHD is made. Otherwise, GH therapy should be halted for 2 to 3 months, followed by a thorough reevaluation. A recommended algorithm for this evaluation is shown in Figure 24-50.¹⁴⁹⁶

As in childhood GHD, laboratory testing is imperfectly precise for diagnosis of ongoing GHD. Some patients have results that neither indicate nor eliminate ongoing GHD but are intermediate, suggesting either probable or partial GHD. If ongoing GHD is considered to be present or probable, assessment of body composition, BMD, and fasting lipid levels should be determined. The decision to reinstitute GH treatment is then based on a discussion with the

patient and family regarding the risks and benefits in light of the laboratory test results and the risk for metabolic consequences (see Figure 24-50).¹⁴⁹⁶ In addition, caution should be exercised in considering whether to continue GH therapy when there is a known risk of diabetes or malignancy. This is also an opportunity for a thorough clinical reassessment and a determination of the need for replacement of other hormones. The transition to adult GH replacement should be arranged as a close collaboration between endocrinologists who treat pediatric patients and those who treat adult patients and should include discussion with the patient and family. A discussion of many transition issues was reported by Clayton and associates from a European consensus meeting.¹⁴⁵⁴

Growth Hormone Treatment of Other Forms of Short Stature

Prader-Willi Syndrome. Guidelines for the clinical management of PWS were published after an international multidisciplinary expert meeting in 2007.¹⁴⁹⁷ Short stature due to GH insufficiency is almost always present in children with PWS. In a large cohort of 1135 children with PWS starting GH treatment, median height SDS was -2.2 (range, -4.1 to -0.3) at a median age of 6.4 years (range, 1.3 to 12.9 years).¹⁴⁹⁸

Serum levels of IGF1 are reduced in most children with PWS.¹⁴⁹⁹⁻¹⁵⁰² Studies have shown that spontaneous GH secretion is reduced, and 70% of children with PWS have GH peaks of less than 10 µg/L during pharmacologic stimulation tests.¹⁵⁰³ Although most experts agree that prior GH testing is not required before GH treatment is initiated, it can be helpful. GH treatment of growth failure in PWS is an FDA-approved indication. GH treatment in children with PWS aims to improve childhood growth, final adult height, and body composition (see review by Burman and associates¹⁵⁰⁷). Numerous clinical trials have documented the efficacy of GH therapy. In randomized, controlled studies there were significant increases in height and growth velocity and a significant decrease in percent body fat, as well as increased percentage of fat-free mass, improved muscle strength and agility, and increased fat oxidation during the first year of GH treatment.^{1500,1504-1508} Stabilization of these parameters occurs after the second year of therapy. Lean body mass increased significantly during the first 2 years in children with PWS who received GH treatment, compared with no treatment.¹⁵⁰⁹⁻¹⁵¹⁰ GH therapy for 2 additional years resulted in continued beneficial effects on body composition. When the dose of GH was reduced to 0.3 mg/m² per day, these improvements were not maintained.¹⁵⁰⁹

BMD improves in children with PWS treated with GH. In two German cohorts, the mean spontaneous adult heights were reported in one study as 162 cm in boys and 150 cm in girls¹⁵¹¹ and the other as 159 cm in boys and 149 cm in girls.¹⁵¹² In the Kabi International Growth Study database, 33 patients (21 boys and 12 girls) reached adult height, and two thirds of them were above -2 SDS; the median adult height was -1 SDS after a mean duration of 8.4 years.¹⁵¹³ Another study with 21 adults (13 boys, 8 girls) revealed a mean adult height of 0.3 SDS after a mean duration of 7.9 years of GH treatment.¹⁵¹⁴ In this cohort, the strength and agility that were evident during the initial 2 years continued into adulthood. The patients also reported a higher quality of life and reduced depression.¹⁵⁰⁶ In 55 children monitored during 4 years of continuous GH treatment (1 mg/m² per day), body composition was significantly improved, mean height normalized, head

GH, growth hormone; GHD, growth hormone deficiency; CPHD, combined pituitary hormone deficiencies; BMD, bone mineral density; LBM, lean body mass.

circumference increased, and BMI significantly decreased. GH treatment had no adverse effects on bone maturation, blood pressure, glucose homeostasis, and serum lipids.¹⁵¹⁵

Before GH therapy is begun, screening for hypothyroidism is indicated because of the association with primary and central hypothyroidism.^{1516,1517} Continued screening is also recommended. Treatment with GH beginning as early as 2 years of age is recommended, but there may be additional benefits to starting therapy between 6 and 12 months of age. Several studies have found improvements in motor development, muscle tone, head circumference, and, possibly, cognition and behavior.^{1518,1519}

Since October 2002, several reports of unexpected deaths in infants and children with PWS have been published.¹⁵²⁰⁻¹⁵²²

Between 1985 and 2006, the NCGS monitored the safety and efficacy of recombinant human GH in 54,996 children. Two deaths were reported in patients with PWS.¹⁵²³ Although death from presumed obesity-induced hypoventilation or apneic events in PWS without GH treatment is well described, the occurrence of such deaths during GH administration raises the question of whether GH exacerbates this condition.^{1524,1525} Tonsillar hypertrophy and fluid retention associated with GH therapy are potential risk factors. Most of the deaths, with or without GH treatment, were related to obesity or to a complicated course of a relatively mild respiratory tract infection, sleep apnea, adenoid or tonsillar hypertrophy (or both), hypoventilation, and aspiration. The obesity-hypoventilation syndrome is the

more likely etiologic factor, suggesting that ventilatory and pulmonary function should be assessed with polysomnography studies before and during GH treatment.^{1524,1526}

In a recent review that included 64 children (42 boys and 22 girls, 28 receiving GH treatment), the highest death risk occurred during the first 9 months of GH treatment.¹⁵²² Therefore, it is recommended that GH treatment be started at a low dose (e.g., 0.25 to 0.30 mg/m² per day or 0.009 to 0.012 mg/kg per day) and increased during the first weeks and months to reach the standard replacement dosage of approximately 1 mg/m² per day or 0.24 mg/kg per week. Patients should be monitored for sleep apnea and IGF1 levels. The GH dose should be decreased if there is evidence of high IGF1 levels, especially if associated with edema, worsening or new onset of snoring, headache, or acromegalic clinical features.

Five prospective studies have evaluated the effects of GH treatment on breathing disorders in PWS.^{680,1505,1527,1528} Carbon dioxide responsiveness, resting ventilation, and airway occlusion pressure improved during 6 to 9 months of GH treatment,¹⁵²⁸ and the inspiratory and expiratory muscle strength improved during 12 months of GH treatment, compared with controls.¹⁵⁰⁵ In a double-blind, placebo-controlled, crossover study, the apnea-hypopnea index (AHI) was found to decrease in 12 children with PWS, compared with controls, after 6 months of GH therapy although the difference was not statistically significant.⁶⁸⁰ Another study found a decrease in AHI in most of the adults and children studied after 6 weeks of GH therapy.¹⁵²⁹ A subset of patients had an increased AHI with more obstructive events, but most of these latter patients had upper respiratory tract infections and adenoid/tonsil hypertrophy, and two of them had high IGF1 levels. In another study in 35 prepubertal children with PWS, the AHI did not significantly change during 6 months of GH therapy.¹⁵³⁰ However, four of these children had an increase in the number of episodes of obstructive apnea during an upper respiratory illness; these were not present after recovery. Therefore, it is recommended that obesity-related sleep and breathing problems be evaluated before and vigilantly monitored after GH treatment begins. Polysomnography and ear, nose, and throat evaluations should be performed as necessary.

A recent study¹⁵³¹ showed that 60% of PWS patients had central adrenal insufficiency. This may explain the high rate of sudden death especially during infection-related stress. The authors concluded that patients with PWS should be treated with hydrocortisone during stress until adrenal insufficiency can be ruled out.^{1531,1532}

Between 30% and 70% of children with PWS have scoliosis.^{1514,1533-1537} Weight control is a vital part of its prevention and management. Therefore, before GH treatment is initiated, spinal radiographs and, if appropriate, orthopedic assessment are recommended. Reports of scoliosis worsening during GH treatment reflect the natural history of this condition rather than a side effect of treatment in most cases, and discontinuation of GH is not indicated.

In view of the childhood findings of low lean body mass and high fat content, osteopenia, and some degree of glucose intolerance ameliorated by GH, the issue of long-term therapy through adulthood must be considered and studied.¹⁵³⁸⁻¹⁵⁴⁰ After growth is complete, attainment of a normal peak bone mass, continued improvement of muscle mass and strength, reduction of body fat, prevention of cardiovascular morbidity, and improvement in well-being and quality of life are potential benefits of continued GH therapy.¹⁵⁴¹ Adult GHD and low IGF1 levels have been reported in patients with PWS.^{1502,1542} Short-term GH

treatment in GH-naïve adults with PWS has been reported to modestly improve body composition, cognition, motor performance, and social status.¹⁵⁴² Further long-term studies are needed on adolescents with PWS transitioning to adult therapies.

Chronic Renal Disease. Chronic renal disease (CRD) is regarded as indication for the commencement of GH administration. Short stature is more severe in children with congenital renal disorders than in children with acquired renal diseases.^{888,1543,1544} Even after renal transplantation, final height is below the lower limit of normal in about 50% of children.^{915,1545} GH treatment is able to increase height velocity and height SDS^{900,1546,1547} and significantly improves final height¹⁵⁴⁸⁻¹⁵⁵⁰ in patients with CRD (Figs. 24-51 and 24-52). The therapy should be implemented if short stature persists for longer than 6 months and in subjects with marked deceleration of growth velocity, and it should be continued until transplantation is performed.¹⁵⁵¹ However, the first-year response to GH is less than in short children with GHD.¹⁵⁵²

GH accelerates growth in children with CRD, at least over 5 years of therapy.¹⁵⁵³⁻¹⁵⁵⁶ Using a GH dosage of 0.05 mg/kg per day, Fine and colleagues¹⁵⁴⁶ reported a mean first-year growth rate of 10.7 cm in GH recipients and 6.5 cm in the placebo group; in the second year, GH-treated patients had a mean growth rate of 7.8 cm/year compared with 5.5 cm/year in placebo recipients, resulting in an improvement of height SDS from -2.9 to -1.5. Twenty patients who were treated for 5 years reached a normal height SDS of -0.7, with a mean height increase of 40 cm.¹⁵⁵⁶ The youngest patients (<2.5 years of age) had the most impressive growth response to GH therapy (14.1 cm/year). Doses recommended in children with CRD are higher than in GHD patients (i.e., about 0.35 mg/kg per week)¹⁵⁵⁷ because growth patterns in these patients are dose dependent.¹⁵⁵⁸ Deleterious effects on renal function and progression of osteodystrophy were not observed.^{1559,1560} This treatment regimen does not adversely affect renal graft function after transplantation, nor is there significant

Figure 24-51 Annual growth velocity (mean \pm standard deviation) in 20 growth-retarded prepubertal patients with chronic renal insufficiency who were treated with growth hormone. (From Fine RN, Kohaut E, Brown D, et al. Long-term treatment of growth retarded children with chronic renal insufficiency with recombinant human growth hormone. *Kidney Int.* 1996;49:781-785. Reproduced with permission of R.N. Fine.)

Figure 24-52 Height standard deviation score (SDS) in 20 growth-retarded prepubertal patients with chronic renal insufficiency (mean \pm standard deviation). Note that the basal height is outside the normal range (at -2.6 SDS), enters the normal range within 1 year of treatment initiation, and is not different from the mean by the 5th year of growth hormone therapy. (From Fine RN, Kohaut E, Brown D, et al. Long-term treatment of growth retarded children with chronic renal insufficiency with recombinant human growth hormone. *Kidney Int.* 1996;49:781-785. Reproduced with permission of R.N. Fine.)

“catch-down” growth after the transplantation.¹⁵⁶¹ The final height in 38 German children treated with GH for an average of 5.3 years was -1.6 ± 1.2 SDS, an increment of 1.4 SDS over the pretreatment baseline. The final height of an untreated control group was -2.1 ± 1.2 , or 0.6 SDS below baseline.¹⁵⁴⁹

More recently, adult heights of 178 French patients treated with GH were reported. Mean adult height was 162.2 cm in men and 152.9 cm in women, and 46% were more than -2 SDS for height. Adult height SDS was correlated with height SDS and spontaneous height velocity before treatment and with the effect of treatment. These adult heights were significantly better when compared with historical cohorts of patients not treated with GH.¹⁵⁶²

In 2009, a review of longitudinal data from 7189 patients enrolled in the chronic renal insufficiency registry of the North American Pediatric Renal Trials and Collaborative Studies (NAPRTCS) revealed that 827 patients (11.5%) had received GH. A total of 787 children with CRD who were previously naïve to GH treatment and received recombinant human GH for 1 to 4 years (median, 1.5 years) were paired with 787 control patients and monitored for 4 years. The GH-treated group had a significantly greater height velocity SDS than the control group at 2.5 years. Among 220 pairs evaluated at 2 years, the height SDS of the GH-treated group was 0.56 SDS higher than that of the control group ($P < .05$). Treatment with GH had no significant impact on BMI or estimated glomerular filtration rate (GFR).¹⁵⁶³

The magnitude of response to GH treatment depends on the GH dosage. A dose of 0.35 mg/kg per week appears to be optimal for short patients with CRD; half of this dose was less effective, and doubling did not significantly improve the response in double-blind studies.^{1554,1564} Long-term GH treatment has also been shown to be safe and effective for extremely short (-4.0 SDS) children with

nephropathic cystinosis and should be considered if nutrition and cysteamine treatment do not prevent growth failure.¹⁵⁴⁴ Because children are often short at the time of renal transplantation, have hormone findings of relative GH insensitivity, and receive chronic prednisone therapy, GH is sometimes administered in the post-transplantation period. Data after 1 and 2 years of treatment of such children and adolescents¹⁵⁶⁴⁻¹⁵⁶⁷ indicated a large increment of growth velocity at year 1 and a smaller benefit at year 2. As with GH treatment of CRD, the pharmacologic regimen overcomes the relative GH insensitivity. Individual patients show a wide variation in response, and predictors include age, GFR, need for dialysis treatment, target height, and pretreatment growth rate.^{9,1568}

A mathematical model for prediction of the individual response to GH in prepubertal children with CRD was developed from the KIGS.¹⁰ Thirty-seven percent of the variation in the first-year growth response was explained by this model, with the greatest first-year response in younger children who had no weight reduction, no hereditary renal disorder, and high residual renal function. There was a small GH dose effect during the first treatment year.¹⁰ Such models, using clinical variables, may allow individualized GH treatment decisions in children with CRD.

Considerable assessment must yet be undertaken to demonstrate whether there is increased growth over a longer term, that renal function does not deteriorate during therapy, and that the risk of rejection is not enhanced. GH treatment does not appear to cause an accelerated decline of allograft function¹⁵⁶⁹⁻¹⁵⁷¹ nor changes in histopathologic findings,¹⁵⁷² but exacerbation of chronic rejection by GH therapy remains a possibility.¹⁵⁷³ Use of nonsteroid-based immunosuppressive regimens may obviate the need for post-transplantation GH treatment.

A short-term study in chronic well-nourished dialysis patients showed that combined administration of moderate doses of GH with recombinant human IGF1 (rhIGF1) had a complementary effect on protein metabolism.¹⁵⁷⁴ This approach is theoretically reasonable because GH administration results in an increase in protein synthesis but does not significantly inhibit proteolysis,¹⁰³⁸ whereas the predominant effect of IGF1 is the inhibition of proteolysis.¹⁵⁷⁵ Confirmation by longer-term studies is needed to assess whether this favorable anabolic effect persists and to determine the safety profile of this intervention.^{888,900,915,1543-1552,1554,1557,1558,1564,1576,1577}

Juvenile Idiopathic Arthritis. Juvenile idiopathic arthritis (JIA) is often complicated by growth deficiency. The decrease in linear growth usually correlates with the severity of the disease, although catch-up growth may not occur during remissions. The final height is less than -2 SDS in 11% of patients with polyarticular JIA and in 40% of those with systemic JIA.^{1578,1579} Serum GH levels are normal or low, usually with low plasma IGF1 levels.^{1580,1581} The pathogenesis of short stature is thought to be GH insensitivity associated with both the inflammatory process and glucocorticoid treatment.^{1582,1583} Several trials have been conducted to determine whether GH replacement therapy is effective in patients with JIA.¹⁵⁸³⁻¹⁵⁸⁸ Trial of GH replacement using GH dosages ranging from 0.1 to 0.46 mg/kg per week increased serum levels of IGF1 and linear growth velocity. However, the trials all had significant interindividual variability.¹⁵⁸⁹ GH therapy for up to 3 years was notable for a decrease in the loss of growth velocity associated with the active phase of JIA.¹⁵⁸⁷

In a randomized, controlled trial of GH therapy (0.33 mg/kg per week for 4 years) in 31 children with JIA,

a height increase of 1 SDS was found, compared with a decrease of 0.7 SDS in the untreated control group.¹⁵⁸⁸ The GH-treated patients had a significantly greater final height compared with untreated control patients (-1.6 ± 0.25 SDS versus -3.4 ± 2.0 SDS; $P < .001$).¹⁵⁹⁰ As expected, the severity of inflammation negatively affected the efficacy of GH therapy.^{1588,1590} In a randomized trial of normal-height children with JIA treated with high-dose GH therapy (0.46 mg/kg per week) starting within 12 to 15 months after initiation of glucocorticoid therapy, the 3 year follow-up showed that the heights of GH-treated children remained normal (-1.1 SDS at baseline and -0.3 SDS after 3 years) while linear growth of the control patients declined from -1.0 SDS to -2.1 SDS.¹⁵⁹¹ In the randomized, controlled trials published to date, patients were followed for up to 7 years, and no substantial differences were found in disease activity variables, including worsening of preexisting bone deformities, between GH-treated and control patients.¹⁵⁸²⁻¹⁵⁸⁸

Because chronic inflammation, glucocorticoid treatment, and GH therapy are all associated with decreased sensitivity to insulin, children with JIA are at risk for impaired glucose homeostasis.^{496,1589,1592} Therefore, monitoring of glucose tolerance using blood glucose, fasting insulin, and HbA_{1c} assays at 6- to 12-month intervals is recommended. More intensive monitoring with oral glucose tolerance tests at baseline and then once yearly during treatment may be indicated.

Turner Syndrome. Patients with TS have a final height averaging 143 cm in the United States,^{10,1100} about 20 cm lower than the mean final height of normal women.¹⁰⁹⁸ The goals of growth-promoting therapies are to attain a normal height for age as early as possible, to progress through puberty at a normal age, and to attain a normal adult height.

Before the availability of recombinant GH, there were conflicting data concerning its efficacy in this disorder,^{1593,1594} but the ability of GH to accelerate growth has now been demonstrated in multiple reports. Growth responses are not affected by the karyotype. In 1983, a randomized, controlled North American study of treatment with GH (at a dose of 0.375 mg/kg per week) with or without added oxandrolone was initiated, with a mean age at onset of treatment of approximately 9 years.¹⁵⁹⁵ Analysis of all 62 girls enrolled in the study at near-final height showed a mean stature of 152.1 cm in the group treated with GH plus oxandrolone (a gain of 10.3 cm compared with the height predictions derived from Lyon and colleagues,¹⁰ whereas girls receiving GH alone averaged 150.4 cm (a gain of 8.4 cm) (Fig. 24-53).¹¹⁰⁰ In another arm of this study, addition of estrogen to the GH regimen before age 15 years lowered the final height gain from 8.4 cm to 5.1 cm.¹⁵⁹⁶ In a reassessment of North American data in the NCGS, early initiation of GH treatment was shown to allow estrogen administration at a physiologic age without loss of adult height.^{1597,1598}

Several other studies^{1110,1599} using higher doses of GH showed even greater gains in adult height outcomes. In a multicenter trial, Sas and coworkers used a maximum GH dose of approximately 0.63 mg/kg per week for 4.8 estrogen-free GH treatment years beginning at a mean age of 8.1 years, resulting in a gain of 16 cm over the modified Lyon and colleagues' projection.^{10,1110} In the same study, the group receiving a GH dose similar to that in the American studies achieved a height gain of 12.5 cm by age 16 with 4.8 estrogen-free GH treatment years starting at 7.9 years. In these girls, induction of puberty at a normal (not delayed) age was associated with these excellent height

Figure 24-53 Adult heights of patients with Turner syndrome treated with growth hormone (GH) or with a combination GH plus oxandrolone and of historical controls, relative to each subject's projected adult height (indicated by the dotted zero line). The mean increments in relative adult height are indicated. The diamond symbols in the combination group indicate two subjects with poor compliance who terminated treatment early. (From Rosenfeld RG, Attie KM, Frane J, et al. Growth hormone therapy of Turner syndrome: beneficial effect on adult height. *J Pediatr*. 1998;132:319-324.)

outcomes.¹⁶⁰⁰ Carel and colleagues,¹⁵⁹⁹ using 0.7 mg/kg per week in a group that received 5.1 estrogen-free GH treatment years beginning at 10.2 years, gained 10.6 cm over the projections of Lyon and colleagues.¹⁰ The group receiving a conventional dose (0.3 mg/kg per week) gained only 5.2 cm with 3.0 estrogen-free GH treatment years starting at 11 years. Because girls with TS usually have a normal GH secretory pattern, provocative GH testing should be performed only in those whose growth is clearly abnormal relative to that expected for patients with TS, as determined by plotting lengths and heights on TS-specific growth curves.^{10,1103,1107,1601,1602}

Although it was well established that GH therapy was effective in increasing final adult height, the magnitude of the gain in height varied in the earlier studies, depending on study design and treatment parameters. In 2005, in the first randomized, controlled trial to follow GH-treated subjects with TS to final height, the Canadian Growth Hormone Advisory Committee corroborated the increases in adult stature reported by studies with historical controls.^{1100,1600,1603,1605} In the Canadian study, girls with TS (age 7 to 13 years) who were randomized to receive GH (0.3 mg/kg per week; maximum weekly dose, 15 mg) achieved a final adult stature 7.2 cm taller than that seen in the control group after an average of 5.7 years. Factors predictive of taller adult stature include a relatively tall height at initiation of therapy, tall parental heights, young age at initiation of therapy, a long duration of therapy, and a high GH dose.^{1110,1598,1606-1609}

Although the optimal age for initiation of GH treatment has not been established, preliminary data from the Toddler Turner Study, in which 88 girls between the ages of 9 months and 4 years were randomized to receive GH or no GH therapy, showed that GH therapy is effective beginning as early as 9 months, with a safety profile similar to that in older children with TS.¹⁶¹⁰ Treatment with GH should be considered as soon as growth failure is evident. GH therapy in the United States is typically initiated at the FDA-approved dose of 0.375 mg/kg per week. The dose can be changed in response to the patient's growth response and IGF1 levels. Growth prediction models may be helpful in determining the potential effects of changes in dosing.¹⁶⁰⁶

Studies have shown that higher doses produce a relatively small gain in final height, although there is no apparent increase in short-term adverse events.¹⁶¹¹ In a study by the Dutch Working Group, the mean gain in final height with 4 IU/m² per day (0.045 mg/kg per day), 6 IU/m² per day, and 8 IU/m² per day averaged 11.9 ± 3.6, 15.7 ± 3.5, and 16.9 ± 5.2 cm, respectively.¹⁶⁰⁰ However, when GH was given at the higher doses, IGF1 levels were often above the normal range, which theoretically could lead to long-term adverse effects.¹⁶¹²

In girls naïve to GH who are older than 9 years of age and in those with extreme short stature, consideration can be given to using higher doses of GH and adding a nonaromatizable anabolic steroid, such as oxandrolone.¹¹⁰⁰ The maximum suggested dose of oxandrolone is 0.05 mg/kg per day, because higher doses have been associated with virilization and accelerated skeletal maturation. Liver enzymes should be monitored. Therapy may be continued until a satisfactory height has been attained (bone age >14 years) or until the yearly growth velocity falls to less than 2 cm/year. The children should be monitored at 3- to 6-month intervals.¹⁶¹³

The substantial variations in GH-induced growth increments in these studies were presumably related to GH dose, duration of estrogen-free GH treatment years, and age at initiation of GH and estrogen administration, as well as the population and parental adult heights. Additionally, the *GHRd3* polymorphism has been reported to be associated with increased responsivity to GH in girls with TS.⁷⁸² Transdermal or depot estrogen administration, as opposed to oral estrogen, may also contribute positively to growth outcomes.^{1614,1615} In these higher-dose treatment studies, hyperinsulinism with presumed insulin resistance was evident but reversible.^{1599,1616} Other data suggest that impaired insulin secretion may ultimately be the significant issue in patients with TS,^{1617,1618} although long-term GH therapy has been well tolerated.

None of these studies was placebo-controlled to adult height, and some studies have yielded much poorer height outcomes,¹¹¹¹ so some uncertainty existed until the randomized, controlled, multicentered Canadian study, in which the mean height gain ascribed to GH treatment was 7.3 cm at 1 year after cessation of the treatment protocol. Estrogen was initiated at 13 years of age.¹⁶⁰³ Another temporally matched control study from Italy showed a gain of 8.1 cm.¹⁶⁰⁵ These studies corroborated and supported the information that had accumulated from historical data on natural growth in TS juxtaposed to the available GH treatment results. Such data, in aggregate, provides convincing support that GH can both accelerate growth velocity and increase adult height.

Recommendations include seeking the diagnosis vigorously at any age in every girl with otherwise unexplained short stature and initiating therapy at that young age (i.e., at diagnosis or in early childhood). One must bear in mind

that growth velocity in girls with untreated TS can be slowed as early as the 1- to 3-year-old period.^{1104,1105} Treatment with the FDA-approved GH dosage of 0.375 mg/kg per week should be initiated and compliance should be monitored with auxologic and IGF1 measurements; continued normal thyroid status should be assured. Oxandrolone may be added to the regimen in the late-diagnosed girl. Estrogen therapy should be initiated at an appropriate physiologic age in girls who started GH therapy at a young age, but it should be delayed as long as clinically reasonable in those whose GH therapy was initiated at a late age. Often, growth-promoting and pubertal needs must be balanced, and the therapeutic approach should be individualized. The diminished areal bone density in TS is enhanced by GH, but estrogen therapy is needed to normalize volumetric density (i.e., not simply size).¹⁶¹⁹ Absence of an adverse impact of GH on aortic diameters is reassuring, given the predisposition of such patients for dissecting aneurysms.⁶⁹¹ Use of statistical prediction models for long-term growth in TS may permit a more quantitative assessment of individual therapeutic efficacy.¹⁶⁰⁶

Despite evidence for aggressive GH treatment of girls with TS to achieve adequate adult heights and relatively high quality-of-life assessments in adulthood,^{589,1620} health-related issues continue to imperil outcomes. Carel and colleagues¹⁶²¹ reviewed health outcomes of 568 adult French women (in their mid-20s) with GH-treated TS who had a mean height of 150.9 cm (having gained about 9 cm over prediction) and found that neither height nor height gain was associated with quality-of-life scores. Rather, issues regarding cardiologic and otologic health concerns and delay of pubertal initiation beyond 15 years were of greater concern. In contrast, a long-term follow-up assessment of 49 women from the Netherlands who had reached a mean adult height of 160.7 cm (a gain of >15 cm), suggested that the high quality-of-life scores were related to height gain and adequate estrogenization.

The NCGS recently published data on the efficacy and safety of GH therapy in 5220 children with TS treated during the last 20 years. A total of 442 adverse events were reported for these patients, including 117 that were considered to be serious. Seven deaths occurred, including five from aortic dissection or rupture. The incidences of intracranial hypertension, slipped capital femoral epiphysis, scoliosis, and pancreatitis were increased compared with other patients in the registry who did not have TS. Ten new-onset malignancies occurred, including six in patients without known risk factors. The number of patients who developed IDDM also appeared to be increased. It is believed that these adverse events are likely to be unrelated to treatment with GH. The incidence of aortic dissection or rupture reflects the higher baseline risk in TS.¹⁶²²

Two echocardiography studies reported normal left ventricular morphology and function in girls with GH-treated TS^{1623,1624} and two MRI studies found no deleterious effect of GH treatment on aortic diameter.^{691,1613,1625,1626} Because GH treatment can alter craniofacial proportions, all girls with TS treated with GH should receive periodic orthodontic follow-up.¹⁶²⁷ These studies were not controlled, but their findings emphasize the broad range of health concerns in women with TS and affirm the need for multidisciplinary follow-up care.

Small for Gestational Age. Studies employing GH in short children born SGA have been hampered by the heterogeneity of this group of patients, whose poor growth may reflect maternal factors, chromosomal disorders, dysmorphic syndromes (e.g., RSS, Dubowitz syndrome),

toxins, and idiopathic factors.¹⁶³² A 2001 consensus statement recommended that SGA be defined as a birth weight or length at least 2 SD below the mean.¹⁶²⁸ Almost 90% of infants born SGA undergo catch-up growth within the first 2 years of life, and those who do not would then be eligible for GH treatment.^{37,1127,1129,1167,1630,1631,1632} Based on these proportions, and because the prevalence of "short SGA" is 2 to 3 per 1000 children, between 1 in 300 and 1 in 500 children are eligible for GH treatment, as approved in the United States in 2001 and in Europe in 2003. It appears that GH mediates the postnatal catch-up growth.¹⁶³³ Children born SGA appear to grow at a low-normal growth velocity during childhood,¹⁶³⁴ but puberty tends to occur at a somewhat earlier age and to progress rapidly, resulting in decreased pubertal height gain and an adult height about 1 SD (approximately 7 cm) below the mean^{37,1164,1167,1635-1638} and about 4 cm below the midparental target height.¹¹²⁹

The impaired postnatal growth observed in children born SGA is probably due to many factors, including generalized cellular hypoplasia,¹⁶³⁹ altered diurnal GH secretion patterns,^{232,1149,1151,1634,1640} and, potentially, abnormalities in the GH-IGF axis resulting from GH sensitivity as determined by the presence or absence of exon 3 of the GHR.^{1641,1642,1645} Deletions and mutations of the IGF1 gene have been reported in patients with profound IUGR, microcephaly, deafness, and postnatal growth failure.^{340,341,1643} SGA patients have also been reported to have IGF1 gene polymorphisms or missense mutations resulting in low serum IGF1 concentrations.^{1139,1140,1167,1644-1646} Reduced levels of IGF2 expression, associated with hypomethylation of the telomeric domain of chromosome 11p15 were found in a cohort of SGA patients who had RSS.¹¹⁷⁴ Mutations in the type I IGF receptor gene (one compound heterozygous, one nonsense) were found in two patients with IUGR and poor postnatal growth (one with elevated IGF1).³⁴⁹

The low levels of IGF1 and IGFBP3 in many infants with IUGR, apparently related to fetal malnutrition, do not seem to predict the degree of subsequent growth impairment,¹¹⁴⁸ although continuing low levels are associated with poor catch-up growth.¹⁶⁴⁷ Short children born SGA make up a substantial portion of growth-retarded patients seen in pediatric endocrine practices.^{1129,1167,1648} Because these children may have heights in the range seen in IGF deficiency syndrome, therapeutic attempts are appropriate, assuming that the insulin resistance noted in these thin, small children¹¹⁶⁰ does not become a clinical issue. Encouraging growth responses have been obtained with GH treatment.

The FDA approval of GH for the long-term treatment of growth failure in children born SGA who fail to manifest catch-up growth by age 2 was based on data obtained from four randomized, controlled, open-label, clinical trials that enrolled 209 patients between the ages of 2 and 8 years. Height velocity was determined after 1 year without treatment, and then patients were randomized to receive either GH treatment (34 or 69 mg/kg per day [0.24 or 0.48 mg/kg per week]) or no treatment for 2 years, after which a crossover design occurred. Children who received the higher GH dose had an increase of about 0.5 SDS in height after 2 years, compared with the children who received the lower dose, although both treated groups had significant increases in height velocity compared with untreated children (prescribing information for Genotropin somatotropin of recombinant DNA origin for injection, Pfizer, Inc., New York, 2006). In Europe, the criteria for treatment differ from those in the United States: height SDS below -2.5, height velocity SDS below 0 during the previous year, and age of greater than 4 years.

The data documenting efficacy in regard to adult height continues to be limited despite European regulatory authorities' requiring this evidence before approval. A meta-analysis of final height data for 56 children born SGA was performed at the request of European authorities and demonstrated a mean height increase of 1.9 SDS for subjects treated with GH at 34 mg/kg per day versus 2.2 SDS for 69 mg/kg per day. A meta-analysis of three randomized studies of 28 patients reported that GH treatment for 7 to 10 years, initiated at doses of 34 to 69 mg/kg per day, can be expected to increase adult height by about 1.0 to 1.4 SDS.¹⁶⁴⁹ A larger, randomized, controlled study of 91 GH-treated and 33 untreated French adolescents (mean age, 12 years) reported a lower between-group difference of 0.6 SDS in adult height after 2.7 years of treatment.¹⁶⁵⁰

The many studies documenting efficacy of GH therapy in thousands of children with SGA are far too numerous to report in detail here and have been reviewed elsewhere.^{1649,1651,1652} Although results vary, it appears that GH treatment can be expected to result in a 1-cm increment in height gain each year. The factors that can increase the gain in height include a greater height deficit relative to the midparental height, a higher GH dose, initiation of therapy at an earlier age, longer treatment duration, and the proposed presence of the *GHRd3* allele.^{782,1628,1651,1653} In a prediction model derived from KIGS SGA data, Ranke and coworkers¹⁶⁵³ found that age and GH dose were strong predictors of initial growth but that growth achieved during the first year was a powerful predictor of later growth.

Children born SGA, especially those who have rapid postnatal weight gain, have reduced insulin-mediated glucose uptake and are more likely to have insulin resistance.^{1160,1654-1659} However, there have been no solid data documenting an increased risk of NIDDM.¹⁶⁵⁸ There have been reports of several children in GH registration studies who had mild, transient hyperglycemia (prescribing information for Genotropin somatotropin of recombinant DNA origin] for injection, Pfizer, Inc., New York, 2006). Insulin resistance during GH treatment in children born SGA has been reported^{1611,1660,1661} and typically resolves after discontinuation of GH.¹⁶⁶² In a large database of children treated with GH, no differences in glucose regulation were found in 1900 children born SGA compared with children with ISS.¹⁶⁶³ With 6000 patient-years of exposure, no cases of diabetes mellitus have been reported during GH treatment.¹⁶⁶³⁻¹⁶⁶⁶

The European product labeling for GH treatment of children born SGA reads, "The management of these patients should follow accepted clinical practice and include safety monitoring of fasting insulin and blood glucose before treatment and annually during treatment."¹⁶⁵² In addition to insulin resistance alone, children born SGA have an increased risk of metabolic syndrome.^{1665,1667-1669} The current literature provides no information on whether GH treatment in childhood increases risks for adult metabolic disease. Long-term follow-up studies are needed to determine the metabolic risk associated with GH treatment.

Osteochondrodysplasias. GH therapy has been studied in several skeletal dysplasias. The largest published study in achondroplasia involved 40 children; during the first year of treatment, the height velocity increased from 3.8 to 6.6 cm/year, and in the second year it decreased to approximately 5 cm/year.¹⁶⁷⁰ A modest improvement was seen in the ratio of lower limb length to height. Although GH was well tolerated, atlantoaxial dislocation during GH therapy

was reported in one patient. In another study, normal growth velocity was achieved for up to 6 years in 35 subjects, with a significant increment in height SDS for at least 4 years¹⁶⁷¹; in that study, vertebral growth was disproportionately greater than limb growth.

Bridges and Brook¹⁶⁷² reported on the effects of GH therapy in 27 patients with hypochondroplasia; response was maximal during the first year of treatment, but substantial benefit was seen through 4 years of treatment in pubertal subjects. Much of the growth response represents an increase of spinal length; with leg-lengthening procedures, some of these patients may achieve adult height within the normal range.¹⁶⁷³

Experience with GH treatment is limited in other skeletal disorders, such as dyschondrosteosis, hereditary multiple exostoses, osteogenesis imperfecta, and Ellis-van Creveld syndrome.

SHOX Haploinsufficiency and Léri-Weil Syndrome. Patients with mutations or deletions of the *SHOX* gene have variable degrees of short stature with or without mesomelic skeletal dysplasia. If untreated, short patients with *SHOX* deficiency remain short in adulthood. The *SHOX* gene is located in the pseudoautosomal region 1 (PAR1) on the distal end of the X and Y chromosomes at Xp22.3 and Yp11.3.^{1674,1675} Because genes in PAR1 do not undergo X inactivation, normal individuals express two copies of the *SHOX* gene. This gene encodes a homeodomain transcription factor that is expressed during early fetal life in the growth plate and functions in the regulation of chondrocyte differentiation and proliferation.^{1088,1676,1677} *SHOX* haploinsufficiency (or deficiency) is the primary cause of short stature in patients with LWD (see earlier discussion).^{1125,1678-1680} *SHOX* mutations and deletions are also found in patients with short stature without clinical evidence of dyschondrosteosis.¹⁶⁸¹⁻¹⁶⁸³

Clinical manifestations of *SHOX* deficiency include bowing of the forearms and lower legs, cubitus valgus, Madelung deformity or partial dislocation of the ulna at the wrist and elbow, short fourth and fifth metacarpals, and a high-arched palate along with characteristic radiologic signs.^{1087,1125,1680,1682,1684,1685,1686} Longitudinal growth data to final height in subjects with *SHOX* deficiency not treated with GH are lacking. In a randomized 2-year study of 52 prepubertal subjects with a *SHOX* gene defect, the first-year height velocity in the GH-treated group was significantly greater than in the untreated control group (mean \pm standard error of the mean [SE], 8.7 ± 0.3 versus 5.2 ± 0.2 cm/year; $P < .001$) and was similar to the first-year height velocity to GH-treated subjects with TS (8.9 ± 0.4 cm/year; $P < .592$). GH-treated subjects with *SHOX* deficiency also had significantly greater second-year height velocity (7.3 ± 0.2 versus 5.4 ± 0.2 cm/year; $P < .001$), second-year height SDS (-2.1 ± 0.2 versus -3.0 ± 0.2 ; $P < .001$), and second-year height gain (16.4 ± 0.4 versus 10.5 ± 0.4 cm; $P < .001$) compared with untreated subjects.¹⁶⁸⁷

In a more recent retrospective, 2-year study of 14 patients with *SHOX* deficiency, 13 of whom had LWD, GH treatment improved height velocity and height standard SDS by 1.1, which was sustained over 2 years. This is equivalent to a gain of approximately 7 cm in height.¹⁶⁸⁸ These results were not different from those achieved with GH therapy in girls with TS, in contrast to the study from Rappold and coworkers,¹⁶⁸⁷ which revealed a greater height deficit in girls with TS than in those with *SHOX* deficiency. Therefore, GH treatment is likely to result in significant final height benefit for most patients with *SHOX* deficiency.

Turner Syndrome and Langer Mesomelic Dysplasia. Homozygous mutation of the *SHOX* gene results in the

Langer type of mesomelic dwarfism (i.e., LMD). A child with LMD and TS was found to have a *SHOX* gene abnormality resulting from a downstream allele deletion in her normal X chromosome. Although there have been numerous studies documenting growth improvement with GH therapy in patients with TS^{1100,1599,1622,1689} and in those with heterozygous *SHOX* gene deletions,^{1680,1690,1691} only one case of growth response to GH therapy in the rare condition of LMD with TS has been found. Growth rates of 3.46, 3.87, 2.3, and 0.7 cm/year were observed in the first, second, third, and fourth years of GH therapy, respectively, and there was no clinical deterioration of the skeletal deformities in this patient. Because there was a failure to achieve growth improvement with GH therapy, the authors concluded that GH therapy was not beneficial in patients with the severe short stature caused by combined TS and LMD resulting from homozygous *SHOX* deficiency.¹⁶⁹²

Noonan Syndrome. Since 1994, when a gene for Noonan syndrome was mapped to chromosome 12 (12q24.1) and a mutation in the protein tyrosine phosphatase nonreceptor type 11 (*PTPN11*) was identified and characterized in familial cases, at least three other gene mutations have been identified.^{1114,1693-1696} While contributing to the broad heterogeneity of NS, these mutations have not completely localized the cause of the short stature. Several studies have reported effects of GH on near-adult height in patients with Noonan syndrome,¹⁶⁹⁷⁻¹⁷⁰¹ but all involved small numbers of patients with varied enrollment ages, treatment durations, GH doses, and responses. The most recent and largest study of the response to GH in children with Noonan syndrome came from the NCGS, a postmarketing observational study of recombinant human GH treatment in children with various disorders. A total of 370 patients with Noonan syndrome (mean enrollment age, 11.6 years) received GH (mean dosage, 0.33 mg/kg per week) for a mean of 5.6 years. In the 65 patients with data to derive near-adult height, the mean gain above the projected height was 10.9 ± 4.9 cm in boys and 9.2 ± 4.0 cm in girls. Duration of prepubertal recombinant human GH therapy and height SDS at puberty were important contributors to the near-adult height. No new adverse events were observed. The authors suggested that greater growth optimization would be possible with earlier initiation of therapy.¹⁷⁰² This height increase was similar to the change observed in patients with TS but significantly less in those with idiopathic GHD in the same study.

Most experience with GH treatment of short stature in Noonan syndrome has been limited to small, uncontrolled studies in which few patients reached final height.^{1113,1703,1704} The clinical diagnosis of a dysmorphic syndrome potentially makes the treatment groups heterogeneous, although identification of a mutant *PTNN11* gene¹¹¹⁴ helps with characterization. Overall, treatment results for 3 to 4 years are similar to those attained in patients with TS; mean growth velocities improve by 2 to 4 cm/year (over baseline rates of approximately 4 cm/year) during the first 4 years of therapy, with patients gaining from about -3.5 to -1.7 SDS of stature without inordinate advancement of bone age.^{1113,1121,1123,1703,1704} Those children with identifiable *PTPN11* mutations are reported to have a poorer response to GH treatment in terms of growth and IGF production, suggesting impaired efficiency of phosphorylation-dependent GH signaling pathways.¹¹²¹⁻¹¹²³ Although the initial anecdotal experience suggested progression of ventricular hypertrophic cardiomyopathy, this was not confirmed in larger, carefully monitored studies.^{1113,1705,1706}

Idiopathic Short Stature (Subtle Errors throughout the Growth Axis). Although children with ISS, by definition, are without an identifiable cause of growth retardation, the term clearly encompasses a heterogeneous group that may include children with constitutional growth delay, genetic short stature, or subtle defects of the GH-IGF axis. Even though they are often grouped in one category, children with ISS have been shown to have a broad range of provocative GH responses, ranging from normal to elevated, and a wide range of serum IGF concentrations, from normal to IGF deficient. This group may also include children with unidentified syndromes or unidentified chronic illnesses or endocrine disorders. Children with ISS may experience stressful behavioral circumstances, but studies suggest that the relationship of psychosocial problems to the short stature is variable.¹⁷⁰⁷⁻¹⁷¹¹ Nonetheless, hormonal intervention to enhance growth, with the aim of diminishing such difficulties, has been used.

Although the specific etiologies are often unknown, GH treatment has been used widely.¹⁷⁰² Important questions have been raised about the financial, ethical, and psychosocial impact of GH therapy in "normal" short children.^{1705,1712-1715} Given the cost of GH, the financial implications of treating such children are considerable. The point is well taken that 5% of the population will always be below the 5th percentile, whether we treat with GH or not, and that focusing on short stature could potentially handicap an otherwise normal child psychologically and socially. No convincing data have been presented to show that GH treatment of short children definitively improves psychological, social, or educational function.¹⁷¹⁵⁻¹⁷¹⁷ A possible exception is the improved intellectual function in SGA children treated with GH.¹⁷¹⁸ Furthermore, final adult height in the subset of children with CDGD (probably a common inclusion, although not ISS as defined in the FDA approval) may be adequate without any treatment.⁴⁰⁻⁴²

Finally, the known and unknown treatment risks GH therapy in otherwise apparently normal children, even if exceedingly small, are a legitimate concern.¹⁷¹⁹ The failure to report levels of IGF1, IGFBP3, and GHBP in many studies and differing interpretations of endogenous GH secretion studies (e.g., assay variance, control group size), as well as the heterogeneity of the patient groups, confounds assessment of response data. Nevertheless, it is clear that many children who do not meet conventional criteria for the diagnosis of GHD and who fall under the heading of ISS have as great a degree of growth retardation as children with bona-fide GHD and might be considered suitable candidates for growth-promoting therapy.

Members of the Growth Hormone Research Society, the Lawson Wilkins Pediatric Endocrine Society, and the European Society for Pediatric Endocrinology meeting in 2007 published a manuscript detailing their agreement on the evidence-based evaluation and management of ISS in children. They agreed that the primary goal of therapy should be the attainment of normal adult height. They also agreed that the expectation from patients and their families that taller stature is associated with positive changes in quality of life should be discouraged.¹⁷¹⁴ Physicians should inform families about the available therapeutic options and provide a realistic expectation for height gain with therapy, including the fact that there may be variability in the outcome and the psychological counseling options should be discussed. In addition, the patient and family should be aware that therapy may be discontinued if the growth response is poor or if the child no longer provides assent. The physician is responsible for continued monitoring of

efficacy and safety and should provide flexibility in treatment options.

The studies that ultimately led to approval of GH treatment in the United States included the long-term, randomized, double-blind, placebo-controlled trial at the National Institutes of Health by Leschek and associates¹³⁷¹ and the randomized dosing trial of the European Idiopathic Short Stature Study Group.¹⁷²⁰ In the former trial, which used a less optimal regimen of 0.22 mg/kg per week given thrice-weekly in subjects with a mean starting height of almost -3 SDS, the treated children had mean final height gain of 3.7 cm over the control group.¹³⁷¹ In the latter randomized study, GH doses of 0.24 and 0.37 mg/kg per week, given as a regimen of six doses per week in children with a mean starting height of -3.0 to -3.4 SDS, the improvement in the higher-dose group exceeded that in the lower-dose group by 3.6 cm, with subjects achieving a final height of -1.12 SDS.¹⁷²⁰ When the data from the two trials were combined, there was a cumulative gain of 7.3 cm in the group treated with 0.37 mg/kg per week, compared with placebo.

In a meta-analysis looking at an aggregate group of 1089 children, there were four controlled trials that presented adult height data showing treatment benefits ranging from 0.54 to 0.84 SDS, corresponding to a mean effect on growth of 5 to 6 cm.¹⁷²¹ McCaughey and associates¹⁷²² found that eight prepubertal girls treated with GH at a dose of approximately 0.34 mg/kg per week experienced a mean height SDS of -1.14 after 6.2 years of treatment. This was a 7.6-cm greater gain than that observed in the control groups, whose mean height SDS (-2.55) did not change during the study.

Concerns had been raised that GH treatment might accelerate pubertal onset and progression in children with ISS, resulting in failure to improve height SDS for bone age^{1723,1724} and offsetting the positive responses observed during the early years of GH treatment.¹⁷²⁵ In the European ISS study,¹⁷²⁶ there was no evidence of accelerated pubertal or skeletal maturation in the group receiving the higher dose, in contrast to data reported by Kamp and colleagues¹⁷²⁷ with a 30% greater GH dose. This hypothetical effect of advancing maturation has not been substantiated by additional studies.^{1398,1722,1728-1730} Taken together, these data show that GH treatment of prepubertal children with ISS increases growth velocity and final height.

The auxologic criteria for GH therapy in the United States are based on FDA approval of GH treatment for children shorter than -2.25 SDS (1.2 percentile). Some believe that children should be treated if their height is below -2.0 SDS and more than 2.0 SDS below their mid-parental target height or if their predicted height is below -2.0 SDS (or both). Although there is no consensus on the age for initiating treatment, most studies of GH therapy in children with ISS have involved children from 5 years to early puberty. There are no accepted biochemical criteria for initiating GH treatment in ISS. The bone age is used to predict adult height, although in a longitudinal study of ISS subjects, bone age delay had an effect on the precision of the prediction. In children with a bone age delay of about 2 years, the average adult height was almost equal to the predicted height; in children with no bone age delay, the adult height was greater than the initial predicted height; and if the bone age was delayed by more than 2 years, the adult height was significantly below the predicted adult height.¹⁷³¹ The psychological benefits of GH therapy in children with ISS are unproven,¹⁷³² but medical and psychological intervention should be considered for the child who seems to suffer from his or her short stature.

The clinical trials of the treatment of ISS with GH in the literature often did not contain long-term control groups; hence, the results show variable growth responses.^{1719,1733-1737} Most short children treated with GH experience growth acceleration that is usually sustained over the first several years of therapy,¹⁷⁰³ with attenuation of the treatment response over time. In general, a slower pretreatment growth velocity and a higher weight-to-height ratio—factors suggestive of GHD and, to a lesser degree, bone age retardation—are associated with better early growth responses.¹⁷³⁸ Three thousand children were classified as having ISS in the KIGS database, with 153 having reached final height.¹⁷²⁸ GH treatment (0.2 to 0.25 mg/kg per week) resulted in achievement of target height in patients with familial short stature, although they continued to have short stature as adults (−1.7 SDS in males and −2.2 SDS in females), with a mean gain during therapy of 0.6 to 0.9 SDS. In children who did not have familial short stature, the mean final height was greater for males (−1.4 SDS), although not for females (−2.3 SDS), with average gains of 1.3 and 0.9 SDS, respectively. These attained heights were quite different from the midparental target heights, which were near 0 SDS. Hintz and colleagues¹⁷²⁰ assessed adult height in 80 North American children with ISS who were treated for up to 10 years at a GH dose of 0.3 mg/kg per week. At the conclusion of the study, the mean height SDS was −1.4 SDS with a gain of 1.3 SDS, results quite similar to those from the KIGS database. Although the Hintz study was not placebo controlled, the data were compared with predicted and actual final heights in two groups of untreated short children followed for similar periods. Compared to untreated children, treated boys achieved a mean of 9.2 cm and girls 5.7 cm stature above predicted heights.

Several additional studies have documented the increase in final height with GH therapy in children with ISS, although the responses have been highly variable and dose dependent. The mean increase in adult height in children with ISS is 3.5 to 7.5 cm (with an average duration of therapy of 4 to 7 years) when compared with historical controls,^{1370,1739} with patients' pretreatment predicted adult heights,¹⁷²⁵ or with nontreatment or placebo control groups.^{1371,1721} Multiple factors affect the growth response to GH, and the best response is seen in children who are younger or heavier, those receiving higher GH doses, and those who are shortest relative to their target height. Adult height outcome is influenced negatively by age at initiation of therapy and positively by midparental height, initial height, delayed bone age, and the magnitude of the first-year response to GH.^{1731,1740} A 2-year study suggested that an increase in IGF1 correlates with height gain.¹³⁷¹

Studies using monotherapy with GnRH agonists have shown only a small and variable effect on final adult height, so GnRH agonist therapy is not recommended. Furthermore, GnRH agonists have been shown to have short-term adverse effects on BMD,¹⁷⁴¹ and psychological consequences of delayed puberty have been suggested.¹⁷⁴² However, combination therapy with a GnRH agonist and GH has potential value in increasing final height, with treatment lasting at least 3 years.^{1743,1744}

Monitoring of GH treatment should include height, weight, pubertal development, and adverse effects (scoliosis, tonsillar hypertrophy, papilledema, and slipped capital femoral epiphysis) two to three times per year. After 1 year of therapy, the height velocity SDS and the change in height SDS should be calculated. The bone age may be obtained to reassess height prediction and if one is considering intervention to delay puberty. IGF1 levels may be helpful in guiding GH dose adjustment. Because elevated

blood glucose levels in patients with GH-treated ISS have not been reported, routine monitoring of glucose metabolism is not advised.

The FDA-approved dose for GH in ISS is 0.3 to 0.37 mg/kg per week.¹⁷⁴⁵ The dose may be increased if the growth response is inadequate and compliance was assured. However, there are no data regarding the long-term safety of GH doses higher than 0.5 mg/kg per week in children with ISS. IGF1 levels may be helpful in assessing compliance and GH sensitivity. IGF1 levels that are elevated (>2.5 SDS) should prompt consideration of GH dose reduction. IGF-based dose adjustments in children with ISS increased short-term growth when higher IGF targets were selected, but long-term studies with respect to efficacy, safety, and cost effectiveness have not been done.¹⁷²⁷ If the growth rate continues to be inadequate, GH treatment should be stopped and alternative therapies considered. The duration of treatment is controversial, with consideration given for stopping treatment when near-adult height is achieved (height velocity <2 cm/year or bone age >16 years in boys or >14 years in girls) if height is in the normal adult range (above −2 SDS). Stopping therapy may be influenced by satisfaction of the patient and family with the resulting height, an ongoing cost/benefit analysis, or desire of the child to stop for other reasons (e.g., dissatisfaction with daily injections).

The possible side effects in GH-treated children with ISS are similar to those previously reported in children receiving GH therapy for other indications, with no long-term adverse effects documented.^{1746,1747} Post-treatment surveillance with a focus on cancer prevalence and metabolic side effects is advisable.

The average cost of GH treatment of children with ISS is \$10,000 to \$20,000 per centimeter of growth improvement.¹⁷³⁹ The benefits are less clear,¹⁷³⁹ because it is unknown whether a gain in height improves quality of life. Therefore, recommendations for treatment that increases adult height should be balanced against the high cost of these therapies.

Miscellaneous Causes of Growth Failure. In addition to the clinical conditions described earlier, GH has been employed in the treatment of short stature associated with a variety of other conditions involving postnatal growth failure. In general, such trials have been uncontrolled and have not included sufficient numbers of subjects for efficacy to be evaluated. Examination of such treatments should be continued in the large international databases.

Down Syndrome. The encouraging results of GH trials in TS led to studies of GH therapy in children with Down syndrome. In several preliminary studies, GH accelerated growth in such patients, although ethical issues were raised concerning the appropriateness of such therapy.^{1093,1748-1750} In the uncontrolled NCGS experience, 23 children experienced a 1.3 SDS height gain over the first 4 years of GH therapy.¹⁷⁰³ No convincing data exist that GH improves neurologic or intellectual function in such patients. The increased risks of diabetes mellitus and leukemia in children with Down syndrome could be augmented by GH therapy.¹⁷⁵¹

Normal Aging and Other Catabolic States. Detailed consideration of the potential use of GH in normal aging is beyond the scope of this chapter. The rationale for such therapy is based on the concept of the "somatopause," a term that highlights the progressive decline in GH secretion after 30 years of age, as reflected in decreasing IGF1 levels. Aging can be viewed as a catabolic state, with the potential that GH therapy might reverse or retard the loss

of muscle mass and strength and the decrease in bone density that occur with aging. Clinical studies are in progress.

Growth failure, often with impaired final adult height, is a characteristic clinical finding in endogenous or exogenous Cushing's syndrome. Excess glucocorticoids cause a catabolic state characterized by increased proteolysis, decreased protein synthesis, lowered osteoblastic and increased osteolytic activity, and insulin resistance.¹⁷⁵² GH treatment blunts some of these catabolic actions but increases the insulin resistance.¹⁷⁵³ Mauras and Beaufre¹⁰³⁹ showed that IGF1 therapy similarly induces an anabolic response, despite excess glucocorticoids, but does not cause insulin resistance. GH treatment after transplantation¹⁵⁶⁹⁻¹⁵⁷¹ and in other glucocorticoid-treated children¹⁰²⁸ causes some height increments, but does not produce as good a response as in individuals not taking glucocorticoids. GH does enhance bone formation and increases osteoblastic activity in such children.¹⁷⁵⁴ The marked increase in IGF1 levels during GH treatment may be sufficient to overcome the local insensitivity to IGF action.^{421,910,911,1755}

GH therapy is also being investigated in catabolic states such as burns, tumor cachexia, major abdominal surgery, AIDS, sepsis, metabolic acidosis, and situations requiring total parenteral alimentation. GH should not be used in critically ill patients, because a randomized, controlled trial demonstrated increased morbidity and mortality with GH treatment of such patients.¹⁷⁵⁶

The FDA-approved indications for the use of GH for purposes other than stimulation of growth are (1) GHD in adults, (2) AIDS-associated wasting or cachexia, and (3) short-bowel syndrome requiring total parenteral nutrition.

Side Effects of Growth Hormone

Pituitary-derived human GH had an enviable safety record for a quarter of a century but proved to be an agent for transmission of the fatal spongiform encephalopathy, CJD.^{1389,1757} Although pit-GH was removed from use in the United States in 1985, and later throughout the world, more than 200 patients with GH-derived CJD have been identified.¹³⁹¹⁻¹³⁹³ Although recombinant DNA-derived GH does not carry this risk, the experience with pit-GH serves as a grim reminder of the potential toxicity that can reside in "normal" products used for physiologic replacement.

Extensive experience with recombinant GH over more than 20 years has been encouraging.^{1272,1664,1758,1760} Concerns have been raised about a number of potential complications, which clearly require continued follow-up and assessment. This evaluation has been greatly facilitated by the extensive databases that have been established by GH manufacturers, in particular Genentech (NCGS)¹⁵²³ and Pharmacia (KIGS).^{1664,1761,1762}

Development of Leukemia. The development of leukemia as a complication of GH therapy was first reported in five cases from Japan in 1988¹⁷⁶³; to date, more than 50 cases of leukemia have been reported in GH-treated patients. Many of the cases are from Japan,¹⁷⁶⁴ but some are from the United States.^{1390,1759} One difficulty in assessing the role of GH treatment in this disorder is that many GH-deficient children have conditions that predispose to the development of leukemia, such as prior malignancy, a history of irradiation, or concurrent syndromes which themselves are associated with the development of leukemia (e.g., Bloom's syndrome, Down syndrome, Fanconi's anemia). GH-treated patients who develop leukemia do so at a later age than in the normal population. Patients have

included recipients of both pit-GH and recombinant GH, and leukemia has occurred both during treatment and after termination of therapy. Calculations of relative risk are imprecise but vary from sevenfold in Japan to twofold to fourfold in the United States. Leukemia also has been reported in GH-deficient individuals without any history of GH therapy, raising the possibility that the GH-deficient state, by itself, may be a predisposing factor.^{1762,1765}

It is not possible to be certain whether GH is a causative agent in the development of leukemia. If it is, the increase in risk appears to be modest and may arise from the underlying state rather than from GH therapy. Worldwide, the number of cases of new leukemia in GH-treated children with no known risk factors is approximately what would be expected on a patient-year basis.^{1523,1758,1766,1767}

This issue should be discussed with all potential recipients of GH, but it appears that the risk is limited to those children with high risk factors. Particular care should be used in prescribing GH therapy for children with a past history of leukemia or lymphoma or other disorders conveying an increased risk of leukemia. In a study of more than 600 children with prior leukemia who were treated with GH, the relapse rate was within the expected range, consistent with no effect of GH replacement therapy on recurrence of leukemia.^{1672,1759,1768}

Data from more than 88,000 GH-treated patients with more than 275,000 patient-years at risk did not reveal an increased risk for nonleukemic extracranial neoplasms.^{1523,1672,1758}

Recurrence of Central Nervous System Tumors. Because many recipients of GH have acquired GHD due to CNS tumors or their treatment, the possibility of tumor recurrence with therapy is of obvious importance. Estimates of CNS tumor recurrence rates in non-GH-treated children and adolescents are difficult to obtain, bearing in mind the vast array of treatment programs used in the past 3 decades. In a total of 1083 patients compiled from 11 reports who were not treated with GH, 209 (19.3%) had recurrences.¹⁷⁶⁸⁻¹⁷⁷⁸ Such data in a heterogeneous group, including patients with craniopharyngiomas, gliomas, ependymomas, medulloblastomas, and germ cell tumors, provide a background for assessing recurrence rates in GH-treated youth. Reports from nine centers, encompassing 390 patients, indicated recurrence in 64 patients (16.4%) at the time of publication,^{1768,1769,1778-1783} which is not much different from the recurrence rate observed in a much larger number of untreated patients. In a particularly well done comparative study at three pediatric neuro-oncology centers comprising 1071 brain tumor patients, 180 patients were treated with GH for a mean of 6.4 years, and 31 of them were monitored for more than 10 years; the relative risk of recurrence or death was similar with and without GH treatment.¹⁷⁸²

In a study of 361 cancer survivors (including 172 brain tumor patients), disease recurrence of all cancers in GH-treated children did not differ from recurrence in those children not treated with GH. However, there was an overall increased risk of 3.21 (95% confidence interval, 1.88 to 5.46) for second neoplasms, mostly meningiomas.¹⁷⁸⁴ A follow-up of this study continued to show the increased risk of second neoplasm, but the rate ratio was lower at 2.15.¹⁷⁸⁵ The decreased rate ratio with longer follow-up raised the possibility that GH treatment may accelerate the manifestation of these tumors, rather than increasing the absolute rate. A similar increased risk for second neoplasms, also largely meningiomas, was found in GH-treated adult patients.¹⁷⁸⁶

Cranial irradiation seems to be a most important predisposing factor, but the role of GH remains uncertain. Extensive analysis of 4410 patients with a history of brain tumor or craniopharyngioma before GH therapy in the NCGS and KIGS databases^{1664,1758,1787} showed a similar lack of increased tumor recurrence. In the NCGS series, recurrence rates of the most common CNS neoplasms, craniopharyngioma (6.4%), primary neuroectodermal tumors (medulloblastoma, ependymoma; 7.2%), and low-grade glioma (18.1%) were lower than or similar to those reported in non-GH-treated children.^{1768,1788,1789}

Despite these comforting data, the relatively short median follow-up times reported, even in the huge international databases, must temper the willingness to eliminate any relationship of GH therapy to recurrence of intracranial neoplasia.

Pseudotumor Cerebri. Pseudotumor cerebri (idiopathic intracranial hypertension) has been reported in GH-treated patients.^{1523,1664,1758,1790} The disorder may develop within months after treatment starts or as long as 5 years into the course; it appears to be more frequent in patients with renal failure than in those with GHD.¹⁷⁵⁸ The mechanism for the effect is unclear but may reflect changes in fluid dynamics within the CNS. Pseudotumor has also been described after thyroid hormone replacement in patients with hypothyroidism. In any case, clinicians should be alert to complaints of headache, nausea, dizziness, ataxia, or visual changes. Significant fluid retention with edema or hypertension is rare.¹⁷⁹¹ Because of the possible association of pseudopapilledema with GHD, perhaps representing a variant of optic nerve hypoplasia,¹⁷⁹² careful ophthalmologic evaluation should be undertaken in patients with suspected GH therapy-associated pseudotumor cerebri to avoid overdiagnosis and invasive treatments.

Slipped Capital Femoral Epiphysis. Slipped capital femoral epiphysis is associated with both hypothyroidism and GHD. Whether GH therapy plays a role in this disorder has been difficult to determine, in part because the incidence of slipped capital femoral epiphysis varies with age, gender, race, and geographic locale. The reported incidence is between 2 and 142 cases per 100,000 population; the data in the KIGS and NCGS studies are in this range.^{1523,1664,1758} Accordingly, although slipped capital femoral epiphysis cannot be attributed to GH therapy per se, complaints of hip and knee pain or limp should be evaluated carefully. The occurrence of such pain in a GH-treated child with an exceedingly rapid growth rate should lead to consideration of this diagnosis.

Scoliosis. Both progression of preexisting scoliosis and new-onset scoliosis have been described in children treated with GH.¹⁵²³ The numbers are extremely small, with only 238 reported cases among 54,996 patients in the NCGS database. There is specific concern for GH effects on scoliosis in TS and PWS patients, in whom the underlying rate of scoliosis is increased. Although the rate of scoliosis in GH-treated TS patients was higher than in other GH-treated patients, it remained rare, being reported in only 0.69% of patients.¹⁶²² PWS by itself has a rate of scoliosis of 30% to 80%, and GH treatment does not appear to increase the rate or severity of scoliosis in PWS patients.^{1537,1793}

Diabetes Mellitus. The association of GH treatment with insulin resistance is well documented.¹⁷⁹⁴ Data from the KIGS and NCGS databases have been used to estimate the

incidence of type 2 diabetes mellitus (T2DM) in GH-treated patients as approximately 14 to 22 cases per 100,000 patient-years.^{1523,1664,1758} Although insufficient information is available to determine whether this represents an increased incidence when compared with the baseline risk in similar individuals, it is higher than the overall incidence of T2DM in children (0.8, 8.1, and 11.8 per 100,000 person-years for ages 5 to 9, 10 to 14, and 15 to 19 years, respectively).¹⁷⁹⁵ An earlier report of the NCGS data indicated that not all of the children with T2DM were obese, because their BMI ranged from 13.2 to 38.1 kg/m² (mean, 22.8 kg/m²).¹⁷⁵⁸ Therefore, the reduction of insulin sensitivity induced by GH is a concern that demands close assessment in high-risk patients such as those with PWS or TS or a history of IUGR. Studies of the impact of decades of GH therapy on insulin sensitivity are warranted.

Miscellaneous Side Effects.^{1523,1664,1758} Other potential side effects of GH therapy include prepubertal gynecomastia,¹⁷⁹⁶ pancreatitis,¹⁷⁹⁷ growth of nevi^{1798,1799} (although typically without evidence of malignant degeneration¹⁷⁵⁹), behavioral changes, worsening of neurofibromatosis, hypertrophy of tonsils and adenoids, and sleep apnea. A report¹⁸⁰⁰ of reduced testicular volume and elevated gonadotropin levels in four young adult men previously treated with GH for ISS was not confirmed by a double-blind, placebo-controlled study,¹⁸⁰¹ nor by the international databases.¹⁸⁰² This list of side effects is only partial. It is best for the clinician to remember that GH and the peptide growth factors it regulates are potent mitogens with diverse metabolic and anabolic actions. All patients receiving GH treatment, even as replacement therapy, must be carefully monitored for side effects.

For the most part, the side effects of GH are minimal and rare. When they do occur, a careful history and physical examination are adequate to identify their presence. Management of these side effects may include transient reduction of dosage or temporary discontinuation of GH.¹²³⁷ In the absence of other risk factors, there is no evidence that the risk of leukemia, brain tumor recurrence, or slipped capital femoral epiphysis is increased in recipients of long-term GH treatment. Any patient receiving GH who has a second major medical condition (e.g., being a tumor survivor) should be followed up in conjunction with an appropriate specialist such as an oncologist or neurosurgeon. Whereas GH has been shown to increase the mortality of critically ill patients in intensive care units,¹⁸⁰³ there is no evidence that GH replacement therapy needs to be discontinued during intercurrent illness in children with GHD.

The Question of Long-Term Cancer Risk. Several epidemiologic studies have suggested an association between high serum IGF1 levels and an increased incidence of malignancies.^{1804,1805} The calculated risk of cancer in those studies was also increased for patients with low IGFBP3 levels. Additional studies are being conducted to verify or disprove these associations, but the role of GH also should be carefully examined. Although IGF1 levels were not statistically associated with cancer risk, the combination of high IGF1 and low IGFBP3 was related to a heightened risk.¹⁸⁰⁶ Because GH positively influences production of both peptides, this finding casts doubt on its role as a driving force in the IGF-cancer relationship. A potential confounder in these studies is the variability of serum IGF1 levels that may be observed normally and the consequent substantial movement of a given individual's risk designation in differing quartiles when multiple samples are obtained.¹²⁴⁷ Additionally, the effects of high IGFBP3 levels

on the incidence of premenopausal breast cancer further underscore the complexity of these relationships.¹⁸⁰⁷ The necessity of long-term, well-designed studies, with a sufficient number of patients to prevent incorrect and inappropriately ominous conclusions, is apparent.¹⁸⁰⁸

Epidemiologic studies assessing the risk of malignancy in patients with acromegaly found differing results, with some,¹⁸⁰⁹⁻¹⁸¹¹ but not others,^{1812,1813} identifying significant associations between acromegaly and colon cancer risk. The small size and uncontrolled retrospective nature of these studies and the multiple possible sources of bias make these reports difficult to interpret. The largest study to date, reviewing more than 1000 patients, indicated no overall increased cancer incidence in acromegaly.¹⁸¹⁴ Although colon cancer risk was also not increased in that study, the mortality rate was higher, suggesting an effect of GH or IGF on established tumors.¹⁸¹⁵ A prospective analysis of colon cancer and colonic polyps in acromegalics did not observe an association between these two diseases when using either autopsy series or prospective colonoscopy screening series for the control population.¹⁸¹⁶ Acromegaly is associated with a marked increase in the incidence of benign hyperplasia in several organs, including colonic polyps.¹⁸¹⁷ Such findings suggest that the GH-IGF1 axis may lead to symptomatic benign proliferative disease, which could be associated with symptoms, such as rectal bleeding, that would lead to a potential detection (or ascertainment) bias.

Children receiving GH do not appear to have a greater risk of de novo or recurrent tumors.^{1272,1664,1758} A cohort of 1848 patients treated with GH in the United Kingdom was assessed after as long as 40 years and found to have increased rates of colorectal cancer and Hodgkin's disease, but the tumor-associated deaths were so few that a single patient death would markedly alter the risk ratios.^{1818,1819} No increased incidence of cancer was found in GH recipients among adults who were treated for GHD.^{1455,1820} These reports represent imperfect, uncontrolled studies, but the experience gained through them strongly suggests that GH therapy is not associated with future development of neoplasms in the absence of other risk factors.

The use of IGF1 and IGFBP3 in the monitoring of GH recipients, both adult and pediatric, has been recommended and endorsed by international bodies such as the Growth Hormone Research Society¹²³⁶ and the Drug and Therapeutics Committees of the Lawson Wilkins Pediatric Endocrine Society and the European Society of Pediatric Endocrinology.^{1818,1819} Until the issue of cancer risk in GH therapy is fully resolved, the prudent approach appears to be regular monitoring of both IGF1 and IGFBP3 and alteration of the GH dose to ensure that the theoretical risk profile induced by GH therapy is favorable. This can be done by avoiding the unlikely situation of a GH-treated patient with an IGF1 level at the upper end and a IGFBP3 level at the lower end of the normal range. In the 21st century, many GH-deficient patients will receive lifelong GH replacement, emphasizing the importance of long-term, regular monitoring of IGF1 and IGFBP3.^{1820,1821} Although many issues still remain in fully discerning the relationship, if any, between the GH-IGF axis and the risk of cancer, current data strongly suggest the safety of present indications for use of GH in children and adults.^{1822,1823}

IGF1 Treatment

In 2005, the FDA approved the use of rhIGF1 for "long term treatment of growth failure in children with severe primary IGF-1 deficiency and in children with GH gene deletions who have developed neutralizing antibodies to GH. Severe primary IGF-1 deficiency is defined by height

SD score less than -3.0 and a basal IGF-1 SD score less than -3.0 and normal or elevated GH. Severe primary IGF-1 deficiency includes patients with mutations in the GHR, post-GHR receptor signaling pathway, and IGF-1 gene defects" (Increlex [rhIGF1] prescribing information, 2009, Tercica, Inc.). Clinical trials to study the safety and efficacy of rhIGF1 therapy have been conducted mostly in individuals with proven mutations in the GHR; fewer than 10% of enrollees have had GH insensitivity due to GH antibodies. Because of the rarity of GHR mutations, the clinical trials have been small. When all clinical trials are combined, the total number of children treated to date is less than 200, and relatively few have been treated for longer than 5 years. A discussion of the published clinical trials follows.

When 40 $\mu\text{g/kg}$ of IGF1 was administered every 12 hours to six adults with GHR deficiency, normal serum IGF1 levels were maintained for 2 to 6 hours after injection, followed by a rapid decline because of low serum levels of IGFBP3.¹¹⁹ Hypoglycemia did not occur, mean 24-hour GH levels were suppressed, and urinary calcium was increased, demonstrating the potential therapeutic utility of subcutaneous IGF1. A number of short-term growth-related studies with subcutaneous IGF1 treatment at varied doses have been reported. Despite slight differences in IGF1 dosage and inclusion criteria, the short-term effects of IGF1 on growth in GH insensitivity were consistent: growth increased from pretreatment rates of 3 to 5 cm/year to 8 to 11 cm/year on average. In five children with GHR deficiency, single daily doses of 150 $\mu\text{g/kg}$ for 3 to 10 months resulted in growth acceleration to rates of 8.8 to 13.6 cm/year.¹⁸²⁴ Twice-daily injections of 120 $\mu\text{g/kg}$ increased the growth rate from 6.5 to 11.4 cm/year in another patient.¹⁸²⁵ Wilton¹⁸²⁶ reported collaborative data on the treatment of 30 patients, ages 3 to 23 years, with GH insensitivity due to GHR deficiency or IGHD 1A with anti-GH antibodies; the dose of IGF1 varied from 40 to 120 $\mu\text{g/kg}$ twice daily. With the exception of the two oldest individuals, growth rates increased in Wilton's subjects by at least 2 cm/year. A mean increment of more than 4 cm/year in growth velocity was found in 11 prepubertal children treated with 80 $\mu\text{g/kg}$ twice daily.¹⁸²⁷ This study also demonstrated a significant inverse relationship between growth response to exogenous IGF1 and the severity of the GH insensitivity phenotype.

Longer-term studies of IGF1 treatment of GH insensitivity demonstrated a progressive waning effect of IGF1 on growth velocity.¹⁸²⁸ Data from 17 patients in a European collaborative trial who were treated for at least 4 years showed an increase in mean height SDS from -6.5 to -4.9 , with two adolescents reaching the 3rd percentile. Children who received rhIGF1 for 2 years or less had a higher growth velocity than those children who received rhIGF1 for longer periods. In the longest treatment study,^{1829,1830} outcomes were similar to those in the European study, with an initial burst of growth (from 4.0 to 9.3 cm/year) followed by slowing to just above baseline (4.8 cm/year) by the sixth year of therapy. Height SDS improved from -5.6 to -4.2 by the end of the sixth year.

These limited data indicate that rhIGF1 is effective in increasing statural growth, but the growth response is neither as robust nor as sustained as the growth response to GH among children with GHD. GH treatment of GH-deficient children results in sustained supranormal growth velocity, and children can achieve adult heights in the normal range. In contrast, the near-final height of children with GH insensitivity who received rhIGF1 therapy was below -4 SDS. The suboptimal growth response to rhIGF1 compared with

recombinant human GH has been attributed to (1) inability of rhIGF1 to increase IGFBP3 and ALS levels, leading to decreased delivery of IGF1 to target tissues; (2) lack of GH-induced proliferation of prechondrocytes in the growth plate; (3) absence of GH-induced local IGF1 at the growth plate; and (4) difficulty in using higher doses of IGF1 because of the risk of hypoglycemia.¹⁸³¹

IGF1 treatment has also been administered to individuals with IGF1 gene deletion¹⁸³² and post-GHR signaling defects with growth patterns similar to those of children with GH insensitivity due to GHR deficiency. Patients with Noonan syndrome and the *PTPN11* gene mutation experience a less robust response to GH therapy than do those without that mutation. Because *PTPN11* may play a role in downstream GH signaling, it has been suggested that rhIGF1 therapy may be efficacious in this population.¹⁸³³ It has also been suggested that children with renal failure and short stature may benefit from rhIGF1, because there may be diminished GHR signaling.¹⁸³⁴ Limited studies have examined the efficacy of IGF1 therapy in patients with severe insulin resistance due to insulin receptor defects (leprechaunism),¹⁸³⁵ liver disease,¹⁸³⁶ neurologic disorders or injuries,¹⁸³⁷ or critical illnesses.¹⁸³⁸ These studies are investigational, and routine IGF1 therapy in children with these disorders is not indicated.

The most common adverse effect of rhIGF1 is hypoglycemia. In some studies, it occurred in almost half of the patients with GH insensitivity treated with rhIGF1,¹⁸³⁰ usually within the first month of therapy. Importantly, individuals with GHR defects, the highest proportion of enrollees in these treatment studies, have baseline hypoglycemia. In a 6-month, placebo-controlled trial, 67% of children receiving placebo experienced hypoglycemia, compared with 85% of children receiving rhIGF1—a difference that was not statistically significant.¹⁸³⁹ In a study of 23 patients with GH insensitivity, hypoglycemia was noted before the start of treatment; after 3 months, 2.6% of glucose values in those receiving placebo were less than 50 mg/dL, compared with 5.5% of glucose values in those receiving rhIGF1.¹⁸³⁰ The hypoglycemia is avoidable with adequate food intake. In 18 patients with low IGF1 and IGFBP3 levels, blood glucose was monitored after 2 weeks of rhIGF1 in the setting of regular meals, and no levels lower than 60 mg/dL were observed.¹⁸⁴⁰

Patients with GH insensitivity treated with rhIGF1 have also experienced lymphoid tissue hypertrophy, encompassing tonsillar/adenoidal growth and associated snoring and sleep apnea, and thymic and splenic enlargement.¹⁸³⁰ The hypertrophy occurred in 22% of patients, with 10% of patients requiring tonsillectomy/adenoidectomy. Acromegaly coarsening of the face was observed in patients of pubertal age.¹⁸³⁰ Studies have reported an increase in BMI with treatment and a twofold to threefold increase in body fat as assessed by dual-energy x-ray absorptiometry (DEXA).¹⁸⁴¹ Intracranial hypertension with associated papilledema as also been observed in as many as 5% of treated patients. Headache is also frequent, but at least one placebo-controlled study found no difference in headache frequency between treatment and placebo groups.¹⁸³⁹ Anti-IGF1 antibodies develop in about half of treated patients during the first year, but they have no effect on the response.^{1830,1842} As with recombinant human GH treatment, an increased cancer risk with rhIGF1 treatment is an unknown but legitimate concern, considering the role of IGF1 in neoplasias and the increased cancer risk associated with hypersomatotropism.^{1843,1844}

Approval by the FDA and the European Agency for the Evaluation of Medical Products of rhIGF1 has ignited debate

about expansion of the diagnosis of severe IGF1 deficiency and consequent expanded use of rhIGF1 beyond those patients with neutralizing GH antibodies or documented mutations in the GHR, GHR signaling pathways, or the IGF1 gene. Some advocate that individuals with ISS, low serum IGF1, or poor response to a GH trial may have unidentified subtle alterations in GHR signaling and could benefit from treatment with rhIGF1.¹⁸⁴⁵ Others express reservations about expanding the diagnosis of IGF1 deficiency and rhIGF1 use, postulating that the response of children with ISS to rhIGF1 may be minimal considering the lower long-term growth response of children with GHR defects treated with IGF1 compared with GH-deficient children treated with GH. Another theoretical concern regards negative feedback of rhIGF1 on GH secretion, which leads to diminished IGF1-independent effects of GH on growth.^{1831,1846}

Other Treatments to Promote Growth

GnRH Agonists

Increasing Adult Height of Children with Idiopathic Short Stature. The effect of GnRH agonist therapy on adult height has been studied in girls with ISS and normal puberty (8 to 10 years of age); there was a mean gain of 0 to 4.2 cm, compared with predicted height.^{1741,1847-1858} In boys with rapidly progressing puberty, GnRH agonist therapy increased adult height compared with predicted height,^{1859,1860} with mean gains of 4.4 to 10 cm in those receiving the combination therapy, compared with 0.5 to 6.1 cm in untreated controls.^{1744,1861}

In these studies, the effects of GH cannot be definitively separated from those of the GnRH agonist. In two randomized studies of adopted girls with normal puberty, treatment with a GnRH agonist plus GH was compared with GnRH agonist alone, and a 3-cm height gain was demonstrated with the combination therapy.^{1862,1863}

Disadvantages of the use of GnRH agonists in children with ISS include absence of pubertal growth acceleration, delayed puberty with potential psychosocial disadvantage, and decreased BMD. Long-term follow-up studies are lacking. A panel of experts concluded that GnRH agonist therapy alone in children with ISS and normally timed puberty is minimally effective in increasing adult height, may compromise BMD, and cannot be suggested for routine use.¹⁸⁶⁴ Combined GnRH agonist and GH therapy leads to a significant height gain but may have adverse effects. Routine use of GnRH agonists in children with ISS being treated with GH cannot be suggested (level of evidence, C-III).

Increasing Adult Height of Children Born Small for Gestational Age. Short children born SGA usually have a normal pubertal timing, although some of them have rapidly progressing puberty, and may be treated with GH.^{1629,1865} Data on the additional effect of treatment with GnRH agonists are limited. Routine use of the combination of a GnRH agonist and GH in children born SGA cannot be suggested.

Increasing Adult Height of Children with Growth Hormone Deficiency. Some children with GHD are short at the start of puberty and at risk for short adult stature. Retrospective studies evaluating the addition of GnRH agonists to GH therapy involved a limited number of subjects and provided controversial results.¹⁸⁶⁶⁻¹⁸⁶⁸ Three prospective studies that reported near-adult or adult heights showed a height gain of -1 SDS,¹⁸⁶⁹⁻¹⁸⁷¹ possibly without detrimental effect on BMD.¹⁸⁷² Routine use of combined therapy with a GnRH agonist and GH in GH-deficient children with low predicted adult height at onset of puberty cannot be suggested (level of evidence, C-III).

Aromatase Inhibitors. Men with estrogen deficiency due to aromatase gene defects or estrogen resistance due to inactive estrogen receptors experience growth into the third decade, demonstrating the role of estrogen in growth plate fusion.^{21,23} The aromatase enzyme catalyzes aromatization of testosterone and androstenedione to estradiol and estrone, respectively. Various studies have been conducted to explore the efficacy of the aromatase inhibitor class of drugs delaying growth plate fusion and increasing height in disorders associated with short stature in boys. Studies to date have been small, and many have used adjuvant treatments, including GH, GnRH agonist, or testosterone, so the singular effect of the aromatase inhibitor has been unclear. Additionally, most studies to date have been short term and have measured changes in predicted adult height, with only one study investigating the effect on final adult height.

Aromatase inhibitors were first tried in disorders of sex steroid excess and precocious puberty, with only modest, if any, effects on predicted adult height. Treatment of boys with familial male-limited precocious puberty with testolactone, a first-generation aromatase inhibitor, resulted in an improvement in predicted adult height only after 5 to 6 years of treatment.¹⁸⁷³⁻¹⁸⁷⁵ The improvement in predicted adult height after 6 years was robust, however, at 12.9 cm compared with untreated controls. Case reports using the second-generation aromatase inhibitor, anastrozole, also resulted in modest improvements in predicted adult height.¹⁸⁷⁶ In contrast, first- and second-generation aromatase inhibitors have not significantly affected predicted adult height in patients with McCune-Albright syndrome.¹⁸⁷⁷⁻¹⁸⁷⁹ In children with congenital adrenal hypoplasia, addition of aromatase inhibitors did not significantly affect predicted adult height.^{1880,1881}

Aromatase inhibitors have also been used in boys with CDGD. Boys with CDGD who received the second-generation aromatase inhibitor letrozole, in combination with testosterone, for 12 months experienced an increase in predicted adult height of 5.1 cm compared with controls treated with testosterone alone.¹³⁷⁴ When followed to adult height, those boys who received letrozole in addition to testosterone achieved a final adult height 5.7 cm higher than that of boys receiving testosterone alone.¹³⁷⁶ In prepubertal boys with ISS, 2 years of treatment with letrozole increased the predicted adult height by 5.9 cm compared with placebo.¹⁸⁸² In GH-deficient boys treated with GH, the addition of anastrozole for 3 years increased predicted adult height by 6.7 cm, compared to an increase of 1.0 cm in boys treated with GH alone.¹⁷⁴⁰ The results of these preliminary, small trials indicate that aromatase inhibitors may be able to increase adult height, but larger, longer trials are needed to determine the optimal conditions and duration of treatment to significantly increase final adult height. In addition, longer follow-up will be needed to demonstrate the safety of such treatments in peripubertal and pubertal boys.

Given the observation of decreased BMD in males with defects in estrogen synthesis or action, the effects of short-term aromatase inhibitor therapy on BMD were investigated in these treatment studies. None of the studies found a difference in BMD as assessed by DEXA scans in patients who received aromatase inhibitor or placebo for up to 3 years.^{1740,1883,1884} In boys with CDGD or ISS who received letrozole, serum high-density lipoprotein (HDL)-cholesterol was significantly lower than in placebo-treated boys, but boys with GHD who received anastrozole did not have a significant difference in HDL-cholesterol.¹⁸⁸⁵ This discrepancy was postulated to be a result of the lower potency of

anastrozole compared with letrozole, rather than the underlying disorder. Evidence in animals suggests a role for estrogen and estrogen receptor signaling in spermatogenesis. The one study that examined sperm function after aromatase inhibitor therapy did not find a detrimental effect.¹⁸⁸⁶ Clearly, longitudinal follow-up is needed to better characterize the safety and efficacy of aromatase inhibitors to promote growth.

Oxandrolone. Oxandrolone, an anabolic steroid, has been used to increase growth velocity in a number of disorders. Because it cannot be aromatized to estrogen, it should not accelerate skeletal maturation. In general, studies evaluating the effect of oxandrolone on growth have found that it increases growth velocity but is not associated with an increase in final height.

Clinical Trials of Efficacy. Numerous studies have investigated oxandrolone therapy in boys with CDGD. The studies have found that oxandrolone increases growth velocity in these boys.^{1352,1353,1355-1357,1887} The typical response is an increase in growth velocity from approximately 4 to 4.5 cm/year up to 8 to 9 cm/year. Although treatment does not decrease final height, as might occur with accelerated skeletal maturation from excessive sex hormone exposure, neither does it increase final height.^{1353,1357,1887} Therefore, oxandrolone can be used to accelerate the growth of boys with CDGD to allow them to increase their height sooner than they would naturally, but it does not increase their final adult height.

Oxandrolone has been studied in girls with TS, both as a single agent and as combined therapy with GH. As in boys with CDGD, oxandrolone increases the growth rate in girls with TS.^{1593,1888,1889} Although some studies found no effect on final height with oxandrolone treatment alone,¹⁸⁹⁰ others found a mean increase in final height of up to 5.2 cm with oxandrolone treatment.^{1888,1889} Studies of oxandrolone in combination with GH treatment of girls with TS have found a modest increase in final height, compared with GH treatment alone.^{1601,1604}

Side Effects. No significant side effects have been reported in boys treated with oxandrolone for CDGD. Although oxandrolone has significantly less androgenic effects than testosterone, mild virilization has been reported in girls taking oxandrolone, including clitoromegaly. This is less of a concern at lower doses. Hepatic dysfunction, including hepatic failure, has been reported with oxandrolone treatment.^{1891,1892}

Diagnosis and Treatment of Excess Growth and Tall Stature

Diagnosis

The normal distribution of height predicts that 2.5% of the population will be taller than 2 SD above the mean. The most common cause of tall stature is familial, and the diagnostic evaluation centers on distinguishing tall or constitutional stature from rare pathologic causes of tall stature. As with short stature, children with tall stature must be evaluated relative to familial growth patterns and parental target heights.¹⁸⁹³ When a family history of tall stature is available and the growth rate and physical examination findings are normal, support and reassurance are frequently all that is needed without further testing. A careful assessment of pubertal status and bone age facilitates prediction of adult height and discussions with the patient and family. If the history suggests an underlying disorder or growth rate is accelerated, additional testing

should be done to investigate the GH-IGF axis, chromosomal disorders, puberty, or other rare causes.

In GH excess, serum IGF1 levels are elevated, although high IGF1 levels may be a normal manifestation of puberty. Basal serum GH levels may be normal to increased, but serum GH is not suppressed by administration of glucose (1.75 g/kg body weight up to a maximum of 100 g). Although abnormalities of the sella turcica can be evident on lateral skull films, the demonstration of increased GH-IGF secretion should lead to radiologic evaluation of the hypothalamus and pituitary by MRI or computed tomography.

Treatment

Definitive treatment of GH-secreting tumors requires surgical ablation, either transsphenoidally or with a more aggressive surgical approach if large. As described in Chapter 9, somatostatin analogs, dopamine agonists, and GH-receptor antagonists are important components of treatment programs for GH excess.

In the past, most patients treated for familial tall stature were females. The numbers of patients treated in the United States has fallen markedly over the past 4 decades as tall stature in girls has become increasing acceptable socially and psychologically. In general, treatment is reserved for extreme cases, for predicted adult heights greater than 198 cm (6 feet 6 inches) in males or 183 cm (6 feet 0 inches) in females. Before deciding on therapy, the risks of therapy (discussed later) should be taken into account, as should the tendency to overestimate height prediction in prepubertal children based on bone age and Bailey-Pinneau tables.^{1205,1894,1895} Therapy, when elected, is aimed at acceleration of puberty to cause premature epiphyseal fusion.^{1896,1897} Therefore, the optimal time for treatment is before the onset of puberty, and the earlier the age of referral, the more likely it is that treatment will decrease final height.

Typically, ethinyl estradiol at 0.15 to 0.3 mg/day is started, and the dosage is increased, if needed and tolerated, to maximum of 0.5 mg/day. Conjugated estrogens, 7.5 to 10 mg/day, have also been used. Cyclic progestins may be added if breakthrough bleeding occurs. Treatment should be continued until the epiphyses fuse, because post-treatment growth may be substantial if treatment is stopped early.¹⁸⁹⁵ In prepubertal girls, estrogen therapy can decrease final adult height by as much as 5 to 6 cm relative to predictions; the decrement is lessened if therapy is begun after puberty has started. The use of high-dose estrogen in otherwise normal children must be weighed against the known and unknown toxicity of such therapy,¹⁸⁹⁸ including nausea, weight gain, edema, and hypertension. During the initial phases of therapy, growth is accelerated as the child rapidly progresses through puberty. Other potential problems associated with high-dose estrogen therapy, such as thromboembolism, cystic hyperplasia of the breast, endometrial hyperplasia, and cancer, have not been definitely associated with estrogen therapy in children with tall stature but should be discussed with the patient and family.

In males, estrogen therapy is likely to be most efficacious but undesirable to the patient and family. Androgens have been used to accelerate skeletal maturation via aromatization to estrogen, but virilization is rapid. Benefits must be balanced against risks, and therapy should be individualized.

Puberty: Ontogeny, Neuroendocrinology, Physiology, and Disorders

DENNIS M. STYNE • MELVIN M. GRUMBACH

Puberty is not a *de novo* event but rather a phase in the continuum of development of gonadal function and the ontogeny of the hypothalamic-pituitary-gonadal system from the fetus to full sexual maturation and fertility. During puberty, secondary sexual characteristics appear, and the adolescent growth spurt occurs, resulting in the striking sex dimorphism of mature individuals; fertility is achieved, and profound psychological effects ensue.¹ These changes result from stimulation of the gonads by pituitary gonadotropins and a subsequent increase in gonadal steroid output.

Humans are the most reproductively successful of mammals, and many anthropologists have attributed this success to the prolonged pattern of human growth and development² and to the delay in attaining full sexual maturity. The human scheme of growth involves a childhood stage and an adolescent stage that includes an adolescent or pubertal growth spurt (Fig. 25-1). Not even our closest biologic relative, the chimpanzee, which matures twice as rapidly as the human, unequivocally exhibits

these two stages, including the unique human adolescent growth spurt. Learning and practice of adult behaviors related to sex and childrearing, particularly provisioning children (not just infants) with food,³ which is unique to humans,⁴ is considered a critical part of human success. Tool making preceded the evolutionary development of adolescence, suggesting that the evolution and value of human childhood and adolescence and this unique pattern of growth and development have had significant roles in the reproductive success of humans.^{3,5}

In the developed world, reproductive maturity occurs years earlier than psychosocial maturation, causing a mismatch between biologic stages and psychosocial expectations and roles (Fig. 25-2).⁶ In past eras, such as the Neolithic, Greek, or Roman periods, there was not such a mismatch, because menarche occurred at an age similar to today (9 to 14 years), and psychosocial maturation in a simpler world occurred at an age close to that of reproductive maturity. With increased population, the advent of

Figure 25-1 Evolution of the human pattern of postnatal growth and development during the first 20 years of life. Specimens include *A. afar*, *Australopithecus afarensis*, a “bipedal chimpanzee”; *A. africa*, *Australopithecus africanus*; *H. habilis*, *Homo habilis*, the toolmaker; *H. erectus 1*, early *Homo erectus*; *H. erectus 2*, late *Homo erectus*; *H. sapiens*, *Homo sapiens*. The early hominid australopithecine specimens from South Africa date to about 3.0 to 1.5 million years ago. *H. afarensis*, although a hominid (family of all human species), retained many anatomic features of nonhominid species, such as an adult brain size of about 400 mL compared with *H. habilis* (650 to 800 mL), early *H. erectus* (850 to 900 mL), late *H. erectus* (up to 1100 mL), and modern *H. sapiens* (about 1400 mL). Infancy is the period when the mother’s breast milk is the sole or most important source of nutrition, and in preindustrialized societies, it ends at about 36 months. Childhood is the period after weaning, when the child depends on others for food and protection; this period ends when the growth of the brain in weight is almost complete, at about age 7 years. The juvenile stage is defined as prepubertal individuals who are no longer dependent on their parents for survival. The adolescent stage, which begins with the onset of puberty, ends when adult height is attained.²⁵ The pattern in *A. afarensis* is no different from that of the chimpanzee (*Pan troglodytes*). Notice the first appearance of the childhood stage in *H. habilis* (arising about 2 million years ago) and the first appearance of the adolescent stage in *H. erectus 2* (about 500,000 years ago); *H. sapiens* arose about 120,000 to 150,000 years ago. (Modified from Bogin B. Growth and development: recent evolutionary and biocultural research. In: Boaz NT, Wolfe LD, eds. *Biological Anthropology: The State of the Science*. Bend, OR: International Institute for Human Evolutionary Research, 1995:49-70.)

agriculture, and the growth of cities and later urban centers, menarche occurred later, and the complexity of life led to a delay in the attainment of an adult role in society. In modern times, the age of menarche has decreased, but the age of social adulthood still occurs later, causing a discrepancy that probably has not occurred previously in human history.

Figure 25-2 The relationship between the likely range of ages of menarche (green) and achievement of psychosocial maturity (pink) from 20,000 years ago to the current day. The mismatch in timing between these two processes is a novel phenomenon. (From Gluckman PD, Hanson MA. Evolution, development, and timing of puberty. *Trends Endocrinol Metab*. 2006;17:7-12.)

FETAL ORIGINS OF ADULT DISEASE

There are long-lasting effects of abnormalities in fetal and neonatal growth. As seen in longitudinal studies, low birth weight followed by rapid weight gain in infancy (i.e., catch-up growth) leads to tall childhood stature and early pubertal development. Poor prenatal nutrition and small-for-gestational-age (SGA) status tends to advance the age of menarche⁷ and the age of adrenarche,⁸ and a secondary effect of increased postnatal nutrition, often leading to overweight or obesity, also lowers the age of puberty. **Figure 25-3** describes the relationship between excessive adipose tissue and early puberty. A prospective study demonstrated that a lower expected birth weight ratio (i.e., ratio of observed infant’s birth weight to median birth weight appropriate for maternal age, weight, height, parity, infant sex, and gestational age) and a higher body mass index (BMI) at 8 years led to an earlier age of menarche.⁹ Girls who are longer and lighter at birth and subsequently have greater BMI values at 8 years tend to have earlier menarche.¹⁰ Rapid weight gain in the second to ninth months but not thereafter correlated with a greater BMI at 10 years and with earlier menarche in a longitudinal study.¹¹

Many international studies find a relationship between low birth weight or catch-up growth and chronic diseases in adulthood. Birth weight and rate of postnatal growth—not prematurity alone—are inversely related to cardiovascular mortality and prevalence of insulin resistance syndrome (i.e., metabolic syndrome or syndrome X), which consists of hypertension, impaired glucose tolerance, and elevated triglyceride levels, among a growing list of other features. This outcome is attributed to fetal and neonatal *metabolic programming*, in which early adjustments to

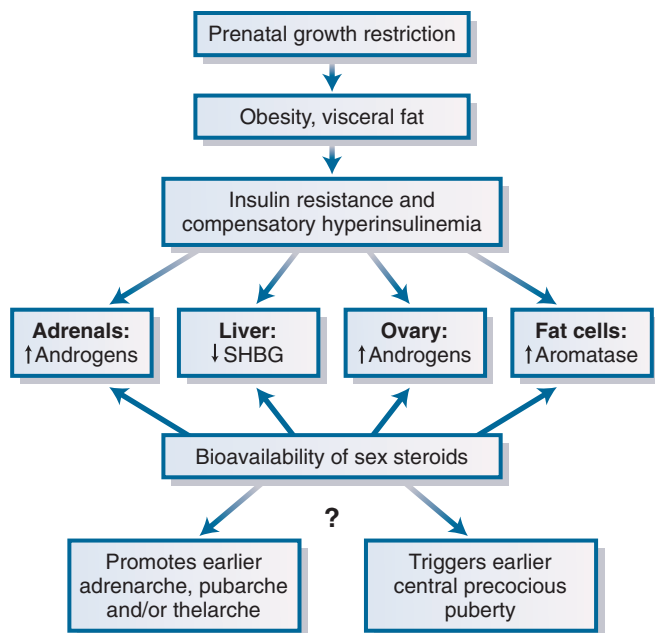

Figure 25-3 Proposed endocrine pathways linking childhood obesity and insulin resistance to early pubertal onset and maturation. Childhood obesity and the predisposition to visceral adiposity after intrauterine growth restraint lead to insulin resistance and peripheral hyperinsulinemia. Insulin acts on various organs, including the adrenals, liver, ovary, and fat cells, to increase sex steroid bioavailability. Elevated circulating and tissue sex steroid levels in obese prepubertal children can have only mild local effects or activate early hypothalamic-pituitary puberty and early reproductive maturation. (From Ahmed ML, Ong KK, Dunger DB. Childhood obesity and the timing of puberty. *Trends Endocrinol Metab.* 2009;20:237-242.)

enhance survival in difficult intrauterine circumstances set the stage for later disorders. Insulin resistance, which may be the basis for most of these complications or may be just one feature of the syndrome, may spare nutrients from use in muscle, leaving them available for the brain. This mechanism can minimize central nervous system (CNS) damage in the fetus during periods of malnutrition.

DETERMINANTS OF THE AGE OF PUBERTY AND MENARCHE

Although historical records show that puberty occurs at an earlier age today, most evidence derives from reports of the age of menarche (Table 25-1). Age of menarche is removed by several years from the first sign of secondary development in girls,^{12,13} and modern studies demonstrate correlation coefficients of only 0.37 between age of menarche and age of onset of puberty, suggesting both unique and similar factors exerting effects on these ages.¹⁴ Changes in health and socioeconomic status in regions where data were collected during different decades leads to complexity in the interpretation of modern national data.

Recalled age of menarche is considered to be accurate within 1 year (in 90% of cases) up to 30 years after the event. Contemporaneous recordings are performed with the probit method of asking for a response of “Yes” or “No” to the question, “Are you menstruating?” However, the results are subject to social pressures of the culture and socioeconomic group considered.¹⁵

The Developed World

The average age of menarche in industrialized European countries has decreased by 2 to 3 months per decade over the past 150 years, and in the United States, the decrease has been approximately 2 to 3 months per decade during the past century (Fig. 25-4).^{12,16} However, this secular trend has slowed in developed countries such as the United States, Australia, and Western Europe since approximately 1940, presumably due to improved socioeconomic status, better health, and the benefits of urbanization. There is a relatively small range of ages of menarche in the well-off developed world, where lower socioeconomic classes do not have an increased burden of disease or malnutrition. Chronic diseases previously increased the age of menarche, and delay in menarche is still associated with serious conditions (e.g., celiac disease, asthma) that are not adequately treated. The standard deviation of the mean age of menarche also decreased, suggesting a diminished number of those maturing very late, as might be found among disadvantaged people.¹⁷ Teasing out the various factors involved in any remaining, more subtle secular trends will require further long-term study and newer methodologic approaches in areas where nutrition and health are optimal or close to it.¹⁸ Remarkably, a reverse secular trend is reported in certain areas of Europe, leading to a later age of menarche. This has been attributed to a resurgence of physical and psychological stress, as was seen in previous eras (e.g., World War II).¹⁸

There are cross-sectional and limited longitudinal data from the 20th century demonstrating a secular trend in the United States, including ethnic influences.¹⁹ The age of menarche in the United States was 12.8 years according to the 1973 U.S. National Center for Health Statistics National Health Education Study,²⁰ and data from the Third National Health and Nutrition Examination Survey (NHANES III, 1988-1994) indicate that the median age at that time was

Figure 25-4 The changes in age at menarche between 1840 and 1978 illustrate the advance in the age at menarche in Western Europe and the United States since 1840 and slowing of this trend since about 1965. (Modified from Tanner M, Eveleth PB. Variability between populations in growth and development at puberty. In: Berenberg SR, ed. *Puberty, Biologic and Psychosocial Components*. Leiden, The Netherlands: H.E. Stenfort Kroese, 1975:256-273.)

12.43 years, 0.37 years earlier than in 1973.²¹ During a 20-year period in the Bogalusa Heart Study, the median menarcheal age decreased by approximately 9.5 months among African American girls compared with 2 months among white girls,²² leading to a 4-month difference. Between the ages of 5 and 9 years, African American girls in the Bogalusa study had taller stature and greater weight, factors that were predictive of menarche before age 11.0 years. African American girls have advanced secondary sexual development compared with white American girls of the same age during the first three stages of puberty,²³ and they have an advanced bone age²⁴; this may be related to the higher prevalence of obesity among African American girls and to an ethnic-specific genetic influence.^{23,25,26}

Obesity is defined as a BMI (calculated as weight in kilograms divided by height in meters squared) above the 95th percentile for age, and overweight is defined by the Centers for Disease Control and Prevention (CDC) as a BMI greater than the 85th percentile for age. Many studies have reported on the effect of the epidemic of childhood obesity and overweight on age of menarche.^{27,28} Most cross-sectional and longitudinal studies^{19,25,29} found an inverse relationship between menarcheal age or other stages of puberty and BMI or other reflections of adiposity.³⁰ If the population in the 1970s had had the same range of BMI values as was found in the 1990s, the projected age of menarche would have been the same in the 1970s as it was in the 1990s.³¹ Girls had a greater prevalence of overweight or obesity between the ages of 8 and 10 years if they were

in puberty or had advanced breast development.³² A study of the age at onset of puberty in U.S. boys of various ethnic groups, although controversial because of a lack of physical examination of testicular size, if accurate, indicated a direct relationship between BMI and age at onset of puberty in boys.³³

International data support the effects of BMI on puberty, but earlier onset of pubertal growth does not lead to a taller adult height.³⁴ Children in Denmark show no secular trend to earlier pubertal development; there was an effect of increased BMI associated with earlier pubertal development, but this was not sufficient to explain the difference between Danish and U.S. ages at puberty, suggesting genetic or environmental influences.²⁶

Longitudinal studies are limited in number but of great importance in the evaluation of a secular trend. The longitudinal National Heart, Lung, and Blood Institute (NHLBI) Growth and Health Study followed 1266 white and 1313 African American girls from 9 or 10 years of age for 10 or more years. The mean age of menarche among whites was 12.7 years, and among African Americans, it was 12.1 years; a direct relationship was found between weight and BMI and the age of menarche.²⁵ Of these girls, 51.6% started puberty with only one manifestation. Those who experienced breast development first (i.e., thelarche pattern), rather than the appearance of pubic hair (i.e., adrenarche pattern), had an earlier menarche (12.6 versus 13.1 years); this was associated with a greater BMI and body weight, which was not true for those girls manifesting the adrenarche pattern.³⁵ These findings support the analysis of

NHANES III, in which girls with earlier breast development had greater BMI values at the time of menarche than those with adrenarche occurring first.³⁶

African American girls in the National Longitudinal Study of Adolescent Health (Add Health) were 1.55 times more likely than white girls to have menarche before 11 years of age,³⁷ and Mexican Americans were 1.76 times more likely to do so than whites. Asians were 1.65 more likely than whites to mature later than 14 years. Those undergoing early menarche were twice as likely to be overweight, and African American girls had a 2.57-fold greater risk for overweight if they had menarche before they were 11 years old. Among early-menarcheal African Americans, 57.5% had a BMI greater than the 85th percentile, and 32.5% had a BMI greater than the 95th percentile. A longitudinal study of 180 girls between the ages of 5 and 9 years demonstrated that those with a higher percentage of body fat at 5 years; those with a higher percentage of body fat, higher BMI percentile, or larger waist circumference at 7 years; those with larger increases in the percentage of body fat from 5 to 9 years; and those with larger increases in waist circumference from 7 to 9 years old were more likely to exhibit earlier pubertal development at 9 years.³⁸

During the past 40 years, menarcheal age in the white subjects in the Fels Longitudinal Study has remained stable even as BMI has increased, with no relationship shown between the two. Subjects with early menarche had a tendency to increase BMI after menarche,³⁹ demonstrating that increased weight appears to be a consequence rather than determinant of the age at menarche and that secular changes in BMI and in mean age at menarche may be independent phenomena. There was a rise in BMI, waist circumference, hip circumference, and serum levels of luteinizing hormone (LH), androstenedione, testosterone, and dehydroepiandrosterone sulfate (DHEAS) during the years immediately after menarche in a shorter longitudinal study.⁴⁰

The composition of diet and the amount of calories in the diet may relate to menarche. The prospective, longitudinal Harvard Longitudinal Studies of Childhood Health and Development found that girls had earlier menarche if they were taller and consumed more animal protein and less vegetable protein as early as 3 to 5 years old and that they had earlier peak growth velocity if they had higher dietary fat intake at 1 to 2 years old and higher animal protein intake at 6 to 8 years. Peak height velocity (PHV) increased, controlling for body size, if more calories and animal protein were consumed 2 years before peak growth.⁴¹ A positive relationship between high fiber intake and age of menarche⁴² held true in a comparison of 46 countries. On the other hand, lifelong vegetarian dietary intake does not affect the age of menarche,⁴³ and a low-fat diet in otherwise healthy, prepubertal, 8- to 10-year-old children with elevated low-density lipoprotein (LDL) cholesterol produced no difference in age of menarche or pubertal progression.⁴⁴ Phytoestrogen intake delays breast development, particularly in girls with lower BMI values.⁴⁵

The Developing World

The interaction of socioeconomic conditions, nutrition, energy expenditure, states of health, and puberty is of particular importance in areas of the world where nutrition is suboptimal; where the most rapid improvement is found, such as in Oaxaca, Greenland, or South Korea, the age of menarche decreases more rapidly.⁴⁶ Where standards of living do not change, neither does the age of menarche. In South America and Africa, some rural children fare better and have earlier puberty and taller stature than

urban children, demonstrating a trend of adverse health and nutritional conditions in crowded urban centers. Malnourished individuals have later age of menarche across the world.⁴⁷

As a whole, these reports indicate that populations existing in the most difficult conditions who experience improvement in socioeconomic status demonstrate a greater decrease in the age of menarche. Once a minimum nutritional status or state of health is reached, the effects of socioeconomic status on the age of menarche are minimized or eliminated, but increased BMI can lower the age of menarche further.

Stress and Puberty

Theories aiming to explain influences on the age of puberty address energetics, stress suppression, psychosocial acceleration, paternal investment, and child development, each of which may have various effects on the timing and progression of pubertal development.⁴⁷ Evolution optimizes allocation of limited resources to maximize fitness and allow reproductive success.⁴⁸

Stress is variably reported to increase or decrease the age of menarche, depending on the study. The absence of a father or lower parental education increases the likelihood of early menarche and of acceleration of puberty in boys.⁴⁹ The question arises of whether psychological stress decreases the age of menarche or stress arises from earlier menarche. War increases the age of voice breaking in boys (e.g., in Bach's choir during the War of Austrian Succession in 1727-1749), and the age of menarche increased during World War II and during more recent hostilities in the former Yugoslavia; poor nutrition, rather than stress, may be a factor in such times.^{47,50} Sexual abuse is associated with earlier onset of puberty and earlier menarche compared with a control population.^{51,52} In contrast, the age of menarche from the California Childhood Health and Development Study confirmed the mother-daughter association on age of menarche but found no influence of family stress in early life on early menarche.⁵³

Short alleles of the GGC-repeat polymorphism of the androgen receptor gene (*AR*) are associated with aggression and impulsivity, increased number of sexual partners, sexual compulsivity, and lifetime number of sex partners of males and with paternal divorce, father absence, and early age of menarche in females.⁵⁴ This implies a genetic basis to the relationship between absence of father and early puberty in girls, because this allele can be transferred from the absent father to the daughter who develops early menarche. Other studies have found no relationship between the GGC-repeat polymorphism and aberrant fathering behavior to explain the relationships among adverse early experiences, early menarche, and early sexual activity.⁵²

Genetic Effects on Puberty and Menarche

There remains a difference in age at attainment of stages of puberty in different countries even with stability in socioeconomic factors; for example, Japanese boys undergo changes in testicular size about 1 year earlier than Swiss boys do.⁵⁵ When socioeconomic and environmental factors lead to good nutrition, general health, and infant care, the age at onset of puberty in normal children appears to be determined largely by genetic factors.

The important role played by genetic factors in the onset of puberty is illustrated by the similar age of menarche in members of an ethnic population and in

mother-daughter and sibling or twin pairs.⁵⁶⁻⁵⁸ The correlation between mother and daughter patterns should theoretically be equal to sister-sister age at menarche if only genetic factors are operative, but because sister-sister correlations are higher than mother-daughter correlations, environmental influences must provide an additional influence beyond genetic factors.⁵⁹

Concordance of ages of pubertal developmental stages and menarche is closer between monozygotic than dizygotic twins, supporting the influence of genetic factors. Monozygotic twins reared together have more similar ages of menarche than those reared apart, and dizygotic twins reared together are less similar than either of the monozygotic groups, pointing to environmental influences on genetic factors. Some twin research suggests that additive genetic factors account for 96% of the variance in the age of puberty in girls and 88% of the variance in boys (although other sources from the United States, Australia, Great Britain, Finland, and Norway have found genetic effects accounting for between 50% and 80% of the variance), with the remainder resulting from shared and nonshared environmental influences.^{47,60-62}

Investigations of genes related to the timing of puberty reveal variable results. Gonadotropin-releasing hormone type I (GnRH-I) and its receptor (GnRHR) are only modestly related to the age of menarche.⁶³ The LEP1875 and XbaI and PvuII polymorphisms of the estrogen receptor α (ER α) gene (*ESR1*) and maternal age at birth (i.e., >30 or <30 years) were associated with age of menarche.^{64,65} High-activity *CYP17* alleles involved in estrogen formation and high-activity *CYP1A2* and *CYP1B1* alleles, whose gene products metabolize estradiol, are not associated with pubertal stage, whereas the high activity *CYP3A4** 1B/1B girls had an earlier age of onset of normal puberty alleles.⁶⁶ Girls with longer (>8) TAAAA repeats in their sex hormone-binding globulin gene (*SHBG*) have a later age of menarche than those with fewer repeats.⁶⁷ A joint analysis of genome-wide association studies enrolling a total of 17,438 women revealed 10 associated single-nucleotide polymorphisms (SNPs) ($P = 1 \times 10^{-7}$ to 3×10^{-13}) for age of menarche; these were clustered at 6q21 (in or near the gene *LIN28B*) and at 9q31.2 (in an intergenic region).⁶⁸ Study of 15,297 Icelandic women demonstrated a significant association between rs314280[T] on 6q21, near the *LIN28B* gene, and age of menarche (1.2 months later per allele; $P = 1.8 \times 10^{-14}$); a second SNP within the same linkage disequilibrium (LD) block, rs314277, splits rs314280[T] into two haplotypes with different effects (0.9 months and 1.9 months per allele).⁶⁹ A meta-analysis of genome-wide association data for 17,510 women demonstrated the strongest signal related to age of menarche $\times 10^{-9}$, where the nearest genes include *TMEM38B*, *FKTN*, *FSD1L*, *TAL2*, and *ZNF462*, and the next strongest signal near the *LIN28B* gene (rs7759938; $P = 7.0 \times 10^{-9}$), which also influences adult height.⁷⁰

However, in other large studies (e.g., that of Gajdos and colleagues⁷¹), there was no association of genes with age of menarche. Further study is required to clarify the most important relationships.

Health Effects of Age at Menarche

Many international studies show that earlier age at menarche is associated with a greater risk of development of breast cancer.⁷² Menarche at less than 12 years increases the risk by about 50% compared with menarche at 16 years⁷³; the risk of premenopausal breast cancer decreases 9% per year of delay in menarche, and the risk for postmenopausal breast cancer decreases 4%.⁷⁴ In

disease-discordant monozygotic twins, the one with cancer recalled puberty to be earlier, and in disease-concordant twins, the one with earlier menarche had the earlier diagnosis of breast cancer.⁷⁵ Women with breast cancer were taller and leaner in childhood and had increased height velocity at age 4 to 7 years and age 11 to 15 years; higher BMI increased this risk. These variables were particularly significant in women with early menarche (at age < 12.5 years),⁷⁶ but some studies confirmed the role of childhood growth but not an effect of age of menarche.^{77,78} Increased birth weight raises the risk of breast cancer, with no relationship to age of menarche in some studies.^{78,79}

There is indirect evidence relating earlier menarche to increasing likelihood of hepatocellular carcinoma.⁸⁰ On the other hand, later age of menarche (>14 years) is associated with an increased risk of glioma or non-Hodgkin's lymphoma.^{81,82}

Evidence from the Fels Longitudinal Study of white females revealed that girls with self-reported menarcheal age of less than 11.9 years (classified as early menarche; 23% of the sample) had adverse cardiovascular risk factors such as elevated blood pressure and glucose intolerance unrelated to body composition.⁸³

Miscellaneous Effects

Seasonality of menarche has been observed. In a U.S. cohort of 3000 college students, those born after 1970 had an earlier age of menarche and a more pronounced frequency peak in July. Factors hypothesized to contribute to seasonality of menarche include stress and the photoperiod.⁸⁴ In Peru, puberty begins at a later age, and pubertal development lasts longer at high altitudes than at low altitudes even when nutritional status is similar.⁸⁵ There is a north-to-south decrease in the age of menarche in Europe¹⁷ that results from environmental factors or genetic influences. Left-handedness may increase the age of menarche.

SECONDARY SEXUAL CHARACTERISTICS AND PHYSICAL CHANGES OF PUBERTY

Female Development

Two distinct phenomena occur in the female. The development of the breast and its modified apocrine glands is primarily under the control of estrogens secreted by the ovaries (Fig. 25-5); the growth of pubic and axillary hair (Fig. 25-6) is mainly under the influence of androgens secreted by the adrenal cortex and the ovary. Breast cancer develops in rodents exposed to environmental toxins (e.g., endocrine disruptors) that alter normal mammary development, and this same relationship is postulated to occur in girls exposed to endocrine-disrupting chemicals, especially if development occurs early.⁸⁶ Aromatase is present in adipose tissue, and estrogen produced in excess adipose tissue may stimulate breast development at an earlier age in obese girls. Peripubertal girls also demonstrated elevated values of androgens, especially just before the onset of puberty and in the early stages, but there is also decreased LH secretion, suggesting that central pubertal development may not be the cause of the physical signs of pubertal development.^{87,88}

The five stages of breast development described by Tanner are the most widely used staging mechanism (see Fig. 25-5). Initial breast development may be unilateral for

Figure 25-5 Stages of breast development according to Marshall and Tanner.¹⁰⁷⁶ Stage 1: preadolescent; elevation of papilla only. Stage 2: breast bud stage; elevation of breast and papilla as a small mound, with enlargement of the areolar diameter. Stage 3: further enlargement of the breast and areola, with no separation of their contours. Stage 4: projection of the areola and papilla to form a secondary mound above the level of the breast. Stage 5: mature stage; projection of the papilla only, resulting from recession of the areola to the general contour of the breast. (Photographs from Van Wieringen JD, Wafelbakker F, Verbrugge HP, et al. *Growth Diagrams 1965 Netherlands: Second National Survey on 0-24 Year Olds*. Netherlands Institute for Preventative Medicine TNO, Groningen, The Netherlands: Wolters-Noordhoff, 1971.)

several months, causing unfounded concern by girls or parents. Needless surgical biopsies are carried out for this normal variation, and an ultrasound examination may preempt unfounded concerns about breast cancer. If concern arises about breast cancer during puberty (a rare event), ultrasound evaluation is suggested because of the dense nature of the tissue at this stage. Inherited or sporadic agenesis of the breast allows no glandular or fat enlargement, regardless of the level of estrogen stimulation.⁸⁹ Virginal breast hypertrophy, an extreme and rapid increase in breast size at the onset of puberty, is rare but is attributed in part to increased sensitivity to estrogen action or to increased local estrogen synthesis and growth factors.

Changes in the diameter of the papilla of the nipple are sequential and are linked to stages of pubertal development. Nipple papilla diameter (3 to 4 mm) does not increase much during pubic hair stage 1 to 3 or breast stage 1 to 3 but does increase after breast stage 3, providing an

objective method of differentiating stage 4 from stage 5 (final diameter, approximately 9 mm).⁹⁰ The stage of breast development usually progresses along with the stage of pubic hair development in normal girls, but because different endocrine organs control these two processes, discordance can occur. Therefore, breast and pubic hair developmental stages should be classified separately for greatest accuracy (Table 25-2 and Fig. 25-7). Increase in height velocity (rather than breast development) is usually the first sign of puberty in girls, although breast budding is what most lay or medical observers first notice.

Dulling and thickening of the vaginal mucosa from the prepubertal reddish, glistening appearance occurs as the lining cells cornify and the secretion of clear or whitish discharge increases in the months before menarche as a result of estrogen action. Girls may notice light-colored discharge on their underwear at this stage. The vaginal pH decreases as menarche approaches due to the increase in

Figure 25-6 Stages of female pubic hair development according to Marshall and Tanner.¹⁰⁷⁶ Stage 1: preadolescent; the vellus over the pubes is not further developed than that over the anterior abdominal wall; there is no pubic hair. Stage 2: sparse growth of long, slightly pigmented, downy hair that is straight or only slightly curled, appearing chiefly along the labia. This stage is difficult to see on photographs. Stage 3: hair is considerably darker, coarser, and curlier. The hair spreads sparsely over the junction of the pubic region. Stage 4: hair is adult in type, but the area covered by it is still considerably smaller than in most adults. There is no spread to the medial surface of the thighs. Stage 5: hair is adult in quantity and type, distributed as an inverse triangle of the classic feminine pattern. The spread is to the medial surface of the thighs but not up the linea alba or elsewhere above the base of the inverse triangle. (Photographs from Van Wieringen JD, Wafelbakker F, Verbrugge HP, et al. *Growth Diagrams 1965 Netherlands: Second National Survey on 0-24 Year Olds*. *African-American girls enter puberty approximately 1 to 1½ years earlier than white girls and begin menses 8½ months earlier.

Mean age for stage 2: 11.3 ± 1.1; mean age for stage 3: 12.5 ± 1.5.

(Data from Roche AF, Weilens R, Attie KM, et al. The timing of sexual maturation in a group of U.S. white youths. *J Pediatr Endocrinol.* 1995;8:11-18; Herman-Giddens ME, Slora EJ, Wasserman RC, et al. Secondary sexual characteristics and menses in young girls seen in office practice: a study from the Pediatric Research in Office Settings network. *Pediatrics.* 1997;99:505-512.)

lactic acid produced by lactobacilli in the vaginal flora. The length of the vagina increases from about 8 cm at onset of puberty to 11 cm at menarche. Thickening, protrusion, and rugation of the labia majora and minora occur. Fat is deposited in the area of the mons pubis, and the appearance of the labia majora becomes wrinkled. Occasionally, the labia minora may enlarge on one or both sides enough to suggest a tumor; childhood asymmetric labium majus enlargement is a disorder of prepuberty or early puberty.⁹¹ The clitoris enlarges slightly, and the urethral opening

becomes more prominent. Photographic atlases of normal female prepubertal genitalia are available and include standards for the variation in appearance of the hymenal opening; this information is invaluable in the examination of a victim of suspected child abuse.

Male Development

The growth and maturation of the penis usually correlates closely with pubic hair development, because both features are under androgen control. However, the stages of pubic hair development and genital development should be determined independently, because discordant stages provide clues to potential disease states of the adrenal gland or testes (Figs. 25-8 and 25-9 and Table 25-3).

Growth of the testes is usually the first sign of puberty in the male, and it begins approximately 6 months after the average chronologic age of initiation of breast development in girls (see Fig. 25-4). Pubertal testicular enlargement is indicated when the longitudinal measurement of a testis is greater than 2.5 cm (excluding the epididymis) or the volume is greater than 4 mL. The testicular volume index ($[\text{length} \times \text{width of right testis} + \text{length} \times \text{width of left testis}] / 2$) and testicular volume, measured by comparing the testes with ellipsoids of known volume, correlate with the stages of puberty.^{92,93} A longitudinal study supported the utility of adding a stage 2a when testicular volume is 3 mL; further pubertal progression occurred within 6 months in 82% of boys who had reached this 3-mL phase (Table 25-4).⁹⁴ The most significant changes in serum testosterone and calculated free testosterone occur at the transitions of testicular volume between 1 and 2 mL, 2 and 3 mL, 6 and 8 mL, and 10 and 15 mL, suggesting the denotation of stages pre-1 (testis, 1 mL), pre-2 (testis, 2 mL), early (testis, 3 to 6 mL), middle (testis, 8 to 12 mL), late-1 (testis, 15 to 25 mL, the boy has not reached final height), and late-2 (testis, 15 to 25 mL, the boy has reached final height).⁹⁵ The right testis is normally larger than the left testis, and the left testis is located lower in the scrotum than the right testis.

Figure 25-7 The sequence of events at puberty in females. Diagram of the sequence of events at puberty in males. An average is represented in relation to the scale of ages; the range of ages within which some of the changes occur is indicated by the numbers below. The ages are from British girls 40 years in the past, so the sequence of changes, rather than the ages, is the important factor. (From Marshall WA, Tanner JM. Variations in pattern of pubertal changes in girls. *Arch Dis Child.* 1969;44:291-303.)

Figure 25-8 Stages of male genital development and pubic hair development according to Marshall and Tanner.¹⁰⁷⁶ *Genital development:* Stage 1: preadolescent. Testes, scrotum, and penis are about the same size and proportion as in early childhood. Stage 2: the scrotum and testes have enlarged; the scrotal skin shows a change in texture and some reddening. Stage 3: growth of the penis has occurred, at first mainly in length but with some increase in breadth; there is further growth of the testes and scrotum. Stage 4: the penis is further enlarged in length and breadth, along with development of the glans. The testes and scrotum are further enlarged. The scrotal skin has further darkened. Stage 5: genitalia are adult in size and shape. No further enlargement takes place after stage 5 is reached. *Pubic hair development:* Stage 1: preadolescent; the vellus over the pubic region is not further developed than that over the abdominal wall; there is no pubic hair. Stage 2: sparse growth of long, slightly pigmented, downy hair that is straight or slightly curled, appearing chiefly at the base of the penis. Stage 3: hair is considerably darker, coarser, and curlier and spreads sparsely over the junction of the pubes. Stage 4: hair is adult in type, but the area it covers is still considerably smaller than in most adults. There is no spread to the medial surface of the thighs. Stage 5: hair is adult in quantity and type, distributed as an inverse triangle. The spread is to the medial surface of the thighs but not up the linea alba or elsewhere above the base of the inverse triangle. Most men will have further spread of the pubic hair. (Photographs from Van Wieringen JD, Wafelbakker F, Verbrugge HP, et al. *Growth Diagrams 1965 Netherlands: Second National Survey on 0-24 Year Olds*. Netherlands Institute for Preventative Medicine TNO. Groningen, The Netherlands: Wolters-Noordhoff, 1971.)

The phallus should be measured while stretched and in the flaccid state, because there is much variation among individuals in the length of the unstretched penis. The length of the erectile tissue (excluding the foreskin) increases from an average of 6.2 cm in the prepubertal state to 12.4 ± 2.7 cm in the white adult. Ethnic differences have been identified; the mean value in African American men is 14.6 cm, and in Asians, it is 10.6 cm.⁹⁶

As in girls, the areolar diameter increases in boys during puberty, with a distinct separation between the sexes

Figure 25-9 Diagram of the sequence of events at puberty in males. An average is represented in relation to the scale of ages, and the range of ages within which some of the changes occur is indicated by the numbers below. The ages are from British boys 40 years in the past, so the sequence of changes, rather than the ages, is the important factor. (From Marshall WA, Tanner JM. Variations in the pattern of pubertal changes in boys. *Arch Dis Child*. 1970;45:13-23.)

occurring in stage 4, when female areolar diameter increases much more than in the male. In gynecomastia, the areolar diameter increases to above-normal values.

Studies of Pubertal Development

National Trends in Pubertal Development

Physical examination with palpation of gonads or breasts by trained observers is the most accurate method of assessment of pubertal development. Detection of the onset of stage 2 breast development in an overweight girl on physical examination may be difficult even for a trained observer (although stage 3 usually is obvious). Visual observation of the stage of development in person (not by photographs)

‡Volume by comparison with orchidometer.

§Measurement with calipers and average volume of both testes calculated as follows: 0.52 × longitudinal axis × transverse axis.

is one step removed from physical examination and palpation; errors in the evaluation of breast tissue in obese girls or the stage of testicular enlargement in boys may occur. Visual observation by multiple observers was used in NHANES III (and in the National Health Examination Survey [NHES] that occurred more than 20 years earlier), and visual observation is subject to interobserver variation. In a study by Pediatric Research in the Office Setting (PROS), a network fostered by the American Academy of Pediatrics, specially trained pediatricians, nurse practitioners, or physician assistants (225 offices), used palpation for 30% of the study population and visual inspection for all members of a convenience sample of 17,070 girls across the United States.⁹⁷

The availability of only limited numbers of trained personnel for examination or subjects' refusal of embarrassing examinations sometimes leads to the use of proxy measures. Photographs or drawings of pubertal development allow self-reporting or parental reporting of pubertal progress, but correlations range widely from 0.48 to 0.91 compared with physicians' examinations or visual observation of subjects.^{47,98} The answers to self-assessment may be influenced by the subjects' wishes to conform with their understanding of normal development and may be less accurate in some ethnic groups than others, similar to reported menarcheal age. Obese girls may overestimate breast developmental stage, and boys may overestimate pubic hair development. Individuals with learning disabilities, chronic diseases (e.g., cystic fibrosis, Crohn's disease), or psychological conditions (e.g., anorexia nervosa) may have less accurate pubertal staging.⁹⁹ Self-report is related to testosterone values for boy and girls and is said to be accurate enough if precision is not needed.¹⁰⁰ With all of its difficulties, physical examination remains the best method to accurately evaluate large populations.

Limits of Normal Pubertal Development

The U.S. Health Examination Survey (HES) enrolled subjects who were 12 years old; although it is useful for defining the upper limits of normal pubertal development, the survey is uninformative about the lower limits of the age at onset of puberty.^{20,23,101} A longitudinal study (see Tables 25-2 and 25-3) that enrolled 9.5-year-old white boys and girls added much to the determination of the mean age at attainment of stages of puberty¹⁰²; however, it started too

late to include normal children entering puberty at an earlier age. Two studies used data from NHANES III. One¹⁰³ found onset of stage 2 breast development for African Americans, Mexican Americans, and whites to occur at 9.5, 9.8, and 10.3 years, respectively, and pubic hair stage 2 to occur at 9.5, 10.3, and 10.5 years, respectively, using a sample of 1623 girls. The other study¹⁰⁴ reported that the ages for onset of stage 2 breast development were 9.5 years for African Americans, 9.8 years for Mexican Americans, and 10.4 years for white Americans, whereas the onset of stage 2 pubic hair occurred at 10.4 years for white Americans, 9.4 years for African Americans, and 10.6 years for Mexican Americans in a sample of 2145 girls.

Because the PROS started at 3 years of age but ended at 12 years of age, it excluded a proportion of normal children who enter puberty at a later age,⁹⁷ although the probit statistical method can estimate events even when only a portion of the population has achieved the event. This study was criticized because the subjects were not matched for the many factors considered in a national study such as NHANES. The standard deviation of the longitudinal study described earlier¹⁰² was low, 1.0 years or less in most cases, whereas the cross-sectional study had a larger standard deviation of approximately 2 years.⁹⁷ Any study of puberty will demonstrate a limit in the spread of the upper end of the age at onset of puberty curve, because rarely do individuals with the most severe constitutional delay of puberty (CDP) spontaneously enter puberty after 18 years of age. There may be a skewing of the normal age at onset of puberty to an earlier spread of ages.

A study of the age of pubertal stages in children in NHANES revealed that in those with normal BMI values, pubertal signs occurred before 8.0 years of age in fewer than 5% of the non-Hispanic white, female population, although thelarche occurred before age 8.0 in 12% to 19% of normal-BMI, non-Hispanic black and Mexican American girls; the 5th percentile for menarche was 0.8 years earlier for non-Hispanic black than non-Hispanic white subjects.³⁰ Although the appearance of pubic hair occurred in up to 3% of 8.0-year-old girls with normal BMI values in all ethnicities, it did occur significantly earlier in the minority groups. Girls with the higher BMI values had a significantly higher prevalence of thelarche between the ages of 8.0 and 9.6 years and pubarche from the ages of 8.0 to 10.2 years, compared with girls with normal BMI values. Menarche was significantly more likely to occur in younger girls with elevated BMI values. In boys with normal BMI values, pubic hair appeared in fewer than 2% before 10.0 years. The study authors concluded that pubertal development in girls with normal BMI values before 8 years of age is premature. These data support other analyses of NHANES III, in which the heaviest girls tended to have thelarche before pubarche and the heaviest boys had pubarche before gonadarche.³⁶

The latest and largest multiracial and ethnic study of the age at onset of puberty in 2114 American boys between the ages of 8 and 19 years suggested that a decrease has occurred over past decades, but these observations are controversial.³³ Using the NHANES III database, the investigators determined that the onset of pubic hair occurs earlier in African American boys than in white boys, with a tendency to later onset in Mexican American boys. Between the ages of 8 and 9 years, no white boys had pubic hair, whereas 5.3% of African American boys were at least at Tanner stage 2.³³ The age of genital development was based on the visual change in scrotal skin and enlargement of the testes; by the beginning of age 8, the earliest age studied, 29.35% of white boys, 37.8% of African American

boys, and 27.3% of Mexican American boys reportedly had genital development. The heights and weights of boys reaching the earlier stages of puberty were greater than reported in the past, although the adult heights and weights were equivalent to the past data. However, several aspects of this study have been questioned.¹⁰⁵ For example, the observers for NHANES III did not physically measure testicular volume, and a one-stage variance was allowed between the observers' findings and the quality control, a variance that is quite significant between stage 1 and 2 of pubertal development in boys because it defines the very onset of puberty. These observations are being further investigated by a PROS project studying pubertal development in boys. If it is confirmed that there is an earlier onset of puberty in a substantial number of boys before the previously accepted lower age limit of 9 years, the guidelines for normal pubertal development in boys will have to be revised downward.

Taking these data as a whole, it seems reasonable to set the lower range of normal puberty at 8 years in girls and 9 years in boys. The influence of BMI must be taken into account. Obese boys characteristically enter puberty early, especially when there is an *MCR4* mutation, but obesity is also associated with delayed puberty.¹⁰⁶ Fröhlich's syndrome (i.e., adiposodysgenesis, originally described in a patient with tuberculosis involving the hypothalamic-pituitary axis), is a constellation of endocrine abnormalities, combining findings of obesity and hypogonadism due to a hypothalamic-pituitary disorder.

The latest comprehensive evaluation of secular changes compared data available from the U.S. HES (3042 white boys, 478 African American boys, 2065 white girls, and 505 African American girls from 1966 to 1970), the Hispanic Health and Nutrition Examination Survey (HHANES: 717 Mexican American boys and 512 Mexican American girls from 1982 to 1984), and NHANES III (259 white boys, 411 African American boys, 291 white girls, 415 African American girls, 576 Mexican American boys, and 512 Mexican American girls from 1988 to 1994).¹⁰⁷ The analysis showed no strong evidence of a secular trend toward earlier puberty between 1966 and 1994 in non-Hispanic black boys and non-Hispanic black and white girls, although there was some evidence of earlier puberty in non-Hispanic white boys between 1966 and 1994 and in Mexican American boys and girls between 1982 and 1994.^{104,108}

Spanish investigators demonstrated that the earlier normal girls entered puberty, the longer the duration of puberty before menarche.¹⁰⁹⁻¹¹¹ In one of these studies, girls who started puberty at 9, 10, 11, 12, and 13 years of age experienced menarche 2.77, 2.27, 1.78, 1.44, and 0.65 years later, respectively, demonstrating a normalizing trend that keeps the age of menarche relatively stable in the group as a whole.¹⁰⁹ These data may suggest that earlier onset of the first stages of puberty may not exert major effects on the age of menarche. This contrasts with a suggestion of a decrease in the time required to transit puberty from start to end in Dutch and Swedish boys and girls.¹⁷

In sum, the data show that African American girls develop before white girls, regardless of socioeconomic issues. There is evidence that rising BMI values in childhood are associated with earlier pubertal maturation, which may explain some of the increasing age differences between these ethnic groups. This suggests that an irrefutable decrease in the age at puberty in the overall population of girls may be realized in the future due to the increased BMI percentiles. Environmental disruptors may also play a role. Although there is evidence for earlier menarche, a secular trend toward earlier puberty in girls in the

absence of increased BMI cannot be supported from these data because of the different ages studied and lack of comparable studies over past decades.^{108,112}

The United States is lacking a comprehensive, large, longitudinal study that would start early enough to include the youngest normal pubertal subjects and last long enough to include the oldest and that would be based on direct physical examination rather than observation. Such a study must be balanced in terms of ethnic groups, and the planners must use the predicted increase of certain ethnic populations in the United States, to avoid the unfortunate position we now have as we look back and try to draw conclusions about secular trends without sufficient data from various ethnic groups.¹⁰⁸

From all of the longitudinal and some of the cross-sectional data, we may consider the mean age at onset of puberty in boys to be 11 years, with the normal limits being 9 to 14 years.¹⁰² It is possible that some normal boys, especially African American boys, will enter puberty or adrenarche between 8 and 9 years of age.

Guidelines for the normal variation in pubertal development for girls in the United States are controversial. In the cross-sectional, convenience sample study, 3.0% of white girls had stage 2 breast development in their sixth year and 5.0% by the seventh year, whereas 6.4% of African Americans had stage 2 breast development by the sixth year and 15.4% by the seventh year. African American girls have an earlier onset of pubertal development by about 1 year, even though their average age at menarche in the cross-sectional study was only 8.5 months different (12.2 years for African Americans and 12.9 for whites). We may combine these findings and set the normal range for age at puberty in white girls at 7 to 13 years and in African American girls at 6 to 13 years.

These guidelines help the decision of which children with early onset of puberty are candidates for expensive diagnostic tests and for consideration of long-term therapy, because many of those children who appeared to have mild sexual precocity in years past may now be considered to represent normal variation. We emphasize that family history, the rapidity of development of secondary sex characteristics, the rate of growth, and the presence or absence of CNS or other types of disease must enter into the decision to evaluate a child. We recommended these ideas in previous editions of this textbook, and the Drug and Therapeutics and Executive Committees of the Lawson Wilkins Pediatric Endocrine Society support such a revision of the lower limit of the normal age at onset of puberty to age 7 for white girls and age 6 for African American girls, with no changes in the current guidelines for evaluating boys, which target those with signs of puberty developing before 9 years of age.¹¹³

Several studies indicate the likelihood of missing serious endocrine disorders if the new guidelines are followed.¹¹⁴⁻¹¹⁶ With all of these studies, it may be inferred that if the examining physician looks for signs and symptoms of disease rather than just relying on the age criteria, somewhat less than 10% of true precocious puberty will be missed; of those cases, some (probably many) will be so mild as to not need intervention and may represent variations of normal. A multinational study from Europe suggested that valid indications for magnetic resonance imaging (MRI) of the CNS in the diagnosis of precocious puberty are puberty onset in girls before 6 years of age, in agreement with our recommendations, and an estradiol value higher than the 45th percentile (in the laboratory performing the diagnostic tests) for girls with central precocious puberty (CPP), a new criterion.¹¹⁷

Other Physical and Biochemical Changes of Puberty

The gender difference in voice develops during puberty. In the peripubertal period, the length of the vocal cords in boys and girls is about 12 to 15 mm, of which the membranous portion is 7 to 8 mm.¹¹⁸ In adult men, the vocal cords attain a length of 18 to 23 mm (membranous portion, 12 to 16 mm), whereas in women, the cords enlarge only slightly (13 to 18 mm). During puberty, the male larynx, cricothyroid cartilage, and laryngeal muscles enlarge, leading to the appearance of an Adam's apple. The largest changes in singing and speaking frequencies occur between Tanner genital stages 3 and 4; breaking of the voice occurs at approximately 13 years, and the adult voice is achieved by about 15 years.

Facial hair in boys is first apparent on the corners of the upper lip and the upper cheeks; it then spreads to the midline of the lower lip and finally to the sides and the lower border of the chin. The first stage of facial hair development usually occurs during pubic hair stage 3 (average age of 14.9 years in the United States), and the last stage occurs after pubic hair stage 5 and genital stage 5.

Axillary hair appears at approximately 14 years in boys. Ninety-three percent of African American girls have axillary hair by age 12, in contrast to 68% of white girls.⁹⁷ Axillary sweat glands begin to function as the hair appears. The appearance of circumanal hair slightly precedes that of axillary hair in boys.

Comedones, acne, and seborrhea of the scalp appear as a result of the increased secretion of gonadal and adrenal sex steroids.¹¹⁹ Early-onset acne correlates with the development of severe acne later in puberty. Acne vulgaris, the most prevalent skin disorder in adolescence, appears at a mean age of $12.2 \pm$ a standard deviation (SD) of 1.4 years (range, 9 to 15 years) in boys and progresses with advancement through puberty. However, acne vulgaris can be the first notable sign of puberty in a girl, preceding pubic hair and breast development.¹¹⁹ Analysis of the Nurses Study indicates that intake of milk and skim milk is related to the development of acne, an association suggested to reflect the hormone content of milk.¹²⁰ At late prepuberty, comedones are present in many boys, and 100% of boys have comedones by genital stage 5.

Facial morphology changes with pubertal development leading to the mature appearance. The mandible and nose enlarge more in boys, but they and the maxilla, brow, frontal sinuses, and middle and posterior fossae enlarge in both sexes, mainly during the pubertal growth spurt. Children with isosexual precocity have the facial appearance of older children, and individuals with delayed puberty have faces of younger children. There is a greater change in various measurements of the face compared with measurements of the skull, with the jaw showing the most increase.¹²¹

The size of the thyroid gland evaluated by ultrasonography increases roughly 40% to 50% with growth in height, weight, surface area, and fat-free mass during puberty but not with BMI.¹²² Lymphoid tissue growth reaches a maximum at about age 12 and thereafter decreases with pubertal progression.

A host of other physiologic and biochemical measurements change with the onset of puberty and must be interpreted in terms of the stage of pubertal development. Age-related standards should be used in all laboratories but often are not, and the interpreting clinician must turn to a textbook of pediatrics or the *Harriet Lane Handbook*. For example, hemoglobin levels increase at puberty in boys; the effect appears to be mediated by androgen, because

treatment of boys with CDP with testosterone and letrozole (to block aromatization to estrogen) resulted in increased hemoglobin levels, even in the absence of a rise in insulin-like growth factor type 1 (IGF1).¹²³ The use of biomarkers of pubertal onset and progression will play a role in the upcoming child health study that proposes to longitudinally follow children from conception to adulthood to determine normal changes and the effects of environmental exposures, among other factors.⁹⁹

The peak cohort of germ cells in the fetal ovary is attained at 16 to 20 weeks of gestation.¹²⁴⁻¹²⁷ Primordial follicles start to appear at 20 weeks of fetal life, and primary follicles soon follow; they constitute the lifelong store of follicles for the individual, which decreases with development and aging. Follicle-stimulating hormone (FSH) receptors have not been detected in midtrimester human fetal ovaries; fetal pituitary FSH is not required for proliferation of oogonia, oocyte differentiation, or formation of primordial follicles.¹²⁴ During fetal life and childhood, follicular growth to the large antral stage occurs, but before menarche, all developing follicles are destined to undergo atresia (Fig. 25-10). Large preovulatory follicles are rarely present before puberty.

The ultrasound appearance of the prepubertal ovary changes with pulsatile gonadotropin secretion, and a multicystic appearance occurs with more than six follicles of at least 4 mm in diameter; this appearance differs from that found in the polycystic ovary syndrome (PCOS). During prepuberty, the ovarian volume is 0.2 to 1.6 mL on ultrasound scans, and after the onset of puberty, the volume increases to 2.8 to 15 mL. Tall girls have greater ovarian volume than average-size girls.

The uterus grows until the age of 16 years under the influence of estradiol, progesterone, growth hormone (GH), and IGF1.¹²⁸ Ultrasound studies (Fig. 25-11) show that the corpus of the uterus increases during pubertal progression, from an initial tubular shape to a bulbous structure; the length of the uterus increases from 2 to 3 cm to 5 to 8 cm; and the volume increases from 0.4 to 1.6 mL to 3 to 15 mL.¹²⁹ Decreased uterine size is found in patients with Turner syndrome, childhood exposure to radiotherapy, abnormalities in *HOX* and *WNT* gene expression, and maternal cigarette smoking can decrease uterine size at adolescence. Smaller uterine size is associated with an increased risk of miscarriage and failed implantation.

Uterine ultrasonography measurements are proposed to aid the clinician in differentiating premature thelarche from precocious puberty. The addition of color Doppler studies may improve accuracy of the diagnosis of precocious puberty and can differentiate the condition from premature thelarche. A Doppler study showed the lowest impedance of the uterine artery to be in girls with established CPP.¹³⁰

Endometriosis is considered to be an estrogen-dependent process, although it has been reported in premenarcheal girls. It was suggested that this cause for chronic abdominal pain is more common than previously considered. One proposed explanation for early-onset endometriosis is that the condition results from müllerian rests.¹³¹

MENARCHE AND TEENAGE PREGNANCY

Menarche usually occurs in the 6-month period preceding or following the fusion of the second and first distal phalanges and the appearance of the sesamoid bone¹³²; this

Figure 25-10 Schematic representation of the growth of ovarian follicles during infancy and childhood. Type 1 (primordial follicle) and type 2 (primary follicle) are composed of a small oocyte and a few to a ring of flat granulosa cells. In the diplotene (nesting) stage of prophase, primary follicles are the predominant form of oocyte and constitute the reservoir of cells from which follicular growth occurs. Types 3 to 5 (preantral follicles) are follicles that have entered the growth phase; the oocyte is enlarging and is surrounded by a zona pellucida, and granulosa cells increase in number and differentiate. The growth of the oocyte is complete by the end of the preantral stage, and the increased follicular size is caused by follicular growth and fluid accumulation. Types 6 to 8 represent antral follicles (graafian follicles) and contain a fully grown oocyte, a large number of granulosa cells, a fluid-filled cavity, and a well-developed theca external to the basement membrane. Large preovulatory follicles are absent (10,000 to 15,000 μm). Follicular growth and atresia take place throughout childhood. All follicles that enter the growth phase become atretic, and this can occur at any stage in their development but mainly involves large antral follicles. (From Peters H, Byskov AG, Grinstead J. Follicular growth in fetal and prepubertal ovaries of humans and other primates. *Clin Endocrinol Metab*. 1978;7:469-485.)

corresponds to Tanner stage 4 in most cases. The 95th percentile for menarche is 14.5 years, although many textbooks define primary amenorrhea as absence of menses at 16 years. Reconsideration of the age at onset of female puberty may lead to a reconsideration of the definition of primary amenorrhea. Anovulatory cycles are common in the first years after menarche. There is a reported prevalence of 55% anovulation in the first 2 years after menarche that decreases to 20% anovulatory cycles by the fifth year; others have observed a lower number of ovulatory events shortly after menarche and 5 years after the event. With the high prevalence of PCOS, it is unclear how often delayed regularity is an early sign of PCOS or normal variation. Although the number of pregnancies for U.S. teenagers 15 to 19 years old has been decreasing since 1991, teen childbearing rose 3% in 2006; however, the birth rate fell 2% in 2008 to 41.5 per 1000, reversing this trend,¹³³ and the birth rate for Hispanic teenagers declined to a historic low.

Male Testicular Development in Puberty

The testes are active during the prepubertal period albeit at a lower level than during pubertal development.^{124,134} During pubertal development, the testes increase in size, principally because of the growth of the seminiferous tubules associated with the onset of spermatogenic activity and mitosis of Sertoli cells, and testosterone production increases (Fig. 25-12 and Table 25-5). The Sertoli cells are the major cell type in the seminiferous cords in prepuberty

and early puberty, but in the adult, germ cells predominate. During progression through puberty, the Sertoli cells cease to undergo mitosis, differentiate into adult-type Sertoli cells, and form occlusive junctions with the development of the blood-testes barrier. Although Leydig cells are found in early gestation and during the neonatal period of testosterone secretion, the interstitial tissue is composed principally of undifferentiated mesenchyme-type cells during childhood. With pubertal development and rising serum LH levels, adult-type Leydig cells appear (Table 25-6). It is suggested that three phases of Leydig cell maturation correspond with ages of increased testosterone production: 14 to 18 weeks of fetal life, 2 to 3 months after birth, and puberty through adulthood.¹³⁵ The seminal vesicle enlarges through childhood to puberty to hold 3.4 to 4.5 mL, or 70% of the seminal fluid. The mean blood flow in the testes increases to adult values (measured by Doppler sonography) in boys, with a testicular volume greater than 4 cm³.

Spermatogenesis

The first histologic evidence of spermatogenesis appears between ages 11 and 15 years (see Figs. 25-6, 25-11, and 25-31A). Spermaturation may be the first sign of pubertal development, but the presence of sperm in urine is intermittent and therefore not a reliable indicator in all boys, although in large groups, it holds promise.⁹⁹ Spermaturation is more prevalent in early puberty than in late puberty, suggesting that there may be a continuous flow of sperm

Figure 25-11 High-resolution pelvic ultrasonography. *Top left*, Prepubertal uterus. *Top right*, Prepubertal ovary demonstrating four small follicular cysts (arrows). *Bottom left*, Pubertal postmenarchal uterus. *Bottom right*, Ovarian cyst in a girl with true precocious puberty.

through the urethra in early puberty but that ejaculation is necessary for sperm to appear in the urine in late puberty.¹³⁶ Spermaturia in the first morning urine specimen occurs at a mean chronologic age of 13.3 years, and at a mean pubic hair stage 2 to 3 in one study (or 16 years in another study), but may be found in normal boys with bilateral testicular volumes of only 3 mL and no signs of puberty.¹³⁷ Normospermia (i.e., normal sperm concentration, morphology, and motility) is not present until a bone age of 17 years.¹³⁸ The first conscious ejaculation occurs at a mean chronologic age of 13.5 years in normal boys and at a mean bone age of 13.5 years in boys with delayed puberty.¹³⁹ The potential for fertility is reached before an adult phenotype is attained, before adult plasma testosterone concentrations are reached, and before PHV occurs.

Adolescent Growth

Pubertal Growth Spurt

The pubertal growth spurt may be divided for purposes of comparison into three stages: the time of prespurt minimal growth velocity in peripuberty just before the spurt (takeoff velocity); the time of most rapid growth, or PHV; and the stage of decreased velocity and cessation of growth at epiphyseal fusion. The greatest postnatal growth occurs in infancy; growth decreases to the nadir known as the minimal prespurt velocity, the slowest period of growth in childhood, immediately before the pubertal growth spurt.

During puberty, boys and girls experience a growth velocity greater than at any postnatal age since infancy (but palling in comparison to fetal growth, when one fertilized cell grows to 7 pounds in 9 months). Boys reach PHV

Figure 25-12 Left, The diagram shows the developmental stages of testicular germ cells based on electron microscopic findings in the rabbit. Notice the differences between prespermatogonium and spermatogonium. Right, The diagram shows maturation of testicular cell types in the rabbit from prepubertal appearance (left) to onset of spermatogenesis (right). Interstitial cells undergo changes in shape, size, and arrangement in the process of Leydig cell differentiation. (From Gondos B. Testicular development. In: Johnson AD, Gomes WR, eds. *The Testis*, vol 4. New York, NY: Academic Press, 1977:1-37.)

approximately 2 years later than girls and are taller at takeoff (Fig. 25-13); PHV occurs during stage 3 to 4 of puberty in most boys (see Fig. 25-9) and is completed by stage 5 in more than 95% of boys. Boys achieve a PHV of 9.5 cm/year at a mean of about 13.5 years, with a greater PHV in those who mature earlier than in those who mature later.¹⁴⁰ The pubertal growth spurt in girls (PHV in girls is approximately 8.3 cm/year at a mean chronologic age of

11.5 years) occurs between stages 2 and 3 (see Fig. 25-7). Boys grew a mean of 28 cm, and girls grew 25 cm between takeoff and cessation of growth in a study in the United Kingdom.¹⁴¹ Although the 8 to 11 cm of increased height gained during the pubertal growth spurt in boys has been held mainly responsible for the difference in adult height between the sexes,¹⁴⁰ twin studies indicate that the difference in adult height results more from the later onset of

TABLE 25-5						
Mean Values of Various Body Measurements and Serum Hormone Levels by Pubertal Stage in Boys (Ohio)*						
Variable	PS1	PS2a	PS2b	PS3	PS4	PS5
Age (yr)	11.44 (NS)	12.18	12.79	13.74	14.63	15.19
Height (cm)	144.2	149.8	154.6	162.3	169.9	173.3
Weight (kg)	38.18	41.65	47.27	54.67	61.11	66.88
Body mass index (kg/m ²)	18.1	18.4	19.5	20.6	21.0	22.2
Testosterone (nmol/L [ng/dL])						
Blacks	0.8 (23)	3.0 (86)	4.9 (141)	11.5 (331)	13.4 (338)	15.5 (449)
Whites	0.6 (16)	2.9 (83)	4.6 (132)	9.7 (281)	13.3 (383)	14.6 (422)
Free testosterone (pmol/L [ng/dL])	11 (0.33)	60 (1.74)	114 (3.28)	294 (8.49)	413 (11.9)	504 (14.5)
DHEAS (μmol/L [μg/dL])	2.71 (99.7)	3.31 (121.8)	4.04 (148.7)	4.75 (175.0)	5.08 (187.0)	5.89 (217.0)
TeBG (nmol/L)	34.6 (NS)	33.3 (NS)	28.4	21.5	14.4	10.7

*Subjects were 515 boys from Ohio, including 237 blacks and 278 whites, aged 10-15 yr at intake, who were monitored every 6 mo for 3 yr. All values were significant by Duncan post-hoc analysis at *P* < .01 except those marked NS. Pubertal stages were defined as follows: PS1, absence of pubic hair; testicular volume <3 mL; PS2a, absence of pubic hair; testicular volume ≥3 mL; PS2b, Tanner stage 2 pubic hair; PS3-5, Tanner pubic hair stages 3-5. DHEAS, dehydroepiandrosterone sulfate; TeBG, testosterone-binding globulin. Modified from Biro FM, Lucky AW, Hoster GA, et al. Pubertal staging in boys. *J Pediatr*. 1995;127:40-46.

TABLE 25-6

Cellular Activity in Human Testis at Various Stages of Development

Stage	Germ Cells	Sertoli Cells	Leydig Cells
Prepubertal	Prespermatogenic cells are present	Predominant cells in seminiferous cords	Scattered, partially differentiated cells are present
Pubertal	Initiation of spermatogenesis	Increased complexity, formation of occlusive junctions	Fully differentiated cells appear
Adult	Active spermatogenesis, predominant cells	Individual cells associated with groups of germ cells	Groups of fully differentiated cells are present

From Gondos B, Kogan S. Testicular development during puberty. In: Grumbach MM, Sizonenko PC, Aubert ML, eds. *Control of the Onset of Puberty*. Baltimore: Williams & Wilkins, 1990:387-398. © 1990, the Williams & Wilkins Co., Baltimore.)

pubertal growth in boys rather than a difference in growth rate between the genders. The difference in bone widths between boys and girls is in large part established before puberty.¹⁴²

A mathematical model that attempts to define the various stages of the pubertal growth curve based on longitudinal data separates the infancy, childhood, and pubertal phases of growth and allows evaluation of growth despite variation in the age at onset of puberty. A slowly decelerating childhood component is the base, with a sigmoidal pubertal component added during secondary sexual development (see Fig. 25-13C). The infancy-childhood-puberty (ICP) model detected the onset of the pubertal growth spurt, predicted the actual magnitude of the pubertal growth spurt, and predicted adult height using only the age at onset of puberty and a measurement of height.¹⁴³ Tanner and Davies¹⁴⁴ constructed growth curves for American children using data from the National Center for Health Statistics, and data calculated from theoretical growth curves can be adjusted for time of PHV.

Daily, meticulous observations of girls during puberty over 120 to 150 days show stasis periods in each girl (three to seven events lasting between 7 and 22 consecutive days); steep changes in each girl (one to four episodes, with the sum of these steep changes calculated as a percentage of total growth during the study period ranging from 15.3% to 42.9%); and continuous growth the remainder of time, with no rhythms or cycles found.¹⁴⁵ Clinicians observe an integrated growth rate during puberty, rather than these various complex patterns occurring during shorter periods of observation.

In a large Swedish registry, faster linear growth during infancy and childhood was associated with earlier PHV during adolescence but less height gain between 8 and 18 years, although greater height and BMI at birth were associated with later PHV in adolescence and more height gain between the ages of 8 and 18 years.¹⁴⁶

Because girls reach PHV about 1.3 years before menarche, there is limited growth potential after menarche; most girls grow only about 2.5 cm taller after menarche, although there is a variation from 1 to 7 cm. The ages at menarche, takeoff, and PHV are not good predictors of adult height because the duration of pubertal growth is the more important determinant. Later onset of puberty and

consequent increase in height at takeoff of the pubertal growth spurt can be balanced by a decrease in actual height achieved during PHV and result in no net change in adult height. However, early onset of puberty can diminish ultimate adult stature,¹⁴⁷ prolonged delay of puberty can increase stature, and an older age at menarche leads to taller adult height in women. The age at PHV and the age at initiation of puberty correlate well with the rate of passage through the stages of pubertal development in normal children. Physical examination of a boy can reveal that he is likely to have significant growth left (if he is in early puberty), whereas limited growth is likely in boys who are in late puberty.

Stature and the upper-to-lower (U/L) segment ratio, defined as the length from the top of the pubic ramus to the top of the head divided by the distance from the top of the pubic ramus to the sole of the foot, change markedly during the peripubertal and early pubertal periods because of the elongation of the extremities.¹⁴⁸ At birth, the U/L ratio is about 1.7; at 1 year, it is 1.4; and at 10 years, it is 1.0 in a normal healthy individual. The legs begin to grow before the trunk, although late in puberty, during the growth spurt, growth of the legs is similar to growth of the upper torso.¹⁴⁹ The mean U/L segment ratio of white adults is 0.92, and that of African American adults is 0.85. There are no differences in U/L segment ratio between the sexes. In general, hypogonadal patients have delayed epiphyseal fusion and lack a pubertal growth spurt; therefore, their extremities grow for a prolonged period, leading to a decreased U/L segment ratio and an increased span for height, a condition known as *eunuchoid proportions*. Eunuchoid proportions are found in subjects with defects in estrogen synthesis and estrogen receptor deficiency, but normal proportions occur in patients with complete androgen insensitivity syndrome, demonstrating the primary role of estrogen in mitigating or establishing these proportions.¹⁵⁰⁻¹⁵² The distal parts of the extremities, the hands and feet, grow before the proximal parts; a rapid increase in shoe size is a harbinger of the pubertal growth spurt. Boys with Klinefelter's syndrome have long legs but not long arms, a physical feature that can assist diagnosis before the onset of puberty. The shoulders become wider in boys, and the hips enlarge more in girls. The female pelvic inlet widens, mainly because of growth of the os acetabuli. The size of the head approaches the adult size by age 10 years, and the brain reaches 95% of adult size by the onset of puberty.

Bone Age. Skeletal maturation is assessed by comparing radiographs of the hand, the knee, or the elbow with standards of maturation in a normal population.¹⁵³⁻¹⁵⁵ Ossification centers appear in early life, the bones mature in shape and size and develop articulation of surfaces; ultimately, the epiphyses or growth plates fuse with their shafts. Bone age, an index of physiologic maturation, does not have a well-defined relationship in normal children to the onset of puberty because it appears to be more variable than chronologic age.¹⁵⁶ However, bone age is useful for predicting the age of menarche, and in boys, the onset of normal, premature, and delayed puberty correlates better with the onset of secondary sexual development than does chronologic age. Bone age advancement has no relation to the passage through puberty of normal boys.¹⁵⁶

Bone age, height, and chronologic age can be used for prediction of adult height from the Bayley-Pinneau tables¹⁵⁷ (or by the use of the Roche-Wainer-Thissen or Tanner-Whitehouse techniques). Skeletal maturation is more advanced in girls than in boys of the same chronologic age

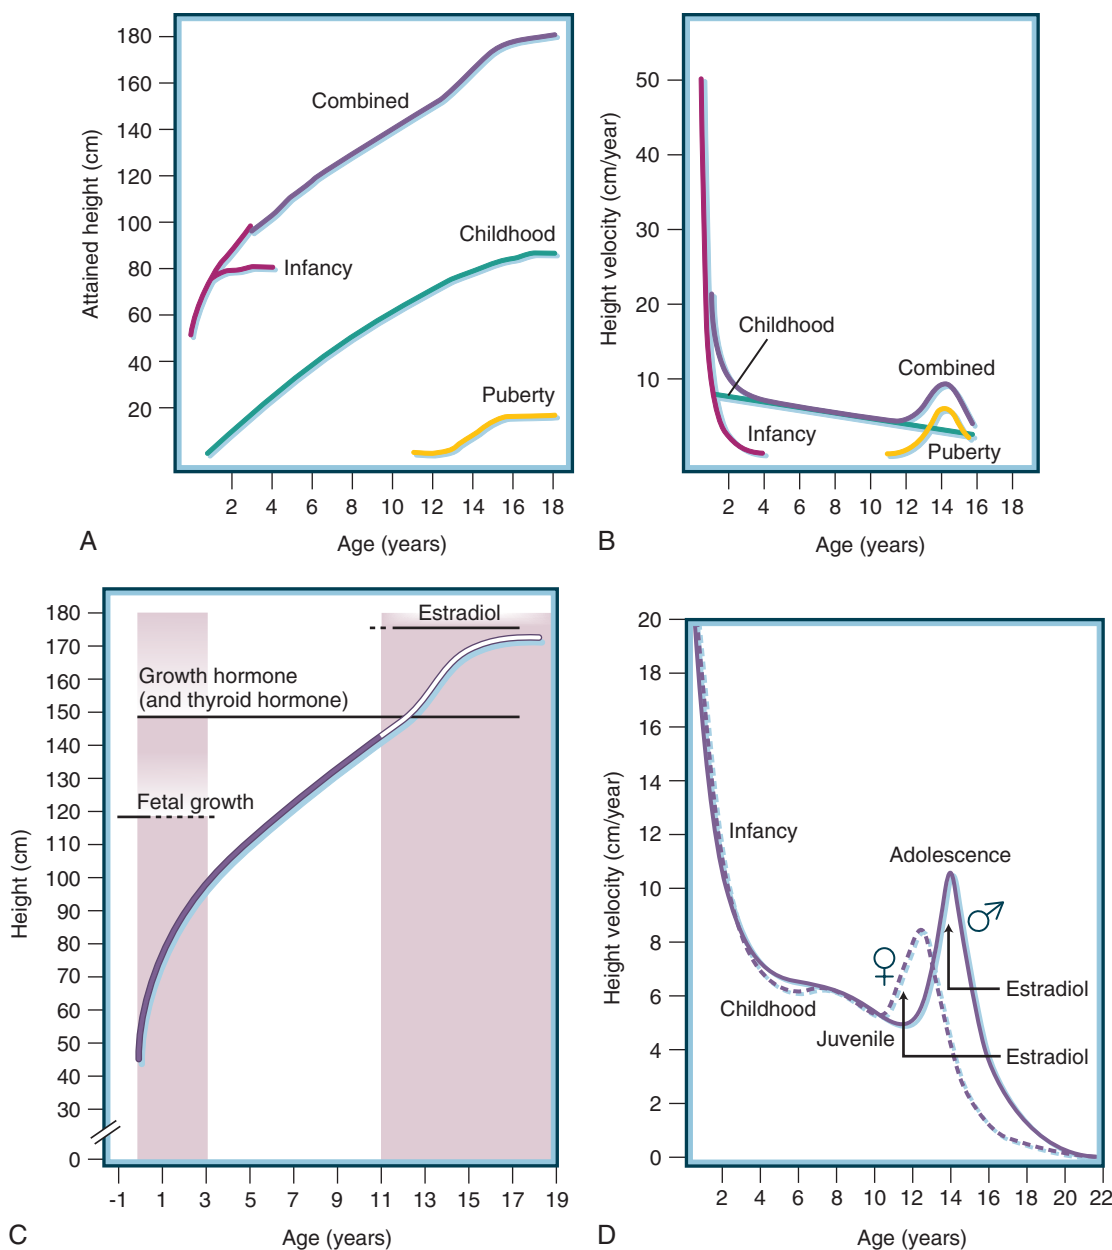

Figure 25-13 The infancy-childhood-puberty (ICP) model of Karlberg for mean attained height (**A**) and height velocity (**B**) for boys. The mean value for each component (infancy, childhood, and puberty) and their sums (combined growth [**A**] and combined velocity [**B**]) are plotted. The growth curve for an individual represents the additive effect of the three biologic phases of the growth process (ICP). Karlberg has provided mathematical functions for each component of his model. *Infancy*: This component starts before birth and falls off by age 3 to 4 years. It can be described by the exponential function $y = a + b[1 - \exp(-ct)]$. Average total gain in height for Swedish boys is 79.0 cm (44.0% of final height) and for girls is 76.8 cm (46.2%). *Childhood*: This phase begins at the end of the first year of life and continues to mature height. A second-degree polynomial function describes this component: $y = a + bt + ct^2$. Average total gain in height for boys is 85.2 cm (47.4%) and for girls is 78.4 cm (47.3%). *Puberty*: The model for the pubertal growth spurt is a logistic function: $y = a/[1 + \exp(-b(t - t_p))]$. Average total gain in height for boys is 15.4 cm (8.6%) and for girls is 10.9 cm (6.5%); y designates attained height at time t in years from birth; a , b , and c are constants; t_p is the age at peak height velocity. **C**, A schematic male growth chart shows the features of the ICP pattern overlaid and illustrates the predominant endocrine mechanisms controlling each phase of growth. The first shaded area emphasizes the decreasing velocity of infantile growth as the individual leaves the rapid growth phase of fetal life. The open area is the childhood phase, which continues and magnifies the decreased velocity of growth into a plateau of rather constant growth during childhood. These two phases depend largely on the effects of growth hormone (GH) and thyroid hormone, with no or little effect derived from gonadal steroids. In the next period of the pubertal growth spurt, gonadal steroids exert their direct and indirect effects. Gonadal steroids exert direct effects on the bone by stimulating the generation of insulin-like growth factor I (IGF-I) and other growth factors locally, and they exert indirect effects by stimulating increased GH secretion, which exerts its own effects on bone and stimulates the production of IGF-I. In the female, the major gonadal steroid involved in the pubertal growth spurt is estradiol, whereas in the male, testosterone and estradiol (arising mainly from the aromatization of testosterone) are the major gonadal steroids. **D**, The adolescent growth spurt in girls and boys (growth velocity curves). Notice the later onset of the pubertal growth spurt in boys and the approximately 2-year difference in peak height velocity and the greater magnitude of peak height velocity compared with girls. The timing of the effects of estradiol is indicated. Progressive epiphyseal fusion terminates the growth spurt and leads to final or adult height. (**A** and **B**, Adapted from Karlberg J. On the construction of the infancy-childhood-puberty growth standard. *Acta Paediatr Scand Suppl.* 1989;356:26-37; **C** and **D**, From Grumbach MM. Estrogen, bone, growth, and sex: a sea change in conventional wisdom. *J Pediatr Endocrinol Metab.* 2000;13[suppl 6]:1439-1455.)

because the early pubertal bone ages of 11 years in girls and 13 years in boys are equivalent stages of bone maturation by the hand-wrist method. African American children have slightly more advanced bone ages than do white children of the same chronologic age.¹⁵⁸ A difference between bone age and chronologic age must exceed 2 standard deviations to be of biologic significance. Standard deviations may range from a few months in infancy to 1 year in later adolescence; a 2-year variation of bone age from chronologic age is within normal limits in middle teenage years. As commonly estimated, bone age is imprecise and is a qualitative rather than a quantitative measure.¹⁵⁵ The development of techniques for scanning radiographs coupled with computer analysis may increase the precision of the procedure.¹⁵⁹

Skeletal Density. Prevailing views locate the determinants of adult bone density in large part in genetic tendencies and the appropriate acquisition of bone mineral in childhood during growth. Osteoporosis and osteopenia are important conditions of the adult that are held to have antecedents in youth, and increasing interest focuses on bone health in children and adolescents, including the effects of age of menarche, nutrition, exercise, and genetics on normal skeletal development.^{160,161} However, a contrary view based on other clinical studies and animal models holds that distant-past patterns of bone growth are less important than recent conditions and that childhood bone growth does not exert a strong effect on adult bone density.¹⁶² A relationship of bone density exists between generations if the effects of age and puberty are eliminated: 60% to 80% of variance in peak bone mass is attributed to genetic factors.¹⁶³ This controversy is not resolved.

Areal bone mineral density (BMD) represents a two-dimensional image and is a function of the size of bone; this is the measurement most often available clinically with commercial dual-energy x-ray absorptiometry (DEXA)

devices. Smaller bones attenuate the radiation beam less than larger bones, and this factor must be considered in the interpretation when measuring bone density using commercial DEXA devices. BMD of the total body, lumbar spine, and femoral neck measured by DEXA increases at a mean annualized rate of 0.047 g/cm² for boys and 0.039 g/cm² for girls (Fig. 25-14A). Longitudinal studies of total-body DEXA assessments indicate that boys accumulate 407 g/year and girls 322 g/year of mineral (i.e., 359 mg/day for boys and 284 mg/day for girls); 26% of adult calcium is laid down during the adolescent years of peak calcium accretion—14 years (mean) for boys and 12.5 years for girls.¹⁶⁴ BMD approaches a maximum accretion in girls by the age of 16 years, and in boys by about 17 years, with the difference in timing related to the disparity in PHV; the rate then decreases, reaching a plateau in the third decade of life.¹⁶⁵ Although quantitative computed tomography (CT) demonstrates an increase in the cortical bone density of the lumbar spine with age, less increase in cancellous bone density with age occurs until the later stages of puberty. Increased BMD correlates well with height, weight (a main determinant of bone density in adolescent and postpubertal females), age, pubertal development, and BMI but has less relationship with serum IGF1 levels. Some consider that the concept of age at peak bone density attainment is too simplistic and prefer to consider the strength of the bone and its geometry.¹⁶⁶

Volumetric bone density (bone mineral apparent density [BMAD]) represents the amount of bone within the periosteal envelope and is of more physiologic importance, because it does not rely on the size of the bone that is changing during growth, particularly pubertal growth (see Fig. 25-14A). Volumetric bone density grows in a region-specific pattern, and conditions in childhood and adolescence that affect the accrual of bone mineral have different effects based on the length of time the affected bone has left to achieve its maximum bone mineral content (BMC);

Figure 25-14 **A**, Periosteal diameter of the metacarpal bones does not differ before puberty in boys and girls. During puberty, the periosteal diameter expands in boys and ceases to expand in girls, whereas medullary diameter remains fairly constant in boys throughout growth but contracts in girls. **B**, In boys, delayed puberty may reduce periosteal apposition, leaving a smaller bone with a thinner cortex but normal medullary diameter (top). In girls, delayed puberty may result in reduced endocortical apposition, leaving a normal or larger bone (if periosteal apposition continues in absence of the inhibitory effect of estrogen) with a thinner cortex and larger medullary diameter (bottom). (**A** and **B**, from Seeman E. Pathogenesis of bone fragility in women and men. *Lancet*. 2002;359:1841-1850.)

deficits may occur in limb dimensions (prepuberty), spine dimensions (early puberty), or volumetric bone density by interference with mineral accrual (late puberty).¹⁶⁷

Calculations for BMAD are made as follows:

Spine BMAD = spine BMC ÷ (spine area)^{1.5} = spine BMC divided by the square root of (spine area)³

Femoral neck BMAD = femoral neck BMC divided by (femoral neck area)²

Whole body BMAD = BMC divided by height (cm) as a means of correcting for bone size

The patterns of areal or volumetric bone density differ during development.¹⁶⁸

DEXA device manufacturers sometimes provide standards for children and adolescents. Children are often referred for evaluation of osteoporosis because their DEXA results are compared with young adult values although they have not come close to reaching maximal bone density. Bone reaches its adult size and PHV occurs before maximal BMC is reached¹⁶⁹; these factors may result in a period of increased fragility and susceptibility to trauma characteristic of adolescence. Lean body mass is related to skeletal density (stronger in boys than girls) and fat mass and skeletal density (stronger in girls than in boys).¹⁷⁰ Standards are available to interpret BMC in terms of lean body mass, which appears to be better related to normal bone growth than to chronologic age; muscle stress is an important factor in the development of bone.¹⁷¹ Normative data for pediatric DEXA studies are available from various centers.^{165,171-173}

An applet available on the Stanford University web site (<http://www-stat-class.Stanford.EDU/pediatric-bones> [accessed February 2011]) generates a Z-score for BMD or BMAD measurements at the lumbar spine (L2-4), hip, or whole body using the Hologic 1000W with respect to the age, gender, and ethnicity of the subject.

Quantitative ultrasound standards are available for children and adolescents.¹⁷⁴ Because they do not require radiation exposure, they may achieve wider use in childhood.

Seeman presented what he considers to be two fallacies in the interpretation of densitometry.¹⁶⁸ The first is the concept that volumetric BMD increases during growth. It does not. Growth builds a bigger, not more dense, skeleton. Second is the idea that peak volumetric BMD is higher in men than in women. It is not. Bone size is greater and is underestimated in patients with larger bones than controls. The misconceptions occur because the result of areal bone density is the BMC per unit projected bone area of bone in the coronal plane, or an areal BMC (g/cm²). Too often, the "areal" element is deleted, and "content" is replaced by density, so that BMC per unit projected area is called BMD, even though volumetric bone density is the desired measurement. Although BMC may normally be higher in boys than in girls and rises with development, volumetric bone density of the long bones is identical in boys and girls. In contrast to the long bones, volumetric bone density increases at the spine in both sexes.^{165,167,168}

The increase in BMD during the prepubertal and pubertal years reflects the increase in the size of the long bones. Legs grow more rapidly than the trunk in prepubertal girls, but during puberty, there is more truncal growth. Boys develop greater bone size due to increased periosteal apposition (increasing bone strength) and endosteal resorption compared with girls; girls add bone on the endocortical surface, which may serve as a reservoir for calcium for later lactation and pregnancy.¹⁷⁵

Birth weight, weight gain during infancy, and weight gain during the years 9 through 12 influence bone mass achieved at 21 years.¹⁷⁶ The BMD at the beginning of puberty predicted the peak bone mass at sexual maturity and appeared to predict the likelihood of osteoporosis as an adult in longitudinal studies, suggesting a method of identification of those most in need of intervention (see Fig. 25-18).¹⁷⁷ The mechanostat concept posits that developmental changes in bone strength result from the increasing loads imposed by larger muscle forces, which stimulate bone mineral acquisition. In a longitudinal study, a rise in lean body mass occurred before peak BMC, and fat mass later exerted more influence.¹⁷⁸ Increased physical activity is generally beneficial for bone health, but excessive running, gymnastics, and cheerleading are progressively more likely to lead to stress fractures,¹⁷⁹ and excessive exercise can lead to the female athletic triad. Femoral head strength increases markedly during puberty, and the femoral neck increases in density more with impact load sports such as running (compared with active load sports such as swimming); only 3 to 12 minutes of daily exercise increases femoral bone density in early pubertal children,¹⁸⁰ with greater increases occurring during puberty.

Prepubertal girls engaged in gymnastics have increased bone density in the limbs that are more often used, and this occurs in a dose-response manner.¹⁸¹ A longitudinal study of gymnasts and their mothers found that these effects do not mainly result from genetic influences. Female adolescent athletes have increased bone density, although the effects last only as long as the activity continues.

Calcium intake during puberty has been documented to strongly affect bone density later in life in most studies¹⁶³; the effect of increased ingestion of calcium may last only as long as the calcium is administered. Pubertal girls are estimated to get well below the recommended intake levels, and even recommended levels may be too low for optimal mineralization. Children who avoid dairy products and are without calcium supplementation have an increased prevalence of fractures in the prepubertal period, even with minor trauma.¹⁸² Early pubertal girls cannot increase gastrointestinal calcium absorption enough to compensate for a poor diet, as older individuals may. African American children retain more calcium than white children do, and the bone structure is thicker in African American children; the difference in vertebral bone density between ethnic groups appears to develop by late puberty. Randomized, placebo-controlled clinical trials between 1985 and 2005 that enrolled normal children for at least 3 months revealed a small effect of calcium supplementation in the upper limb, but the increase in BMD was not thought to influence the likelihood of a fracture later in life.¹⁸³ However, the lack of effects applies only to normal children, and studies of subjects with disorders of puberty that affect bone development may reveal other findings. Remarkable calcium intake is directly related to the rate of bone age advancement to a degree.¹⁸⁴ Increased sodium intake at the expense of calcium intake adversely affects bone accretion. Adequate zinc intake is another factor related to BMD in puberty.

Vitamin D status is a concern, because 32% of girls with low calcium intake were also vitamin D deficient and had elevated serum concentrations of parathyroid hormone (PTH) and thyroid hormone receptor-associated protein-5b (TRAP-5b), as well as significantly lower cortical volumetric BMD of the distal radius and tibia shaft,¹⁸⁵ and another 46% had low-normal concentrations of vitamin D. Deficient calcium and vitamin D can lead to secondary hyperparathyroidism in adolescence.

Girls with heterozygote ER α genotype (Pp) and high levels of physical activity had significantly higher bone mass, higher BMD, and thicker cortex at loaded bone sites (compared with the distal radius, which is not a weight-bearing bone) than their counterparts with low physical activity.¹⁸⁶ These results suggest that high physical activity benefits those with heterozygous ER genotypes, and the less favorable Pp genotype may be compensated by increasing the amount of leisure-time physical activity at early puberty.

Studies of male athletes are less common than those of girls, but 16- to 19-year-old athletic boys can still gain more bone mass in the spine and femora than nonathletic controls.¹⁸⁷ Abnormalities of puberty impair bone accretion in both sexes and are mainly consequences of estrogen deficiency due to decreased secretion or peripheral aromatization of androgens (see Fig. 25-14B). A 1.9-year increase in mean age at menarche in young women was associated with lower radial areal BMD T-scores; lower trabecular number, thickness, and spacing; and cortical thickness without a reduction in cross-sectional area, a finding compatible with less endocortical accrual and a possible explanation of how late menarche is a risk factor for forearm osteoporosis.¹⁸⁸ Urinary adrenal hormone metabolites are related to the achievement of increased proximal radial diaphyseal bone strength; the level of urinary androstenediol at about 8 years of age is an early predictor of diaphyseal bone strength in late puberty (about 16 years of age).¹⁸⁹ Peripheral conversion of adrenarchal dehydroepiandrosterone by 17 β -hydroxysteroid dehydrogenase (17 β -HSD) to androstenediol may be associated with radial bone accretion during growth. CDP was thought to lead to decreased areal bone density in adulthood, but normal volumetric bone density was recently found in adults previously affected by CDP,¹⁹⁰ and the same is thought to occur with primary hypogonadism.

Testosterone administration to normal prepubertal boys increases calcium retention and bone growth and also increases bone density in adolescents with CDP, testosterone-deficient Klinefelter's syndrome, or male hypogonadotropic hypogonadism. Bone density is increased in females with excess androgens, whereas girls with anorexia nervosa, hypothalamic amenorrhea, or ovarian failure have decreased bone density.

Serum levels of inorganic phosphate, alkaline phosphatase, serum osteocalcin (Gla-protein level), collagen type I N-telopeptides (NTX),¹⁹¹ and procollagen type I carboxyl-terminal propeptide (PICP); the cross-linked C-terminal telopeptide of type I collagen (ICTP), procollagen type III amino-terminal propeptide (P3NP), and tartrate-resistant acid phosphatase isoform 5b; and urinary pyridinoline, deoxypyridinoline, and galactosyl-hydroxylysine excretion reflect the increased osteoblastic activity and growth rate during childhood and pubertal growth in both sexes, with values reaching a peak at midpuberty and decreasing thereafter.¹⁹²

Body Composition. Just as endocrine changes bring about remarkable changes in secondary sexual development and growth, body composition is dramatically affected. GH and gonadal steroids play major roles in this process.¹⁹³ Lean body mass, skeletal mass, and body fat are equal in prepubertal boys and girls, but by maturity, men have 1.5 times the lean body mass and almost 1.5 times the skeletal mass of women, whereas women have twice as much body fat (25%) as men (13%), producing a gynecoid (woman-like) or android (man-like) appearance.¹⁹⁴ Lean body mass increases by the age of 6 years in girls and 9.5 years in boys. Boys

acquire fat-free mass more quickly and for a longer period than girls during puberty; stability is attained by 15 to 16 years in girls and 2 to 3 years later in boys.¹⁴⁰ Fat mass increases in girls at an average rate of 1.14 kg/year, but the fat mass does not change in boys during the pubertal years, leading to the greater fat value in girls than boys with age.¹⁴⁰

Weight is not an adequate reflection of body fat. The BMI is often invoked in describing the shape of the body in age-adjusted terms and is used as a better, if imperfect, reflection of body fat. BMI changes with age, and there is no specific number indicating normal or abnormal BMI at all stages of development, as there is for adults. Reference charts of BMI compared with age and gender between the 3rd and 97th percentiles are available online (www.CDC.gov/growthcharts/clinical_charts.htm [accessed February 2011]) for interpretation of BMI values.

Increased visceral fat (i.e., intra-abdominal adipose tissue, or IAAT) in obese teenagers is associated with hypertriglyceridemia, decreased high-density lipoprotein (HDL)-cholesterol, and small, dense, cholesterol-laden very-low-density lipoprotein (VLDL) particles. Subcutaneous fat is associated with large, lipid-laden VLDL particles, which are removed directly from the circulation and pose less risk. The subcutaneous adipose tissue that leads to visibly different body forms is only an imperfect reflection of this internal distribution of fat cells, because increased IAAT may cause metabolic derangements without increasing total-body fat. Studies support the role of increased intra-abdominal fat in children as a cause of insulin resistance and dyslipidemia, with small adipocytes demonstrating limited storage ability, leading to increased ectopic fat deposition in myocytes and hepatocytes.^{195,196} Waist-to-hip ratios may not reflect IAAT in children and adolescents, because subcutaneous abdominal fat may be low despite increased visceral fat.¹⁹⁵ However, there is renewed interest in waist circumference in children as a reflection of IAAT; standards are available and are being studied to determine clinical implications.¹⁹⁷

The generalized distribution of fat in males (central fat, apple-shaped, android), which is different from that in females (lower body fat predominance, pear-shaped, gynecoid), develops largely during puberty as males become more android than they were in prepuberty, although girls start and remain gynoid. There are ethnic differences in the pattern of change, and Asians have the most significant changes.¹⁹⁸

DEXA is used to determine the percentage of body fat, water, and bone mineral with great accuracy but cannot differentiate visceral from subcutaneous adipose tissue. CT was used until the validation of MRI to determine intra-abdominal and subcutaneous fat distribution without the use of radiation.¹⁹⁹

A *strength spurt* occurs during puberty after the pubertal growth spurt. Muscle mass is 54% of body weight in adolescent boys and 42% of body weight in adolescent girls, with the difference partly due to the presence of more muscle cells and larger muscle cells in men. There is little gender difference before 8 years of age, but by 14 years, boys usually have developed greater lean leg mass and greater power than girls.²⁰⁰

Obesity, Puberty, and the Metabolic Syndrome

Between NHANES II and NHANES III, a period of roughly 20 years, there was more than a tripling of the prevalence of children and adolescents above the 95th percentile in weight (denoted by the CDC as *overweight*), to a prevalence of 17.1%, and a 50% increase in those above the 85th percentile (denoted as *at risk for overweight*).²⁰¹

Excessive body fat during childhood and adolescence has significant medical effects early and later in life.²⁰² Obesity, glucose intolerance, and hypertension in childhood are strongly associated with increased rates of premature death among Native Americans, but childhood hypercholesterolemia is not.²⁰³

Serum Lipids in Normal Puberty and in Obesity and the Metabolic Syndrome. Testosterone increases serum levels of LDL-cholesterol and decreases HDL-cholesterol concentrations, accounting for the adverse LDL/HDL ratio in men compared with women.²⁰⁴ Post-heparin hepatic lipase activity is increased by exogenous androgens (and decreased by estrogens), accounting for the decrease in HDL after androgen treatment or after a rise in endogenous androgen secretion.

The epidemic of obesity has led to the advent of the metabolic syndrome in youth. Diagnosis of metabolic syndrome varies among studies, and a generally accepted definition is needed.²⁰⁵ Elevated cholesterol levels in children and adolescents track to adult values in longitudinal studies.²⁰⁶ Although familial hypercholesterolemia leads to carotid intimal plaques by puberty, random autopsies demonstrate macroscopic or microscopic evidence of arteriosclerosis in normal youth without familial hypercholesterolemia, and the tendency is increased by obesity. By 15 to 19 years, 2% of autopsied males had advanced (American Heart Association grade 4 or 5) atherosclerotic coronary artery lesions associated with increased serum cholesterol, obesity, and hypertension.²⁰⁷

Girls are already expressing dissatisfaction with their weight in the third to the fifth grade, and restrictive dieting begins.²⁰⁸ Nutrition suffers with dieting because the intake of fruits, vegetables, and calcium is decreased. Some ethnic groups more often try to gain weight, apparently due to parental suggestion that they are too thin.

Insulin and Insulin Resistance. Insulin resistance is a hallmark of obesity and is thought to be the cause of or an associated factor in the metabolic syndrome associated with cardiac disease.²⁰⁹ Euglycemic clamp techniques are the gold standard for measurement of insulin resistance. Fasting insulin concentrations offer little insight into insulin resistance in an individual, and equations such as the homeostatic model assessment (HOMA) that are based on fasting insulin levels offer little more; however, fasting insulin values²⁰⁶ are used in epidemiologic studies and offer more useful information. The fasting insulin concentration increases twofold to threefold with peak height velocity, insulin secretion after a glucose load increases over prepubertal levels, and insulin-mediated glucose disposal in peripheral tissues decreases in the hyperinsulinemic euglycemic clamp or the minimal model frequently sampled intravenous glucose tolerance test (IVGTT),²¹⁰ showing increased insulin resistance during normal puberty. Insulin sensitivity is inversely related to pubertal stage and BMI.

The response of insulin to an oral glucose tolerance test is greater in African American subjects than in white subjects at all stages of pubertal development; this ethnic difference in insulin resistance is suggested as a cause for the increased incidence of type 2 diabetes among African American adults compared with white adults and appears to offer a similar explanation of the ethnic disparity in youth, with white teenagers having greater insulin sensitivity than African American or Hispanic youth.^{211,212} Insulin resistance occurs early in the course of Turner syndrome and thalassemia major, but even in Turner syndrome, in

which there is an underlying increase in insulin resistance, there seems to be low or no risk of these conditions developing with GH treatment.

With the increased prevalence of type 2 diabetes (non-insulin-dependent diabetes mellitus, or NIDDM), proposed screening criteria are being evaluated. Currently, children with a BMI higher than the 85th percentile should be screened if they (1) have a family history of type 1 diabetes, (2) have signs of insulin resistance (e.g., acanthosis nigricans, functional ovarian hyperandrogenism, hypertension, dyslipidemia), or (3) belong to one of several specific ethnic groups (e.g., African American, Native American, Hispanic American, Asian American). If a fasting plasma glucose level is higher than 126 mg/dL or a 2-hour postprandial value is higher than 200 mg/dL, or if there are symptoms such as weight loss, polyuria, or polydipsia and a casual plasma glucose level is higher than 200 mg/dL, the diagnosis of diabetes is likely, and determination of the type of diabetes (type 1 or 2) is appropriate.

Patients with type 1 diabetes (insulin-dependent diabetes mellitus, or IDDM) usually require an increase in the dose of insulin for euglycemic control at puberty. The cause of insulin resistance has been attributed in part to increased fat oxidation at puberty, which correlates with rising serum IGF1 levels and may be linked to increased GH secretion. However, there is no evidence that GH treatment alone increases the likelihood of development of type 2 diabetes or impaired glucose tolerance. Weight gain increases in children with type 1 diabetes during puberty, leading to a higher incidence of obesity in children with IDDM than would be expected from family patterns. Some adolescents with IDDM, predominantly girls, reduce their insulin use in order to lose weight, with dire consequences. Retinopathy due to IDDM characteristically appears in the teenage years or later, but duration and control of diabetes in the prepubertal years are contributing factors. The American Diabetes Association recommends screening for microalbuminuria, an indicator of the development of diabetic nephropathy. Microalbuminuria may develop quite early in puberty rather than in the later stages.²¹³

A normal individual adapts to the changes in the physiologic rise in pubertal insulin resistance, but an individual at genetic risk for type 2 diabetes, with the accompanying defect in pancreatic beta cell function,²¹⁴ may not adapt to the insulin resistance and, with the additional insulin resistance characteristic of obesity, may develop clinical type 2 diabetes during the pubertal years or earlier. Type 2 diabetes in children or adolescents should not be confused with the various forms of monogenetic diabetes (previously called maturity-onset diabetes) or diabetes of the young (MODY), which are inherited as autosomal dominant traits.

Several syndromes of insulin resistance combine hyperglycemia and virilization.²¹⁵ The Kahn type A syndrome features include a lean, muscular adolescent female phenotype with acanthosis nigricans, hirsutism, oligomenorrhea or amenorrhea, and ovarian hyperthecosis and stromal hyperplasia associated with abnormalities of the insulin receptor gene. Hyperandrogenism, insulin resistance, acanthosis nigricans (HAIR-AN) syndrome and PCOS are less severe than Kahn type A and usually manifest in adolescent females. Persons with Robson-Mendenhall syndrome have severe insulin resistance (possibly leading to diabetic ketoacidosis), dysmorphic facies, acanthosis nigricans, thickened nails, hirsutism, dental dysplasia, abdominal distention, and phallic or clitoral enlargement. The Robson-Mendenhall syndrome, similar to the Donahue (leprechaunism) syndrome, which shares some of these features,

is caused by homozygous or compound heterozygote defects in the insulin receptor gene. Kahn type B syndrome is caused by inhibitory or stimulatory antibodies to the insulin receptor and sometimes occurs with acanthosis nigricans and ovarian hyperandrogenism. This syndrome can occur with ataxia-telangiectasia syndrome or in otherwise normal adolescents. Individuals with the Seip-Berardinelli syndrome combine lipodystrophy and severe insulin resistance and complete or partial absence of subcutaneous fat with increased growth and skeletal maturation, muscle hypertrophy, acanthosis nigricans, hypertrichosis, organomegaly, and mild hypertrophy of the external genitalia.

Most of these NIDDM syndromes can be treated with oral hypoglycemic agents initially; progression of the disorder may require the use of insulin. Several girls with these syndromes of insulin resistance have been described to have low serum gonadotropin values during puberty without response to GnRH but with enlarged ovaries, suggesting a direct role for insulin in stimulating the growth of the ovary. The hypoleptinemic state found in various degrees of lipodystrophy does not appear to affect pubertal progression, but administration of leptin has led to resumption of menstrual periods in some females and adjustment of testosterone production toward normal levels in males.²¹⁶

Obese teenage girls with predominant abdominal adiposity and insulin resistance may have early puberty, early menarche, and longer exposure to an endocrine profile, predisposing to breast cancer.⁷⁷ Insulin resistance is characteristic of the state of functional ovarian hyperandrogenism seen after a history of premature pubarche. This constellation is more frequent in children with a history of low birth weight.

Blood Pressure. Blood pressure is related to the age, gender, and height of the child using appropriate standards (available at <http://pediatrics.aappublications.org/cgi/content/full/114/2/S2/555> [accessed February 2011]). Blood pressure increases with pubertal maturation, related to increased stature and synchronized with the pubertal growth spurt, suggesting some relationship in the control of the two processes.²¹⁷ Hypertension is becoming common in puberty as a comorbidity of obesity. Increased blood pressure at puberty depends on BMI²¹⁸ and height, factors that are interrelated. Blood pressure in childhood and adolescence is predictive of adult blood pressure (tracking).^{206,219} Blood pressure rises in African American children at lower BMIs than in white children, making the problem worse in the African American population. In sexual precocity, blood pressure rises above prepubertal levels to values commensurate with body size and BMI.

CENTRAL NERVOUS SYSTEM ANATOMY, FUNCTION, PSYCHOLOGY, AND ELECTROENCEPHALOGRAPHIC RHYTHM

Brain anatomy and function change substantially during late childhood and adolescence (Fig. 25-15A). Behavior or psychopathology that becomes evident at this time has its basis in these changes and exposures dating from early life and the prenatal period, all interacting against a genetic background. Puberty is the time of appearance of the ability to solve complex problems in a mature manner. An

increase in cortical metabolic rate in infancy is followed by a late childhood decline to adult levels; this decline ceases by the end of the second decade. The prefrontal association cortex, an area of the brain that is concerned with forward planning and regulatory control of emotional behavior, continues to develop until the age of 20 to 25 years.⁴ Stress at various stages of development, even in early childhood, may cause psychological manifestations during puberty.²²⁰

The anatomic changes revealed by functional MRI studies of the prefrontal cortex, an area that is involved with emotional regulation and planning, occur during a time of physical maturation and are likely to relate to many of the characteristic behavior changes of puberty.⁴ The volume of white matter increases linearly between 4 and 22 years of age due to an increase in myelination during development, and there are more complex changes in gray matter.²²¹ A reduction in cortical synaptic density and neuronal density, analogous to programmed cell death, occurs between 2 and 16 years of age, and this pruning of synapses appears to be linked to improved memory.²²² This change in gray matter follows an inverted U-shaped curve of increase from the age of 6 years. Longitudinal studies using dynamic mapping of human cortical development demonstrate that higher-order association cortices (e.g., those involved in executive function, attention, and motor coordination) mature after lower-order somatosensory, motor, and visual cortices mature, and those areas that are phylogenetically older mature before newer ones.^{223,224} Intrauterine excess of androgens leads to enlargement of the amygdala, and girls reach greater mass of gray matter 2 years before boys during puberty, demonstrating aspects of the effects of sex steroids on brain growth and remodeling in human beings. Increased LH levels are related to areas of increased white matter density, including the cingulum, middle temporal gyrus, and splenium of the corpus callosum; there is a genetic overlay to this relationship. Gray matter volume, at least in girls, appears to be related to a pubertal increase in estradiol levels.²²⁵

Brain plasticity decreases during puberty. Examples include the inability to learn to speak a foreign language without an accent after puberty and recovery of a child from the effects of a CNS injury that in an adult might have led to aphasia. Loss of plasticity may be maladaptive to our rapidly changing world and extended life span compared with prehistoric times.²²⁶ Plasticity allowed developmental learning before puberty, but lack of plasticity and a standard response to conditions in the adult allowed success in that static environment of the past.

Mania, depression, obsessive-compulsive disorders, and schizophrenia are more common after puberty. They are postulated to be related to alterations of the normal changes in brain architecture and function that occur during puberty.

Sleep Patterns in Puberty

Increased sleep is characteristic of the period of growth and development across species. Because sleep is a time of vulnerability, threats leading to stress are antithetical to normal sleep, and a feeling of safety is thought to be necessary to allow sleep to proceed normally as the adolescent is preparing for independence and increased self-care in a possibly hostile world. Rising complexity of brain function during puberty is reflected in increases in the amplitude and frequency of delta waves (0- to 3-Hz electroencephalographic waves) found during deep sleep, which appears more related to age than to pubertal development or growth.²²⁷ The function of deep sleep (i.e., slow-wave or

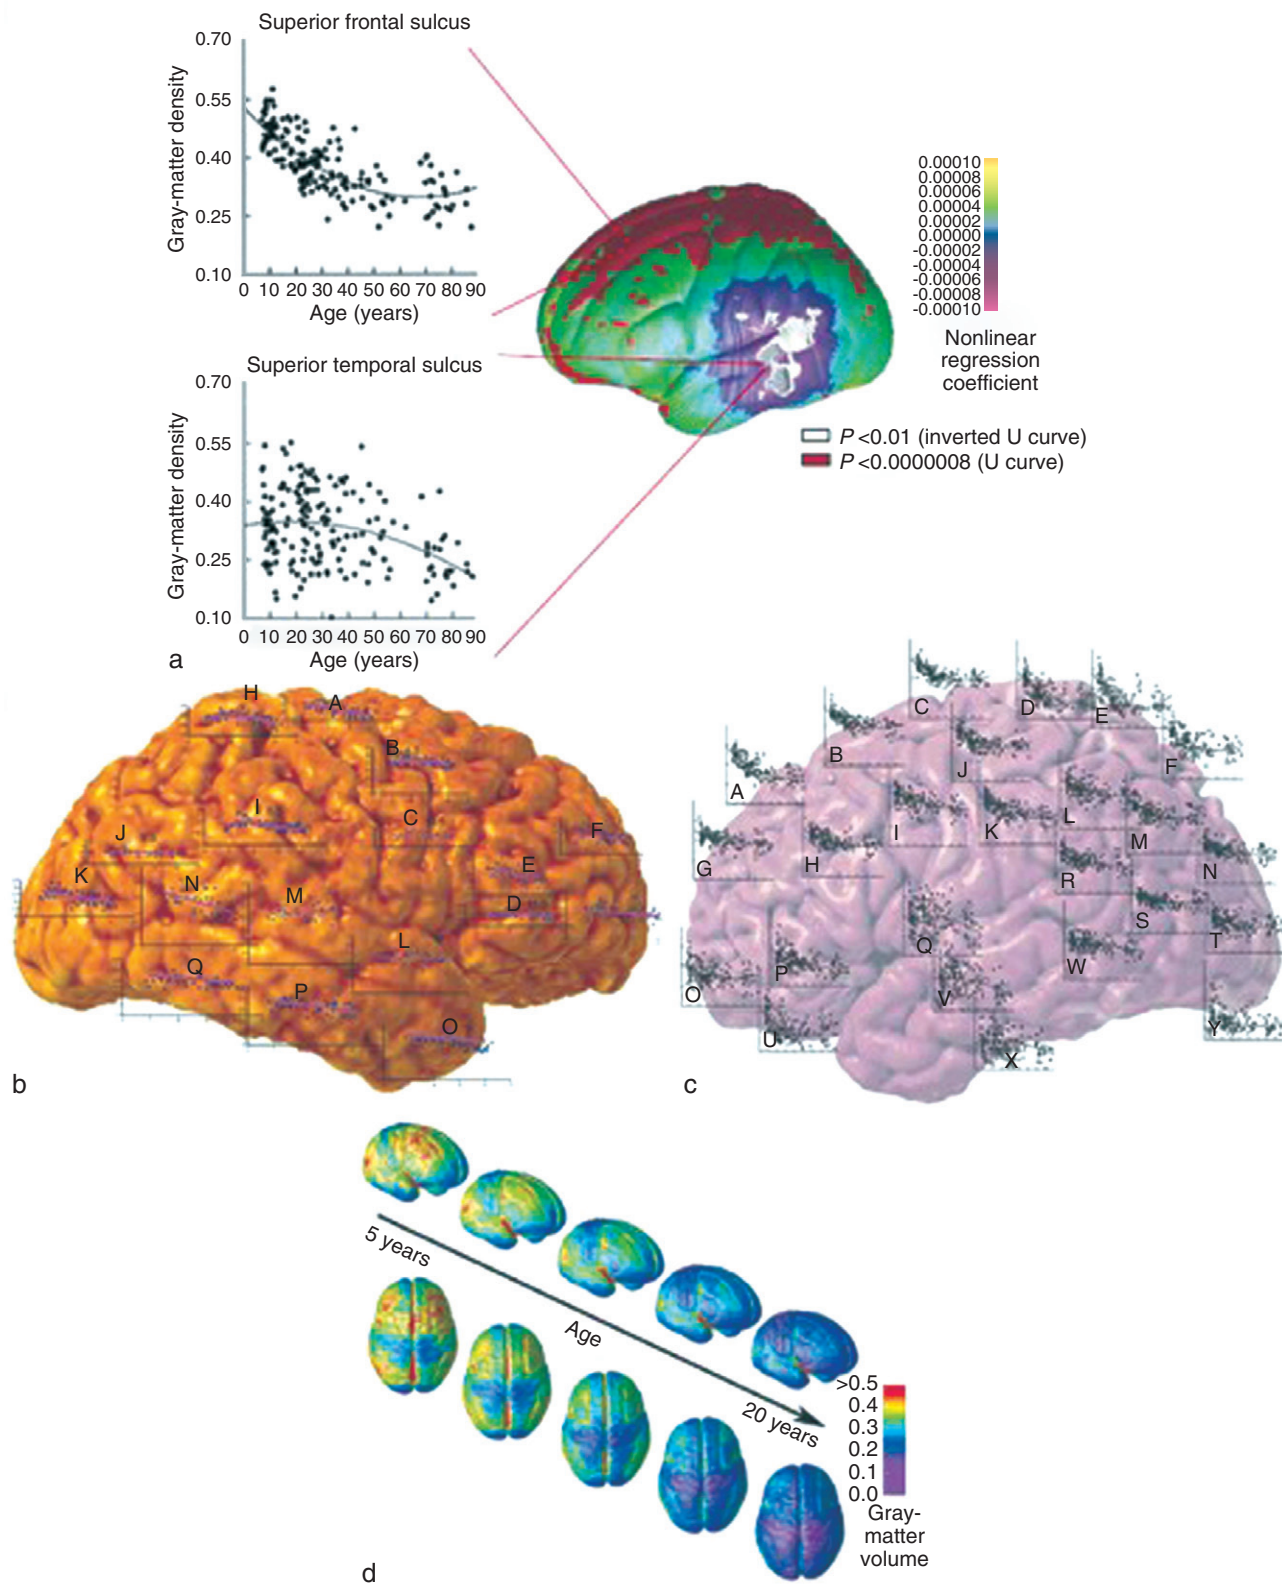

Figure 25-15A Mapping brain change over time. Brain changes in development can be identified by fitting time-dependent statistical models to data collected from subjects cross-sectionally (i.e., across a group of subjects at a particular time) or longitudinally (i.e., following individual subjects as they aged), or both. Measurements such as cortical thickness are then plotted onto the cortex using a color code. Trajectory of gray matter loss over the human life span is based on a cohort of 176 subjects between 7 and 78 years of age.¹¹ Letter *a* represents a region in which the gray matter density decreases rapidly during adolescence (i.e., superior frontal sulcus in which the decrease in gray matter is described by a quadratic equation represented by an inverted U-shaped curve), or follows a more steadily declining time course during the life span (i.e., superior temporal sulcus in which the decrease in gray matter is described by a quadratic equation represented by a U-shaped curve). In *b* and *c*, plots superimposed on the brain show how gray matter density decreases for particular regions with age, with the regions denoted by different letters. (From Sowell ER, Peterson BS, Thompson PM, Welcome SE, Henkenius AL, Toga AW. Mapping cortical change across the human life span. *Nat Neurosci.* 2003; 6:309-315.) Brain maturation and change in gray matter density is mapped by year of age in *d* with fractional change in gray matter shown by color coding (*c* and *d*). (From Toga AW, Thompson PM, Sowell ER. Mapping brain maturation. *Trends Neurosci.* 2006;29:146-159.)

Figure 25-15B Assessment of chronotype (time of awakening in the absence of external cues) using the MCTQ database (N ≈ 25,000). Age distribution within the database (**A**). Distribution of chronotypes (**B**). Age-dependent changes (**C**) in average chronotype (\pm SD) are highly systematic (except for the age groups of 19, 21, 22, and 23, all other age-dependent averages \pm SD are significantly different from that of age group 20; t-test, $P < .001$). Age-dependent changes of the chronotype (**D**) are different for males and females (filled circles and black line: females; open circles and gray line: males). Gray areas indicate significant male-female differences (t-test, $P < .001$). (From Roenneberg T, Kuehnele T, Pramstaller PP, et al. A marker for the end of adolescence. *Curr Biol*. 2004;14:R1038-R1039.)

non-rapid eye movement sleep) is thought to be restorative to learning and other activities of the waking state, and the most restorative portion is high-amplitude delta-wave sleep. During adolescence, the time spent in deep (stage 4) sleep declines by 40% to 50%, and increased (19.7%) stage 2 sleep occurs with pubertal development. The decline of slow-wave sleep during adolescence may reflect developmental changes of the brain.

When an individual is allowed to “run free,” the period is entrained (synchronized) to the earth’s 24-hour light-dark cycle. Because human beings had little to do after dark, evolution favored an early bedtime, but within this schedule, developmental changes occur. One-year-old infants sleep an average of 11 hours per day, and by age 18, if circumstances permit, the mean is 8 hours. Older people have earlier waking times and rate themselves as more morning-like than adolescents or young adults; because children are also morning-like, there is an inverted U-shaped curve of preferred times of awakening across the span of development. This change to evening from morning alertness during puberty appears to be related to biologic factors, in contrast to social factors; in the past, social factors were thought to be more important.

Without the pressure of work or school, adolescents would stay up longer and awaken hours later than a normal weekday schedule would dictate, a schedule far different from the one they followed at a younger age. Adolescents with early school starts awaken earlier than those with later school starts, but they do not change the time they go to

sleep, leading to great variation in the amount of sleep attained. Data from the Add Health study showed decreased self-reported sleep duration during self-reported pubertal development, with girls reporting more problems with sleep (e.g., insomnia, insufficient sleep, awakening tired) as puberty progressed but with no such relationship seen in boys.²²⁸ There is an increase in daytime sleepiness during adolescence, particularly during midpuberty up to stage 3 to 4, even if total sleep time is held constant during longitudinal multiple-year studies.²²⁹ With voluntary sleep deprivation (e.g., with late-night homework habits), sleepiness can reach levels seen in narcolepsy and sleep apnea. Adolescents adapt more poorly to changes in sleep patterns than other age groups; this is manifested in the difference in hours awake between the school week and the weekend. Adolescents are able to shift to a later schedule more easily than to an earlier schedule. When self-selected bedtimes are late during summer but have to be changed to allow school attendance, the adjustment is particularly lengthy and difficult.

After study of 27,000 individuals, it was proposed that the point of inflection from evening alertness during adolescence (after a morning-like pattern in childhood) to morning alertness in adulthood might be used as a marker of the end of adolescence, a sign that developmental remodeling of brain pathways is completed.²³⁰ The age of this inflection point is about 20.9 years in males and 19.5 years in females, who have an earlier change in this and other aspects of puberty than males (see Fig. 25-15B).

Normal Pubertal Behavior and Pathology in Puberty

Most of this chapter deals with the biochemical and physical changes of puberty, but there are also profound psychosocial changes during this period, usually denoted as *adolescence*. Although the attainment of an adult role in society occurs within a few years after achievement of reproductive maturity in non-Western societies, the more technologically advanced the society, the more protracted the time allowed for adolescent psychosocial development. The prolonged period of adolescence in current society, ranging from 11 to 20 years in the United States, arose recently in human history, beginning no more than 100 years ago in Western society.

As expressed by Remschmidt, the most important psychological and psychosocial changes in adolescence are the emergence of abstract thinking, the growing ability to absorb the perspectives or viewpoints of others, an increased capacity for introspection, the development of personal and sexual identity, the establishment of a system of values, increasing autonomy from family and personal independence, greater importance of peer relationships of sometimes subcultural quality, and the emergence of skills and coping strategies to overcome problems and crises.²³¹

Adolescence may be divided into three periods (early, middle, and late) by chronologic age. However, these periods may be reached at different maturational ages, because rates of physiologic maturation differ among individuals in these age groups.²³²

Early adolescence (age 11 to 15 years) encompasses most of the physical changes of puberty and in American society includes a profound social change from the sheltered, single-classroom environment of elementary school to the multiple-classroom and multiple-teacher experience of middle school or junior high school. The individual develops a maturing, but not mature, capacity for abstract thought and decision-making processes in contrast to the concrete reasoning of childhood.

Middle adolescence (ages 15 to 17 years) is the period of the high school years, a calmer period than early adolescence. The school experience is not a striking change, and many of the most prominent biologic and physical changes of puberty have been accomplished. There is acceptance of some increased autonomy (e.g., drivers' permits and licenses are allowed), but the individual still lives at home. The individual emotionally moves away from the family and is less influenced by his or her peer group than are early adolescents; friendships assume an increasingly important role.

Late adolescence starts at the senior year of high school and is the age of acceptance of adult roles in work, family, and community. If the individual attends college, this stage is prolonged.

Behavior and Normal Puberty

Almost 100 years ago, Hall, without using what would be considered contemporary research techniques, characterized the maturing child as experiencing *Sturm und Drang* (i.e., storm and stress), which is normally restrained by cultural influences.²³³ Contrary to this view, most recent empiric studies describe adolescent development as a continuous, adaptive phase of emotional growth characterized more by stability rather than disorder and more by harmonious relationships between generations rather than conflict. Although mood changes are normally more rapid

(occurring over hours or days) and marked in teenagers than in adults, these shifts must be differentiated from long-standing mood and behavior changes associated with serious psychopathology.

Turmoil, or truly tumultuous behavior, in adolescence is not a normal phase but may reflect psychopathology that requires diagnosis and treatment. It is often misdiagnosed as a temporary problem of adjustment reactions of adolescence. When the conditions extend from adolescence to the adult stage, they are more severe. A 4-year longitudinal study of normal first-year U.S. high school students showed that 25% experienced *continuous growth*, characterized by smooth, well-adjusted functioning despite stressful situations; 34% experienced *surgent growth*, demonstrating good adaptation in general and short periods of difficulty and distress after some stressful situations. Twenty-one percent were judged to be in *turmoil*, characterized by mood swings, anxiety, and depression; these teenagers mainly came from homes characterized by conflict, familial mental illness, and socioeconomic distress. Many with adolescent turmoil had not "grown out of it" when studied 5 years later and eventually were diagnosed with unipolar and bipolar depressive disorders. It may be concluded that 80% to 90% of adolescents do well psychologically during puberty and are happy individuals, but 10% to 20% have significant difficulties.²³⁴

Mood and Self-Image in Puberty

Young girls at the beginning of puberty frequently exhibit a negative self-image but a positive body image; positive peer relationships and superior adjustment improvement are observed with continued breast development. Mood in adolescence is not closely related to stage of puberty, but a significant curvilinear trend is seen for depressive affect (i.e., an increase followed by a decrease), for impulse control (a decrease followed by an increase), and according to the level of serum estradiol. These data suggest that hormonal changes may be more important than physical changes as determinants of certain mood and behavior patterns during adolescence.

Behavior in Variations of the Normal Age at Onset of Puberty

Within the normal limits of pubertal development, early-maturing girls and late-maturing boys have the greatest prevalence of adjustment reactions in puberty and thereafter. Boys and girls who mature earlier are at increased risk for abuse.²³⁵

Early-developing boys are perceived to be more mature, attractive, and smart and are given more leadership roles; late-developing boys are more insecure, more susceptible to lower levels of self-esteem and body image, and more vulnerable to peer pressure, especially in working-class and minority groups. Most of these difficulties of late maturation focus on the decreased height of the individual rather than the lack of sexual development. Social maturation lags even after androgen treatment in patients with severe CDP. Delayed social maturation may put boys at risk for missing educational opportunities.

In contrast, early-maturing girls tend to experience more difficulty, especially in the junior high school setting, where they may attract the attention of older, more mature boys and have a higher prevalence of internalizing symptoms and disorders. Early puberty may lead to negative body image in girls, compared with boys, in whom the effect is positive. Early maturation may increase a

propensity to violent behavior, which is fostered by living in a disadvantaged neighborhood. Early pubertal maturation in girls may be related to a small IQ advantage over late-maturing girls. Late-maturing girls are often more comfortable, remaining with the support of their families longer, and they are less often brought to medical attention than late-maturing boys. Early- and late-maturing girls have a tendency to engage in health-risking behaviors involving strategies to lose weight, strategies to increase muscle, disordered eating, use of food supplements and steroids, and exercise dependence—tendencies not found in boys at the same developmental stages.

Risk-Taking Behavior

Adolescents who function at lower levels of cognitive complexity or concrete thinking and have an early onset of puberty demonstrate an increase in risk-taking behavior. The age at onset of cigarette smoking and alcohol use is proportional to the age at onset of puberty in girls: early-maturing girls partake earlier, and boys may follow the same pattern.

Sexuality during Puberty

By the time they reach age 19 years of age, 7 of 10 teens have engaged in sexual intercourse (data from http://www.guttmacher.org/pubs/fb_sex_ed02.html [accessed February 2011]). Factors such as the onset of puberty, weak self-concept, having tried smoking or drinking, and not being overweight were significantly associated with early sexual activity in girls. For boys, older age, a poor relationship with parents, low household income, and having tried smoking were factors significantly associated with sexual activity. Add Health revealed that adolescents at the upper and lower ends of the intelligence distribution were less likely to have sex.

Fertility is reached well before adult phenotype is acquired. The number of pregnancies for U.S. girls aged 15 to 19 years is 41.5 per 1000.¹³³ Sexuality appears to be correlated with testosterone production in boys in some studies, but in others, it appears to be modified by the social effects of pubertal maturation. Religious activity may decrease the likelihood of sexual activity.

The social pressures are more mixed in their messages to girls, both encouraging sexuality and restricting it in a way more disparate than that encountered by boys. The earlier onset of puberty today compared with previous centuries has had a profound effect on societal norms of sexual behavior.⁶

A randomized, double-blind, placebo-controlled, crossover clinical trial of boys and girls with delayed puberty addressing the effects of administration of oral conjugated estrogen to girls and testosterone enanthate to boys at three dose levels that were intended to simulate early, middle, and late pubertal levels demonstrated modest or no effects. Boys had increased nocturnal emission and touching behaviors at the middle and high doses but no other effects. Girls demonstrated a significant increase in “necking” related to the administration of estrogen only at the late pubertal dose and no other effects.

HORMONAL AND METABOLIC CHANGES IN PUBERTY

Increased amplitude and alterations of the patterns of GnRH secretion at puberty initiate and regulate the

sequential increases in secretion of pituitary gonadotropins and gonadal steroids that culminate in fertility.

Gonadotropins

Because of the pulsatile secretion of GnRH, gonadotropin secretion is also episodic. The newer immunometric super-sensitive assays allow accurate measurement in small pediatric samples. The results are lower than previously reported by the older assays.

During the first 2 years after birth, plasma levels of LH and FSH rise intermittently to adult values and occasionally higher but then remain low until puberty. Ultrasensitive assays and third-generation assays for LH and FSH²³⁶⁻²³⁸ confirm earlier evidence of pulsatile secretion of the gonadotropins in prepuberty and indicate that the basal immunoreactive levels of LH are much lower than previously reported.^{237,238} The serum FSH level is higher than the LH level in prepubertal boys and girls.²³⁹ There is a more striking rise in serum LH amplitude by at least 1 year before the onset of puberty (i.e., the peripubertal period immediately preceding the appearance of signs of sexual maturation), whereas FSH rises more consistently through male puberty rather than before, with increased pulse amplitude. An increased amplitude of LH and FSH secretion occurs at night in prepubertal boys and girls by 5 years of age^{237,238}; the amplitude and frequency of such peaks increase, and daytime secretion increases with the progression of pubertal development.

In girls, FSH levels rise during the early stages of puberty, and LH levels tend to rise in the later stages; from beginning to late puberty, the LH concentration rises more than 100-fold. In boys, FSH levels rise progressively through puberty, and LH levels rise and reach an early plateau (Figs. 25-16 and 25-17).

Figure 25-16 Mean plasma estradiol, follicle-stimulating hormone (FSH), and luteinizing hormone (LH) concentrations in prepubertal and pubertal females by pubertal stage of maturation (1, prepubertal; 5, menstruating adolescents) and the mean bone age for each stage. Single daytime values of gonadotropins have limited usefulness because of pulsatility of gonadotropin release and the increased amplitude of LH pulses during sleep throughout puberty. The gonadal steroid values, however, are useful in determining the stage of pubertal development. To convert FSH values (LER-869) to international units per liter, multiply by 8.4. To convert LH values (LER-960) to international units per liter, multiply by 3.8. To convert estradiol values to picomoles per liter, multiply by 3.671. (From Grumbach MM. Onset of puberty. In: Berenberg SR, ed. *Puberty, Biologic and Social Components*. Leiden, The Netherlands: H.E. Stenfert Kroese, 1975:1-21. Reprinted by permission of Kluwer Academic Publishers.)

Figure 25-17 Mean plasma testosterone (after solvent extraction and chromatography) and gonadotropin levels in normal boys by stage of maturation (I, prepubertal) and mean bone age for each stage (see Fig. 25-16). To convert testosterone values to nanomoles per liter, multiply by 0.03467. (From Grumbach MM. Onset of puberty. In: Berenberg SR, ed. *Puberty, Biologic and Social Components*. Leiden, The Netherlands: H.E. Stenfort Kroese, 1975:1-21. Reprinted by permission of Kluwer Academic Publishers.)

Disorderly patterns of secretion of LH, but not FSH, were noted just before the onset of puberty; this was followed by, first, increased orderliness in early puberty and, then, increased disorderliness again in later puberty. This suggests that a more integrated feedback system operates in early puberty and is then followed by less stability.²⁴⁰

Doses of exogenous GnRH that are relatively ineffective in stimulating gonadotropin or gonadal steroid secretion before puberty become effective with the onset of puberty; an amplification occurs in the hypothalamic-pituitary-gonadal axis with progression of puberty.^{241,242} Although the GnRH test usually requires multiple sampling after the administration of GnRH, a single determination at 30, 45, or 60 minutes may suffice with the new, sensitive assays. Use of a GnRH agonist in a single dose with determination of serum gonadotropins and sex steroids can help to differentiate the pubertal from the prepubertal state. The basal values of serum LH and FSH measured in modern supersensitive assays are reported to predict the onset of pubertal development as well as GnRH testing does; a value of serum LH greater than 4 mIU/mL measured by immunochromiluminometric assay is consistent with the onset of puberty. Moreover, the use of these ultrasensitive assays to determine concentrations of LH and FSH in urine reveals a pattern of a 5-fold rise in urinary FSH in boys and girls, with a 50-fold rise in urinary LH in boys and a 100-fold rise in girls during puberty.²⁴³

In addition to the well-defined quantitative changes that occur in the pattern of FSH and LH in the pituitary gland, serum, and urine during development, qualitative changes occur. The pattern of glycosylation of the α and the β subunits of the gonadotropins is influenced by maturation, GnRH secretion, and the effects of gonadal steroids on the pituitary gonadotrophs. Variation in glycosylation that affects the size and charge of the hormone is the principal cause of the heterogeneity of FSH and LH and the large number of isoforms that vary according to the more acidic or more basic charge.²⁴⁴ This pleomorphism

has an important effect on biologic half-life and biologic activity and provides an additional mechanism of regulating the biologic activity of the gonadotropins. Discrepancies between serum bioactivity and immunoactivity of LH during pubertal development have been reported by some but not all researchers. However, a change in the isoforms of FSH released during puberty may favor the secretion of increased bioactive FSH, which may favor reproductive development.²⁴⁴

Gonadal Steroids

Only recently has it been appreciated that many actions on linear skeletal growth, skeletal maturation, and accretion of bone mass thought to be due to testosterone in the male are mainly attributable to its peripheral aromatization to estrogen (Table 25-7).

Testosterone

The Leydig cells of the testes produce testosterone and, in lesser amounts, androstenedione, α 5-androstenediol, dihydrotestosterone, and estradiol, although a small amount of testosterone is derived from extraglandular conversion of androstenedione secreted by the testes and the adrenal. In the female, extraglandular conversion of ovarian and adrenal androstenedione accounts for almost all of the circulating testosterone.

Previous methods of determination of low levels of sex steroids have been demonstrated to be inaccurate.^{245,246} This insensitivity is mainly due to the presence of interfering substances and relative insensitivity of antibodies used in assays. Now, larger national laboratories are beginning to use high-performance liquid chromatography tandem mass spectrometry (HPLC-MS/MS), which allows the accurate measurement of extremely low values present in pediatric samples.²⁴⁷ These newer techniques may lead to

TABLE 25-7

Early Clinical Clues to the Effect of Estrogen on Growth and Skeletal Maturation in the Male

Complete androgen insensitivity (resistance) syndrome (Zachmann M, Prader A, Sobel EH, et al. Pubertal growth in patients with androgen insensitivity: indirect evidence for the importance of estrogen in pubertal growth of girls. <i>J Pediatr</i> . 1986;108:694-697)
Short-term estradiol administration increased rate of ulnar growth in prepubertal boys (Caruso-Nicoletti M, Cassorla FG, Skerda MC, et al. Short term, low dose estradiol accelerates ulnar growth in boys. <i>J Clin Endocrinol Metab</i> . 1985;61:896-898)
Aromatase inhibitor decreased rapid growth and skeletal maturation in testotoxicosis, whereas antiandrogen had no effect on skeletal maturation (Laue L, Jones J, Barnes K, et al. Treatment of familial male precocious puberty with spironolactone and deslorelin. <i>J Clin Endocrinol Metab</i> . 1993;76:151-155)
Aromatase excess syndrome in boys associated with increased rate of growth and skeletal maturation, elevated plasma estrogen concentrations, but prepubertal testosterone values (Stratakis CA, Vottero A, Brodie A, et al. The aromatase excess syndrome is associated with feminization of both sexes and autosomal dominant transmission of aberrant P450 aromatase gene transcription. <i>J Clin Endocrinol Metab</i> . 1998;83:1349-1357)
Estrogen-secreting tumors: adrenal and testicular neoplasms (especially Peutz-Jeghers syndrome) (Bulun SE, Rosenthal IM, Brodie AM, et al. Use of tissue-specific promoters in the regulation of aromatase cytochrome P450 gene expression in human testicular and ovarian sex cord tumors, as well as in normal fetal and adult gonads. <i>J Clin Endocrinol Metab</i> . 1993;77:1616-1621)

From Grumbach MM. Estrogen, bone, growth, and sex: a sea change in conventional wisdom. *J Pediatr Endocrinol Metab*. 2000;13(suppl 6):1439-1455.

revision of some of the results (described here) obtained by older methods.

Prepubertal boys and girls have plasma testosterone concentrations of less than 0.3 nmol/L (0.1 ng/mL),^{236-238,248} except during the first 3 to 5 months of infancy in the male, when pubertal levels are found. Nighttime elevations of serum testosterone levels are detectable in the male by 5 years of age, before the onset of physical signs of puberty, and increase during early puberty after the appearance of sleep-entrained secretion of LH and increased pituitary sensitivity to GnRH. The 60-minute lag between the peak of LH and the increase in testosterone is presumably due to synthesis and secretion of the steroid. In the daytime, increases in testosterone levels are detectable at approximately 11 years in boys after the testis volume is greater than 4 mL, with a consistent increase throughout puberty. The steepest increment in testosterone concentration occurs between pubertal stages 2 and 3 in males (see Fig. 25-17 and Table 25-5). The ratio of testosterone to epitestosterone in the urine, which is used to evaluate "doping" of athletes, may be elevated normally during puberty.

Free testosterone measurements may be determined by dialysis or by calculation using testosterone values and available protein binding sites; the accuracy of the testosterone assay can be problematic.²⁴⁷ Nonetheless, if the total testosterone concentration on which the free testosterone level is based is measured by a highly specific assay, free or bioavailable testosterone determinations are helpful in evaluation of PCOS or nonclassic congenital adrenal hyperplasia (CAH) in girls.

A sensitive mammalian cell recombinant bioassay for androgen bioactivity strongly correlates with serum immunoreactive testosterone concentration and demonstrates a rise with pubertal development in concert with progression of pubic hair and penile development in patients with CDP.²⁴⁹ In contrast to this specific bioassay, a novel, highly sensitive transcriptional androgen receptor-mediated bioassay system demonstrated higher circulating values of bioactive androgen in menopausal women and is now being directed toward children.²⁵⁰

The values of sex steroids measured in saliva are much lower than in the serum, but trauma (even tooth brushing) that leads to blood in the specimen can influence the results, and the accuracy of the basic assay is critical (see earlier discussion).²⁴⁷ The steroid level in saliva is not a direct representation of free steroid in the serum, as is often claimed. Testosterone in saliva is said in some reports to correlate well with serum levels of testosterone in normal subjects and in patients with chronic disease (e.g., cystic fibrosis). Salivary progesterone is said to rise with the progression of puberty. Salivary dehydroepiandrosterone (DHEA) is higher after the onset of puberty than before. Salivary steroid measurements, if accurate, can increase the ability of investigators to address the relationship between development and behavior in a noninvasive manner, but it may take the use of LC/MS-MS in salivary assays to achieve such accuracy.

Estrogens

In the female, estradiol is secreted principally (90%) by the ovary; a small fraction of circulating estradiol arises from the extraglandular conversion of testosterone and androstenedione. In the male, approximately 75% of estradiol is derived from extraglandular aromatization of testosterone and (indirectly) androstenedione, and 25% is from testicular secretion.

In the fetus and at term, estrogen is high due to conversion of fetal and maternal adrenal C19-steroids to estrogen

by the placenta, but they drop precipitously during the first few days of life. Plasma estradiol levels are so low in prepuberty that detection by standard immunoassays was difficult, but a rise through puberty and a diurnal rhythm were described with a sensitive radioimmunoassay (Table 25-8; see Fig. 25-16).²⁵¹ Estrone levels rise early and reach a plateau by midpuberty. A highly sensitive bioassay demonstrated higher estradiol concentrations in girls than in boys before puberty, with a rise through puberty until the pubertal growth spurt and a decrease thereafter. There is a significant correlation between peak growth velocity and the rise in estradiol concentration; the rise is earlier in girls than in boys, but bioactive estradiol levels are equivalent at peak growth velocity.^{151,252} The higher estrogen levels in girls may be an important factor in the more advanced levels of skeletal maturation in girls compared with boys and may play a part in their earlier onset of sexual maturation. A new human cell bioassay measuring total estrogenic bioactivity (rather than estradiol alone) in children has an extremely sensitive detection limit of less than 1 pg/mL.²⁵³

The daily peak of estradiol in early pubertal girls occurs about 6 to 9 hours after the peak of serum LH detected during the night, apparently related to time required for synthesis. In all stages of puberty, boys have higher concentrations of estrone than estradiol, and levels of both estrogens are lower than those measured in girls at comparable stages.

Hormonal Control of the Pubertal Growth Spurt

Postnatal growth follows a specific pattern: a very high growth rate just after birth is followed by a declaration that continues until 3 years of age; next, there is a slower phase of deceleration until puberty. The subsequent pubertal growth spurt, the second greatest period of postnatal growth, is followed by maturation of the spine and long bones until adult height is reached.¹⁴⁰ Many factors influence the growth plate.²⁵⁴ The adolescent growth spurt in normal girls and boys depends on estradiol and GH levels,^{150,255-257} among other factors.

Hormonal control of the pubertal growth spurt is complex (Fig. 25-18; see Fig. 25-14). GH is involved in increasing growth at puberty through stimulation of IGF1 production. Gonadal steroids have two effects on pubertal growth: (1) induction of an increase in GH secretion, with a consequent increase in IGF1 production, thereby indirectly stimulating pubertal growth, and (2) a direct effect on cartilage and bone through stimulation of local production of IGF1 and other local factors.^{151,258,259}

Gonadal Steroids

In the developing human skeleton, gonadal steroids have growth-promoting and maturational effects on chondrocytes, osteoblasts, and other bone constituents.^{150,151} This action, which eventually leads to epiphyseal fusion and the cessation of longitudinal growth in boys and girls, is mediated mainly by estrogen that is directly secreted (in girls) or arises from the conversion of testosterone and androstenedione to estrogen in peripheral tissues by aromatase (see Table 25-8). Detection of estrogen resistance resulting from a null mutation in the gene encoding the estrogen receptor and from derangements in the *CYP19A1* gene, leading to severe cytochrome P450 aromatase deficiency, has highlighted the cardinal role of estradiol (but not testosterone) in both boys and girls in the pubertal growth spurt, completion of epiphyseal maturation, and normal skeletal proportions and mineralization.^{150,151} Individuals

TABLE 25-8

Plasma Gonadal Steroid Values in Children

Steroid and Assay	Age	Normal Values		Sample Volume (Pediatric Minimums)
		Males	Females	
Testosterone, by LC-MS/MS (ng/dL)	Term infant	75-400	20-64	0.18 mL serum (Quest) 0.5 mL serum (Esoterix) 0.15 mL serum (ARUP)
	1-7 mo	Levels decrease rapidly in first week to 20-50, then increase to 60-400 between 20 and 60 days. Levels then decline to prepubertal range by 7 mo	Levels decrease during the first month to <10 and remain at that level until puberty	
	7-12 mo	<16	<11	
	Tanner stage I	<16	<16	
	Tanner stage II	<167	<40	
	Tanner stage III	7-762*	<60	
	Tanner stage IV	25-912	<62	
	Tanner stage V	110-975	<68*	
Androstenedione, by RIA after extraction (ng/dL)	Term infant	20-290; levels decrease to 10-80 after 1 week	20-290 ng/dL; levels decrease to 10-80 after 1 week	0.25 mL serum (Esoterix) 0.5 mL serum (Quest)
	1-11 mo	6-68	6-68	
	Prepubertal	8-50	8-50	
	Tanner I	8-50	8-50	
	Tanner II	31-65	42-100	
	Tanner III	50-100	80-190	
	Tanner IV	48-140	77-225	
	Tanner V	65-210	80-240	
DHT, by extraction chromatography, RIA (ng/dL)	1-6 mo	12-85	<5	0.5 mL serum (Esoterix) 1.1 mL serum (Quest)
	Prepubertal	<5	<5	
	Tanner II-III	3-33	5-19	
	Tanner IV-V	22-75	3-30	
Estradiol, by LC-MS/MS (ng/dL)	Newborn	Levels are markedly elevated and fall during first week to <1.5	Levels are markedly elevated and fall during first week to <1.5	1.2 mL serum (Esoterix)
	1-11 mo	Levels increase to 1-3.2 between 1-2 mo, then decrease to <1.5 by 6 mo	Levels increase to 0.5-5 between 1 and 2 months, then decrease to <1.5 during the first year	
	Prepubertal	<1.5	<1.5	
	Tanner I	0.5-1.1	0.5-2	
	Tanner II	0.5-1.6	1-2.4	
	Tanner III	0.5-2.5	0.7-6	
	Tanner IV	1-3.6	2.1-8.5	
	Tanner V	1-3.6	3.4-17	
Estradiol, by extraction chromatography, RIA (ng/dL)	Tanner stage I	0.3-1.5	0.5-1	0.6 mL (Quest)
	Tanner stage II	0.3-1	0.5-11.5	
	Tanner stage III	0.5-1.5	0.5-18	
	Tanner stage IV	0.3-4	2.5-34.5	
	Tanner stage V	1.5-4.5	2.5-41	
Estradiol, chemiluminescent immunoassay (ng/dL)	0-8	0.7-0.8	0.7-1.4	0.2 mL serum (ARUP)
	9-10	0.7-1.1	0.7-3.2	
	11-12	0.7-2.2	0.7-3.8	
	13-14	0.7-2.4	1-9.1

Figure 25-18 Interactions of the major growth-promoting hormones during puberty. Plus (+) indicates stimulatory action; minus (–) indicates inhibitory action. Circulating insulin-like growth factor I (IGF I) arises mainly from liver, but other tissues also contribute (i.e., endocrine action). Growth hormone (GH) and gonadal steroids have a direct stimulatory effect on the generation of IGF I (i.e., paracrine action) locally in bone and cartilage cells. For simplification, the feedback loops for IGF I and gonadal steroids on the hypothalamic-pituitary unit are omitted. FSH, follicle-stimulating hormone; GRF, growth hormone-releasing factor; LH, luteinizing hormone; SRIF, somatotropin release-inhibiting factor.

with a mutation in the *ER α* gene (*ESR1*) or the *CYP19A1* gene encoding aromatase continue to grow, lack a pubertal growth spurt, and have open epiphyses and osteopenia.^{150,151,255-257} Estrogen treatment of men with aromatase deficiency leads to epiphyseal closure, cessation of growth, and a striking increase in bone mass.²⁶⁰⁻²⁶² Patients with aromatase excess, who produce excess estrogen, have advanced skeletal maturation and rapid growth and ultimately reach short adult stature.²⁶³

Although estradiol secreted by the ovary has long been recognized as the major sex steroid responsible for the pubertal growth spurt, skeletal maturation, and bone mineral accrual in females, until the detection of the rare human genetic defects in estrogen synthesis or action, conventional wisdom dictated that testosterone mediated these maturational changes during puberty in males. Now it is known that estrogen (not androgen) is the critical sex hormone in males and females in the pubertal growth spurt, skeletal maturation, accrual of peak bone mass, and maintenance of bone mass in the adult. Estrogen stimulates chondrogenesis in the epiphyseal growth plate,²⁶⁴ increasing pubertal linear growth. At puberty, estrogen promotes skeletal maturation and the gradual progressive closure of the epiphyseal growth plate.¹⁵⁰ The use of a supersensitive assay for plasma estradiol in prepubertal and pubertal boys revealed a high positive correlation between estradiol concentrations and peak growth velocity (but not serum GH level), which was greatest about 3 years after the onset of puberty,²⁵² further implicating estrogen in the pubertal growth spurt and skeletal maturation of boys and girls.

There are estrogen receptors, both *EP α* and *ER β* , in the growth plate chondrocytes.²⁵⁴ Histologic studies of the bone and cartilage of rodents treated with corticosteroids or estrogen and clinical evaluations of children with precocious puberty support the theory that senescence of the growth plate occurs because of estrogen exposure in precocious puberty, causing decreased growth during treatment with GnRH agonists.²⁶⁵

The high rate of bone turnover in early puberty followed by a decrease in periosteal apposition and endosteal resorption within cortical bone and decreased bone remodeling within cortical and cancellous bone mediated by apoptosis of chondrocytes in the growth plate and osteoclasts within cortical and cancellous bone, is mediated in part by estrogen. This leads to a reduction in bone turnover markers at menarche, reflecting the closure of the epiphyseal growth plates.²⁶⁶

Girls with Turner syndrome without estrogen exposure retain elevated markers of bone turnover. Prepubertal girls with Turner syndrome tend to lose bone, but that ceases when estrogen therapy begins; administration of estrogen may best be started earlier in these patients.²⁶⁷ During puberty and into the third decade, estrogen has an anabolic effect on the osteoblast and an apoptotic effect on the osteoclast, increasing bone mineral acquisition in the axial and appendicular skeletons. Evolutionary theory suggests that positive effects of estrogen on bone density, added to mechanical loading, allow women to carry increased weight for pregnancy and lactation; this process is unnecessary after reproduction, and osteoporosis becomes more common at menopause.²⁶⁸

Testosterone may also have a direct action on bone in the human male, because androgen receptors are found in human tibial growth plates in osteoblasts and chondrocytes, osteocytes, mononuclear cells, and endothelial cells of blood vessels in the bone marrow.²⁶⁹ Androgens that cannot be aromatized to estrogen still cause an increase in growth rate, presumably due to interaction with these receptors. The greater increase in periosteal bone deposition, the resultant thickening of cortical bone and greater bone strength, and the greater bone dimensions²⁶⁹ in boys probably result from direct effects of testosterone. Androgens may protect men against osteoporosis by maintenance of cancellous bone mass and expansion of cortical bone.

A pubertal growth spurt leading to adult height close to that of genotypic men occurs in individuals with the complete form of androgen resistance, demonstrating the critical role of estrogen rather than androgen in the adolescent growth spurt in boys. A modest decrease in BMD Z-scores occurs in the spine but not in the hip based on age-specific female standard values, but the reductions are greater when male standards are used. Affected women have an increased prevalence of fractures, even with estrogen replacement. This suggests that lack of a direct effect of testosterone on the skeleton, especially the spine, has a part in the defects in bone mineralization observed in women with complete androgen insensitivity (see Table 25-8).²⁷⁰

Growth Hormone and Growth Factors

GH secretion approximately doubles during puberty in boys and girls in the basal state or after stimulation but decreases after pubertal development. Remarkably, peak values after hexarelin, a 6-amino-acid GH-releasing peptide (or GH secretagogue) stimulates as much growth hormone secretion in prepuberty as in puberty. The greater elevation in girls starts at an earlier age and pubertal stage than in boys due to the earlier onset of puberty in girls. GH secretion increases coincident with the onset of breast development (Tanner stage 2) and is maximal at Tanner stage 3 to 4 breast development; in boys, GH rises later and peaks at stage 4 genital development. GH secretion and IGF1 levels decrease after late puberty in both sexes. Adolescents of normal height have an inverse relationship between weight and GH levels. Increased GH pulse amplitude and content of GH secreted per pulse (not but frequency, metabolic clearance rate, or intersecretory burst interval and half-life

of GH) in the basal state are mainly responsible for the augmented GH levels.²⁷¹

The increase in estradiol at puberty, which in boys results from testicular secretion and extraglandular synthesis from testosterone and androstenedione and in girls from secretion by the ovaries, is the principal mediator of the increase in pulse amplitude and amount of GH secreted per pulse.²⁷² Administration of exogenous androgens in delayed puberty raises GH secretion. Transdermal application of testosterone increases spontaneous GH secretion overnight independent of growth hormone-releasing hormone (GHRH), because infusion of GnRH antagonist does not affect this phenomenon.²⁷³ The effect of testosterone is mediated mainly through its conversion to estradiol, because treatment of late pubertal boys with tamoxifen, an estrogen receptor blocker, causes smaller GH secretory peaks and fewer GH secretory episodes. Exogenous estrogen increases the peak GH reached after insulin-induced hypoglycemia, exercise, and arginine, a priming effect that is used in clinical practice, because estrogen administered before a provocative test in prepubertal subjects increases the GH response. Androgens that cannot be aromatized to estrogen (e.g., oxandrolone, dihydrotestosterone) have less effect on GH secretion; however, androgen blockade with flutamide increases GH secretion.^{274,275} Dihydrotestosterone, which is not aromatized to estrogen, does not increase GH secretion or the plasma concentration of IGF1 and may decrease the integrated GH secretion, but it still stimulates increased growth rate, suggesting a possible direct effect of androgen on pubertal growth independent of GH²⁵⁸ or estradiol. Increased GH secretion also occurs in sexual precocity. GH secretion decreases with the fall in gonadal steroid levels after treatment of CPP with potent GnRH agonists.²⁷⁶

GH deficiency or GH resistance causes an attenuated pubertal growth spurt, indicating the importance of GH and IGF1 in this process. Severe primary or secondary hypogonadism leads to a minimal or absent growth spurt, demonstrating the primary role of gonadal steroids in pubertal growth. Hypopituitary patients deficient in GH and gonadotropins do not have an adolescent growth spurt when GH alone is replaced; gonadal steroids must also be given, substantiating the interaction of GH and gonadal steroids in the pubertal growth spurt. In normal puberty, neither the magnitude of the increase in GH secretion nor the concentration of plasma IGF1 correlates with the PHV of the pubertal growth spurt. Although a threshold level of GH secretion is necessary, the extent of the growth spurt correlates with gonadal sex steroid secretion. Individuals with both CPP and GH deficiency (usually as a consequence of cranial irradiation for a brain tumor) have a growth spurt clinically indistinguishable from that of CPP and normal GH secretion.²⁵⁸ After treatment with a GnRH agonist for sexual precocity, growth velocity in patients with GH deficiency and CPP is decreased and pubertal progression is suppressed, illustrating the direct effect of gonadal steroids, principally estradiol, on the pubertal growth spurt.

Urinary GH excretion reflects serum levels and changes occurring with pubertal development. A peak is reached at pubertal stage 3 to 4. The level is higher in boys than in girls.

Growth Hormone–Binding Protein

Growth hormone–binding protein (GHBP) has the same amino acid sequence as the extracellular component of the GH receptor, and serum concentrations are directly related to the amount of GH receptors. In normal children, the

plasma GHBP level is inversely related to 24-hour GH secretion. The serum GHBP level rises early in childhood and also through puberty in some cross-sectional studies, but not in others. Because plasma GHBP does not change appreciably with the onset of puberty, at the time of the pubertal growth spurt there is a relative increase in unbound (free) GH in relation to GH bound to GHBP. GHBP is related to adiposity, and it may be this factor that accounts for the increased levels of GHBP in girls compared with boys, the rise in GHBP in girls with precocious puberty, and the negative influence of testosterone on GHBP levels.²⁷⁷

Insulin-Like Growth Factor Type I

Concentrations of IGF1 rise during puberty to levels higher than those of prepuberty or adulthood; they remain elevated past the time of PHV, with a peak attained 1 or 2 years after the pubertal growth spurt (later in boys than in girls) and then fall to normal adult levels.^{276,278} The pattern of the GH-dependent serum levels of IGF-binding protein 3 (IGFBP3) in pubertal development is similar to that of serum IGF1.²⁷⁹ However, serum IGFBP3 concentrations correlate with BMI even though IGF1 does not. Measurement of free IGF1 shows the same pattern of change with development as the that of total IGF1, a slow rise in serum free IGF1 in prepuberty followed by a steeper rise during puberty. A decrease of free IGF1 is associated with age in the later stages of puberty.^{279,280} The increase in the serum ratio of IGF1 to IGFBP3 at the time of the pubertal growth spurt appears to result from production, because proteolysis of IGFBP3 does not change in puberty in normal children. The testosterone level in boys and the estradiol level in girls correlate with the rise in IGF1 concentration, but gonadal steroids are not the direct cause of the increase in circulating IGF1 levels; rather, GH secretion approximately doubles during puberty due to the effect of estrogen causing augmented release of GH.

Plasma IGF1 concentrations are high for chronologic age in sexual precocity and low in delayed puberty. Estrogen mediates the pubertal increase in IGF1 concentration through increased secretion of GH, with an additional effect through the gonadal steroid-induced local generation of IGF1 in cartilage and bone. Treatment with GnRH agonist in a 16-year-old boy with a homozygous mutation in the WSXWS-like motif of the human GH receptor (GHR) causing Laron syndrome led to a further decrease in the already low serum levels of IGF1 and IGFBP3, which did not reverse with dihydrotestosterone treatment, suggesting a direct effect of estradiol on IGF1 production.²⁸¹ Children with CPP treated with a GnRH agonist showed suppression of the untreated elevated serum GH concentrations and a decrease in plasma IGF1 concentrations, although not to prepubertal values, supporting the concept that GH is the major (but not the only) factor that raises circulating IGF1 levels in puberty.^{276,282}

A confounding factor is the relative roles of hepatic-generated circulating IGF1 (i.e., endocrine role) and of locally produced IGF1 (i.e., paracrine/autocrine role) in linear growth. For example, mice with a totally deleted hepatic IGF1 gene have strikingly reduced circulating levels of IGF1 but normal postnatal body and bone growth.²⁸³

GH stimulates local IGF1 production in resting zone chondrocytes, located at the epiphyseal end of the growth plate in the area known as the reserve zone or stem cell zone, through GH receptors in the chondrocytes. This IGF1 production stimulates, through autocrine and paracrine effects, the clonal expansion of proliferating chondrocytes derived from the resting chondrocyte or germ cells. GH

and IGF1 can reduce the stem cell cycle time, proliferating cell cycle time and duration of the hypertrophic phase, a phase that leads to apoptosis, leaving the cells serving as a scaffold for the mineralization and production of new bone.

Other Hormones

There are glucocorticoid receptors in human growth plates, mostly in hypertrophic chondrocytes. However, children with chronic adrenal insufficiency who receive appropriate replacement therapy have a normal pubertal growth spurt despite deficient adrenal androgen secretion, indicating a minimal impact of these adrenal androgens on normal growth at puberty.²⁸⁴

Hypothyroid subjects lack a pubertal growth spurt even when the disorder is accompanied by sexual precocity.²⁸⁵ Thyroid hormone has a permissive role in the pubertal growth spurt but is a requisite for normal growth. Hypothyroidism decreases GH secretion and affects growth indirectly. However, thyroid hormone also interacts with the thyroid hormone receptors $\alpha 1$ and β , whose proteins are found in early proliferating chondrocytes of the human growth plate, and the messenger RNA (mRNA) found in other developing stages of chondrocytes and osteoblasts. Thyroid hormones also interact with the local effects of IGF1 and GH at the growth plate.²⁵⁴

Adrenal Androgens. There is a progressive increase in plasma levels of Δ^5 -steroids, DHEA, and DHEAS in boys and girls that begins before age 8 (skeletal age of 6 to 8 years) and continues through early adulthood (Table 25-9). The increase in the secretion of adrenal androgen and its precursors is known as *adrenarche*, and the appearance of pubic hair caused by adrenarche is known as *pubarche*. Plasma DHEA levels have a diurnal rhythm similar to that of cortisol, but plasma levels of DHEAS show less variation and are a useful biochemical marker of adrenarche.

DHEA is the predominant precursor to more potent androgens in females, and DHEAS cannot be converted. DHEAS is produced from DHEA by the action of SULT2A1, mainly in the adrenal glands and the liver. The sulfate donor phosphoadenosine phosphosulfate (PAPS) is required by SULT2A1, and in human beings, PAPS is synthesized by the two isoforms of PAPS synthase, PAPSS1 and PAPSS2.²⁸⁶

Testosterone-Binding Globulin. Between 97% and 99% of circulating testosterone and estradiol is reversibly bound to testosterone-binding globulin (TeBG) (i.e., sex steroid-binding globulin); prepubertal levels of TeBG are approximately equal in boys and girls, but a decrease in TeBG level occurs with advancing prepubertal age and the

concomitant increase in the plasma gonadal steroid levels. At puberty, there is a small decrease in TeBG levels in girls; as a consequence of testosterone, there is a greater decrease in boys, although the drop observed in normal boys is attenuated by treatment with tamoxifen, even with advancing pubertal development.²⁸⁷ The rise in adrenal androgen levels at adrenarche may explain the early drop in TeBG levels, which allows more circulating free hormone at a given concentration of testosterone. Although the plasma concentration of testosterone is 20 times greater in men than in women, the concentration of free testosterone is 40 times greater.²⁸⁸ Boys with hypogonadotropic hypogonadism and patients with the androgen resistance syndrome show the same characteristic fall in TeBG levels at puberty, but values are intermediate between those of normal adult males and females.

Prolactin. Prolactin levels rise in girls during puberty. Prepubertal mean (\pm standard error) plasma prolactin concentrations are 4.0 ± 0.5 $\mu\text{g/L}$ in boys and 4.5 ± 0.6 $\mu\text{g/L}$ in girls. Late pubertal girls and adult women have higher concentrations of prolactin (7.5 ± 0.7 and 8.3 ± 0.7 $\mu\text{g/L}$, respectively), whereas the mean concentration in adult men is 5.2 ± 0.4 $\mu\text{g/L}$.²⁸⁹ This sex difference is probably a consequence of the higher estradiol levels during puberty in girls and in women.

Inhibin, Activin, and Follistatin. Inhibin and follistatin inhibit and activin stimulates FSH β -subunit expression and therefore affect FSH biosynthesis and secretion. Inhibin may also be an inhibitor of LH release in the follicular phase.²⁹⁰ These hormones are synthesized in a variety of tissues in addition to the gonads and have diverse activities apart from those on the reproductive apparatus.²⁹¹

Two distinct binding proteins for inhibin and activin are present in the circulation, the gonads, and other tissues: α_2 -macroglobulin, a high-capacity, low-affinity binding protein and follistatin, a glycosylated, single-peptide chain that functions as a high-affinity binding protein and as a regulator of activin bioactivity (e.g., in the pituitary gland, a site of synthesis of activin and follistatin).²⁹¹ Inhibin, a heterodimeric glycoprotein product of the Sertoli cell of the testes and the ovarian granulosa cell (as well as the placenta and other tissues), exerts negative feedback action on the secretion of FSH from the pituitary. Inhibin is composed of an α -subunit and one of two β -subunits, β_A or β_B , which respectively form inhibin A or inhibin B, dimers with apparently identical function. Inhibin is a member of the transforming growth factor- β (TGF- β) superfamily that includes anti-müllerian hormone (AMH, also called müllerian-inhibiting factor) and the dimers of two inhibin

TABLE 25-9

Mean Serum Concentrations (mmol/L [ng/mL]) of DHEAS during Childhood

	6-8 yr	8-10 yr	10-12 yr	12-14 yr	14-16 yr	16-20 yr
By Chronologic Age						
Boys	0.5 (188)	1.6 (586)	3.4 (1260)	3.6 (1330)	7.2 (2640)	7.2 (2640)
Girls	0.8 (306)	3.2 (1170)	3.1 (1130)	4.6 (1690)	6.9 (2540)	6.3 (2320)
By Bone Age						
Boys	0.98 (360)	1.6 (574)	3.4 (1250)	5.8 (2150)	10.9 (4030)	
Girls	0.73 (276)	3.1 (1130)	4.33 (1560)	7.1 (2610)	3.9 (1450)	

DHEAS, dehydroepiandrosterone sulfate.

Modified from Reiter EO, Fuldaer VG, Root AW. Secretion of the adrenal androgen, dehydroepiandrosterone sulfate, during normal infancy, childhood, and adolescence, in sick infants, and in children with endocrinologic abnormalities. *J Pediatr*. 1977;90:766-770.

subunits, activin A and activin B, which stimulate the release of FSH from pituitary cells.²⁹¹ Synthesis and secretion of gonadal inhibin is induced by FSH. Inhibin plays a role in the feedback regulation of FSH secretion during puberty in males and females.²⁹¹

During pregnancy, the placenta secretes inhibin A, and the fetal membranes secrete inhibin A and inhibin B, but for at least the first 20 weeks of gestation, only inhibin A is detected in maternal serum. In umbilical cord serum from term female newborn infants, no inhibin dimer was detected, whereas cord serum from male newborns contained inhibin B, the only inhibin detected in adult males.²⁹² In the human fetal testis, α and β_B (but not β_A) subunits were present in Sertoli and Leydig cells at 16 weeks' gestation; by 24 weeks' gestation, immunoexpression of both subunits was greater in the Sertoli cells. Postnatally, the expression of both subunits was decreased by 4 months of age. Inhibin subunits were not detected in the fetal ovary, nor was immunoreactive follistatin present in fetal or neonatal gonads.²⁹³

In large cross-sectional studies using highly specific inhibin B and inhibin A immunoassays that correlate with the bioactivity of inhibin and distinguish inhibin B from inhibin A, the mean concentration of serum inhibin B in males increased between prepuberty (a stage when it is higher than the undetectable levels in castrate men)²⁹⁴ and the first stage of puberty; when the strong correlation with chronologic age was taken into account, a correlation with LH and testosterone values remained. From genital stage 2 of puberty on, inhibin B levels were relatively constant, despite a rise in the mean concentration of serum FSH between stages 2 and 3, after which the FSH value was relatively unchanged. By genital stage 3, a negative partial correlation between inhibin B and FSH was found that persisted as puberty advanced, and by genital stage 4, there was a clear negative correlation of inhibin with serum FSH. Dimeric inhibin B rises twice during development, reflecting the two periods of Sertoli cell proliferation in infancy and in early puberty, whereas an inverse relationship between inhibin and FSH is seen at midpuberty and thereafter, indicating the development of negative feedback inhibition. In the early stages of puberty, inhibin B values are closely related to LH and testosterone levels, but in stage 3, when inhibin B values peak, this relationship is lost, and inhibin B values become more closely related to FSH levels.²⁹⁵

Serum levels of inhibin A and B increase early in puberty in girls, although there are individual increases in the prepubertal period directly related to FSH levels demonstrating sporadic follicular development in the infant and child due to FSH stimulation. Inhibin B is predominant in the follicular phase, as is inhibin A during the luteal phase. Inhibin A and inhibin B peak in midpuberty, and inhibin B is thereafter decreased. During the early stages of puberty, inhibin B values are related to estradiol and FSH values, but these relationships diminish with the progression of puberty.²⁹⁶ Although there is no significant change in activin during female puberty, follistatin decreases from a midpuberty peak to later values that fall below prepubertal values.

Serum values of FSH regulating proteins follow circadian patterns, with higher values of LH and FSH overnight, just after a nadir of inhibin B. Follistatin concentrations were found to reach their greatest value in early morning, and activin A concentrations declined coincident with the nighttime increase in FSH levels in pubertal girls.²⁹⁷ Diurnal variation of inhibin B in boys in the peripubertal or early pubertal period demonstrates a fall in inhibin during the

night as LH and, subsequently, testosterone rise, showing the negative feedback effect of testosterone on inhibin B secretion.²⁹⁸ Recombinant FSH treatment, which raises testosterone secretion, suppresses inhibin B, demonstrating the ability of testosterone to negatively influence inhibin B secretion.²⁹⁹ Administration of a GnRH agonist led to an increase in the FSH level by 30 minutes as well as an increase in the inhibin B level in girls older than 5 years of age by 8 hours and in boys by 20 hours.³⁰⁰ The baseline inhibin B concentration was greater in boys than in girls, baseline activin A concentrations were greater in girls, and activin did not change with GnRH administration. Testosterone administration to boys in Tanner stage 2 led to decreased FSH and LH, increased activin, and decreased inhibin B levels but caused no change in follistatin. Estradiol administered to girls in Tanner stage 1 or 2 led to decreased LH and FSH and increased activin A levels but no change in inhibin B or follistatin concentrations, whereas administration of estradiol to girls with Turner syndrome led to decreased serum levels of FSH, although the effectively nondetectable levels of activin and inhibin did not change.³⁰¹

A low concentration of inhibin B in men and pubertal boys is an indicator of impaired seminiferous tubule function.³⁰² Early pubertal boys with testicular defects have higher FSH concentrations and low inhibin levels. Inhibin B is the form most closely related to testicular function, and it is absent in orchidectomized men. Inhibin B is related to Sertoli cell function in prepuberty, but a developmental change occurs during puberty so that later in life, inhibin B concentration is related to spermatogenesis. Prepubertal boys with the Sertoli cell-only syndrome had normal inhibin B levels, whereas postpubertal affected boys and men with Sertoli cell-only syndrome and early-stage spermatogenic arrest had undetectable or low levels of inhibin B, whereas those with late-stage spermatogenic arrest or obstructive azoospermia had normal or near-normal levels of serum inhibin B.²⁹⁴ In prepuberty, the α and the β_B inhibin subunits are expressed in Sertoli cells, but during puberty and in men, fully differentiated Sertoli cells express only the α -subunit; the β -subunit is expressed in germ cells. Inhibin B in the adult appears to be a product of germ and Sertoli cells. In prepubertal boys, basal plasma inhibin B concentrations have a high correlation with the incremental testosterone response to administration of human chorionic gonadotropin (hCG), and they provide a useful assessment of the presence of testes and their function.³⁰³

Anti-müllerian Hormone. AMH, a 14-kd glycoprotein dimer that is structurally related to the subunit of inhibin and TGF- β , is produced by the Sertoli cell of the fetal testis and later in gestation by granulosa cells of the fetal ovary. Immunoassayable concentrations of AMH³⁰⁴ rise from birth to relatively high levels during the first year of life in males, decrease by age 10 years, and decrease further during puberty. Newborn females have low or nondetectable serum levels of AMH, which rise only slightly thereafter; serum AMH concentrations are virtually nondetectable in most girls just before puberty.^{304,305} Serum levels of AMH and of estradiol after GnRH analogue stimulation are increased in low-birth-weight and high-birth-weight female infants, suggesting altered follicular development.³⁰⁶ Increased post-stimulation FSH levels and low adiponectin concentrations are observed only in high-birth-weight infants, indicating that altered ovarian function occurs by a different mechanism than that found in low-birth-weight infants.

Serum levels of AMH and inhibin B are inversely related to androgen concentrations in pubertal boys, and values in boys with CPP are appropriate for pubertal stage rather than chronologic age. Elevated serum AMH concentrations occur in the newborn period, at puberty, and thereafter in androgen resistance.³⁰⁴ Treatment with recombinant FSH and hCG in hypogonadotropic hypogonadism increases testosterone and decreases the elevated levels of serum AMH (due to immature Sertoli cells) and inhibin B, further demonstrating this relationship.²⁹⁹ AMH is slightly higher in boys with delayed puberty than in pubertal age-matched controls and lower in those with testicular dysgenesis associated with impaired virilization than in normal boys. Boys with isolated cryptorchidism have normal values of AMH, and AMH and inhibin B are absent in anorchia, allowing a differential diagnosis^{304,307} during the first month after birth.³⁰⁸ Dysgenetic testes secrete only low serum AMH levels; the testosterone response to hCG indicates the presence of testicular tissue.³⁰⁷

AMH is elevated in girls with PCOS and in girls with oligomenorrhea without classic AMH. This finding suggests that oligomenorrheic adolescents may have increased antral follicle number, similar to that observed in girls with PCOS.³⁰⁹ AMH is a useful gonadal tumor marker because values are elevated in males with primitive Sertoli-like tumors and in girls and women with granulosa cell tumors.

Insulin-Like 3. During puberty, serum levels of insulin-like 3 (INSL3), a protein produced by the Leydig cell, rise in normal boys under LH stimulation and in those in whom increased secretion is induced by letrozole treatment. Values do not increase in Klinefelter's syndrome, in which the initial rise levels off during midpuberty.³¹⁰ INSL3 may serve as another indication of Leydig cell function.

Prostate-Specific Antigen. Prostate-specific antigen (PSA) is detectable in male and female cord blood and in the serum of infants, but PSA concentrations decrease to undetectable levels during childhood. PSA concentrations rise to the measurable range with the onset of puberty in the male and correlate with the progression of pubertal stage, the size of the testes, serum LH and testosterone concentrations, and, presumably, the size of the prostate.^{311,312} PSA values are increased to the pubertal range in boys with idiopathic CPP, and they decrease with GnRH agonist treatment.

CENTRAL NERVOUS SYSTEM AND PUBERTY

Two independent but associated processes (controlled by different mechanisms but closely linked temporally) are involved in the increased secretion of sex steroids in the peripubertal and pubertal period. In the first process, adrenarche, the increase in adrenal androgen secretion^{284,313} precedes by approximately 2 years the second process, gonadarche, which is a consequence of the pubertal reactivation of the hypothalamic-pituitary gonadotropin-gonadal apparatus.^{314,315}

The onset of puberty is a consequence of maturational changes, including the development of secondary sexual characteristics, the adolescent growth spurt, the attainment of fertility, and psychosocial changes, all emanating from the disinhibition or reaugmentation of the hypothalamic GnRH pulse generator and gonadotropin secretion, causing an increase in gonadal steroid secretion (Table

25-10).^{241,314} The events characterizing the development of gonadal function can be viewed as a continuum extending from sexual differentiation and the ontogenesis of the hypothalamic-pituitary gonadotropin-gonadal system during fetal life and early infancy,^{124,239,314-317} through a juvenile pause (in which the system is suppressed to a low level of activity, discussed later),^{314,315} to the attainment of full sexual maturation and fertility during puberty, leading to the ability to procreate (Fig. 25-19). In this light, puberty does not represent the initiation or first occurrence of pulsatile secretion of GnRH or pituitary gonadotropins but the reactivation or disinhibition of GnRH neurosecretory neurons in the medial basal hypothalamus and the endogenous, apparently self-sustaining oscillatory secretion of GnRH after the period of quiescent activity during childhood. An increase in the pulsatile release of GnRH heralds the onset of puberty in primates and other mammals.^{124,315-319} The CNS, and not the hypothalamic GnRH pulse generator, pituitary gland, gonads, or gonadal steroid target tissues, restrains activation of the hypothalamic-pituitary-gonadal system during the prepubertal years.^{241,314,318,319}

Certain CNS lesions involving the hypothalamus and nearby structures can advance or delay the onset of human puberty.^{241,314,320} CPP, including cyclic ovulation in girls and spermatogenesis in boys, can result from a variety of CNS disorders. Several regulatory systems control puberty (Fig. 25-20):

1. In primates, the neural component controlling gonadotropin secretion resides in the medial basal hypothalamus, including the arcuate region. There are about 1500 to 2000 transducer GnRH neurosecretory neurons, which are not segregated into a specific nucleus but are functionally interconnected. These GnRH neurons comprise the GnRH pulse generator, which drives and controls the pituitary gonadal components, stimulates the release of LH and FSH, and translates neural signals into a periodic, oscillatory

TABLE 25-10

Hypothesis of the Control of the Onset of Human Puberty

1. *Central Dogma:* The CNS exercises the only major restraint on the onset of puberty. The neuroendocrine control of puberty is mediated by the hypothalamic GnRH-secreting neurosecretory neurons in the medial basal hypothalamus, which act as an endogenous pulse generator (oscillator).
2. The development of reproductive function is a continuum extending from sexual differentiation and the ontogeny of the hypothalamic-pituitary-gonadal system in the fetus to the attainment of full sexual maturation and fertility.
3. In the prepubertal child the GnRH pulse generator, operative in the fetus and infant, functions at a low level of activity (the juvenile pause) because of steroid-independent and steroid-dependent inhibitory mechanisms.
4. Puberty represents the *reactivation* (disinhibition) of the CNS suppressed GnRH pulse generator characteristic of late infancy and childhood, leading to increased amplitude and frequency of GnRH pulsatile discharges, to increased stimulation of the pituitary gonadotropes, and finally to gonadal maturation. Hormonally, puberty is initiated by the recrudescence of augmented pulsatile GnRH and gonadotropin secretion, mainly at night.

CNS, central nervous system; GnRH, luteinizing hormone-releasing hormone. From Grumbach MM, Kaplan SL. The neuroendocrinology of human puberty: an ontogenetic perspective. In Grumbach MM, Sizonenko PC, Aubert ML, eds. *Control of the Onset of Puberty*. Baltimore, MD: Williams & Wilkins, 1990:1-68. © 1990, the Williams & Wilkins Co., Baltimore.

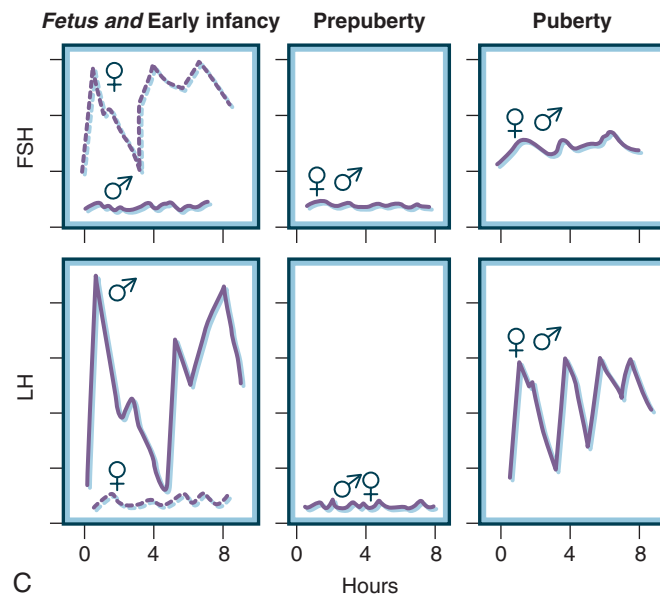

Figure 25-19 A, Kisspeptin receptor (KISS1R, formerly called GPR54) and the gonadotropin-releasing hormone (GnRH) neuron. KISS1 messenger RNA-expressing neurons in the medial basal hypothalamus synapse with GnRH neurons. Activation of the kisspeptin receptor on the GnRH neuron entrains the release of GnRH into the portal circulation, which induces the gonadotropes to release luteinizing hormone (LH) and follicle-stimulating hormone (FSH). **B**, Postulated ontogeny of the dual mechanism for the inhibition of puberty. *Dashed arrows indicate inhibition*. Notice the action of both components during the juvenile pause (i.e., prepuberty) (see Fig. 25-38 for the relative roles of these two mechanisms during development). MBH, medial basal hypothalamus. **C**, Change in the pattern of pulsatile FSH and LH secretion in the fetus and early infancy, prepuberty, and puberty (data from Waldhauser et al.¹⁰⁷⁷). Notice the pulsatile secretion in the fetus and infant and the striking difference in the amplitude of FSH and LH pulses between male and female infants. After infancy, the amplitude and frequency of gonadotropin pulses decrease greatly for almost a decade (i.e., juvenile pause) until the onset of puberty. (**A**, Diagram modified from Smith JT, Clifton DK, Steiner RA. Regulation of the neuroendocrine reproductive axis by kisspeptin-GPR54 signaling. *Reproduction*. 2006;131:623-630; **B** and **C**, Modified from Grumbach MM, Kaplan SL. The neuroendocrinology of human puberty: an ontogenetic perspective. In: Grumbach MM, Sizonenko PC, Aubert ML, eds. *Control of the Onset of Puberty*. Baltimore, MD: Williams & Wilkins, 1990:1-68.)

chemical signal, GnRH, in a coordinated manner. These pulses appear to be generated by a propagated depolarization, the firing of action potentials in individual cells, and the resulting influx of calcium through L-type calcium channels.³²¹

2. In response to the GnRH rhythmic signal, the pituitary gonadotrophs, which contain the seven-transmembrane domain G_s -coupled LH/hCG receptors (LHCGRs),³²² release LH and FSH in a pulsatile manner. Each LH and FSH pulse is induced by a pulse of GnRH.
3. The gonads, which are modulated primarily by the amplitude of the gonadotropin pulse, transmit the episodic gonadotropin signal into pulsatile secretion of gonadal steroids.³²³

This control mechanism is common to all mammalian species. At the last two levels—the pituitary gland and the gonad—the target cells contain receptors for the peptide hormones that mediate the cellular response to the signal.^{322,323} Diverse adaptive mechanisms and strategies have evolved among species and between the sexes that influence the biology and timing of puberty. Photoperiodicity and seasonal breeding, biologic clocks, and pheromones are integral parts of the pubertal process in some species but not humans. The most enlightening studies on the neuroendocrinology of human puberty have emerged from studies of humans and nonhuman primates.

Pattern of Gonadotropin Secretion

Tonic Secretion

Tonic, or basal, secretion is regulated by a negative, or inhibitory, feedback mechanism in which changes in the concentration of circulating gonadal steroids and inhibin result in reciprocal changes in the secretion of pituitary gonadotropins. This is the pattern of secretion in the male and one of the control mechanisms in the female. Clinical studies reveal that testosterone and estradiol in the male have independent effects on LH secretion. Inhibition of LH by testosterone requires aromatization for its pituitary but not its hypothalamic effects, and estradiol-induced negative feedback on LH occurs at the level of the hypothalamus.³²⁴

In the female, cyclic secretion involves a positive, or stimulatory, feedback mechanism in which an increase in circulating estrogens, to a critical level and of sufficient duration, initiates the synchronous release of LH and FSH (i.e., preovulatory LH surge) that is characteristic of the normal adult woman before menopause.

Pulsatile Secretion

Generation of the GnRH pulse is an intrinsic property of the GnRH neurosecretory neuronal network, and other

Figure 25-20 Organization and characteristics of the hypothalamic-pituitary-gonadal system. The medial basal hypothalamus (MBH) contains the transducer gonadotropin-releasing hormone (GnRH) neurosecretory neurons. These neurons translate neural signals into a periodic, oscillatory chemical signal, GnRH. This MBH complex functions as an GnRH pulse generator (oscillator), which is frequency coded and releases GnRH from its axon terminals at the median eminence as a largely synchronous, intermittent discharge into the primary capillary plexus of the hypothalamo-hypophyseal portal circulation. The GnRH pulse generator is influenced by biogenic amine neurotransmitters, peptidergic neuromodulators, neuroexcitatory amino acids, and neural pathways. During the follicular phase in women and men, a GnRH pulse (estimated indirectly by monitoring luteinizing hormone [LH] pulses in peripheral blood) occurs approximately every 90 to 120 minutes throughout the day. Changes in the frequency and probably in the amplitude of the GnRH secretory episodes modulate the pattern of LH and follicle-stimulating hormone (FSH). The major site of action of testosterone and progesterone is on the GnRH pulse generator, because these two classes of steroids decrease LH pulse frequency, but a pituitary site of action has also been described. Estrogens have major direct inhibitory and stimulatory effects on the GnRH-primed pituitary gonadotroph; the inhibitory or negative feedback action is associated with a decrease in the frequency and the amplitude of pituitary LH secretion. Evidence supports the negative and positive feedback action of estrogen on the GnRH pulse generator. Inhibin has a direct inhibitory effect on the pituitary gland and the secretion of FSH. The secretion of gonadal steroids by the gonads is controlled mainly by the amplitude of the gonadotropin signal. (Adapted from Grumbach MM, Kaplan SL. The neuroendocrinology of human puberty: an ontogenetic perspective. In: Grumbach MM, Sizonenko PC, Aubert ML, eds. *Control of the Onset of Puberty*. Baltimore, MD: Williams & Wilkins, 1990:1-68.)

factors modulate the fundamental autorhythmicity of the GnRH neuron, including the downstream effects of cyclic adenosine monophosphate (cAMP)-gated cation channels on the regulation of pulsatility by cAMP.³²⁵ The immortalized GnRH neurosecretory neuronal cell line and cultured monkey GnRH-I neurons exhibit spontaneous pulsatile release of GnRH at a frequency similar to that observed in vivo. Patch-clamped primary GnRH neurons show disordered patterns of release that are sensitive to increased extracellular potassium; firing activity can be stimulated by exposure to estrogen in a manner that appears to function through the estrogen receptor.³²⁶

The secretion of FSH and LH is always pulsatile or episodic, regardless of developmental stage, due to the pulsatility of the GnRH pulse generator. The pulsatile secretion of immunoreactive FSH in normal adults is less prominent than that of LH; this is attributed in part to the longer half-life of FSH compared with LH, to differences in the factors that modulate the action of GnRH on FSH and LH release by the gonadotrophs (especially gonadal steroids, inhibin, and possibly activin and follistatin), and to intrinsic differences in the secretory pattern of the two gonadotropins. For example, a change in the frequency of GnRH pulses can modify the ratio of FSH to LH released; midfollicular-phase concentrations of estradiol and adult male concentrations of plasma testosterone have a greater inhibitory effect on the response of FSH to pulsatile injections of GnRH, compared with that of LH.³²⁷

Intermittent or pulsatile administration (e.g., GnRH, 1 µg/minute for 6 minutes every hour) induces pulsatile release of LH and FSH in adult monkeys in which hypothalamic lesions have obliterated the arcuate nucleus region and eliminated endogenous GnRH secretion.³²⁸ Continuous infusion of GnRH inhibits gonadotropin secretion because of desensitization of GnRH receptors on the gonadotroph. Pulsatile GnRH administration reestablished gonadotropin secretion in animals in which gonadotropin secretion was suppressed by the continuous infusion of GnRH (Fig. 25-21). The GnRH signal to the pituitary gonadotrophs of the adult is frequency coded.

The GnRH neurosecretory neurons of the hypothalamic GnRH pulse generator that arise in the olfactory placode exhibit spontaneous autorhythmicity and function intrinsically as a neuronal oscillator for entrainment of the repetitive release of GnRH. The autorhythmicity in the GnRH neurosecretory neurons^{329,330} involves cAMP and cyclic nucleotide-gated cation channels associated with oscillatory increases in intracellular calcium ions (Ca^{2+}), a hallmark of neurosecretion and gap junctional communication. Moreover, the immortalized GnRH neuronal cell line contains neuronal nitric oxide (NO) synthase, and NO generated by GnRH neurons may act as an intercellular or intracellular messenger.³³¹ GnRH acting as an autocrine factor may play a role in the synchronization mechanism. GnRH is synthesized in these neurons and released episodically from axon terminals at the median eminence into the primary plexus of the hypothalamic-hypophyseal portal circulation; it is then transported by the portal vessels to the anterior pituitary gland to produce the pulsatile LH and FSH secretion.

Ontogeny

In all vertebrates examined, GnRH neurons arise in the embryo from the epithelium of the olfactory placode and migrate in a rostrocaudal direction by an ordered spatio-temporal course along the pathway of the nervous

Figure 25-21 The Knobik paradigm. Effect of pulsatile administration of gonadotropin-releasing hormone (GnRH) in contrast to continuous infusion of GnRH in adult oophorectomized rhesus monkeys in which gonadotropin secretion has been abolished by lesions that ablated the medial basal hypothalamic GnRH pulse generator. Notice the high concentrations of plasma luteinizing hormone (LH) and follicle-stimulating hormone (FSH) in monkeys given one GnRH pulse per hour, the suppression of gonadotropin secretion by continuous infusion of GnRH even though the total dose of GnRH was the same, and the restoration of FSH and LH secretion when the pulsatile mode of GnRH administration was reinitiated. (From Belchetz PE, Plant TM, Nakai Y, et al. Hypophyseal responses to continuous and intermittent delivery of hypothalamic gonadotropin releasing hormone. *Science*. 1978;202: 631-633.)

terminalis-vermonasal complex to the forebrain.^{319,332} The terminalis-vermonasal complex also originates in the olfactory placode and forms a connection between the nasal septum and the forebrain. This contrasts to the pattern of growth hormone-releasing factor (GRF), thyrotropin-releasing factor (TRF), or corticotropin-releasing factor (CRF) neurosecretory neurons, which originate from ventricular zones within the embryonic forebrain.³³³

The GnRH green fluorescent protein model demonstrates an increase in dendritic and somal spines in adult mice compared with juveniles, suggesting an increase in direct excitatory inputs to GnRH neurons and increased glutamatergic stimulation of GnRH neurons across the time of puberty.³³⁴ Embryonic GnRH neurons of the olfactory placode and the hypothalamus coexpress mRNAs for GnRH and the type 1 GnRH receptor. These neurons demonstrate spontaneous electrical pulsatile activity, which can be stimulated by GnRH agonist and abolished by GnRH antagonist in the same pattern as GnRH pulses, all in a calcium-dependent manner (i.e., the intracellular calcium responses are stimulated by the agonist and inhibited by the antagonist).³³⁵

Human Fetus

GnRH immunoreactivity was observed in the epithelium of the medial aspect of the olfactory placode of the normal human fetus by 42 days of gestation but not at 28 to 32 days (Table 25-11).³³² No GnRH neurosecretory neurons were found in the brain, including the hypothalamus, of a 19-week gestational male human fetus with Kallmann's syndrome,³³⁶ and the olfactory bulbs were absent. However, dense clusters of GnRH cells and fibers were present in the nose, including the nasal septum and cribriform plate, and within the dural layers of the meninges under the forebrain. The GnRH neurosecretory neurons migrate from the olfactory placode to the hypothalamus in normal humans and other mammals.

TABLE 25-11

Early Development of the Human Fetal Pituitary and Hypothalamus

Gestational Age (wk)	Hypothalamus	Pituitary	Portal Circulation
3	Forebrain appears		
4		Rathke's pouch in contact with stomodeum	
5	Diencephalon differentiated	Rathke's pouch separated from stomodeum and in contact with infundibulum; pituitary in culture can secrete corticotropin, prolactin, GH, FSH	
6	Premammillary preoptic nucleus; GnRH detected	Intermediate-lobe primordia; cell cords penetrate mesenchyme around Rathke's pouch	
7	Arcuate, supraoptic nucleus	Sphenoidal plate forms	
8	Median eminence differentiated; TRH detected	Basophils appear	Capillaries in mesenchyme
9	Paraventricular nucleus; dorsal medial nucleus	Pars tuberalis formed; β -endorphin detected*	
10	Serotonin and norepinephrine detected*	Acidophils appear	
11	Mammillary nucleus; primary (hypothalamic) portal plexus present; β -endorphin and opioidergic neurons detected*	Secondary (pituitary) portal plexus present; catecholamines detected by IF	Functional hypothalamic hypophyseal portal system
12	Dopamine present		
13	Corticotropin-releasing hormone detected*	α -Melanocyte-stimulating hormone detected	
14	Fully differentiated hypothalamus	Adult form of hypophysis developed	

*Hormone is detected at this gestational age but may be present earlier.

FSH, follicle-stimulating hormone; GH, growth hormone; GnRH, luteinizing hormone-releasing hormone; IF, immunofluorescence; TRH, thyrotropin-releasing hormone.

Modified from Gluckman P, Grumbach MM, Kaplan SL. The human fetal hypothalamus and pituitary gland. In: Tulchinsky D, Ryan KJ, eds. *Maternal-Fetal Endocrinology*. Philadelphia, PA: WB Saunders, 1980:196-232.

Aberrant migration of the GnRH neurons leads to delayed or absent pubertal development due to hypogonadotropic hypogonadism, and anosmia or hyposmia is a cardinal feature of Kallmann's syndrome and the CHARGE syndrome (see later discussion).

The number of the GnRH neurons and the GnRH mRNA levels in nonhuman primates and mice do not appear to change during pubertal development. The ability of the GnRH neuron to respond to electrical or neurochemical (e.g., glutamatergic, kisspeptinergic) stimuli does not change with pubertal development.³³⁷

GnRH has been detected in human embryonic brain extracts by 4.5 weeks and in the fetal hypothalamus by 6 weeks (see Table 25-11); the fetal pituitary gonadotrophs are responsive to GnRH.²³⁹ The hypothalamic-hypophyseal portal system is functional by 11.5 weeks' gestation,³³⁸ and by 16 weeks, axon fibers that contain GnRH are present in the median eminence and terminate in contact with capillaries of the portal system.^{124,239,314,316}

In fetal sheep, the hypothalamus secretes GnRH in a pulsatile manner.^{339,340} The available data are consistent with the development of a human fetal hypothalamic GnRH pulse generator by at least the end of the first trimester.

The human fetal gonad is affected by placental gonadotropins and by fetal pituitary FSH and LH.^{124,316} The placental gonadotropin hCG may play an important role in the secretion of testosterone by the Leydig cells of the fetal testes during masculinization of the wolffian ducts and the external genitalia at 8 to 13 weeks' gestation. However, it is uncertain whether functional hCG/LH and FSH receptors are present in the fetal testis by 12 weeks of gestation and whether the early fetal testis responds to hCG. Fetal Leydig cells are a unique population of Leydig cells limited to the fetus and infant, which regress to be followed by the differentiation of adult-type Leydig cells in the peripubertal period.^{124,316,341} Fetal testosterone and hCG levels, but not LH levels, were decreased in fetuses

studied after elective second-trimester abortions between 11 and 19 weeks' gestation, with no significant change in testicular responsiveness.¹²⁸ The proportion of nonfunctional LHCGR transcripts in fetal testes was 2.3-fold lower than in adults, so that available ligand may exert a greater effect. Fetal hCG was reduced, and the ratio of inactive to active LHCGR isoforms was lowered by maternal smoking. Second-trimester fetal testosterone levels appear to decrease due to decreasing maternal hCG, because Leydig cell LH/hCG responsiveness remains constant. Even with the decrease of fetal hCG caused by maternal cigarette smoking, because the ratio of inactive to active LHCGR isoforms is reduced, testosterone remains normal due to fetal gonadotropin stimulation.

Compared with the adult type, fetal Leydig cells form tightly opposed clusters joined by gap junctions and lack Reinke crystals; they are resistant to hCG/LH-induced desensitization (hCG/LH produce upregulation of LHCGRs); and they contain little aromatase activity and few estradiol receptors. In contrast to the fetal testis, FSH receptors in the fetal ovary appear only late in the second trimester, well after completion of male phenotypic differentiation, demonstrating a sex difference in the stage of gestation at which fetal pituitary gonadotropins have an important effect on the development of the fetal gonad. In the anencephalic fetus (which is deficient in hypothalamic GnRH, resulting in deficiency of pituitary gonadotropins), the testes appear hypoplastic by early in the third trimester; however, the ovaries in this disorder are normal until at least 32 weeks' gestation.^{124,316,320} Androgen receptor (AR) mRNA expression is lower, and AMH mRNA expression is higher in fetal testicular Sertoli cells than in adult testes. This may explain the failure of testicular testosterone to support spermatogenesis and to suppress AMH at that stage. AR was expressed in peritubular and Leydig cells.³⁴² Patients with androgen insensitivity syndrome have an increase in circulating testosterone and AMH and have combined gonadotropin stimulation that is consistent

with a failure of testosterone to repress AMH in the absence of AR signaling.

The human fetal pituitary gland contains FSH and LH by 10 weeks, secretion begins by 11 to 12 weeks, and the gonadotropin content increases until approximately 25 to 29 weeks of gestation.^{124,239,316,317,320} Fetal serum LH and FSH concentrations rise to peak levels by midgestation and then decrease to low values in umbilical venous blood at term. The serum concentrations of FSH and LH and of bioactive FSH at 17 to 24 weeks' gestation are strikingly higher in female than in male fetuses, and in both sexes, they decrease remarkably between 25 and 40 weeks of gestation. Mean FSH and LH concentrations are elevated at the beginning of the third trimester and decrease with advancing gestational age to undetectable values in term fetuses. Mean FSH values are higher in female fetuses between 26 and 36 weeks, whereas the mean LH level is higher in males. In the ovine fetus, LH and FSH are secreted in a pulsatile manner in response to the episodic secretion of fetal hypothalamic GnRH; human fetal pituitary gonadotropins are probably released in the same mode. The mean FSH and LH content of fetal pituitary glands is greater in female than in male fetuses at midgestation. This difference has been ascribed to the higher concentration of plasma testosterone between 11 and 24 weeks in the male fetus (the only major difference in gonadal steroids between the male and female fetus) and to fetal testicular inhibin.^{124,316} The decrease in serum FSH and LH concentrations during late gestation and near term is attributed to maturation of the negative feedback mechanism, the development of gonadal steroid receptors in the hypothalamic-pituitary unit,^{239,317,343} and the effect of inhibin.^{124,316}

In vitro studies indicate that the human fetal pituitary gland is responsive to GnRH as early as 10 weeks' gestation; the GnRH-stimulated release of LH is greater in second-trimester fetal pituitary cells cultured from females than in those cultured from males and is augmented by estradiol in both sexes.³⁴⁴ In vivo studies during middle and late gestation demonstrate the stimulating action of exogenous GnRH on fetal FSH and LH release by 16 weeks, with a striking sex difference in the FSH response and a fall in responsiveness to GnRH in late gestation. Anencephalic infants and some infants with neonatal hypothalamic hypopituitarism^{124,316} have an absent or diminished gonadotropin response to GnRH,^{124,239} in contrast to the brisk increase demonstrated in the normal infant.

A pattern of increasing synthesis and secretion of FSH and LH leading to peak serum concentrations at castrate levels, probably the result of relatively autonomous, unrestrained activity of the fetal hypothalamic GnRH pulse generator and subsequent stimulation of the fetal gonadotrophs by GnRH, is followed by a decline after midgestation that persists to term, probably due to maturation of the negative feedback mechanism³⁴³ and increasing sensitivity of the GnRH pulse generator to the inhibitory effects of the high concentration of sex steroids (estrogens and progesterone from the placenta and, in the male, testosterone from the fetal testes) in the fetal circulation^{239,314}; in the male fetus, there is also a contributory effect on the decrease in FSH by testicular inhibin in late gestation.^{124,316} The increasing CNS control of gonadotropin secretion seems to require the maturation of gonadal steroid receptors (intracellular or on the cell surface, or both) in the fetal hypothalamus and in the pituitary gonadotrophs.²³⁹

Sheep Fetus

By 0.6 gestation, the secretion of fetal LH and FSH is pulsatile,³³⁹ mediated by the hypothalamic GnRH pulse

generator.^{314,340,343} A sex difference in gonadotropin secretion occurs in ovine and human fetuses,³¹⁴ and orchiectomy (but not oophorectomy) in the ovine fetus leads to increased pulsatile secretion of LH and, to a lesser degree, of FSH.³⁴⁵ Opioidergic neurons have a tonic suppressive effect on the pulsatile release of GnRH in the ovine fetus,^{314,346} and the excitatory amino acid analogue N-methyl-D-aspartate (NMDA) evokes an LH pulse mediated by GnRH. The excitatory amino acids, glutamate and aspartate, can stimulate the GnRH pulse generator directly or indirectly.³⁴⁷ Glutamate is present in abundance in the hypothalamus and is released from glutamatergic neurons by exocytosis in an ATP- and calcium-dependent process.³⁴⁸ FSH stimulates inhibin synthesis by the ovine fetal testis and ovary, and administration of an inhibin-rich extract inhibits fetal FSH but not LH secretion, evidence of the functional capacity of the FSH-fetal gonadal inhibin feedback system.^{349,350} These observations provide support for the central role of this process in the regulation of the CNS in hypothalamic GnRH-pituitary gonadotropin unit.

Human Neonate and Infant

In both sexes, the concentration of plasma FSH and LH is low in cord blood as a consequence of the inhibitory effect of the high levels of placental derived estrogens, but within a few minutes after birth, the concentration of LH increases abruptly in peripheral blood (about 10-fold) in the male neonate, but not in the female; this is followed by an increase in serum testosterone concentration during the first 3 hours that persists for 12 hours or longer.^{314,351} After the fall in circulating levels of steroids of placental origin (especially estrogens) during the first few days after birth, the serum concentrations of FSH and LH increase and exhibit a pulsatile pattern with wide perturbations during the first few months of life. FSH pulse amplitude is much greater in the female infant and is associated with a larger FSH response to GnRH throughout childhood; LH pulses are of greater magnitude in the male. This striking sex difference also is present in agonadal male and female infants^{314,352} and in infant rhesus monkeys.³⁵³ This sex difference may in part be related to the effect of testosterone in the male fetus on the development and function of the hypothalamic-pituitary apparatus.^{124,316}

The high gonadotropin concentrations are associated with a proliferation of Sertoli cells and gonocytes (and their transformation into spermatogonia) and with a transient second wave of differentiation of fetal-type Leydig cells and increased serum testosterone levels in male infants during the first few postnatal months³⁴¹ and increased estradiol levels intermittently during the first year of life and part of the second year in females.³⁵⁴ The mean FSH concentration is higher in females than in males during the first few years of life. By approximately 6 months of age for boys and 2 to 3 years for girls, the concentration of plasma gonadotropins decreases to the low levels that are present until the onset of puberty (earlier in boys than girls) in the juvenile phase.^{314,355}

The neonatal-to-midinfancy surge in pulsatile gonadotropin secretion, sex hormones, and inhibin—the so-called postnatal surge (i.e., mini-puberty)—is attributable to an increase in GnRH pulse amplitude and is associated in the male infant with the following³¹⁶:

1. Increase in testicular volume (by direct measurement) due to increased seminiferous tubule length (about a sixfold increase in year 1)
2. Rapid expansion of the Sertoli cell population (which makes up 85% to 95% of seminiferous tubular cell mass)

3. High concentration of circulating inhibin B (low in hypogonadotropic hypogonadism)
4. Sertoli cell number, including postnatal proliferation, as a determinant of spermatogenic function

The increase in circulating testosterone in the normal male infant may lead to facial comedones and even to acneiform lesions, and the increase in gonadotropins may lead to a transient increase in testicular size, but there may be more subtle changes. An LH and testosterone surge is absent in those with the complete androgen insensitivity syndrome. In the McCune-Albright syndrome, an activating mutation in the G_{α} gene primarily expressed in the Sertoli cell can cause macroorchidism due to Sertoli cell proliferation and hyperfunction with increased concentration of serum inhibin B and AMH but without increased testosterone levels due to Leydig cell hyperplasia, elevated gonadotropins, or signs of puberty.³¹⁶

The postnatal surge apparently is not essential for masculine-typical psychosexual development. The brain in patients with congenital hypogonadotropic hypogonadism, including Kallmann's syndrome, is masculinized by testosterone therapy at puberty despite the lack of an infantile surge in gonadotropins and testosterone.

The transient postnatal to midinfancy function of the GnRH pulse generator in the male infant may be related to future spermatogenic function and fertility.^{356,357} Sertoli cells and germ cells proliferate for about 100 days after birth (indicating mitotic activity and the transformation of gonocytes into adult dark [Ad] spermatogonia, the stem cells for spermatogenesis), with a subsequent decrease, mainly by apoptosis, after about 6 months of age, coincident with the waning of gonadotropins and testosterone.

Neural Control

Maturation of the CNS is the outcome or consequence of the totality of environmental and genetic factors that retard or accelerate the onset of puberty. It is a provocative but unproven hypothesis that a metabolic signal related to body composition is an important factor in the maturation or activation of the hypothalamic GnRH pulse generator and not a result of the early hormonal and body composition changes in human puberty. In either event, clinical and experimental data support the contention that the factors influencing the timing of puberty are expressed finally through CNS regulation of the onset of puberty.^{241,314} In humans, the pineal gland and melatonin do not appear to have a major effect on this control system.^{314,358}

Timing and Onset of Puberty

Genetic Neural Control

Because many levels control the onset of pubertal development, a systems biology approach holds promise in characterizing the complex components of this neural and neuroendocrine network. It appears that normal and some types of abnormal puberty are under polygenic control.³⁵⁹ Although the increased pulsatile release of GnRH is most frequently considered, this change is caused by a balance in the inhibitory and excitatory factors through coordinated changes in transsynaptic and glial-neuronal communication, increased stimulatory factors (most prominently glutamate and kisspeptin), and decreased inhibitory tone, mostly through GABAergic neurons (i.e., those secreting γ -aminobutyric acid [GABA]) and opioidergic neurons and ultimately controlled by gene expression. Glial cells affect GnRH secretion through growth

factor-dependent cell-cell signaling coordinated by numerous unrelated genes. A second level of genes is postulated to control cell-cell interaction. The third-highest level of control occurs through transcriptional regulation of the subordinate genes by other higher-level genes that maintain the function and integration of the network. New genomic and metabolomic methods should illuminate these complex processes.

Although the action of multiple genes (i.e., quantitative or polygenic inheritance) on the time of onset of puberty (e.g., on stature) has long been recognized, little is known about the gene loci involved in this complex quantitative trait or the effect of gene interactions (i.e., epistaxis) on this paradigm of complex traits. Genetic factors are estimated to account for 50% to 80% of the variation in the onset of normal puberty. These complex traits have been analyzed by linkage analyses (in which quantitative trait loci have been shown to relate to the age of menarche) and by large-scale haplotype-based association studies. Pedigree analyses have revealed relative risks for delay of puberty in kindreds with histories of CDP compared with those without such a history; for example, for first-degree relatives, the risk for a 2-SD delay in the onset of puberty is 4.8. There are clear genetic influences on the time of onset of puberty in monogenetic disorders, such as *KAL1* or *KISS1R* (*GRP54*) mutations, that can prevent pubertal development (see later discussion).

Nutrition and Metabolic Control

The genetic effects on the time of onset of puberty and its course are influenced by environmental factors (e.g., socioeconomic factors, nutrition, general health, geography) operating through the CNS. It has long been postulated that some alteration of body metabolism linked to energy metabolism may affect the CNS restraints on pubertal onset and progression, because of the earlier age of menarche in moderately obese girls, delayed menarche in states of malnutrition and chronic disease and with early rigorous athletic or ballet training, and changes in gonadotropin secretion and amenorrhea in girls with anorexia nervosa, voluntary weight loss, and strenuous physical conditioning.³⁶⁰

An *invariant mean weight* (48 kg) for initiation of the pubertal spurt in weight, the maximal rate of weight gain, and menarche in healthy girls regardless of chronologic age was proposed in the 1970s, but the concept generated controversy and criticism, in part because the empiric estimations and the equations used to determine fat mass were challenged and because no direct measurements supported the theory.³⁶¹ A more recent, 5-year longitudinal study of 469 girls revealed that there was a similar percentage of body fat associated with the onset of puberty, although there was a spread of chronologic ages at onset.³⁶² Body composition in the 2 years before puberty had a modest impact on the age of pubertal growth, but higher fat mass led to more rapid progress through pubertal stages.³⁶³

The relationships of adipose tissue mass, fat metabolism, and energy balance to reproduction were illuminated by the discovery of the genes encoding leptin, an adipocyte satiety factor,^{364,365} and its receptor.³⁶⁶ Considerable interest has focused on the potential role of leptin in the control of the onset of puberty—from a proposal that it was an essential, if not a key, factor in triggering the onset of puberty to one in which it had a more subsidiary role. Leptin is a well-established afferent satiety factor in humans; it acts on the hypothalamus, including nuclei controlling appetite, to suppress appetite.^{124,316,367} Leptin reflects body fat and therefore energy stores and has an

important role in the control of body weight and the regulation of metabolism.³⁶⁵

Ob/ob mice (which lack leptin) and db/db mice (which lack leptin receptors) are obese and exhibit hypogonadotropic hypogonadism, providing evidence for an important role of leptin in reproduction. Administration of recombinant leptin to hypogonadal ob/ob mice and to rats experiencing pubertal delay associated with food restriction in the rat partially reverses the hypogonadism. However, leptin administration to normal prepubertal rats did not advance the time of onset of puberty. A critical threshold level of leptin was necessary for puberty to begin and advance, but leptin alone (as in administration to normal rodents) was insufficient to promote puberty; it was but one among several permissive factors.³⁶⁸

The site of action of leptin in its effect on the hypothalamic GnRH-pituitary gonadotropin apparatus that was uncertain is clarified by experiments in the mouse by the Elias group.³⁶⁸ Even though leptin receptors (LepR) were reported to be expressed in immortalized mouse GnRH (GT1) cells, leptin receptors are not expressed on GnRH neurons in vivo. Mice with selective deletion of the long form (signaling) of the leptin receptor underwent normal puberty and fertility. Kiss1 neurons express the leptin receptor (Ob-Rb isoform), and the suggestion was advanced that the effect of leptin on puberty onset and fertility was mediated through the Kiss1/Kiss1n complex. Mice with selective deletion of the leptin receptor from Kiss1 neurons underwent normal puberty and fertility, strongly suggesting that the action of leptin on hypothalamic GnRH-pituitary gonadotropin system is not mediated through Kiss1 neurons.^{368,369} The Elias group obtained evidence that the leptin receptor is expressed at a high level in ventral pre-mammillary neurons (PMV). The PMV neurons express the excitatory neurotransmitter glutamate which stimulate either GnRH neurons or GnRH terminals in the median eminence or both sites.³⁶⁸ These observations dissociate the

action of leptin on reproductive function and on nutrition (Fig. 25-22).

Leptin levels in the male rhesus monkey were similar during the advancement of prepuberty to puberty. In peripubertal 3- to 5-year-old rhesus monkeys fasted for 2 days, the administration of leptin prevented the decrease in plasma gonadotropins detected in the untreated animals. Continuous infusion of leptin into the lateral ventricle of agonadal male monkeys failed to evoke an increase in GnRH on gonadotropin secretion.³¹⁸

Is leptin the peripheral, somatic trigger for the onset of puberty to the CNS, or does it have a permissive role, signaling the hypothalamus and the GnRH pulse generator that a critical energy store has been attained? A longitudinal study of serum leptin levels in prepubertal and pubertal boys and girls showed leptin to increase gradually during the prepubertal years, with similar levels in the two sexes.³⁷⁰ During puberty, leptin continued to rise in girls, whereas in boys, the leptin mean levels peaked at Tanner stage 2³⁷¹ and decreased to prepubertal concentrations by genital stage 5. This decrease is attributed to the effect of testosterone on leptin secretion.³⁷² Adipose tissue mass, percentage of body fat, and age correlated with leptin levels, among other variables,^{370,373} but there was no correlation between 24-hour serum estradiol and leptin concentrations in nonobese and obese prepubertal and early pubertal girls. Serum leptin levels rose after administration of pulsatile GnRH administration for 36 hours to children with delayed puberty but not after a single dose of buserelin, a GnRH agonist, suggesting that, rather than puberty's being triggered by leptin, pubertal increase in GnRH pulsatility increases leptin.³⁷⁴

Leptin circulates in both a free form and a high-molecular-weight, bound form. Leptin-binding activity in serum is highest in childhood and decreases to relatively low levels during puberty. Free leptin is postulated to have more relevance to reproductive development than total

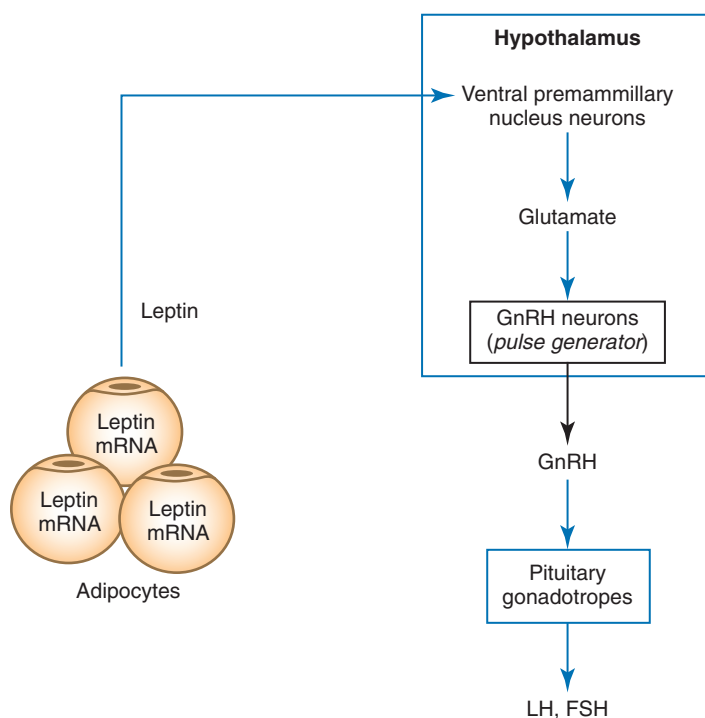

Figure 25-22 The leptin receptor is expressed in ventral pre-mammillary neurons (PMV). Leptin secreted by adipocytes evokes release of the excitatory neurotransmitter glutamate from the PMV leading to activation of GnRH neurons. Leptin functions as a permissive factor, not a trigger, in the onset of human puberty. In rodents, leptin advances the onset of puberty and plays a key role in initiating puberty and infertility. The hypothalamic pathway that regulates energy expenditure and food intake by leptin is independent of the effect of leptin on reproduction.

leptin measured in the circulation; the soluble leptin receptor appears to be higher in males than in females and is inversely related to leptin levels later in development in females.³⁷⁵ A study of a 132 monozygotic female twin pairs and 48 dizygotic female twin pairs demonstrated a rise in leptin throughout puberty and a decrease in the soluble leptin receptor between stages 1 to 2, leading to a rise in the free leptin index between stages 1 and 2; there was greater heritability for the soluble leptin receptor than leptin,³⁷⁶ and there was also high heritability of free IGF1 values. There is no known relationship between leptin and leptin receptor gene polymorphism and CDP; however, the presence of a short allele of leptin was associated with heavier weight, whereas those who were thin, had significant bone age delay, and had increased frequency of parental pubertal delay were less likely to have this leptin short allele.³⁷⁷

As in the ob/ob mouse, human beings with a homozygous mutation in the leptin gene³⁷⁸ or the leptin receptor³⁷⁹ have morbid obesity and a striking delay in puberty because of hypogonadotropic hypogonadism. In a pedigree affected by a stop codon mutation in the gene encoding leptin, a 23-year-old man failed to attain puberty because of hypogonadotropic hypogonadism,³⁷⁸ and two affected women were prepubertal and amenorrheic, one until 29 years of age, after which she began to have irregular, scanty periods, and the other until age 36 years, at which time she began to menstruate monthly. A 9-year-old girl with a bone age of 13 years who was affected with congenital leptin deficiency lost weight and had an early pubertal pattern of LH release in response to the administration of GnRH after treatment with recombinant leptin.³⁸⁰ A 4-year-old affected relative of this 9-year-old girl benefited from the metabolic improvement that occurred with leptin administration but did not undergo early pubertal development, indicating the permissive nature of leptin on puberty.³¹⁸

Boys with CDP have lower mean levels of leptin than expected and can enter puberty without an increase in circulating leptin. Two women with congenital lipoatrophic diabetes (Berardinelli-Seip syndrome), which is associated with absence of subcutaneous and visceral adipose tissue, did not have a delay in menarche despite severe hypoleptinemia, and one of the women had three unaffected children.³⁸¹ Severe leptin deficiency causes hypogonadotropic hypogonadism, suggesting that a critical level of leptin and a leptin signal are required to achieve puberty, but a rise in leptin is not required to trigger puberty.^{370,373} In summary, leptin is a permissive factor (tonic mediator) and not a trigger (phasic mediator) in the onset of human puberty (Table 25-12).

In a longitudinal study of boys leading up to an increase in morning salivary testosterone concentrations, they had a relatively constant ratio of basal metabolic rate (BMR) to lean body mass (LBM) but an increase in the ratio of BMR to total daily energy expenditure. A subtle energy-dependent process is in play, possibly related to an increase in brain BMR as a secondary phenomenon at the initiation of puberty or indicating that a central rise in BMR is a signal for the onset of puberty.³⁸²

Ghrelin is the natural ligand for the GH secretagogue receptor but also serves as an orexigenic signal that is increased after food deprivation; ghrelin is usually negatively correlated with BMI. Ghrelin administration delays pubertal development in rats due to gonadal and central effects, suggesting a link between malnutrition and the decrease in reproductive development or function.³⁸³

Adiponectin is an adipocytokine produced in fat cells that has antidiabetic, antiatherogenic effects, and

TABLE 25-12

Leptin and Puberty: A Permissive Factor, Not a Trigger for the Onset of Puberty

Pro-Trigger Evidence

Congenital leptin deficiency or congenital leptin resistance related to mutations is associated with delayed puberty and gonadotropin deficiency, evidence that the virtual absence of leptin or the leptin signal leads to severe hypogonadotropic hypogonadism. In congenital leptin deficiency, administration of leptin led to a reduction in weight and an early pubertal pattern of luteinizing hormone release in an affected prepubertal girl.

Pro-Permissive Evidence

A sharp rise in circulating leptin does not occur at the onset of puberty. In prepubertal and early pubertal girls, the rise in serum leptin did not correlate with the increase in serum estradiol. In constitutional delay in growth and adolescence, an increase in prepubertal leptin levels is not essential for the onset of puberty. In congenital lipoatrophic diabetes, despite the absence of subcutaneous and visceral adipose tissue and, as a consequence, severe hypoleptinemia, puberty can occur at the usual age and fertility is reported. Supportive experimental data exist in rodents, sheep, and nonhuman primates.

From Grumbach MM. The neuroendocrinology of human puberty revisited. *Horm Res.* 2002;57(suppl 2):2-14.

anti-inflammatory effects. Adiponectin decreases in the face of excess fat mass in obesity and is suppressed by rising testosterone and DHEAS levels. The concentration of adiponectin falls during pubertal development in males but remains rather stable in females with advancing Tanner stage.³⁸⁴

Resistin is an adipocytokine belonging to the resistin-like molecular family of cysteine-rich molecules (RELMs). Values increase with pubertal development in boys, and this appears to be true in girls as well, although the evidence is weaker. Because resistin serum levels were elevated in mouse models of obesity, it was considered to be a potential link between insulin resistance and obesity, but serum resistin levels appear to relate more to pubertal development than to insulin resistance.³⁸⁵

Mechanisms of Control

Diverse strategies and adaptive mechanisms have evolved to control puberty in different species.^{315,318,319} In rodents, exteroceptive factors and cues, including light, olfaction, and pheromones, have an important influence by way of the CNS on gonadotropin secretion. In seasonal-breeding species such as sheep, the length of the light-dark cycle is critical, and the pattern of gonadotropin secretion is different. In contrast, male and female primates exhibit an estrogen-provoked LH surge.

In humans and nonhuman primates, after the initial development and function in the fetus, the infantile surge of increased LH and FSH secretion occurs; this is followed by a decade of suppression (but not absence) of activity of the hypothalamic GnRH pulse generator and the resulting quiescence of the pituitary gonadotropin-gonadal axis, known as the prepubertal period or juvenile pause (Table 25-13).^{124,314,315,318,319} Then there is gradual disinhibition and reactivation, mainly at night during late childhood,^{314,315,318,319,386,387} and, finally, the increased amplitude of the GnRH pulses, reflected in the progressively increased and changing pattern of circulating LH pulses, that occurs with the approach of and during puberty. Two interacting

mechanisms have been proposed to explain the juvenile pause (Fig. 25-23).^{314,386}

Gonadal Steroid–Dependent Negative Feedback Mechanism. There are three lines of evidence for an operative negative feedback mechanism in prepubertal children^{241,314}:

1. The pituitary of the prepubertal child secretes small amounts of FSH and LH, showing a low level of activity of the hypothalamic-pituitary-gonadal complex.
2. In agonadal infants and prepubertal children (e.g., in Turner syndrome), secretion of FSH and, to a lesser degree, LH is increased, suggesting that even low levels of hormones secreted by the normal prepubertal gonad inhibit gonadotropin secretion by a sensitive, functional, tonic, negative feedback mechanism (Fig. 25-24).^{241,314,354,386,387}
3. The low level of gonadotropin secretion in childhood is shut off by administration of small amounts of gonadal steroids, showing that the hypothalamic-pituitary gonadotropin unit is highly sensitive (approximately 6 to 15 times more sensitive than in the adult) to the feedback effect of gonadal steroids.^{241,314,388}

Gonadal Steroid–Independent (Intrinsic) Central Nervous System Inhibitory Mechanism. The diphasic pattern of basal and GnRH-induced FSH and LH secretion from infancy to adulthood is similar in normal individuals and in agonadal patients, but in the latter, gonadotropin concentrations are higher, except during the middle childhood nadir.^{386,387} The high plasma concentrations of FSH and LH in agonadal children between infancy and about 4 years of age and the increased gonadotropin reserve reflect the absence of gonadal steroid inhibition (see Fig. 25-24) of the hypothalamic-pituitary unit by the low plasma levels of gonadal steroids.³¹⁴ However, the striking fall in gonadotropin secretion between the ages of 4 and 11 years suggests the presence of a CNS inhibitory mechanism that restrains the hypothalamic GnRH pulse generator, independent of gonadal steroid secretion. The resulting fall in gonadotropin secretion in agonadal children does not result from gonadal steroid feedback (because functional gonads are lacking)

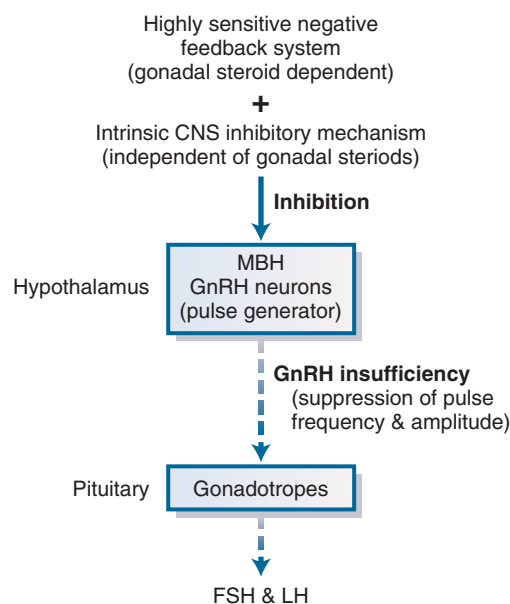

Figure 25-23 Postulated dual mechanism of restraint of puberty involves gonadal steroid-dependent and gonadal steroid-independent processes (i.e., intrinsic central nervous system [CNS] inhibitory mechanism). MBH, medial basal hypothalamus. FSH, follicle-stimulating hormone; GnRH, gonadotropin-releasing hormone; LH, luteinizing hormone. (Modified from Grumbach MM, Kaplan SL. The neuroendocrinology of human puberty: an ontogenetic perspective. In: Grumbach MM, Sizonenko PC, Aubert ML, eds. *Control of the Onset of Puberty*. Baltimore, MD: Williams & Wilkins, 1990:1-68.)

nor from increased secretion of adrenal steroids (because concentrations are low and glucocorticoid suppression of the adrenal does not augment the concentration of circulating gonadotropins).³¹⁴ A CNS steroid-independent inhibitory mechanism for suppression of the hypothalamic GnRH pulse generator seems to be the dominant factor in restraint of puberty between the ages of 4 and 11 years,^{314,389} and a gradual loss of this intrinsic CNS inhibitory mechanism leads to disinhibition or reactivation of the GnRH pulse generator at puberty.

Interaction of the Negative Feedback Mechanism and the Intrinsic Central Nervous System Inhibitory Mechanism. The negative feedback mechanism and the intrinsic CNS inhibitory mechanism appear to interact in restraining puberty (see Fig. 25-24). During the first 2 to 3 years of life, the gonadal-steroid negative feedback mechanism seems to be dominant, but beginning at about 3 years of age, the intrinsic CNS inhibitory mechanism becomes dominant and remains so during the rest of the juvenile pause, as evidenced by the fall in FSH and LH levels between the ages of 3 and 10 years despite the lack of functional gonads. The negative feedback mechanism remains operative during the juvenile pause; agonadal patients in this age group have higher mean plasma FSH levels than normal prepubertal children and a greater FSH and LH response to the acute administration of GnRH.^{386,387} As puberty approaches, the CNS inhibitory mechanism gradually wanes, initially during nighttime sleep, and the hypothalamic GnRH pulse generator becomes less sensitive to gonadal steroid negative feedback (see Fig. 25-24).³¹⁴ After the onset of puberty, gonadal-steroid negative feedback becomes the dominant mechanism in restraining gonadotropin secretion (along with inhibin), as reflected in the

Figure 25-24 Interaction of the negative feedback mechanism and the putative intrinsic central nervous system (CNS) inhibitory mechanism in restraining puberty as extrapolated from the pattern of change in the concentrations of follicle-stimulating hormone (FSH) and luteinizing hormone (LH) in agonadal infants, children, and adolescents. Triangles designate patients with the 45,X karyotype. Circles indicate Turner syndrome patients with X chromosome mosaicism or structural abnormalities of the X chromosome, or both. Notice the values for the 2- and 3-day-old infants. The solid line represents a regression line of best fit. The hatched area indicates the mean plasma values for normal females. To convert FSH values to international units per liter, multiply by 8.4. For about the first 3 years of life, the sensitive gonadal steroid negative feedback mechanism has a dominant role in restraining gonadotropin secretion, as exemplified by the high gonadotropin concentrations in this age group in the absence of gonads (and gonadal steroid feedback). A major role of the intrinsic CNS inhibitory mechanism in this age group is unlikely in light of the rise in gonadotropins to castrate levels in the absence of functional gonads. From 4 to 6 years of age, the postulated intrinsic CNS inhibitory mechanism is dominant, as indicated by the fall in FSH and LH concentrations in the absence of gonads. Even in this age group, the augmented gonadotropin response evoked by GnRH and the slightly higher mean basal gonadotropin concentrations in agonadal individuals support a role, although a subsidiary one, for gonadal steroid negative feedback in the suppression of gonadotropin secretion during this period of the juvenile pause. The investigators suggested that the intrinsic CNS inhibitory mechanism suppresses the functional GnRH pulse generator. After about 10 years of age, the CNS inhibition gradually wanes, resulting in disinhibition of the GnRH pulse generator. The gonadal steroid negative feedback mechanism with an adult-type set point and inhibin play a dominant role in regulating the GnRH pulse generator and pituitary gonadotropin system. For conversion to SI units, see Figure 25-16. (Modified from Grumbach MM, Kaplan SL. The neuroendocrinology of human puberty: an ontogenetic perspective. A diphasic pattern of gonadotropin secretion in patients with the syndrome of gonadal dysgenesis. *J Clin Endocrinol Metab*. 1975;40:670-674. Copyright by The Endocrine Society.)

increased gonadotropin concentrations that are characteristic of the adolescent with severe primary hypogonadism.³¹⁸ The postulated ontogeny of this dual mechanism of restraint of puberty is illustrated in Figure 25-24.

The intrinsic CNS inhibitory mechanism remains elusive.³¹⁹ In the rhesus monkey, despite the damping of the GnRH pulse generator during the juvenile pause, the content of hypothalamic GnRH and GnRH mRNA during this phase is similar to that in the infant or the adult monkey. Low-amplitude LH and FSH pulses are detectable by sensitive and specific immunoradiometric assays in the juvenile pause, demonstrating a low level of activity of the GnRH pulse generator.³¹⁹ The end of the juvenile pause is marked by an increase in LH pulse amplitude that is most evident during the early hours of sleep.

Potential Components of the Intrinsic Central Nervous System Inhibitory Mechanism. Children with CPP associated with posterior hypothalamic neoplasms (usually a pilocytic astrocytoma), irradiation of the CNS, midline CNS developmental abnormalities such as septo-optic

dysplasia with deficiency of one or more pituitary hormones, or other CNS lesions provide indirect evidence for an inhibitory neural component located in or projecting through the posterior hypothalamus. These lesions compromise the neural pathway, which inhibits the hypothalamic GnRH pulse generator and results in its disinhibition and activation leading to CPP.³¹⁴ For example, a suprasellar arachnoid cyst can cause CPP by compressing and distorting the hypothalamus,³¹⁴ but the puberty is reversed with regression of the hormonal and physical features of puberty after decompression of the cyst due to reversal of the disinhibition of the CNS inhibitory mechanism of the posterior pituitary (Fig. 25-25). Precocious sexual maturation can be induced in the juvenile female rhesus monkey by posterior hypothalamic lesions; such lesions advance the age at onset of a pubertal increase in LH secretion and the time of the first positive feedback effects of estrogen.³¹⁹

The GnRH-secreting hypothalamic hamartoma, a heterotypic mass of nervous tissue that contains GnRH neurosecretory neurons³⁹⁰ attached to the tuber cinereum or the floor of the third ventricle, can cause CPP.³⁹¹ The GnRH

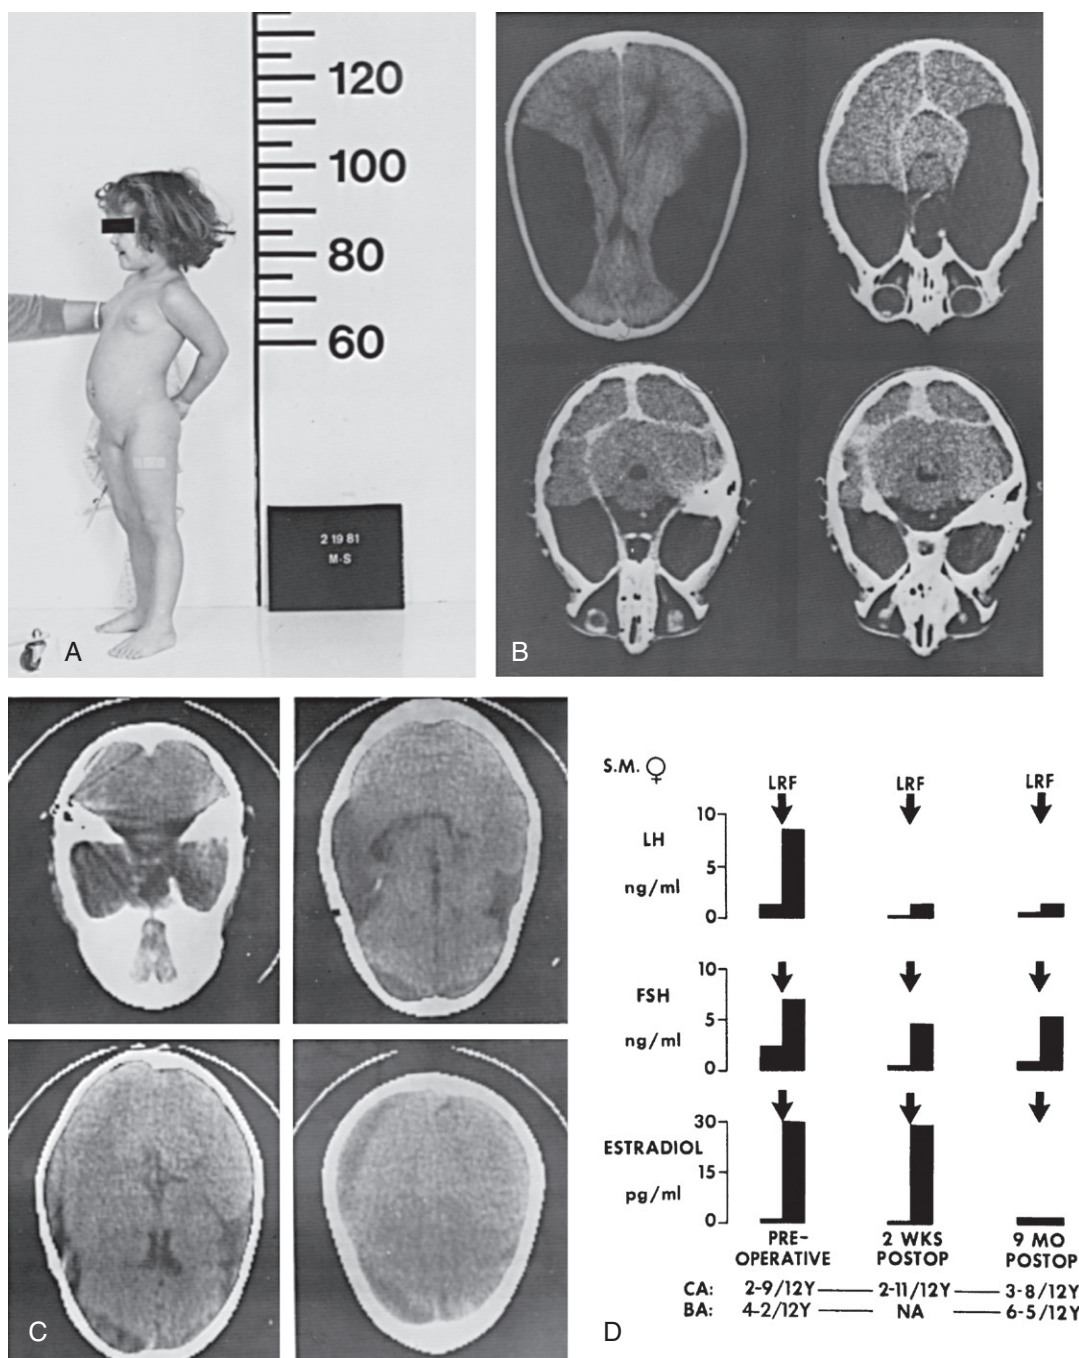

Figure 25-25 **A**, True precocious puberty in a 2.75-year-old girl is caused by a large, bilateral, congenital suprasellar arachnoid cyst. Signs of sexual precocity were observed during the preceding year. The head circumference was +5 SD above the mean value for age, and frontal bossing was present. Breasts were Tanner stage 3. The serum estradiol level was 26 pg/mL, the estrone level was 38 pg/mL, and the dehydroepiandrosterone sulfate (DHEAS) level was less than 3 μ g/dL. The serum luteinizing hormone (LH) concentration rose from 1.4 to 8.7 ng/mL (LER-960) after intravenous administration of gonadotropin-releasing hormone (GnRH), which constitutes a pubertal response. Bone age was 3.5 years. Pelvic ultrasonography showed pubertal-size uterus and ovaries. To convert estrone values to picomoles per liter, multiply by 3.699. To convert DHEAS values to micromoles per liter, multiply by 0.02714. For other conversions, see Figure 25-16. **B**, Cranial computed tomography (CT) scans show a low-density fluid collection in the middle cranial fossa, thinning of the cortex, and striking compression of the lateral and third ventricles. **C**, Cranial CT scans 8 months later, after decompression of the arachnoid cyst and creation of a communication between the cyst and the basal cerebrospinal fluid cisterns and a cystoperitoneal shunt. Notice the striking decrease in size of the fluid collections and expansion of the cerebral cortex. **D**, Basal and peak LH and follicle-stimulating hormone (FSH) concentrations after GnRH administration in SM and serum estradiol values before surgical decompression and 2 weeks and 9 months after surgical decompression of the arachnoid cyst. Notice the prepubertal LH response to GnRH and fall in serum estradiol level by 9 months after surgery. The bone age had increased by 3 years over an 11-month period, but the velocity returned to normal. The patient remained prepubertal during follow-up. (From Grumbach MM, Kaplan SL. The neuroendocrinology of human puberty: an ontogenetic perspective. In: Grumbach MM, Sizzenko PC, Aubert ML, eds. *Control of the Onset of Puberty*. Baltimore, MD: Williams & Wilkins, 1990:1-68.)

Figure 25-26 Hypothalamic hamartoma as an ectopic gonadotropin-releasing hormone (GnRH) pulse generator that escapes the intrinsic central nervous system (CNS) inhibitory mechanism and results in true precocious puberty. Two possible mechanisms are proposed. *Left*, The GnRH neurosecretory neurons in the hamartoma are functioning as a GnRH pulse generator without activation of the suppressed, normally located GnRH pulse generator. *Right*, The hamartoma acts as an ectopic GnRH pulse generator but communicates with and activates (possibly through axonic connections or by GnRH itself) the normally located hypothalamic GnRH pulse generator, which then functions synchronously with the hamartoma.

neurons within the hamartoma with their axon fibers projecting to the median eminence secrete GnRH in pulsatile fashion. We consider the hypothalamic hamartoma to be an ectopic GnRH pulse generator that functions independently of the CNS inhibitory mechanism, which normally restrains the hypothalamic GnRH pulse generator (Fig. 25-26).^{314,391} An analogy can be drawn between the GnRH-secreting hypothalamic hamartoma and the rescue of fertility in GnRH-deficient hypogonadal (hyp/hyg) mice by transplantation of fetal or neonatal hypothalamic tissue into the third ventricle.³⁹² Some rare, large hypothalamic hamartomas that cause CPP contain TGF- α , an astroglia-derived growth factor, with few or no GnRH neurosecretory neurons, raising the possibility that the secretion of TGF- α may interact directly or indirectly to stimulate GnRH release.

Noradrenergic, dopaminergic, serotonergic, and opioidergic pathways; inhibitory neurotransmitters (e.g., GABA); excitatory amino acids (e.g., glutamic acid, aspartic acid); nitrergic transmitters; other brain peptides, including neurotrophic and growth factors; and corticotropin-releasing hormone (CRH) affect the hypothalamic GnRH pulse generator (see Table 25-13).³⁴⁷ Melatonin is not a critical restraining factor in primates, nor are endogenous opioid peptides.^{314,318}

The GnRH pulse generator is inhibited by GABA (the most important inhibitory neurotransmitter in the primate brain) and GABAergic neurons during prepuberty, but exogenous administration of GABA in prepuberty is ineffective because of the high local endogenous GABA levels (Fig. 25-27).³¹⁹ Both GAD65 and GAD67 forms of glutamic acid decarboxylase (GAD), the enzyme that catalyzes the conversion of glutamate to GABA, are present in the mediobasal hypothalamus, the site of the GnRH pulse generator. Antisense oligodeoxynucleotides for GAD67 and GAD65 mRNAs infused into the stalk median eminence of prepubertal monkeys induced a striking increase in GnRH release, whereas nonsense D-oligos did not. These studies provided additional support for GABA arising from interneurons as the intrinsic CNS inhibitor during the juvenile pause of prepuberty.

Figure 25-27 The striking developmental changes in γ -aminobutyric acid (GABA) and gonadotropin-releasing hormone (GnRH) release between the prepubertal and the pubertal rhesus monkey as measured in 10-minute perfusate samples from the stalk of the median eminence. Multiple samples were obtained from each animal. Mean \pm SEM; ** $P < .01$; * $P < .05$ versus prepubertal monkeys. (From Mitsushima D, Hei DL, Terasawa E. γ -Aminobutyric acid is an inhibitory neurotransmitter restricting the release of luteinizing hormone-releasing hormone before the onset of puberty. *Proc Natl Acad Sci U S A*. 1994;91:395-399.)

GABA acting through GABA_A and GABA_B receptors affects GnRH secretion in the perfused mouse GT1 GnRH-releasing neuronal cell line.³⁹³ Conversely, chronic, repetitive administration of bicuculline, a GABA inhibitor, into the base of the third ventricle of a prepubertal monkey caused premature menarche and the onset of the first ovulation.³¹⁹ Although GABA is inhibitory in the juvenile and adult brain it is excitatory early in brain development through the postnatal period, increasing the intracellular Ca²⁺ concentration.³⁹⁴ The switch from dominance of the gonadal steroid-dependent negative feedback mechanism in infancy and early childhood to dominance of the intrinsic CNS inhibitory mechanism may be associated with the developmental switch of GABAergic synaptic transmission from excitatory to inhibitory.

The onset of puberty in the rhesus monkey is characterized by a decrease in GABAergic (and possibly neuropeptide Y [NPY]) inhibition of the hypothalamic GnRH pulse generator and increased release of glutamate,³¹⁹ the major excitatory amino acid neurotransmitter in the hypothalamus. The sensitivity to the stimulatory glutamatergic input into the GnRH pulse generator increases strikingly after the onset of puberty, but it is the reduction in GABAergic inhibition that is the critical factor in disinhibition of the GnRH pulse generator.³¹⁹

A persistent question has been how a single central signal can activate GnRH neurons to cause LH release and bring about ovulation by simultaneous suppression of GABA and stimulation of glutamate release, both of which converge in the anteroventral periventricular nucleus (AVPV). Most neurons in the AVPV of female rats express both vesicular glutamate transporter 2 (VGLUT2), a marker of hypothalamic glutamatergic neurons, and glutamic acid decarboxylase and vesicular GABA transporter (VGAT), markers of GABAergic neurons. These dual-phenotype neurons are twice as prevalent in females than in males and are the main targets of the E2 binding site in the region.³⁹⁵ Moreover, dual-phenotype synaptic terminals contact GnRH neurons, and at the time of the surge, VGAT-containing vesicles decrease and VGLUT2-containing vesicles increase in these terminals. Dual-phenotype GABA/glutamate neurons may act as central transducers of hormonal and neural signals to GnRH neurons to simultaneously decrease GABA and increase glutamate release.

NELL2, a protein containing epidermal growth factor (EGF)-like repeats, is selectively expressed in the glutamatergic neurons containing VGLUT1 and in those expressing VGLUT2 in the postnatal rodent brain. NELL2 mRNA abundance increases selectively in the medial basal hypothalamus of the female rat, reaching a peak at the end of the juvenile period, and declines at the time of puberty with less change observed in the preoptic area. Intraventricular administration of antisense oligodeoxynucleotides to NELL2 reduced GnRH release from the medial basal hypothalamus and delayed the initiation of female puberty. Therefore, NELL2 plays an important role in glutamate-dependent processes of neuroendocrine regulation in puberty.³⁹⁶

Excitatory NMDA stimulates LH release in neonatal³⁹⁷ and adult rats, fetal sheep,³⁴⁷ and prepubertal³¹⁸ and adult rhesus monkeys, and its receptors are widely distributed throughout the CNS, including the hypothalamus.³⁹⁸ NMDA evoked GnRH secretion from rat hypothalamic explants³⁹⁹ from a GnRH neuronal cell line and acutely stimulated the GnRH pulse generator in the ovine fetus but did not have a direct effect on pituitary gonadotrophs.³⁴⁷ Immortalized GnRH neurons contain ionotropic NMDA receptors that mediate the release of GnRH by NMDA.⁴⁰⁰

The prepubertal male rhesus monkey may be forced to enter puberty by repetitive intravenous administration of NMDA; in the prepubertal and pubertal female rhesus monkey, NMDA administered centrally and peripherally induced the release of GnRH.^{319,401}

Description of the role of kisspeptins and their receptors (KISS1R or GRP54) in the CNS hypothalamic-pituitary-gonadal axis led to a flurry of investigation (Figs. 25-28 and 25-29; see Fig. 25-19).^{402,403} KISS1 is a human metastasis suppressor gene at gene map locus 19p13.3, and KISS1 mRNA is found in placenta, testes, pancreas, liver, small intestine, and the brain, mainly in the hypothalamus and basal ganglion.^{404,405} KISS1 mRNA is present in the primate in the medial arcuate nucleus only, but in the mouse, it occurs in the arcuate, periventricular, and anteroventral periventricular nuclei, regions important in reproductive function.^{406,407} The product of the KISS1 gene is a 145-amino-acid peptide, but the cleaved and secreted product is a 54-amino-acid protein known as metastatin or kisspeptin, which binds to an endogenous receptor.

The KISS1 receptor, KISS1R (formerly called GPR54), is a G protein-coupled receptor found in the brain, mainly in the hypothalamus and basal ganglia, and in the placenta, from which it was first isolated and sequenced. KISS1R is coexpressed within GnRH neurons in the rat, in the medial and lateral sections of the arcuate nucleus and the ventral aspect of the ventromedial hypothalamus in mice,⁴⁰⁸ and in primates.⁴⁰⁶ Although the expression of KISS1R mRNA does not increase with development in the mouse, kisspeptin mRNA increases dramatically in the AVPV nucleus, and the number of receptors responsive to kisspeptin increase with development.⁴⁰⁹ Activation of GnRH neurons by kisspeptin at puberty in the mouse reflects a dual process involving an increase in kisspeptin input from the AVPV and a post-transcriptional change in KISS1R signaling within the GnRH neuron. Increases in kisspeptin lead to increased GnRH release by means of an interneuron, rather than acting directly on the GnRH-secreting neurons.⁴¹⁰

Mice transfected with mutant KISS1R genes exhibited hypogonadotropic hypogonadism, although they had normal content of GnRH in their hypothalamus⁴¹¹ and were responsive to GnRH or gonadotropin administration,

Figure 25-28 Inactivating mutations of the gonadotropin-releasing hormone receptor GnRHR (closed circles) and the kisspeptin receptor (KISS1R, formerly GPR54) (open circles) were identified in patients with isolated hypogonadotropic hypogonadism. The dashed line indicates the intracellular domain of KISS1R. The seven-transmembrane G protein-coupled receptor model is used for illustration of both receptors. (From de Roux N. GnRH receptor and GPR54 inactivation in isolated gonadotrophic deficiency. *Best Pract Res Clin Endocrinol Metab.* 2006;20:515-528.)

Figure 25-29 Post-translational maturation of gonadotropin-releasing hormone (GnRH) (top) and kisspeptins (Kp). Doublets of basic residues and glycine are indicated by shaded vertical bars. Enzymes involved in the normal maturation are indicated. PAM, peptidyl glycine α -amidating monooxygenase; PHM, peptidyl α -hydroxylating monooxygenase. (From de Roux N. GnRH receptor and GPR54 inactivation in isolated gonadotropic deficiency. *Best Pract Res Clin Endocrinol Metab.* 2006;20:515-528.)

suggesting normal function of the gonadotroph GnRH receptors and the gonadal LH and FSH receptors despite the mutation. The intact mouse also releases significant LH boluses after kisspeptin administration, an effect that is abolished in the KISS1R^{-/-} mouse, which lacks the receptor.⁴⁰⁸ Underfed prepubertal mice have decreased hypothalamic KISS1, but kisspeptin administration leads to increases in KISS1R mRNA, which in turn leads to increased in vivo LH secretion and in vitro GnRH secretion.³³⁵ Chronic kisspeptin administration to these underfed mice restores vaginal opening and enhances gonadotropin and estrogen responses.

Administration of kisspeptin into the rostral preoptic area (RPOA), medial preoptic area (MPOA), paraventricular nuclei (PVN), and arcuate nuclei of the hypothalamus of male adult rats increased plasma LH and testosterone substantially,⁴¹² and intracerebral kisspeptin administration stimulated the release of FSH, albeit at a far higher dose than needed to stimulate LH release.^{413,414} Because the release of FSH is abolished with blockade of GnRH, GnRH modulates the central actions of kisspeptin in the rodent. In the rat, the mRNA for kisspeptin and its receptor increase at puberty, and administration of intracerebral injection of kisspeptin in prepubertal female rats caused large peaks of LH and advanced vaginal opening as a sign of pubertal development and premature ovulation.^{415,416} The ovulation elicited by peripheral kisspeptin in the prepubertal female rat is abolished by blockade of GnRH.⁴¹⁷

KISS1 and KISS1R mRNA expression is found in the posterior two thirds of the arcuate nucleus of the monkey.⁴¹⁸ Kisspeptin-beaded axons make only infrequent contacts with GnRH neurons in the medial basal hypothalamus, whereas in the median eminence, kisspeptin and GnRH axons were found in extensive and intimate association with GnRH contacts on kisspeptin perikarya and dendrites were observed. Nonsynaptic pathways of communication in the median eminence may offer a possible mechanism of kisspeptin regulation of GnRH release

and provide an anatomic basis for reciprocal control of kisspeptin neuronal activity by GnRH.⁴¹⁹ Although KISS1 increases with puberty in intact male and female monkeys, KISS1R mRNA levels increase in intact females but not in agonadal male monkeys. Administration of KISS1 through intracerebral catheters to GnRH-primed juvenile female rhesus monkeys stimulates GnRH release, but this release is abolished by infusion of GnRH antagonist. These findings have led to the postulation that KISS1 signaling through the KISS1R of primate hypothalamus may be activated at the end of the juvenile pause and may contribute to the pubertal resurgence of pulsatile GnRH release at puberty.⁴⁰⁶ Short-term administration of kisspeptin raises gonadotropin secretion in men and nonhuman primates (Fig. 25-30A). Just as continuous infusion of GnRH suppresses GnRH release, continuous infusion of kisspeptin decreased the response of gonadotrophs in the agonadal male monkey to boluses of kisspeptin. However, the release of FSH and LH after a bolus of NMDA or GnRH was maintained, demonstrating that the desensitization of the KISS1Rs was selective for kisspeptin administration (see Fig. 25-30B).⁴²⁰ This down-sensitization of the KISS1Rs after continuous kisspeptin infusion may have a therapeutic function in CPP in the future, similarly to how GnRH agonists are used.

Administration of testosterone to castrated young male monkeys led to decreased kisspeptin mRNA in the mediobasal hypothalamus, but not in the preoptic area. There was no change in KISS1R expression. This suggests that feedback inhibition of gonadotropin secretion by testosterone is mediated by kisspeptin upstream of the GnRH network.⁴²¹

KISS1R mRNA is expressed in the pituitary gland, and there is evidence that kisspeptin can act directly on the gonadotroph to prompt LH secretion.⁴¹³ In sheep, kisspeptin colocalizes to a high proportion of GnRH receptor cells in the preoptic area, as well as various neuronal fibers within the external neurosecretory zone of the median eminence. This raises the possibility that both kisspeptin and GnRH are secreted into the pituitary portal system to affect the pituitary gland.⁴²² There are also single-labeling KISS1R cells in the preoptic area, and the number rises with ovariectomy.

Spontaneous mutations in the KISS1/KISS1R axis are rare but instructive in elucidating the role of KISS1 in pubertal development; hypogonadotropic hypogonadism and CPP occur with different mutations of KISS1R. These cases, augmented with studies of various animal species, suggest that kisspeptin acting through the KISS1R stimulates GnRH secretion.

NPY has been suggested as a component of the central restraint mechanism³¹⁸ in the male rhesus monkey. A small study of girls demonstrated higher NPY concentrations in those with CDP than in those with normal onset of puberty, supporting this relationship.⁴²³

These observations provide additional evidence that the hypothalamic GnRH neurosecretory neuron is not a limiting factor in puberty, as is the GnRH pulse generator; the anterior pituitary gland, gonads, and gonadal steroid end organs are functionally intact in the fetus and prepubertally and can be fully activated by the appropriate stimulus. CNS restraint of puberty lies therefore above the level of the autorhythmic GnRH neurosecretory neurons in the hypothalamus. Figure 25-31 contrasts the direct and indirect effects of the GABA inhibitory and excitatory amino-acid stimulatory neurotransmitters (as represented by NMDA and other glutamate receptors) on GnRH release. In the primate, the GABA hypothalamic neural network

Figure 25-30 **A**, Effects of kisspeptin-54 (4 pmol/kg/min) or saline infusion in male volunteers (n = 6) on mean plasma. Each volunteer received both kisspeptin-54 and saline infusions and acted as their own controls. **B**, Effect of single sequential boluses of human metastin 45-54 (Met-Kisspeptin 10) (black arrow), N-methyl-D-aspartate (NMDA) (gray arrow), and gonadotropin-releasing hormone (GnRH) (white arrow) on plasma luteinizing hormone (LH) concentrations (mean ± SEM) during the last 3 hours of the 98-hour intravenous infusion (shaded box) of human metastin 45-54 at a dose of 100 µg/hr (closed circles) or vehicle compared with the LH response to the same bolus of human metastin 45-54 1 hour before (day 1) and 21 hours after (day 5) the termination of continuous human metastin 45-54 or vehicle infusion. Infusion of human metastin 45-54 (asterisk) was significantly different ($P < .05$) from the preinjection mean; n = 3. (**A**, From Dhillo WS, Chaudhri OB, Patterson M, et al. Kisspeptin-54 stimulates the hypothalamic-pituitary gonadal axis in human males. *J Clin Endocrinol Metab*. 2005;90:6609-6615; **B**, from Seminara SB, Dipietro MJ, Ramaswamy S, et al. Continuous human metastin 45-54 infusion desensitizes G protein-coupled receptor 54-induced gonadotropin-releasing hormone release monitored indirectly in the juvenile male rhesus monkey (*Macaca mulatta*): a finding with therapeutic implications. *Endocrinology*. 2006;147[5]:2122-2126.)

seems to be the major component of the intrinsic CNS inhibitory mechanism during the juvenile pause.

Sleep-Associated Luteinizing Hormone Release and Onset of Puberty

In sensitive radioimmunoassays, a diurnal rhythm of serum LH, FSH, and testosterone is already demonstrable in 5- to 6-year-olds, short but otherwise normal girls, demonstrating that preparation for the changes of puberty starts long before the physical features and classic endocrine markers of puberty appear.^{237,314,424} Although adult men and women during most phases of the menstrual cycle have little difference in the amplitude or frequency of LH pulses over a 24-hour period, sleep-associated pulsatile release of LH is prominent in early and midpuberty; only in late puberty are prominent LH-secretory episodes detected during the day, but they are still less than during sleep until the adult pattern is achieved. Augmented LH release during sleep leads to a rise in the plasma concentration of testosterone at night in boys, in children with CPP, in glucocorticoid-treated children with CAH who have an advanced bone

age and early onset of true puberty, and in agonadal patients during the pubertal age period, suggesting that it does not depend on gonadal function. There is significantly increased excretion of urinary LH in prepubertal children at night compared with the day.

Sleep-enhanced LH secretion can be viewed as a maturational phenomenon related to changes in the CNS and in the hypothalamic restraint of GnRH release. Episodic release of gonadotropins is suppressed by anti-GnRH antibodies and by the administration of gonadal steroids or certain catecholaminergic agonists and antagonists and is augmented by the opioid antagonist naloxone. Naloxone does not alter the testosterone-mediated suppression of LH, nor does it alter the testosterone effect on LH pulsatility in boys in early to middle puberty.⁴²⁵ We have suggested that an increase in endogenous GnRH secretion at puberty has a priming effect on the gonadotroph²⁴¹ and leads to increased sensitivity of the pituitary to endogenous or exogenous GnRH. In monkeys, a striking increase in pulse amplitude and a lesser increase in pulse frequency occurs between prepuberty and puberty.^{318,319} Sleep-associated LH

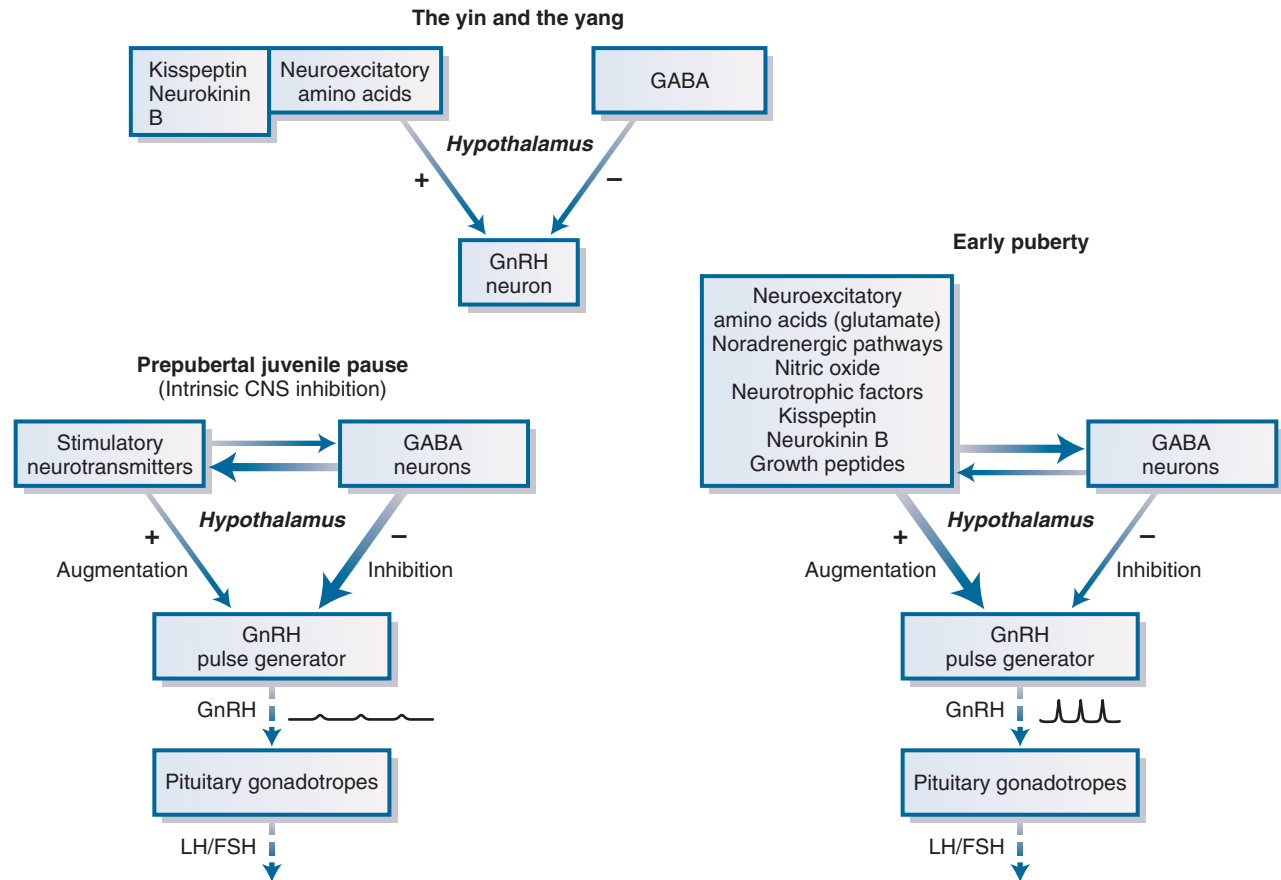

Figure 25-31 The yin and yang of the neuroendocrinology of the prepubertal juvenile pause and its intrinsic central inhibition of the gonadotropin-releasing hormone (GnRH) pulse generator and the reversal of this inhibition and termination of the juvenile pause, which leads to the onset of puberty. The GABAergic neuronal network and its neurotransmitter γ -aminobutyric acid (GABA) constitute the most ubiquitous inhibitory transmitter in the hypothalamus and the brain. During the prepubertal juvenile pause, this neurotransmitter system appears to play the major neural role in inhibiting the GnRH pulse generator. Suppression of GABA inhibition during this period promptly results in reactivation of the suppressed GnRH pulse generator in the rhesus monkey. With the approach of puberty, GABA inhibition of the GnRH pulse generator wanes, and its reactivation gradually occurs. This reactivation likely is augmented by stimulatory neurotransmitters (e.g., kisspeptin excitatory amino acids), some of which depend on increased gonadal steroids for their activation, and by neurotrophic factors and growth peptides. A critical component of the reawakening of the GnRH neuronal network is the increase, independent of sex steroids, in *KISS1* mRNA expression in kisspeptinergic neurons in the medial basal hypothalamus and the secretion of kisspeptins, the cognate ligands for the kisspeptin receptor (*KISS1R*, formerly *GPR54*) on the surface of the GnRH neuron.⁴⁰⁶ As a consequence, the amplitude and, to a lesser extent, the frequency of GnRH pulses increase, which leads to increased pulsatile secretion of follicle-stimulating hormone (FSH) and LH and the activation of the ovary and testis. As shown experimentally in monkeys, the GnRH pulse generator can function in the absence of hypothalamic stimulatory factors. The nature of and factor or factors responsible for this transition from central inhibition and the postulated dominance of GABA in the release of inhibition and reactivation of the GnRH pulse generator are unknown.

release in the peripubertal period correlates with increased sensitivity of the pituitary gonadotrophs to administration of GnRH in the peripubertal period and in puberty and is an indication that the hypothalamic GnRH pulse generator initially is less inhibited during sleep, even in prepubertal children.

Pituitary and Gonadal Sensitivity to Tropic Stimuli

Endogenous GnRH secretion is estimated indirectly and qualitatively by determining the pulsatile pattern of LH and by the gonadotropin response to exogenous GnRH at different stages⁴²⁶ and in disorders of the hypothalamic-pituitary-gonadal system. The release of LH after administration of GnRH is minimal in prepubertal children beyond infancy, increases during the peripubertal period and puberty^{241,314} (Fig. 25-32), and is still greater in adults (depending on the phase of the menstrual cycle in women).⁴²⁷ These results support the concept that the

prepubertal state is characterized by functional GnRH deficiency.^{241,314,315,428} FSH release after the administration of GnRH is comparable in prepubertal, pubertal, and adult males, indicating similar pituitary sensitivity to GnRH, but females release more FSH than males at all stages of sexual maturation.^{241,426} There is a striking reversal of the FSH/LH ratio after administration of GnRH to males or females between prepuberty and puberty (see Fig. 25-32).²⁴¹

These observations suggest a striking change in pituitary sensitivity to GnRH in prepubertal and pubertal individuals and indicate a sex difference in the "dynamic reserve" of pituitary FSH²⁴¹ because the pituitary gonadotrophs of prepubertal females are more sensitive to GnRH than those of prepubertal males, even though the concentration of circulating gonadal steroids is very low in both sexes at that stage of maturation. Prepubertal girls have a larger readily releasable pool of pituitary FSH than prepubertal or pubertal males, possibly related in part to

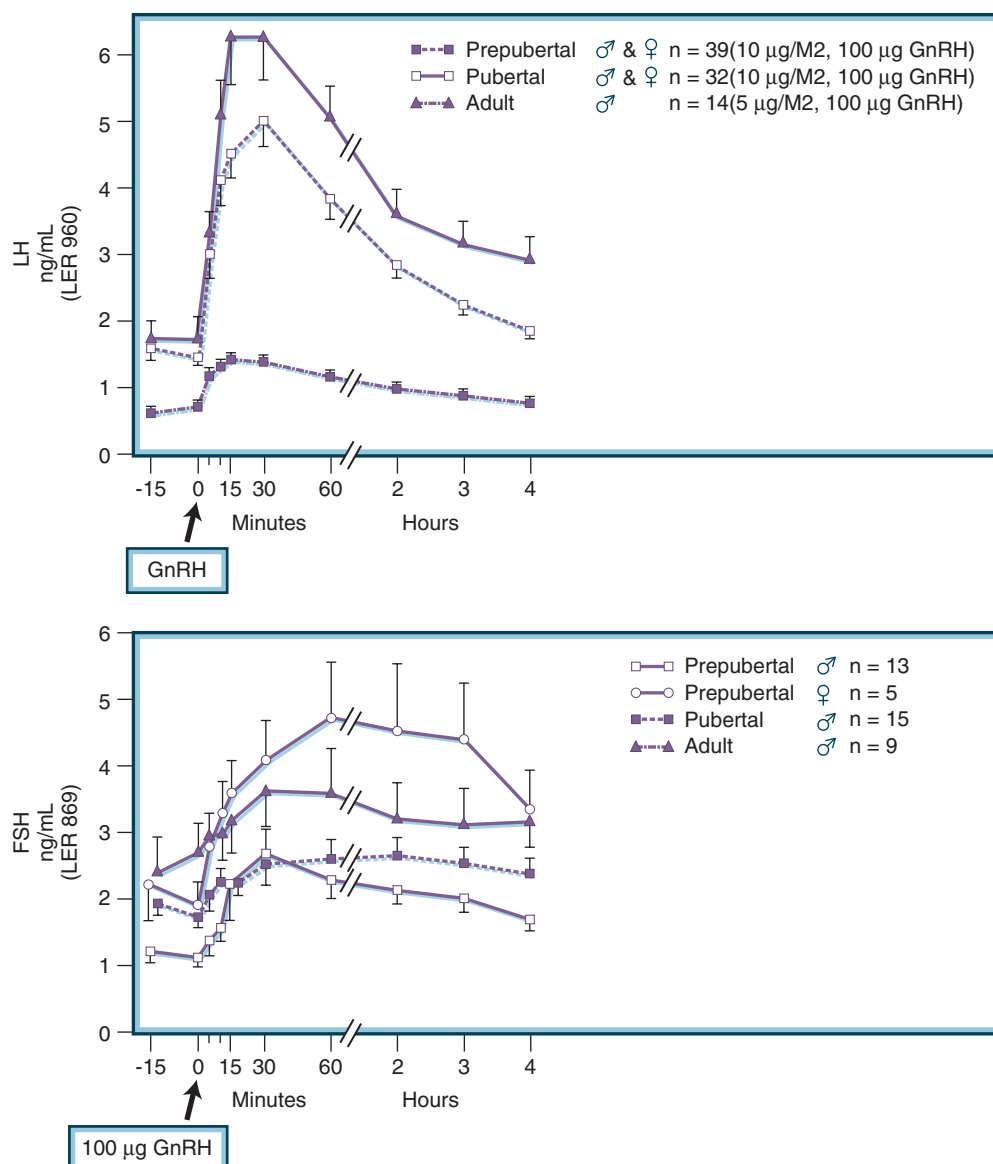

Figure 25-32 Changes in plasma luteinizing hormone (LH) (top) and follicle-stimulating hormone (FSH) (bottom) levels in prepubertal, pubertal, and adult individuals. Notice the limited LH response in prepubertal children compared with that of pubertal and adult subjects. The FSH response to gonadotropin-releasing hormone (GnRH) is similar in prepubertal, pubertal, and adult males. In females, the FSH response is significantly greater than that of prepubertal, pubertal, or adult males. For conversion to SI units, see Figure 25-16. (Modified from Grumbach MM, Roth JC, Kaplan SL, et al. Hypothalamic pituitary regulation of puberty in man: evidence and concepts derived from clinical research. In: Grumbach MM, Grave GD, Mayer FE, eds. *Control of the Onset of Puberty*. New York, NY: John Wiley & Sons, 1974:115-166.)

the higher concentration of inhibin B in prepubertal boys (see Fig. 25-32). These may be factors in the higher frequency of idiopathic CPP in girls and in the occurrence of premature thelarche.⁴²⁹ The available data are consistent with the hypothesis that less GnRH is required for FSH than for LH release.

This change in responsiveness of the gonadotrophs is apparently mediated by increased pulsatile secretion of GnRH^{241,314}; the increased LH response to synthetic GnRH is one of the earliest hormonal markers of puberty onset. Studies of the effects of acute and chronic administration of synthetic GnRH in hypergonadotropic hypogonadism, hypogonadotropic hypogonadism, constitutionally delayed growth and adolescence, and idiopathic precocious puberty indicate that the degree of previous exposure of gonadotrophs to endogenous GnRH appears to affect

both the magnitude and the quality of LH responses—a self-priming phenomenon.^{241,242,430} With the approach of puberty, the derepression of the hypothalamic GnRH pulse generator and the increased pulsatile secretion of GnRH augment pituitary sensitivity to GnRH and enlarge the reserve of LH.⁴³¹ Reduction in the frequency of exogenous GnRH pulses (from one per hour to one every 3 hours) in adult rhesus monkeys with ablative hypothalamic lesions that eliminated endogenous GnRH secretion increased the FSH/LH ratio,⁴³² suggesting that GnRH pulse frequency is one factor affecting relative secretion of FSH and LH. Inhibin and endogenous gonadal steroids may also affect this ratio through action on the hypothalamus or the pituitary, or both.

Pulsatile administration of GnRH to prepubertal monkeys promptly initiates puberty (and ovulatory

menstrual cycles in females) and restores complete gonadal function in adult monkeys with hypothalamic lesions.^{318,433} Similar studies in humans yielded comparable results for prepubertal children, patients with anorexia nervosa, and adults with hypothalamic-hypogonadotropic hypogonadism.^{424,434-436} These results provide further support for reactivation of the hypothalamic GnRH pulse generator as the first hormonal change in the onset of puberty.

Responsiveness of the gonads to gonadotropins increases during puberty. For example, the augmented testosterone secretion in response to administration of hCG at puberty in boys is probably a consequence of the priming effect of the increase in endogenous secretion of LH (in the presence of FSH)⁴³⁷ on the Leydig cell.

Maturation of Positive Feedback Mechanism

Estrogen exerts suppressive effects from late fetal life to peripuberty, when the positive action of endogenous (or exogenous) estradiol on gonadotropin release is not demonstrated.^{241,314,438} A positive feedback effect, which is required for ovulation, is a late maturational event in puberty and probably does not occur before midpuberty in normal girls.^{241,314,438} The positive feedback effect requires an increased concentration of plasma estradiol for a sufficient length of time during the latter part of the follicular phase in later pubertal and adult women.^{328,427}

Among the requirements for the positive feedback action of estradiol on gonadotropin release at puberty²⁴¹ are ovarian follicles that are primed by FSH to secrete sufficient estradiol to reach and maintain a critical level in the circulation; a pituitary gland that is sensitized to GnRH and contains a large enough pool of releasable LH to support an LH surge; and sufficient GnRH stores for the GnRH neurosecretory neurons to respond with an acute increase in GnRH release in addition to the usual adult pattern of pulsatile GnRH secretion (this last requirement is controversial in humans but not in lower animals).

Estrogen exerts effects at the anterior pituitary and the hypothalamus.⁴³⁹ In the rhesus monkey, positive and negative feedback can occur in adult ovariectomized females in whom the medial basal hypothalamus is surgically disconnected from the remainder of the CNS.³¹⁸ In monkeys with hypothalamic lesions, unvarying, intermittent GnRH administration leads to sufficient estradiol release from the ovary to induce an ovulatory LH surge in the absence of an increase in the dose of the GnRH pulses.^{328,433} Estradiol has a positive feedback effect directly on the pituitary gland in normal women, and prolonged administration of estradiol is accompanied by an augmented LH response to GnRH administration. The fact that the major positive feedback action on the pituitary gland is demonstrable in the absence of an increase in pulsatile GnRH secretion suggests that the failure to elicit positive feedback action with administration of estradiol to prepubertal girls may be related to the inadequate GnRH pulses or insufficient LH reserve, or both.

Gonadotropin cyclicity and estradiol-induced positive feedback can be demonstrated by midpuberty and before menarche but may be insufficient to induce an ovulatory LH surge even when there is an adequate pituitary store of readily releasable LH and FSH.^{1,241,355,438} The ovary does not secrete estradiol at a high level or long enough to induce an ovulatory LH surge. We visualize the process leading to ovulation as a gradual one in which the ovary (i.e., the *zeitgeber* for ovulation³²⁸) and the hypothalamic-pituitary-gonadal complex become progressively more integrated and synchronous until an ovary primed for ovulation secretes sufficient estradiol to induce an ovulatory LH surge.³⁵⁵

As many as 55% to 90% of cycles are anovulatory during the first 2 years after menarche, but the proportion decreases to less than 20% of cycles by 5 years after menarche.⁴⁴⁰ The mechanism of ovulation seems unstable and immature, and it does not appear to have attained the fine tuning and synchronization that are requisite for maintenance of regular ovulatory cycles. However, the prevalence of PCOS adds to the irregularity of menses and anovulation in puberty.

Overview of Current Concept

Puberty is not an immutable process; it can be arrested or reversed. Environmental factors and certain disorders that affect the onset or progression of puberty mediate their effects by direct or indirect suppression of the hypothalamic GnRH pulse generator and its periodic oscillatory signal, GnRH. Table 25-14 lists some of these factors.

ADRENAL ANDROGENS AND ADRENARCHE

Speculation has focused on the mechanism of adrenarche (the adrenal component of pubertal maturation), the fact that adrenarche occurs earlier than gonadarche (the maturation of the hypothalamic-pituitary-gonadal system), and the interaction between adrenal and gonadal hormones at puberty.^{284,441,442}

Nature and Regulation of Adrenal Androgens

The major adrenal androgen precursors secreted by the adrenal cortex are DHEA, DHEAS, and androstenedione, which can undergo extraglandular metabolism to produce physiologically active testosterone and estradiol¹⁵⁰; however, adrenal androgens do not directly activate the androgen receptor. DHEA and especially DHEAS (which binds avidly to serum proteins, particularly albumin) are useful biochemical markers of adrenal androgen secretion and the onset of adrenarche. Androstenedione is the major androgen secreted by the ovary during and after puberty, and it is more readily converted to potent androgens than DHEA or DHEAS.

Cross-sectional and longitudinal studies have demonstrated a progressive increase in the plasma concentration of DHEA and DHEAS in boys and girls approximately 2 years before the increase in gonadotropin and gonadal steroid secretion that continues through puberty (13 to 15 years),^{284,443,444} reaches a peak at age 20 to 30 years, and then gradually decreases (Fig. 25-33).⁴⁴² The increase is not associated with increased sensitivity of the pituitary gonadotrophs to GnRH⁴²⁹ or with sleep-associated LH secretion and occurs at an age when the hypothalamic-pituitary-gonadal complex is functioning at a low level.²⁸⁴ The importance of adrenarche is a matter of long-term debate. DHEA is a neurosteroid with parallel patterns of increase along with cortical maturation from approximately age 6 years to the middle 20s, suggesting that adrenarche affects brain development. DHEAS may increase activity of the amygdala and hippocampus and promote synaptogenesis within the cortex, with effects on fearfulness, anxiety, and memory that increase social interaction with unfamiliar individuals and shape cognitive development.⁴⁴⁵

Associated with the increase in adrenal secretion of DHEA and DHEAS (and independent of a change in the secretion of cortisol or aldosterone) is the appearance and growth of the zona reticularis (i.e., the principal source of

TABLE 25-14

Postulated Ontogeny of the Hypothalamic-Pituitary-Gonadal Circuit**Fetus**

Medial basal hypothalamic GnRH neurosecretory neurons (pulse generator) operative by 80 days of gestation
 Pulsatile secretion of FSH and LH by 80 days of gestation
 Initially unrestrained secretion of GnRH (100 to 150 days of gestation)
 Maturation of negative gonadal steroid feedback mechanism by 150 days of gestation—sex difference
 Low level of GnRH secretion at term

Early Infancy

Hypothalamic GnRH pulse generator highly functional after 12 days of age
 Prominent FSH and LH episodic discharges until approximately age 6 mo in males and 18 mo in females, with transient increases in plasma levels of testosterone in males and estradiol in females

Late Infancy and Childhood

Intrinsic CNS inhibition of hypothalamic GnRH pulse generator operative; predominant mechanism in childhood; maximal sensitivity by approximately 4 yr of age
 Negative feedback control of FSH and LH secretion highly sensitive to gonadal steroids (low set point)
 GnRH pulse generator inhibited; low amplitude and frequency of GnRH discharges
 Low secretion of FSH, LH, and gonadal steroids

Late Prepubertal Period

Decreasing effectiveness of intrinsic CNS inhibitory influences and decreasing sensitivity of hypothalamic-pituitary unit to gonadal steroids (increased set point)
 Increased amplitude and frequency of GnRH pulses, initially most prominent with sleep (nocturnal)
 Increased sensitivity of gonadotrophs to GnRH
 Increased secretion of FSH and LH
 Increased responsiveness of gonad to FSH and LH
 Increased secretion of gonadal hormones

Puberty

Further decrease in CNS restraint of hypothalamic GnRH pulse generator and in the sensitivity of negative feedback mechanism to gonadal steroids
 Prominent sleep-associated increase in episodic secretion of GnRH gradually changes to adult pattern of pulses about every 90 min
 Pulsatile secretion of LH follows pattern of GnRH pulses
 Progressive development of secondary sexual characteristics
 Spermatogenesis in males
 Middle to late puberty—operative positive feedback mechanism and capacity to exhibit an estrogen-induced LH surge
 Ovulation in females

CNS, central nervous system; FSH, follicle-stimulating hormone; LH, luteinizing hormone; GnRH, LH-releasing hormone.

Modified from Grumbach MM, Roth JC, Kaplan SL, et al. Hypothalamic-pituitary regulation of puberty in man: evidence and concepts derived from clinical research. In: Grumbach MM, Grave GD, Mayer FE, eds. *Control of the Onset of Puberty*. New York, NY: John Wiley & Sons, 1974:115-166.

DHEA and DHEAS) that occurs coincidentally with adrenarche (Fig. 25-34).

In contrast to the zona glomerulosa and fasciculata, four main features distinguish the zona reticularis:

1. There is a low level of expression of 3β -HSD/ $\Delta^{4,5}$ -isomerase type 2 and CYP21 mRNAs and enzyme activities.⁴⁴⁶
2. Abundant dehydroepiandrosterone (hydroxysteroid) sulfotransferase activity is found.⁴⁴⁷
3. There is a relative increase in 17,20-lyase versus 17α -hydroxylase activity of CYP17, the enzyme that

catalyzes both activities.⁴⁴⁷ These characteristics are shared by the fetal zone of the fetal adrenal cortex.⁴⁴⁷

4. There is expression of major histocompatibility complex (MHC) class II (HLA-DR) antigens,⁴⁴⁸ which are not expressed in the fetal zone of the fetal adrenal cortex.

In contrast to the zona fasciculata, the zona reticularis has an increased ratio of 17,20-lyase to 17α -hydroxylase. An Arg347Ala mutation in human CYP17 resulted in

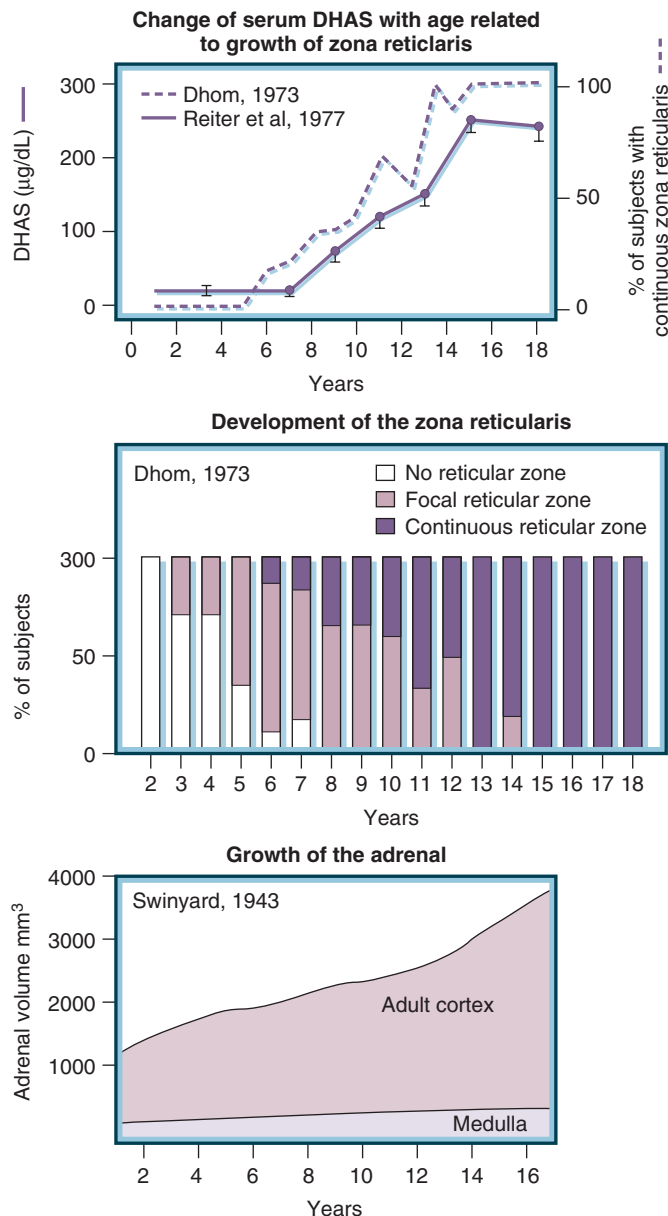

Figure 25-33 Relation of plasma dehydroepiandrosterone sulfate (DHEAS [DHAS]) levels to growth of the zona reticularis and increase in adrenal volume with age. *Top*, The close correlation between the development of the zona reticularis and the increase in the plasma DHEAS level. *Middle*, The age at which focal islands of reticular tissue or a continuous reticular zone was found in a series of patients with sudden death who had not had an antecedent illness. *Bottom*, The increase in adrenal volume at the time of puberty. For conversion to SI units, see Figure 25-26. (From Grumbach MM, Richards HE, Conte FA, et al. Clinical disorders of adrenal function and abnormal puberty: assessment of the role of the adrenal cortex and abnormal puberty in man and evidence for an ACTH-like pituitary adrenal androgen stimulating hormone. In: James VHT, Serio M, Giusti G, et al., eds. *The Endocrine Function of the Human Adrenal Cortex*. New York, NY: Academic Press, 1978:583-612.)

Figure 25-34 Adrenarche and the zona reticularis. The rise in circulating dehydroepiandrosterone sulfate (DHEAS) levels is the biochemical hallmark of adrenarche. The diagram compares and contrasts the major steroidogenic pathway in the zona fasciculata with that in the zona reticularis. In contrast to the zona fasciculata, the expression of 3 β -hydroxysteroid, Δ^4 isomerase type 2 messenger ribonucleic acid (mRNA), and its activity (the enzyme that irreversibly traps Δ^5 precursors into Δ^4 steroids) is very low in the zona reticularis, whereas the expression of and activity of steroid sulfotransferase is high. A single gene, *CYP17* (now designated *CYP17A1*), encodes a single enzyme that has 17 α -hydroxylase and 17,20-lyase activity, but the ratio of 17,20-lyase to 17 α -hydroxylase activity is relatively high in the zona reticularis compared with that in the zona fasciculata. Some of the factors that seem to amplify the increased 17,20-lyase activity of *CYP17* are the augmented serine phosphorylation of the enzyme and the apparent increased abundance of the electron-donating redox partner, including P450 reductase and of cytochrome *b*₅.

strikingly decreased 17,20-lyase activity but retention of 17 α -hydroxylase activity.^{449,450} Two XY phenotypic females with hypergonadotropic hypogonadism and normal mineralocorticoid and glucocorticoid function had isolated 17,20-lyase deficiency due to homozygous mutations at the Arg347 or the Arg358 residue in *CYP17*.⁴⁵⁰

In contrast to these observations of loss of 17,20-lyase activity with retention of 17 α -hydroxylase activity, the ratio of human 17,20-lyase to 17 α -hydroxylase activities was increased by increased phosphorylation of serine and threonine residues on the *CYP17* enzyme⁴⁵¹ and by the increased abundance of redox partners such as cytochrome P450 oxidoreductase and by cytochrome *b*₅, which preferentially promotes 17,20-lyase activity by allosterically affecting the interaction between *cyp17* and P450 oxidoreductase.^{449,452} These studies provided a provisional hypothesis of the mechanisms that appear to be involved in the relatively increased 17,20-lyase activity of the zona reticularis, although not its regulation (see Fig. 25-34).

Regulation of adrenal androgen secretion in the zona reticularis is postulated to be based on a dual-control mechanism. First, corticotropin (ACTH, adrenocorticotropin) is obligatory, as evidenced by the findings in cases of ACTH deficiency or resistance.⁴⁵³ Second, the mechanism requires the action of an unidentified adrenal androgen-stimulating factor, possibly pituitary in origin or from a nonadrenal source, or an intra-adrenal event.²⁸⁴ This concept is illustrated in Figure 25-35.^{284,313,441,449,454}

CRH has been advanced as an adrenal androgen secretagogue that has stimulatory action on the zona reticularis. The intravenous infusion of human CRH into dexamethasone-suppressed young men increased DHEA, DHEAS, and androstenedione secretion within 3 hours. Similar results were obtained in adolescent girls with hyperandrogenism and a history of premature adrenarche.⁴⁵⁵ CRH directly stimulates DHEAS secretion and the expression of *CYP17* by the fetal adrenal cortical cells.⁴⁵⁶ Leptin in vitro vigorously stimulates 17,20-lyase activity and transiently stimulates 17 α -hydroxylase activity of the microsomal

enzyme *CYP17*, implying a role in adrenarche,⁴⁵⁷ but no clinical evidence suggests a pivotal role of leptin in adrenarche. Therefore, a distinct hormone or factor that in addition to ACTH stimulates the zona reticularis and adrenal androgen secretion has not been isolated, and the mechanism regulating adrenarche remains unknown.⁴⁵⁸

A distinct adrenal androgen-stimulating factor, whether of pituitary, intra-adrenal, or other origin, may explain the following observations²⁸⁴:

1. The spurt in adrenal growth and the differentiation and growth of the zona reticularis at adrenarche occur independently of an increase in ACTH or cortisol secretion but correlate with the increase in plasma levels of DHEAS (see Fig. 25-34).
2. Cortisol and adrenal androgen secretions vary independently with age, during normal and premature adrenarche, and in Cushing's disease, starvation, malnutrition, anorexia nervosa, and chronic disease.
3. Unlike cortisol secretion, the secretion of DHEA and DHEAS in response to ACTH administration varies with age.
4. Dissociation of adrenarche and gonadarche occurs in a variety of disorders of sexual maturation (see Fig. 25-35), including premature adrenarche (i.e., onset of pubic or axillary hair before 8 years of age), chronic adrenal insufficiency, CPP (when the onset is before age 6 years), primary hypogonadism, isolated gonadotropin deficiency, and anorexia nervosa.⁴⁴²

A longitudinal study of 42 children demonstrated that an increase in BMI (but not the value itself at any age) was related to the rise in urinary excretion of DHEAS, suggesting that a change in nutritional status is one physiologic regulator of adrenarche.⁴⁵⁹

Adrenal Androgens and Puberty

The earlier onset of adrenarche than gonadarche and the contribution of adrenal androgens to the growth of pubic and axillary hair have led some to suggest that adrenal

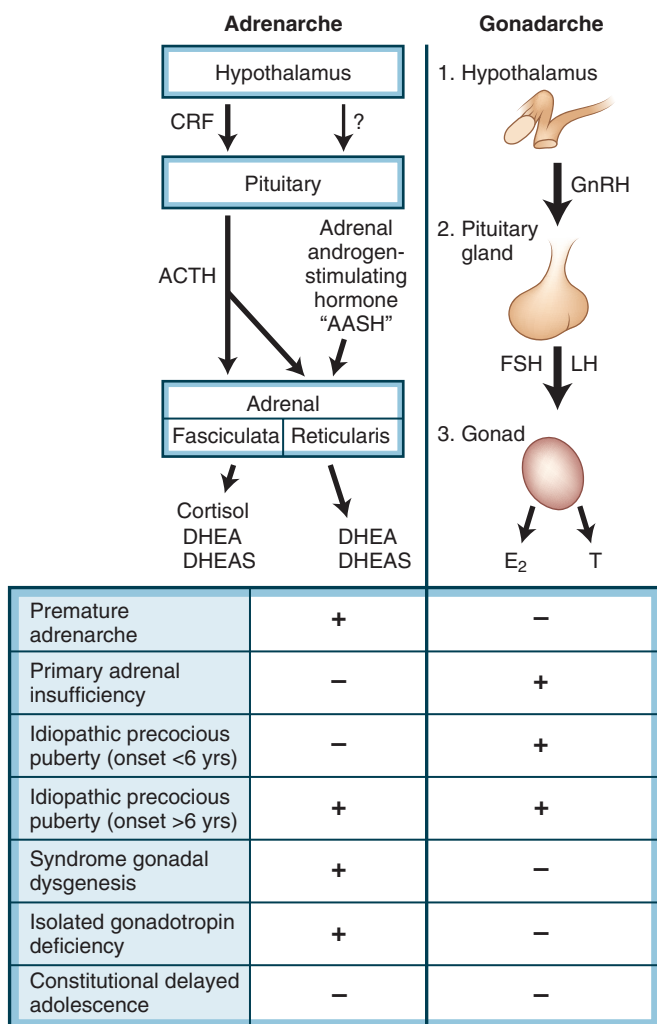

Figure 25-35 Hypothesis of the control of pituitary adrenal androgen secretion by a putative separate adrenal androgen-stimulating hormone acting on a corticotropin (ACTH)-primed adrenal cortex. Although this diagram suggests that adrenal androgen-stimulating hormone (AASH) arises from the pituitary gland, a distinct pituitary factor with AASH activity has not been isolated; an extrapituitary factor is not excluded. The lower part of the diagram shows the relationship of adrenarche to gonadarche, including dissociation in various clinical disorders of sexual development (+, present; —, absent). (Modified from Sklar CA, Kaplan SL, Grumbach MM. Evidence for dissociation between adrenarche and gonadarche: studies in patients with idiopathic precocious puberty, gonadal dysgenesis, isolated gonadotropin deficiency, and constitutionally delayed puberty. *J Clin Endocrinol Metab*. 1980;51:548-556. Copyright by The Endocrine Society.)

androgens in normal children are an important factor in the onset of puberty and the maturation of the hypothalamic-pituitary-gonadal complex.

Although CPP may occur when the prepubertal child has previously been exposed to excessive levels of androgens from an endogenous or exogenous source (e.g., after the initiation of glucocorticoid therapy in congenital virilizing adrenal hyperplasia, after removal of a sex steroid-secreting adrenal or gonadal neoplasm),^{284,460} there is little evidence that adrenal androgens play an important qualitative or rate-limiting role in the onset of puberty in normal children.²⁸⁴ Most patients with premature adrenarche, who secrete excessive amounts of adrenal androgens for their age, enter puberty and experience menarche within the normal age range.²⁸⁴ Moreover, prepubertal children who have congenital or acquired chronic adrenal insufficiency

(i.e., Addison's disease) and consequently have deficient or absent adrenal androgen secretion usually have a normal onset and normal progression through puberty when given appropriate glucocorticoid and mineralocorticoid replacement therapy.²⁸⁴ Studies of children with chronic adrenal insufficiency, isolated gonadotropin deficiency, hypergonadotropic hypogonadism, or androgen resistance suggest that adrenal androgens in girls and boys are not essential for the adolescent growth spurt, whereas gonadal steroids secreted by the testis and ovary are essential and act in concert with GH.²⁸⁴ The transient increase in height velocity (about 1.5 cm/year in both sexes) that occurs in middle childhood (6 to 7 years) and lasts about 2 years terminates while the serum DHEAS level continues to increase. This increase in height velocity is related to the cyclic pattern of prepubertal growth and to genetic regulation of growth rather than to an increase in adrenal androgen or GH secretion.^{451,461}

DISORDERS OF PUBERTY

Delayed Puberty and Sexual Infantilism

The upper limits of the normal age of onset of puberty are 14 years for boys and 13 years for girls (Table 25-15). Functionally, delayed puberty can be divided into disorders that affect the operation of the GnRH pulse generator, the pituitary gland, or the gonad.

Idiopathic or Constitutional Delay in Growth and Puberty

Otherwise healthy girls who spontaneously enter puberty after the age of 13 years and boys who begin after 14 years have constitutional delay in growth and adolescence, the most common diagnosis for delayed puberty. Affected individuals usually are short (2 SD below the mean value of height for age) at evaluation and have been shorter than their classmates for years, although growth velocity and height are usually appropriate for bone age (Fig. 25-36 and Table 25-16). Family history in as many as 77% of cases reveals a mother who had delayed menarche or a father (or sibling) who entered puberty late (i.e., age 14 to 18 years), and the pattern in some cases suggests dominant inheritance with incomplete penetrance.^{462,463} Constitutional delay in development is physiologic immaturity with a slow tempo of maturation; full sexual maturity will be reached, but the process takes longer than usual. Because of delay in reactivation of the GnRH pulse generator, there is functional deficiency of GnRH for chronologic age but not for the stage of physiologic development. Adrenarche and gonadarche occur later in individuals with constitutional (idiopathic) delay in growth and adolescence,⁴⁶² whereas adrenarche usually occurs at a normal age in patients with isolated gonadotropin deficiency.⁴⁴² Bone age is delayed at presentation, but after a bone age of approximately 12 to 14 years for boys or 11 to 13 years for girls is achieved, sexual maturation begins, although bone age is not a fully reliable indicator.

Most of these patients with CDP are thin, but 25% are above the 85th percentile in BMI for age, and their bone age is less delayed than in classic thin patients (i.e., they tend to achieve taller adult stature).⁴⁶² There is no impairment of olfaction, as in Kallmann's syndrome, and undescended testes are uncommon. Plasma gonadal steroid levels are low in pediatric assays at the time of presentation, but as bone age advances, the serum gonadotropin

concentration and the amplitude of LH pulses increase (initially at night); the basal serum gonadotropin concentrations measured by third-generation assays and the LH response to GnRH or GnRH agonists reflect maturation of the hypothalamic-pituitary system.

The first signs of secondary sexual development occur within 1 year after LH rises to pubertal levels in response to administration of 100 µg of intravenous synthetic GnRH or subcutaneous GnRH agonist or within 1 year after

gonadotropin and testosterone or estradiol concentrations begin to increase spontaneously above prepubertal values.^{241,314} An 8 a.m. serum testosterone value of 0.7 nmol/L (20 ng/dL) heralds the development of phenotypic puberty in boys within 12 to 15 months.⁴⁶⁴ CDP is more common in boys and may be a counterpart of idiopathic CPP, a condition that is many times more common in girls. Familial short stature is a physiologic variant of growth in which the velocity of development and bone age

Figure 25-36 A boy age 16 years and 2 months has constitutional delay in growth and puberty. His height is 149.5 cm (4 SD below the mean value for age); upper-to-lower body ratio is 1.1 (retarded for age); phallus is 6.0×1.6 cm; testes are 2.5×1.4 cm; and the scrotum showed early thinning. At a chronologic age of 15 years and 4 months, the bone age was 11 years and the sella turcica was normal. The plasma concentration of luteinizing hormone (LH) was 0.7 ng/mL (LER-960); the concentration of follicle-stimulating hormone (FSH) was 0.5 ng/mL (LER-869). On gonadotropin-releasing hormone (GnRH) testing, the plasma concentration of LH increased to 2.2 ng/mL (an increment of 1.5 ng/mL), and the testosterone level rose from 52 to 77 ng/dL. The testes subsequently spontaneously enlarged, and the patient progressed through puberty. For conversion to SI units, see [Figures 25-16 and 25-17](#). (From Styne DM, Grumbach MM. Puberty in the male and female: its physiology and disorders. In: Yen SCC, Jaffe RB, eds. *Reproductive Endocrinology*, 2nd ed. Philadelphia, PA: Saunders, 1986:313-384.)

are normal but stature is decreased, in contrast to CDP, which is a disorder of tempo that secondarily impairs growth. The combination of CDP and familial short stature leads to conspicuous shortness during adolescence, especially when other children increase their growth velocity, and referrals occur more often with this combination than with either condition alone. Because no single test reliably

distinguishes between CDP and isolated hypogonadotropic hypogonadism (IHH), watchful waiting is usually in order.

The growth rate before the actual onset of puberty in constitutional delay is often suboptimal for chronologic age, but growth velocity usually increases to normal levels after puberty begins.⁴⁶⁵ Affected boys seem to be more distressed by short stature than by delay in sexual development.

GH release in the basal state and in response to GH secretagogues, including the administration of GHRH, is low for age and may be decreased further in children with CDP, but the amplitude of GH secretion and the GH response to GHRH is greater after administration of exogenous (aromatizable) androgens or estrogens. Therefore, CDP may constitute a temporary state of functional GH insufficiency for chronologic age but not for bone age. IGF1 interacts with gonadotropins in the ovary and testis, and the relatively low secretion of GH (and presumably intragonadal IGF1) in CDP may impair the gonadal response to gonadotropins.⁴⁶⁶

Patients with constitutional delay in adolescence and growth do not reach their predicted height in some reports,⁴⁶⁷ especially if the family is tall. Girls with CDP⁴⁶⁸ have a mean deficit in adult height of 2.4 cm below the mean predicted height, although the range of adult height varies about 10 cm above or below predictions. An alternative explanation for reduced adult stature is that the patients most likely to be referred are those that combine genetic short stature with CDP.⁴⁶⁷ The magnitude of the catch-up in linear growth during puberty in boys is a major determinant of adult height.⁴⁶⁹ Heavier individuals with CDP reach greater height than those who are thinner.⁴⁶² When the genetic tendency for growth is greater, subjects with CDP reach taller adult stature. The role of bone density in CDP was discussed earlier.

Because 15% to 20% of adult height is gained during puberty, many approaches have been tried to increase stature in otherwise normal, short children. Delaying the onset or progression with puberty by the use of GnRH agonists was suggested by some, but a decrease in bone density 1 year after cessation led to warnings that routine administration of this treatment carries substantial risk.⁴⁷⁰ The additional psychological risk of delaying puberty in otherwise normal children should also be considered, and this treatment is neither established nor recommended.

Although GH therapy seemed likely to increase adult height in CDP, results from initial clinical trials were disappointing.⁴⁷¹

The U.S. Food and Drug Administration (FDA) approved GH treatment for children who are predicted to reach an adult height less than the 1st percentile (160 cm), which includes some children with CDP, and some studies reported an increase in adult height with this treatment. The GH level rises during pubertal development, and the FDA approved GH therapy in larger doses for subjects with GH deficiency during puberty. However, there are only moderate effects of increased GH doses during puberty on adult height, and both overshadow, although male gender has a positive effect and age at onset of puberty has a negative effect, the effects of the change in dose on adult height.⁴⁷²

The combination of GnRH agonist therapy with GH treatment in attempts to increase adult height in children who were normal except for genetic short stature and in SGA children led to inconclusive results or to increased predicted or near-final height, which does not necessarily translate into increased adult height. This approach to treatment remains experimental. Review of a large database

TABLE 25-16

Constitutional Delay in Growth and Adolescence

A variation of normal
Males more often seek assistance
Family history of delayed menarche or delayed secondary sexual characteristics
Height is often below the 5th percentile, but growth rate is normal for skeletal age
Onset of adrenarche is delayed
The combination of genetic short stature and constitutional delay leads to more profound short stature
Final height is less than predicted

from a postmarketing survey did not support the efficacy of this approach,⁴⁷³ and there was no good follow-up evaluation of adult height. This combination therapy cannot be supported by substantial evidence.⁴⁷⁴

The cost of GH for treatment of non-GH-deficient short stature is exceptionally high: \$14,000 per cm or \$35,000 per inch gained.⁴⁷⁵ Payers are reluctant in many cases to cover the cost of the GH therapy for those without confirmed GH deficiency. There are few controlled studies of adult height, but more such studies are strongly recommended to determine the efficacy of this treatment in short, normal children.⁴⁷⁶

Because the critical role of estradiol in skeletal maturation was appreciated, treatment with a potent aromatase inhibitor to increase adult height by inhibiting skeletal maturation aroused interest.^{150,151,257} A double-blind, randomized, placebo-controlled study enrolled boys with CDP who were treated with 6 months of monthly testosterone or testosterone plus an added 12-month trial of daily oral letrozole (a potent fourth-generation aromatase inhibitor). The results revealed a mean increase in predicted adult height of 5.1 cm in the letrozole plus testosterone group⁴⁷⁷; a subsequent study supported these promising effects on increasing the time of pubertal growth height without affecting the development of male secondary sex characteristics, but there are few data on actual adult height.⁴⁷⁷ The boys in the group treated with testosterone and letrozole developed increased bioactive testosterone, analyzed by a cellular assay, compared with control boys.²⁴⁹ Serum

testosterone measured by HPLCMS/MS can reach levels of more than 1000 ng/dL. However, markers of bone turnover decrease, and vertebral abnormalities may develop with the use of these agents in idiopathic short stature.⁴⁷⁸ A 1-year study of the aromatase inhibitor anastrozole plus GH, compared with GH treatment alone, in boys demonstrated no ill effects on body composition, plasma lipids, bone metabolism, or the tempo of puberty (although estrogen decreased, as expected with the use of anastrozole), and the predicted height was increased.⁴⁷⁹ This treatment has not been supported by long-term studies observing patients up to adult height, and concerns about possible effects on bone density must be addressed, probably until the patients are at least 20 to 25 years old, before this off-label therapy can be recommended.⁴⁸⁰

Hypogonadotropic Hypogonadism: Sexual Infantilism Related to Gonadotropin Deficiency

Insufficient pulsatile secretion of GnRH and the resulting FSH and LH deficiency lead to delayed sexual maturation. The phenotype in hypogonadotropic hypogonadism can vary from severe sexual infantilism to apparent CDP (both conditions may be found in the same family⁴⁸¹). There may be an absolute or relative quantitative deficiency of pulsatile GnRH, or the deficiency may be qualitative, especially in females; it may involve abnormalities in amplitude or frequency of GnRH pulses or in both components (Fig. 25-37).

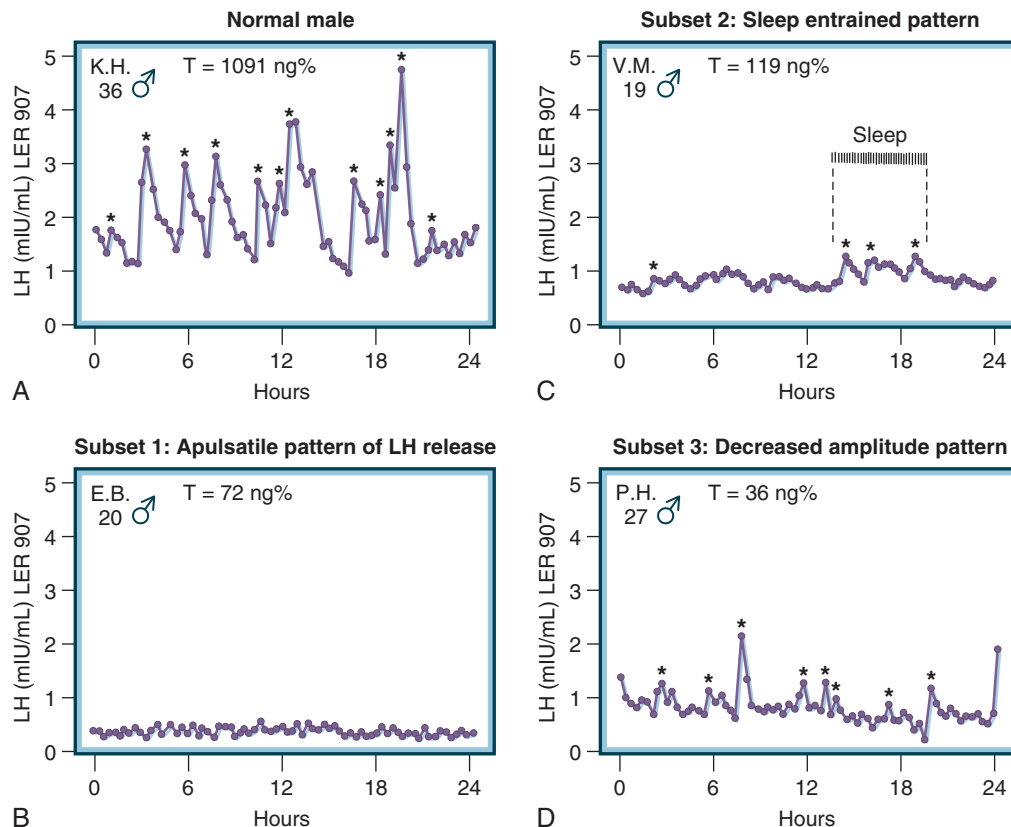

Figure 25-37 Various patterns of pulsatile luteinizing hormone (LH) secretion that can occur in isolated hypogonadotropic hypogonadism (**B** to **D**) are compared with LH secretion in a normal man (**A**). **A**, Discrete LH pulses occur about every 2 hours in a normal 36-year-old man. **B**, Typical apulsatile LH pattern is associated with a low testosterone concentration usually found in isolated hypogonadotropic hypogonadism. **C**, Pattern of developmental arrest with low-amplitude nocturnal LH pulses is apparent only during sleep. **D**, Low-amplitude LH pulse pattern occurs during sleep and wake periods. To convert LH values to international units per liter, multiply by 1.0. (From Spratt DL, Crowley WF. Hypogonadotropic hypogonadism: GnRH therapy. In: Krieger DT, Bardin CW, eds. *Current Therapy in Endocrinology and Metabolism*, 1985-1986. Toronto, Canada: BC Decker, 1985:155-159.)

Patients with IHH usually are of normal height in early or middle adolescent years, whereas patients with CDP usually have a normal growth rate for bone age but are short for chronologic age. In contrast to CDP patients, those with hypogonadotropic hypogonadism usually do not respond to GnRH stimulation, nor do they have a pulsatile LH profile commensurate with bone age. Although serum concentrations of plasma FSH and LH and urinary gonadotropins are low, the differences are relative rather than absolute and are not diagnostic for an individual.

Hypogonadotropic hypogonadism may result from a genetic or developmental defect present at birth but remain undetected until the age of expected puberty, or it may be caused by a tumor, inflammatory process, vascular lesion, irradiation, or trauma to the hypothalamus. Similarly, hypogonadotropic hypogonadism may arise from lesions or defects that involve the pituitary gland directly. When GH is affected as well as gonadotropins, impaired growth is manifested by decreased growth velocity, especially during the expected pubertal growth spurt, and short stature.

Central Nervous System Tumors

Extrasellar masses may interfere with GnRH synthesis, secretion, or stimulation of pituitary gonadotrophs. Most patients with hypothalamic-pituitary tumors causing gonadotropin deficiency have one or more additional pituitary hormone deficiencies (or an increased serum prolactin level with prolactinomas). Those with GH deficiency due to a neoplasm have late onset of growth failure compared with those who have idiopathic and familial hypopituitarism, in which growth failure starts early in life. The presence of anterior and posterior pituitary deficiencies in infancy suggests a midline developmental defect, but the development of this combination after infancy ominously suggests an expanding CNS lesion.

Craniopharyngioma. Craniopharyngioma is a common CNS neoplasm of nonglial origin. It is the most common

brain tumor associated with hypothalamic-pituitary dysfunction and sexual infantilism and comprises 80% to 90% of neoplasms found in the pituitary and up to 15% of all intracranial tumors in childhood.⁴⁸² This tumor of the Rathke pouch originates from epithelial rests along the pituitary stalk that extend superiorly to the hypothalamus. Craniopharyngiomas may reside within or above the sella turcica, or, more rarely, they may be found in the nasopharynx or the third ventricle. Craniopharyngioma appears to be a monoclonal tumor, and about 50% have cytogenetic abnormalities such as gains in 1q, 12q, and 17q or β -catenin gene mutations in the case of the uncommon adamantinomatous craniopharyngioma.⁴⁸²

Craniopharyngiomas are usually symptomatic before age 20 years, with the peak incidence occurring between the ages of 6 and 14 years. CNS signs develop as the tumor encroaches on surrounding structures. Symptoms of craniopharyngioma include headache, visual disturbances, short stature, diabetes insipidus, vomiting, and weakness of one or more limbs. Visual defects (including bilateral temporal field deficits), optic atrophy or papilledema, and signs of GH deficiency, delayed puberty, and hypothyroidism are features of craniopharyngiomas.⁴⁸³ Although most patients are below the mean in height and height velocity at diagnosis, a long, indolent course is possible. Deficiencies of gonadotropins, GH, thyrotropin (TSH), ACTH, and arginine vasopressin are common. The serum concentration of prolactin is normal or increased. Delayed bone age is common and may point to the onset of tumor growth.

About 70% of patients with a craniopharyngioma have suprasellar or intrasellar calcification (found in fewer than 1% of normal individuals) and an abnormal sella turcica, which are sometimes found on radiographs taken for other indications, including orthodontia.⁴⁸³ CT (but not MRI) reveals fine calcifications that are not apparent on lateral skull radiographs, and CT or MRI with contrast (the diagnostic procedure of choice) can determine whether the tumor is cystic or solid and indicate the presence of hydrocephalus (Fig. 25-38).⁴⁸⁴

Figure 25-38 Craniopharyngioma in a short 5-year-old girl with a history of frontal headaches, impaired vision, and poor growth. *Left*, Midline, sagittal, T1-weighted image shows a hyperintense region superiorly and an inferior hypointense region. The combination of hyperintense and hypointense areas in a non-contrast-enhanced examination is the most characteristic finding for craniopharyngioma. Notice the erosion of dorsum sellae (solid arrow) and posterior pituitary bright spot. *Right*, Coronal, T1-weighted image shows tumor extending upward to the inferior frontal horns, narrowing the foramen of Monro, and causing mild hydrocephalus. The open arrows indicate the upper border of the hyperintense area of the tumor.

Smaller craniopharyngiomas, usually intrasellar, can be treated by transsphenoidal microsurgery, but larger or suprasellar masses usually require craniotomy, and the approach must be individualized. The combination of limited tumor removal and radiation therapy leads to a satisfactory neurologic prognosis, better cognitive outcome, and better endocrine outcome compared with attempts at complete surgical extirpation.⁴⁸³ Frequent and early tumor relapse after apparently complete resection and tumor progression after incomplete resection suggest the wisdom of radiation therapy after surgery.⁴⁸⁴ Postoperative hyperphagia and obesity (BMI >5 SD above normal) can be striking and correlate with the magnitude of hypothalamic damage on cranial MRI. Injury to the hypothalamic ventromedial nuclei (associated with increased parasympathetic activity and hyperinsulinemia) or to the paraventricular nuclei may cause these findings, and insulin suppression may be helpful.⁴⁸⁵ Aberrant sleep patterns and even narcolepsy and daytime somnolence may follow surgical treatment of craniopharyngiomas, with melatonin improving sleep patterns in some.⁴⁸⁶ Although the endocrine complications are more manageable, the combination of antidiuretic hormone insufficiency (i.e., diabetes insipidus) and impaired sense of thirst remains a complex management problem.

A Rathke-cleft cyst is often discovered as an incidental finding on MRI, but it can produce symptoms and signs indistinguishable from those of a craniopharyngioma, such as precocious or delayed puberty.⁴⁸⁷ Surgical drainage and excision of the cyst wall are customary.

Other Extrasellar Tumors. Germinomas (i.e., pinealomas, ectopic pinealomas, atypical teratomas, or dysgerminomas) and other germ cell tumors of the CNS are the most common extrasellar tumors that arise in the suprasellar hypothalamic region and in the pineal region that commonly cause sexual infantilism. Peak incidences occur in the second decade and during infancy. They are found more often in males.⁴⁸⁸ Polydipsia and polyuria are the most common symptoms, followed by visual difficulties and abnormalities of growth and puberty⁴⁸⁹ or movement disorders. Diagnosis is often delayed for months to years because the findings are attributed to psychiatric disorders. Deficiencies of vasopressin and GH are most common, but other anterior pituitary hormone deficiencies (including gonadotropin deficiency) and elevated serum prolactin levels are also frequent. Determination of the concentration of hCG in spinal fluid and in serum and assessment of α -fetoprotein levels provide useful tumor markers in children and adolescents with germ cell tumors. Germ cell tumors in boys cause isosexual GnRH-independent sexual precocity by secretion of hCG (see "Sexual Precocity"). Tumors secreting hCG cause precocious puberty in boys, and there has been one case report of an affected girl.

Subependymal spread of germ cell tumors along the lining of the third ventricle is common, and seeding may involve the lower spinal cord and corda equina. MRI with contrast enhancement is useful in the detection of isolated enlargement of the pituitary stalk, an early finding that requires periodic MRI monitoring, especially in patients with diabetes insipidus.^{489,490} The size of the pituitary gland increases by 100% between year 1 and year 15, but the pineal gland does not normally change in size after the first year of life; any later enlargement indicates a mass lesion.⁴⁹¹ Pineal cysts are a rare cause of CPP.

Irradiation is the preferred treatment for pure germ cell tumors such as germinomas; surgery is rarely indicated,

except for biopsy to establish a tissue diagnosis.⁴⁹⁰ Chemotherapy alone is inadequate, but the combination of chemotherapy and radiation therapy can be successful,^{492,493} and both treatment methods are recommended for a mixed germ cell tumor. Because testicular germ cell tumors are occasionally found years after successful therapy for CNS germ cell tumors, long-term surveillance is indicated.^{494,495} Hypothalamic and optic gliomas or astrocytomas, occurring as part of neurofibromatosis (von Recklinghausen disease) or arising independently, can also cause sexual infantilism.

Only 2% to 6% of all surgically treated pituitary tumors occur in childhood and adolescence, with about 1 in 1,000,000 children affected.⁴⁸² Most functional pituitary adenomas are ACTH secreting, with prolactinomas secreting GH or nonfunctioning adenomas occurring less commonly, although prolactinomas manifest most often in adolescence. Most pituitary tumors are monoclonal lesions caused by mutations of *GNAS*.

A survey of 44 cases reported that 61% of prolactinomas were macroadenomas (more often in boys; hypopituitarism and growth failure were common) and 39% were microadenomas (more often in girls; delayed puberty was common).^{496,497} Only 2 of these 29 patients had delayed onset of puberty,⁴⁹⁷ although primary amenorrhea was the presenting symptom in 13 of 20 pubertal females. Presenting symptoms included oligomenorrhea and galactorrhea in the girls and headache in the boys. Galactorrhea may be demonstrable only by manual manipulation of the nipples (blood samples for prolactin should be obtained before examination or many hours later, because manipulation of the nipples raises prolactin levels).

Dopaminergic therapy is often successful in decreasing prolactin values.⁴⁹⁸ Transsphenoidal resection of microprolactinomas in children and adolescents is an effective treatment.⁴⁹⁷ The dopamine agonist bromocriptine may decrease serum prolactin concentrations and decrease tumor size, which is a useful approach before surgery of large macroprolactinomas is undertaken and when resection of the adenoma is incomplete. Pubertal progression and normal menstrual function in girls usually follows reduction of serum prolactin levels. Pituitary apoplexy followed cabergoline treatment of a macroprolactinoma in a 16-year-old girl; this complication has been seen in adults treated with bromocriptine,⁴⁹⁹ and tricuspid regurgitation may be a cumulative effect.⁵⁰⁰ High serum levels of macroprolactin, a complex of immunoglobulin G and monomeric prolactin with little biologic activity in vivo, cross-react in commercial prolactin assays, leading to a finding of pseudohyperprolactinaemia.⁵⁰¹

Other Central Nervous System Disorders Leading to Delayed Puberty

Langerhans Cell Histiocytosis. Langerhans cell histiocytosis (i.e., Hand-Schüller-Christian disease or histiocytosis X) is a clonal proliferative disorder of Langerhans histiocytes or their precursors. It is characterized by the infiltration of lipid-laden histiocytic cells or foam cells in skin, viscera, and bone.⁵⁰² The cause is not clear, because there are features of a neoplasm and features of a reactive immunologic disorder. Diabetes insipidus, caused by infiltration of the hypothalamus or the pituitary stalk, is the most common endocrine manifestation, with GH deficiency and delayed puberty possible. The lung, liver, and spleen, cyst-like areas in flat and long bones, and the dorsolumbar spine may be involved. "Floating teeth" within rarefied bone of the mandible, absent or loose teeth, and exophthalmos

due to infiltration of the orbit are seen. Mastoid or temporal bone involvement may lead to chronic otitis media. Treatment with glucocorticoids, antineoplastic agents, and radiation therapy is promising in terms of survival, but more than 50% of patients have late sequelae or disease progression. The natural waxing and waning course of this rare disease makes evaluation of therapy difficult and highlights the importance of national treatment protocols.⁵⁰²

Postinfectious Inflammatory Lesions of the Central Nervous System, Vascular Abnormalities, and Head Trauma. Tuberculous or sarcoid granulomas of the CNS are associated with delayed puberty. The original case of adiposogenital dystrophy, or Fröhlich's syndrome, is thought to have been caused by tuberculosis rather than a neoplasm. Hydrocephalus may cause delayed puberty that can be reversed with decompression, as may pressure from a subarachnoid cyst.

Irradiation of the Central Nervous System. Irradiation of the CNS for treatment of tumors, leukemia, or neoplasms of the head and face may result in the gradual onset of hypothalamic-pituitary failure.^{503,504} Although GH deficiency is the most common hormone disorder resulting from irradiation, gonadotropin deficiency, hypothyroidism, and decreased bone density also occur.⁵⁰⁵ Self-reported fertility was reported to be lower in women who received CNS radiotherapy for acute lymphoblastic leukemia at about the time of menarche,⁵⁰⁶ although the average age of women in this long-term study was in the early 20s, and longer follow-up of fertility may change the results.

Isolated Hypogonadal Hypogonadism

A defect involving the GnRH pulse generator or gonadotrophs without an anatomic lesion causes selective deficiency of gonadotropins, producing IHH (Tables 25-17 and 25-18).^{507,508} Puberty fails to begin by 14 years in boys and 13 years in girls, or pubertal maturation is incomplete or transient. In boys, micropenis or undescended testes or both signs are evidence of a fetal testosterone deficiency caused by gonadotropin deficiency. Prepubertal concentration of gonadal sex steroid values (testosterone in boys; estradiol in girls) and low serum gonadotropin levels or values within the normal range (i.e., normal in the basal state but not in the secretory state) are characteristic. Concentrations of gonadal sex steroids and gonadotropins are low, pulsatile LH secretion is virtually absent, and the LH response to GnRH or GnRH agonist administration is deficient in the severe form. The testes are small and may be hard to find, and serum inhibin B, an estimate of seminiferous tubule function, is low.^{509,510}

TABLE 25-17

Isolated Gonadotropin Deficiency

Males more commonly affected
 Familial (more common in females) or sporadic (more common in males)
 Height normal for age; tall adult height if untreated
 Eunuchoid skeletal proportions
 Delayed bone age
 Small, often cryptorchid testes: diameter <2.5 cm prepubertal size; phallus may be small
 Normal adrenarche
 Examine for anosmia or hyposmia (Kallmann's syndrome)
 Look for associated malformations (facial, central nervous system, skeletal, renal)

TABLE 25-18

Features of Kallmann's Syndrome

Clinical

GnRH deficiency: absent or arrested puberty
 Anosmia or hyposmia
 In infancy: microphallus; cryptorchidism
 Normal stature and growth in childhood
 Normal adrenarche
 Eunuchoid proportions
 Associated midline defects (e.g., cleft lip, cleft palate, midline cranial anomalies)
 MRI: aplasia or hypoplasia of olfactory bulbs and/or sulci

Prevalence

Approximately 1 in 7500 males, 1 in 50,000 females; 10% prevalence of Klinefelter's syndrome

Inheritance

Sporadic and familial cases; genetic heterogeneity
 X-linked
 X-linked recessive (Kallmann et al.)
 X chromosome deletion: Xp22.3 (Meitinger T et al.)
 Autosomal
 Dominant (sex limitation) (Santen and Paulsen; Merriam et al.)
 Recessive (White et al.)

Anatomy

Developmental field defect
 Aplasia or hypoplasia of olfactory bulb and sulcus
 Arrested migration of GnRH neurosecretory neurons from olfactory placode to medial basal hypothalamus

GnRH, luteinizing hormone-releasing hormone; MRI, magnetic resonance imaging.

(From Meitinger T, Heye B, Petit C, et al. Definitive localization of X-linked Kallmann's syndrome (hypogonadotropic hypogonadism and anosmia) to Xp22.3: close linkage to the hypervariable repeat sequence CRI-S232. *Am J Hum Genet.* 1990; 47:664-669; Merriam GR, Beitins IZ, Bode HH. Father-to-son transmission of hypogonadism with anosmia: Kallmann's syndrome. *Am J Dis Child.* 1977; 131:1216-1219; Santen RJ, Paulsen CA. Hypogonadotropic eunuchoidism. I. Clinical study of the mode of inheritance. *J Clin Endocrinol Metab.* 1973;36:47-54; White BJ, Rogal AD, Brown KS, et al. The syndrome of anosmia with hypogonadotropic hypogonadism: a genetic study of 18 new families and a review. *Am J Hum Genet.* 1983; 15:417-435.)

IHH may occur in families (about 20% to 30% of patients), or it may occur sporadically. In contrast to CNS tumors (in which patients usually have GH deficiency and growth failure) and to CDP (in which patients are short for chronologic age), height is appropriate for age in patients with IHH (Fig. 25-39). Because the levels of gonadal steroids, particularly estradiol, are too low to cause epiphyseal fusion at the normal age, increased arm span for height and a decreased ratio of upper to lower body segments (i.e., eunuchoid body proportions) are present. If the condition is left untreated, growth continues, and adult height is tall.^{509,511}

Kallmann's Syndrome

Anosmia or hyposmia resulting from agenesis or hypoplasia of the olfactory lobes or sulci is associated with GnRH deficiency in Kallmann's syndrome, the most common form of IHH (see Table 25-18).^{507,512} The condition was first observed in 1856, in the autopsy of a 40-year-old man with micropenis, small cryptorchid testes, and absence of the olfactory bulbs, but Kallmann described a familial pattern in 1944 (Fig. 25-40). The prevalence is 1 of every 10,000 males and 1 of every 5000 females. Although the loss of olfaction usually correlates with the degree of GnRH deficiency, even in complete anosmia, the GnRH deficiency

Figure 25-39 A girl aged 18 years and 8 months has isolated gonadotropin deficiency (i.e., sexual infantilism and primary amenorrhea). Her height is 173 cm (+1 SD), weight was 66.5 kg (+1 SD), and the skeletal age was 13 years. Adrenarche with pubic hair development occurred at age 13.5 years. At the time of the photograph, pubic hair was in stage 3, and there was slight breast and nipple development resulting from a previous short course of estrogen therapy. Immature labia minora and majora were observed, and no estrogen effect was seen on the vaginal mucosa. Olfactory testing results were normal. The plasma luteinizing hormone (LH) (LER-960) level after gonadotropin-releasing hormone (GnRH) administration rose from 0.5 to 1.8 ng/mL (a prepubertal response). Serum estradiol was undetectable. The dehydroepiandrosterone sulfate (DHEAS) level was 92 μ g/dL (appropriate for pubic hair stage 2). Notice the discrepancy between adrenarche and gonadarche. For conversion to SI units, see Figures 25-16 and 25-25. (From Styne DM, Grumbach MM. Puberty in the male and female: its physiology and disorders. In: Yen SCC, Jaffe RB, eds. *Reproductive Endocrinology*, 2nd ed. Philadelphia, PA: Saunders, 1986:313-384.)

may be partial (see “Isolated Luteinizing Hormone Deficiency”).⁵¹⁰ Because affected individuals often do not notice impaired olfaction; testing with graded dilutions of pure scents is necessary. Rarely, affected males with severe delay of puberty spontaneously increase their testicular size and enter full puberty.⁵¹³ Patients with Kallmann’s syndrome have no or diminished nocturnal pulses of gonadotropins found in normal prepubertal boys, although daytime values are equal. Undescended testes and gynecomastia are common in this and all types of hypogonadotropic hypogonadism in boys.⁵⁰⁹ The magnitude of the GnRH deficiency correlates with the size of the testes. Micropenis occurs in about one half of males with Kallmann’s syndrome (Fig. 25-41).

Associated defects that are inconsistently present include cleft lip, cleft palate, imperfect facial fusion, seizure disorders, short metacarpals, pes cavus, neurosensory hearing loss (rarely found in the X-linked form⁵¹⁴), cerebellar ataxia and nystagmus, ocular motor abnormalities, unilateral or rarely bilateral renal aplasia or dysplasia, and mirror

movements of the upper extremities (i.e., bimanual synkinesia), limited to the X-linked form (see Table 25-18). Genetic details can be found in the *Online Mendelian Inheritance in Man* (OMIM) catalog (available at <http://www.ncbi.nlm.nih.gov/sites/entrez?db=omim> [accessed February 2011]).

A variety of deletions and mutations of the *KAL1* gene have been described, including large and small (exon) deletions, point mutations, and a variety of nonsense mutations leading to frameshift and premature stop codons.^{514,515} The *KAL1* mutations are more prevalent in Japanese than in white patients, and they can be associated with normal olfactory function.⁵¹⁶ The defect in some rare patients with no *KAL1* mutation but X-linked inheritance may be located in the promoter region of the *KAL1* gene. Kallmann’s syndrome associated with X-linked ichthyosis caused by steroid sulfatase deficiency, mental retardation, and chondroplasia punctata occurs in a contiguous gene syndrome.⁵¹⁷ Only 14% of familial cases and 11% of sporadic cases

Figure 25-40 A boy aged 15 years and 10 months had isolated gonadotropin deficiency and anosmia (Kallmann’s syndrome). He had undescended testes, but after administration of 10,000 U of human chorionic gonadotropin (hCG), the testes descended and were palpable in the scrotum. His height was 163.9 cm (+1.5 SD); the upper-to-lower body ratio was 0.86, which is eunuchoid. The phallus measured 6.3 \times 1.8 cm, and the testes were 1.2 \times 0.8 cm. The concentration of plasma luteinizing hormone (LH) was less than 0.3 ng/mL; the follicle-stimulating hormone (FSH) level was 1.2 ng/mL; and the testosterone level was 16 ng/dL. After 100 μ g of gonadotropin-releasing hormone (GnRH), the plasma LH level (LER-960) was 0.7 ng/mL, and the FSH level (LER-869) was 2.4 ng/mL. For conversion to SI units, see Figures 25-16 and 25-17. (From Styne DM, Grumbach MM. Puberty in the male and female: its physiology and disorders. In: Yen SCC, Jaffe RB, eds. *Reproductive Endocrinology*, 2nd ed. Philadelphia, PA: Saunders, 1986:313-384.)

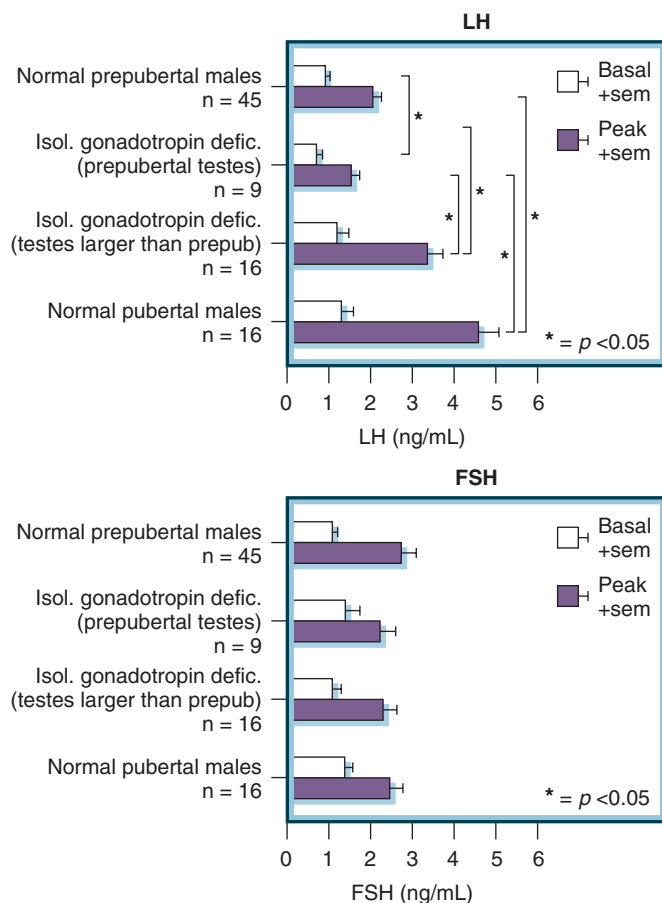

Figure 25-41 Serum luteinizing hormone (LH) and follicle-stimulating hormone (FSH) responses to the administration of gonadotropin-releasing hormone (GnRH) in 25 males with an isolated gonadotropin deficiency with or without anosmia were segregated according to whether the volume of the testes was prepubertal or greater than 2.5 cm³. Testicular volume in those with testes larger than 2.5 cm³ was as large as 4 cm³. Basal and GnRH-stimulated gonadotropin levels after the intravenous injection of 100 µg GnRH (peak value) are shown ($P < .05$). For conversion to SI units, see Figure 25-16. (From Van Dop C, Burstein S, Conte FA, et al. Isolated gonadotropin deficiency in boys: clinical characteristics and growth. *J Pediatr*. 1987;111:684-692.)

involve mutations in the *KAL1* gene on the X chromosome, but these patients are more likely to have complete absence of gonadotropin secretory pulses and absence of migration of GnRH neurons to the hypothalamus.⁵¹⁸ Hypogonadotropic hypogonadism is rarely caused by a mutation in the *KAL1* gene in females.

The autosomal dominant form is known as Kallmann's syndrome type 2 (KAL2), and the associated gene is the fibroblast growth factor receptor 1 gene, *FGFR1* (previously called *KAL2*) with a gene map locus of 8p11.2-p11.1. Mutations result in autosomal dominant Kallmann's syndrome, autosomal dominant normosmic hypogonadotropic hypogonadism, or delayed puberty. KAL2 is associated with mental retardation, choanal atresia, short stature, congenital heart defects, and sensorineural hearing loss, and its presentations are more varied than those of KAL1.

The loss-of-function mutation of the *FGFR1* gene interferes with migration of the olfactory cells to the olfactory bulb.⁵¹⁹ Anosmin 1, a neuronal protein, may act through *FGFR1* to bring about fibroblast growth factor (FGF) signaling. KAL1 partially escapes inactivation in females, and it is postulated that enough KAL1 may be produced in affected females, despite *FGFR1* haploinsufficiency, to

maintain adequate FGF signaling and allow olfactory function and GnRH neuron migration. One kindred of Kallmann's syndrome contained four women with *FGFR1* mutations that were transmitted to affected male offspring, although the mothers had normal reproduction and olfaction.⁵¹⁹

Although gain-of-function mutations of the *FGFR1* gene are associated with craniosynostosis, a loss-of-function mutation is not associated with lack of fusion of the cranial sutures. One kindred with an *FGFR1* mutation (Arg622X) in the tyrosine kinase domain, in which some of the manifestations were temporary, has been reported; the mother of the proband had delayed puberty, and the maternal grandmother had anosmia, whereas the proband with KAL2 exhibited normal LH levels, testosterone production, and spermatogenesis after prior testosterone therapy.⁵²⁰

Studies of mice revealed that the early emergence of GnRH neurons from the embryonic olfactory placode requires FGF8 signaling as a ligand mediated through *FGFR1*.⁵²¹ About 30% of FGF8/*FGFR1* loss-of-function mutations are associated with cleft palate, whereas *FGFR1* mutations may rarely lead to cartilage abnormalities in the ears, nose, or digits.⁵²² An unusual kindred with a proband demonstrating severe ear anomalies, mandibular hypoplasia, thoracic dystrophia, and other usual findings was associated with an Arg622 mutation in the *FGFR1* gene, and investigation for hypogonadism is indicated when such facial abnormalities occur.⁵²³ Prevalence of *FGFR1* mutations in the Japanese population is equal to the prevalence among whites.⁵¹⁶

Knockout mice lacking the *PROK2* gene (formerly called *KAL4*), which encodes prokineticin 2, an 81-amino-acid peptide that signals through the G protein-coupled product of the *PROKR2* gene (formerly called *KAL3*), had defective development of the olfactory bulbs and failed migration of GnRH neurons.⁵²⁴ This model led to demonstration of loss-of-function mutations in *PROKR2* or *PROK2* in 9% of patients with Kallmann's syndrome,⁵²⁵ who were mostly heterozygous, although homozygous and compound heterozygous mutations were also described. Fibrous dysplasia, sleep disorder, severe obesity, synkinesia, and epilepsy have been described in patients with *PROK2* or *PROKR2* mutations, and 3% of IHH patients were affected in one study.

The CHARGE syndrome (colobomata, heart anomalies, choanal atresia, retardation, genital and ear anomalies) includes IHH and hyposmia, including absent olfactory bulbs. In autosomal dominant familial cases, causative mutations were found in *CHD7*, which encodes a chromatin-remodeling factor, which in a small percentage of cases were found in patients with Kallmann's syndrome and in some patients with IHH due to apparent loss-of-function mutations. Patients with CHARGE syndrome should be evaluated for hypogonadotropic hypogonadism, especially if there is deafness and hypoplasia of the semicircular canals.⁵²⁶

Apparent autosomal recessive inheritance characterizes other kindreds with Kallmann's syndrome type 3 (KAL3), for which the affected gene is *PROKR2*. Unilateral renal agenesis, hypotelorism, cleft lip and palate, and a midline cranial fusion defect occur. Although renal aplasia is characteristic of *KAL1* mutations and cleft palate and dental agenesis are characteristic of *FGFR1* mutations in KAL2, these findings can occur in Kallmann's patients without *KAL1* or *FGFR1* mutations.⁵¹⁶

Therefore, the various forms of Kallmann's syndrome result from heterogeneous mutations in which the phenotype can vary. For example, a 20-year-old man with the

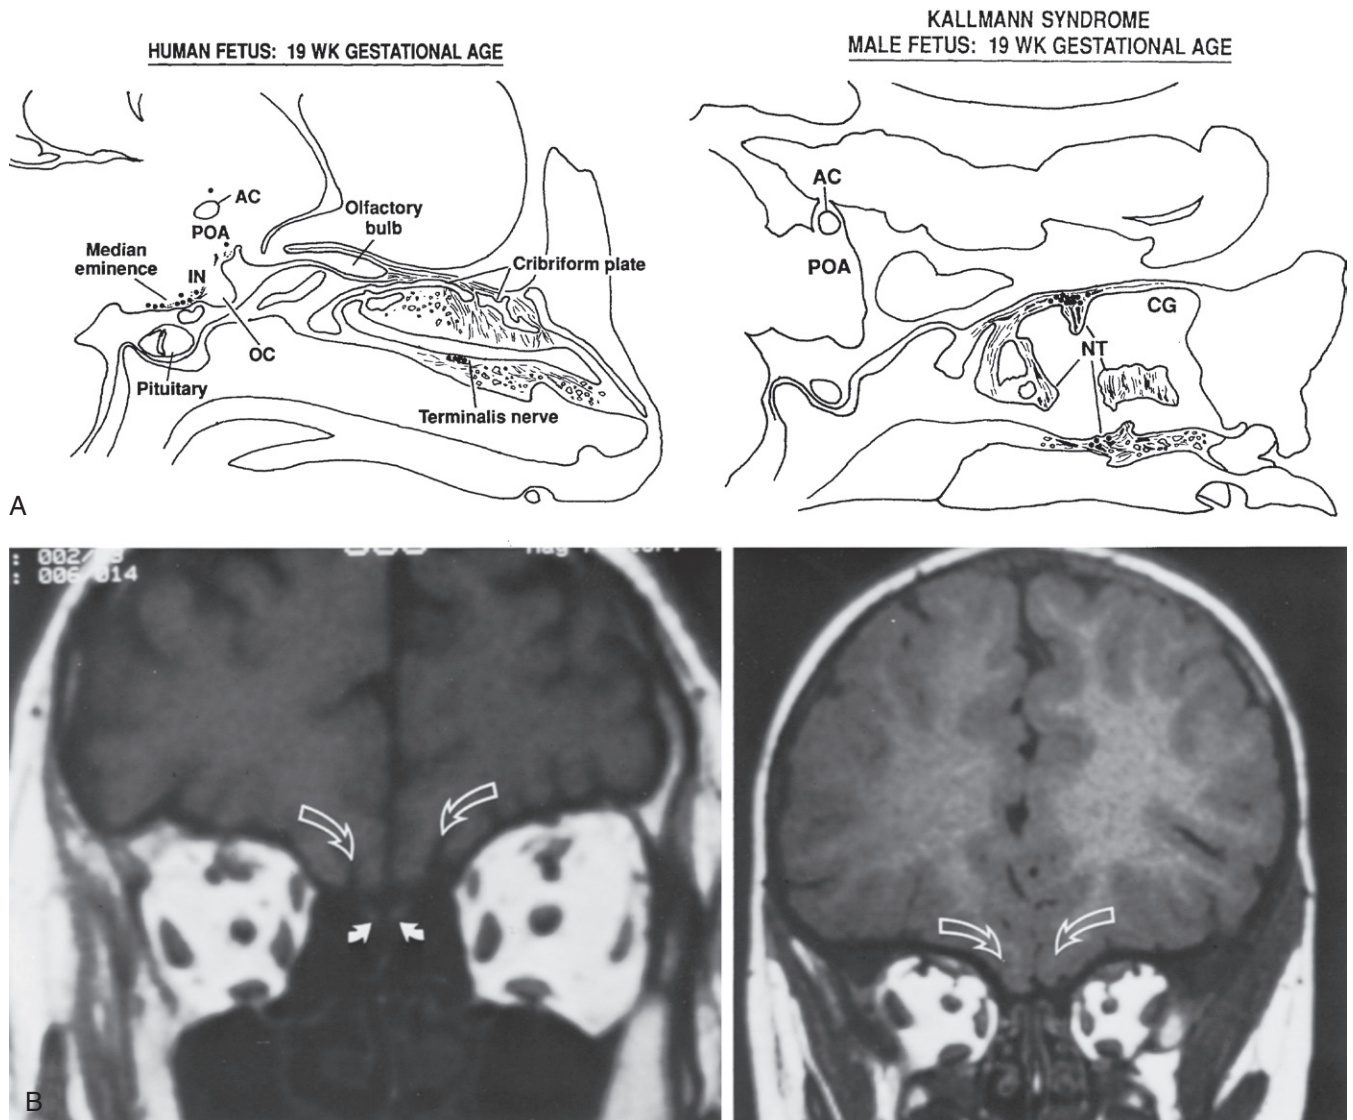

Figure 25-42 Comparison of the brain and nasal cavities of a normal 19-week-old male fetus (upper left) and those of a male fetus of similar age with Kallmann's syndrome caused by an X chromosome deletion at Xp22.3 (upper right). In the normal fetal brain, the gonadotropin-releasing hormone (GnRH) neurosecretory neurons (black dots) are located in the hypothalamic area, including the medial basal hypothalamus, the anterior hypothalamic area, and of interest regarding hypothalamic hamartoma as an ectopic GnRH pulse generator, the premammillary and retromammillary areas. A small cluster of GnRH neurons exists among the fibers of the terminalis nerve on the floor of the nasal septum. In the male fetus with Kallmann's syndrome, no GnRH neurons were detected in the hypothalamic region, including the basal hypothalamus, median eminence, and preoptic area. The GnRH cells fail to migrate to and enter the brain from their origin in the nose; these cells end in a tangle beneath the forebrain on the dorsal surface of the cribriform plate and in the nasal cavity. AC, anterior commissure; CG, crista galli; IN, infundibular nucleus; NT, terminalis nerve; OC, optic chiasm; POA, preoptic area. Lower panels show magnetic resonance imaging scans of brain (coronal section, T1-weighted image). Lower left, Normal olfactory sulci (open arrows) and bulbs (solid arrows) in a 15-year-old boy. Lower right, Absent olfactory sulci (open arrows) and bulbs in a 17-year-old, anosmic, sexually infantile boy with Kallmann's syndrome.

complete picture of Kallmann's syndrome had an identical twin brother (proved by genetic fingerprinting) with anosmia but a normal adult phenotype and normal plasma testosterone and gonadotropin concentrations.⁵²⁷

Other postulated defects that may interfere with GnRH neuron migration are mutations in the genes for neural cell adhesion molecules (NCAM) and related proteins, such as tenascin, laminin, and phosphacan. Various glycoconjugates may also be involved.

In classic, X-linked KAL1, fetal GnRH neurosecretory neurons do not migrate from the olfactory placode to the medial basal hypothalamus, where they should constitute the GnRH pulse generator, but instead end in a tangle around the cribriform plate and in the dural layers adjacent

to the meninges beneath the forebrain.³³⁶ Abnormal or absent olfactory bulbs or folds are seen on MRI scans. Coronal and axial cranial MRI scans of the olfactory bulbs and sulci, unilaterally or bilaterally, reflect this defect in about 90% of cases and can point to the diagnosis,⁵²⁸ especially in affected infants and prepubertal-age children (Fig. 25-42).⁵²⁸

Other Forms of Isolated Hypogonadotropic Hypogonadism

Inheritance of hypogonadotropic hypogonadism (Table 25-19) with none of the other features of Kallmann's syndrome may be found in autosomal dominant (gene map

TABLE 25-19

Molecular Basis for Developmental Disorders Associated with Hypogonadotropic Hypogonadism

Gene	Phenotype	Complex Phenotype
ISOLATED HYPOGONADOTROPIC HYPOGONADISM		
Kallmann's Syndrome or Normosmic IHH (with the Same Mutant Gene)		
<i>KAL1</i> (Xp22.3)	X-linked Kallmann's syndrome	Anosmia/hyposmia, renal agenesis, dyskinesia
<i>FGFR1</i> (<i>KAL2</i>) (8p11.2)	Autosomal dominant Kallmann's syndrome (± recessive)	Anosmia/hyposmia, cleft lip/palate
<i>FGF8</i> (ligand for <i>FGFR1</i>)(10q25)		
<i>NELF</i> (9p34.3)	Autosomal dominant (?) Kallmann's syndrome	
<i>PROK2</i> (3p21.1)	Autosomal recessive Kallmann syndrome	
<i>PROKR2*</i> (20p12.3)		
<i>CHD7</i> (8p12.1)	Autosomal dominant (some)	CHARGE syndrome includes hyposmia
Normosmic Isolated Hypogonadotropic Hypogonadism		
<i>GNRH1</i> (8p21-11.2)	Autosomal recessive	
<i>GNRHR*</i> (4q13.2-3)	Autosomal recessive (± dominant)	
<i>GPR54*</i> (19p13.3)	Autosomal recessive	
<i>SNRPN</i>		Prader-Willi syndrome
Lack of function of paternal 15q11-q13 region or maternal uniparental disomy		Obesity
<i>LEP</i> (7q31.3)	Autosomal recessive	Obesity
<i>LEPR</i> (1p31)	Autosomal recessive	Obesity
<i>NROB1</i> (<i>DAX1</i>) (X21.3-21.2)	X-linked recessive	Adrenal hypoplasia
<i>TAC3</i> (12q13-12)	Autosomal recessive	
<i>TACR3</i> (4q25)	Autosomal recessive	
Multiple Pituitary Hormone Deficiencies		
<i>PROPI</i> (<i>POU1F1</i>)	Autosomal recessive GH, PRL, TSH, and LH/FSH (less commonly, later-onset ACTH deficiency)	
<i>HESX1</i> (<i>RPX</i>)	Autosomal recessive; and heterozygous mutations	Septo-optic dysplasia
	Multiple pituitary deficiencies including diabetes insipidus, but LH/FSH uncommon	
<i>LHX3</i>	Autosomal recessive GH, PRL, TSH, FSH/LH	Rigid cervical spine
<i>PHF6</i>	X-linked; GH, TSH, ACTH, LH/FSH	Borjeson-Lehmann syndrome: mental retardation; facies

*A G-protein-coupled receptor.

ACTH, corticotropin; CHD7, chromatin-remodeling factor; *DAX1*, dosage-sensitive sex reversal-adrenal hyperplasia congenita critical region on the X chromosome, gene 1; FGF, fibroblast growth factor; FSH, follicle-stimulating hormone; GH, growth hormone; *GNRH*, gonadotropin-releasing hormone; *GPR54*, kisspeptin G-protein-coupled receptor 54; *HESX1*, homeobox gene expressed in ES cells; IHH, idiopathic hypogonadotropic hypogonadism; *LEP*, leptin; LH, luteinizing hormone; *LHX3*, lim homeobox gene 3; *NELF*, nasal embryonic luteinizing hormone-releasing factor; *NROB1*, nuclear receptor family 0, group B, member 1; *PHF6*, plant homeodomain-like finger gene; PRL, prolactin; *PROK2*, prokineticin 2; *PROPI*, prophet of Pit-1; R, receptor; *SNRPN*, small nuclear ribonucleoprotein polypeptide SmN; *TAC3*, neurokinin3; TSH, thyroid-stimulating hormone.

locus 19p13.3, 9q34.3), autosomal recessive (8p21-p11.2), or X-linked recessive (Xp21) disorders.⁵²⁹⁻⁵³¹ Males with cerebellar ataxia and deficient gonadotropin production are reported in kindreds with X-linked inheritance (possibly a variant form of Kallmann's syndrome), and hypogonadotropic hypogonadism may be associated with the multiple lentigenes and basal cell nevus syndromes.

Only about 15% of normosmic hypogonadotropic patients have a definable genetic defect. The combination of human genetic studies and mouse models has led to the discovery of many genes involved in gonadotropin regulation.⁵³² The human equivalent of the mouse nasal embryonic GnRH factor gene (*Nelf*) is *NELF*; a mutation of this gene was found in 1 of 65 patients with IHH but in none of 100 controls, suggesting an etiologic role for this mutation.⁵³³

Gonadotropin-Releasing Hormone Gene Mutations. The GnRH gene (*GNRH1*) would seem a likely candidate for the cause of hypogonadotropic hypogonadism, but although mutations of the GnRH receptor gene (*GNRHR*) were

identified years ago, mutations in the *GNRH1* gene were not demonstrated until 2009. An autosomal recessive form had been described in the mouse (*hyg/hyg*), in which there is a deletion of part of the GnRH gene. A homozygous *GNRH1* frameshift mutation in human beings, characterized by the insertion of an adenine at nucleotide position 18 (c.18-19insA) in the sequence encoding the N-terminal region of the signal peptide-containing protein precursor of GnRH (prepro-GnRH), was found in a teenage brother and sister who had normosmic IHH.⁵³⁴ When expressed *in vitro*, the mutant peptide did not demonstrate immunoreactive GnRH. One patient of 310 with severe, congenital, normosmic IHH (with micropenis, bilateral cryptorchidism, and absent puberty) had a homozygous frameshift mutation that is predicted to disrupt the three C-terminal amino acids of the GnRH decapeptide and to produce a premature stop codon.⁵³⁵ Of four patients with normosmic IHH, one had a nonsynonymous missense mutation in the eighth amino acid of the GnRH decapeptide; one had a nonsense mutation that causes premature termination within the GnRH-associated peptide (GAP), which lies

C-terminal to the GnRH decapeptide within the GnRH precursor; and two had sequence variants that cause non-synonymous amino acid substitutions in the signal peptide and GnRH-associated peptide.

KISS1/KISS1R Axis. The KISS1/KISS1R axis plays a role in the increased amplitude of GnRH signaling in puberty. KISS1/KISS1R axis mutations are rare. Of 30 normosmic subjects with hypogonadotropic hypogonadism who were evaluated, 1 person had two missense mutations in KISS1R (Cys223Arg in the fifth transmembrane helix and Arg297Leu in the third extracellular loop); the former had no activity, and the latter manifested as mildly decreased signaling ability.⁵³⁶ Homozygous deletions of 155 nucleotides in the KISS1R gene encompassing the splicing acceptor site of the intron 4–exon 5 junction and part of exon 5 were found in all affected family members with IHH,⁵³⁷ but unaffected family members had no deletion or only one mutant allele. Another kindred had a Leu48Ser mutation in the second intracellular loop (IL2) of KISS1R, and another had two separate mutations in the gene, Arg331Xaa and Xaa399Arg.⁴¹¹ The latter patient had decreased secretion of GnRH and decreased response to GnRH administration. A line of mice transfected with the affected gene exhibited hypogonadotropic hypogonadism with decreased GnRH in the hypothalamus but were responsive to GnRH or gonadotropin administration. Agonist stimulation may stabilize the switch II region of G α to promote opening of G α switch II to facilitate exchange of guanosine diphosphate (GDP) and guanosine triphosphate (GTP).⁵³⁸ The Leu148Ser mutation does not affect the expression, ligand-binding properties, or protein interaction network of KISS1R, but diverse KISS1R functional responses are markedly inhibited.

Gonadotropin-Releasing Hormone Receptor Mutations. Mutations of the gene encoding the type 1 GnRH receptor (*GNRHR*, gene map locus 4q21.2) that affect the G protein-coupled, seven-transmembrane segments lead to various degrees of familial and sporadic hypogonadotropic hypogonadism with normosmia.^{529,531,539,540} A *GNRHR* mutation is found in about 40% to 50% of cases of familial, autosomal recessive, normosmic IHH and in about 17% of sporadic cases of normosmic IHH.

Mutations in hypogonadal hypogonadism with amino acid substitutions in the extracellular N-terminal domain (Thr32Ile), the second extracellular loop (Cys200Tyr), the third intracellular loop (Leu266Arg), and the sixth transmembrane helix (Cys279Tyr) were found to affect specific GnRH binding.^{541,542} Except for Thr32Ile, there was no significant inositol phosphate accumulation after GnRH stimulation, demonstrating loss of function even if binding was accomplished. However, an increased dose of GnRH allowed stimulation of the gonadotropin subunit and *GNRHR* promoters and the ability to partially activate extracellular signal-regulated kinase 1 and stimulate cAMP response element (CRE)–luciferase activity. A higher dose of GnRH caused the Cys200Tyr mutant to stimulate gonadotropin subunit and *GNRHR* promoter activity because this mutant reduces cell surface receptor expression.

Another human GnRH receptor (*GNRHR*) gene mutation of a highly conserved sequence located in the second-transmembrane helix impairs *GNRHR* effector coupling due to loss of surface expression of the receptor and leads to a severe manifestation of IHH.⁵⁴³

Certain GnRH receptor defects may be rescued by pharmacologic agents that can act as a folding template, correcting the structural defects caused by the mutations and

allowing function to occur. A small, membrane-permeant molecule demonstrated pharmacologic rescue (i.e., ligand binding and restoration of receptor coupling to effector) of five naturally occurring missense mutations of the GnRH receptor in families with IHH.⁵⁴⁴ These molecules also allowed rescue of intentionally manufactured defective receptors with internal or terminal deletions or substitutions at sites expected to be involved in the establishment of tertiary receptor structure. This approach may allow a therapeutic approach to conditions caused by mutations that result in protein misfolding.

The clinical presentation of patients with mutations in the GnRH receptor is heterogeneous, and impairment of signal transmission is highly variable (e.g., severe features of IHH, sexual infantilism, long-delayed puberty with reversal in adulthood, relatively mild hypogonadism and infertility), even within the same pedigree and especially in patients with compound heterozygous mutations.⁵⁴⁵ In all types of congenital gonadotropin deficiency, male patients are likely to manifest micropenis (penile length <2.0 cm at birth and in infancy) due to lack of fetal gonadotropin stimulation of fetal testes during the last half of gestation. Rarely, boys with congenital GH deficiency have micropenis even if gonadotropin function is normal.⁵⁴⁶ Because testosterone therapy is effective in increasing penile size (see later discussion), sex reversal is not indicated in these cases of microphallus.

X-Linked Congenital Adrenal Hypoplasia and Hypogonadotropic Hypogonadism. A rare deletion or mutation in the dosage sensitive sex reversal-A (DSS) adrenal hypoplasia congenita gene on the X chromosome gene 1 (*NROB1*, formerly called *DAX1*; gene map locus Xp21.3-p21.2)⁵⁴⁷⁻⁵⁴⁹ leads to an X-linked recessive disorder of adrenocortical organogenesis. The gene encodes an orphan receptor, a member of the nuclear receptor superfamily, that is a putative transcriptional repressor mapping to the Xp21 locus. A double dose of *NROB1* is associated with a female phenotype or ambiguous genitalia in 46XY males. The *NROB1* protein has a novel domain in the N-terminus that contains two putative unique zinc finger motifs, and the C-terminus contains a conserved ligand-binding domain that binds DNA, localizes in the nucleus, and contains a transcriptional silencing domain that antagonizes the steroidogenic factor 1 (SF1, also called NR5A1) transactivation function.⁵⁵⁰ *NROB1* has an SF1 response element in the 5′-promoter region that is another orphan member of the nuclear hormone receptor superfamily. Both *NROB1* and SF1 are expressed in the adrenals, gonads, pituitary, and hypothalamus, raising the possibility of an important interaction between these two genes and their products.

Rare abnormalities of *NROB1* are characterized by severe glucocorticoid, mineralocorticoid, and at puberty, androgen deficiency.^{551,552} The abnormal structure of the adrenal cortex resembles that of the fetal zone because it consists of disorganized, vacuolated, cytomegalic cells with a normal mature cortex.⁵⁵¹ The severe primary adrenal insufficiency with hyponatremia, hyperkalemia, acidosis, and hypoglycemia is characterized by failure to thrive, vomiting, poor feeding, dehydration, circulatory collapse, and increased pigmentation, and is lethal if not treated early in life in affected boys.⁵⁵¹

Adrenoleukodystrophy may manifest with adrenal failure long before neurologic symptoms develop, and some cases of X-linked Addison's disease may represent this diagnosis. This condition is in the differential diagnosis of adrenal hypoplasia. Plasma renin activity, plasma cortisol,

and aldosterone levels are low. Symptomatic adrenal insufficiency may first manifest in later childhood. In male infants, signs of salt-wasting are usually the most prominent feature, but cortisol deficiency is detectable, and adrenal insufficiency includes deficient secretion of the zona reticularis steroids, DHEA, and DHEAS. An early sign of elevated ACTH is increased skin pigmentation. The testes are undescended in fewer than one half of patients; micropenis is rare, but urogenital abnormalities and hearing loss occasionally are present. Boys who do not present with clinical evidence of adrenal insufficiency in infancy often have a more insidious onset during childhood or adulthood.^{553,554}

In a pedigree in which two affected boys had a hemizygous *NROB1* nonsense mutation and neonatal onset of adrenal insufficiency, a maternal aunt who was homozygous for the mutation had sexual infantilism and primary amenorrhea, but even after decades of follow-up, she maintained normal adrenal function. A maternal grandfather who carried the same mutation was asymptomatic.⁵⁵⁵ This pedigree highlights the limitations and complexities of genotype and phenotype correlations. Most commonly, due to hypogonadotropic hypogonadism, signs of sexual maturation at the age of puberty (e.g., pubic and axillary hair, testicular enlargement) are lacking, and the concentrations of serum FSH, LH, and testosterone are low.⁵⁵¹ Delayed puberty is a manifestation in some female carriers of a *NROB1* mutation.

Intragenic mutations in *NROB1* (i.e., frameshift mutations, nonsense mutations, and missense mutations) indicate that the hypogonadotropic hypogonadism is an intrinsic characteristic of the disorder, a manifestation of the single-gene mutation and not a result of involvement of a contiguous gene.⁵⁵⁶ The *NROB1* gene is expressed in the adrenal cortex, in testes (and weakly in the ovary), and in the hypothalamus and pituitary. There is evidence of GnRH deficiency and an abnormality in the gonadotrophs, yielding a mixed picture of hypothalamic and intrinsic gonadotroph defects⁵⁵¹ with absent or erratic pulsatile secretion of LH. Even if basal immunoreactive LH and FSH levels are normal, gonadotrophs seem to lack bioactivity. In some affected boys, the GnRH pulse generator and pituitary gonadotropin apparatus is intact and functional in infancy and early childhood, and the GnRH-gonadotroph defects do not manifest until later in childhood or during the peripubertal period.⁵⁵⁷ Azoospermia unresponsive to gonadotropin treatment was detected in a few affected men.^{554,558}

A deletion of the adrenal hypoplasia congenita locus (at Xp21) can include the glycerol kinase (*GK*) and Duchenne muscular dystrophy (*DMD*) genes if it extends centromerically or produce mental retardation if there is extension toward the telomere, leading to contiguous gene syndromes.

Other mutations of the X chromosome may be associated with IHH. Two brothers were reported who had hypogonadotropic hypogonadism, obesity, and short stature associated with a maternally inherited pericentric inversion, (X)(p11.4q11.2). Because the breakpoint is not related to other genes associated with pubertal disorders, it is not clear whether this is a functional relationship or a coincidence.⁵⁵⁹

Other Presentations of Hypogonadotropic Hypogonadism

Neurokinin B (encoded by *TAC3*) is a member of the tachykinin superfamily of 127 neuropeptides that includes

substance P and neurokinin A. Its cognate G protein-coupled receptor 126 is NK3R, which is encoded by *TACR3*. Studies demonstrate loss-of-function mutations in this system in familial, congenital hypogonadotropic hypogonadism; administration of pulsatile GnRH caused resumption of gonadotropin secretion (Fig. 25-43).^{560,561} A survey of 345 patients with normosmic hypogonadotropic hypogonadism found 13 rare, distinct nucleotide sequence coding variants (three 108 nonsense, six nonsynonymous, and four synonymous mutations [one predicted to affect splicing]) in *TACR3* and one 109 homozygous single-base-pair deletion, resulting in complete loss of neurokinin B. Of the 16 males for whom phenotype information was available, 15 had micropallus, and none of the females had spontaneous thelarche. When subjects were assessed after discontinuation of therapy, 6 of 7 males and 4 of 5 females demonstrated evidence for reversibility of their hypogonadotropism.⁵⁶²

Mutations in the prohormone convertase 1 gene (*PCSK1*, also called *PC1*) led to extreme childhood obesity, hypocortisolemia, defects in conversion of proinsulin to insulin leading to hypoglycemia, and isolated partial hypogonadotropic hypogonadism allowing spontaneous pubertal development but primary amenorrhea. The hypogonadal hypogonadism probably resulted from impaired processing of GnRH or neuropeptides involved in its secretion. Findings in another subject extended to gastrointestinal disturbance, small intestinal malabsorption related to monosaccharide and fats, and elevation in progastrin and proglucagon levels, showing that prohormone processing in enteroendocrine cells was abnormal.⁵⁶³

Isolated Luteinizing Hormone Deficiency. Isolated LH deficiency (fertile eunuch syndrome) is associated with deficient testosterone production (which responds to hCG administration) in the presence of variable spermatogenesis; the disorder may be idiopathic or may result from a hypothalamic pituitary neoplasm. A homozygous Gln106Arg mutation in the first extracellular loop of the GnRH receptor at gene map locus 4q21.2 was associated with normal testicular volume (17 mL) but with apulsatile, low gonadotropin values and low testosterone values⁵⁴⁵ in one subject. After hCG stimulation, he developed adequate spermatogenesis to father a child, and after cessation of hCG treatment, he demonstrated adult testosterone values and pulsatile gonadotropin secretion, an example of reversibility of the syndrome.

Isolated Bioinactive Luteinizing Hormone. A 17-year-old boy with a history of delayed puberty, the only known patient with isolated bioinactive LH, had a striking discrepancy between elevated immunoactive and absent bioactive LH due to a mutation in the gene encoding the LH β -subunit.⁵³⁰ The subject had a homozygous mutation in exon 3 of the LH β -subunit gene (Glx54Arg). Apparently absent Leydig cells and arrested spermatogenesis improved with hCG treatment. The heterozygote mother exhibited only 50% of normal binding of serum LH to the LH receptor. The patient's normal male sex differentiation most likely resulted from the action of hCG. The absence of a micropenis, as found in male infants with congenital GnRH deficiency, suggests the possibility of initially bioactive LH in utero.

Isolated Follicle-Stimulating Hormone Deficiency. Homozygous or compound heterozygous mutations in the FSH β -subunit have been reported in three females and two males^{323,530,564} with delayed puberty or poorly developed

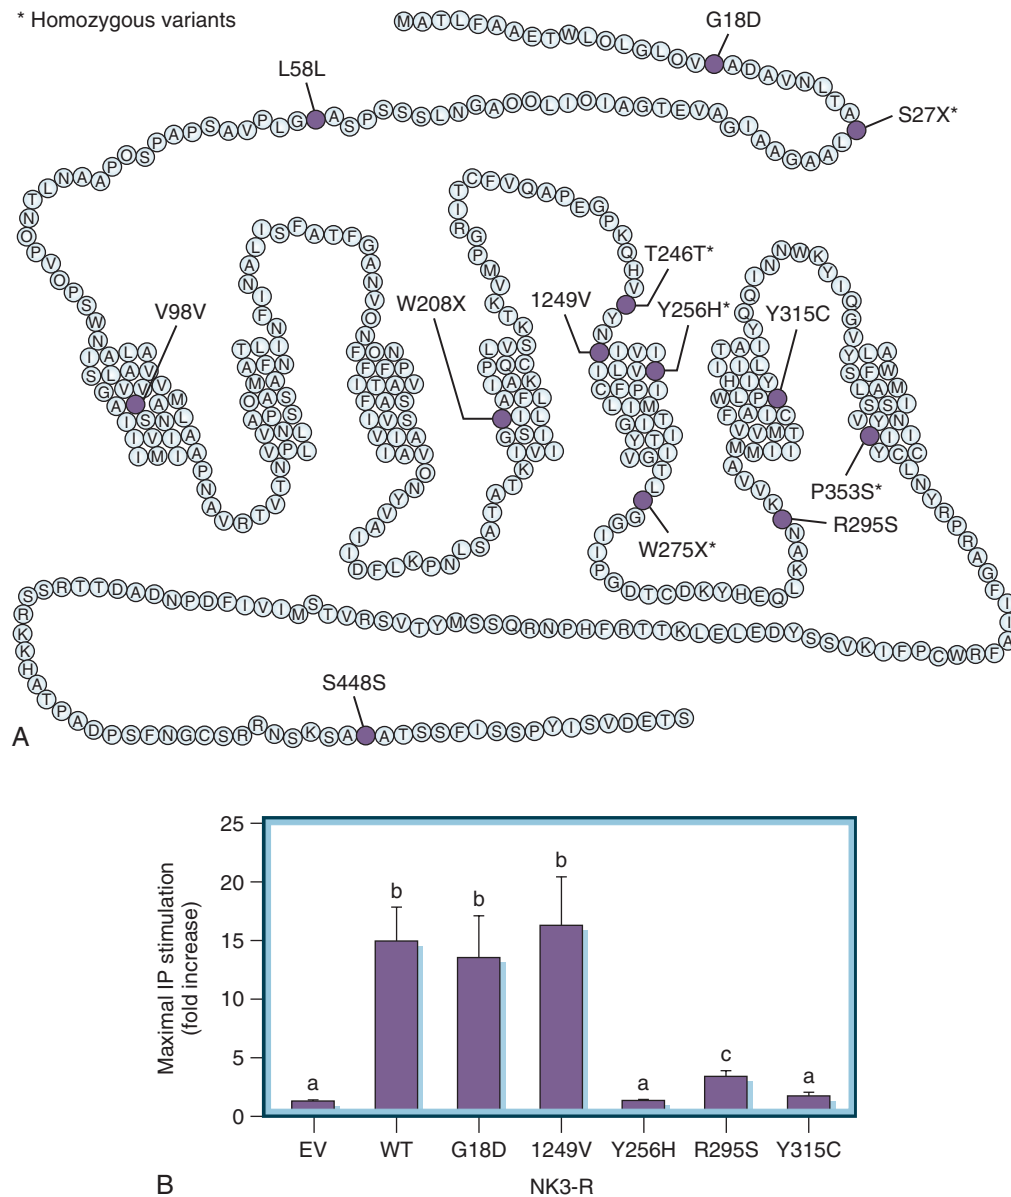

Figure 25-43 **A**, Schematic of mutations in the NK3-R, which is encoded by *TAC3*. **B**, Effects of mutations in *TAC3* on neurokinin B (NKB)-mediated activation of signal transduction. COS-7 cells transfected with wild-type (WT) G18D, 1249V, Y256H, R295S, and Y315C NK3-R or empty vector (EV) were treated with NKB (10^{-7} M) for 1 hour. A significant increase in inositol phosphate (IP) accumulation occurred in cells transfected with WT, G18D, or 1249V NK3-R. In contrast, there was a marked reduction in NKB-stimulated IP production in cells transfected with Y256H, R295S, or Y315C NK3-R, or with EV. a, b, and c denote significantly different fold increases in IP accumulation. (From Gianetti E, Tusset C, Noel SD, et al. *TAC3/TACR3* mutations reveal preferential activation of gonadotropin-releasing hormone release by neurokinin B in neonatal life followed by reversal in adulthood. *J Clin Endocrinol Metab*. 2010;95:2857-2867.)

secondary sex characteristics and with primary amenorrhea but normal adrenarche in the women. The LH concentration was elevated, the serum level of estradiol was low, and immunoactive FSH was absent. Two of the three women had a homozygous nonsense mutation (Val61X) in the FSH β -subunit gene at gene map locus 11p13, and the other was a compound heterozygote (Cys51Gly/Val61X). The two men had azoospermia; small, soft testes; and absence of serum FSH. One had normal puberty and normal LH and testosterone values, with a missense mutation (Cys82Arg), and the other had slightly delayed puberty, low testosterone and inhibin B levels, high LH levels, and a nonsense mutation (Val61X).

Developmental Defect of the Midline

Septo-optic or optic dysplasia is caused by abnormal development of the prosencephalon leading to small, dysplastic, pale optic discs with a double outline and pendular (evenly moving side to side) nystagmus; blindness may occur. A midline hypothalamic defect may cause GH deficiency, diabetes insipidus, and ACTH, TSH, and gonadotropin deficiency. Short stature and delayed puberty may result, although CPP is an alternative.⁵⁶⁵ The septum pellucidum is often absent in association with optic hypoplasia or dysplasia, which is readily demonstrable by imaging techniques.⁵⁶⁶ In the University of California at San Francisco

(UCSF) series, the syndrome was associated with decreased maternal age. The pituitary may be hypoplastic due to the lack of hypothalamic stimulatory factors, and the neurohypophysis may have an ectopic location identified by the location of the posterior pituitary hot spot on MRI. The condition is usually sporadic, but one brother and sister were affected from a consanguineous union, and a mutation in *HESX1* at gene map locus 3p21.2-p21.1 is rarely found.⁵⁶⁷ Abnormalities of the corpus callosum and cerebellum are common on MRI. Four groups are described: those with normal MRI results, those with abnormalities of the septum pellucidum and with a normal hypothalamic-pituitary area, those with abnormalities of the hypothalamic-pituitary area and a normal septum pellucidum, and those with abnormalities in both areas.⁵⁶⁸ No endocrine abnormalities were described in the first group, but the others had progressively more endocrine abnormalities, with precocious puberty most common in the second group. Early diagnosis is important because of the risk of sudden death associated with adrenal insufficiency.

The solitary median maxillary incisor syndrome is associated with the eponymous midline defect and with a prominent midpalatal ridge (torus palatinus) and hypopituitarism. The defect in this autosomal dominant condition is in the sonic hedgehog gene (*SHH*) at gene map locus 7q3.⁵⁶⁹

Other congenital midline defects ranging from complete dysraphism and holoprosencephaly to cleft palate or lip are associated with hypothalamic-pituitary dysfunction. Delayed puberty is rarely described in duplication of the hypophysis. Myelomeningocele (myelodysplasia) is associated with endocrine abnormalities, including hypothalamic hypothyroidism, hyperprolactinemia, and elevated gonadotropin concentrations, and with CPP.

Long-term follow-up of hypogonadotropic hypogonadism or partial pubertal development revealed that even with defined genetic defects, interruption of androgen treatment for several weeks (mean, 6 weeks) revealed restoration of normal gonadal function, including pulsatile LH secretion and spermatogenesis in adulthood.⁵¹³ Of the 15 patients described, 4 had anosmia, 6 had absent puberty, 9 had partial puberty at first, and all had abnormal GnRH-induced LH secretion. Three of 13 evaluated with genetic analysis who reversed their hypogonadotropic hypogonadism had mutations in *FGFR1* or *GNRHR*. Long-term follow-up is necessary, even for patients with established genetic defects.

Idiopathic Hypopituitary Dwarfism

In addition to *HESX1* mutations, autosomal recessive mutations in homeobox genes encoding transcription factors involved in the early aspects of pituitary development lead to hypogonadotropic hypogonadism and other pituitary hormone deficiencies.⁵⁷⁰ *PROP1* mutations at gene map locus 5q cause GH and TSH deficiency and produce delayed puberty or late onset of secondary hypogonadism in adulthood and rarely cause ACTH deficiency (Fig. 25-44).⁵⁷¹ In one study of 73 patients with idiopathic multiple pituitary hormone deficiencies, 35 had a mutation in *PROP1*.⁵⁷² Homozygous Arg73Cys mutation of *PROP1* allowed spontaneous puberty in 2 of 10 affected family members.⁵⁷³ ACTH deficiency is more rarely a feature of *PROP1* deficiency.

Homozygous mutations occur in the *LHX3* gene at gene map locus 9q34.3. It encodes a member of the LIM class of homeodomain proteins, which are associated with multiple pituitary hormone deficiencies, including LH and FSH, and with severe restriction of head rotation.⁵⁷⁴

Figure 25-44 A 20-year-old man with idiopathic hypopituitary dwarfism and deficiencies of gonadotropins, thyrotropin, corticotropin, and growth hormone had a history of arrested hydrocephalus. His height was 129 cm (-8 SD), the phallus was 2 cm long, and the testes measured 1.5×1 cm. He had received thyroid hormone and glucocorticoid replacement. The basal luteinizing hormone (LH) level was less than 0.2 ng/mL (LER-960), follicle-stimulating hormone (FSH) level was 0.5 ng/mL (LER-869), and testosterone level was less than 0.1 ng/mL. In response to 100 μ g of gonadotropin-releasing hormone (GnRH), the plasma LH concentration increased slightly to 0.6 ng/mL, and there was no increase in the plasma testosterone level. The excretion of urinary 17-ketosteroids was 1.1 mg/24 hours. The bone age was 10 years, and the volume of the sella turcica was small on skull radiographs. For conversion to SI units, see Figures 25-16 and 25-17. (From Styne DM, Grumbach MM. Puberty in the male and female: its physiology and disorders. In: Yen SCC, Jaffe RB, eds. *Reproductive Endocrinology*, 2nd ed. Philadelphia, PA: Saunders, 1986:313-384.)

The familial forms of multiple pituitary hormone deficiencies with autosomal recessive or X-linked inheritance are less common. The degree of hormone deficit and the age at onset of pituitary hormone deficiencies may vary within a single kindred having the same genetic defect.

The X-linked form of hypopituitarism can be associated with duplication of the *SOX3* gene.⁵⁷⁵ Deficiency of *SOX2*, a transcription factor involved in early hypothalamic-pituitary embryonic development, leads to anterior pituitary hypoplasia. Patients with *SOX2* mutations have major eye abnormalities, including anophthalmia, microphthalmia, and coloboma. They also have hypogonadotropic hypogonadism as the most common pituitary defect, in contrast to most other types of pituitary hypoplasia, demonstrating GH deficiency most frequently.⁵⁷⁶

There is an association between breech delivery (especially for male infants), perinatal distress, and idiopathic hypopituitarism.^{124,577} Malformations of the pituitary stalk demonstrable by MRI are common in these patients.¹²⁴ Common to many patients with idiopathic hypopituitary

dwarfism is early onset of growth failure; late onset of diminished growth is an ominous finding, suggesting the presence of a CNS tumor.

Isolated GH deficiency allows spontaneous pubertal development when the bone age reaches the pubertal stage of 11 to 13 years, usually after the corresponding chronological age is reached. Associated gonadotropin deficiency does not allow spontaneous puberty, even when the bone age advances to the pubertal stage during GH therapy.

Miscellaneous Conditions

Prader-Willi Syndrome

Prader-Willi syndrome is an autosomal dominant disorder that combines a tendency for intrauterine growth retardation, delayed onset and poor fetal activity, infantile central hypotonia, and lethargy, followed by early-onset childhood hyperphagia, pathologic obesity, and carbohydrate intolerance (leading to type 2 diabetes in 25% of patients at a mean age of 20 years). Features include short stature, small hands and feet, mild to moderate mental retardation, and emotional instability, including perseveration, obsessions, and compulsions. Almond-shaped eyes, a triangular mouth, and narrow bifrontal diameter combined with delayed puberty and hypogonadotropic hypogonadism caused by hypothalamic dysfunction are characteristic. Despite the late or absent puberty, there is a tendency to early adrenarche^{578,579} or even precocious puberty in a few cases.

Affected boys usually have a micropenis and cryptorchidism, and an underdeveloped scrotum is common. In a study of 37 adults with Prader-Willi syndrome, none achieved full genital development, and primary testicular defects were suggested.⁵⁸⁰ Serum AMH levels were near the lower limits of normal, inhibin B levels were consistently low or undetectable, and in the adults, FSH levels were high, although LH levels were normal. Two adults had undetectable levels of LH and FSH, but in contrast to the others, they had high AMH levels. Female subjects exhibit underdevelopment of the labia majora, labia minora, or clitoris. Amenorrhea occurs in about one half of cases, and irregular menses are common in others. Weight reduction may lead to menarche in some females, because severe obesity may play a role in the impaired puberty in some patients. Dietary therapy during years 2 through 10 can provide effective treatment of obesity but may decrease growth, although contemporaneous GH therapy may overcome slow growth.⁵⁸¹

The role of relative GH deficiency in this disorder is uncertain and controversial. The FDA approved Prader-Willi syndrome as an indication for recombinant human GH treatment without a requirement for assessing GH secretion. Genetic testing is used to confirm the clinical diagnosis of the syndrome. GH treatment in a dose of (0.24 mg/kg/wk subcutaneously given 6 to 7 times per week) was shown in long-term, randomized, controlled trials to decrease body fat, increase fat utilization, lean body mass, linear growth, and energy expenditure and possibly to improve physical strength and motor development.⁵⁸² Children with Prader-Willi syndrome are at risk for sudden death due to gastrointestinal, respiratory, or cardiac complications.⁵⁸³ However, the report of sudden deaths due to respiratory complications during GH treatment led to a recommendation for evaluation for sleep apnea or respiratory difficulties before instituting GH therapy. More recent data cast doubt on the beneficial effects of GH on body composition and BMI, but higher parental educational status was correlated with better clinical outcome.⁵⁸⁴

This distinct genetic disorder, with a frequency of about 1 case in 15,000 to 30,000 people, is rarely familial (i.e., the recurrence risk depends on the type of the genetic defect). It is caused by abnormalities involving the long arm of chromosome 15 in the q11-q13 region. Approximately 70% of Prader-Willi cases are caused by a paternal deletion of 15q11-q13 (commonly 3 to 5 mega-base pairs long); 20% to 25% of cases involve maternal uniparental disomy (isodisomy or heterodisomy) in which both chromosomes 15 are derived from the mother, possibly by nondisjunction during maternal meiosis, representing a striking example of genomic imprinting.⁵⁷⁸ In 2% to 5% of cases, an imprinting center defect has been detected. Lack of a functional paternal 15q11-q13 region, caused by any of a variety of genetic mechanisms, can result in the syndrome. One imprinted gene, that for small nuclear ribonucleoprotein associated polypeptide SmN (SNRPN), which is implicated in splicing pre-mRNA, is expressed in the brain, including the hypothalamus, and has been advanced as one explanation of the syndrome.

Elevated serum concentrations of the GH secretagogue and orexigenic gastrointestinal hormone ghrelin are found in the basal state in Prader-Willi syndrome. Increased levels are identified after meals, when values should be suppressed, and are a possible cause of the insatiable appetite. Administration of the somatostatin analogue octreotide leads to a decrease in basal ghrelin values and some decrease in values after meals,⁵⁸⁵ but no change in appetite was demonstrated in preliminary study.

Laurence-Moon and Bardet-Biedl Syndromes

The Laurence-Moon syndrome has frequently been combined with the Bardet-Biedl syndrome; both are autosomal recessive traits, and both combine retinitis pigmentosa and hypogonadism of various causes. Many Bardet-Biedl patients have developmental delay, as do all of the Laurence-Moon patients. The Laurence-Moon syndrome was considered to be associated with spastic paraplegia, whereas the features of Bardet-Biedl syndrome included postaxial polydactyly, onset of obesity (usually in early infancy), and renal dysplasia, and it had a relatively high prevalence among the Bedouin of the Middle East. The genetically and phenotypically heterogeneous Bardet-Biedl syndrome is linked to multiple loci that map to, for example, 20p12, 16q21, 15q22.3-q23, 14q32.1, 11q13, 4q27, 3p12-q13, and 2q31. In most cases, three mutant genes are required for the phenotype.⁵⁸⁶ However, a 22-year study of 26 families in Newfoundland revealed lack of correlation of the phenotype with the genotype, and the study authors stated that there is no justification for continuing to separate Bardet-Biedl syndrome from Laurence-Moon syndrome.⁵⁸⁷ The Biemond syndrome II has similar features, with iris coloboma, hypogenitalism, obesity, polydactyly, and developmental delay, but it is a distinct entity.

Functional Gonadotropin Deficiencies

The effects of malnutrition, which can lead to functional hypogonadotropic hypogonadism, should be separated from the primary effects of chronic systemic disease, some of which have direct effects on the function of the hypothalamic-pituitary unit or the gonads. Even if nutrition is adequate, puberty may be affected. Weight loss of any cause to less than 80% of ideal weight for height can lead to gonadotropin deficiency and low serum leptin levels; weight regain usually restores hypothalamic-pituitary gonadal function over a variable period, although the weight needed to restart menstrual periods varies

among individuals and is related to the weight at which menstruation first ceased.⁵⁸⁸

If adequate nutrition and body weight are maintained in patients with regional enteritis or chronic pulmonary disease, gonadotropin secretion is usually adequate. Cystic fibrosis also delays puberty and the age of PHV, in large part through malnutrition.⁵⁸⁹ The age of menarche in girls with cystic fibrosis is related to maternal age, as expected, but it is delayed by approximately 1 year compared with menarche in the mother, an effect that is mainly related to nutritional status.⁵⁹⁰ However, even with normal pubertal progression, boys with cystic fibrosis almost universally have oligospermia caused by obstruction of the spermatic ducts, which is unrelated to nutritional status. The greater prevalence of reproductive difficulties in male patients with cystic fibrosis compared with female patients may reflect the greater prevalence of the cystic fibrosis transmembrane regulator (CFTR) in male reproductive tissues (e.g., epididymis, vas deferens), and more viscid luminal contents, which ultimately damage the testes and can lead to absence of the epididymides and the vas deferentia.⁵⁹¹ Normal ovaries do not express CFTR, and endometrial tissue expresses it only after puberty, with variable levels found in cervical epithelium and the fallopian tubes. Even though the *CFTR* gene and its protein are expressed in the human hypothalamus, mutations in the corresponding gene did not appear to affect LH and FSH secretion in an immortalized mouse hypothalamic GnRH-secreting cell line.

Jamaican boys and girls with sickle cell disease had delayed pubertal growth spurt and PHV, although adult height was comparable to that of normal adults; girls were said to have a marginally to significantly delayed onset of menstruation.⁵⁹² Boys with sickle cell anemia often exhibit impaired Leydig cell function caused by ischemia of the testes or gonadotropin deficiency, or both.

Thalassemia carries the risk of hemochromatosis due to transfusional iron deposition in the pituitary and hypothalamus; as a consequence, patients may have hypogonadotropic hypogonadism⁵⁹³ and impairment of testicular function.⁵⁹⁴ Primary hypothyroidism is prevalent in this condition, but it is only part of the problem of sexual maturation and growth failure due to GH deficiency.⁵⁹⁵ Before the advent of subcutaneous chelation therapy (with monitoring of serum ferritin), complete absence of pubertal development occurred in more than 40% of patients with thalassemia. The gonads can be stimulated by exogenous gonadotropins, and satisfactory sexual development, including fertility, can be promoted by the use of hCG and human FSH in many patients without gonadal damage,⁵⁹⁶ although pituitary and gonadal damage may be severe in children with poorly controlled disease. Desferrioxamine therapy may cause skeletal dysplasia and compromise pubertal growth.⁵⁹⁷ Decreased BMD in thalassemia makes early recognition and treatment of the problem all the more important.

Cytotoxic effects of the alkylating agents used to prepare patients for bone marrow transplantation in this condition add to the problem. Treatment after the onset of puberty is safer for gonadal function in boys but not necessarily in girls. Girls with early bone marrow transplantation and apparently normal pubertal development have elevated serum FSH levels and menstrual abnormalities ranging up to amenorrhea,⁵⁹⁸ suggesting that gonadal impairment is universal in girls with thalassemia major after bone marrow transplantation.

Growth in stature was delayed in boys with acute immunodeficiency syndrome (AIDS), even when the weight for

height was equal to that of normal boys. AIDS did not affect serum testosterone concentrations, but bone age was delayed, as was the progression through the stages of puberty. Because GH secretion is rarely affected by AIDS, poor growth appeared more related to the delay in pubertal development. These concerns also apply to children with prenatally acquired human immunodeficiency virus (HIV) infection. Prepubertal children with HIV infection had lower IGFBP3 levels than case controls, and the DHEAS-to-cortisol ratio was also higher in infected children.⁵⁹⁹

Chronic gastrointestinal disease (e.g., Crohn's disease) is often accompanied by delayed puberty, and therapy to restore nutrition, if successful, enables puberty to progress. The pubertal growth spurt is compromised by active inflammatory bowel disease, especially if glucocorticoid therapy is necessary. Celiac disease decreases the growth rate in childhood and adolescence, but with appropriate dietary restrictions, final adult height appears to be normal.

Chronic renal disease is associated with delayed pubertal development and decreased pulsatile gonadotropin secretion due to a decrease in the mass of bioactive and immunoactive LH secreted rather than an alteration of the frequency. Successful renal transplantation usually restores gonadotropin secretion and improves growth. Immunoreactive gonadotropin concentrations may be elevated, presumably because of impaired renal clearance, but the response to GnRH is blunted in severe renal impairment. TeBG is elevated in chronic renal failure, and the level of free testosterone is low. Survivors of renal transplantation who are undergoing immune suppression and alternate-day steroid treatment often have delayed onset of puberty and decreased pulsatility of GH and gonadotropins at night.

Patients with nephrotic syndrome have poor pubertal growth, poor secondary sexual development, and deficient gonadotropin secretion in a pattern resembling CDP. Glomerulonephritis treated with alternate-day glucocorticoid therapy leads to a late, diminished, but prolonged pubertal growth spurt that can result in a normal final height.

Children with early onset of leukemia and long-term remission experience puberty at an appropriate age or with only a slight delay, whereas patients with initial symptoms of leukemia in late childhood may have considerable delay of pubertal development. Radiation treatment to the CNS may cause hypogonadotropic hypogonadism or GH deficiency, or both, and irradiation of the abdomen or pelvis and certain types of chemotherapy, especially if administered during puberty, may impair gonadal function and cause primary hypogonadism, although ovarian function may return even in the face of elevated serum gonadotropin levels.⁶⁰⁰ Total-body irradiation for bone marrow transplantation exerts the most significant effects, such as severe GH deficiency in 50%, hypothyroidism in 56%, and hypogonadism in 83% of males, and 100% of women had ovarian failure; insulin resistance was found in 83% and dyslipidemia in 61%.⁶⁰¹ Children with leukemia treated with CNS irradiation had a diminished pubertal growth spurt and diminished final height. Long-term follow-up studies demonstrate the rising incidence of the metabolic syndrome in childhood cancer survivors,^{505,602,603} and data indicate GH deficiency with chemotherapy in the absence of radiation therapy.

Hypothyroidism may delay the onset of puberty or menarche (except in extreme cases in which puberty starts early); treatment with levothyroxine reverses this pattern, but there is likely to be a permanent loss of height if the diagnosis is delayed. Poorly controlled diabetes mellitus can lead to poor growth, fatty infiltration of the liver, and

sexual infantilism (i.e., Mauriac syndrome), which is probably related to poor nutritional status. Prepubertal children are most vulnerable to poor glycemic control, and pubertal subjects exhibit normal growth unless severe hyperglycemia occurs. The degree of control necessary to avoid these complications cannot be exactly quantified, but adolescents with even moderately poor control frequently manifest some degree of growth impairment and delayed puberty or irregular menses. Cushing's disease can be associated with delayed onset or arrest of gonadarche, which usually is corrected by transsphenoidal removal of an ACTH-secreting pituitary adenoma.^{604,605}

Anorexia Nervosa and Variants

Anorexia Nervosa. Anorexia nervosa, a common cause of gonadotropin deficiency in adolescence, is a functional disorder. Prevalence is increased among girls (it is the third most common chronic disease of adolescent girls),⁶⁰⁶ and it starts at ever-younger ages, but it is rare in boys. It is characterized by a distorted body image, obsessive fear of obesity, and food avoidance that can cause severe self-induced weight loss (to less than 85% of normal weight for age and height or a BMI <17.5 kg/m² after cessation of growth), primary or secondary amenorrhea in affected females, widespread endocrine disorders, and even death. Specific diagnostic details are provided in the *Diagnostic and Statistical Manual of Mental Disorders*, fourth edition [DSM-IV] criteria of the American Psychiatric Association.⁶⁰⁷ The onset of amenorrhea precedes the onset of severe weight loss. Controversy exists regarding inclusion of amenorrhea in the DSM-V, because some individuals with classic psychological profiles still have menses.⁶⁰⁸

Other common features include onset in middle adolescence, hyperactivity, defective thermoregulation with hypothermia and sensitivity to cold, constipation, bradycardia and hypotension, decreased basal metabolic rate, dry skin, fine or downy hypertrichosis, peripheral edema, and parotid enlargement. The pathogenesis is multifactorial and includes a genetic factor and a well-characterized psychological component.⁶⁰⁹ Before the diagnosis of anorexia nervosa is made, organic disease must be excluded; a girl with macroprolactinoma may present with signs consistent with anorexia nervosa. The prevalence of anorexia nervosa is increased among individuals with Turner syndrome.

Anorexia nervosa has considerable endocrine ramifications.⁶¹⁰ The concentrations of plasma FSH, LH, leptin, and estradiol and the excretion of urinary gonadotropins are characteristically low. There may be a reversion to a circadian rhythm of LH secretion and to the sleep-associated increase in episodic LH secretion or LH response to GnRH characteristic of early puberty, or the amplitude of the pulsatile episodes may be diminished, as in the pattern of prepubertal children, if onset occurs during puberty. Pulsatile administration of intravenous GnRH at 90- to 120-minute intervals can produce LH pulses that are indistinguishable from the normal pubertal pattern, demonstrating functional GnRH deficiency. Serum leptin levels are low, consistent with the strikingly decreased mass of adipose tissue, and increase with regain of weight.^{611,612} Other hormonal changes include increased mean concentrations of plasma GH and plasma cortisol; low levels of plasma IGF1, DHEAS, and T₃ with normal levels of T₄ (unless the low thyroxine syndrome is present) and TSH; a decreased rise in serum prolactin after administration of thyrotropin-releasing hormone (TRH) or insulin-induced hypoglycemia; and a diminished capacity

to concentrate urine. This condition must be considered in the differential diagnosis of growth failure in younger subjects.

Lower heart rates, lower systolic blood pressure, lower body temperature, anemia, and leukopenia are found in persons with anorexia nervosa.⁶¹³ The ratio of bone age to chronologic age is significantly lower in girls with anorexia nervosa and correlates positively with duration of illness and markers of nutritional status. All measures of BMD are lower, and the most significant predictors of bone density are lean body mass, BMI, and age at menarche. Because treatment of decreased bone density in these individuals has not been proved to be effective, prevention is paramount.⁶¹⁴

Normal endocrine and metabolic function may follow weight gain, but amenorrhea may persist for months, suggesting persistent hypothalamic dysfunction. Free leptin was an important determinant of menstrual recovery in one longitudinal study.⁶¹⁵ In view of the associated mortality rate, parenteral alimentation may be indicated in resistant patients with severe weight loss, especially in those with infection or an electrolyte imbalance. Treatment of this disorder requires skillful management, understanding, patience, and psychiatric consultation.⁶⁰⁹

Functional amenorrhea can occur in women with normal weight but decreased percentage of body fat, and it is characterized by normal basal levels of gonadotropin and normal gonadotropin response to GnRH stimulation but lack of or an inadequate midcycle LH surge and a decrease in normal pulsatile secretion (amplitude or frequency, or both) of gonadotropins.⁶¹⁶ These patients have higher than average cortisol values; decreased levels of free thyroxine (T₄), free triiodothyronine (T₃), and total T₄ with normal TSH levels; and decreased leptin concentrations that are probably caused by subtle dysfunction of eating patterns and altered energy expenditure.⁶¹⁷ The consequences range from severe estrogen deficiency to anovulation to a short luteal phase. Reduced bone density is a concern.

Bulimia nervosa is thought to be a variant of anorexia nervosa,⁶⁰⁹ but separation into two conditions is an approach favored by some.⁶¹⁸ Bulimia occurs in about 1.5% of young women. In this disorder, the individual consumes large amounts of food, but induced vomiting follows food gorging. A hand lesion from the induced vomiting (i.e., Russell's sign) and an abnormal level of serum electrolytes are useful clinical markers. Abuse of laxatives, diet pills, and diuretics is frequent. Although weight loss is not frequent, amenorrhea is common. Bulimia is especially prevalent in high school and college female students. A history of childhood sexual abuse is more common than in unaffected adolescents.

Cessation of growth can occur in infants and young children with psychosocial dwarfism. Stressful social situations can also inhibit growth and physical pubertal development at adolescence.

Exercise, Hypo-Ovarianism, and Amenorrhea: The Female Athlete Triad. In 1992, the American College of Sports Medicine defined the female athletic triad as primary or secondary amenorrhea, disordered eating, and osteoporosis.^{619,620} Although there are substantial endocrine effects of excessive athletic training in girls, elite prepubertal and pubertal female athletes suffer relatively few physical injuries. Because there is no demonstrable effect on pubertal development from moderate exercise in subelite female runners, moderate exercise should not be discouraged during adolescence.

Bulimia, anorexia nervosa, or anorexia athletica is most often found in girls engaged in sports that emphasize weight.⁶²¹ Teenage ballet dancers are lighter, have less body fat, and have a high incidence of delayed puberty and of primary and secondary amenorrhea than less physically active girls. Factors other than decreased body weight can impair pubertal progression and delay menarche through inhibition of the hypothalamic GnRH pulse generator in healthy ballet dancers and female athletes.

Athletes who began strenuous training before menarche have a delay in menarcheal age.⁶²² However, genetic influences overlie changes due to weight or activity because there is a positive correlation between the delayed menarche found in athletic girls and the age of menarche of their mothers. Artistic and rhythmic gymnasts have delay in menarche when compared with their mothers and sisters,⁶²³ and the former have a more significant delay.^{624,625}

Higher bone density is reported in the femurs of gymnasts compared with those of ballet dancers and controls, but lower radial bone density in the gymnasts and ballet dancers reflects the effect of the application of force on bone remodeling; a positive relationship between serum leptin and tibial bone density is found.⁶²⁶ The bone density of female long distance runners is greater in those with regular menses than those with menstrual irregularities. Osteopenia in later life may result from amenorrhea in ballet dancers, even with estrogen replacement, and nutrition therapy is considered important to improve outcome.⁶²⁷

Thinness and strenuous physical activity appear to act synergistically, but strenuous exercise training by itself may inhibit the GnRH pulse generator, mediated in part by endogenous opioidergic pathways involving β -endorphin. When the strenuous physical activity is interrupted (e.g., by injury), puberty advances, and menarche often occurs within a few months in those with amenorrhea, in some cases before a significant change in body composition or weight. Even though gonadarche is retarded, adrenarche is not delayed.

Female athletes of normal weight who have less fat and more muscle than nonathletic girls (e.g., ice skaters, swimmers) are also at risk for delayed puberty and for primary and secondary amenorrhea. However, the mechanism apparently is different from the hypothalamic amenorrhea in runners and ballet dancers. In swimmers, menstrual cycles frequently are irregular and anovulatory rather than absent, and the plasma concentrations of DHEAS and LH were higher than normal, but plasma estrogen levels were normal.⁶²⁸

Prospective study of gymnasts contrasted with swimmers demonstrated decreased growth velocity, stunting in leg length growth, and in some studies, decreased height prediction in the gymnasts.⁶²⁹ Extensive training (10 to 12 hours/week) may be excessive for prepubertal girls.

Prolactin levels may be elevated in women athletes and may contribute to the delayed menarche found in this group.⁴⁹⁷ Osteopenia can result from the associated chronic hypoestrogenism.⁶³⁰

Scoliosis in girls usually develops during the pubertal growth spurt and more often occurs in girls with a more rapid pubertal growth spurt. Ballet dancers have a higher incidence of scoliosis than the general population and often have delayed puberty. Idiopathic scoliosis in the general population is associated with a statistically earlier age of menarche and an early adolescent growth spurt. The strongest association with scoliosis is taller stature at the time of the pubertal growth spurt. Adult height in familial constellations of scoliosis does not vary from the family norm.

Although men are less affected than women, men may also be affected by rigorous physical training. They may have decreased LH response to GnRH and decreased spontaneous LH pulse frequency and amplitude; the serum testosterone level is normal or low with extreme activity levels.

Other Causes of Delayed Puberty

Marijuana use has been associated with gynecomastia and is a putative cause of pubertal delay. Gaucher disease caused delay in pubertal development in two thirds of patients in one study. Girls with familial dysautonomia have delayed menarche and often have a severe premenstrual syndrome. The condition is ultimately compatible with pregnancy. Chronic infections may delay the onset of puberty.

Diabetes mellitus type 1 is associated with delayed menarche.⁶³¹ Remarkably, this may occur no matter the degree of glycemic control.

Hypergonadotropic Hypogonadism: Sexual Infantilism Caused by Primary Gonadal Disorders

The most common forms of primary gonadal failure are associated with sex chromosome abnormalities and characteristic physical findings.⁶³² Testicular or ovarian dysfunction as an isolated finding is less commonly a cause of pubertal hypergonadotropic hypogonadism.

Boys

Klinefelter's Syndrome and Its Variants. Klinefelter's syndrome (i.e., syndrome of seminiferous tubular dysgenesis) and its variants occur in approximately 1 in 1000 males, and they are the most common forms of male hypogonadism.^{632,633} However, less than 10% are diagnosed before puberty, leaving those with decreased androgen production and no treatment susceptible to decreased bone mass.⁶³⁴ The invariable clinical features include small, firm testes as an adult (<3.5 cm long); impaired spermatogenesis; and a male phenotype, usually with gynecomastia and long legs but not long arms (Fig. 25-45).⁶³² Prepubertally, patients can be detected by the disproportionate length of the extremities, decreased upper-to-lower body ratio without an increase in arm span rather than eunuchoid proportions, in which arm span and leg length are increased. Tall stature for family size is common in this disorder due to the disproportionate growth of the legs.

Infants with Klinefelter's syndrome have early evidence of testicular failure because testicular volume and penile length are decreased and the neonatal surge in testosterone is decreased. Muscle tone is also lower in some.⁶³⁵ Before the age of 12 years, gonadotropin concentrations are in the prepubertal range, but levels usually rise with pubertal progression. Rarely, low gonadotropin concentrations occur when hypogonadotropic hypogonadism is associated with 47,XXY Klinefelter's syndrome or coexisting constitutional delay.

Hyalinization and fibrosis of the seminiferous tubules and pseudoadenomatous changes of the Leydig cells develop after puberty; prepubertal testes show only subtle histologic changes, although the testes are small, and the germ cell content is reduced, whereas Sertoli cells are normal in abundance and appearance before 2 years of age. Older prepubertal subjects have normal seminiferous tubules. Adult-type spermatogonia are found in peripubertal boys, and older boys had no germ cells; the testes degenerate in an accelerated manner at the onset of puberty.⁶³⁶ However, there is a 44% success rate for sperm

Figure 25-45 47,XXY Klinefelter's syndrome in 17-year-old identical twins. At age 15, gynecomastia was observed. The twins had a eunuchoid habitus and poorly developed male secondary sexual characteristics. Both were 187 cm tall; arm spans were 187 cm and 189.5 cm; the voices were high pitched; the testes measured 1.8×1.5 cm; and penis length was 7.5 cm. Gynecomastia and signs of androgen deficiency were more evident in the twin on the left. Urinary gonadotropin levels were greater than 50 mU/24 hours. The testes exhibited extensive tubular fibrosis, small dysgenetic tubules, and clumping or pseudoadenomatous formation of Leydig cells; germ cells were rare. The microscopic appearance was typical of seminiferous tubule dysgenesis. (Patient data from Grumbach MM, Barr ML. Cytologic tests of chromosome sex in relation to sexual anomalies in man. *Recent Prog Horm Res.* 1958;14:255-324.)

retrieval from testicular tissues and a 55% success rate for use of microdissection testicular sperm aspiration. Intracytoplasmic sperm injection led to the birth of 101 children, in whom there was no apparent increase in congenital or genetic defects.⁶³⁷

Serum FSH, LH, inhibin B, and AMH levels in nonmosaic XXY infants did not differ from those of control infants. Serum testosterone levels during the first 3 months followed the normal rise in infancy but were lower than those of controls. However, AMH levels were undetectable in XXY adolescents, and inhibin B levels decreased from normal to the low levels characteristic of adult Klinefelter's syndrome during late puberty⁶³⁸ after an unequivocal increase in serum testosterone (>2.5 nmol/L) levels and degeneration of Sertoli cells.

There is variation in Leydig cell function among childhood and pubertal subjects, but the plasma concentration of testosterone fails to rise to normal adult levels. The onset of puberty usually is not delayed, but impaired Leydig cell reserve and low testosterone levels may lead to slow progression or arrest of pubertal changes. Testosterone replacement should be considered when the LH level rises above

the normal range of values but is not necessary in all subjects in early puberty.⁶³⁹ Serum estradiol-to-testosterone ratios and TeBG levels are higher than those in normal males, which indicates an increased estrogen effect and decreased testosterone effect that may account in part for the gynecomastia characteristic of Klinefelter's syndrome. Testosterone administration does not appear to reduce the gynecomastia, but dihydrotestosterone may help. Aromatase inhibitors or estrogen receptor antagonists initially held promise but do not seem to be effective after longer trials. If the gynecomastia does not regress within 2 years, reduction mammoplasty is required. Breast cancer may develop in these individuals, and monitoring for this possibility is important.

The androgen receptor gene is located on the X chromosome and encodes a ligand-dependent transcription factor with highly polymorphic CAGn trinucleotide repeats in the coding sequence of the first exon. The length of the translated polyglutamate tract in the N-terminal transactivation domain of the resulting protein and the length of this polyglutamate tract is inversely proportional to receptor transactivation activity. The shorter the repeat sequence

within the range of normal variation, the more active the androgen receptor, and small changes in this activity may result in more significant effects in Klinefelter's syndrome, in which testosterone secretion may already be impaired. A negative correlation between CAGn repeat length and penile length, but not testicular size, in children has been reported.⁶⁴⁰ Another study found a positive association between CAGn repeat length and body height, an inverse relationship to bone density and arm span to body height, and the presence of longer CAGn repeats for gynecomastia and smaller testes in adults.⁶⁴¹ A paternal origin of the extra X chromosome is associated with later onset of puberty and longer CAG repeats.⁶³⁶

Behavior and Development in Klinefelter's Syndrome. Neurobehavioral abnormalities, primarily in language, speech, learning, and frontal executive functions, are common, even universal, in Klinefelter's syndrome, but severe retardation is uncommon.²³³ These problems may lead to evaluation in childhood and the prepubertal recognition of the syndrome. The prevalence of adjustment problems in adolescence is increased. Psychopathology is a rare finding in most studies, and a 20-year follow-up of 47,XXY individuals showed little or no variation from nonaffected controls in employment, social status, mental or physical health, and criminality.⁶⁴² Because patients with clinical or psychological problems are referred more often for evaluation, some earlier studies may be skewed to suggest more significant deficits than is prevalent in an unselected population of XXY individuals.

The global IQ in unselected populations of Klinefelter's syndrome subjects is normal or near normal, but verbal IQ, in contrast to that of patients with Turner syndrome, is usually lower (e.g., 10 to 20 points) than performance IQ.⁶⁴³

Prepubertal Klinefelter's syndrome patients have reduced left hemisphere specialization for verbal tasks and enhanced right hemisphere specialization for nonverbal tasks. However, these abnormalities tended to normalize after puberty began, suggesting hemispheric reorganization during puberty. Hypotheses are advanced supporting the effect of prenatal testosterone on cerebral dominance and on language and reading pathology.

There is controversy about the indication for testosterone treatment of infants or adolescents with Klinefelter's syndrome. Although there is a growing feeling among parents that testosterone treatment in the early pubertal period improves language, reading, behavior, and self-image in boys with Klinefelter's syndrome, no well-controlled studies supporting this contention are available, and long-term studies are needed.

Other Aspects of Klinefelter's Syndrome. Conditions associated with Klinefelter's syndrome include aortic valvular disease and ruptured berry aneurysms (six times the normal rate); breast carcinoma (20 times the rate in normal men and one fifth that of women); other malignancies such as acute leukemia, lymphoma, and germ cell tumors at any midline site; systemic lupus erythematosus; and osteoporosis in about 25% of affected adults. There is an increased risk of diabetes mellitus, thyroid disease, fatigue, varicose veins, and essential tremor.

About 20% of mediastinal germ cell tumors are associated with Klinefelter's syndrome, and they occur at a younger age than the mediastinal germ cell tumors that are not associated with the syndrome.⁶⁴⁴ With rare exceptions, these germ cell tumors, which may be located in the midline anywhere from the CNS to the pelvis, secrete hCG and induce sexual precocity. Klinefelter's syndrome needs to be considered in boys with hCG-secreting germ cell

tumors, especially if the tumor is located in the mediastinum or CNS.

Other Forms of Primary Testicular Failure

Chemotherapy. Cancer therapy, especially irradiation of the gonads or the use of alkylating chemotherapeutic agents, affects testicular function and can lead to adult infertility.^{645,646} Chemotherapeutic agents used in the treatment of nephrotic syndrome or leukemia, such as cyclophosphamide or chlorambucil, have led to Sertoli cell, Leydig cell, and germ cell damage in prepubertal patients; these effects are sometimes reversible. Chemotherapy for childhood Hodgkin's disease, including chlorambucil, vinblastine, Mustargen, Oncovin, procarbazine, and prednisone, may allow spontaneous progression through puberty, but FSH and LH concentrations may be elevated, and the inhibin B concentrations decrease during puberty, indicative of gonadal damage. Normal basal LH values may raise hope that Leydig cell function is normal, but if there is an exaggerated rise of the LH level after GnRH, compensated Leydig cell damage is present. The basal serum FSH level and rise in LH and FSH levels after GnRH correlate with the dose of cyclophosphamide. COPP/MOPP chemotherapy for Hodgkin's disease can cause severe damage to Sertoli and germinal cells, but it has less effect on Leydig cells, even if therapy occurred in the prepubertal period. Lower dosing or limiting therapy to less than three courses is suggested to decrease these complications.⁶⁴⁷ The combination of Adriamycin, bleomycin, vinblastine, and dacarbazine (ABVD regimen) can cause germ cell depletion. Although initially it was thought that some degree of prepubertal gonadal maturation was necessary before these drugs could cause gonadal damage, gonadal damage can occur earlier as a result of therapy in the prepubertal period but may not be demonstrable until the age of puberty.⁶⁴⁸

Radiation Therapy. Radiotherapy of the gonads can cause primary testicular failure, usually resulting in azoospermia, although normal testosterone secretion may occur with elevated LH and FSH values (i.e., compensated Leydig cell failure). The gonads must be shielded from the treatment unless they are the focus of therapy.

Sperm Preservation. Sperm preservation by cryopreservation is an option for a boy who will undergo chemotherapy or radiation therapy. Alternatively, testicular tissue can be preserved frozen, later to be reimplanted in the subject's own testis or to be stimulated to maturity for use in intracytoplasmic sperm injection. Other methods of preserving fertility years after treatment for childhood cancers are under consideration. This is not established clinical care, but initial study suggests the technique is acceptable to parents and safe.⁶⁴⁹

Testicular Biosynthetic Defects. The 46,XY disorder of sex development is caused by 17 α -hydroxylase/17,20-lyase deficiency resulting from mutations in *CYP17A1* at gene map locus 10q24.3; it is associated with sexual infantilism and a female phenotype. The testosterone biosynthetic defect blocks the synthesis of testosterone and adrenal androgens, impairing masculinization at all stages of development.⁶⁵⁰ Associated cortisol deficiency and increased mineralocorticoid secretion in this condition lead to hypertension, decreased serum potassium levels, and metabolic alkalosis. Elevated serum progesterone levels and decreased plasma renin activity are helpful diagnostic features.⁶⁵¹ Glucocorticoid replacement suppresses ACTH and mineralocorticoid excess and corrects the electrolyte abnormalities, but no sexual development occurs unless exogenous gonadal steroids are administered. Less-severe deficiencies are associated with ambiguous genitalia. *CYP17A1* mutations leading to isolated 17,20-lyase deficiency are rare.

A rare autosomal recessive condition is steroidogenic acute regulatory protein (StAR) deficiency, in which the ability to produce C21-, C19-, and C18-steroids is lost; severely affected patients have lipid-laden adrenal glands. The adrenals and gonads have a severe impairment of the conversion of cholesterol to pregnenolone.⁶⁵² The large adrenal glands may be visualized on ultrasound, CT, or MRI. Death often occurs in infancy because of unrecognized glucocorticoid and mineralocorticoid deficiencies. Affected individuals physically appear to be sexually infantile females, whether their karyotype is 46,XY or 46,XX; because of the absence of gonadal or adrenal androgen production, the affected XY phenotypic females do not develop secondary sexual characteristics, including pubic hair.⁶³³ However, XX females with a null mutation⁶⁵³ develop female sex characteristics at puberty, including pubic hair and multicystic ovaries, but they also have primary or secondary amenorrhea. In contrast to the fetal testis, the fetal ovary, which is insensitive to FSH and steroidogenically inactive, is undamaged in fetal life and remains so until the onset of puberty. Under FSH stimulation during puberty and with recruitment of ovarian follicles, the ovaries undergo progressive damage and cyst formation. Ovarian damage and impairment of ovarian StAR-independent steroidogenesis appears to be related to lipid deposition in the ovary.⁶⁵⁴

Luteinizing Hormone Resistance. Presumptive evidence of LH resistance caused by an LH receptor⁶⁵⁵ abnormality on the Leydig cell was reported in an 18-year-old boy with a male phenotype, no male secondary sexual development, gynecomastia, elevated plasma LH levels, and early pubertal plasma testosterone concentrations that did not increase after hCG administration; there was no elevation of testosterone precursor levels. The testes were prepubertal in size and had the microscopic appearance of normal prepubertal testes. Plasma membrane receptor preparations from the testes bound only one half as much radiolabeled hCG as control testes.

In affected males, this autosomal recessive disorder is caused by a mutation in *LHCGR*, the gene encoding the G protein-coupled, seven-transmembrane LH/hCG cell receptor³²³ at gene map locus 2p21. Mutations that cause a more severe compromise in LHCGR function are associated with XY disorders of sex development. Homozygous deletion of exon 10 or the homozygous missense mutations Ser616Tyr and Ile625Lys of the LH receptor are associated with micropenis (but not hypospadias) due to partial impairment of LH receptor function, leading to a discordance with a poor response to LH but not to hCG. Nephropathic cystinosis in boys leads to hypergonadotropic hypogonadism.

Anorchia and Cryptorchidism. A 46,XY male without palpable testes may have intra-abdominal testes, which carry an increased risk of malignant degeneration; anorchia (i.e., vanishing testes syndrome, caused by perinatal torsion), in which no testes are found at laparotomy; or retractile testes, a variation of normal.^{352,632,656} About 50% of bilateral, nonpalpable testes are undescended, and the other 50% are testicular remnants from vanishing testes that usually do not contain germ cells, are found in the scrotum, are not at risk for carcinoma, and need not be removed if the history is certain.⁶⁵⁷ The prevalence of undescended testes is between 3% and 4% at birth, but it is higher in low-birth-weight, preterm, and SGA males, and the prevalence of these conditions is also increasing. More than two thirds of these descend by 3 months, but there remains a prevalence of undescended testes of about 1% after age 12 months.⁶⁵⁷ If at one time there was a male phenotype and

male internal ducts, functioning fetal testes capable of secreting testosterone and AMH were present early during fetal life but degenerated thereafter. Administration of 2000 U of hCG (3000 U/m²) intramuscularly usually evokes an increased concentration of plasma testosterone after 72 hours when functional Leydig cells are present. The lack of a rise in testosterone concentration, in conjunction with an increased plasma concentration of FSH and LH or an augmented gonadotropin response to GnRH, is evidence for the diagnosis of bilateral anorchia. Alternatively, measurement of plasma AMH can indicate the presence of testicular tissue in a range of suspected conditions in prepubertal boys, from presumed anorchia to male pseudohermaphroditism and true hermaphroditism.³⁰⁵ The serum inhibin B level is a useful indicator of the presence of functional testicular tissue; values correlated with the testosterone response to hCG administration, and values less than 15 pg/mL indicated anorchia.³⁰³

Discovery of unilateral cryptorchidism may represent the presence of a descended testis on one side and none on the other side, and this presents a diagnostic dilemma. In 90% of cases,⁶⁵⁸ there is testicular compensatory hypertrophy of the descended testis if there is absence of the contralateral testis, probably due to elevation of FSH secretion. Because the finding does not universally predict monorchia, laparoscopy is recommended for diagnosis of this condition if ultrasound is unsuccessful. Although there are many statements in the literature that the contralateral descended testis has increased risk of carcinoma in an individual with unilateral undescended testes, analysis suggests the risk is the same as that in the general population.⁶⁵⁷

Studies of cryptorchidism may include all of the conditions mentioned earlier, ranging from retractile testes to unilateral or bilateral cryptorchidism, and conclusions may vary because of the heterogeneous data. A recent review of the international literature on cryptorchidism updated conventional wisdom on the subject.⁶⁵⁷

Cryptorchid testes may demonstrate congenital abnormalities and may not function normally even if brought into the scrotum early in life. The descended testis in a unilaterally cryptorchid boy may show abnormal histologic features; these patients have a 69% incidence of decreased sperm counts. Unilateral cryptorchid patients can be infertile even if they received early treatment of unilateral cryptorchism. Because descended and undescended testes may be affected, there may be preexisting disease that is manifested by the lack of descent of one testis. Patients undergoing orchiopexy may sustain subtle damage to the vas deferens, leading to the later production of antibodies to sperm that may result in infertility.

Cryptorchid testes may descend into the scrotum during more prolonged treatment with hCG (3000 U/m² of surface area, given intramuscularly every other day for six doses) or with intranasal GnRH or a combination of hCG and GnRH treatment.^{659,660} Although such descent occurs in retractile testes, it can occur in true cryptorchid testes but only when descent is not prevented by local anatomic obstructions. One theory posits that hormonal treatment may decrease the number of spermatogonia compared with individuals who had only orchiopexy. Because testicular descent normally occurs by 1 year of age, orchidopexy is recommended between 12 and 18 months in those whose testes are not expected to descend spontaneously. One study linked testicular descent to an adequate neonatal surge of LH and testosterone by 4 months in AGA infants and by 6 months in premature infants; the study authors recommended treatment be considered earlier than at 1 year.⁶⁶¹

Two critical steps in the maturation of germ cells are described in the normal prepubertal testis that do not occur in the unilaterally undescended testes. First, at 2 to 3 months of age, the gonocytes (primitive spermatogonia) in the fetal stem cell pool transform into the adult dark spermatogonia, which become the adult stem pool (possibly related to the early infancy surge in LH, FSH, and testosterone. Second, at 4 to 5 years of age, meiosis begins, and primary spermatocytes appear.⁶⁶² The contralateral descended testis is affected but less so than the undescended testis. Identification of the gonocyte transformation has influenced recommendations on the timing of orchidopexy. Postpubertal orchidopexy is associated with a greater than 85% prevalence of azoospermia or oligospermia. It has been surmised that cryptorchid testes, even if replaced in the scrotum, may never have normal spermatogenic function as a consequence of an early abnormality in germ cell maturation, vascular damage to the testicular circulation during orchidopexy, or an intrinsic testicular defect. However, in a later study of men with cryptorchidism, the paternity rate was 65% for men who had had bilateral cryptorchidism, compared with 90% for the formerly unilateral cryptorchid men and 93% for control men. The reduction in fertility was supported by semen and hormone analyses.⁶⁵⁶ Successful fertilization was reported by the use of intracytoplasmic injection of sperm extracted from the testes of cryptorchid men who had orchidopexy after puberty.⁶⁶³

The incidence of testicular carcinoma in England at all ages increased from 2 per 100,000 in 1909 to 4.4 per 100,000 in 1999, with a rise noticed during puberty,⁶⁶⁴ although the data are nation specific, and there is an approximately 10-fold range between countries.⁶⁵⁷ The most contemporary careful studies indicate an overall relative risk of testicular carcinoma in cryptorchidism of 2.5 to 8, with the highest risk associated with intra-abdominal rather than inguinal testes and higher risks observed for those with abnormal chromosomes, syndromes, or late or no orchidopexy. Adverse environmental factors may be important in the apparent increase in testis cancer, cryptorchidism, hypospadias, and low semen quality, and related factors may be explained by the testicular dysgenesis syndrome.⁶⁶⁵

Early orchidopexy seems to reduce the risk of carcinoma of the testes,⁶⁶⁶ although dysgenetic testes, even if located in the scrotum, carry an increased risk of malignant transformation.⁶³² Undescended testes remain at a higher temperature than descended testes, and undescended testes have a maturation arrest at the conversion of the gonocytes to spermatogonia, which appears to direct the testes toward malignant degeneration.⁶⁶⁶ Orchidopexy before 12 years of age (considered as the age of puberty and therefore an appropriate cutoff for analysis although 10 years is considered in the same manner by some) usually is considered to decrease the risk of cancer, but later orchidopexy must balance the risk of anesthesia with the risk of cancer.⁶⁵⁷ There is a very small risk of carcinoma of the testes in prepuberty, but the absence of carcinoma in situ in prepuberty is not an assurance that carcinoma will not develop in adult life. Periodic sonography of the testis of undescended patients is recommended after the onset of puberty.

Retractile testes can descend into the scrotum but then reascend. They are considered a normal variation, but a requirement for orchidopexy was reported for 22.7% in a series of 150. The finding of one case of testicular carcinoma in a boy with spontaneous descent in this series led to a suggestion of following such cases in the long term.⁶⁶⁷ The risk of breast cancer associated with gynecomastia is increased in men with a history of undescended testes,

orchidopexy, orchitis, testicular injury, infertility, or any cause of delayed puberty.

Small for Gestational Age. SGA predisposes males to reproductive problems and is associated with the testicular dysgenesis syndrome. Males born SGA tend to have smaller testes and lower testosterone and higher LH levels,⁶⁶⁸ suggesting an impairment of fertility, as is found in SGA females. Adult males born SGA have increased aromatase and 5 α -reductase activities, leading to elevated levels of estradiol and dihydrotestosterone.⁶⁶⁹ Of most concern is the fact that elevated estradiol levels in males increase the risk of testicular cancer and do not provide the protective effect on cardiovascular health as found in females. The level of inhibin B is elevated in significantly SGA boys (i.e., mean birth weights >2 SD below the mean for gestational age), although other studies with higher-birth-weight SGA boys demonstrated no such changes.⁶⁷⁰

Girls

Syndrome of Gonadal Dysgenesis and Its Variants. The most common form of hypergonadotropic hypogonadism in the female is the syndrome of gonadal dysgenesis (Turner syndrome and its variants), a sporadic disorder with an incidence of 1 per 2500 liveborn girls in which all (i.e., X chromosome monosomy with haploinsufficiency) or part of the second sex chromosome (i.e., partial sex chromosome monosomy) is absent.^{632,671} About 99% of 45,X conceptuses abort spontaneously, and 1 in 15 spontaneous abortions has a 45,X karyotype. The 45,X karyotype is associated with female phenotype, short stature, sexual infantilism, and various somatic abnormalities.

Sex chromosome mosaicism or structural abnormalities of an X or Y chromosome (affects about 40% of individuals with Turner syndrome) may modify the features of this syndrome. The syndrome of gonadal dysgenesis and its variants are found in a continuum ranging from the typical 45,X phenotype to a normal male or female phenotype.⁶³² Comprehensive recommendations for the diagnosis and management of Turner syndrome were presented by an international committee.⁶⁷²

45,X Turner Syndrome. Short stature and sexual infantilism are typical features of sex chromatin-negative 45,X gonadal dysgenesis (Turner syndrome), which is the karyotype found in approximately 60% of cases (Fig. 25-46).⁶³² The short stature is caused by loss of a homeobox-containing gene that is located on the pseudoautosomal region (PAR1) of the short arms of the X (p22) and Y (p11.3) chromosomes^{673,674} and encodes an osteogenic factor. This short stature homeobox-containing gene (*SHOX*)⁶⁷³ was previously called the pseudoautosomal homeobox osteogenic gene (*PHOG*). Because it is located on the PAR1 of the short arm of the X and Y chromosomes, it escapes X-chromosome inactivation. *SHOX* haploinsufficiency is responsible for, in addition to abnormal growth, mesomelic growth retardation, and Madelung deformity of the wrist (i.e., bilateral bowing of the radius with a dorsal subluxation of the distal ulna)^{674,675,676} in Leri-Weill dyschondrosteosis (i.e., *SHOX* haploinsufficiency). Langer mesomelic dysplasia, which includes severe dwarfism with striking hypoplasia or aplasia of the ulnar and fibula, is caused by *SHOX* nullizygosity. *SHOX* haploinsufficiency appears to be responsible for 2.0 SD of the approximately 3.0 SD deficit in stature and the skeletal abnormalities in Turner syndrome.⁶⁷⁶⁻⁶⁷⁹ On the other hand, patients with complete gonadal dysgenesis and tall stature had a 45,X/46,X der(X) and three doses of the *SHOX* gene due to the *SHOX* duplication on the der(X) chromosome. A method of relating the *SHOX* genotype to phenotypic manifestations has been developed.⁶⁸⁰

Figure 25-46 Left, A girl aged 14 years and 10 months with the typical form of the syndrome of gonadal dysgenesis (Turner syndrome). The X chromatin pattern was negative, and the karyotype was 45,X. She was short (height, 134.5 cm; height age, 9 years and 5 months) and sexually infantile except for the appearance of sparse pubic hair. She exhibited characteristic stigmata of the syndrome: a short, webbed neck; shield-like chest with widely separated nipples; bilateral metacarpal signs; puffiness over the dorsum of the fingers; cubitus valgus; increased number of pigmented nevi; characteristic facies; and low-set ears. The bone age was 13.5 years; the urinary 17-ketosteroid level was 5.1 mg/day; and the urinary gonadotropin level was greater than 100 mU/day. Vaginal smears and the urocytogram showed an immature pattern in which cornified squamous cells were absent. Female secondary sexual characteristics were induced with estrogen therapy, and the cyclic administration resulted in periodic estrogen withdrawal bleeding. Right, A 45,X girl aged 9 years and 11 months with Turner syndrome. Apart from short stature (height, 118 cm; height age, 6 years and 11 months), increased pigmented nevi, and subtle changes in the fingers and toes, she had few somatic anomalies. In contrast to the patient on the left, the main clinical feature was short stature.

Turner syndrome may be recognized in the newborn period or before. The 45,X abortuses have edema and large hygromas of the neck that may be seen on prenatal ultrasound studies. This lymphatic defect is the basis for the loose skinfolds that ultimately form the webbed neck (i.e., pterygium colli). Affected newborn infants may also have lymphedema of the extremities; the term *Bonnevie-Ullrich syndrome* has been applied to newborn infants with these features of Turner syndrome.

Frequent features are distinct facies with micrognathia, a fish-mouth appearance, high-arched palate with dental abnormalities, epicanthal folds, ptosis, low-set or deformed ears, short neck with low hairline, webbing (i.e., pterygium colli), and recurrent otitis media, often leading to impaired hearing (25% of affected adults require hearing aids).⁶³² A broad, shieldlike chest leads to the appearance of widely spaced nipples, and the areolae are often hypoplastic. Skeletal defects include short fourth metacarpals and cubitus valgus (which may develop after birth), Madelung deformity of the wrist (in about 7%), genu valgum, and scoliosis.

There are extensive pigmented nevi, a tendency to keloid formation, and hypoplastic nails.⁶³² Lymphatic obstruction leads to the infantile puffiness of extremities and pterygium colli and to a distinctive shape of the ears. Cardiovascular anomalies affect the left side of the heart and include coarctation of the aorta in about 10% (40% of these have associated webbing of the neck), aortic stenosis, and bicuspid aortic valves; the latter individuals are at risk for a dissecting aortic aneurysm. An echocardiogram of the cardiovascular system must be performed, and prophylactic antibiotics are indicated if an anatomic abnormality is demonstrated. Elevated values on the ambulatory arterial stiffness index (AASI) may be another risk factor for later serious cardiac disease.⁶⁸¹ Abnormal pelvocaliceal collecting systems, abnormal position or alignment of the kidneys, and an abnormal vascular supply to the kidney are encountered in 30% to 60% of patients. Recurrent urinary tract infections are common. Defects of the gastrointestinal system include intestinal telangiectasias and hemangiomas that rarely can lead to massive gastrointestinal

bleeding. The prevalence of inflammatory bowel disease, chronic liver disease, and colon cancer is increased.^{671,682} Autoimmune diseases, such as Hashimoto thyroiditis (16-fold relative risk) and Graves' disease, are common, and an association with juvenile rheumatoid arthritis and psoriatic arthritis has been described.^{671,682}

The age of diagnosis of Turner syndrome continues to be delayed, with the exception of newborns with the striking phenotype of the Bonnevie-Ullrich syndrome. It is recommended that all prepubertal age girls below -2.0 SD who have at least two somatic stigmata of the syndrome have a karyotype analysis; early diagnosis is key for optimal management of the growth failure and the detection of occult features of the syndrome.⁶⁸³

Pelvic ultrasonography or MRI usually permits the detection of even a small, infantile uterus and reveals streak gonads. Ultrasensitive estrogen bioassays can confirm decreased ovarian function in girls with Turner syndrome because estradiol values are significantly lower than those found in average girls. Long-term follow-up of affected women previously treated with GH and estrogen demonstrated normal adult uterine length only in those with 45,X/46,XX karyotypes, whereas those with pure 45,X karyotypes had a smaller uterus length and volume.⁶⁸⁴ The streak gonads result in sexual infantilism, but in about 10% of cases, puberty, menarche, and rarely, pregnancy may occur.⁶³² Women with some of the variants have been able to achieve fertility and deliver normal infants. Affected adults can undergo hormone replacement to prepare the uterus to receive a donated embryo and proceed to delivery. Unfortunately, some patients receiving a donated ovum have died because of dissection or rupture of the aorta, and caution should be used in recommending this technique.⁶⁸⁵ Long-term regular follow-up of adults with Turner syndrome with echocardiography is recommended.

Intrauterine growth retardation with a mean deficit in birth length of 2.6 cm (-1.24 SD) and a slow childhood growth rate result in a loss of about 8 to 9 cm (-3.0 SD) by age 3 years in girls with Turner syndrome.⁶⁸⁶ A major portion of the height deficit occurs during the first 3 years of life. Decreased growth rate occurs at the time of expected puberty, and the pubertal growth spurt is absent in those without pubertal development. Subjects who undergo spontaneous puberty have decreased growth in the first year after birth and another decrease at 7 to 8 years. This may reflect a suppressive effect of estrogen on growth in those retaining some ovarian function.⁶⁸⁷ Untreated individuals with Turner syndrome in the United Kingdom and United States have a mean final height of approximately 142 to 143 cm, which is about 20 cm less than the average height of normal women; the adult stature of these patients correlates with midparental height and with the height of unaffected women of the same ethnic group. Haploinsufficiency of the *SHOX* gene is estimated to contribute two thirds of the height deficit. It is postulated that a second gene on the short arm of the X chromosome that does not undergo X-chromosome inactivation contributes the other one third of the deficit. In girls with Turner syndrome with spontaneous puberty, pubertal height velocity was transiently higher than in girls with amenorrhea, but adult height was not different.⁶³² Specific growth curves are available for plotting the growth of affected children.⁶⁸⁸

GH treatment is approved by the FDA for Turner syndrome to increase height. The addition of estrogen therapy at low doses has exerted no effect on adult height or actually reduced the adult height obtained with GH therapy administered alone. The length of GH exposure before

estrogen treatment was the major determinant of whether GH and estrogen treatment increased final height.^{689,690} With an early age of initiation of GH therapy, low-dose estrogen can be introduced at an appropriate age (about age 13) without compromising adult height. However, if GH is started early enough (e.g., 2 to 8 years old), estrogen therapy may be added at an age (about 13 years) appropriate for the institution of puberty.⁶⁷⁰ Percutaneous estrogen may be more beneficial than oral estrogen therapy. An adult height of 149 to 155 cm was achieved compared with an untreated control group, which reached a height of 142 cm even if estrogen administration started at the normal age of puberty or GH administration was started at a later age.⁶⁹¹ The average height gain in various studies has varied from 4 to 16 cm, and a systematic review of the literature shows a 5-cm gain to be the most likely outcome.⁶⁹² This variability in gain in height is incompletely understood, but many factors have been implicated, including the age of initiation of therapy, dose duration, age (especially number of years from beginning hGH treatment) at beginning estrogen replacement, number of injections per week, compliance, and whether the last measured height represented the final height. Early initiation of hGH therapy (e.g., 2 to 8 years of age) and a mean duration of treatment of about 7 years can lead most treated Turner patients to achieve an adult height greater than 150 cm; a Dutch study reported the mean adult height was 162.3 ± 6.1 cm.⁶⁹³ Evaluation of bone density is technique specific, but GH treatment of Turner syndrome for at least 1 year showed no difference in volumetric BMD, although lean body mass was higher and fat mass was lower than in the controls.⁶⁹⁴ GH treatment of Turner patients has been safe, and untoward events are uncommon.⁶⁹² There is some degree of improvement of the abnormal body proportions of Turner syndrome with hGH treatment, but the disproportionate growth of the foot may dissuade some girls from continuing treatment to maximal benefit on height. Five-year follow-up of young adults with Turner syndrome demonstrated continued beneficial effects of GH on blood pressure, lipid levels, and increased adult height.^{695,696}

A nationwide survey of 632 Danish girls with Turner syndrome demonstrated an increased prevalence of fractures, mainly in the forearm, compared with controls. The prevalence was higher still in the absence of ovarian function and in girls with family history of fractures and presumed familial disorders of bone density.⁶⁹⁷ It appears that estrogen therapy is critical for the prevention and repair of osteoporosis, but for adolescents and adults, the optimal dose preparation and site of delivery for the prevention of osteoporosis is not known.

About 50% of patients with Turner syndrome have a tendency toward impaired glucose tolerance without GH treatment; in some, this may be caused by associated obesity, and risk of type 2 diabetes mellitus is increased. Although glucose values do not change with GH therapy, insulin levels reversibly rise during treatment, indicating an additional degree of insulin resistance caused by the GH.⁶⁹⁸ Turner syndrome patients as young as 11 years can already have elevated serum cholesterol concentrations before treatment with GH or estrogen. The biphasic pattern of gonadotropin secretion in normal infancy and childhood is exaggerated in Turner syndrome (see Fig. 25-22).^{386,387}

The appearance of pubic hair (i.e., pubarche) is often delayed in the syndrome of gonadal dysgenesis, even though adrenarche, as assessed by the increase in concentration of plasma DHEAS, occurs at the normal age.⁴⁴² Girls

with ovarian failure demonstrate early adrenarche, and therefore higher serum values of DHEAS but later pubarche, whereas those who demonstrate at least beginning breast development follow a course of adrenarche similar to that of unaffected girls.⁶⁹⁹ This suggests that ovarian function is necessary to convert DHEA to the active androgens responsible for the appearance of pubic hair in normal girls. The pubic hair of affected individuals is sparse, but estrogen therapy increases the growth of pubic hair despite a lack of increase in adrenal androgen secretion, and estrogen affects pubic hair appearance.⁷⁰⁰

Behavior and Development of Turner Syndrome. Counseling and a peer support group are exceedingly important components of long-term management. Girls with Turner syndrome younger than 6 years did not perceive that they had a problem with height, but by 7 to 12 years and especially by 13 to 15 years, affected Turner girls have a strong desire for GH therapy and even unrealistic expectations of what GH therapy can accomplish in terms of adult height. GH therapy improved self-esteem even if there remained a significant difference in height between Turner girls and the normal range. Height gained with GH therapy did not affect quality of life, although cardiac defects and otologic complications did.⁷⁰¹ Girls who have discontinued GH therapy after reaching adult height showed no evidence of depression but still had remaining problems with self-perception and bodily attitude despite significant height gains.⁷⁰² Psychological problems in Turner syndrome are not necessarily diminished with GH treatment and an increase in adult height.

Turner syndrome girls resemble normal girls in verbal and language skills, and IQ is normal when verbal ability, including comprehension and vocabulary, are considered, but visual-constructional or visual-perceptual spatiotemporal processing, visuomotor coordination, and mathematical ability (particularly in geometry) may be impaired, leading to a decrease in the performance of IQ tests due to mistakes on operation and alignment processes. Girls with 45,X mosaicism associated with a 46,XX cell line, 45,X/46,XX, scored closer to normal than those with other types of mosaicism. Only 3.3% of girls with Turner syndrome have developmental delay in the absence of a variant of Turner syndrome caused by a ring X chromosome. It is useful to monitor the patient's progress in high school mathematics. There are consistent MRI abnormalities in the right parietal lobe and the occipital lobes, and decreased volumes in these areas are implicated in defects in visual-spatial processing. Using positron emission tomography, decreased glucose metabolism is found in the right parietal and occipital lobes.⁷⁰³ These anatomic data relate to the difficulties in visual-spatial skills found in most studies of girls with Turner syndrome, because these problems are most closely linked to the right parietal region.

There is an increased risk of impaired social adjustment in Turner syndrome. Those with the 45,X pattern demonstrate a significant decrease in social competence scores; have an increase in total behavior problems; have increased attention problems, with difficulty in schooling, peer relationships, and concentration; and exhibit immaturity, hyperactivity, nervousness, and withdrawn behaviors. Structural abnormalities of the X chromosome were associated with more behavior problems than a missing X chromosome or mosaicism of the X chromosomes. Mental retardation and a severe phenotype are associated with small ring X chromosomes that undergo X inactivation, resulting in X chromosome disomy for genes that are affected by X inactivation. The 45,X individuals in whom the X is of paternal origin (X^p) show better adjustment and

social cognition as a group than X^m individuals. Documented mental health problems may be rooted in the increased peer ridicule experienced by girls with Turner syndrome rather than a biologic abnormality.⁷⁰⁴

Transition of girls with Turner syndrome to adult care is best carried out by an experienced team, which is ideally composed of an endocrinologist; cardiologist; nephrologist; reproductive endocrinologist; audiologic physician; ear, nose, and throat surgeon; plastic surgeon; dentist; and psychologist because of the multiplicity of complications that affected individuals may encounter in the areas of growth failure, cardiovascular disease, gonadal failure, and learning disabilities.⁷⁰⁵

Sex Chromatin-Positive Variants of the Syndrome of Gonadal Dysgenesis. Mosaicism of 45,X/46,XX; 45,X/47,XXX; or 45,X/46,XX/47,XXX chromosomes is associated with a chromatin-positive buccal smear and usually with fewer manifestations of the syndrome of gonadal dysgenesis. Likewise, structural abnormalities of the X chromosome can be associated with fewer phenotypic features of the syndrome. Lack of genetic material on the long or the short arm of the second X chromosome can cause decreased gonadal function; loss of all or part of the short arm of the X leads to the physical findings of Turner syndrome.⁶³² Depending on the location and extent of the deletion on the short arm of the X chromosome, these patients may be more likely to have modest pubertal growth and some spontaneous pubertal development.

Sex Chromatin-Negative Variants of Gonadal Dysgenesis. These variants include 45,X/46,XY mosaicism and structural abnormalities of the Y chromosome. Affected individuals have phenotypes that vary from that of classic gonadal dysgenesis to that of ambiguous genitalia to phenotypic males.⁶³² Patients may present with short stature, delayed puberty, and a history of hypospadias repair. There is variable testicular differentiation, ranging from a streak gonad to functioning testes. Patients with mosaicism involving a Y cell line or abnormalities of the Y chromosome are at risk for neoplastic transformation of the dysgenetic testes. Gonadoblastomas, which are benign, nonmetastasizing tumors, may arise within the gonad and produce testosterone or estrogens. The neoplasm may become calcified sufficiently to be detected on an abdominal radiograph. The appearance of feminization or virilization in a patient with dysgenetic gonads and a Y cell line may indicate gonadoblastoma formation. Of greater significance is the increased prevalence of malignant germ cell tumors, arising within the dysgenetic gonad or gonadoblastoma. Examples are dysgerminomas, mature teratomas, and testicular intraepithelial neoplasia.⁷⁰⁶ These tumors occur more often in postpubertal subjects and rarely in children.⁶³²

46,XX and 46,XY Gonadal Dysgenesis. The term *pure gonadal dysgenesis* refers to phenotypic females with sexual infantilism and a 46,XX or 46,XY karyotype without chromosomal abnormalities.⁶³²

Familial and Sporadic 46,XX Gonadal Dysgenesis and Its Variants. The usual phenotype of 46,XX gonadal dysgenesis includes normal stature, sexual infantilism, bilateral streak gonad, normal female internal and external genitalia, and primary amenorrhea. The streak gonad occasionally produces estrogens or androgens, but malignant transformation is rare. Incomplete forms of this condition may result in hypoplastic ovaries that produce enough estrogen to cause some breast development and a few menstrual periods, followed by secondary amenorrhea. This heterogeneous syndrome occurs sporadically or with autosomal recessive inheritance, and in some instances, it is

associated with other congenital malformations. Some familial cases have been associated with sensorineural deafness (i.e., Perrault syndrome).⁶³²

Familial and Sporadic 46,XY Gonadal Dysgenesis and Its Variants. A phenotype that includes female genitalia with or without clitoral enlargement, normal or tall stature, bilateral streak gonads, normal müllerian structures, sexual infantilism, and a eunuchoid habitus is typical of 46,XY gonadal dysgenesis. About 15% of the patients have a deletion or mutation in the *SRY* gene. If the dysgenetic testes produce significant amounts of testosterone, slight clitoral enlargement may occur at birth, and virilization may ensue at puberty. The incomplete form of 46,XY gonadal dysgenesis may involve any degree of ambiguity of the external genitalia and internal ducts. The risk of neoplastic transformation of the streak gonads or dysgenetic testes is increased, and gonadectomy is indicated. The disorder is usually transmitted as an X-linked or sex-limited autosomal dominant trait or less commonly as an autosomal recessive trait.⁶³²

Other Causes of Primary Ovarian Failure. The prevalence of primary ovarian failure is increasing as a consequence of the long-term effects of cytotoxic chemotherapy and radiation therapy as these agents prolong the lives of children and adolescents with cancer.⁶⁴⁵ The same pattern occurs for males with testes that have been treated with these modalities.

Radiation Therapy. Radiation therapy that includes the ovaries within the field can cause primary ovarian failure. It is useful to surgically move the ovaries out of the radiation field if they are not the target of therapy, thereby greatly decreasing the dose of radiation to them. Ovarian transposition before radiation therapy is compatible with normal menses, pubertal development, and pregnancy in most cases. The uterus may be affected by radiation and may not expand normally during pregnancy.

Chemotherapy. Successful treatment of childhood acute lymphoblastic leukemia has become commonplace. In a large study by Quigley and colleagues, boys and girls after cytotoxic chemotherapy had extensive germ cell damage, as evidenced by increased FSH secretion, and boys had decreased testicular size for the stage of puberty. The concentration of plasma inhibin B is usually decreased, providing a sensitive indicator of damage to the germinal epithelium. Many of the girls at puberty had evidence of a compensated decrease in ovarian follicular function. Quite likely as a result of cranial irradiation, the mean age of menarche was advanced about 12 months despite the ovarian damage; puberty was not advanced in the boys. The type of chemotherapy determines the effects on the gonads. The ovary is less vulnerable to the effects of irradiation and chemotherapy than the testis. The prevalence of ovarian damage does not appear to be high, because fertility and regular menses are reported in most females treated as children.⁷⁰⁷ Nevertheless, age at treatment has a significant role. Treatment between 13 and 19 years was associated with a more than twofold increase in premature ovarian failure during the third decade. Attempts to protect the gonads by suppressing the pituitary-gonadal axis with gonadal steroids or GnRH agonists are probably ineffective.⁷⁰⁸ Careful endocrine follow-up of children and adolescents treated with chemotherapy or radiation therapy is essential.

Autoimmune Oophoritis. Premature menopause may occur at any age before the normal climacteric and has been reported in adolescent girls. Cessation of ovarian function usually manifests as secondary amenorrhea.⁷⁰⁹ Autoimmune oophoritis can cause ovarian failure leading

to primary amenorrhea, oligomenorrhea, arrest of puberty, and occasionally cystic enlargement of the ovaries. Most often, it is associated with other autoimmune endocrinopathies, especially autoimmune Addison's disease, in which it may precede the onset of adrenal insufficiency, but it rarely occurs in isolated premature ovarian failure. Glucocorticoid therapy may improve, at least temporarily, ovarian function.

Type I autoimmune polyglandular insufficiency, also known as autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy (APECED), is a rare systemic autoimmune disorder with an array of clinical features, including hypoparathyroidism, adrenal insufficiency, gonadal failure, diabetes mellitus, pernicious anemia, hypothyroidism, chronic hepatitis, mucocutaneous candidiasis, dystrophic nail hypoplasia, vitiligo, alopecia, keratinopathy, and intestinal malabsorption. Thirty-six percent of women with APECED exhibited ovarian failure before age 20, whereas only 4% of affected men had testicular failure by that age. This autosomal recessive disorder is caused by more than 42 mutations in the *CDK14* (AIRE-1) gene at gene map locus 21q22.3. A study of genotype and phenotype correlations demonstrated a higher prevalence of candidiasis in the patients with the most common mutation, R257X, although HLA class II is a significant determinant.⁷¹⁰ This contrasts with earlier studies, which suggested a phenotype-genotype correlation for other features.

Autoimmune oophoritis occurs in more than 20% of patients with autoimmune adrenal insufficiency. Various autoantibodies have been detected in autoimmune oophoritis, including autoantibodies to cytochrome P450 steroidogenic enzymes; some are organ specific, whereas others react with antigens in more than one tissue and more than one cell type.

Homozygous Galactosemia. Homozygous galactosemia due to mutation in the galactose-1-phosphate uridylyl-transferase gene (*GALT*) is commonly associated with primary ovarian failure, from failure to develop puberty to primary or secondary amenorrhea and premature menopause, but puberty is usually normal in males, and the risk of testicular dysfunction is low; compound heterozygotes have normal onset of puberty. Dietary restriction programs have not prevented the ovarian failure, nor are other means of avoiding ovarian failure effective. The pathogenesis of galactose-induced ovarian toxicity remains unclear but probably involves galactose itself and its metabolites, such as galactitol and UDP-galactose.⁷¹¹ Most cases are detected by newborn screening programs.

Haploinsufficiency of the *FOXL2* Gene. A rare autosomal dominant disorder involving eyelid dysplasia and premature ovarian failure is caused by haploinsufficiency of the *FOXL2* gene, a member of the winged helix/forkhead family of transcription factors.⁷¹² The eyelid abnormalities include small palpebral fissures, ptosis, and a small skin-fold extending inward and upward from the lower lid (i.e., epicanthus inversus). The gene is expressed in the follicular cells, and the mutations that lead to haploinsufficiency are associated with an increased rate of follicular atresia. The degree of ovarian failure varies from primary amenorrhea to irregular menses and premature ovarian failure, with ultrasound findings ranging from normal-appearing ovaries to streak gonads with an inconsistent number of primordial follicles found on ovarian biopsy.⁷¹³ The infertility component of the syndrome is limited to females. Animal studies provide insights into other genetic mutations that may cause premature ovarian failure in humans, including mutations of *BMP15*, *FMR1*, *POF1B*, and *FOXO3A*.⁷¹⁴

Congenital Disorders of Glycosylation-1: Carbohydrate-Deficient Glycoprotein Syndrome Type Ia. The congenital disorders of glycosylation-1 (i.e., carbohydrate-deficient glycoprotein syndrome type Ia) include an autosomal recessive disorder associated with circulating glycoproteins deficient in their terminal carbohydrate moieties, including a wide range of glycoproteins, enzymes, binding proteins, and coagulation factors.⁷¹⁵ A typical isoform pattern of serum transferrin detected by isoelectric focusing is used as a diagnostic test. The dominant clinical feature is the neurologic manifestations of involvement of the central and peripheral nervous system. Among the other organ systems affected is the pituitary-gonadal system.

The hypergonadotropic-hypogonadism is more severe in females because males virilize at puberty. The ovary and the pituitary are affected. Affected girls have sexual infantilism; the ovaries are hypoplastic or atrophic. High serum FSH and LH levels exhibited normal electrophoretic isoform patterns, but they appeared to have decreased but not absent FSH bioactivity in an FSH bioassay. However, in the only three girls tested, a response to the administration of human menopausal gonadotropin was indicated by an increase in serum estradiol and, in one patient, by ovarian follicular growth. These observations suggest an abnormality in the FSH molecule and the ovary, which in the latter case was a defect in the configuration and activation of the FSH receptor itself and the binding of ligand, or a post-receptor defect.

Resistant Ovary. The resistant ovary is a heterogeneous cause of primary hypogonadism, a syndrome associated with elevated concentrations of plasma FSH and LH and ovaries that contain primordial follicles. The syndrome is usually idiopathic, but an increasing number of genetic abnormalities are described in addition to the more common X-chromosomal defects.⁷¹⁶

Follicle-Stimulating Hormone Receptor Resistance: Gene Mutations and Hypergonadotropic Hypogonadism. The FSH receptor is a member of the G protein-linked receptor, seven-transmembrane superfamily. It has a large, extended extracellular ligand-binding domain.³²³ An autosomal recessive disorder due to a mutation in the extracellular ligand-binding domain of the FSH receptor in affected females in six Finnish families mainly from the north central region⁶⁵⁵ resulted in delayed (40%) or normal puberty but primary amenorrhea, elevated gonadotropin levels, and hypergonadotropic ovarian dysgenesis with arrest of ovarian follicular development at the primary follicle stage and continued atresia. The clinical features are very similar to the findings in FSH-deficient mice generated by targeted disruption of the gene encoding the FSH β -subunit. This disorder likely is responsible for most cases of the "resistant" ovary syndrome. The FSH receptor gene contains 9 small exons (1 through 9) that encode the extracellular ligand-binding domain and one large exon¹⁰ that designates the remainder of the receptor, including the seven-transmembrane and intracellular domains. The Finnish mutation, an Ala1989Val substitution, is in the extracellular domain. Expression of the mutation in transfected cells indicated a small FSH effect on cAMP production, a striking reduction of FSH-binding capacity, but apparently normal binding affinity.

The FSH receptor mutation in the Finnish patients is not a null mutation. It remains to be determined whether the loss or complete inactivation of the FSH receptor leads to failure of puberty and sexual infantilism or to estrogen synthesis by the immature ovarian follicles described in the FSH β -subunit knockout mouse. Affected males in these families are normally masculinized at puberty but tend to

have small testes. They have a variable degree of spermatogenic insufficiency, but not azoospermia, increased plasma concentrations of FSH and LH, decreased inhibin B levels, and normal plasma testosterone values.⁷¹⁷

Luteinizing Hormone and Human Chorionic Gonadotropin Resistance. LH/hCG resistance due to mutations in the gene encoding the seven-transmembrane LHCGR is discussed in Chapter 23. In the affected XY individual, this autosomal recessive disorder leads to various degrees of male pseudohermaphroditism; the mildest form is represented by an isolated micropenis.⁷¹⁸ Less severe mutations of the LHCGR may be associated with delayed puberty. In affected females, LH/hCG resistance does not affect pubertal maturation but does lead to amenorrhea with high serum LH levels but normal FSH and estradiol concentrations.⁷¹⁹

Polycystic Ovary Syndrome. PCOS, or functional ovarian hyperandrogenism, does not delay the onset of puberty but often delays menarche or causes menstrual abnormalities. It can have serious long-term metabolic consequences such as dyslipidemia and insulin resistance over and above androgen excess and reproductive difficulties.⁷²⁰

Noonan Syndrome. Individuals with Noonan syndrome (i.e., pseudo-Turner syndrome, Ullrich syndrome) have webbed neck, ptosis, down-slanting palpebral fissures, low-set ears, short stature, cubitus valgus, and lymphedema, and which explains why this phenotype has been called pseudo-Turner syndrome.⁶³² Features that differentiate these individuals from those with Turner syndrome include triangular facies, pectus excavatum, right-sided heart disease (e.g., pulmonic stenosis, often with valve dysplasia; atrial septal defect) compared with the left-sided heart disease in Turner syndrome, hypertrophic cardiomyopathy, varied blood clotting defects, and an increased incidence of mental retardation. Females with Noonan syndrome have normal ovarian function. Males have normal differentiation of external genitalia but may have undescended testes; germinal aplasia or hypoplasia and impaired Leydig cell function may be present. Puberty may be delayed by an average of 2 years. Stature is decreased after normal birth length and weight, with a mean adult height of 162.5 cm (63.9 inches) for men and 152.7 cm (60.1 inches) for women, usually following the -2 SD curve. The pubertal growth spurt is often delayed or attenuated, but final height usually is at the low limits of normal.

Administration of hGH is approved by the FDA for use in Noonan syndrome. GH increased the growth rate, with a mean gain in near-adult height above the projected value of 10.9 cm (males) and 9.2 cm (females), which is less than in patients with GH deficiency.⁷²¹ Men with Noonan syndrome may have osteopenia, which has been attributed to estrogen deficiency because estrogen administration improves the decreased bone mineral content.⁷²²

Noonan syndrome is inherited as an autosomal dominant trait.⁶³² A gene implicated in Noonan syndrome has been localized to the long arm of chromosome 12 (12q24.2-q24.31), and a mutation in *PTPN11* was identified, but at least three other gene mutations have been identified. The incidence is estimated at 1 case in 1000 to 1 in 2500 people. One parent may have features of the syndrome in 40% to 60% of cases. About 50% of patients are thought to have new mutations.

Frasier Syndrome. Chronic renal failure is combined with gonadal dysgenesis in the Frasier syndrome. Although most patients present with ambiguous genitalia, this diagnosis should be considered for any phenotypic female with end-stage renal disease (due to focal segmental

glomerulosclerosis) and sexual infantilism. The karyotype may be 46,XY or 46,XX.

Diagnosis of Delayed Puberty and Sexual Infantilism

When girls remain prepubertal at 13 years or boys remain prepubertal at 14 years, the physician must make a clinical judgment about who are variants of the norm and who require extensive evaluation and treatment (Figs. 25-47 and 25-48; Tables 25-20 and 25-21). A boy who has not completed secondary sexual maturation within 4.5 years after onset of puberty or a girl who does not menstruate within 5 years after onset may have a hypothalamic, pituitary, or gonadal disorder. The diagnosis of hypergonadotropic hypogonadism is readily established by elevation of random plasma LH and FSH concentrations. However, differentiating the diagnosis of hypogonadotropic hypogonadism from constitutional delay in growth and adolescence is more difficult because of the overlap in physical and laboratory findings for the two conditions, including an inability to differentiate normal from low concentrations of serum gonadotropins (see Table 25-21). Most boys with pubertal delay have a self-limited variant in the tempo of growth and pubertal-onset CDP.

History taking must elicit all symptoms of chronic or intermittent illnesses and all details pertaining to growth and development, as well as questioning about the patient's sense of smell. Has puberty failed to occur, or did it begin but failed to progress or even regressed? Disorders of pregnancy, abnormalities of labor and delivery, and birth

trauma, if part of the patient's history, suggest that a congenital or neonatal event may be related to the delay in puberty. Poor linear growth and poor nutritional status during the neonatal period and childhood may reflect long-standing abnormalities of development. Family history may reveal disorders of puberty or infertility, anosmia, or hyposmia in relatives and delay in the age at onset of puberty in parents or siblings. Recalled age of pubertal onset is relatively reliable in women but less often accurate in men. A history of consanguinity is important in the detection of autosomal recessive disorders.

The physical examination starts with determination of height and weight. The upper-to-lower segment ratio or sitting height is calculated, and the arm span is measured and compared with the height. A growth chart is plotted to represent graphically the increase in stature and to assess growth velocity from birth (see Chapter 42). Late-onset growth failure usually indicates a serious condition requiring immediate evaluation. Weight is plotted to determine states of malnutrition. BMI should be calculated and plotted by age and gender in this era of epidemic obesity or to further determine nutritional status. The height velocity should be documented over a period of at least 6 months, preferably 12 months. The signs of puberty are assessed, and the stage of secondary sexual development is determined by physical examination according to the standards presented earlier (see Figs. 25-5, 26-6, and 25-8). Questionnaires with pictures are used to allow a child to determine his or her own stage of puberty in some studies but do not replace the physical examination, and there is a tendency to overestimate development early in puberty

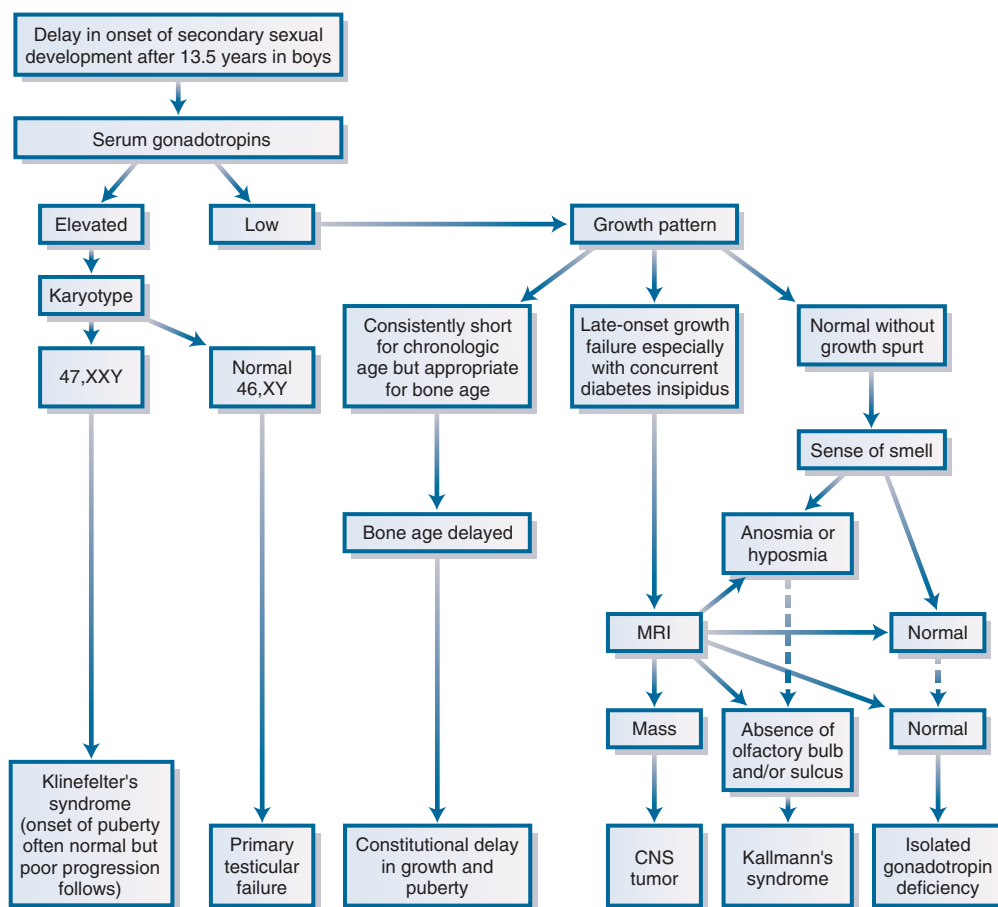

Figure 25-47 Flow chart for the evaluation of delayed puberty in boys.

Figure 25-48 Flow chart for the evaluation of delayed puberty in girls.

and underestimate it late in puberty. The length and width of the testes is measured in boys, or the volume is assessed using an orchidometer. The length and diameter of the stretched penis are determined in boys, and the diameter of glandular breast tissue and areolar size are determined in girls. The presence or absence of galactorrhea is documented. Obese boys often appear to have a small penis because of excessive adipose tissue surrounding the phallus; only when the fat is retracted can the full extent of phallic development be assessed. This is among the most common causes of inappropriate referral for hypogonadism. The extent of pubic and axillary hair is assessed, as is the degree of acne or comedones. The possibility of cryptorchidism or retractile testes should be determined if no testes are palpated in the scrotum. Neurologic examination, including examination of the optic discs and visual fields by frontal confrontation perimetry, may reveal findings, suggesting the presence of a CNS neoplasm or a developmental defect. Determination of olfaction is important because many patients with Kallmann's syndrome wait years for the correct diagnosis to be made even in the presence of classic findings; physicians must remain alert to the possibility of this diagnosis. The stigmata of gonadal dysgenesis (i.e., Turner syndrome) or the small testes and gynecomastia of Klinefelter's syndrome may suggest a karyotypic abnormality. Complete physical examination, including the lungs, heart, kidney, and the gastrointestinal tract, is important in the search for a chronic disorder that may delay puberty.

Laboratory studies (Table 25-22) include determination of plasma LH and FSH concentrations by sensitive third-generation assays in pediatric endocrine laboratories, measurement of the rise in the LH level after GnRH or GnRH agonist administration, determination of testosterone concentrations in boys and estradiol levels in girls in pediatric endocrine laboratories using HPLC-MS/MS, all with pediatric standards for that laboratory, and measurements of T_4 and prolactin concentrations in boys and girls if the clinical features warrant. One of the few national endocrine laboratories should be used for determinations of the hormones of puberty, because most local laboratories are interested only in differentiating the normally higher adult values from inappropriately low levels, and they cannot determine the gradations of the low levels found in puberty. Results of commercial immunochemiluminometric (ICMA) LH and FSH assays are reported to be more sensitive for use in pediatrics than immunofluorometric (IFMA) assays.⁷²³ Several national laboratories began using liquid chromatography with tandem mass spectrometry methods for improved sensitivity and specificity and determinations in children (and women) for increased accuracy.²⁴⁷ Newer ultrasensitive bioassays may be made available commercially for the determination of low values of testosterone and estradiol or for total androgen or estrogen.

Radiographic examination may include bone age determination and, if the history or physical examination is consistent with a CNS lesion, an MRI of the brain, with

TABLE 25-20

Differential Diagnostic Features of Delayed Puberty and Sexual Infantilism

Condition	Stature	Plasma Gonadotropins	GnRH Test LH Response	Plasma Gonadal Steroids	Plasma DHEAS	Karyotype	Olfaction
Constitutional delay in growth and adolescence	Short for chron. age, usually appropriate for bone age	Prepubertal, later pubertal	Prepubertal, later pubertal	Low, later normal	Low for chron. age, appropriate for bone age	Normal	Normal
Hypogonadotropic Hypogonadism							
Isolated gonadotropin deficiency	Normal, absent pubertal growth spurt	Low	Prepubertal or no response	Low	Appropriate for chron. age	Normal	Normal
Kallmann's syndrome	Normal, absent	Low	Prepubertal or no response	Low	Appropriate for chron. age	Normal	Anosmia; pubertal growth spurt or hyposmia
Idiopathic multiple pituitary hormone deficiencies	Short stature and poor growth since early childhood	Low	Prepubertal or no response	Low	Usually low	Normal	Normal
Hypothalamic-pituitary tumors	Late-onset decrease in growth velocity	Low	Prepubertal or no response	Low	Normal or low for chron. age	Normal	Normal
Primary Gonadal Failure							
Syndrome of gonadal dysgenesis (Turner's syndrome) and variants	Short stature since childhood	High	Hyperresponse for age	Low	Normal for chron. age	45,X or variant	Normal
Klinefelter's syndrome and variants	Normal to tall	High	Hyperresponse at puberty	Low or normal	Normal for chron. age	47,XXY or variant	Normal
Familial XX or XY gonadal dysgenesis	Normal for age	High	Hyperresponse	Low	Normal for chron. age	46,XX or 46,XY	Normal

chron., chronologic; DHEAS, dehydroepiandrosterone sulfate; GnRH, gonadotropin-releasing hormone; LH, luteinizing hormone.

specific attention to the pituitary and hypothalamic area using contrast. CT can detect calcification, in contrast to MRI scans or plain radiographs, in most cases. Ultrasound evaluation of the uterus and ovaries provides useful information about the state of development of these structures but only if the ultrasonographer has experience with children and young adolescents.

Assessment of karyotype should be considered for all short girls, even in the absence of somatic signs of Turner syndrome and especially if puberty is delayed or unexplained short stature is involved. Karyotype assessment should be performed for boys with suspected Klinefelter's syndrome stigmata or behavior.

A presumptive diagnosis of constitutional delay in growth and adolescence is made if the history and growth chart reveal a history of short stature but a consistent growth rate for skeletal age (and no signs or symptoms of hypothalamic lesions), if the family history includes parents or siblings with delayed puberty, if the physical

examination (including assessment of the olfactory threshold) is normal, if optic discs and visual fields are normal, and if the bone age is significantly delayed. In classic cases, MRI of the hypothalamic-pituitary region may not be necessary. The rate of growth in these patients is usually appropriate for bone age; a decrease in growth velocity occurs in some normal children just before the appearance of secondary sexual characteristics and may awaken concerns if such a pattern occurs in these subjects. The onset at puberty correlates better with bone age than with chronologic age, although bone age is not any better at estimating the onset of puberty in normal boys than is chronologic age.¹⁵⁶

TABLE 25-21

Endocrine Diagnosis of Constitutional Delayed Adolescence and Hypogonadotropic Hypogonadism

No single test reliably discriminates between the two diagnoses.
Onset of puberty in boys is indicated by
Testes >2.5 cm in diameter
Serum testosterone concentration >50 ng/dL
Pubertal LH response to GnRH bolus
Pubertal pattern of LH pulsatility

LH, luteinizing hormone; GnRH, LH-releasing hormone.

TABLE 25-22

Endocrine and Imaging Studies in Delayed Adolescence

Initial assessment
Plasma testosterone or estradiol
Plasma FSH and LH
Plasma thyroxine (and prolactin)
Bone age and lateral skull roentgenograph
Test of olfaction
Follow-up studies
Karyotype (short, phenotypic females)
MRI with contrast enhancement
Pelvic ultrasonography (females)
GnRH test
hCG test (males)
Pattern of pulsatile LH secretion
Visual acuity and visual fields

FSH, follicle-stimulating hormone; hCG, human chorionic gonadotropin; LH, luteinizing hormone; MRI, magnetic resonance imaging.

Elevated concentrations of gonadotropins and gonadal steroids to early pubertal levels precede secondary sexual development by several months; measurements of serum LH, FSH, estradiol, or testosterone levels in appropriate assays may help to predict future development. The third-generation LH assays are sufficiently sensitive to allow in most boys the determination of the onset of endocrine puberty with a single blood sample, but a dynamic GnRH test is still often performed using GnRH agonists. The use of 10 µg of GnRH instead of 100 µg can differentiate constitutional delay from hypogonadotropic hypogonadism, but the virtual absence of synthetic native GnRH supplies means that this is not practical for clinical use.⁷²⁴ The measurement of gonadotropins 40 minutes to 1 hour after a subcutaneous injection of GnRH agonist is the current method of testing dynamic secretion of gonadotropins in the absence of native GnRH supplies.

Measurement of an 8 a.m. serum testosterone level provides an accurate indication of impending pubertal development; a value of greater than 0.7 nmol/L (20 ng/dL) predicts enlargement of testes to greater than 4 mL by 12 months in 77% of cases and in 15 months in 100% of cases, whereas of those with a value less than 0.7 nmol/L, only 12% entered puberty in 12 months and only 25% entered puberty in 15 months. This technique may help predict spontaneous pubertal development, but it still requires considerable watching and waiting.⁴⁶⁴ A 5-year longitudinal study of boys with delay of pubertal onset aimed to determine indicators of CDP and those of hypogonadal hypogonadism.⁷²⁵ An initial basal morning testosterone level of more than 1.7 nmol/L was observed in 55% of patients with constitutional delay exclusively (predictive positive value [PPV] = 100%; predictive negative value [PNV] = 59%). For those with a basal morning testosterone level of less than 1.7 nmol/L, a measurement of the LH peak 3 hours after the GnRH agonist Triptorelin had a PPV of 100% if the upper threshold was set at 14 IU/L, and the PNV was 72%. Because no lower threshold could discriminate hypogonadotropic hypogonadism from constitutional delay if the LH peak 3 hours after Triptorelin was <14 IU/L, hCG stimulation was invoked. In constitutional delay, the PPV of a serum testosterone increment of more than 9 nmol/L (PNV = 72%) after hCG stimulation was 100%, and in isolated hypogonadal hypogonadism patients, the PPV of a rise in testosterone of less than 3 nmol/L (PNV = 82%) after hCG was 100%. However, 29% of the studied population had an increase in testosterone levels after hCG between these thresholds and could not be classified by testing alone, limiting the use of these techniques. Another study suggests that a ratio of peak to basal free α -gonadotropin subunit after GnRH ranging from more than 3.7 to 4.8 can differentiate constitutional delay from hypogonadotropic hypogonadism.⁷²⁶ These methods require continued evaluation before they become standard clinically, and there does not appear to be a practical and reliable endocrine test for indisputably differentiating constitutional delay in growth and adolescence from hypogonadotropic hypogonadism. Watchful waiting remains the procedure of choice when a patient does not fulfill the delineated criteria and fall into a diagnosable grouping.

A typical patient with isolated gonadotropin deficiency is of average height for age and has eunuchoid proportions; has low plasma concentrations of gonadal steroids, LH, and FSH; and has no increase or a blunted response of LH after GnRH or GnRH agonist administration. The amplitude and usually the frequency of LH pulses are decreased when serial blood samples are studied over a 24-hour period. In some forms of Kallmann's syndrome, the sense of smell is

absent or impaired. However, as stated, differentiation of isolated gonadotropin deficiency in the absence of hyposmia or anosmia from CDP may be difficult at initial study. Gonadotropin-deficient patients may be as short as those with constitutional delay in growth and adolescence, and concentrations of LH and FSH in hypogonadotropic hypogonadism may be indistinguishable from those of normal prepubertal children or children with constitutional delay. Sometimes, years of observation are necessary to detect the appearance of spontaneous and progressive signs of secondary sexual development or to document rising concentrations of gonadotropins or gonadal steroids before the diagnosis is clear. There is a tendency for hypogonadotropic patients to undergo adrenarche at a normal age and to have higher DHEAS concentrations than those with constitutional delay in growth, and this pattern is helpful in making the differential diagnosis.⁴⁴² In most cases, absence of the first signs of sexual maturation or failure of a rise in gonadotropins or gonadal steroid levels by age 18 years in the presence of a normal concentration of serum DHEAS for chronologic age supports the diagnosis of isolated gonadotropin deficiency.

Patients with deficiency of gonadotropins combined with deficiency of other pituitary hormones require careful evaluation for a CNS neoplasm. Visual field or optic disc abnormalities support the diagnosis of CNS tumor; even if these tests are normal, cranial MRI should be done to evaluate the pituitary gland and stalk and the hypothalamic region. MRI appears superior to CT for detecting mass lesions and developmental abnormalities of the hypothalamic-pituitary region.

Treatment of Delayed Puberty and Sexual Infantilism

Patients with constitutional delay in growth and adolescence ultimately have spontaneous onset and progression through puberty. Often, reassurance and continued observation to ensure that the expected sexual maturation occurs are sufficient. However, the stigma of appearing less mature than one's peers can cause psychological stress. These individuals may be unable to participate in the dating activities their friends are starting; smaller size may lead them to avoid participation in athletics; immature appearance may lead to ridicule, especially in the locker room; and schoolwork may suffer because of their poor self-image. Some children feel such intense peer pressure and low self-esteem that only the appearance of signs of puberty can reassure them and enable them to participate in sports and social activities with their peers. Poor self-image in late-maturing boys may carry into adulthood, even after normal puberty ensues. Growth retardation appears more often responsible for most of the stress rather than the delay in pubertal development itself.

For psychological reasons, for boys 14 years old or older who show no signs of puberty, a 3- to 6-month course of testosterone enanthate, cypionate, or cyclopropionate (50 mg is the safest starting dose, but some suggest up to 100 mg given intramuscularly every 4 weeks) may be helpful. Because starting with the higher dose of 100 mg can lead to priapism in treatment-naïve boys, care, lower dosage, and short-acting preparations are advisable. Decades of experience confirm no effect on adult height of low dosages in the short term.^{727,728} The low dose of testosterone enanthate is considered to be safe but can raise apolipoprotein B (apoB) and decrease HDL-cholesterol and apoAI levels (estradiol increases HDL-cholesterol and decreases triglycerides, LDL-cholesterol, and apoB).²⁰⁴

Although the use of exogenous androgens may improve self-image and start the secondary sexual changes of puberty, low-dose androgen use does not improve final height.

Alkylated testosterone preparations should be avoided because of the risk of peliosis hepatitis (i.e., hemorrhagic liver cysts), which is not related to dose or duration of treatment. Although regression is possible with discontinuation of testosterone treatment, progression to liver failure can occur.

A course of low-dose oxandrolone (2.5 mg/day orally) is sometimes used as an oral alternative to intramuscular testosterone enanthate; this agent increases growth through androgenic effects reflected by suppression of LH and FSH but does not stimulate GH secretion, because it is not aromatized to estrogen. The temporary increase in growth velocity found with oxandrolone does not affect adult height in most studies. Oral treatment with 2.5 mg of fluoxymesterone (Halotestin) for 6 to 60 months allows increased pubertal development without adverse effect on adult height, although the necessity to take a daily dose may decrease compliance. Testosterone undecanoate at 40 mg/day is likewise an effective but expensive treatment for those opting for an oral therapy (not FDA approved for this use). This treatment can increase the growth rate but does not result in a change in LH pulsatility; mean overnight LH, testosterone, or SHBG levels; or free androgen index, PSA, and testicular volume values. Transdermal testosterone may be applied as a daily patch or a gel (not FDA approved for this use), although experience with these forms of androgen is more limited than with the other forms. Preliminary experience suggests that overnight (about 8 to 9 hours) or every-other-night use of a 2.5-mg Androderm patch can achieve physiologic testosterone levels, produce lower SHBG levels, promote growth and virilization, and increase BMD in hypogonadal teenagers without significant side effects. An overnight study of transdermal testosterone (5 mg of Viormone) applied overnight (8 to 12 hours) for 4-week periods in boys with delayed puberty and short stature raised salivary testosterone levels, stimulated leg growth measured by knemometry (i.e., sensitive short-term measurements of leg growth), and stimulated bone turnover, as reflected by increased serum alkaline phosphatase levels.⁷²⁹ Testosterone cream is approved for adults and is undergoing clinical trials for use in teenagers with delayed puberty.

For girls 13 years of age or older, a 3- to 4-month course of ethinyl estradiol (5 µg/day orally) or conjugated estrogens (0.3 mg/day orally) may be used to initiate maturation of the secondary sexual characteristics without unduly advancing bone age or limiting final height. Transdermal estrogen has been used in clinical trials for decades in the treatment of delayed puberty or hypogonadism with beneficial results on physical development and bone density and is entering widespread use.⁷³⁰ However, there is new support for such therapy based on understanding the adverse effects of oral estrogen that enters the portal circulation initially at a high dose (first pass) and stimulates the production of proteins such as C reactive protein, angiotensin precursor, and activated protein C, which are involved in cardiac complications. This contrasts with dermal estrogen, which is administered in lower dosages and reaches its therapeutic targets relatively unchanged and in lower, more physiologic concentrations; there is no change in the listed proteins with dermal estrogen administration.⁷³¹ Estrogen patches are undergoing clinical testing for use in initiating or promoting pubertal development in hypogonadal or delayed pubertal girls.

The long-term safety and effects on bone density of aromatase inhibitor therapy remains unknown, and this therapy cannot be recommended for routine use for increasing adult height. GnRH agonists cannot be recommended to prolong growth due to concerns about bone density.

If during the 3 to 6 months after discontinuing gonadal steroid therapy spontaneous puberty does not ensue or the concentrations of plasma gonadotropins and plasma testosterone in boys or plasma estradiol in girls do not increase, the treatment may be repeated. Only one or two courses of therapy usually are necessary. When treatment is discontinued after bone age has advanced, for example, to 12 to 13 years in girls or 13 or 14 years in boys, patients with constitutional delay usually continue pubertal development on their own, whereas those with gonadotropin deficiency do not progress and may regress.

Functional hypogonadotropic hypogonadism associated with chronic disease is treated by alleviating the underlying problem. Delayed puberty in this situation is usually a result of inadequate nutrition and low weight or excessive energy expenditure. When weight returns to normal values, puberty usually occurs spontaneously. Treatment with T₄ allows normal pubertal development in hypothyroid patients with delayed puberty.

Permanent hypogonadism of any cause leads to lifelong therapy. The transition of care from the range of age normally considered to be adolescence, administered by a pediatric practitioner, to adult life, administered by a practitioner experienced in adult endocrinology, presents important implications for a change in the manner medical care is presented. Changes in the individual's autonomy and implications of legal distinctions arise, and some have suggested that this transition period should be considered another stage of the life span.⁷³²

Congenital or acquired gonadotropin deficiency as a result of a lesion or surgery requires replacement therapy with gonadal steroids at an age approximating the normal age of onset of puberty (Tables 25-23 and 25-24). An exception may occur when GH deficiency coexists with gonadotropin deficiency; if bone age advancement and epiphyseal

TABLE 25-23

Management and Treatment of Delayed Puberty**OBJECTIVE**

Determine site and etiology of abnormality
Induce and maintain secondary sexual characteristics
Induce pubertal growth spurt
Prevent the potential short-term and long-term psychological, personality, and social handicaps of delayed puberty
Ensure normal libido and potency
Attain fertility

THERAPY**Concerned But Not Anxious or Socially Handicapped Adolescent**

Reassurance and follow-up (tincture of time)
Repeat evaluation (including serum testosterone or estradiol) in 6 mo

Psychosocial Handicaps, Anxiety, Highly Concerned

Therapy for 4 mo
Boys: testosterone enanthate 100 mg IM q4wk at 14-14.5 yr of age, or overnight transdermal testosterone patch
Girls: ethinyl estradiol 5-10 mg/day PO or conjugated estrogens 0.3 mg/day PO or overnight ethinyl estradiol patch at 13 yr of age
No therapy for 4-6 mo; reevaluate status including serum testosterone or estradiol; if indicated repeat treatment regimen

TABLE 25-24

Hormonal Substitution Therapy in Hypogonadism

Boys

Goal: to approximate normal adolescent development *when diagnosis is established*
Initial therapy: at 13 yr of age, testosterone enanthate (or other long-acting testosterone ester) 50 mg IM every month for about 9 mo (6-12 mo)
Over the next 3-4 yr: gradually increase dose to adult replacement dose of 200 mg q2-3 wk
Testosterone gel is coming into widespread use as discussed in the text
Begin replacement therapy in boys with suspected hypogonadotropic hypogonadism by bone age ≤ 14 yr
To induce fertility at appropriate time in hypogonadotropic hypogonadism: pulsatile GnRH or FSH and hCG therapy

Girls

With a firmly established diagnosis of hypogonadism (e.g., girls with 45,X gonadal dysgenesis), begin hormonal substitution therapy at 12-13 yr of age
Goal: to approximate normal adolescent development
Initial therapy: ethinyl estradiol 5 mg by mouth or conjugated estrogen 0.3 mg (or less) by mouth daily for 4-6 mo or preferably estradiol transdermally
After 6 mo of therapy (or sooner if breakthrough bleeding occurs), begin cyclic therapy:
Estrogen: first 21 days of month
Progestagen: (e.g., medroxyprogesterone acetate 5 mg PO) 12th to 21st day of month
Gradually increase dose of estrogen over next 2-3 yr to conjugated estrogen 0.6-1.25 mg or ethinyl estradiol 10-20 mg daily for first 21 days of month or estradiol patch
In hypogonadotropic hypogonadism, to induce ovulation at appropriate time: pulsatile GnRH or FSH and hCG therapy

FSH, follicle-stimulating hormone; GnRH, luteinizing hormone-releasing hormone; hCG, human chorionic gonadotropin.

fusion are brought about by testosterone or estradiol replacement before therapy with GH causes adequate linear growth, adult height will be compromised. However, if puberty is not initiated early enough, the patient may suffer psychological damage. It is advisable to initiate puberty in these patients with low-dose gonadal steroids by age 14 in boys and age 13 in girls, regardless of the definitive diagnosis of gonadotropin deficiency. Isolated GH-deficient patients may have a delayed onset of puberty; with GH administration, puberty usually occurs at an appropriate age but may progress faster than in normal individuals. Children with GH deficiency showed a correlation between the age of onset of induced puberty and adult height for those who were also gonadotropin deficient, whereas those who underwent spontaneous puberty, which occurred earlier than the age of hormone-induced puberty in the gonadotropin-deficient children, had a decreased final height. This supports the advisability of waiting to initiate puberty in GH- and gonadotropin-deficient children. Height at the onset of puberty is also correlated with adult height in GH-deficient children. However, artificially delaying puberty with a GnRH analogue to attempt to achieve a greater final height has been attempted in isolated cases of GH deficiency or with normal-variant short stature, but concern over decreased bone density seen in subjects treated with GnRH analogues led to warnings about the use of this agent in GH-deficient patients. There is inadequate evidence to recommend this therapy.⁴⁷⁴

Microphallus due to hypothalamic deficiencies³¹⁶ may be treated with one or two 3-month courses of testosterone

enanthate, with 25 mg per month given intramuscularly to enlarge the size of the penis.⁷³³ Although concern was raised that early testosterone therapy might not allow the attainment of a normal adult penile size, experience has shown otherwise. The concern that the penis might not respond to androgens later in life if exposed to testosterone in childhood, a pattern observed in the rat, proved incorrect. Positive psychological outcomes and attainment of normal stretched penile length have been reported.^{546,734} It is appropriate to treat male infants and children with micropenis due to gonadotropin or GH deficiency with short courses of androgens to enlarge the penis into the normal childhood range. Patients with isolated congenital GH deficiency occasionally have micropenis that may be successfully treated with GH replacement alone. It is not appropriate to sex reverse a male infant because of microphallus caused by fetal testosterone or GH deficiency.

Episodic administration of GnRH elicits pulsatile LH and FSH release and gonadal stimulation in prepubertal children or hypogonadotropic patients. Portable pumps are used to administer episodic GnRH over prolonged periods. Pulsatile GnRH therapy can induce puberty and promote the development of secondary sexual characteristics and spermatogenesis in men⁷³⁵ and ovulation in women, but it is not practical for the routine induction of puberty in adolescent boys and girls with gonadotropin deficiency. Pregnancy can be achieved with this regimen in women and spermatogenesis in men with hypogonadotropic hypogonadism. A lower frequency of GnRH administration favors FSH secretion, whereas a faster frequency favors LH secretion and ultimately has been associated with a PCOS-like picture, although the hypothalamic-pituitary-gonadal axis usually is sufficiently robust to accommodate various frequencies of GnRH secretion.

Human menopausal gonadotropin and hCG can be used as effective substitutes for recombinant human pituitary LH and FSH to produce full gonadal maturation, but this regimen is cumbersome and expensive. Long-term gonadal steroid replacement therapy is the treatment of choice for hypothalamic or pituitary gonadotropin deficiency until fertility is desired.⁷³⁶

Hypergonadotropic hypogonadism is treated by replacement of testosterone in boys and estradiol in girls. For treatment of gonadal dysgenesis, estrogen therapy should be initiated when the patient is age 13 (bone age > 11 years) to allow secondary sexual development at an appropriate chronologic age. The Klinefelter's syndrome is compatible with various degrees of masculinization at puberty; some patients require testosterone replacement. The concentration of plasma testosterone and LH should be monitored every 6 months during puberty and yearly thereafter. If the LH level rises more than 2.5 SD above the mean value or the testosterone level decreases below the normal range for age, testosterone replacement therapy is indicated. FSH is increased due to lack of inhibin from affected testes.

Patients receiving gonadal steroid replacement follow the same treatment regimen whether the diagnosis is hypogonadotropic hypogonadism or hypergonadotropic hypogonadism (see Table 25-24). Various testosterone preparations are available with several routes of administration. Alkylated testosterone preparations should be avoided because of the risk of peliosis hepatitis (i.e., hemorrhagic liver cysts), which is not related to dose or duration of treatment; although regression is possible with discontinuation of testosterone treatment, progression to liver failure can occur. Males may receive testosterone enanthate, propionate, or cypionate (50 to 100 mg every 4 weeks intramuscularly) at the start, although priapism has

been reported with the higher starting dose in a testosterone-naïve boy; later, the dosage is gradually increased to 200 to 300 mg every 2 to 3 weeks. Low-dose replacement therapy is appropriate until well into the pubertal growth spurt. Testosterone may be administered by cutaneous patch on scrotal skin or nonsexual skin to cause secondary sexual development in hypogonadal adolescents; patches may be given at night to recreate the diurnal variation of testosterone seen in early puberty. Physiologic values of serum testosterone may be reached with these patches, along with secondary sexual development. A teenage boy may be less likely to apply a patch daily, and biweekly or monthly injections may allow better compliance; nonetheless, 2.5- and 5-mg dermal testosterone patches may be useful in motivated teenagers. New testosterone gel preparations, usually rubbed onto the forearms, are approved for adults but not for adolescents. Testosterone ointment may be used as therapy for micropallus to enlarge the size of the phallus intentionally, but a normal infant or child contacting the skin of an individual treated with testosterone gel (before it is absorbed) runs the risk of unplanned testosterone effects.⁷³⁷

Initially, girls 12 to 13 years old are given ethinyl estradiol (5 µg/day orally) or conjugated estrogens (0.3 mg/day orally) on the first 21 days of the month. The dose is gradually increased over the next 2 to 3 years to 10 µg of ethinyl estradiol or 0.6 to 1.25 mg of conjugated estrogen for the first 21 days of the month. The maintenance dose should be the minimal amount to maintain secondary sexual characteristics, sustain withdrawal bleeding, and prevent osteoporosis. After breakthrough bleeding occurs, or no later than 6 months after the start of cyclic therapy, a progestagen (e.g., 5 mg/day of medroxyprogesterone acetate) is added on days 12 through 21 of the month. Undesirable effects are uncommon but may include weight gain, headache, nausea, peripheral edema, and mild hypertension. The benefits of transdermal estrogen treatment were discussed earlier. Application of portions of transdermal 17β-estradiol patches at night (not FDA-approved for this use) were shown to mimic levels of estrogen produced in early puberty and to slowly bring about breast development⁷³⁰; other therapeutic schedules are possible. Estradiol gel (not FDA approved for this use) in an increasing dose from 0.1 to 1.5 mg given over a 5-year period is reported to be safe and effective as replacement therapy in girls with Turner syndrome.⁷³⁸ As with testosterone, children must not be in contact with the preparation because untoward estrogen effects may occur. Patches and gels are not approved for use in adolescents.

There is a concern about the increased risk of endometrial and breast carcinoma in patients receiving chronic estrogen replacement therapy, including patients with Turner syndrome.⁷³⁹ The use of progestational agents to antagonize the effect of estrogens reduces the risk of endometrial cancer, but the best answer about the optimal dose of estrogen and progesterone to enhance development without unduly increasing the risk of cancer must come from future studies. Estrogen replacement is important for its anti-osteoporosis action on bone. Bone density is decreased in Turner syndrome in part because of hypogonadism at puberty, and this tendency becomes more severe with age in patients who discontinue or do not receive estrogen replacement therapy. Transdermal estrogen can increase bone density in subjects with Turner syndrome who have finished statural growth.⁷⁴⁰ We lack adequate controlled studies on optional sex steroid replacement regimens in young adolescent women. Biosynthetic hGH therapy in Turner syndrome causes an increase in growth rate, with an increase in adult height approaching

or reaching the lower range of the normal growth curves possible.

Patients with hypopituitarism may complain of sparse pubic hair growth or, in girls, total absence of pubic hair. Pubic hair thickens further in affected males with hCG treatment, which adds the testicular contribution of testosterone to the exogenous testosterone therapy. GH therapy in GH- and gonadotropin-deficient males enhances the steroidogenic response of the testes to hCG administration. Adolescent or young adult women have been given a low dose (25 mg) of long-acting intramuscular testosterone every 4 weeks to stimulate the growth of pubic hair without virilization. Oral DHEAS treatment is suggested to improve pubic hair growth in hypopituitary girls.⁷⁴¹

Sexual Precocity

Sexual precocity (Table 25-25) is the appearance of any sign of secondary sexual maturation before the lower limit of the normal age at onset of puberty (i.e., 9 years for boys, 7 years for white girls, and 6 years for African American girls). These cutoffs assume that there are no signs or symptoms of CNS disorders or other serious diseases that might cause sexual precocity; evaluation is indicated in those cases regardless of age. Careful evaluation is essential at these lower age ranges in girls who have only minimal, relatively nonprogressive signs of sexual precocity. These newer limits are controversial, but if the cautions described are heeded, the limits are appropriate.

If sexual precocity results from premature reactivation of the hypothalamic GnRH pulse generator/pituitary gonadotropin-gonadal axis, the condition is GnRH dependent and is termed *central precocious puberty* (CPP), complete precocious puberty, or true (complete) isosexual precocity (ISP). Pulsatile LH release has a pubertal pattern, and the rise in the concentration of LH after GnRH administration is indistinguishable from the normal pubertal pattern of serum LH. If extrapituitary secretion of gonadotropins or secretion of gonadal steroids independent of pulsatile GnRH stimulation leads to virilization in boys or feminization in girls, the condition is termed *incomplete ISP*, pseudoprecocious puberty, or GnRH-independent sexual precocity. The production of excessive estrogens in males leads to inappropriate feminization, and the production of increased androgen levels in females leads to inappropriate virilization; these conditions are termed *contrasexual precocity* or heterosexual precocity. Disorders causing sexual precocity are therefore separated into those in which the increased secretion of gonadal steroids depends on GnRH stimulation of pituitary gonadotropins and those in which it is unrelated to activation of the hypothalamic GnRH pulse generator.

In all forms of sexual precocity, increased gonadal steroid secretion increases height velocity, somatic development, and the rate of skeletal maturation; because of premature epiphyseal fusion, sexual precocity can lead to the paradox of tall stature in childhood but short adult height (Table 25-26). Untreated females with idiopathic CPP demonstrated a mean adult height of 151 to 155 cm.⁷⁴²⁻⁷⁴⁶ In the few reports of adult height in boys with untreated precocious puberty, mean adult stature was 155.4 cm ± 8.3 SD, with all subjects well below midparental height and far below the father's height from the data available.^{743,747}

Serum alkaline phosphatase reflects growth, and IGF1 concentrations reflect the degree of sexual development rather than chronologic age, as do most chemistry and hematology values. The serum concentrations of the propeptide of type III procollagen (P-III-NP) in normal

Classification of Sexual Precocity**TRUE PRECOCIOUS PUBERTY OR COMPLETE ISOSEXUAL PRECOCITY (GNRH-DEPENDENT SEXUAL PRECOCITY OR PREMATURE ACTIVATION OF THE HYPOTHALAMIC GNRH PULSE GENERATOR)**

Idiopathic true precocious puberty
CNS tumors
 Optic glioma associated with neurofibromatosis type I
 Hypothalamic astrocytoma
Other CNS disorders
 Developmental abnormalities including hypothalamic hamartoma of the tuber cinereum
 Encephalitis
 Static encephalopathy
 Brain abscess
 Sarcoid or tubercular granuloma
 Head trauma
 Hydrocephalus
 Arachnoid cyst
 Myelomeningocele
 Vascular lesion
 Cranial irradiation
True precocious puberty after late treatment of congenital virilizing adrenal hyperplasia or other previous chronic exposure to sex steroids
True precocious puberty due to gain of function mutations:
 in KISS1R/GRP54 gene
 in KISS1 gene

INCOMPLETE ISOSEXUAL PRECOCITY (HYPOTHALAMIC GNRH-INDEPENDENT)**Males**

Gonadotropin-secreting tumors
 hCG-secreting CNS tumors (e.g., chorioepitheliomas, germinoma, teratoma)
 hCG-secreting tumors located outside the CNS (hepatoma, teratoma, choriocarcinoma)
Increased androgen secretion by adrenal or testis
 Congenital adrenal hyperplasia (CYP21 and CYP11B1 deficiencies)
 Virilizing adrenal neoplasm
 Leydig cell adenoma
 Familial testotoxicosis (sex-limited autosomal dominant pituitary gonadotropin-independent precocious Leydig cell and germ cell maturation)
 Cortisol resistance syndrome

Females

Ovarian cyst
Estrogen-secreting ovarian or adrenal neoplasm
Peutz-Jeghers syndrome

Both Sexes

McCune-Albright syndrome
Hypothyroidism
Iatrogenic or exogenous sexual precocity (including inadvertent exposure to estrogens in food, drugs, or cosmetics)

VARIATIONS OF PUBERTAL DEVELOPMENT

Premature thelarche
Premature isolated menarche
Premature adrenarche
Adolescent gynecomastia in boys
Macroorchidism

CONTRASEXUAL PRECOCITY**Feminization in Males**

Adrenal neoplasm
Chorioepithelioma
CYP11B1 deficiency
Late-onset adrenal hyperplasia
Testicular neoplasm (Peutz-Jeghers syndrome)
Increased extraglandular conversion of circulating adrenal androgens to estrogen
Iatrogenic (exposure to estrogens)

Virilization in Females

Congenital adrenal hyperplasia
 CYP21 deficiency
 CYP11B1 deficiency
 3 β -HSD deficiency
Virilizing adrenal neoplasm (Cushing's syndrome)
Virilizing ovarian neoplasm (e.g., arrhenoblastoma)
Iatrogenic (exposure to androgens)
Cortisol resistance syndrome
Aromatase deficiency

puberty and in CPP parallel the normal pubertal growth curve and also parallel the changes in growth rate in children treated with GnRH agonists.⁷⁴⁸ Blood pressure matches that of normal subjects of the same height and gender after correcting for bone age rather than chronologic age according to the latest standards for blood pressure.⁷⁴⁹

True or Central Precocious Puberty: Complete Isosexual Precocity

In the UCSF series of more than 200 patients with CPP,⁷⁴² girls had true precocious puberty (i.e., GnRH-dependent CPP) five times more commonly than boys, and idiopathic CPP was eight times more common in girls than in boys (Table 25-27). Others reported a 10-fold increased prevalence of precocious puberty in girls compared with boys.⁷⁵⁰ CNS abnormalities occurred at least as often as idiopathic CPP in boys, whereas in girls neurologic lesions were one fifth as common as idiopathic disorders. Therefore, it is essential to search for a CNS cause for CPP, especially in

boys, because sexual precocity may be the only manifestation of a CNS tumor (Tables 25-28 and 25-29).^{389,742} However, most children referred for evaluation have the benign variants leading to premature thelarche or premature adrenarche.¹¹⁵

Idiopathic True or Central Precocious Puberty. In otherwise healthy girls, those with onset of puberty at 6 to 8 years of age represent one end of the normal range of age at puberty onset⁹⁷; those with constitutional delay in growth and adolescence fall at the opposite end of the normal range of variation. The nature of the striking sex difference in the prevalence of idiopathic CPP (females » males), compared with that of constitutional delay in growth and puberty (males » females) is poorly understood. There may be a history of early maturation in families of affected subjects⁷⁵⁰; rarely, CPP is transmitted as an autosomal recessive trait in boys and girls.⁷⁴² A familial pattern is far more likely to occur in girls than in boys.⁷⁵¹ However, most children develop CPP with no familial tendency and no signs of organic disease; these children have *idiopathic* CPP. This condition, which may manifest in infancy (see

Table 25-27), is commonly associated with electroencephalographic abnormalities.⁷⁵² The age at onset is 6 to 7 years for about 50% of affected girls, 2 to 6 years for about 25%, and during infancy for 18% (Fig. 25-49).⁷⁴² Patients with organic forms of CPP, especially if associated with hypothalamic hamartoma, have an earlier mean age at onset than those with the idiopathic form.^{391,742}

In boys (Fig. 25-50), the testes usually enlarge under gonadotropin stimulation before any other signs of puberty are seen; in girls, an increase in the rate of growth, the appearance of breast development, enlargement of the labia minora, and maturational changes in the vaginal mucosa are the usual presenting signs, with variable manifestations of pubic hair depending on the age at onset. Progression of secondary sexual maturation may be more rapid than normal, but a waxing and waning course of development may occur.⁷⁵⁵ Spermatogenesis in males and ovulation in females often occur, and fertility is possible. The rapid growth is associated with the increased GH secretion and elevation of serum IGF1 levels resulting from stimulation by estradiol.^{150,151,276,756} The ratio of bone age to chronologic age and the rise of IGF1 above normal values

Figure 25-49 Age at onset of idiopathic true precocious puberty in 106 children. At all ages, the frequency is greater in females than in males. The peak prevalence in girls is between ages 6 and 8 years. (From Kaplan SL, Grumbach MM. The neuroendocrinology of human puberty: an ontogenetic perspective. In: Grumbach MM, Sizonenko PC, Aubert ML, eds. *Control of the Onset of Puberty*. Baltimore, MD: Williams & Wilkins, 1990:1-68.)

Figure 25-50 Left, A boy aged 2 year 5 months with idiopathic precocious puberty. He had pubic hair and phallic and testicular enlargement by 10 months of age. At 1 year, his height was 86 cm (+4 SD); the phallus measured 10×3.5 cm, and the testes measured 2.5×1.5 cm. The plasma luteinizing hormone (LH) level was 1.9 ng/mL (LER-960); the follicle-stimulating hormone (FSH) level was 1.2 ng/mL (LER-869); and the testosterone level was 416 ng/dL. After 100 μ g of gonadotropin-releasing hormone (GnRH), the plasma LH level increased to 8.4 ng/mL, and the FSH level increased to 1.8 ng/mL, a pubertal response. When photographed, the patient had been treated with medroxyprogesterone acetate for 1.5 years. His height was 95.2 cm (+1 SD), the phallus was 6×3 cm, and the testes were 2.4×1.3 cm. Basal concentrations of LH (LER-960) were 0.9 ng/mL; the FSH (LER-869) level was 0.8 ng/mL; and the testosterone level was 7 ng/dL. After 100 μ g of GnRH, LH concentrations rose to 2.3 ng/mL, whereas FSH concentrations did not change when he was on treatment with medroxyprogesterone acetate. For conversion to SI units, see Figures 25-16 and 25-17. Right, A girl aged 3 years and 3 months with idiopathic true precocious puberty had recurrent vaginal bleeding since she was 9 months old. Her height age was 4 years and 5 months; bone age was 8 years and 10 months. (Left, From Styne DM, Grumbach MM. Puberty in the male and female: its physiology and disorders. In: Yen SCC, Jaffe RB, eds. *Reproductive Endocrinology*, 2nd ed. Philadelphia, PA: Saunders, 1986:313-384.)

for age are predictive of outcome: more mildly affected children progress less rapidly and tend to maintain their target height, and this may represent a benign entity.⁷⁵⁷

Before beginning treatment, it is essential to establish the rapidly progressive nature of the sexual precocity.^{758,759} In a subset of girls, the tempo is relatively slow and the sexual precocity may not be sustained.^{742,755,760} The growth rate normally for age, skeletal maturation progresses in accordance with chronologic age, and there is little to no risk of impairment of final height⁷⁵⁵; estrogen and IGF1 concentrations are normal or only slightly elevated.⁷⁵⁷ If height prediction is normal at the time of diagnosis rather than reduced, the patient does not require therapy.^{759,761} The efficacy of treatment with GnRH in those with onset after 6 years of age is inconsistent.⁴⁷⁴ In some girls, we have observed within a period of 1 to 2 months the return of a prepubertal pattern of LH pulsatility during sleep, a prepubertal LH response to GnRH, and a concentration of plasma estradiol equivalent to the prepubertal state. Unlike typical patients, such girls do not exhibit the initial hyperresponse of plasma estradiol and LH to the GnRH agonist or the physical changes of the estrogen effect, and they tend to have lower serum IGF1.

Many girls in this subset have clinical and hormonal features that fall between those of premature thelarche and CPP and are typical of neither condition⁷⁶²; this is denoted *exaggerated thelarche*. About 10% of girls with apparently classic premature thelarche progress to definite CPP, but there are no signs at the time of first presentation to differentiate them from girls who continue with the pattern of premature thelarche. In most patients in this situation, the onset of breast development was first noticed after 2 years of age.⁵⁵⁶ Therapy is not indicated if a pubertal pattern of pulsatile LH secretion during sleep is not present or if the basal LH measured by ultrasensitive assay or the LH response to exogenous GnRH or GnRH agonist is prepubertal. The most severely affected girls are the ones who respond best to GnRH agonist therapy.^{758,763}

The uterus and ovaries increase in size in CPP. The ovaries also may develop a multicystic appearance (but not a polycystic appearance) that may remain even after successful treatment with a GnRH agonist.⁷⁶⁴ CPP in females does not lead to premature menopause. However, there is increased risk in girls for the development of carcinoma of the breast^{72,73,765} in adulthood. Psychosexual development is advanced modestly in patients with sexual

Figure 25-51 Left, Mean basal plasma luteinizing hormone (LH) level (LER-960) and mean peak and increment after intravenous gonadotropin-releasing hormone (GnRH) (100 μ g) in normal prepubertal and pubertal females and in females with idiopathic true precocious puberty. The mean peak and increments of plasma LH are higher in true precocious puberty than in normal puberty. Right, Basal follicle-stimulating hormone (FSH) level (LER-1364) and mean peak and increment after intravenous GnRH (100 μ g) in normal prepubertal and pubertal females with true precocious puberty. The concentration of FSH and the response to GnRH were greater in females with true precocious puberty and normal puberty than in prepubertal females. (From Kaplan SL, Grumbach MM. Pathogenesis of sexual precocity. In: Grumbach MM, Sizonenko PC, Aubert ML, eds. *Control of the Onset of Puberty*. Baltimore, MD: Williams & Wilkins, 1990:620-660.)

precocity (about 1.5 years in girls with idiopathic CPP). The pituitary gland undergoes hypertrophy in early infancy, puberty, and pregnancy and also increases in size on MRI imaging in patients with CPP.⁷⁶⁶ T1-weighted images indicate a convex upper border of the pituitary gland in both normal patients and those with CPP, indicating the similarity in the physiologic changes in both conditions. Pituitary gland hyperplasia (height >1 cm) is a rare finding reported in CPP. The empty sella syndrome is less frequently observed in patients with CPP than in patients with pituitary hypofunction. Empty sella is found in 10% of children who are imaged for suspected hypothalamic-pituitary disorders including hypogonadotropic hypogonadism.^{767,768}

The gonadotropin and gonadal steroid concentrations in plasma, the LH response to GnRH administration, and the amplitude and frequency of LH pulses are in the normal pubertal range (Figs. 25-51 and 25-52).^{429,769} The third-generation gonadotropin assays allow diagnosis of CPP by the determination in a single serum sample of LH in the basal state in most (but not all) girls.⁷⁷⁰ Gonadotropin determination 30 to 60 minutes after a single subcutaneous dose of GnRH or GnRH agonist can diagnose CPP with high specificity and sensitivity.⁷⁷¹⁻⁷⁷³ Adrenarche usually does not accompany gonadarche in girls with CPP who are younger than 5 or 6 years of age⁴⁴²; pubic hair is sparse or absent initially in such girls. When the onset of CPP occurs after age 6 years, it is usually associated with adrenarche that is early for chronologic age but not for bone age.

A small proportion of patients with CPP proven by a pubertal response of LH to GnRH and increased pulsatile LH secretion at night may revert spontaneously to a more immature pubertal state, persist without further progression, or fluctuate between progression and regression.^{742,755,774} There is a continuum in girls with CPP from premature thelarche, through unsustained or slowly progressive precocious puberty, to the relatively rapid progression of sexual maturation once it has begun.⁷⁵⁰

In the UCSF experience and that of others, normal pregnancies have occurred in women with idiopathic CPP, CPP triggered by a CNS abnormality,⁷⁴² or premature menarche.

Pregnancy has occurred in patients with CPP as early as 5 years of age (an unfortunate result of childhood sexual abuse).

Central Nervous System Tumors Causing True Precocious Puberty. Sexual precocity may be the first manifestation of a hypothalamic tumor of any cell type when it arises in or impinges on the posterior hypothalamus. Neurologic symptoms such as headaches and visual disturbances may develop, and children may have diabetes insipidus, hydrocephalus, or optic atrophy caused by an enlarging tumor in addition to precocious puberty.⁷⁴² CPP resulting from CNS tumors (see Table 25-29) has about the same prevalence in boys and in girls in the population; however boys have a lower overall prevalence of precocious puberty, and neurologic abnormalities account for two thirds of those with CPP. In the UCSF experience, a CNS tumor was present in at least half of this group.⁷⁴²

A CNS neoplasm must be considered in the differential diagnosis of any patient with CPP.^{389,775} The location of CNS tumors causing CPP makes surgical removal difficult. A conservative approach calls for biopsy of the neoplasm and radiation or chemotherapy or both, depending on the pathologic findings. Optic and hypothalamic glioma (often associated with neurofibromatosis), astrocytoma, ependymoma, and, rarely, craniopharyngioma may cause CPP by impinging on the neural pathways that inhibit the GnRH pulse generator in childhood or as a consequence of cranial irradiation for treatment of a brain tumor. Pineal neoplasms are associated with loss of upward gaze (Parinaud's syndrome) due to brain stem compression.

The prevalence of CPP is increased after cranial irradiation for local tumors or leukemia.^{258,776,777,778} even if radiotherapy targets the pituitary gland.⁷⁷⁹ The combination of GH deficiency and CPP can occur in children previously subjected to therapeutic irradiation of the CNS in association with a CNS neoplasm and in those with a variety of other CNS abnormalities, including developmental malformations and head trauma.²⁵⁸ The lack of GH may not be apparent because of increased growth resulting from the elevated gonadal steroid levels; GH-deficient children with

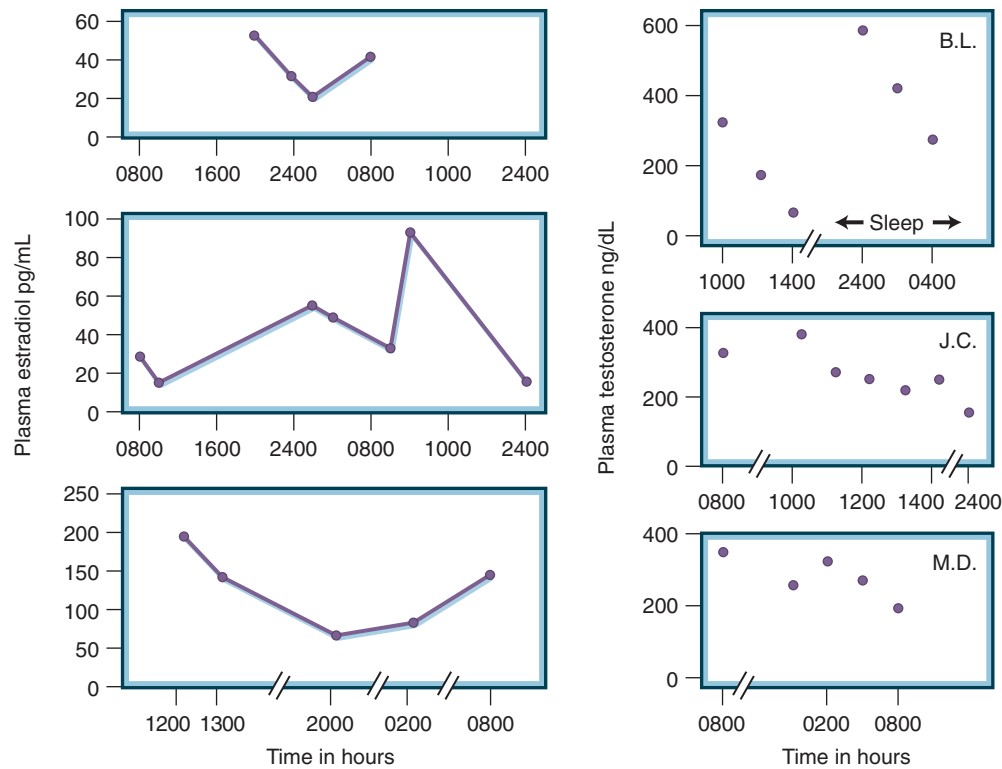

Figure 25-52 Left, Serial determinations of plasma estradiol in three girls with idiopathic true precocious puberty. Notice the striking fluctuations in values. Right, Serial determinations of plasma testosterone in three boys with true precocious puberty (B.L. and J.C. have a hypothalamic hamartoma; M.D. has the idiopathic form). For conversion to SI units, see Figures 25-16 and 25-17. (From Kaplan SL, Grumbach MM. Pathogenesis of sexual precocity. In: Grumbach MM, Sizonenko PC, Aubert ML, eds. *Control of the Onset of Puberty*. Baltimore, MD: Williams & Wilkins, 1990:620-660.)

CPP grow more slowly than GH-sufficient children with CPP but faster than GH-deficient children without sexual precocity. GH-deficient children with CPP have IGF1 concentrations that are intermediate between the higher levels found in GH-sufficient children with sexual precocity and the lower levels found in prepubertal GH-deficient children.²⁵⁸

GH deficiency and CPP can occur with CNS radiation doses of only 18 to 47 Gy, whereas gonadotropin deficiency, TSH deficiency, ACTH deficiency, and hypoprolactinemia usually occur with doses greater than 40 Gy.^{258,779,780} The advance in the age of onset of puberty is reported to be positively correlated with the age of diagnosis of the condition for which the radiation therapy was given (i.e., earlier age at onset of puberty with earlier age at diagnosis) and is also positively correlated with BMI at diagnosis.⁷⁷⁷ Newer radiation treatment regimens using lower doses of radiation for various malignancies may have less influence on advancing the age of menarche and may lead to less long-term morbidity.^{781,782} Treatment with a combination of GH and GnRH agonist is indicated in these patients and results in better growth and improved height prognosis when compared with the use of GnRH agonist alone. Because GH secretion is related to BMI, it is important to rule out a decrease in GH secretion caused by increased BMI in CPP before interpreting the decrease as evidence of GH deficiency.

Hamartomas of the Tuber Cinereum. Hamartomas are congenital malformations composed of a heterotopic mass of nervous tissue containing GnRH neurosecretory neurons, fiber bundles, and glial cells; they are frequently associated with CPP (Fig. 25-53), which usually manifests before the

patient is 3 years of age (Table 25-30).^{742,783} Hypothalamic hamartomas may be sessile or pedunculated and are usually attached to the posterior hypothalamus between the tuber cinereum and the mammillary bodies. These masses project into the suprasellar cistern, and the pedunculated hamartoma has a distinct stalk. They present a characteristic appearance that does not change with time. Hamartomas of the tuber cinereum are not true neoplasms,^{390,391,783} as long-term follow-up demonstrated lack of growth on monitoring by periodic CT or MRI.^{391,784,785} Hamartomas appear

*Hochman HI, Judge DM, Reichlin S. Precocious puberty and hypothalamic hamartoma [literature review]. *Pediatrics*. 1981;67:236-244.

Figure 25-53 **A**, A 17-month-old male infant with hamartoma of the tuber cinereum and true precocious puberty. When the patient was 8 months of age, secondary sexual development was observed, and the patient was misdiagnosed as having congenital virilizing adrenal hyperplasia. He was treated with glucocorticoids, which slowed his growth but did not affect his sexual development and bone age advancement. When he was first seen at 17 months, his height was 84.2 cm, his weight was 14.8 kg, pubic hair stage was stage 2, penis was 10.4×2.2 cm, testes were 1.5×2.8 cm, and the scrotum was thinned and rugated. The bone age was 4.25 years. After gonadotropin-releasing hormone (GnRH) administration, the LH level rose from 0.5 to 3.1 ng/dL (LER-960), the follicle-stimulating hormone (FSH) level rose from 0.5 to 1.2 ng/mL (LER-869), and the testosterone level rose from 409 to 450 ng/dL. The dehydroepiandrosterone sulfate (DHEAS) was 17 μ g/dL (preadrenarchal value). The patient was treated with a potent, long-acting LHRH agonist, deslorelin (D-Trp⁶Pro⁹NET-GnRH), which resulted in arrest of his pubertal advancement and a striking decrease in the plasma concentration of testosterone, LH pulses, and the response to exogenous GnRH. **B**, Computed tomography demonstrated a 1.5-cm mass posterior and rostral to the dorsum sellae, which depressed the flow of the third ventricle. For conversion to SI units, see [Figures 25-16, 25-17, and 25-25](#). **C**, Sagittal, T1-weighted magnetic resonance image shows a hypothalamic hamartoma (white arrow) in a 4-year-old boy with true precocious puberty. The posterior pituitary hot spot is designated by the black arrow. (**B**, From Styne DM, Grumbach MM. Puberty in the male and female: its physiology and disorders. In: Yen SCC, Jaffe RB, eds. *Reproductive Endocrinology*, 2nd ed. Philadelphia, PA: Saunders, 1986:313-384.)

on CT or MRI scans as an isodense, abnormal fullness of the interpeduncular, prepontine, and posterior suprasellar cisterns, occasionally with distortion of the anterior third ventricle. Their appearance and location are related to the clinical manifestation, with distortion of the third ventricle more closely associated with the occurrence of seizures.⁷⁸⁶ There is no enhancement with contrast material. T2-weighted MRIs provide the best visualization of the

lesion ([Fig. 25-54](#)).³⁹¹ However, the solid component of hamartomas may be missed when associated with a subarachnoid cyst if lower-resolution MRI studies are invoked.⁷⁸⁷

The etiologic development of the hypothalamic hamartoma may be the converse of the lack of migration of GnRH neurons in Kallmann's syndrome due to absent production of adhesion molecules coded by the *KAL1* gene. We may postulate that in hypothalamic hamartoma, the *KAL1*

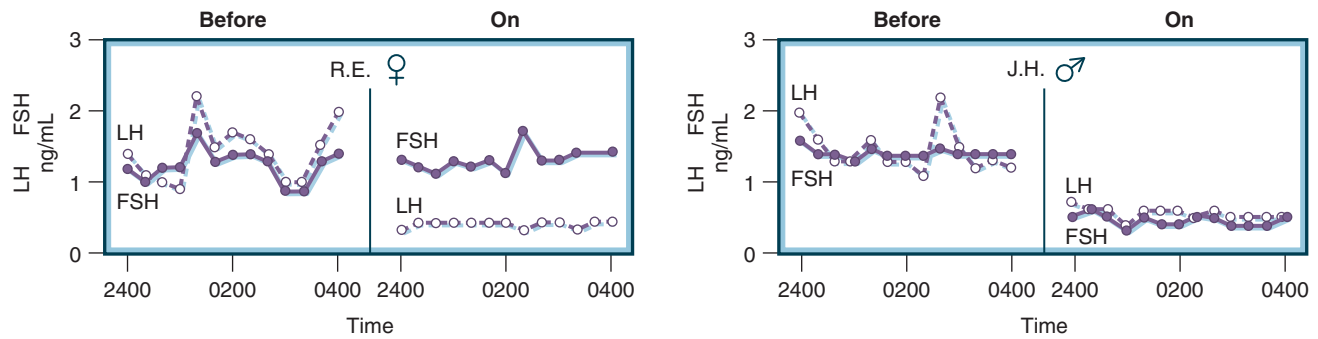

Figure 25-54 Pulsatile luteinizing hormone (LH) secretion before and during gonadotropin-releasing hormone (GnRH) agonist therapy in a boy (right) and a girl (left) with true precocious puberty resulting from a hypothalamic hamartoma. For conversion to SI units, see Figure 25-16.

protein, among other axon-guiding factors, may cause most of the total complement of about 1500 GnRH neurons to migrate to the hamartoma; alternatively, there may be a stimulus to progenitor cells that are capable of synthesizing GnRH to do so while located in the hamartoma.

Hamartomas associated with CPP contain ectopic GnRH neurosecretory cells that are similar to the GnRH-containing neurons in the medial basal hypothalamus. This developmental abnormality exerts its endocrine effects through elaboration and pulsatile release of GnRH.^{389,742} GnRH-containing fibers have been identified passing from the hamartoma toward the median eminence.⁷⁴² We have suggested that the GnRH-containing neurosecretory neurons in the tumor are unrestrained by the intrinsic CNS mechanism that inhibits the normal GnRH pulse generator and act as an ectopic GnRH pulse generator,³¹⁴ either independently or in synchrony with the GnRH neurosecretory neurons in the medial basal hypothalamus, to produce intermittent secretory bursts of GnRH (see Fig. 25-24).³¹⁴ The GnRH is transported to the pituitary by way of the portal circulation and elicits pulsatile release of LH. If the hamartoma were to secrete GnRH in a continuous fashion, CPP would not occur, because the GnRH receptors would be desensitized. About 10% of hypothalamic hamartomas are not associated with CPP.

The hypothalamic hamartoma in two young girls with rapidly progressive CPP did not contain immunoreactive GnRH neurons, but the mass showed a network of astroglial cells containing TGF- α , a member of the EGF family.⁷⁸⁸ This suggests that some hypothalamic hamartomas, by virtue of increased production of TGF- α and of neuregulins synthesized by hypothalamic and astroglial cells through paracrine mechanisms, effect the release of bioactive factors, including prostaglandin E₂, that act on GnRH neurons to increase GnRH secretion. However, these hamartomas were much larger than the typical hypothalamic hamartoma associated with CPP^{391,783}; the mass bulged into the third ventricle in one girl, and in the other, the pituitary gland was hypertrophic and bulged through the diaphragm sellae.⁷⁸⁸ Activation of the GnRH pulse generator through a mass effect and compromise of restraint mechanisms may be the mechanism of CPP, rather than TGF- α signaling. Hypothalamic hamartomas are postulated to elicit their effects via neurons that are able to produce GnRH within the tumor, through the ability to control neurons synaptically connected to GnRH neurons, or through neuronal networks that include GnRH neurons in the hypothalamic hamartoma itself or signaling-competent astrocytic and ependymogial cells.⁷⁸⁹ The precocious sexual development can be controlled by treatment with GnRH agonist therapy.^{785,790,791}

Before 1980, only 37 patients were in the literature with hamartomas of the tuber cinereum, but many more have been reported since the advent of CT and MRI brain scans (see Fig. 25-53 and Table 25-30).⁷⁹² Of girls with CPP studied at the National Institutes of Health, 16% had a hypothalamic hamartoma, 40% had other CNS abnormalities, and 60% had idiopathic CPP. Among boys with CPP, 10% had idiopathic CPP, 50% had a hypothalamic hamartoma, and the rest had other CNS abnormalities including hypothalamic neoplasms.

Hypothalamic hamartomas that cause CPP can be associated with laughing (gelastic), petit mal, or generalized tonic-clonic seizures; mental retardation; behavioral disturbances; and dysmorphic syndromes beginning as early as the neonatal period.^{391,793} Males are more likely to have seizures with these lesions. Seizures can be caused by a hamartoma in the absence of precocious puberty.⁷⁸⁶ The occurrence of seizure is uncommon when the mass diameter of the hamartoma is less than 10 mm, whereas a larger mass is associated with a higher risk.³⁹¹ Larger hamartomas are also associated with precocious puberty.⁷⁹⁴

Although some have advocated neurosurgical removal of these hamartomas because of the occurrence of precocious puberty alone, we do not recommend neurosurgical extirpation in the absence of strong evidence of growth of the mass or of an associated complication such as intractable seizures or hydrocephalus.^{389,391,742,795,796} Gelastic seizures are less amenable to antiepileptic therapy than other hamartoma-related seizures and may require surgical treatment; endoscopic technique is increasingly employed,^{797,798} and gamma knife procedures are used, especially for small lesions.⁷⁹⁹ Refractory seizures have replaced precocious puberty as the main reason to perform surgery in cases of hamartoma of the tuber cinereum. The endocrine result of surgery on these lesions is rarely reported, but in one series of 29 subjects, hypernatremia, low T₄, low GH, and weight gain were encountered.⁸⁰⁰ Prior, unsuccessful surgery may increase the risk for endocrinopathy in these patients. The postoperative endocrine disturbances appear to be transient and mild or asymptomatic, but increased appetite and weight gain appeared in 25% of the subjects and may present an enduring problem. Although there are cases in which removal of a hypothalamic hamartoma led to reversal of the pubertal process,^{783,801} deaths have been reported after attempted operative removal.⁷⁸³ We strongly recommend medical therapy with GnRH agonist in lieu of surgery for the treatment of precocious puberty associated with these hamartomas if seizures are absent or under control.

The Pallister-Hall syndrome is associated with polydactyly, imperfect anus, bifid epiglottis, and hypopituitarism with seizures. This syndrome is not usually associated with

precocious puberty, but one apparent case has been reported.

Other Central Nervous System Conditions. CPP may occur secondary to encephalitis, static cerebral encephalopathy, brain abscess, or sarcoid or tuberculous granulomas of the hypothalamus, with or without tuberculous meningitis.^{503,802,803} CPP can occur after severe head trauma (usually in girls), and it has been associated with cerebral atrophy or focal encephalomalacia occurring after cerebral edema complicating the treatment of severe diabetic ketoacidosis. Children with nontumor hydrocephalus, even if shunted, experience earlier pubertal development, and those who have not been adequately treated may develop CPP.⁷⁴² Delayed puberty is an alternative outcome in a minority of affected children. The growth pattern of children with severe hydrocephalus often includes poor prepubertal growth and an early pubertal growth spurt leading to decreased final height.

Arachnoid Cysts. Arachnoid cysts arising de novo, after infection, or after surgery can cause premature sexual development, possibly with associated GH deficiency.^{314,742} Head nodding, abnormal gait, and abnormalities of visual fields are reported in 30% to 40% of cases. Erosion or enlargement of the sella turcica into a J shape may occur. Decompression and extirpation of a suprasellar arachnoid cyst can reverse the sexual precocity (see Fig. 25-25).^{314,804}

Neurofibromatosis Type 1. Neurofibromatosis type 1 (NF1 or von Recklinghausen's disease) is associated with a propensity to develop the optic chiasmal tumors that are the most common cause⁸⁰⁵ (but not the only cause) of

development of CPP in a child with neurofibromatosis. Most optic gliomas appear during the first decade of life, but only 20% to 30% become symptomatic; these tumors rarely progress in the years after diagnosis.⁸⁰⁵⁻⁸⁰⁷ The tumor suppressor *NF1* gene, located on the long arm of chromosome 17 (q11.2), which has a high mutation rate, encodes a 327-kd protein, neurofibromin, that is widely expressed even though NF1 involves mainly tissues derived from the neural crest. A wide variety of mutations of the *NF1* gene have been reported, especially deletions, nonsense mutations, and truncating mutations distributed over the coding region. In sporadic cases, the new mutation originates in the paternally derived *NF1* allele in most instances, suggesting a role for genomic imprinting. Concentrations of midkine (MK) and stem cell factor, but not EGF, were found to be substantially increased in the serum of NF1 patients compared with healthy controls and serve as a diagnostic feature.⁸⁰⁸ Serum MK levels increase dramatically in patients older than 18 years of age, apparently as a feature of pubertal development. Because serum from patients with NF1 enhances proliferation of human neurofibroma-derived primary Schwann cells and endothelial cells, enhanced levels of circulating growth factors contribute to diffuse tumorigenesis in NF1.

NF1 is characterized by multiple pigmented areas and overgrowth of nerve sheaths and fibrous tissue elements (Fig. 25-55). Multiple café au lait spots are frequent and are smoother in outline (coast of California appearance) than those of the McCune-Albright syndrome (coast of Maine appearance). The diagnosis is made if two or more of the following are observed:

Figure 25-55 A boy aged 8 years and 8 months with neurofibromatosis and precocious puberty resulting from a hypothalamic glioma. He had tonic-clonic seizures at 2.5 years and rapid growth starting at 4 years; an enlarged penis and testes and the presence of pubic hair were first noticed at 7.5 years. At this time, his height was 139.9 cm (+1.4 SD); the phallus was 9 × 3 cm, the right testis measured 5.5 × 3.2 cm, and the left measured 5.4 × 2.9 cm. He had stage 3 pubic hair and 24 large café au lait spots. Computed tomography and pneumoencephalography revealed a 1.5 × 2.5 cm, hypothalamic mass, which was treated with irradiation. The plasma concentration of luteinizing hormone (LH) was 0.5 ng/mL (LER-960); the follicle-stimulating hormone (FSH) level was 0.4 ng/mL (LER-869); and the testosterone level was 221 ng/dL. After 100 µg of intravenous LH-releasing hormone (LHRH), the peak concentration of LH was 4.9 ng/mL, and that of FSH was 1.4 ng/mL, a pubertal response. For conversion to SI units, see Figures 25-16 and 25-17. (From Styne DM, Grumbach MM. Puberty in the male and female: its physiology and disorders. In: Yen SCC, Jaffe RB, eds. *Reproductive Endocrinology*, 2nd ed. Philadelphia, PA: Saunders, 1986:313-384.)

1. Six or more café au lait macules, the greatest diameter being more than 5 mm in prepubertal subjects or more than 12.5 mm in postpubertal subjects
2. Two or more neurofibromas of any type or one plexiform neurofibroma
3. Freckling in the axillae or inguinal region
4. Optic glioma
5. Two or more iris Lisch nodules (ophthalmic hamartomas that occur more frequently after the onset of puberty)
6. A distinctive osseous lesion such as sphenoid dysplasia or pseudoarthrosis
7. A first-degree relative with NF1 according to the criteria described previously

Neurofibromas of the skin in neurofibromatosis may be subcutaneous, sessile or deep, plexiform masses in children; pedunculated lesions develop in later childhood. Internal neurofibromas cause most of the complications. Bone abnormalities such as cysts and pseudoarthrosis, hemihypertrophy, bowing, scoliosis, and skull and facial defects are common (20% of patients); dumbbell-shaped tumors of spinal nerve roots may cause pain, sensory and motor dysfunction, and bone erosions; gliomas or neurofibromas of any part of the CNS, including the optic nerves and the hypothalamus, may calcify. Lisch nodules of the iris are frequent, particularly in adults. Sarcomatous degeneration occurs in 5% to 15% of patients. Other neoplasms include CNS astrocytomas that often involve the visual pathways, ependymomas, meningiomas, neurofibrosarcomas, rhabdomyosarcomas, and nonlymphocytic leukemias. Pheochromocytoma may develop in affected adults.

The clinical manifestations of neurofibromatosis include seizures, visual defects, and either delayed puberty or CPP. Although some manifestations of NF1 are quite common (e.g., café au lait spots, which were found in 99% of a series of 297 subjects), precocious puberty is rarer (found in 3.2% of that same series).⁸⁰⁹ GH deficiency is possible at presentation, but after radiation therapy for associated optic glioma, GH, TSH, ACTH, and gonadotropin deficiency may develop. Developmental delay occurs more often in this population but usually is not severe; there is also an increased incidence of psychiatric disease. Most affected children have some manifestations of the disease by 1 year of age. Screening MRI scans are recommended for early detection of CNS tumors.

Other Central Nervous System Abnormalities. Other CNS abnormalities associated with CPP but without demonstrable lesions on imaging study include epilepsy,⁷⁵² laughing seizures, developmental delay, and the post-traumatic state. Septo-optic dysplasia (described earlier) may be associated not only with multiple pituitary hormone deficiencies and delayed puberty but also, rarely, with CPP.⁵⁶⁵ There may be coexisting deficiencies of some pituitary hormones and excessive secretion of others, including prolactin.

Patients with myelomeningocele (myelodysplasia) have an increased prevalence of endocrine abnormalities, including hypothalamic hypothyroidism, hyperprolactinemia, and elevated gonadotropin concentrations, which in some patients is associated with CPP.

Central Precocious Puberty in Children Adopted from Developing Countries. There was a 15- to 20-fold increased prevalence of CPP among children (with established birth dates) from developing countries who were adopted into Denmark, and other countries have reported similar tendencies. In Sweden, adopted Indian children had pubertal growth spurts similar to those of Swedish children, but adult height was decreased, with the loss of height in childhood

and the early puberty apparently being responsible. Environmental influences, many related to the present obesity epidemic, are posited to exert effects in the reported decrease in age at menarche among children from the developing world. These children, who suffer poor prenatal nutrition and often are SGA, are adopted into families in developed countries,⁸¹⁰ and in that environment of affluence they experience precocious puberty.⁶

A confounding factor in the study of adopted children is the finding that children of immigrant groups who were born in their new country may have earlier puberty than children of the predominant ethnic group of that country; these influences might be genetic, or they might be related to cultural and dietary differences but could complicate the analysis.¹⁷ Foreign children who immigrated to Belgium with their biologic families from developing countries had greatly elevated concentrations of P,P'-DOE, a derivative of the organochlorine pesticide, dichlorodiphenyltrichloroethane (DDT), raising the possibility of a role for endocrine disrupters in their CPP, although this is unproven. Older age at adoption and immigration is a risk factor for precocious puberty.⁸¹¹ Remarkably, children adopted from South Korea do not appear to have this tendency.⁸¹¹

The use of GnRH agonist in addition to GH treatment to increase adult height is reported in affected children, but the combination is not supported by adequate evidence to recommend this combination in adopted children or any children with CPP.⁴⁷⁴ The combination of adoption, living in a culture foreign to the background at birth, and precocious puberty makes these children vulnerable to psychic trauma, which must always be considered.

True Precocious Puberty after Virilizing Disorders. Correction of long-standing virilization may be followed by development of CPP with activation of the hypothalamic-pituitary gonadotropin-gonadal system. This secondary CPP occurs in congenital virilizing adrenal hyperplasia with advanced bone age when glucocorticoid replacement therapy starts after 4 to 8 years.^{284,429} CPP has also been documented in children who received or were exposed to androgens or estrogens for long periods during early childhood for a variety of medical conditions.

Gain of Function Mutations as Cause of CPP

KISSIR/GRP54. Whereas inactivating mutations in the KISS1R receptor cause hypogonadotropic hypogonadism, an autosomal dominant *KISS1R* mutation causing an Arg-386Pro substitution was reported to be associated with CPP. The mutation leads to prolonged activation of intracellular signaling pathways in response to kisspeptin and was speculated to desensitize the receptor to its ligand. The 8-year-old patient had had slowly progressing thelarche since birth, but acceleration of growth, bone age maturation, and secondary sexual development occurred at 7 years of age and was reversed with GnRH agonist treatment. Because the girl was adopted, family studies could not be done.⁷⁵³ It is unclear how many children with apparent idiopathic CPP have such a mutation.

KISS Mutations. Recently, the first detected mutations in the gene encoding *KISS* associated with precocious puberty were reported.⁷⁵⁴ Two novel *KISS1* missense mutations were discovered in three children with idiopathic CPP; these mutations were absent in 400 control alleles. The P74S mutation was identified in the heterozygous state in a boy who developed CPP at 1 year of age.

This variant was resistant to kisspeptin degradation, suggesting more bioavailable peptide to stimulate KISS1R; there was no indication of a change of affinity for the

receptor. The other variant, the H90D mutation, was identified in the homozygous state in two unrelated girls with CPP manifesting from about 6 years of age. It was not clear what biologic changes this mutation brought about to cause the precocious puberty. Heterozygous H90D mutations were previously found in rare patients with isolated hypogonadotropic hypogonadism. The prevalence of *KISS* mutations causing CPP in children previously thought to have "idiopathic" CPP remains to be determined.

Marfan Syndrome. Marfan syndrome may be associated with tall stature and early PHV and menarche⁸¹² compared with North American averages.

Management of Central Precocious Puberty. Table 25-31 addresses the major psychosocial and clinical goals of therapy for CPP.⁷⁹⁵ Three principal agents have been used in the medical treatment of idiopathic or neurologic CPP: medroxyprogesterone acetate, cyproterone acetate, and superactive GnRH agonists.

Medroxyprogesterone Acetate and Cyproterone Acetate. Medroxyprogesterone and cyproterone reversed or arrested the progression of secondary sexual characteristics but had no apparent effect or only a small effect on final height, especially in affected girls.⁶³³ Medroxyprogesterone acetate inhibits gonadotropin secretion by its action on the hypothalamic GnRH pulse generator/pituitary gonadotropin unit and has a direct suppressive effect on gonadal steroidogenesis through 3β -HSD2. Medroxyprogesterone acetate has glucocorticoid action and can suppress ACTH and cortisol secretion, increase appetite and lead to excessive weight gain, and induce hypertension and a cushingoid facies and appearance.^{389,742,813}

Cyproterone acetate has been used outside the United States for the treatment of CPP with advantages and disadvantages similar to those of medroxyprogesterone acetate.³⁸⁹ Cyproterone acetate has antiandrogenic, antigonadotropic, and progestational properties. Cyproterone acetate suppresses the secretion of ACTH and the plasma concentration of cortisol. Fatigue and weakness are common side effects, probably as a consequence of secondary adrenal insufficiency. This agent lacks gluconeogenic activity and does not appear to produce cushingoid features.

The long-term effects of these agents on fertility is not known. For the treatment of CPP, medroxyprogesterone acetate and cyproterone acetate have now been replaced

TABLE 25-32

Action of Gonadotropin-Releasing Hormone Agonists in True Precocious Puberty

A selective, highly specific pharmacologic clamp on the secretion of gonadotropin that produces a "medical gonadectomy"

- Chronic administration induces desensitization of the pituitary gonadotroph to the action of endogenous GnRH

As a consequence:

- Inhibition of pulsatile secretion of LH and FSH
- Inhibition of gonadotropin secretion results in a striking decrease in gonadal steroid output by testes or ovaries and reduction in gonadal size

FSH, follicle-stimulating hormone; GnRH, gonadotropin-releasing hormone; LH, luteinizing hormone.

by the much more effective GnRH agonists; however, they may be used as back-up agents for the occasional patients who develop untoward effects from GnRH agonist therapy.

Superactive Gonadotropin-Releasing Hormone Agonists. The GnRH agonists, synthetic analogues of the amino acid sequence of the natural GnRH decapeptide, are the treatment of choice for CPP of any cause (Tables 25-32 and 25-33).

After initial stimulation, these pharmacologic agents suppress pulsatile LH and FSH release, gonadal steroid output, and gametogenesis, similar to the effects of continuous administration of natural GnRH, which suppresses gonadotropin secretion^{328,814,815} after an initial, brief stimulation of gonadotropin release. The agonist binds to the GnRH receptor on gonadotrophs, and this is followed by desensitization of the gonadotroph to GnRH and down-regulation and loss of receptors. Desensitization persists after receptor levels return to normal as a result of uncoupling of the receptors from the intracellular signaling effector pathway.⁸¹⁶ This regimen functions as a selective, highly specific pharmacologic clamp on the secretion of gonadotropins without interfering directly with release of the other pituitary hormones. In essence, the regimen produces a reversible medical gonadectomy (see Table 25-32).

The superactive agonist analogues of GnRH have about 15 to 200 times the potency of the natural GnRH decapeptide, prolonged action, and low toxicity (see Table 25-33). Replacing the glycine-amide terminus of GnRH with alkyl amines (i.e., ethylamide [NEt]), as in [Pro⁷-NEt]GnRH; substituting certain D-amino acids at position 6, as in [D-Trp⁶]GnRH; or making bulky hydrophobic alterations at position 6, as in [D-Nal(2)⁶]GnRH increases the potency and duration of action.⁸¹⁷ These changes make the molecule more resistant to enzymatic degradation, increase the binding affinity of the analogue for the receptor on the pituitary gonadotroph, increase hydrophobicity, and, with some analogues, increase binding to plasma proteins.^{389,817,818}

The suppressive effects of the GnRH agonists on gonadotropin secretion make them useful in the treatment of CPP^{389,760,819-823} and they are also used in endometriosis and prostatic carcinoma. Although an every-12-week formulation of leuporelin (leuprolide acetate) has shown success in clinical trials as treatment for CPP and has been FDA-approved for adults,⁸²⁴ the pediatric depot preparation of leuporelin is currently the only one that has FDA approval for administration every 4 weeks to children; long-term studies have established its efficacy and safety.^{825,826} The bioavailability of agonists given intranasally is much reduced,^{389,827} as reflected in the need to use a high dose at more frequent intervals. Recently, a subcutaneous implant of histrelin was approved for 12-month treatment of CPP.

TABLE 25-31

Objectives for the Management and Treatment of True Precocious Puberty

Detection and treatment of an expanding intracranial lesion
Arrest of premature sexual maturation until the normal age at onset of puberty
Regression of secondary sexual characteristics already present
Attainment of normal mature height; suppression of the rapid rate of skeletal maturation
Prevention of emotional disorders and handicaps and alleviation of parental anxiety; promotion of understanding by counseling, early sex education, and acceleration of social age
Reduction of risk of sexual abuse and early sexual debut
Prevention of pregnancy in girls
Preservation of future fertility
Diminishment of the increased risk of breast cancer associated with early menarche

From Grumbach MM. True or central precocious puberty. In: Krieger DT, Bardin CW, eds. *Current Therapy in Endocrinology and Metabolism*, 1985-1986. Toronto, Canada: BC Decker; 1989:4-8.

GnRH, luteinizing hormone-releasing hormone; IM, intramuscular; SQ, subcutaneous.

Modified from Grumbach MM, Kaplan SL. Recent advances in the diagnosis and management of sexual precocity. *Acta Paediatr Jpn.* 1988;30(suppl):155-175.

The effectiveness of GnRH agonists in the treatment of CPP varies with the potency of the analogue, dose, route of administration, and compliance.^{389,760,816,828}

Treatment of CPP with a potent GnRH agonist results in 1 to 3 days of increased FSH and LH release and a rise in circulating gonadal steroid levels, followed after 7 to 14 days of treatment by suppression of pulsatile secretion of LH and FSH and of the pubertal LH response to the administration of native GnRH (Figs. 25-56 and 25-57). The isoforms of gonadotropins tend toward a more basic charge. A plasma estradiol concentration of less than 18 pmol/L (5 pg/mL) in girls or a plasma testosterone level of less than 0.7 nmol/L (20 ng/dL) in boys indicates adequate gonadal suppression; this occurs within about 2 to 4 weeks in girls and 6 weeks in boys. GnRH agonist therapy does not affect the secretion of adrenal androgens.^{389,790,819}

Changes in secondary sexual characteristics within the first 6 months of therapy (Fig. 25-58) include reduction in breast size and decrease in pubic hair, cessation of menses if present before treatment, and decreased size of the uterus and ovaries as assessed by pelvic sonography in girls. Some girls have recurrent episodes of hot flushes and moodiness. In boys, pubic hair thins, the testes decrease in size, acne and seborrhea regress, penile erections and masturbation become much less frequent, the high energy level and aggressive behavior diminish, and self-esteem improves.

Height velocity decreases by about 60% during the first year of therapy, with greater decreases found in those with the most advanced bone age and taller relative height.⁸²⁹ Skeletal maturation slows dramatically during the first 3 years, to a rate that often is less than the progression in chronological age. From the second year on, height velocity for bone age is usually appropriate (Fig. 25-59). Bone age is suggested to represent a surrogate for growth plate senescence due to prior exposure to estrogens. Those with the longest courses before treatment, the most advanced physical findings, and the most rapid bone age advancement before therapy have the lowest growth velocities on treatment.

The rate of growth during treatment with GnRH agonists is inversely related to the bone age at the start of

therapy²⁶⁵; best results occur when treatment is begun soon after the onset of precocity and when the bone age is advanced by only a few years.⁸³⁰ There is a striking benefit for those children treated before 5 years of age (girls' height, 164.3 ± 7.7 cm) compared with those treated after age 5 years (157.6 ± 6.6 cm) or with untreated patients (152.7 ± 8.6 cm).⁷⁴³ Adult height in children treated with GnRH agonists is improved, especially when therapy starts before 6 years of age rather than after 8 years of age (Table 25-34).^{474,743,831} Treatment in children with onset of puberty after 6 years of age is not of proven efficacy in increasing adult height. An adult height within the target height occurs with therapy in about 90% of girls and boys.⁸³² We recommend treatment of all affected children with onset of puberty before 6 years of age to ensure an optimal prognosis for adult height. The optimal age at which to discontinue therapy is undetermined because the post-treatment growth spurt is important in determining adult height.⁴⁷⁴

The addition of hGH treatment to the GnRH regimen is a consideration when growth velocity is reduced sufficiently over a 6-month period to compromise predicted final height.⁸³³ This is in contrast to the concern raised regarding therapy with GnRH agonist and GH in normal variant short stature of CDP. This combination is not proven by evidence-based study.⁴⁷⁴

In a preliminary study, the GnRH antagonist, cetrorelix, appeared to bring about more rapid suppression of gonadotropin secretion and to eliminate the flare-up of gonadotropin secretion after administration of GnRH agonist. There are no reports at present concerning the use of cetrorelix as a sole treatment of precocious puberty, but in one unusual case, a girl with purported gonadotropin-independent precocious puberty responded to this treatment, bringing up a possible direct effect of the agent on ovarian function.⁸³⁴ This agent suppresses ovarian but not adrenal function and was proposed to be useful as a test to differentiate the origin of severe hyperandrogenism in adolescence.⁸³⁵

Girls with CPP have a tendency toward obesity that is unrelated to treatment with GnRH agonist^{474,785,836,837}; there is no substantial evidence that GnRH treatment fosters the development of obesity. The BMI before therapy predicts

Figure 25-56 Effect of administration of the gonadotropin-releasing hormone (GnRH) agonist deslorelin (4 µg/kg/day subcutaneously) on pulsatile secretion of luteinizing hormone (LH) (top), LH response to GnRH (middle), and plasma concentration of estradiol (bottom) in a 5-year, 1-month-old girl with idiopathic true precocious puberty. This patient, who had a bone age of 13 years when treatment was begun, has been administered deslorelin for 7 years. During this period, the estimated predicted final height increased by 15 cm. Surprisingly, the bone age advanced by only about 6 months on serial examinations for several years. (Modified from Grumbach MM, Kaplan SL. Recent advances in the diagnosis and management of sexual precocity. *Acta Paediatr Jpn.* 1988;30[suppl]:155-175.)

the BMI value after cessation.⁸³⁷⁻⁸³⁹ However, a recent longitudinal study suggested that, with adequate gonadotropin suppression, BMI for age may improve after at least 2 years of therapy.⁸⁴⁰ Serum leptin values in patients with precocious puberty remains in line with the average for children of similar BMI and pubertal development.⁸⁴¹

The IGF1 concentration in CPP correlates best with the stage of puberty and the plasma concentration of testosterone or estradiol.²⁷⁶ Treatment with GnRH agonist reduces the level of IGF1 to the normal range for bone age but not for chronologic age.²⁷⁶ Gonadal steroids increase plasma IGF1 concentrations in CPP, as in normal puberty. Secretion of GH is increased in CPP to a level comparable to that observed in normal puberty.⁷⁵⁶ Treatment with GnRH agonist usually results in decreased secretion of GH, most

strikingly during sleep, and in a decreased GH response to provocative stimuli.

The depot formulations of GnRH agonists provide continuous exposure to the drug with a single intramuscular injection every 4 weeks (as described earlier) and minimize the problem of compliance.^{743,842} However, irregular or inadequate treatment or poor compliance results in persistent or intermittent increase in the concentration of plasma gonadal steroids, leading to decreased growth but advancing bone age.

Regular assessment is essential, initially at intervals of 1 to 3 months, and should include periodic determinations of plasma testosterone levels in boys and estradiol levels in girls; change in basal concentrations of LH and FSH as measured by third-generation assays or in the LH and FSH response to exogenous GnRH or GnRH agonists; growth, bone age, and secondary sexual characteristics; and, in girls, serial evaluations of ovarian morphology and uterine size by pelvic sonography. A decrease in the size of the ovaries and uterus on pelvic sonography occurs with successful GnRH agonist treatment.^{790,843} Because GnRH is not available, the rise in serum LH and FSH is evaluated 30 to 120 minutes after administration of the GnRH agonist.^{844,845} The LH and FSH responses to GnRH agonist are suppressed with effective therapy, but because standards differ between laboratories, actual cutoff values may differ in clinical practice, depending on location. A 1-year Silastic implant of the histrelin GnRH agonist, although it involves a surgical procedure, eliminates the need to titrate the dose and repeat testing for maximal effect; a second treatment year is reported to be effective.⁸⁴⁶

Whereas urinary excretion of LH correlates with the stage of pubertal development in normal subjects, urinary gonadotropin determinations are not sufficiently sensitive to be used for monitoring purposes in children with CPP.

TABLE 25-34

Effect of GnRH Agonist Treatment on Adult or Near-Adult Height and Height Gain

Chronologic Age at Start of Therapy	No. Patients	Mean Current Height (cm)		Mean Height Gain (cm)*
		Female	Male	
Untreated†				
Total	116	152.7 ± 8.6	155.6 ± 7.7

*Final predicted height minus initial predicted height (Bayley-Pinneau method).

†Final height.

‡Final or near-final height.

F, female; GnRH, gonadotropin-releasing hormone; M, male; UCSF, University of California, San Francisco.

From Paul D, Conte FA, Grumbach MM, et al. Long-term effect of gonadotropin-releasing hormone agonist therapy on final and near-final height in 26 children with true precocious puberty treated at a median age of less than 5 years. *J Clin Endocrinol Metab.* 1995;80:546-551.

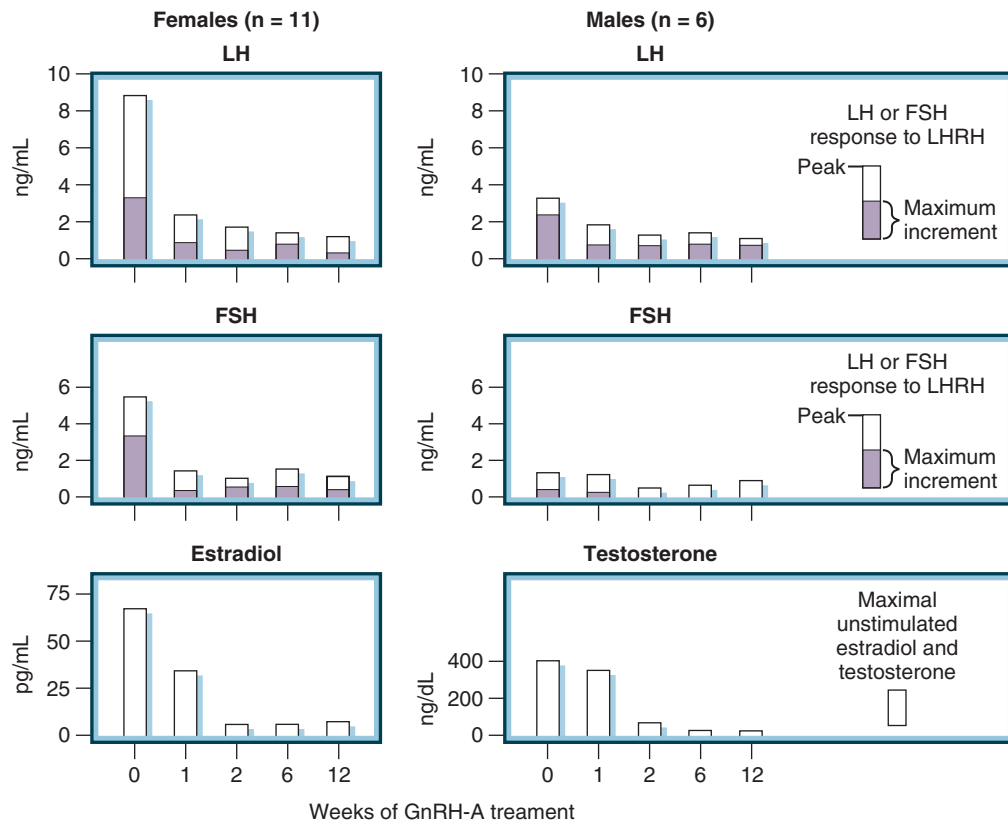

Figure 25-57 Deslorelin treatment (4 $\mu\text{g/kg/day}$ subcutaneously) of girls and boys with true precocious puberty. Effects were seen during the first 12 weeks of treatment on the luteinizing hormone (LH) and follicle-stimulating hormone (FSH) response to a challenge with gonadotropin-releasing hormone (GnRH) (mean peak response and maximum increment) and on the maximal unstimulated concentration of plasma estradiol in the girls and of plasma testosterone in the boys. Notice the relatively rapid change from pubertal values to prepubertal values. For conversion to SI units, see Figures 25-16 and 25-17. (From Styne DM, Harris DA, Egli CA, et al. Treatment of true precocious puberty with a potent luteinizing hormone releasing factor agonist: effect on growth, sexual maturation, pelvic sonography, and the hypothalamic pituitary gonadal axis. *J Clin Endocrinol Metab.* 1985;61:142-181. Copyright by The Endocrine Society.)

When treatment is discontinued, even after 8 years, gonadal suppression is reversed within a few weeks to months, as manifested by a rise in the concentration of plasma gonadal steroids, progression of sexual maturation, and return of menses.^{785,847,848} Menarche occurred at an average of 1.2 to 1.5 years after discontinuation of therapy (range, 0 to 60 months). Ovulation had occurred in 50% of girls by 1 year after menarche and in 90% of those studied 2 or more years after menarche.⁸⁴⁹ Mean ovarian volume was found to remain greater than in normal subjects, and the LH response to GnRH was less than the normal response.^{785,832}

The reversible nature of the therapy has also been confirmed in boys with CPP, because gonadotropins in the basal or GnRH-stimulated state return to normal pubertal values by 1 year after cessation of therapy.⁷⁹¹ Testicular size may take longer to reach normal values.

A report of 46 women studied 12.5 years after cessation of treatment with GnRH agonist revealed an adult height 1.6 cm, or 0.3 SD, below target height, with no evidence of reproductive impairment nor apparent PCOS or hirsutism.⁸⁵⁰ However, an increased prevalence of PCOS has been reported in young women (mean age, 18.1 years) with a history of CPP, with onset at a mean age of 7.65 years.⁸⁵¹ Thirty-two percent of the patients had PCOS according to the Rotterdam definition, and 30% had PCOS according to the Androgen Excess Society; the most common presentation was clinical or biochemical hyperandrogenism, or both, and polycystic ovarian morphology. The study authors did not find any other predictive factors for the

development of PCOS when the diagnosis of CPP was made. These girls would not have qualified for the diagnosis of CPP based on the newest criteria, so it is of concern that these girls with early rather than precocious puberty had such a high prevalence of PCOS.

An international consensus conference convened by the Lawson Wilkins Pediatric Endocrine Society and the European Society for Pediatric Endocrinology reviewed all the world literature on the use of GnRH to determine, in an evidence-based approach, the appropriate use of the agent in precocious puberty. However, few controlled prospective studies have been performed with gonadotropin-releasing hormone analogues in children, so many of the conclusions relied in part on collective expert opinion. The major conclusions were as follows⁴⁷⁴:

- GnRH analogues exert benefit in increasing adult height in children with early-onset CPP (<6 years in girls) and are not routinely recommended after that age.
- The psychosocial effects of CPP and their alteration by GnRH analogues require additional study.
- The use of GnRH analogues does not appear to cause weight gain or long-term diminution of BMD.
- The use of GnRH analogues for conditions other than CPP, such as to increase adult height in children with idiopathic short stature or SGA, or with GH treatment in children, is not recommended.

Although psychosocial factors and parental anxiety that adversely affect the well-being of the child need to be assessed in the decision to initiate GnRH agonist treatment,

Figure 25-58 A girl aged 2 years and 5 months with true precocious puberty after 6 weeks of deslorelin therapy (4 μ g/day subcutaneously). Notice the regression in the size of the breasts; however, the rapid rate of growth had not decreased. At the end of 1 year of therapy, the growth rate was suppressed to 4 cm/year, and bone age advanced only 1 year. BA, bone age; CA, chronologic age; HT, height; WT, weight. (From Styne DM, Grumbach MM. Puberty in the male and female: its physiology and disorders. In: Yen SCC, Jaffe RB, eds. *Reproductive Endocrinology*, 2nd ed. Philadelphia, PA: Saunders, 1986:313-384.)

this therapy cannot be routinely recommended for such concerns (Table 25-35).

Adverse Effects. Rare reactions to GnRH agonists include local and systemic allergic reactions, including asthmatic episodes when the agent is given intranasally. The prevalence of a sterile abscess at the site of intramuscular

TABLE 25-35

Indications for Therapy with Gonadotropin-Releasing Hormone Agonists in True or Central Precocious Puberty

In children with clinical and unequivocal endocrine features of idiopathic true precocious puberty:

- Rapid advancement over a period of 6-12 mo of secondary sex characteristics, height, height velocity, and bone age (increased >2.5 SD for chronologic age) in affected boys and girls
- A plasma testosterone concentration sustained >2.5 nmol/L (>75 ng/dL) in boys <8 yr of age determined by sensitive, specific immunoassay
- A plasma estradiol concentration, recurrently ≥ 36 pmol/L (≥ 10 pg/mL) determined by a sensitive, specific assay capable of quantifying low concentrations of estradiol
- Onset of menarche (and recurrent menses) in girls <9 yr of age
- Psychosocial factors and parental anxiety, including evidence that the child's psychosocial well-being is adversely affected

In children with neurogenic or organic true precocious puberty, especially those with associated GH deficiency, the course is almost invariably progressive and LHRH treatment should not be delayed

LHRH, luteinizing hormone-releasing hormone; SD, standard deviation.

injection of long-acting repository preparations, including leuporelin and triptorelin, is clearly increased (5% to 10%); these reactions are unpredictable and intermittent and in most instances are related to the polylactic and polyglycolic polymer and not to the GnRH agonist itself.⁸²⁶ Switching to daily subcutaneous injections of non-depot preparations or to intranasal preparations is rarely associated with a recurrence. A small increase in serum prolactin above normal limits was described in girls after treatment with GnRH agonist, but galactorrhea was not observed.⁸⁵² Volumetric BMD and peak bone mass are normal during and after discontinuation of GnRH therapy.⁴⁷⁴ Calcium and vitamin D intake must be ensured during treatment to achieve optimal skeletal health.⁸⁵³ However, high fruit and vegetable intake (defined as more than three servings per day, lower than the U.S. government recommended intake) is desirable in all children and may serve in early puberty as a factor to increase bone density, possibly because of decreasing calcium excretion in the urine.⁸⁵⁴

Figure 25-59 Effect of gonadotropin-releasing hormone (GnRH) agonist therapy in true precocious puberty on growth. *Left*, Changes in mean height velocity (cm/year \pm 1 SE) after the initiation of GnRH agonist therapy with D-TRP⁶-PRO⁹-NET (deslorelin) (darker bars) or with nafarelin (lighter bars). A sharp decrease in height velocity occurred within 1 year. *Right*, Mean (\pm 1 SE) height for bone age before and during GnRH agonist treatment. The discrepancy between height and the more advanced bone age decreases (reverts to normal) with chronic GnRH agonist treatment. (From Kaplan SL, Grumbach MM. True precocious puberty: treatment with GnRH agonists. In: Delemarre-Van de Waal H, Plant TM, van Rees GP, et al, eds. *Control of the Onset of Puberty*, 3rd ed. Amsterdam, The Netherlands: Elsevier, 1989:357-373.)

Four patients were reported to have developed slipped capital femoral epiphyses during or just after treatment of CPP with GnRH agonist.⁸⁵⁵ Slipped capital epiphyses occur mostly during the earliest phase of puberty, when growth is beginning to increase, and not after fusion of the triradiate cartilage, so these cases may have a different etiologic course than that found in average pubertal children.

Psychosocial Aspects. Psychological management is a critical aspect of the care of children with CPP.^{389,795,856,857} With the advanced physical maturation for chronologic age, these children tend to seek friends closer to their size, strength, and physical development. Difficulties may arise because they lack the social skills of older children. Sex education of the child and the family is essential and must be given in a skillful, sensitive, and explicit manner; the risks of sexual abuse (in both sexes) and of pregnancy need to be discussed. The parents need to be informed about the management of menses. The onset of sexual activity may be earlier than average but usually remains within the normal range.

It is imperative to provide support in handling the increased height, the advanced sexual maturation, and the effects of gonadal steroids on behavior, activity, and emotional stability. The unrealistic demands and expectations that arise from the discrepancy between the child's physique and his or her chronologic, mental, and psychosexual age require wise counseling, as do the reactions to ridicule by peers and the concern about being different from age-mates. Some of these problems have been mitigated by school acceleration, in which the child is advanced by one or two grades, if this is consistent with the mental and emotional development. These comments are applicable to children with all forms of sexual precocity; the effectiveness of GnRH agonists has reduced but not eliminated many of these issues in CPP.⁷⁹⁵

The GnRH agonists are useful in conjunction with GH in the management of organic or neurogenic CPP with associated GH deficiency (usually as a result of irradiation of the brain), and their use has been advocated even in the absence of precocious puberty to allow a longer period of GH treatment before epiphyseal fusion. A few, usually short-term, studies have evaluated the combination, with variable results. This regimen is experimental, and its cost-effectiveness needs to be considered (see earlier discussion).⁴⁷⁴

Aromatase inhibitors (e.g., letrozole) decrease or eliminate the effect of estrogen on bone age advancement. They may be useful to improve height prognosis in sexual precocity in boys,^{150,151,477,858} but no controlled studies are available, and there has been mixed success with aromatase inhibitors in the treatment of incomplete ISP.^{859,860} Controlled studies are necessary to establish the safety and efficacy and, especially, the effects on adult bone density, which remains a worrisome subject (Table 25-36).

Incomplete Isosexual Precocity: Gonadotropin-Releasing Hormone-Independent Sexual Precocity

In incomplete forms of ISP, such as GnRH-independent sexual precocity (GISP), the secretion of testosterone in boys and estrogen in girls is independent of the hypothalamic GnRH pulse generator (see Table 25-25). There is no pubertal LH response to GnRH or GnRH, and there is no pubertal pattern of pulsatile LH secretion. Patients do not respond to chronic GnRH agonist therapy with suppression of gonadal steroid output. ISP is a consequence of gonadal or adrenal steroid secretion that is independent of GnRH, iatrogenic exposure to gonadal steroids, or, in boys, rare hCG- or LH-secreting tumors.

TABLE 25-36

Potential Use of Aromatase Inhibitors or Estrogen Receptor Antagonists in Disorders of Growth and Sexual Maturation

Growth Disorders or Variants of Normal Growth

- Isolated growth hormone deficiency
 - To restrain epiphyseal maturation
- Genetic short stature/constitutional delay in growth
 - To restrain epiphyseal maturation

Sexual Precocity

- Congenital virilizing adrenal hyperplasia in male and female
 - To reduce dose of glucocorticoid
 - To inhibit conversion of C19 steroids to estrogens (or estrogen action)
 - With or without use of 17,20-lyase inhibitor of anti-androgen
- Testotoxicosis
 - To inhibit conversion of C19 steroids to estrogens
- McCune-Albright syndrome
 - To inhibit conversion of C19 steroids to estrogens (or estrogen action)

Adolescent Gynecomastia

- To inhibit estrogen synthesis (or estrogen action)

From Grumbach MM. Estrogen, bone, growth, and sex: a sea change in conventional wisdom. *J Pediatr Endocrinol Metab.* 2000;13(suppl 6):1439-1455.

Boys

Chorionic Gonadotropin-Secreting Tumors. Several types of germ cell tumors secrete hCG, which may cross-react in some polyclonal LH assays (although they are rarely used presently) and will lead to a positive pregnancy screen. Boys with hCG-secreting neoplasms have slightly enlarged testes (although not to a size consistent with the size of the phallus and other male secondary sex characteristics, because the seminiferous tubules are not affected), and it may be difficult to differentiate these patients from boys in the early stages of CPP on the basis of physical examination alone.^{741,861} However, plasma hCG levels are elevated without an increase in the concentration of FSH or LH measured in specific assays.

Boys with hepatoma or hepatoblastoma present with hepatomegaly or firm, irregular liver nodules, anemia, and precocious puberty⁸⁶²; these are among the most serious of hCG-secreting tumors (Fig. 25-60). hCG is localized to multinucleated tumor giant cells; α -fetoprotein was found in the embryonal-type tumor cells of the hepatoblastoma in one case. The mean age at onset is 2 years, 8 months, but average survival is only 10.7 months after diagnosis.⁸⁶³

Infantile choriocarcinoma is also associated with elevated hCG and is thought to originate in the placenta; infants may be diagnosed at 1 month of age, with a survival time of only 3 months.⁸⁶⁴ About 20% of mediastinal germ cell tumors occur in boys with 47,XXY or mosaic Klinefelter's syndrome, a prevalence 30 to 50 times more common than in unaffected boys. Plasma α -fetoprotein is a useful additional marker for yolk sac (endodermal sinus) or mixed germ cell tumors⁸⁶⁵; the cells in the tumor that secrete α -fetoprotein appear to differ from those that secrete hCG. Rarely, the germ cells contain enough aromatase activity to convert circulating C19 precursors (of adrenal origin after adrenarche) to estradiol, which in some instances is sufficient to induce breast development.^{866,867}

Some teratomas, chorioepitheliomas, and mixed germ cell tumors in the hypothalamic region (or in the mediastinum, lungs, gonads, or retroperitoneum); certain pineal

Figure 25-60 A boy aged 1 years and 5 months with a human chorionic gonadotropin (hCG)–secreting hepatoblastoma. Notice the outline of the large liver (left) and the penile enlargement (right). The testes were 2×1 cm, and pubic hair was stage 2. The plasma hCG level was 50 mIU/mL; the plasma testosterone level was 168 ng/dL; and the plasma α -fetoprotein level was 160,000 ng/mL. Metastatic lesions in both lungs were seen on the chest radiograph. To convert testosterone values to SI units, see Figure 25-26. To convert hCG values to international units per liter, multiply by 1.0. To convert α -fetoprotein values to micrograms per liter, multiply by 1.0. (From Kaplan SL, Grumbach MM. Pathogenesis of sexual precocity. In: Grumbach MM, Sizonenko PC, Aubert ML, eds. *Control of the Onset of Puberty*. Baltimore, MD: Williams & Wilkins, 1990:620-660.)

tumors (usually a germ cell tumor or mixed germ cell tumor)^{861,868}; and, less commonly, a chorioepithelioma or its variants cause sexual precocity in boys by secreting hCG rather than by activating the pituitary gonadotropin-gonadal axis via the hypothalamic GnRH pulse generator.

Calcification of the pineal is found in 8% to 11% of 8- to 11-year-old children and by itself is not indicative of a tumor. Intracranial germ cell tumors account for 3% to 11% of malignant CNS tumors in children and adolescents, with a predominance in the Far East.⁸⁶⁹ Germ cell tumors of the hypothalamus or pineal region constitute fewer than 1% of primary CNS tumors in Western countries but account for 4.5% of such tumors in Japan. The prevalence of intracranial germ cell tumors is 2.6 times greater in males than in females, but germ cell tumors in the suprasellar-hypothalamic region do not exhibit a sex predominance and are generally associated with pituitary hormone deficiencies including diabetes insipidus and delayed puberty.⁴⁹⁰ Germ cell tumors do not cause gonadotropin-induced ISP in females because of the paucity of effects of hCG in prepubertal females. However, CPP may occur through disinhibition of the hypothalamic GnRH pulse generator by local mass effects.

Germ cell tumors that secrete hCG are rarely located in the thalamus and basal ganglia. In “true” pure CNS germ cell tumors (germinomas), hCG cannot be readily detected in the circulation but may be detected in the cerebrospinal fluid.⁴⁹⁰ In mixed germ cell tumors, hCG is commonly found in the blood as well as in cerebrospinal fluid. Extremely elevated levels of hCG in a CNS tumor suggest

a primary intracranial choriocarcinoma or germ cell tumor with a high risk of tumor hemorrhage during biopsy, and surgical removal or debulking rather than diagnostic biopsy may be the initial operative approach.⁸⁷⁰

Mixed germ cell tumors and especially “pure” germinomas are radiosensitive, and if the bone age is less than 11 years, sexual precocity may regress, only to progress later into normal puberty.⁸⁶¹ Long-term survival is reported in 88% of patients with CNS germ cell tumors after appropriate therapy.⁸⁷¹ However, testicular germ cell tumors are occasionally found years after successful therapy for CNS germ cell tumors, so long-term surveillance is always indicated.⁴⁹⁵

Pineal cysts are a rare cause of CPP.⁸⁷²

All pituitary adenomas, including gonadotropin-secreting pituitary adenomas, are exceedingly rare in children. An LH-secreting pituitary adenoma (basal serum LH of 900 IU/L with no rise after GnRH) and a prolactin-secreting pituitary adenoma (215 μ g/L) caused sexual precocity in two boys with serum testosterone levels of 7 nmol/L (200 ng/dL).⁸⁷³ Prepubertal values returned after removal of these “chromophobe” adenomas with suprasellar extension.

Precocious Androgen Secretion Caused by the Adrenal Gland

Virilizing Congenital Adrenal Hyperplasia. Virilizing CAH caused by a defect in 21-hydroxylation (CYP21 deficiency) leads to elevated androgen concentrations and masculinization and is a common cause of GnRH-independent sexual precocity in boys.⁸⁷⁴ Approximately 75% of patients with

CYP21 deficiency have salt loss resulting from impaired aldosterone secretion as well as low serum sodium and high serum potassium concentrations. Increased plasma concentrations of 17-hydroxyprogesterone, increased levels of urinary 17-ketosteroids and pregnanetriol, and advanced bone age and rapid growth are characteristic.

Treatment with glucocorticoids suppresses the abnormal androgen secretion and arrests virilization; treatment with mineralocorticoids, when necessary, corrects the electrolyte imbalance. Virilizing CAH accompanied by hypertension occurs in 11 β -hydroxylase deficiency; the progressive virilization ceases and the blood pressure falls to normal with glucocorticoid therapy. All forms of CAH are inherited as autosomal recessive traits. Untreated virilizing CAH causes anovulatory amenorrhea in females and oligospermia in males; these conditions are reversible with treatment. Delayed treatment of virilizing CAH may reveal GnRH-dependent CPP (secondary CPP) as a consequence of the advanced somatic and hypothalamic maturation resulting from long exposure to adrenal androgen. Further difficulty is presented in the treatment of CAH during the pubertal years, when androgen secretion normally increases and increased clearance of glucocorticoids at puberty in girls may alter dosing requirements.

Virilizing Adrenal Tumor. Virilizing adrenal carcinomas or adenomas secrete large amounts of DHEA and DHEAS and, on occasion, testosterone. Glucocorticoids do not suppress the increased secretion of adrenal androgens to the normal range for age in carcinoma, as they do in CAH. Cushing's syndrome resulting from adrenal carcinoma may cause ISP and growth failure in boys. Rarely, an adrenal adenoma produces both testosterone and aldosterone, leading to sexual precocity and hypertension with hypokalemia.^{875,876}

Adrenal rests, or heterotopic adrenal tissue in the testes, may enlarge (sometimes to massive size) with endogenous ACTH stimulation in boys who have untreated or inadequately treated CAH and may mimic bilateral or unilateral interstitial cell tumors. MRI sonography, including Doppler flow studies of the testes, is useful to define the extent and nature of the testicular masses. In boys in whom the testicular tumors are autonomous and unresponsive to glucocorticoid therapy or improved compliance, surgical management, including enucleation of the tumor or tumors, has been useful to prevent further damage to the testes and improve the potential for fertility.⁸⁷⁷ LH receptors have been detected on adrenal/cortical cells,^{878,879} so LH may stimulate the testes in some patients.

NROB1 (DAX1) Gene Mutations. Two cases of *NROB1* frameshift mutations demonstrated adrenal failure and GnRH-independent sexual precocity that was suppressible by glucocorticoid therapy but not by GnRH agonist. The exceedingly high ACTH levels, possibly acting through the human melanocortin 1 receptor present in human Leydig cells, may have been the underlying cause of the increased steroidogenesis and testosterone secretion that were reversed by glucocorticoid treatment. Because *NROB1* inhibits transactivation of SF1, a regulator of steroidogenic genes, loss of *NROB1* inhibition of SF1 transcriptional activity also may have had a role.^{880,881}

Leydig Cell Tumor. Testicular tumors are rare in childhood, representing 1% to 2% of all pediatric solid tumors, and Leydig cell tumors make up only 1.5% of those.⁸⁸² Androgen-producing Leydig cell tumors are rare causes of sexual precocity in boys. They rarely are malignant and are slow growing but must be treated or epiphyseal fusion will limit height and precocious puberty will affect social development. They derive from primordial mesenchyme, are

classified as interstitial cell tumors, and occur most frequently around the age of 4 to 5 years. Unilateral enlargement (often nodular) of the testis usually occurs in boys with this neoplasm (although 5% to 10% of cases are bilateral); in contrast, both testes are usually of normal size (small) for chronologic age in boys with CAH or a virilizing adrenal tumor.⁸⁸³ Although LH receptor-activating mutations were detected in several boys with sporadic Leydig cell adenomas,⁸⁸⁴ an absence of known mutations occurs in some cases.⁸⁸²

Women with a previous history of CAH or a virilizing tumor may exhibit ovarian hyperandrogenism associated with persistent elevation of LH despite successful treatment of their initial virilizing condition in childhood; this is not usually the case in women who have late-onset CAH.⁸⁸⁵

Familial or Sporadic Testotoxicosis. Pituitary gonadotropin-independent familial premature Leydig cell and germ cell maturation, or testotoxicosis,⁸⁸⁶⁻⁸⁹¹ causes boys to develop secondary sexual characteristics with penile enlargement, which may be present at birth,⁸⁸⁷ and bilateral enlargement of testes to the early or midpubertal range, although the testes often are smaller than expected in relation to penile growth and pubertal maturation (Fig. 25-61). Premature maturation of Leydig and Sertoli cells and spermatogenesis occur.^{886,887,889} Leydig cell hyperplasia may occur; the Leydig cells in affected boys produce dimeric inhibin B as well as testosterone,⁸⁹² and Leydig cells and spermatogonia stain positively for the α and β_B segments of inhibin. The rate of linear growth is rapid, skeletal maturation is advanced, and muscular development is prominent. The presence of prepubertal basal and GnRH-stimulated gonadotropin concentrations, lack of a pubertal pattern of LH pulsatility (as measured by immunologic or bioassay techniques), and normal pubertal or adult testosterone levels and clearance of testosterone are characteristic (Table 25-37).⁸⁸⁷ The onset of adrenarche and its biochemical marker, serum DHEAS, correlate with bone age rather than chronologic age.

Treatment with an GnRH agonist does not suppress testicular function or maturation.^{887,890} In late childhood or early adolescence, fertility is achieved and an adult pattern of LH secretion and response to GnRH is demonstrable⁸⁸⁸; secondary GnRH-dependent CPP may be superimposed on the substrate of testotoxicosis.^{888,889,893} In some adults, impaired spermatogenic function is associated with elevated concentrations of plasma FSH.⁸⁸⁸ Testotoxicosis may occur sporadically, probably as a consequence of a germline mutation or even a postzygotic one, but it is usually inherited as a sex-limited autosomal dominant trait⁸⁸⁸; this probably accounts for the earlier descriptions of "true"

TABLE 25-37

Testotoxicosis: Clinical and Laboratory Characteristics

Sex-limited autosomal dominant inheritance; activating mutation in the gene encoding the LH receptor
Early onset of sexual precocity in boys, with bilateral testicular enlargement
Prepubertal immunologic and biologic LH response to GnRH; prepubertal LH pulse secretory pattern
Concentration of plasma testosterone in pubertal range
Premature Leydig cell and seminiferous tubule maturation
No CNS, adrenal, or testicular abnormalities demonstrable by radiologic or hormonal studies
Lack of suppression of plasma testosterone or physical signs of puberty by GnRH agonist

CNS, central nervous system; LH, luteinizing hormone; GnRH, gonadotropin-releasing hormone.

Figure 25-61 Left, A boy aged 5.5 years and his 28-year-old father with familial testotoxicosis. The boy exhibited signs of sexual precocity by 3 years of age. His height was 130.6 cm (+4.8 SD), and his bone age was 12.5 years. The plasma testosterone level was 267 ng/dL; the dihydrotestosterone level was 46 ng/dL; and the dehydroepiandrosterone sulfate (DHEAS) level was 23 μ g/dL. The plasma luteinizing hormone (LH) and follicle-stimulating hormone (FSH) levels were low, and neither rose after treatment. Pulsatile LH secretion was not demonstrable. Treatment with deslorelin, a gonadotropin-releasing hormone (GnRH) agonist, had no effect. The father had begun sexual maturation by 3 years of age and had reached a final height of 162.6 cm in his early teens. The plasma testosterone level was 294 ng/dL; the LH level was 0.5 ng/mL (LER-960); and the FSH level was 0.5 ng/mL (LER-869). The father had an adult-type LH and FSH response to GnRH; the LH level increased to 7.5 ng/mL, and the FSH level increased to 2 ng/mL. At least 28 male family members over nine generations are affected. To convert dihydrotestosterone values to nanomoles per liter, multiply by 0.03467. For other conversions to SI units, see Figures 25-16 and 25-17. Center, External genitalia of the 5.5-year-old boy. The penis measured 12 \times 2.8 cm; the right testis was 4 \times 2 cm, and the left testis was 3.5 \times 2.5 cm. Right, Testis of the boy showed Leydig cell maturation without Reinke crystalloids and spermatogenesis (Mallory trichrome stain).

precocious puberty in families in which only males were affected. A kindred with nine generations of affected males has been reported⁸⁸⁸; obligatory female carriers of the trait were unaffected, because constitutional activation of the LH receptor on the ovary causes no ill effects.^{888,893}

Heterozygous activating mutations of the heterotrimeric G_s protein-coupled LHCR that in concert transduce the LH/hCG signal to the main effector, adenyl cyclase, are the cause of testotoxicosis (Fig. 25-62).^{893,894} The LH receptor cloned from the human⁸⁹⁵ is a glycoprotein of 80 to 90 kd that belongs to a subfamily of the seven transmembrane-spanning, G protein-coupled receptors. The gene is localized to chromosome 2p21 (the same as for the FSH receptor); it spans at least 70 kilobases and contains 11 exons separated by 10 introns. The large glycosylated N-terminal extracellular hormone binding domain of the 701-amino-acid LHCR⁸⁹⁷ is encoded by exons 1 through 10. A single exon, the large exon 11, encodes the entire G protein-linked transmembrane domain with its seven α -helical segments connected by alternating extracellular and intracellular loops; the intracellular domain; and the three untranslated regions—almost two thirds of the receptor.⁸⁹⁸

Thirteen constitutive activating heterozygous missense mutations, all residing within exon 11, have been reported in more than 60 patients (see Fig. 25-62). Six of these mutations involved the transmembrane helix VI, two the flanking third cytoplasmic loop, one helix V, and one helix II; less commonly, mutations occurred in the first transmembrane helix.^{894,895,899} Nine mutations were located between amino acid residues 542 and 581, suggesting a mutation

hot spot. There appears to be a limited repertoire of mutations in American boys, consistent with a founder effect. European pedigrees are more diverse.⁹⁰⁰ A model of the transmembrane domain of the receptor provides novel suggestions for the structural and functional effects of these activating mutations.⁹⁰¹ Transfected cultured cells with these mutations exhibited increased basal cAMP production in the absence of agonist, observations consistent with a constitutive activating mutation.⁹⁰² Various possibilities for the conformational changes in the LH receptor that lead to its constitutive activation have been considered.⁹⁰³ Inactivating mutations of the LHCR and their clinical consequences are discussed earlier in this chapter.

In one Polish family, the disorder, a Met298Thr mutation in the second transmembrane domain of the LH receptor, led to sexual precocity in one boy but not in the mother, who carried the same mutation, nor in her father (the maternal grandfather) or his son (the maternal uncle), suggesting the involvement of epigenetic factors.⁹⁰⁴ Three boys with sexual precocity due to a sporadic Leydig cell adenoma had an Asp578His mutation in the tumor.^{323,884}

Although affected boys do not respond to chronic administration of an GnRH agonist with suppression of testosterone secretion, testosterone secretion, height velocity and rate of bone maturation, and aggressive and hyperactive behavior have reportedly been decreased by treatment with oral medroxyprogesterone acetate (Table 25-38).^{389,887}

Ketoconazole, an orally active substituted imidazole derivative, suppresses gonadal and adrenal biosynthesis by

Figure 25-62 **A**, The serpentine, seven-transmembrane, G_s protein-coupled human luteinizing hormone/human chorionic gonadotropin (hLH/hCG) receptor with its large extracellular domain and the intracellular domain. The seven helical transmembrane domains are indicated by roman numerals. **B**, Mutations in the LH receptor protein are shown in the schematic structure of the LH receptor protein and localization of the inactivating (open squares) and activating (solid circles) mutations in the human LH receptor. Notice the cluster of mutations in the VI transmembrane helix and third cytoplasmic loop. The Asp578Gly mutation is the most common activating mutation. The short lines across the amino acid chain separate the 11 exons. (**A**, Redrawn from Yano K, Kohn LD, Saji M, et al. A case of male limited precocious puberty caused by a point mutation in the second transmembrane domain of the luteinizing hormone choriogonadotropin receptor gene. *Biochem Biophys Res Commun.* 1996;220:1036-1042.; **B**, from Themmen APN, Huhtaniemi IT. Mutations of gonadotropins and gonadotropin receptors. *Endocr Rev.* 2000;21:551-583.)

inhibiting the enzyme CYP17, which regulates both 17-hydroxylation and the scission (17,20-lyase) of 17 α -hydroxypregnenolone (Δ^5 -17P) to DHEA (see "Nature and Regulation of Adrenal Androgens"). In the dosage used for treatment of testotoxicosis (200 mg every 8 to 12 hours, given orally),⁹⁰⁵ the agent produces a mild transient decrease in cortisol secretion and interferes with binding of testosterone to TeBG. Secondary CPP often occurs when the bone age advances to or has already reached the pubertal range (usually >11.5 years), at which time the addition of an GnRH agonist is appropriate.⁹⁰⁵ Ketoconazole can cause hepatic injury, which is usually mild and reversible, but in rare cases hepatotoxicity is severe. Reversible renal injury, rash, and interstitial pneumonia were reported in a patient who tolerated lower doses, suggesting a dose-response effect.⁹⁰⁶ Nonetheless, five patients treated with ketoconazole experienced no side effects other than one mild and transient elevation of liver enzymes; they had appropriate age of onset of true puberty and reached an adult height almost identical to the target height (a mean increase of 8 cm over the initially predicted height), suggesting great benefit of this therapy in this condition.⁹⁰⁷

TABLE 25-38

Pharmacologic Therapy for Sexual Precocity

Disorder	Treatment	Action and Rationale
GnRH Dependent		
True or central precocious puberty	GnRH agonists	Desensitization of gonadotropes; blocks action of endogenous GnRH
GnRH Independent		
Incomplete sexual precocity		
Girls		
Autonomous ovarian cysts	Medroxyprogesterone acetate	Inhibition of ovarian steroidogenesis; regression of cyst (inhibition of FSH release)
McCune-Albright syndrome	Medroxyprogesterone acetate*	Inhibition of ovarian steroidogenesis; regression of cyst (inhibition of FSH release)
	Third-generation aromatase inhibitor (e.g., letrozole)	Inhibition of P450 aromatase; blocks estrogen synthesis
Boys		
Familial testotoxicosis	Ketoconazole*	Inhibition of CYP17 (mainly 17,20-lyase activity)
	Flutamide or bicalutamide and letrozole or anastrozole	Anti-androgen Inhibition of aromatase; blocks estrogen synthesis
	Medroxyprogesterone acetate*	Inhibition of testicular steroidogenesis

*If true precocious puberty develops, an LHRH agonist can be added. CYP17, cytochrome P450 17 α -hydroxylase/17,20-lyase; LHRH, luteinizing hormone-releasing hormone; FSH, follicle-stimulating hormone; GnRH, luteinizing hormone-releasing hormone.

Modified from Grumbach MM, Kaplan SL. Recent advances in the diagnosis and management of sexual precocity. *Acta Paediatr Jpn.* 1988;30(suppl): 155-175.

The antiandrogen (and antimineralocorticoid) spironolactone, in combination with testolactone, an inhibitor of aromatase (CYP19), the key enzyme in the conversion of androgens to estrogens, is also used to treat testotoxicosis.⁹⁰⁸ The addition of a GnRH agonist is a useful step to suppress pituitary gonadotropin secretion and secondary CPP that may later develop.⁹⁰² More potent nonsteroidal antiandrogens (e.g., flutamide, nilutamide) and aromatase inhibitors (e.g., letrozole) inhibit the rate of skeletal maturation and linear growth by suppressing estradiol synthesis, potentially with greater therapeutic efficacy.^{150,151} The combination of bicalutamide and anastrozole is proposed as another approach.⁸⁵⁹ Table 25-38 lists the various agents used in the treatment of testotoxicosis; which of these agents or combination of agents will be effective and safe for long-term treatment remains to be determined.

A study of an untreated boy with testotoxicosis (GnRH-independent sexual precocity) had the expected pattern of rapid growth and early cessation, and the adult height of 174 cm was within target height range (171.5 to 188.5 cm), indicating the critical importance of individual approaches to affected boys when considering treatment to maximize height.⁹⁰⁸

Follow-up of boys with testotoxicosis indicates an increased risk of seminoma in adult life and Leydig cell adenoma in later childhood.^{909,910} One boy with testotoxicosis developed nodular Leydig cell hyperplasia at 10 years of age.⁹¹¹ These cases support a relationship between an activating mutation of the gene encoding the LH receptor and of Leydig cell tumors.

Gonadotropin-Independent Sexual Precocity and Pseudohypoparathyroidism Type Ia. A mutation in $G_{\alpha s}$ can constitutively activate or inactivate adenylyl cyclase.⁹¹² Two boys who presented in infancy with classic pseudohypoparathyroidism type Ia (PHPIa), a disorder characterized by resistance to hormones whose action is mediated by cAMP, developed signs of sexual precocity with the hormonal characteristics of testotoxicosis (i.e., gonadotropin-independent sexual precocity) at about 24 months of age.⁹¹³ Whereas the alanine residue is usually absolutely conserved in all heterotrimeric G proteins, both of these patients had a unique Ala366Ser mutation⁹¹³ in one allele of the $G_{\alpha s}$ gene. PHPIa is caused by a wide variety of inactivating mutations in $G_{\alpha s}$ that lead to an approximately 50% reduction in $G_{\alpha s}$ activity in functional assays.

The paradox of a $G_{\alpha s}$ mutation causing both inactivation with PHP and constitutive activation with testotoxicosis was resolved by the in vitro demonstration⁹¹⁴ that, unlike other activating mutations of $G_{\alpha s}$ which involve mutations inhibiting its intrinsic GTPase activity and decreasing the rate of hydrolysis of GTP to GDP, the mutation in these two boys caused accelerated dissociation of GDP at 33° C in transfected Leydig cells but was rapidly degraded at 37° C in a lymphoma cell line⁹¹⁴ and at 33° C and 37° C in skin fibroblasts transfected with the mutation.⁹¹³ These observations explain the clinical consequences of increased $G_{\alpha s}$ activity in the testis, which are 3° to 5° C cooler than the body, and the tissue specificity and temperature dependency of the mutation.⁹¹⁴ The mother of one patient appeared to be a mosaic for the $G_{\alpha s}$ mutation; in the other boy, a germline mutation was likely.⁹¹³

Girls. GnRH-independent sexual precocity (GISP) in girls (see Table 25-25) is caused by autonomous estrogen secretion by an ovarian cyst or tumor or an adrenal neoplasm or by inadvertent exposure to estrogen. Girls harboring a teratoma or teratocarcinoma (or a CNS germ cell tumor) that secretes hCG have experienced sexual precocity caused

by concurrent estrogen secretion by the tumor but no effect from the hCG alone; these girls also may have galactorrhea, especially if chorionic somatomammotropin (hCS or hPL) is also secreted.

Autonomous Ovarian Follicular Cysts. The most common childhood estrogen-secreting ovarian mass and ovarian cause of sexual precocity is the follicular cyst.⁹¹⁵ Antral follicles up to about 8 mm in diameter are common in the ovaries of normal prepubertal girls⁹¹⁶ and may be seen in third-trimester fetuses and newborn infants.^{917,918} They may appear and regress spontaneously. Larger follicular cysts may be discovered because of the presence of an abdominal mass or abdominal pain, especially after torsion or as an unexpected finding on pelvic sonography performed for other reasons. Occasionally, the antral follicles secrete estrogen and may form large masses, or the follicular cysts may recur and cause recurrent signs of sexual precocity and acyclic vaginal bleeding. Enlarged antral follicles or cysts occur in premature thelarche, CPP, and transient or incomplete sexual precocity.⁷⁴² In some patients with ovarian follicular cysts, the transient or recurrent sexual precocity is GnRH independent (Fig. 25-63). The concentration of estradiol fluctuates, usually correlating with changes in the size of the follicular cyst or cysts when monitored by pelvic sonography, and may increase to levels found in granulosa cell tumors, although values may also be in the pubertal range.

These patients do not have increased plasma granulosa cell tumor markers such as AMH or inhibin.^{742,769} The concentration of LH is suppressed, a pubertal pattern of pulsatile LH secretion is absent, and the LH rise induced by GnRH is prepubertal.⁷⁴² A constitutive activating mutation of the FSH receptor has not been described in a female, but a heterozygous mutation, Asp567Gly, was detected in the third intracellular loop of the FSH receptor in a hypophysectomized man who, despite the gonadotropin deficiency, was fertile and had normal-sized testes.⁹¹⁹ Accordingly, the possibility that some girls with recurrent ovarian cysts harbor an activating mutation of the FSH receptor seems worthy of study. The McCune-Albright syndrome may lead to recurrent ovarian cysts even in the apparent initial absence of other features of this disorder due to somatic activating mutations in the gene encoding the α -subunit of the heterotrimeric G_s protein. The luteinization of follicular cysts may be related to subtle elevations and increased pulses of plasma FSH. Ovarian cysts and sexual precocity have been associated with the fragile X syndrome in girls.⁹²⁰

Estradiol-secreting ovarian cysts occur in preterm infants born before 30 weeks' gestation; they are associated with edema of the labia majora and, in some instances, of the lower abdominal wall.⁹²¹ The LH and FSH response to GnRH in these patients suggests GnRH dependence, and treatment with medroxyprogesterone acetate is associated with regression of the cysts. A case of massive ovarian edema associated with ovarian cysts found in a 6-month-old with breast and pubic hair development has been reported.⁹²²

GnRH agonists are useful in the treatment of ovarian follicular cysts associated with CPP (GISP) but not of so-called autonomous cysts. However, autonomously functioning ovarian follicular cysts, whether recurrent or manifesting in an isolated episode, often respond to treatment with oral medroxyprogesterone acetate, which seems to prevent recurrence, to accelerate involution of the follicular cysts,^{742,923} and to reduce the risk of torsion. The use of a potent aromatase inhibitor such as letrozole to reduce estradiol secretion is another potential approach to

treatment.⁹²⁴ Surgical intervention is rarely indicated; a large or persistent cyst can be reduced by puncture at laparoscopy and the size of the cyst can be monitored readily by pelvic sonography.

Ovarian Tumors. Ovarian tumors are the most common genitourinary tumors of girls,⁹²⁵ accounting for about 1% of all tumors in girls younger than 17 years of age, but they are rare in the prepubertal period. Most are benign according to some,⁹²⁶ but not all, studies.⁹²⁷ Discrepancy among studies may be due to the method of classification of cysts and potentially malignant lesions. Most ovarian tumors arise from germ cells or sex cord–stromal cells in childhood with fewer than 20% being of epithelial origin, whereas in adults, most are of epithelial origin.⁹²⁸ Early diagnosis of most childhood tumors of the ovary allows successful cure, unlike ovarian cancer in adult women. Most of these girls present with pain or an abdominal mass. Tumors smaller than 5 cm at diagnosis are more likely to be non-neoplastic, and those larger than 10 cm are more likely to be neoplastic.⁹¹⁵ Ultrasonography is helpful in evaluation but does not usually lead to the correct histologic diagnosis. The successful use of tumor markers for diagnosis varies by cause. For example, in one series, cystic teratomas resulted in lactate dehydrogenase (LDH) elevation and an increased erythrocyte sedimentation rate; immature teratomas produced elevated levels of LDH, α -fetoprotein, and cancer antigen 125 (CA125); and granulosa cell tumors had elevated sex steroids (estradiol or testosterone or both).⁹²⁷

Granulosa cell tumor of the ovary is rare in childhood, although theca cell tumors are even less common.⁹²⁹ Characteristic histologic features of juvenile granulosa cell tumors include nodular architecture, follicle formation, abundant interstitial and intrafollicular acid mucopolysaccharide-rich fluid, irregular microcysts, individual cell necrosis, and high mitotic activity (mean activity, 11 mitotic figures per 10 high-power fields). Size can vary from 2.5 to 25 cm, with a mean diameter of 12 cm.

The interstitial mucinous fluid consists predominantly of hyaluronic acid. Prognosis is good, the mortality rate being about 3%. However, the age at diagnosis is related to prognosis, and delay leads to substantial complications. In one series, girls who presented with ISP and were correctly diagnosed had no intra-abdominal spread and had Federation of Gynecology and Obstetrics (FIGO) stage IA disease, whereas those who presented with acute abdominal symptoms had 50% prevalence of intra-abdominal spread and two recurrences after surgery. When the diagnosis was made after normal puberty had begun, some girls experienced virilization or abdominal symptoms; 80% had intra-abdominal spread, and 30% had recurrence with FIGO stage IIC.

Approximately 80% of granulosa cell tumors can be palpated on bimanual examination, whereas fewer than 5% are bilateral or clinically malignant. The concentration of plasma estradiol may increase to high levels, but serum FSH and LH concentrations are usually suppressed. AMH and inhibin are sensitive tumor markers⁹³⁰⁻⁹³² and are used to screen for metastases; an elevated estradiol concentration in a patient younger than 9 years of age or an abnormal rise in concentration of plasma AMH or inhibin at any age suggests recurrence or metastasis.

Occasionally, gonadoblastomas in streak gonads, rare lipoid tumors, cystadenomas, and ovarian carcinomas secrete estrogens, androgens, or both. Even with successful resection of a gonadal sex steroid-secreting neoplasm, the child is at risk for secondary CPP in the future. Gonadal tumors composed of a mixture of germ cells and sex cord–stromal cells that are distinct from gonadoblastoma are usually benign when discovered in female infants or children with 46,XX karyotypes,⁹³³ although neoplastic transformation is a risk,⁹³⁴ because two cases of metastasizing malignant mixed germ cell/sex cord–stromal cell tumors have been described in prepubertal girls with ISP. α -Fetoprotein and other tumor markers aid in diagnosis.

Peutz-Jeghers Syndrome. Peutz-Jeghers syndrome is an autosomal dominant syndrome characterized by mucocutaneous pigmentation of the lips, buccal mucosa, fingers, and toes; gastrointestinal hamartomatous polyposis; and a predisposition to malignancy. It is associated with a rare, distinctive sex cord tumor with annular tubules in both boys and girls.^{935,936} Estrogen secretion by the tumor may lead to feminization and incomplete sexual precocity in boys and girls. Less frequently, an epithelial tumor of the ovary, a dysgerminoma, or a feminizing Sertoli-Leydig cell tumor has been found in patients with Peutz-Jeghers syndrome.⁹³⁷ Children with this disorder should be examined at regular intervals for the presence of gonadal tumors by pelvic sonography. The syndrome is caused by mutations in the gene located on 9p13.3 that encodes a serine/threonine protein kinase, STK11, leading to haploinsufficiency of this novel tumor-suppressing gene.⁹³⁸

Sex cord-stromal cell tumors derive from the celomic epithelium or mesenchymal cells of the embryonic gonads and are composed of granulosa, theca, Leydig, and Sertoli cells. Estrogen secretion from these tumors can cause ISP, and androgen secretion can cause virilization. Inhibin A and B activin are produced, as is AMH; all serve as useful tumor markers. Sex cord-stromal cell tumors not associated with Peutz-Jeghers syndrome are malignant in 25% of cases; these tumors can grow quite large, but those associated with Peutz-Jeghers syndrome are often small and multiple, and they contain calcifications.⁹³⁹

Adrenal Adenomas. Adrenocortical tumors are rare in childhood (0.6% of all childhood tumors and 0.3% of all malignant childhood tumors), but most produce steroid hormones, whereas those in adults usually do not. The median age at diagnosis is 4 years, but 41% of these tumors manifest before 2 years and 71% before 5 years of age. Most cause virilization or Cushing's syndrome, but adrenal tumors may produce estrogen as well as androgens and can cause sexual precocity in a girl or gynecomastia in a boy. One adrenal adenoma found in a 7-year-old girl expressed the gene for aromatase, demonstrating that the tumor could directly produce estrogen⁹⁴⁰ to a level of 145 pg/mL, within the range found in adrenal carcinomas.

Boys and Girls

McCune-Albright Syndrome. McCune-Albright syndrome is sporadic and occurs about twice as often in girls than in boys; it is caused by somatic activating mutations in the gene (*GNAS1*) encoding the α -subunit of the trimeric GTP-binding protein ($G_s\alpha$) that stimulates adenyl cyclase.⁹⁴¹ It is characterized by the triad of irregularly edged hyperpigmented macules (café au lait spots of the coast of Maine type); a slowly progressive bone disorder, polyostotic fibrous dysplasia, that can involve any bone and is frequently associated with facial asymmetry and hyperostosis of the base of the skull; and, more commonly in girls, GnRH-independent sexual precocity (Fig. 25-64 and Table 25-39).⁹⁴² At least two of the features must be present to consider the diagnosis.

Autonomous hyperfunction most commonly involves the ovary, but other endocrine involvement includes thyroid (nodular hyperplasia with thyrotoxicosis or, remarkably, with euthyroid status⁹⁴³); adrenal (multiple hyperplastic nodules with Cushing's syndrome that may occur in the neonatal period⁹⁴⁴), pituitary (adenoma or mammosomatotroph hyperplasia with gigantism, acromegaly, and hyperprolactinemia), and parathyroid (adenoma or hyperplasia with hyperparathyroidism).⁹⁴² Hypophosphatemic vitamin D-resistant rickets or osteomalacia occurs, either because of overproduction of a phosphaturic factor, phosphatonin,⁹⁴⁵

Figure 25-64 A girl aged 7 years and 4 months with gonadotropin-releasing hormone (GnRH)-independent sexual precocity associated with McCune-Albright syndrome. She had breast development since infancy, and it increased noticeably at about 3 years of age; 6 months later, episodes of recurrent vaginal bleeding began. Growth of pubic hair was noticed at about 4 to 5 years. At age 5.5 years, the bone age was 6 years and 11 months; height was +1 SD above the mean value for age. By 6.5 years, when she was seen at the University of California, San Francisco, the bone age had advanced to 9 years, and height was at +1 SD. Breasts were at Tanner stage 4, and pubic hair at stage 3. Extensive, irregular café au lait macules cover the right side of the face, left lower abdomen and thigh, and both buttocks. A bone survey showed widespread involvement of the long bones with typical polyostotic fibrous dysplasia, the floor of the anterior fossa of the skull was sclerotic, and the diploetic space had widened. She has had two pathologic fractures through bone cysts in the right upper femur. Notice the osseous deformities. Plasma estradiol concentrations were consistently in the pubertal range; the LH response to GnRH was prepubertal. Results of thyroid function studies were normal, including the thyrotropin response to thyrotropin-releasing hormone administration, and antithyroid antibodies were not detected. Treatment with oral medroxyprogesterone acetate suppressed menses and arrested pubertal development but did not slow skeletal maturation. Her final height is 142 cm (−2.5 SD). Menstrual cycles are regular.

that is secreted by the bone lesions or because of an intrinsic renal abnormality leading to the excess generation of nephrogenous cAMP in the proximal tubule and, as a result, decreased reabsorption of phosphate.⁹⁴⁶ Hepatocellular dysfunction may occur due to expression of the mutant activating gene in liver cells, which leads to jaundice associated with hepatobiliary disease, and pancreatitis.⁹⁴⁷ Another nonendocrine manifestation is cardiac disease, and patients carry the risk of cardiac arrhythmia and sudden death. This

TABLE 25-39

Clinical Manifestations of McCune-Albright Syndrome in 158 Reported Patients*

Manifestation	% of Patients			Mean Age at Diagnosis (yr) and Range	Comments
	Total (N = 158)	Male (n = 53)	Female (n = 105)		
Fibrous dysplasia	97	51	103	7.7 (0-52)	Polystotic more common than monostotic
Café au lait lesion	85	49	86	7.7 (0-52)	Variable size and number of lesions, irregular border ("coast of Maine")
Sexual precocity	52	8	74	4.9 (0.3-9)	Common initial manifestation
Acromegaly/gigantism	27	20	22	14.8 (0.2-42)	17/26 of patients with adenoma on MRI/CT
Hyperprolactinemia	15	9	14	16.0 (0.2-42)	23/42 of acromegalic patients with PRL
Hyperthyroidism	19	7	23	14.4 (0.5-37)	Euthyroid goiter is common
Hypercortisolism	5	4	5	4.4 (0.2-17)	All primary adrenal
Myxomas	5	3	5	34 (17-50)	Extremity myxomas
Osteosarcoma	2	1	2	36 (34-37)	At site of fibrous dysplasia, not related to prior radiation therapy
Rickets/osteomalacia	3	1	3	27.3 (8-52)	Responsive to phosphorus plus calcitriol
Cardiac abnormalities	11	8	9	(0.1-66)	Arrhythmias and CHF reported
Hepatic abnormalities	10	6	10	1.9 (0.3-4)	Neonatal icterus is most common

*Evaluations include clinical and biochemical data; other rarely described manifestations include metabolic acidosis, nephrocalcinosis, developmental delay, thymic and splenic hyperplasia, and colonic polyps.

CHF, congestive heart failure; CT, computed tomography; MRI, magnetic resonance imaging; PRL, prolactin.

Modified from Ringel MD, Schwindinger WF, Levine MA. Clinical implication of genetic defects in G proteins: the molecular basis of McCune-Albright syndrome and Albright hereditary osteodystrophy. *Medicine (Baltimore)*. 1996;75:171-184.

is a sporadic condition that can be concordant or discordant in monozygotic twins.⁹⁴⁸

Considering children with at least one of the signs of McCune-Albright syndrome, 24% had the classic triad, 33% had two signs, and 40% had only one classic sign. The mutation was detected in 46% of blood samples from patients presenting the classic triad, but in only 21% and 8% of samples from patients with two signs or one sign, respectively. If an affected tissue was available, the mutation was found in more than 90% of the patients no matter what the number of signs. The mutation was found in 33% of the 39 cases of isolated peripheral precocious puberty. Patients with monostotic fibrous dysplasia, isolated peripheral precocious puberty, neonatal liver cholestasis, or the classic McCune-Albright syndrome all had the same molecular defect.⁹⁴⁹ Whereas most endocrine organs involved in McCune-Albright syndrome were not associated with parent specificity,⁹⁵⁰ pituitary adenomas secreting GH expressed NESP55 transcripts, which are mono-allelically expressed from the maternal alleles rather than from the exon 1A paternal allele. Mutation of *GNAS1* involving Arg201His replacement is associated with apparent premature or exaggerated thelarche and early menarche.⁹⁵¹

Most patients have pigmented skin lesions in infancy which usually increase in size along with body growth.⁹⁵² The irregularly bordered, café au lait macules usually do not cross the midline, but they may; they often are located on the same side as the main bone lesions and have a segmented distribution.

The skeletal lesions in the cortex are dysplastic and are filled with spindle cells with poorly organized collagen support; they take the form of scattered cystic areas of rarefaction on radiography and often result in pathologic fractures and progressive deformities (Fig. 25-65). Technetium bone scintigraphy has been the most sensitive approach to the detection of bone lesions before they are visible radiographically. Fractures are most common between the sixth and the tenth year but decline thereafter, and they are more frequent if phosphaturia is present.⁹⁵³ Patients referred for fibrous dysplasia of the bone in one or more locations are often found to have endocrine or

dermatologic manifestations of McCune-Albright syndrome as well as *GNAS1* mutations, so suspicion should be kept high when evaluating fibrous lesions.⁹⁵⁴ If the skull is involved, there may be entrapment and compression of optic or auditory nerve foramina, which can lead to blindness, deafness, facial asymmetry, and ptosis. Asymmetry of the jaw is another manifestation of McCune-Albright syndrome. Fifty percent of affected children in one series manifested bone abnormalities by 8 years of age.⁹⁵² Increased serum GH levels have an adverse effect on the skull deformities, depending on the age at onset; somatostatin analogues have variable efficacy. Irradiation of the hypothalamic-pituitary area may be invoked, but it carries a risk of later occurrence of sarcoma. Rapid control of elevated GH can be achieved by the use of long-acting somatostatin agonists such as pasiprisant.⁹⁵⁵

The sexual precocity often begins during the first 2 years of life and is frequently heralded by menstrual bleeding; the cause is autonomously functioning luteinized follicular cysts of the ovary in girls (Table 25-40).^{742,942} The ovaries contain no corpora lutea and commonly exhibit asymmetric enlargement as a result of a large solitary follicular cyst that characteristically enlarges and then spontaneously regresses, only to recur (Fig. 25-66).^{740,890,942} Serum estradiol is elevated (at times to extraordinarily levels); in contrast, the LH response to GnRH is prepubertal, and the pubertal pattern of nighttime LH pulses is absent at the onset and during the initial years.^{742,956,957} Later in the course of the sexual precocity, when the bone age approaches 12 years, the GnRH pulse generator becomes operative and ovulatory cycles ensue.

An affected girl may progress from GnRH-independent puberty to GnRH-dependent puberty (see Table 25-40).^{742,956,958} GnRH agonists are not effective for treatment in the GnRH-independent stage. Testolactone, a relatively weak aromatase inhibitor, Fadrazole, and anastrozole have been equivocal or not effective. The new, highly potent, specific, third-generation aromatase inhibitors (e.g., letrozole) may be more effective.^{150,151,959} After a single case report of treatment with tamoxifen, an anti-estrogen, showed decreases in bone age advancement, growth rate,

Figure 25-65 Bone lesions in McCune-Albright syndrome. **A**, The skull has severe thickening primarily at the base due to fibrous dysplasia. The auditory and optic nerves can be caught in narrowed foramina, but that is not the case in these patients. **B** and **C**, Distortions of the long bones can develop into a “shepherd’s crook” appearance. Notice the multiple bone cysts.

D

Figure 25-65, cont'd D, Bone scan shows the areas of remodeling that “light up,” depending on the area affected in individual patients. There are examples of patients primarily affected in the craniofacial area or in the appendicular area, or both areas, and the axial skeleton. (Courtesy of Michael T. Collins, M.D., National Institutes of Health, Bethesda, MD, and Sandra Gorges, M.D., University of California, Davis.)

menses, and pubertal development, a multicenter trial demonstrated the utility of this agent in decreasing vaginal bleeding and decreasing the rate of bone age advancement and growth rate in affected girls.⁹⁶⁰ However, ovarian and uterine volumes remained elevated.

Sexual precocity is rare in boys with McCune-Albright syndrome.^{942,961} Affected boys may have asymmetric enlargement of the testes in addition to signs of sexual precocity. The histologic changes and hormonal findings are reminiscent of those observed in testotoxicosis: the seminiferous tubules are enlarged and exhibit spermatogenesis, and Leydig cells may be hyperplastic.⁹⁴² A 3.8-year-old boy with McCune-Albright syndrome (several café au lait lesions on the back and polyostotic fibrous dysplasia) had an Arg201His mutation detected in bone and testis tissue and the unusual feature of macroorchidism (right testis, 9 mL; left testis, 7 mL), but sexual precocity was absent. Basal and GnRH-stimulated gonadotropins and sex steroid levels were prepubertal, but serum inhibin B and AMH concentrations were strikingly elevated. On

histologic examination of the testes, most of the seminiferous tubules were slightly increased in diameter and filled with Sertoli cells but lacked a lumen. The tubules stained intensively for inhibin β_B subunit; mature Leydig cells were absent.⁹⁶² An increased incidence of the rare condition, testicular microlithiasis, was described in boys with McCune-Albright syndrome evaluated by ultrasonography.⁹⁶³

McCune-Albright syndrome may occur concordantly or discordantly in monozygotic twins; familial cases have not been described. In 1986, Happle⁹⁶⁴ posited that the disorder is caused by an autosomal “dominant” lethal gene that results in loss of the zygote in utero and that cells bearing this mutation survive only in embryos mosaic for the lethal gene. Early somatic mutation would lead to a mosaic cell pattern of the distribution of cells containing the mutation. The severity of the disorder would depend on the proportion of mutant cells in various embryonic tissues. The description of somatic mutations in human endocrine tumors that convert the peptide chain of the G_s protein

TABLE 25-40

A Patient with McCune-Albright Syndrome and Recurrent Ovarian Cysts

Chronologic Age (yr)	Bone Age (yr)	Height (cm)	Physical Signs	Basal and Post-LHRH (ng/mL)*†	Plasma Estradiol (pmol/L [pg/mL])	Radiography (Long Bones)
1½	1½	81.1	Café au lait pigmentation, B2, PH1 Vaginal bleeding (×2 mo)	LH 0.6-1.3 FSH 1.9-3.2 DHEAS <50 ng/mL (<0.14 mmol/L)	40 (11)	Normal
1½ 2½	2½	92.4	B1, PH1 B2, PH2 Vaginal bleeding	LH 0.6-1.1 FSH 1.9-3.2 DHEAS <50 ng/mL (<0.14 mmol/L)	55-66 (15-18)	Normal

*Matched standard reagents were LER-960 for LH and LER-869 for FSH. To convert ng/mL to IU/L, multiply LH value by 3.8 and FSH value by 8.4.

†Note the prepubertal LH response to GnRH consistent with GnRH-independent sexual precocity until age 5½ yr and the pubertal LH response at 5½ yr; consistent with the development of secondary true precocious puberty (GnRH-dependent). Note discrepancy between gonadarche and adrenarche as evidenced by preadrenarchal concentration of DHEAS.

B, breast stage; DHEAS, dehydroepiandrosterone sulfate; FSH, follicle-stimulating hormone; GnRH, gonadotropin-releasing hormone; LER, matched standard reagent; LH, luteinizing hormone; LHRH, luteinizing hormone-releasing hormone; PH, pubic hair stage.

Figure 25-66 Serial pelvic ultrasonograms at 2-week intervals of a 6-year-old girl with McCune-Albright syndrome. Breast development and vaginal bleeding coincided with the enlargement of the ovarian cyst; white arrows denote the decreasing size of the cyst. With the spontaneous regression of the large ovarian cyst, the breasts regressed in size, and vaginal bleeding ceased. (From Kaplan SL, Grumbach MM. Pathogenesis of sexual precocity. In: Grumbach MM, Sizonenko PC, Aubert ML, eds. *Control of the Onset of Puberty*. Baltimore, MD: Williams & Wilkins, 1990:620-660.)

into a putative oncogene (referred to as a *gsp* mutation)⁹⁶⁵ raised the possibility of a similar defect in McCune-Albright syndrome that both affects a differentiated function such as a signaling pathway and mediates the regulation of proliferation. These hypotheses are now established, because mutations in the gene encoding the α -subunit of the stimulatory G protein for adenylyl cyclase was identified in the tissues of children with the McCune-Albright syndrome.

The heterotrimeric guanine nucleotide-binding proteins (G proteins) are a subfamily within the large superfamily of GTP-binding proteins and serve to transduce signals from a large number of cell surface receptors with a common structural motif of seven-membrane-spanning domains to their intracellular effector molecules, including enzymes and ion channels; in essence, they couple serpentine cell surface receptors to effectors (Fig. 25-67). For G_s ,

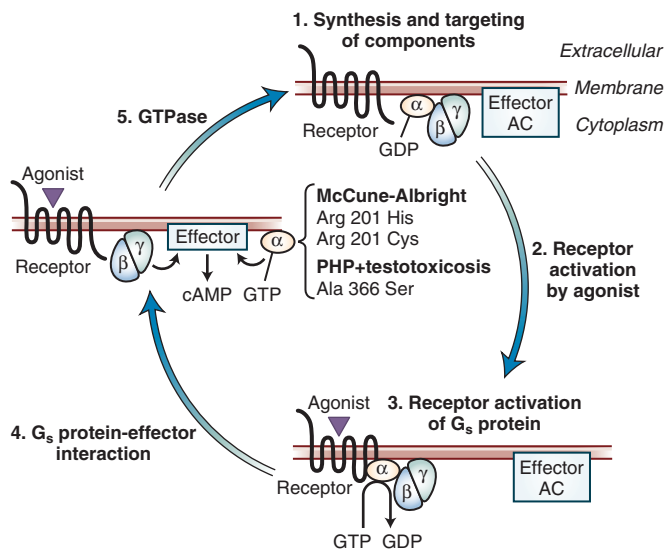

Figure 25-67 The G protein guanosine triphosphatase (GTPase) cycle. The heterotrimeric guanine nucleotide-binding proteins (G proteins), which are composed of three subunits (α , β , γ), couple cell surface receptors consisting of a single serpentine polypeptide having seven helical membrane-spanning domains with an effector. In this instance, adenylyl cyclase (AC) catalyzes the transformation of adenosine triphosphate (ATP) to cyclic adenosine monophosphate (cAMP). The G protein stimulation subunit α (G_s) mediates the stimulation of cAMP generation. In the inactive, unstimulated state, the G protein is a heterotrimer, and GDP is tightly bound to the α -subunit. When the cell surface receptor is activated by its cognate agonist, the receptor catalyzes the release of the tightly bound GDP, which enables GTP to bind to the α -subunit. The GTP-bound α -subunit (α -GTP) dissociates from the tightly bound $\beta\gamma$ dimer, and both play a role in the G protein activation of the effector, adenylyl cyclase. The intrinsic GTPase activity of the α -subunit ends the stimulation of the effector by converting the bound α -GTP to α -GDP; as a consequence, the α -subunit again returns to its inactive state and reassociates with high affinity with the $\beta\gamma$ subunit, yielding the α , β , γ heterotrimer. Disorders of signal transduction can arise from germ cell or somatic mutations at any of the five stages of the cycle. The gain-of-function, activating somatic mutations in the *GNAS1* gene that encodes the G_s α -subunit and leads to McCune-Albright syndrome (shown in the bracket), involves the highly conserved arginine 201 residue. These mutations inhibit the intrinsic GTPase activity of the α -subunit and therefore the conversion of the bound GTP to GDP. The Ala366Ser mutation (shown in the bracket) was detected in two boys, both of whom had pseudohypothyroidism Ia (PHPIa) and testotoxicosis. The mutant protein was constitutively activated in the Leydig cells at the scrotal temperature (32° to 33° C), leading to testotoxicosis, but it was rapidly degraded at body temperature, 37° C, which led to PHPIa. (Modified from Spiegel AM. Mutations in G proteins and G protein-coupled receptors in endocrine disease. *J Clin Endocrinol Metab.* 1996;81:2434-2442.)

the stimulatory G-protein, the effector is adenylyl cyclase, which is controlled by G_s and an inhibitory G protein, G_i .⁹⁶⁶ The heterotrimer is composed of an α -subunit (39 to 45 kD) that binds GTP, has intrinsic GTPase activity, and converts GTP to GDP; a β -subunit (35 to 36 kD); and a smaller γ -subunit (7 to 8 kD). The latter two subunits are tightly but noncovalently associated with each other. Each of the subunits is encoded by a distinct gene. The G proteins function as conformational switches. The GDP-liganded α -subunit is bound to the $\beta\gamma$ -subunits and is in an inactivated state. When the cell surface receptor is activated by its ligand or agonists, the GDP is catalytically released from the α -subunit, enabling GTP to bind. This leads to dissociation of the GTP-activated α -subunit from the bound $\beta\gamma$ -subunits and activation of the effector, adenylyl cyclase. When GTP is hydrolyzed by the intrinsic GTPase activity of G_s , the α - and $\beta\gamma$ -subunits reassociate, and the α -subunit is in the "off" or inactive conformation. The three-dimensional structure of the heterotrimeric G proteins has been determined.⁹⁶⁷⁻⁹⁶⁹

Activating heterozygous mutations in the G_s α -subunit that occurred as an early postzygotic event are described in the McCune-Albright syndrome. The somatic constitutive activating mutation, which leads to excess cAMP production and, in some tissues, cAMP-induced hyperplasia, has a mosaic pattern; the proportion of the hyperactive mutant compared with normal cells varies in different tissues, contributing, at least in part, to the varied clinical findings, the severity, the sporadic nature of the syndrome, and the discordant occurrence in monozygotic twins. A germline mutation is presumed to be lethal to the embryo. Two gain-of-function somatic missense mutations have been described in this disorder, both of which involve the arginine201 residue of the α -subunit.⁹¹² This is the site of covalent modification by cholera toxin: either a cysteine or a histidine is substituted for arginine 201 (see Fig. 25-67).^{961,966,970,971} The arginine 201 residue is critical for α -subunit GTPase activity, and each of these two mutations decreases the GTPase activity of the G_s α -subunit, leading to constitutive activation. These activating mutations have been found in all tissues affected by the syndrome,^{972,973} including bone lesions. There are reports of fertility in adults with McCune-Albright syndrome.

Juvenile Hypothyroidism. Long-standing untreated primary hypothyroidism, usually a consequence of Hashimoto's thyroiditis, is an uncommon cause of incomplete ISP.^{285,974,975} in both girls and boys and occurs in association with impaired growth and delayed skeletal maturation. If the concentration of plasma prolactin is elevated, galactorrhea may be demonstrable, more commonly in affected girls than boys (Figs. 25-68 and 25-69). Girls have breast development, enlarged labia minora, and estrogenic changes in the vaginal smear, usually without the appearance of pubic hair.^{285,976}; some girls have irregular vaginal bleeding²⁸⁵ which could proceed to metrorrhagia, and solitary or multiple ovarian cysts may be demonstrable by pelvic sonography or on physical examination.²⁸⁵ It is important to recognize the condition to avoid unnecessary surgery, which would be a tragic mistake in view of the success of medical management.⁹⁷⁷ In about 80% of boys with juvenile hypothyroidism, the testes are enlarged because of an increase in the size of the seminiferous tubules, but signs of virilization and Leydig cell maturation are absent,⁹⁷⁸ and the plasma concentration of testosterone is prepubertal. Enlargement of the sella turcica and the pituitary gland in the face of hypersecretion of TSH (see Fig. 25-69) has led to the misdiagnosis of a pituitary neoplasm. The hypothyroidism, incomplete sexual maturation, galactorrhea, and pituitary

Figure 25-68 Left and center, Severe, chronic hypothyroidism of Hashimoto's thyroiditis in a girl aged 7 years and 1 month with sexual precocity (without pubic or axillary hair), episodic vaginal bleeding, and galactorrhea. She had symptoms of hypothyroidism and a sharply decreased rate of growth over the previous 2 years (height, -1 SD; bone age, 5 years and 3 months). Breast development was Tanner stage 3, the labia minora were enlarged, and the vaginal mucosa was dull pink, thickened, and rugated, with evidence of an estrogenic effect. No acne, seborrhea, or hirsutism was present. The uterus was of adolescent size, and the endometrial mucosa was in a proliferative phase. Urinary gonadotropins were barely detectable by bioassay. Right, Striking change in appearance after 8 months of thyroid hormone treatment. She had grown 7 cm in height and lost 8.1 kg in weight. The breasts had decreased in size, galactorrhea was no longer demonstrable, the labia minora had regressed, and the vaginal mucosa was pink and glistening (no estrogen effect). Ten weeks after the initiation of thyroid hormone replacement therapy, she developed a right slipped capital femoral epiphysis that was repaired surgically; recovery was uneventful.

Figure 25-69 Left, Radiograph of the skull of a patient with hypothyroidism shows an enlarged pituitary fossa in the lateral view. The dorsum sellae was thin and demineralized, and the floor had a double contour line. The area of the sella turcica was 150 mm². Pneumoencephalography showed a suprasellar mass impinging on the cisterna chiasmatica. After thyroid hormone treatment for 8 months, the volume of the sella had decreased 30% to 100 mm², the dorsum sellae had remineralized, and the double floor was no longer evident. Right, Growth curve illustrates the decrease in growth rate despite sexual precocity and the catch-up growth induced by thyroid hormone therapy. (From Van Wyk JJ, Grumbach MM. Syndrome of precocious menstruation and galactorrhea in juvenile hypothyroidism: an example of hormonal overlap in pituitary feedback. *J Pediatr*. 1960;57:416-435.)

enlargement are reversed or corrected by levothyroxine therapy within a few months.²⁸⁵

In 1960, Van Wyk and Grumbach²⁸⁵ suggested that the syndrome resulted from hormonal overlap in negative feedback regulation with increased secretion of gonadotropins, prolactin, and TSH as a consequence of the chronic hypothyroidism. With the advent of radioimmunoassays for pituitary hormones, increased prolactin secretion was documented in children⁹⁷⁵ and adults with primary hypothyroidism and in affected girls with the syndrome. GH release is usually decreased, as in uncomplicated primary hypothyroidism.

However, the explanation for the sexual maturation remains uncertain. Pubertal development in primary hypothyroidism is usually delayed and is only rarely advanced for chronologic age. By the use of radioimmunoassays for FSH and LH in which the cross-reaction with TSH is negligible, an increased (pubertal) concentration of plasma immunoreactive and bioactive FSH, but not LH, has been detected.⁹⁷⁹ Bioactive LH activity is also low. Increased FSH pulsatility, mainly at night, but not LH release was demonstrated in patients with the syndrome and in some children with primary hypothyroidism who did not exhibit premature sexual maturation.^{979,980} The increased FSH release and the high FSH/LH ratio (in contrast to that observed in normal puberty) seem to account for the increased ovarian estrogen secretion in girls and for the enlarged testes without signs of virilization in affected boys; the suggestion here is that FSH-induced Sertoli cell proliferation is an important determinant of mature testis size.⁹⁸¹⁻⁹⁸³

A GnRH-independent mechanism is likely, because GnRH did not suppress the pubertal LH levels.⁹⁷⁹ Pulsatile TSH release is increased at night, and administration of TRH appears to increase FSH release in normal children (but not in adults). Moreover, the FSH response to TRH, but not GnRH, is augmented in primary hypothyroidism, and this response can occur in gonadotropin-secreting pituitary adenomas. If the latter observations are confirmed, it is likely that the incomplete sexual precocity and the increased prolactin secretion and galactorrhea are a consequence of the increased release of TRH, the increased sensitivity of the mammotrophs and gonadotroph to TRH, or both. This mechanism,²⁸⁵ which has gained support,⁹⁷⁹ would explain the relatively rapid and complete reversal of the syndrome by levothyroxine treatment. Human recombinant TSH at a dose about 1000-fold greater than that of human FSH evoked a dose-dependent cAMP response in COS7 cells transfected with the human FSH receptor, which suggests another possible but less likely mechanism for the FSH-dependent (or FSH-like-dependent) but GnRH-independent sexual precocity.⁹⁸⁴ A direct effect of severe hypothyroidism on the prepubertal testis that leads to overproliferation of Sertoli cells also has been advanced as an explication of the macroorchidism.⁹⁷⁸

Diagnosis of Sexual Precocity

The separation of patients with self-limited benign disorders, such as premature adrenarche, premature thelarche, or normal but early puberty, from those with serious or even potentially fatal disorders is the first step in evaluation (Figs. 25-70 through 25-72 and Table 25-41). The history may reveal symptoms suggesting perinatal abnormalities or injuries, previous infections, adventitious ingestion of or exposure to gonadal steroids, or the presence of similar conditions in family members. Previous measurements should be plotted on a growth chart to determine height velocity and the age at onset of any increase in the rate of growth.

Important aspects of the physical examination include description of the secondary sexual development according to Tanner stages; measurement of the penis and the testes in boys and of the breast tissue in girls; and examination for acne, oily skin, facial and body hair, pubic and axillary hair development, apocrine gland odor, muscular development, and galactorrhea. A careful examination of the external genitalia should be done with a nonrelated chaperone present, because the performance of such an examination has been interpreted by patients as sexual abuse in some cases.⁹⁸⁵ A thorough neurologic examination is indicated, with emphasis on assessment of the visual fields and optic discs and a search for signs of increased intracranial pressure; evaluation for skin lesions associated with the McCune-Albright syndrome or neurofibromatosis; and examination for abdominal, gonadal, or adnexal masses and for coexisting endocrine disease. Bone age is determined in all cases, although it is an imperfect measure.

Ultrasonography of the ovary and uterus is exceedingly useful in the evaluation of affected girls, because standards are available for shape and volume of the uterus and the ovaries.⁹⁸⁶ The largest measurements of uterine size by sonography in infants and children are found at puberty and in the neonatal period. The upper limit of uterine length in the prepubertal state is 3.5 cm. A uterine volume of greater than 1.8 mL is specific for the onset of puberty, but increased ovarian volume is less specific. Patients with premature thelarche were indistinguishable from age-matched controls when this sonographic standard was used.¹²⁹ The presence of microcysts and macrocysts of the ovary also can be detected on ultrasound examination. Cysts may be found in the ovaries in patients with CPP or GnRH-independent ISP; they usually are smaller than 9 mm in the former and larger than 9 mm in the latter condition.⁷⁶³ Ovarian volume is reportedly the best indicator of precocious puberty, and uterine length was best for the differentiation of premature thelarche from premature puberty.⁹⁸⁶ The presence of an endometrial stripe was indicative of precocious puberty.¹²⁹ Ultrasonography of the breast is suggested as a method of determining rapidly progressive versus slowly progressive or transient precocious puberty; accuracy is increased when breast ultrasound findings are added to those of uterine ultrasound and the other factors discussed previously.⁹⁸⁷

Measurements of basal plasma gonadotropin concentrations and the LH response to administration of GnRH or GnRH agonist or the amplitude and frequency of LH pulses, especially at night, using third-generation assays, as well as measurements of the plasma concentration of testosterone in boys or of estradiol in girls using LC/MS-MS assays, are of primary importance in diagnosis. Standards for pubertal development must be available in the laboratories chosen. Girls early in the course of CPP have elevation of estradiol associated with increasing LH levels but not necessarily an increase in the concentration of FSH. Determination of T₄ concentration is indicated when hypothyroidism is suspected. CPP in males usually begins with enlargement of the testes, followed by other signs of secondary sexual maturation. A Leydig cell tumor usually causes asymmetric enlargement of the testes, whereas an extragonadal hCG-secreting tumor is associated with less marked testicular enlargement than occurs at the same stage of masculinization in CPP. Adrenal rests in the testes may enlarge under chronic stimulation from ACTH in boys with inadequately treated CAH or noncompliant boys and may be bilateral, although they are unlikely to closely mimic normal pubertal testicular development. An elevated hCG level with a

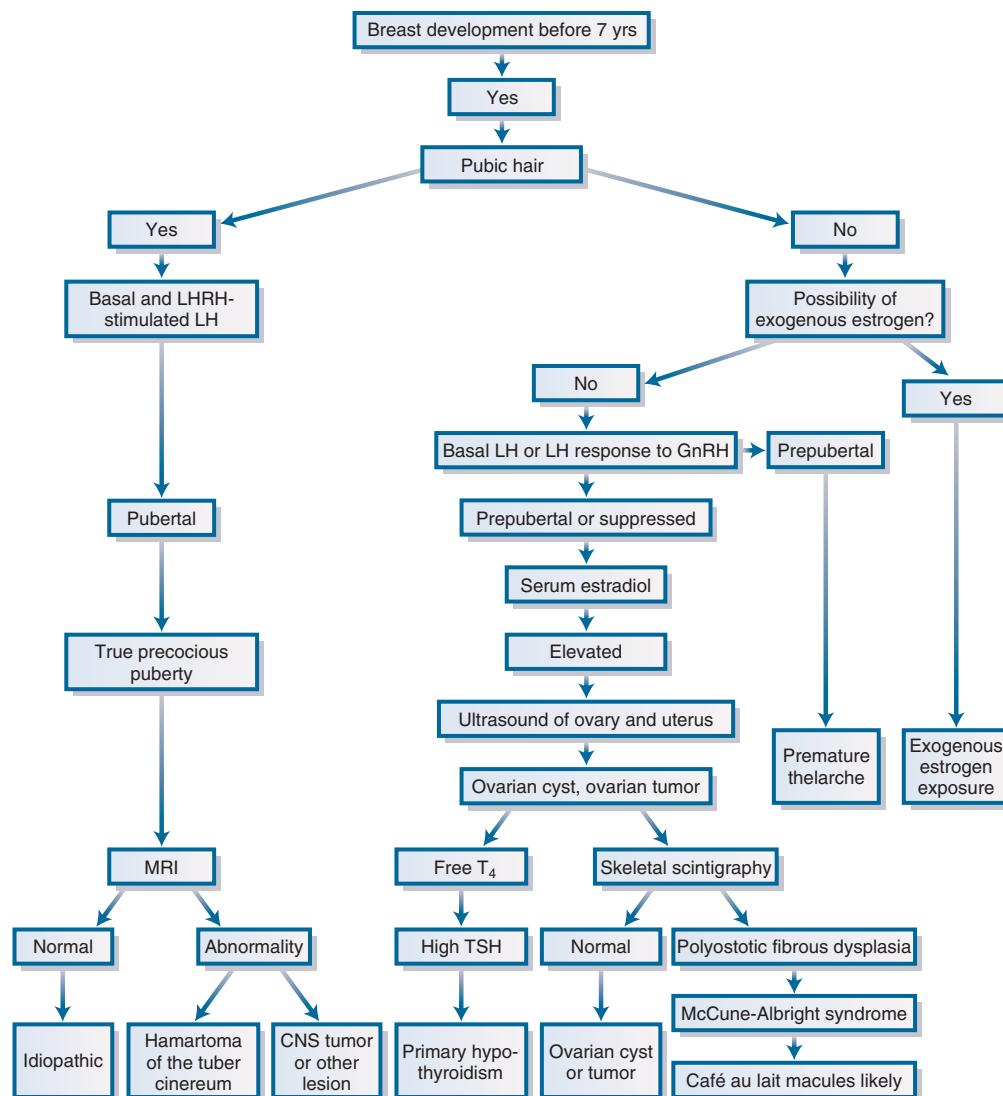

Figure 25-70 Flow chart for diagnosing sexual precocity in girls. CNS, central nervous system; FSH, follicle-stimulating hormone; LH, luteinizing hormone; T₄, thyroxine; TSH, thyroid-stimulating hormone.

prepubertal GnRH test indicates an ectopic, autonomous, gonadotropin-secreting tumor. If this tumor is in the CNS, abnormalities will be present on MRI or CT brain scans. Enlargement of the liver or a mediastinal, retroperitoneal mass in boys with sexual precocity suggests an hCG-producing hepatic or germ cell tumor; the possibility of Klinefelter's syndrome needs to be considered in the latter case.

Pubertal concentrations of LH and FSH, a pubertal mode of pulsatile LH secretion (initially during sleep), or pubertal LH response to GnRH or GnRH agonist confirms the diagnosis of CPP (and in boys differentiates CPP from familial testotoxicosis). A CNS tumor must be considered as a potential cause of this premature activation of the hypothalamic GnRH pulse generator, especially in boys. The evaluation for a CNS tumor as a cause of CPP is similar to the investigation of an hCG-secreting tumor of the CNS. Although CT scanning is now a well established procedure for determining the presence of a CNS abnormality, MRI with contrast is more sensitive for the detection of small tumors in the hypothalamus, such as a hamartoma of the tuber cinereum (see Fig. 25-54). The use of contrast adds to diagnostic certainty and is recommended for MRI of the

CNS. All boys with CPP should have CNS MRI evaluation, but girls do not always receive the same recommendation, because a CNS tumor is less likely in girls than in boys to be the cause of CPP. However, studies using MRI or CT brain scans indicate that the hypothalamic hamartoma is more prevalent in both boys and girls with so-called idiopathic CPP than was previously suspected. An unselected group of girls with precocious puberty and no other symptoms underwent CNS MRI; 15% were found to have intracranial pathology, and the investigators found no clinical difference between those girls and the other 85% of girls studied,⁹⁸⁸ suggesting that CNS MRI is indicated for girls with precocious puberty.

The height of the pituitary gland on MRI correlates with advancing age and with pubertal development; patients with CPP and higher peak LH/FSH ratios had pituitary heights exceeding 6 mm on average, whereas those with a lower LH/FSH ratio or precocious thelarche had lower heights of approximately 5 mm.⁹⁸⁹ The shape of the pituitary gland is also of importance: a convex appearance rather than a flat top is associated with CPP of any cause.⁷⁶⁶ The size and shape of the pituitary gland do not decrease with successful GnRH therapy.

Figure 25-71 Flow chart for the evaluation of pubic hair in normal phenotypic girls before 7 years. DHEAS, dehydroepiandrosterone sulfate; 17-OH-P, 17-hydroxyprogesterone.

The premature appearance of pubic hair, phallic enlargement, and other signs of virilization in a male without enlargement of the testes or the liver suggests the diagnosis of congenital virilizing CAH, virilizing adrenal tumor, or, rarely, Cushing's syndrome. Measurement of plasma 17-hydroxyprogesterone and DHEAS concentrations and their suppressibility with glucocorticoids will distinguish CAH from a virilizing adrenal tumor. If growth rate is suppressed, the possibility of primary hypothyroidism or Cushing's syndrome is raised; elevated plasma concentrations of cortisol, urinary free cortisol, 17-hydroxycorticosteroid, or salivary cortisol after suppression with dexamethasone confirm the latter diagnosis. The appearance in a girl of pubic hair and other signs of virilization, such as clitoral enlargement, acne, deepening voice, muscular development, or growth spurt, is caused by CAH, virilizing adrenal tumor, or virilizing ovarian tumor. Cushing's syndrome caused by an adrenocortical carcinoma can result in virilization associated with growth failure, and a virilizing adrenocortical carcinoma can manifest with so much androgen effect that the Cushing's syndrome is not apparent but rapid growth and virilization are noted; estradiol may be secreted

by these tumors as well as androgens. Virilizing ovarian tumors may be detected by pelvic ultrasonography.

The appearance of pubic hair without other signs of puberty in boys or girls, increased growth, or bone age advancement is usually a result of premature adrenarche but may be the first sign of sexual precocity or of adrenal virilism from other causes.

In a girl, breast development associated with dulling and thickening of the vaginal mucosa and enlargement of the labia minora indicates significant estrogen secretion or iatrogenic exposure to estrogen. The differential diagnosis includes CPP, an estrogen-secreting neoplasm, and a cyst of the ovary. If the plasma concentrations of gonadotropins are in the pubertal range, if LH pulses of pubertal amplitude are detected, or if a pubertal LH response to GnRH or GnRH agonist is elicited, CPP is present. In one report, a child had pubertal-level serum LH due to heterophile antibodies that interfered with the LH assay and fallaciously elevated the values in the basal and stimulated state; after addition of anti-mouse antibody, LH values decreased. As always, clinical observation should be congruent with laboratory findings, and the assays should be

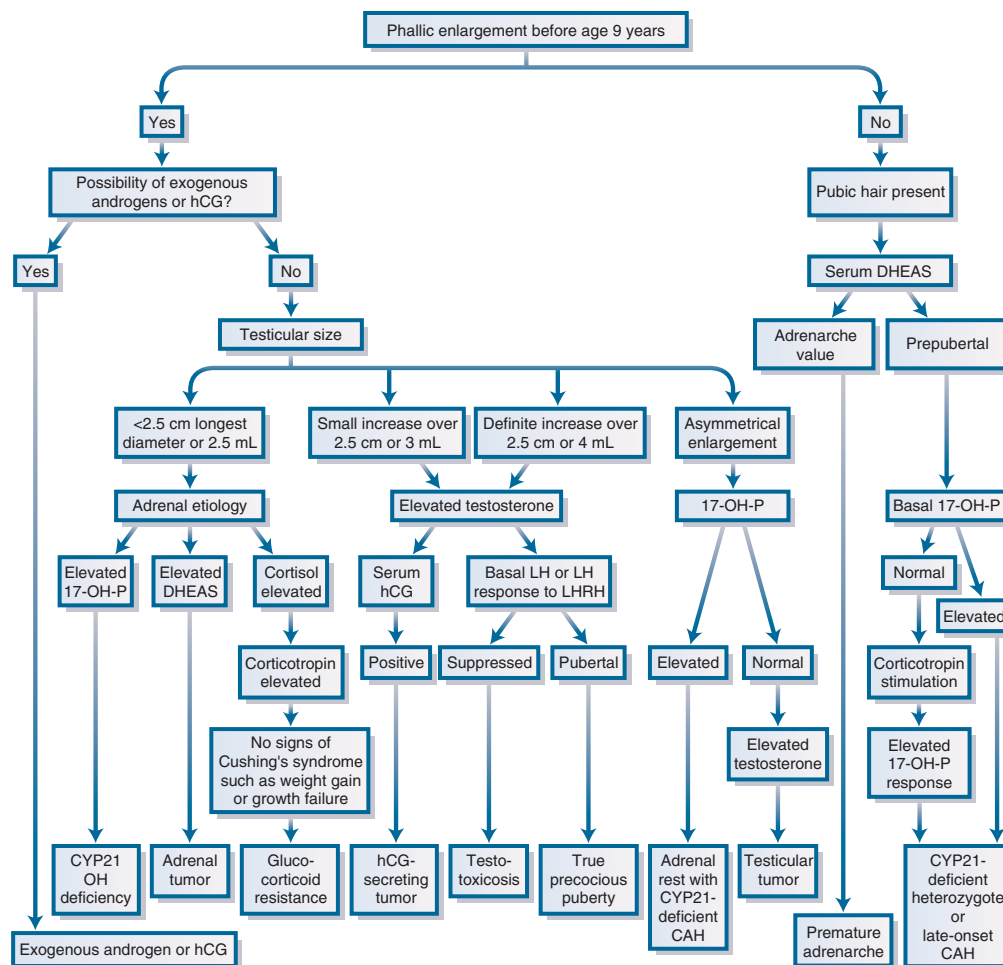

Figure 25-72 Flow chart for diagnosing sexual precocity in a phenotypic male. CAH, congenital adrenal hyperplasia; DHEAS, dehydroepiandrosterone sulfate; hCG, human chorionic gonadotropin; 17-OH-P, 17-hydroxyprogesterone.

highly sensitive and associated with valid pediatric standards.⁹⁹⁰ Estradiol concentrations in girls early in normal puberty or CPP are in the prepubertal range for much of the day, and a single determination may be inadequate to reflect ovarian function.^{151,742}

If the concentration of plasma estradiol is elevated but gonadotropin levels are low, an estrogen-secreting cyst or neoplasm is present or exogenous estrogens are the cause. Ovarian tumors of moderate size can be palpated by bimanual examination. Advances in pelvic sonography allow the delineation of ovarian cysts or tumors and the determination of uterine size, and this procedure has become an essential component of the diagnostic evaluation.¹²⁹ An estrogen-secreting neoplasm of the ovary is usually accompanied by high estradiol concentrations, but some ovarian cysts are associated with concentrations of estradiol as high as those in granulosa cell tumors; the differential diagnosis between these cysts and ovarian neoplasms rarely requires exploratory laparotomy or laparoscopy and usually can be resolved by pelvic sonography and the use of tumor markers. Breast development in the absence of other estrogen effects is almost always a result of premature thelarche.

Iatrogenic Sexual Precocity and Endocrine Disruptors. Prepubertal children are remarkably sensitive to exogenous gonadal steroids and may show signs of sexual

maturation resulting from overlooked sources of androgens or estrogens, such as ingested or absorbed tonics, lotions, or hair creams or straighteners that contain or are inadvertently contaminated with an estrogen.⁹⁹¹ Dermal exposure to estrogen may add up to more than 300 µg, far in excess of a therapeutic dose and possibly greater in infants and children exposed to estrogen dermal gel. Oils containing tea tree and lavender oils were reported to cause gynecomastia in three prepubertal boys and demonstrated estrogenic activity in vitro.⁹⁹² A short course of application of estrogen cream is used to treat labial adhesions, but long courses may lead to breast development or even withdrawal bleeding. In addition to breast development, pigmentation of the areolae and the linea alba and the appearance of pubic hair may be seen in children exposed to dermal estrogen. Children who touch the skin or the towels of men using androgen gel therapy may themselves develop virilization.⁹⁹³ The administration of hCG to boys with undescended testes may induce secretion of testosterone sufficient to cause incomplete sexual precocity.

FDA guidelines define a limit of not more than 1% of normal daily estrogen production in prepubertal children as a safe intake of estrogen⁹⁹⁴; this is equivalent to 0.43 ng/day for boys and 3.24 ng/day for girls, based on the most recent data from extremely sensitive estrogen assays, but food is still a suspected source of endocrine disruption.^{991,995}

TABLE 25-41

Differential Diagnosis of Sexual Precocity

	Plasma Gonadotropins	LH Response to GnRH	Serum Sex Steroid Concentration	Gonadal Size	Miscellaneous
Gonadotropin-Dependent					
True precocious puberty	Prominent LH pulses (premature reactivation of GnRH pulse generator)	Pubertal LH response initially during sleep	Pubertal values of testosterone or estradiol	Normal pubertal testicular enlargement or ovarian and uterine enlargement	MRI of brain to rule out CNS tumor or other abnormality; skeletal survey for McCune-Albright syndrome (by US)
Incomplete Sexual Precocity (Pituitary Gonadotropin-Independent)					
Males					
Chorionic gonadotropin-secreting tumor in males	High hCG, low LH	Prepubertal LH response	Pubertal value of testosterone	Slight to moderate uniform enlargement of testes	Hepatomegaly suggests hepatoblastoma; CT scan of brain if chorionic gonadotropin-secreting CNS tumor suspected
Leydig cell tumor in males	Suppressed	No LH response	Very high testosterone	Irregular, asymmetric enlargement of testes	
Familial testotoxicosis	Suppressed	No LH response	Pubertal values of testosterone	Testes symmetric and >2.5 cm but smaller than expected for pubertal development; spermatogenesis occurs	Familial; probably sex-limited, autosomal dominant trait
Virilizing congenital adrenal hyperplasia	Prepubertal	Prepubertal LH response	Elevated 17-OHP in CYP21 deficiency or elevated 11-deoxycortisol in CYP11B1 deficiency	Testes prepubertal	Autosomal recessive, may be congenital or late-onset form, may have salt loss in CYP21 deficiency or hypertension in CYP11B1 deficiency
Virilizing adrenal tumor	Prepubertal	Prepubertal LH response	High DHEAS and androstenedione values	Testes prepubertal	CT, MRI, or US of abdomen
Premature adrenarche	Prepubertal	Prepubertal LH response	Prepubertal testosterone, DHEAS, or urinary 17-ketosteroid values appropriate for pubic hair stage 2	Testes prepubertal	Onset usually after 6 yr of age; more frequent in CNS-injured children
Females					
Granulosa cell tumor (follicular cysts may present similarly)	Suppressed	Prepubertal LH response	Very high estradiol	Ovarian enlargement on physical examination, CT, or US	Tumor often palpable on physical examination
Follicular cyst	Suppressed	Prepubertal LH response	Prepubertal to very high estradiol	Ovarian enlargement on physical examination, CT, or US	Single or recurrent episodes of menses and/or breast development; exclude McCune-Albright syndrome
Feminizing adrenal tumor	Suppressed	Prepubertal LH response	High estradiol and DHEAS values	Ovaries prepubertal	Unilateral adrenal mass
Premature thelarche	Prepubertal	Prepubertal LH, pubertal	Prepubertal or early estradiol response	Ovaries prepubertal	Onset usually before 3 yr of age
Premature adrenarche	Prepubertal	Prepubertal LH response	Prepubertal estradiol; DHEAS or urinary 17-ketosteroid values appropriate for pubic hair stage 2	Ovaries prepubertal	Onset usually after 6 yr of age; more frequent in brain-injured children
Late-onset virilizing congenital adrenal hyperplasia	Prepubertal	Prepubertal LH response	Elevated 17-OHP in basal or corticotropin-stimulated state	Ovaries prepubertal	Autosomal recessive
In Both Sexes					
McCune-Albright syndrome	Suppressed	Suppressed	Sex steroid pubertal or higher	Ovarian (on US); slight testicular enlargement	Skeletal survey for polyostotic fibrous dysplasia and skin examination for café au lait spots
Primary hypothyroidism	LH prepubertal; FSH may be slightly elevated	Prepubertal FSH may be increased	Estradiol may be pubertal	Testicular enlargement; ovaries cystic	TSH and prolactin elevated; T ₄ low

CNS, central nervous system; CT, computed tomography; CYP, P450 cytochrome isoenzyme; DHEAS, dehydroepiandrosterone sulfate; GnRH, gonadotropin-releasing hormone; hCG, human chorionic gonadotropin; LH, luteinizing hormone; MRI, magnetic resonance imaging; 17-OHP, 17-hydroxyprogesterone; T₄, thyroxine; TSH, thyrotropin; US, ultrasonography.

Epidemics of gynecomastia in boys and thelarche in girls among schoolchildren in Italy were suspected to be caused by contaminated meat. During a 10-year period, more than 600 cases of gynecomastia in boys and premature thelarche or incomplete sexual precocity in girls were discovered in Puerto Rico; this is the highest prevalence reported in the world, about 10 to 15 times higher than that measured in a survey in Olmsted, Minnesota.^{996,997} Maternal ovarian cysts were demonstrated in two thirds of affected Puerto Rican girls. The clandestine use of estrogen preparations in animals to stimulate weight gain, leading to ingestion of estrogen-contaminated meat from these animals, was raised as an possible cause, but this was neither confirmed nor excluded by selected analyses of meat, poultry, and milk in Puerto Rico by the U.S. Department of Agriculture. Significantly elevated concentrations of phthalate and its major metabolites, plasticizers with documented estrogenic and anti-androgenic activity, were found in 28 girls (68%) from a cohort of girls with premature breast development in Puerto Rico,⁹⁹⁸ although methodologic criticism of the study arose. One study found no difference between phthalate concentrations in serum between a cohort of girls with CPP and age-matched (nonpubertal) controls.⁹⁹⁹

Endocrine disruptors clearly affect other species, including vertebrates,¹⁰⁰⁰ but they must be studied in more detail in human beings before specific effects are established. There is convincing evidence for effects of environment on pubertal development when industrial accidents release large amounts of substances but only suggestive epidemiologic evidence that environmental agents are affecting pubertal development in most other situations.¹⁰⁰¹ Girls who were breast-fed or exposed during intrauterine life to polybrominated biphenyls (PBBs) after an accidental exposure of their mothers in Michigan experienced early menarche (by about 1 year of age) and early appearance of pubic hair but not breast development, compared with girls who were not exposed or breast-fed.¹⁰⁰² There was a 9.56 increase in relative risk for precocious puberty treated by GnRH agonist in a localized area in Italy, compared with surrounding areas, suggesting the presence of an endocrine disruptor in the area.¹⁰⁰³ Widespread exposure to 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD), an extremely potent antiestrogenic xenobiotic, in Italy revealed that girls younger than 8 years of age at the time of exposure, who presumably had the highest dose per BMI compared with older girls, showed a tendency for a decrease in age at menarche, suggesting that age of exposure to environmental endocrine disruptors modulates their effects.¹⁰⁰⁴ Exposure in rodents actually causes a delay in vaginal opening and other reproductive effects. Follow-up of adolescents who were exposed to di-(2-ethylhexyl)-phthalate (DEHP), a component of polyvinyl chloride (PVC) that is used in plastic tubing and medical devices, when they underwent extracorporeal membrane oxygenation (ECMO) as neonates demonstrated no effects on pubertal development despite findings of disruption of development in animals exposed to this substance.¹⁰⁰⁵

Increased lead levels in Mohawk girls living near the border of New York and Canada delayed the age of menarche, whereas increased levels of polychlorinated biphenyl (PCB) promoted it¹⁰⁰⁶; surprisingly, variations in BMI exerted no effect of these toxic substances which are concentrated in adipose tissue. In the NHANES III survey, a serum lead level of 0.7 to 2.0 µg/dL delayed menarche and pubic hair development, and African Americans exposed to 3 µg/dL also experienced delay in breast development.¹⁰⁰⁷ A long-term study of puberty in Chapaevsk, Russia, an area

highly contaminated with industrial waste, demonstrated 43% reduced odds of entering stage 2 genitalia among 8- to 9-year-old boys with serum lead levels equal to or greater than 5 µg/dL.¹⁰⁰⁸

There is a high frequency of reproductive problems among adult Danish men, including impaired semen quality, testicular cancer, and increased rate of infantile testicular cancer; these disorders occur in a pattern that is attributed to environmental disruptors, described in the testicular dysgenesis syndrome.⁶⁶⁴ A higher rate of hypospadias in Danish newborns and smaller testes with lower serum inhibin B, compared with Finnish infants, suggested that environmental agents, rather than genetic influences, were responsible. Phthalates were found in the breast milk of mothers from both countries, and although there was no relationship to the finding of hypospadias, there was an indication of altered reproductive hormones in the boys in a pattern suggesting effects on Leydig cells.

Longitudinal observation of girls in Copenhagen, Denmark, using physical examination of breast tissue showed a significant decline in the age of Tanner stage 2 breast development (estimated mean age, 9.86 years in 2006-2008 versus 10.88 years in 1991) and the age at menarche (13.13 versus 13.42 years, respectively); there was no change in serum gonadotropins, but the serum estradiol concentration was decreased in 2006.¹⁰⁰⁹ Changes in BMI did not occur in this study between the cohorts, leaving open the possibility of endocrine-disrupting chemicals as an explanation.

Boys exposed to PCBs and polychlorinated dibenzofurans (PCDFs) in utero from contamination of rice ingested by their mothers had decreased testosterone and defects in postpubertal sperm production in a preliminary study, as well as increased estrogen compared with controls, although there was no difference on physical examination or in age at onset of puberty.¹⁰¹⁰ Boys exposed to DDT in utero did not demonstrate any abnormalities in puberty in a study from Philadelphia, Pennsylvania.¹⁰¹¹ Exposure to PCBs in inner-city girls with reduced BMI values reportedly delayed thelarche.⁴⁵

The study of endocrine disruptors is active, but the ultimate effects of environmental agents on reproductive development are not yet clear. The complexities of type, amount, developmental age at exposure, and other factors are difficult to tease apart. In the United States, chemicals can enter the environment before their safety is proved, whereas in Norway, all new substances must be proved safe before they can enter the environment. Well-designed longitudinal studies are needed in this area.¹⁰¹²

Contrasexual Precocity: Feminization in Boys and Virilization in Girls

Boys. Feminization in a boy before the age of puberty is rare. Rarely, an estrogen-secreting adrenal adenoma or a chorionepithelioma causes gynecomastia. Gynecomastia has been reported in a 1-year-old boy with 11β-hydroxylase deficiency and in boys with late-onset CAH.^{1012a}

Aromatase Excess Syndrome. Gynecomastia in prepubertal boys can be caused by increased extraglandular aromatization of C19 steroids of adrenal origin, such as androstenedione, and subsequent increased extraglandular estrogen production in sporadic or familial cases.²⁵⁷ The autosomal dominant form leads to excess estrogen synthesis from C19 precursors due to aromatase overexpression, especially in fat and skin; it is a consequence of gain-of-function mutations of CYP19, the gene that encodes aromatase, resulting from a chromosome arrangement that gives rise to a cryptic promoter.¹⁰¹³ An autosomal dominant

pattern of prepubertal gynecomastia and adult hypogonadism but not short stature in the presence of elevated serum estrone (with little or no elevation of estradiol) has been reported; the mutations in the CYP19 gene in these patients appeared to be different from those in the families described earlier with gain-of-function mutations resulting from gene inversions.¹⁰¹⁴ In a Turkish kindred, there was a potential rearrangement between CYP19 and TRPM7 genes on chromosome 15q21.2 as a cause of aromatase excess syndrome.¹⁰¹⁵

Feminizing Testicular Tumors. Feminizing testicular tumors may cause gynecomastia in boys younger than 6 years of age who have the Peutz-Jeghers syndrome.⁹³⁶ Aromatase is absent or is present in barely detectable amounts in prepubertal testes, but maximal amounts appear in late puberty. In normal testes, aromatase is predominantly present in the Leydig cells, but in testicular tumors of Sertoli cells or Leydig cells (e.g., associated with the Peutz-Jeghers syndrome), the Sertoli cells of the tumor express aromatase. Both testes may be enlarged, and the histology indicates sex cord or Sertoli cell tumors that form annular tubules and often have areas of calcification; increased estradiol secretion is noted in the basal state, and a further rise occurs after hCG administration. Otherwise, feminizing Sertoli cell tumors are very rare in boys.⁹³⁷ Sonography or MRI of the testes may be useful in making the diagnosis.

In one series, 5% of 581 boys referred for evaluation of gynecomastia were prepubertal at diagnosis (mean age, 9 years) and in 93% no underlying cause was identified.¹⁰¹⁶ Spontaneous resolution was recorded in 6 boys, no change in 15, and further breast enlargement in 6. Prepubertal gynecomastia can be caused by neurofibromatosis.

Girls

Adrenal Causes of Virilization. Virilization in a girl indicates organic disease except for premature adrenarche. CAH resulting from 21-hydroxylase or 11 β -hydroxylase deficiency or from androgen-producing tumors of the adrenal can cause virilization (see earlier discussion of their occurrence in males). Nonclassic or late-onset forms of CAH do not demonstrate ambiguous genitalia, but there is evidence of androgen effect in prepuberty or the teenage years. 3 β -HSD/ Δ^4 -isomerase deficiency is a rare type of CAH characterized by elevated levels of Δ^5 -17P, DHEA, and DHEAS, as well as decreased secretion of aldosterone and cortisol in the severe form. Severely affected patients have mineralocorticoid and glucocorticoid deficiencies and may die in infancy. Excess adrenal androgens lead to virilization in utero and to ambiguous external genitalia, including clitoral enlargement in females with continued virilization after birth. Milder forms of this disorder can cause hirsutism in women. Women with a 46,XY phenotype and incomplete forms of androgen resistance syndrome or 17 β -HSD type 3 deficiency may have virilization as well as breast development at the time of expected puberty. Mutations in the CYP19 gene, which encodes aromatase, is associated with intrauterine masculinization of the external genitalia in affected 46XX individuals and also with progressive virilization, lack of female secondary sex characteristics, multicystic ovaries at the age of puberty, tall stature, and osteopenia.^{255,257}

Cushing's syndrome resulting from adrenal carcinoma usually manifests as growth failure with or without virilization, obesity, and moon facies; striae may not appear until months to years later.

Syndrome of Glucocorticoid Resistance. The syndrome of glucocorticoid resistance has variable manifestations. Some patients demonstrate hyperandrogenic signs such as acne, hirsutism, male-type baldness, menstrual irregularities, and

oligoanovulation and infertility.¹⁰¹⁷ Dexamethasone decreases the excessive adrenal androgen secretion, virilization, and advancing bone age found in general glucocorticoid resistance.

Virilizing Ovarian Tumors. Arrhenoblastoma, also called Sertoli tumor of the ovary, is the most common virilizing ovarian tumor, but it is rare in children. Lipoid-cell tumors of the ovary and gonadoblastomas or Sertoli-cell tumors of the ovary are even more unusual sources of androgens.^{1018,1019}

Variations of Pubertal Development

Premature Thelarche. Unilateral or bilateral breast enlargement without other signs of sexual maturation (e.g., sexual hair, growth of the labia minora, growth of the uterus) is not uncommon in infancy and childhood and is termed *premature thelarche*. The disorder usually occurs by age 2 (>80% of cases) and rarely after age 4.¹⁰²⁰ In a retrospective study in Minnesota, the incidence of premature thelarche was 21.2 per 100,000 patient-years, 60% of cases were identified in patients between 6 months and 2 years of age, and most cases regressed within 6 months to 6 years after diagnosis, although a few persisted until puberty. When 10- to 35-year follow-up was available, no untoward effects on later health, growth, or fertility were evident.⁹⁹⁷ Breast enlargement usually regresses after a few months¹⁰²⁰ but occasionally persists for years or until the onset of normal puberty; in about half of affected girls, the breast development, which is characteristically cyclic, lasts 3 to 5 years. Usually, significant nipple and areolae development is absent, and estrogen-induced thickening and dulling of the vaginal mucosa is uncommon. Enlargement of the uterus on ultrasonography (volume >1.8 mL, length >36 mm) is rare. Measurement of the ellipsoid volume of the uterus ($V = \text{longitudinal diameter} \times \text{anteroposterior diameter} \times \text{transverse diameter} \times 0.523$) is the most sensitive and specific discriminator between premature thelarche and early CPP¹²⁹ and provides better early discrimination than the LH response to GnRH or GnRH agonist. Growth in stature is normal.

This is a benign, self-limited disorder that is compatible with normal pubertal development at an appropriate age; usually, only reassurance and follow-up are necessary. However, the appearance of premature thelarche can be the harbinger of further sexual maturation in a minority of cases, as discussed elsewhere in this chapter.^{763,1021} If onset occurs soon after birth and before 2 years of age, the prognosis for regression is better.¹²⁹ Because the development may be unilateral, it is important to consider the condition in girls who have unilateral breast development so that needless worry about a breast neoplasm is not stimulated in the parents and no unnecessary surgical procedure is carried out, because removal of tissue in premature thelarche may leave the child with no possibility of future breast development. In selected instances, sonography of the breast is useful to distinguish unilateral premature thelarche from less benign conditions. The most common cause of a breast mass in a pubertal girl is fibroadenoma, and although metastatic disease may locate in the pubertal breast, breast carcinoma is exceedingly rare in young patients.

Plasma estradiol levels are slightly higher for age in patients with premature thelarche determined by a highly sensitive estrogen assay.¹⁰²¹ However, there is usually no significant increase in plasma levels of TeBG or in thyroxine-binding globulin, which are indicators of estrogen action on circulating plasma proteins, although a modest increase of TeBG for age has been reported. The urocytogram often

reveals an estrogen effect on squamous epithelial cells in the urine.^{769,1022}

The concentration of serum FSH may be in the pubertal range, nocturnal FSH pulsatility has been detected, and the rise in FSH elicited by administration of GnRH may be augmented for chronologic age, with an FSH/LH ratio higher in precocious thelarche than in normal individuals or in girls with CPP.^{429,774} However, the results overlap those in normal prepubertal girls.

As postulated for some recurrent ovarian cysts, premature thelarche appears to result from the ovarian response to transient increases in FSH levels and possibly from variations in ovarian sensitivity to FSH.^{429,1022} The LH response to GnRH is prepubertal in all cases.⁴²⁹ Plasma inhibin B and FSH levels are higher in girls with precocious thelarche than in control subjects, in a range similar to that observed in patients with precocious puberty.¹⁰²³ Activin concentrations have not been reported. The possible role of a paracrine-acting pituitary factor in stimulating FSH independent of GnRH is not known.

Sonograms of the ovary often show one or several cysts larger than 0.5 cm that disappear and reappear, usually correlating with changes in the size of the breasts, but the volume of the ovary and uterus is prepubertal.¹²⁹ In clinical practice, it is rare to find a cyst at the time of presentation and on ultrasonic study.

Exaggerated thelarche is described as premature thelarche with the added findings of advanced bone age and increased growth rate, which are estrogen effects. The endocrine measurements in the basal state are in the normal prepubertal range, but after GnRH agonist stimulation, the level of FSH (but not of LH) rose higher than in controls or in patients with CPP.⁷⁶² Mutation of *GNAS1* involving Arg201His is associated with apparent premature or exaggerated thelarche and early menarche.⁹⁵¹

Premature Isolated Menarche. Rarely, girls begin periodic vaginal bleeding at between 1 and 9 years of age without any other signs of secondary sexual development. The bleeding can recur for 1 to 6 years and then cease. At the normal age of puberty (3 to 11 years later), secondary sexual development and menses ensue and follow a normal pattern, as does stature. Fertility was later demonstrated after a normal onset of puberty in women with this variant of pubertal development. The cause is uncertain, but it may be a counterpart of premature thelarche. There is a predominance of FSH secretion, but the gonadotropin secretion pattern is not characteristic of CPP.¹⁰²⁴ Isolated menarche may appear before other manifestations of sexual precocity in patients with the McCune-Albright syndrome and in those with the premature sexual maturation that can occur in juvenile hypothyroidism.

Before the diagnosis of premature menarche is accepted, all other causes of vaginal bleeding and precocious estrogen secretion and of exposure to exogenous estrogens should be excluded, including neoplasms, granulomas, infection of the vagina or cervix, and presence of a foreign body. A careful examination for trauma, such as that caused by sexual abuse, is indicated. Urethral prolapse may be misdiagnosed as vaginal bleeding.

Premature Adrenarche. Premature adrenarche (i.e., pubarche) is the precocious appearance of pubic hair or axillary hair or both and, less commonly, an apocrine odor, comedones, and acne, without other signs of puberty or virilization. It is characterized by premature and mild adrenal hyperandrogenism.³¹³ The term *premature adrenarche* refers to the rise in serum concentrations of adrenal androgens that causes the appearance of the pubic hair. In the past, this designation was assigned when these clinical

features appeared before age 8 years in girls or 9 years in boys. Although in boys the 9 years still seems appropriate as a cutoff point, the age of 8 years can no longer be used for American girls, according to the results of the in the PROS study described earlier²⁷ (mean ages are shown in Table 25-1). We recommend that the diagnosis of premature pubarche should be limited to African American girls younger than 6 years of age and white American girls younger than 7 years, which should affect the age at which laboratory studies are initiated unless there are other signs of virilization, such as clitoromegaly or rapid growth.

Premature adrenarche is about 10 times more common in girls than in boys. The prevalence is increased in children with CNS abnormalities without a clear sex difference; the electroencephalogram may be abnormal⁷⁵² in the absence of other neurologic findings. Familial transmission is uncommon.¹⁰²⁵ Premature adrenarche is commonly slowly progressive and does not have an untoward effect on either the onset or the normal progression of gonadarche or final adult height.²⁸⁴ Nonetheless, there is a relationship between reduced fetal growth leading to intrauterine growth retardation and subsequent SGA and the increased prevalence of premature adrenarche, hyperinsulinism, and ovarian hyperandrogenism in life.³¹³

Plasma concentrations of DHEA, DHEAS, androstenedione, testosterone, 17-hydroxyprogesterone, and Δ^5 -17P are comparable to values normally found in pubic hair stage 2.^{443,1026,1027} ACTH stimulation increases serum DHEA and DHEAS concentrations and the excretion of urinary 17-ketosteroids, but the concentrations of plasma 17-hydroxyprogesterone and Δ^5 -17P do not increase to the levels found in individuals with virilizing forms of CAH.¹⁰²⁸ Shorter androgen receptor gene CAG number, indicative of increased androgen sensitivity, is reported in some girls with precocious adrenarche.¹⁰²⁹ As in CAH, dexamethasone suppresses adrenal androgen and androgen precursor secretion. Serum gonadotropin levels in the basal state and after GnRH are in the prepubertal range in patients with premature adrenarche.⁴²⁹ Premature adrenarche occurs independently of gonadarche and results from some factor other than increased secretion of GnRH or ACTH.⁴⁴² Bone age, height, and weight gain are slightly advanced for chronologic age, but normal adult height is commonly achieved,^{1030,1031} except, rarely, in some individuals with unusually high levels of adrenal androgens, hirsutism, acne, and a bone age more than 2.5 SD above the mean value for chronologic age. In a follow-up study of 20 girls, the functional adrenal hyperandrogenism in premature adrenarche was limited to childhood.

Premature adrenarche may be considered to be a developmentally regulated, normal variation in the differentiation, growth, and function of the zona reticularis of the adrenal cortex, marked biochemically by the precocious increase in the concentration of plasma DHEAS to more than 40 $\mu\text{g/dL}$.²⁸⁴ The latter is probably related to the independent increase of 17,20-lyase activity in the developing zona reticularis, which is mediated by increased phosphorylation of serine and threonine residues on the CYP17 enzyme, and the increased abundance of cytochrome b5 and of electron-donating redox partners such as cytochrome P450 oxidoreductase and cytochrome b5, which are essential for the 17,20-lyase activity of this functional microsomal enzyme (see Fig. 25-35).¹⁰²⁸ Nonetheless, the factor stimulating development and function of the zona reticularis, independent of ACTH, remains elusive. In the past, failure to recognize the earlier onset of normal adrenarche, and particularly the striking ethnic differences in African American, Hispanic, and Latin populations,

contributed to the overdiagnosis of premature adrenarche^{313,1032-1034} and, in some instances, to needless laboratory studies.

The appearance of premature pubarche can be a manifestation of nonclassic CAH caused by homozygous or compound heterozygous missense mutations in the *CYP21* gene.¹⁰³⁶ This condition can readily be detected by a plasma 17-hydroxyprogesterone response to ACTH that is at least 6 SD above the mean value. The prevalence of 21-hydroxylase deficiency in children with premature adrenarche is low^{1036,1037} except in some ethnic groups^{1038,1039} (e.g., Hispanics, Italians, Ashkenazi Jews), in which the prevalence may be as high as 20% to 30%.^{1039,1040} The phenotype of premature pubarche is also associated with the rarer nonclassic 11 β -hydroxylase deficiency.

There has been controversy about the prevalence and significance of 3 β -HSD deficiency and a pervasive belief that a mutation in the gene encoding this enzyme is a common cause of premature adrenarche and nonclassic 3 β -HSD deficiency. The possibility of a mutation in the open reading frame of the 3 β -HSD type 2 or type 1 gene (i.e., *HSD3B2* or *HSD3B1*) has been excluded as an uncommon cause of this condition.¹⁰⁴¹⁻¹⁰⁴³ Mutations in *HSD3B2* have been associated with a Δ^5 -17P response to ACTH that exceeds or equals the mean normal value by 6 SD. Of 26 families studied, only 1 family with a mutation (Ala82Thr) had affected females who exhibited premature pubarche; in this family, the affected male was a male pseudohermaphrodite.¹⁰⁴⁴ Therefore, mutation of *HSD3B2* or *HSD3B1* is an uncommon cause of premature pubarche, exaggerated adrenarche, and hirsutism in adolescent girls and women.

The cause of the observed mild deficiency in 3 β -HSD activity is unknown, but it may be multifactorial and may lead to a wide range in secretory capacity of the zona reticularis. A family constellation was described with a dominant pattern of inheritance¹⁰²⁵ of elevated adrenal androgens and androgen precursors that manifested as premature pubarche; later-affected individuals developed hirsutism and anovulation. Several investigators joined to propose hormonal standards for the diagnosis of 3 β -HSD deficiency in cases of apparent premature pubarche and stated that ACTH-stimulated Δ^5 -17P values must exceed 294 nmol/L or 54 SD above the mean for Tanner stage 2 (17 ± 5 nmol/L) or the ratio of Δ^5 -17P to cortisol (F) must be at least 363, which is 3.0 SD above the mean ratio of 20 ± 5 . Studies relating genotype and hormonal analyses in basal and ACTH-stimulated conditions have confirmed that significant elevations of the Δ^5 -17P-to-F ratio are necessary to prove true 3 β -HSD deficiency in genetically proven disease¹⁰⁴⁵ and that this is a rare disorder in patients presenting with putative premature adrenarche. However, patients with a constellation of findings indicating PCOS may have more subtle elevations of these values and present a picture of adrenal impairment of 3 β -HSD activity in the absence of mutations in the gene coding for the enzyme; these children presenting with premature pubarche are postulated to develop clinical PCOS at a later age.¹⁰⁴⁵

DHEA stimulates sebaceous gland activity,¹⁰⁴⁶ and prepubertal acne or comedones may appear in association with elevated serum DHEAS concentrations in some children without the appearance of pubic hair, suggesting that a variant of premature adrenarche may manifest in this manner.¹¹⁹ More significant androgen effects (e.g., clitoral or penile enlargement, rapid growth, hirsutism, deepening of the voice) exclude premature adrenarche and indicate a more severe form of hyperandrogenism.

Although premature adrenarche was usually considered to be a benign condition with no substantial long-term risk, accumulating observations indicate that girls with premature adrenarche are at increased risk of developing functional ovarian hyperandrogenism and PCOS, hyperinsulinism, acanthosis nigricans, and dyslipidemia in adolescence and adult life, especially if fetal growth was reduced and the birth weight was low.³¹³ Affected girls have BMI values similar to those of controls but differing distribution of fat; they are more likely to have increased waist circumference along with measures of insulin resistance.¹⁰⁴⁷ The concept of *exaggerated adrenarche*¹⁰³⁶ was first advanced in relation to a postulated childhood antecedent of PCOS. It has been extended to include rare instances of premature adrenarche associated with excessive responses of Δ^5 -17P, DHEAS, and androstenedione to ACTH found in women with functional adrenal hyperandrogenism.

A recent report of a patient with premature adrenarche, advanced bone age, excessive acne, hyperandrogenic anovulation, very low DHEAS levels, and increased androgen levels demonstrated a mutation in PAPSS2, an enzyme that generates the sulfate donor 3'-phosphoadenosine-5'-phosphosulfate (PAPS), which is required for conversion of DHEA to DHEAS by the enzyme SULT2A1. Although the child was described as having premature pubarche, the androgen effects were greater than those usually encountered in this condition. The DHEA level was not elevated for age, but androstenedione was high due to inadequate formation of DHEAS that decreases the conversion of DHEA to androstenedione. This presentation would ordinarily suggest an ovarian cause of the virilization. This monogenetic defect must be added to the differential diagnosis of premature adrenarche.²⁸⁶

Polycystic Ovarian Disease. PCOS is the most common endocrine disease; it is estimated to affect 10% of women.^{1048,1049} The hallmarks of this condition are hyperandrogenism, hirsutism, anovulation, amenorrhea or oligomenorrhea, and insulin resistance; there is compensatory hyperinsulinemia, with its attendant risk of major metabolic sequelae including type 2 diabetes mellitus, dyslipidemia, an increased propensity to coronary heart disease, and, in about 50% of affected women, obesity. PCOS is considered to be equivalent to the metabolic syndrome in its many manifestations in females. A 2004 review of diagnostic criteria supported most of the original 1990 recommendations.¹⁰⁵⁰ Premature adrenarche is an risk factor for the later development of the PCOS and functional ovarian hyperandrogenism in adolescent and adult women; the magnitude of this risk is unknown, but it appears to be rare, except in girls with a history of SGA.^{7,313,1036,1051} However, catch-up growth after SGA may be as important a factor in the development of PCOS, and even prematurity may be a risk. In an 880-member cohort of 8-year-olds, serum androstenedione and DHEAS levels were directly related to weight gain between 1 and 3 years and current weight and inversely related to birth weight.⁸ However, a Dutch study could not confirm such a relationship between increase in premature adrenarche and SGA birth weight in 181 subjects born with SGA compared with 170 subjects born with appropriate weight for gestational age (AGA).¹⁰⁵²

Plasma plasminogen activator inhibitor 1 (PAI-1), a marker of risk for cardiovascular disease including in women with PCOS, was increased in girls with premature adrenarche, and especially in those with low birth weight, and may be useful in the identification of girls who have an increased risk of developing PCOS.¹⁰⁵³ In certain ethnic groups, and especially in African American and Hispanic girls, there is a greater association of premature adrenarche

with the metabolic syndrome (obesity, hyperinsulinism, dyslipidemia, and other factors that increase the risk of later coronary heart disease) and the development of PCOS in late adolescence and early adulthood,^{313,313,1054,1055} especially if decreased insulin sensitivity and acanthosis nigricans accompany the premature adrenarche. The adrenal steroid pattern in black and Hispanic patients in one of these studies¹⁰⁵⁵ did not differ from that in children with uncomplicated premature adrenarche.

As discussed earlier, hyperinsulinism is associated with many metabolic and endocrine conditions and functional ovarian hyperandrogenism which, in some cases, is heralded by premature adrenarche. Therapeutic approaches to reduce insulin resistance, especially the use of insulin sensitizers, have been introduced into the therapy for PCOS. The most widely used drug is metformin because of its low prevalence of adverse effects and therapeutic efficacy, although its major effect is in decreasing gluconeogenesis from the liver rather than insulin sensitizing. In early studies, this agent resulted in decreased insulin resistance, ovarian hyperandrogenism, and hirsutism in obese and nonobese patients in the treatment of PCOS. A short-term, randomized trial¹⁰⁵⁶ of metformin in 82 children and adolescents with type 2 diabetes mellitus (10 to 16 years of age) provided useful preliminary data to support the safety and efficacy of its use in adolescents with insulin resistance and functional ovarian hyperandrogenism, although metformin is not FDA-approved for such use.

In a trial involving girls just past menarche who had a history of low birth weight and premature adrenarche and were therefore at risk for development of PCOS, metformin prevented this predicted course.⁷ Treatment of 8-year-old girls who had similar risk factors appeared to diminish the risk during short-term studies. The beneficial effects on body composition, dyslipidemia, insulin resistance, and other parameters were present only during therapy; they reverted to increased risk factors after discontinuation of metformin.

In an in vitro study, troglitazone, but not metformin, directly inhibited the steroidogenic enzymes CYP17 and 3 β -HSD,¹⁰⁵⁷ and clinical study suggested that this medication may be efficacious in the treatment of PCOS even though it is not approved for this use by the FDA. These are promising approaches to a still poorly understood syndrome that often manifests during adolescence. Many aspects need to be addressed in the management of this heterogeneous disorder, including, apart from pharmacologic agents, concern about nutrition and physical activity, which are also shown to improve the findings of PCOS.

Adolescent Gynecomastia. Normal boys, usually in the early stages of puberty, may have either unilateral breast enlargement (approximately 25% of boys)¹⁰⁵⁸ or bilateral breast enlargement (approximately 50% to 65% of boys to varying degrees); this commonly occurs between chronological ages 14 and 14.5 years or with pubic hair stages 3 and 4. In these boys, the plasma concentrations of testosterone and estrogen are normal for their stage of puberty. Some have suggested that the ratio of estrogen to androgen or an increase in the ratio of testosterone to dihydrotestosterone is a cause. In a prospective study, adolescent boys with gynecomastia had a lower mean free testosterone concentration, lower weight, higher plasma TeBG levels, and a tendency toward earlier onset of puberty and more rapid progression through puberty.¹⁰⁵⁸ In one study, a significant decrease in the concentration ratio of plasma androstenedione to estrone and estradiol and a similarly low ratio of DHEAS to estrone and estradiol were described in boys with pubertal gynecomastia who had normal ratios of plasma

estrone and estradiol to testosterone. It was postulated that decreased adrenal production of androgens or (more likely) increased peripheral conversion of adrenal androgens to estrogens was a factor in the development of pubertal gynecomastia.¹⁰⁵⁹

Trials of estrogen receptor antagonists (e.g., tamoxifen, raloxifene) or exogenous androgens have had mixed results in gynecomastia, and more study is required. One study of boys (average age, 13 years) with gynecomastia involving a mean of 7 months of treatment with anastrozole demonstrated a substantial decrease in breast area (63%) and volume (53%), as measured manually and by ultrasonography,¹⁰⁶⁰ compared with watchful waiting; however, larger studies are recommended to prove the utility of this approach.

Pubertal gynecomastia usually resolves spontaneously within 1 to 2 years after onset, and reassurance and continued observation are often adequate treatment. Nevertheless, some boys have conspicuous gynecomastia, and if it lasts longer than 2 years, it is likely to become permanent. These children may have sufficient psychological distress to warrant a reduction mammoplasty. Liposuction is an alternative approach, but its efficacy in adolescent gynecomastia remains to be established. Rarely, untreated gynecomastia persists into adulthood.

Gynecomastia is a component of Klinefelter's syndrome, anorchia, primary and secondary hypogonadism, biosynthetic defects in testosterone synthesis, increased aromatase activity in adipose and other tissues (aromatase excess syndrome), Sertoli cell tumors, adventitious exposure to estrogens in meat or cosmetics, and variants of the androgen resistance syndromes, including Rosewater syndrome (familial hypogonadism and gynecomastia) and Reifenstein syndrome (hypospadias, hypogonadism, and gynecomastia). These disorders usually have characteristic findings or environmental circumstances that allow ready differentiation from the normal gynecomastia of puberty.⁶³³ Gynecomastia has been described in association with the administration of drugs such as cimetidine, spironolactone, digitalis, and phenothiazines, with GH therapy, and with the use of marijuana. The aromatase excess syndrome was described earlier.

Macroorchidism. Macroorchidism, without androgenization, is a rare manifestation of the McCune-Albright syndrome⁹⁶² and an occasional finding in prepubertal boys with long-standing primary hypothyroidism. This form of testicular enlargement appears to result from increased FSH secretion, independent of a pubertal increase in LH secretion or a pubertal LH response to GnRH. Testicular adrenal rests in CAH and lymphoma can cause bilateral macroorchidism. It is a feature of severe aromatase deficiency in young male adults²⁵⁷ and in men with an FSH-secreting pituitary macroadenoma. Bilateral megalotestis (testicular volume, 26 mL) in adults can occur as a normal variant.¹⁰⁶¹ One may speculate that some instances of bilateral macroorchidism are the result of a heterozygous constitutive activating mutation of the FSH receptor. As noted earlier, prepubertal enlargement of the testes was reported with a single-base-pair deletion at codon 434 (1301delT) of the *NR0B1/DAX1* gene and led to prepubertal testosterone and gonadotropin values.⁸⁸¹

The fragile X syndrome is associated with developmental delay, a long face and large prominent ears, and macroorchidism in 80% of affected pubertal boys. Macroorchidism may be evident only after careful measurements. The enlarged testes are caused by increased interstitial volume and excessive connective tissue, including increased peritubular collagen fibers, rather than by an

increase in the seminiferous tubules. Enlargement of the testes is demonstrable in the prepubertal period in most patients with fragile X syndrome, but the onset of true macroorchidism (>4 cm) occurs only in the later prepubertal period.¹⁰⁶²

CHAPTER 26

Hormones and Athletic Performance

FABIO LANFRANCO • EZIO GHIGO • CHRISTIAN J. STRASBURGER

EFFECT OF ATHLETIC PERFORMANCE ON HORMONAL SYSTEMS

Catecholamines

The catecholamines norepinephrine and epinephrine are closely coupled in their actions, and they respond rapidly to exercise. Norepinephrine increases from a resting level of 1.2 to 3.0 nmol/L to levels as high as 12.0 nmol/L at maximal exercise.¹ Resting concentrations of epinephrine are 380 to 655 pmol/L. With maximal exercise, epinephrine concentrations can increase up to 3300 pmol/L. Levels of both hormones progressively increase as workload increases. Resting concentrations are achieved within 30 minutes after exercise.¹

Mild exercise produces little or no catecholamine response, whereas at moderate exercise levels, norepinephrine significantly increases with minimal change in circulating epinephrine. At intense or prolonged exercise levels, levels of both hormones increase significantly.² Acute, short-duration, maximal exercise can significantly increase norepinephrine and epinephrine levels. This rapid response

suggests that the levels are primarily regulated through neural release mediated by activation of the sympathetic nervous system. Spillover from active muscle during exercise appears to be the primary contributor, but the kidneys also are a possible source.¹ Moreover, alteration in the ratio of norepinephrine to epinephrine, with a greater increase in the release of epinephrine from the adrenal medulla during exercise, suggests possible hypothalamic mediation in the response to exercise.

Graded exercise produces a lower catecholamine response than continuous, prolonged exercise. The responses are directly related to workload and oxygen uptake and are greater with small muscle groups than with large muscle groups.

Many studies report a higher epinephrine response to exercise in endurance-trained compared with untrained subjects at the same relative intensity as all-out exercise. This higher capacity to secrete epinephrine was observed in response to both physical exercise and other stimuli such as hypoglycemia and hypoxia.³ For some, this phenomenon partly explains the higher physical performance observed in trained versus untrained subjects. These findings have also been reported for anaerobically trained

subjects in response to supramaximal exercise. Studies assessing women remain scarce; the results are less consistent than those for men, and the effects of aerobic versus anaerobic training on the catecholamine response need to be specified.³

Epinephrine and norepinephrine are responsible for many adaptations at rest and during exercise, including cardiovascular and respiratory adjustments and substrate mobilization and use.³ Redistribution of circulation to working muscles and to the skin for heat loss and sweating is mediated by changes in catecholamines directly or indirectly through other intermediate hormones. Moreover, catecholamines may mediate the improvement of mental performance that occurs with exercise.^{3,4}

Fluid Homeostasis and the Vasopressin–Renin–Angiotensin–Aldosterone System

During physical exercise, there is considerable loss of water and electrolytes in sweat, which maintains body temperature by dissipating heat generated from muscle use. The rate of fluid loss due to sweating may be as high as 1500 mL/hour.⁵ Lost fluids are replaced by subsequent ingestion of liquids, modulated by thirst. Replacement of electrolytes is the result of normal food intake. Renal function is the major mechanism by which electrolytes are conserved after exercise.

Fluid and electrolyte homeostasis depends on the action of arginine vasopressin (AVP), natriuretic peptides, the renin–angiotensin–aldosterone (RAA) axis, and catecholamines. These hormonal systems are modified in response to exercise, with different patterns depending on the amount of relative work performed, the duration of exercise, and the training status. Other factors influencing the hormonal response to exercise include the mode of exercise, environmental factors, age and gender of the subjects, and several medical or physiologic conditions.¹ Hormones involved in the regulation of fluid and electrolyte homeostasis show relatively consistent responses among individuals.

AVP concentrations increase during exercise and persist at elevated levels for more than 60 minutes after maximal exercise. The increase in AVP levels during exercise is stimulated by increased plasma osmolality and reduced blood volume.⁶

Atrial natriuretic peptide (ANP) and brain natriuretic peptide (BNP), which may be altered by exercise,¹ also elicit a natriuretic effect. ANP increase is transitory in response to exercise of extended duration, with hormonal values returning to resting levels over time.⁷ Sodium intake may affect the ANP response to exercise; the ANP increase is higher with a high-sodium diet (300 mmol/day) than in the same subjects with a low-sodium regimen (40 mmol/day).⁸ BNP response to exercise is modulated by sodium intake and hydration status.¹ In several study protocols, BNP levels increased in hypertensive subjects during exercise but no changes occurred in normal subjects.^{9,10}

The RAA system is closely coupled and responds to exercise. Increased values of plasma renin activity (PRA) are reported after maximal exercise.¹ The increase in PRA occurs at submaximal workloads of 60% to 70%. With the increase in PRA during exercise, there is a concomitant increase in angiotensin II, which partially mediates the increase in circulating aldosterone concentrations.¹ Elevated levels of aldosterone may persist for days after the end of exercise, depending on water and sodium intake.¹ The primary activator of the RAA system during exercise is the sympathetic nervous system. Release of renin is

modulated by changes in renal sympathetic nerve activity that increase local norepinephrine levels.¹¹ During exercise, increased renin activity correlates with increased norepinephrine concentration in the renal vein.¹¹ The increase in aldosterone with exercise is assumed to be mediated by the increase in angiotensin II in response to activation of the RAA system. However, inhibition of angiotensin-converting enzyme does not attenuate the increase in aldosterone with maximal exercise in healthy subjects.¹² Other factors involved in the activation of aldosterone production include sodium intake, potassium balance, and levels of adrenocorticotrophic hormone (ACTH). The persistent increase in aldosterone long after exercise ceases may be associated with reductions in plasma osmolality and sodium concentrations due to ingestion of water to replace total body water losses.¹ In this way, the interaction of a number of regulating factors is involved in mediating the response of aldosterone.

Hypothalamic–Pituitary–Adrenal Axis

Glucocorticoids

Since the pioneering studies of Davies and Few, it has been known that exercise of an appropriate intensity is a potent stimulus for cortisol secretion.¹³ Glucocorticoids exert many beneficial effects in exercising humans, increasing the availability of metabolic substrates to supply energy for muscles, maintaining normal vascular integrity and responsiveness, and protecting the organism from an overreaction of the immune system in the face of exercise-induced muscle damage.¹⁴

During acute (short-term) exercise, the hypothalamic–pituitary–adrenal (HPA) axis responds to numerous stimuli, demonstrating the regulatory and integrative functions of the HPA axis. These stimuli include neuronal homeostatic signals (i.e., chemoreceptor, baroreceptor, and osmoreceptor stimulation), circulating homeostatic signals (e.g., glucose, leptin, ANP), and inflammatory signals such as interleukin-1 (IL-1), IL-6, and tumor necrosis factor- α (TNF- α).¹⁵

In humans, physical exercise has a greater effect on ACTH and cortisol secretion than can be accounted for by corticotropin-releasing hormone (CRH) alone. Exercise is accompanied by increased AVP release into the systemic circulation, which occurs in proportion to the intensity of the exercise. In humans, pulses of ACTH and AVP secretion are concordant during exercise.¹⁶

Cortisol response depends on the relative exercise workload for both aerobic and strength exercise, and the rise in plasma cortisol levels is associated with an increase in ACTH concentrations.¹⁷ Moderate- to high-intensity exercise—60% and 80% of maximum oxygen consumption ($\dot{V}O_2\text{max}$), respectively—has been shown to provoke increases in circulating cortisol levels, which seemed to result from a combination of hemoconcentration and HPA axis stimulus (i.e., ACTH). In contrast, low-intensity exercise (40%) did not result in significant increases in cortisol levels.¹⁸

Prolonged submaximal physical activity and very brief high-intensity exercise can activate the HPA axis.^{19,20} Duration of physical activity may be important in determining the response of plasma cortisol to exercise. Plasma cortisol increases more after a 42-km kayak race than after a 19-km race.²¹ During a 6-day Nordic ski race, plasma ACTH levels increased and then remained at similar levels throughout the race, whereas the plasma cortisol concentration was highest during the initial 2 days.²²

The type of exercise influences the cortisol response. In contrast to sustained aerobic activity, intermittent exercise of varying intensities, such as in match-play tennis, does not appear to induce activation of the HPA axis.²³ Isometric exercise activates the HPA axis in an intensity-dependent manner.²⁴ Anaerobic exercise induces a greater increase in plasma cortisol than aerobic exercise with the same total work output.²⁵

Response of the HPA axis to physical activity is independent of age. In elderly men, the cortisol response to heavy-resistance exercise is diminished,²⁶ although a reduced effort may be involved. Earlier activation of the HPA axis, accompanied by a more pronounced increase in the activity of the sympathetic nervous system, has been demonstrated in elderly subjects during submaximal aerobic exercise.²⁷ However, no significant difference in cortisol response to aerobic exercise at the same relative intensity has been observed in young and elderly subjects.²⁸

Gender does not affect cortisol response to physical activity. Although men show predominantly increased autonomic, cardiovascular, and carbohydrate oxidation counterregulatory responses to exercise and women have predominantly increased lipolytic and ketogenic responses, plasma cortisol levels respond similarly in men and women.²⁹

Compared with sedentary women, amenorrheic athletic women and athletic women with regular menstrual cycles have blunted cortisol responses to CRH.³⁰ Female sex steroids may play a crucial role in mediating the adrenocortical response to external stimulation; estradiol may impair the glucocorticoid receptor-mediated, slow, negative feedback. A reduction in free cortisol levels after physical exercise was demonstrated in women who used an estrogen-containing contraceptive, compared with women who did not.³¹ Kirschbaum and coworkers³² found that short-term estradiol administration resulted in hyperresponsiveness of the HPA axis to a standardized psychosocial stress task in healthy men. Altogether, estrogens are potent regulators of the HPA axis.³³

Other factors modify the response of the HPA axis to physical activity. The cortisol response to exercise is modulated by hypohydration, meals, and time of day. Independent of external thermal stress, hypohydration (up to 4.8% loss of body mass) greatly amplifies the exercise-induced responses to cortisol. This enhancement probably results from an increased core temperature and cardiovascular demand caused by decreased plasma volume.³⁴ Meals stimulate cortisol release in humans, and exercise performed immediately after food ingestion results in a blunted cortisol response to the stimulus. The cortisol response to exercise also is significantly modulated by time of day. The incremental response of cortisol to exercise is enhanced during evening exercise compared with morning exercise.¹⁴

Repeated acute or chronic stress reduces the sensitivity of the rat HPA axis to glucocorticoid negative feedback.³⁵ Endurance training has been compared with chronic stress in humans.³⁶ When the HPA axis is repeatedly challenged by exercise, humans demonstrate modifications in the activity of the HPA axis, suggesting adaptation to endurance training. During the past decade, several studies have shown that HPA axis activity in resting conditions is similar in endurance-trained subjects and in healthy sedentary subjects.^{33,37,38} However, when the HPA axis is challenged, endurance-trained subjects demonstrate a decreased pituitary sensitivity to the negative feedback of glucocorticoids, which explains their capacity to successfully achieve a second bout of exercise after a short rest

period.³³ Different mechanisms may be involved in this adaptation. At the central nervous system level, neuropeptides and corticosteroid receptors (e.g., glucocorticoid receptors, mineralocorticoid receptors) in the brain and anterior pituitary play a major role in the regulation of circulating cortisol levels. At the peripheral level, tissue sensitivity to glucocorticoids may be different in endurance-trained and sedentary subjects.³⁹ These adaptation processes are finalized to protect the body from the severe metabolic and immune consequences of increased cortisol levels.

Mineralocorticoids

The RAA system components are closely coupled and respond to exercise. PRA values increase after maximal exercise.¹ Progressively higher increases in aldosterone levels have been observed with increasing degrees of exertion. Increased levels of aldosterone may persist for days after the end of exercise, depending on water and sodium intake.¹

Several regulating factors interact to mediate the response of aldosterone. They include the sympathetic nervous system, renin activity, angiotensin II levels, sodium intake, potassium balance, blood volume reductions, and levels of ACTH.¹

Endorphins

Exercise can influence the release of β -endorphin, depending on the intensity and duration of physical activity. If a threshold intensity is exceeded, endogenous opiate levels start to increase. Incremental graded exercise tests elevate β -endorphin levels 1.5- to 7-fold. Short bouts of anaerobic exercise induce a twofold to fourfold increase in β -endorphin levels, depending on the duration of exercise stress.⁴⁰ Lactate and catecholamine concentrations are the main factors correlated with these responses. Duration of aerobic exercise seems to be an independent factor that stimulates β -endorphin release after about 1 hour if a threshold intensity—approximately 55% to 60% of $\dot{V}O_{2\max}$ —is reached.

The psychological and physiologic stresses related to competitive activities are thought to stimulate the secretion of endorphins to counter these negative effects.⁴¹ Little is known about the influence of training status on the release of β -endorphin, and study results are often inconsistent.

Increased endogenous opiate levels in athletes may modulate pain and improve mood.⁴² Sudden cessation of regular training can generate a depressed mood, which is considered to be part of the “detraining syndrome.”⁴⁰ Overall, the action of endogenous opiates can be described as a reward system that makes the athlete continue physical activity.

Hypothalamic-Pituitary-Gonadal Axis

Male Gonadal Axis

The effects of physical activity on the male reproductive system vary with the intensity and duration of exercise, the fitness level of the individual, and his nutritional-metabolic status. Relatively short, intense exercise usually increases serum testosterone levels, and more prolonged exercise usually decreases these concentrations. Endurance and other forms of training can induce subclinical inhibition of normal reproductive function, although clinical expression of reproductive dysfunction with exercise is uncommon in men.⁴³

Increased serum testosterone levels have been reported during relatively strenuous free and treadmill running, weight training, and ergometer cycling.⁴³ The testosterone response increases with increased exercise load.⁴⁴ Similar workloads produce similar responses, regardless of whether the load is aerobic or anaerobic.²⁵ Increased and decreased ambient temperature, altitude, and dehydration have no effect on testosterone response to intense exercise.^{45,46} Acute exercise-induced testosterone increments also are seen in older men, despite their different hormonal profiles.²⁶

Evidence about the gonadotropin response to exercise is inconsistent, because luteinizing hormone (LH) and follicle-stimulating hormone (FSH) levels have been reported to be unchanged, increased, or decreased by short-term strenuous exercise.⁴³ Because the LH response to exercise is inconsistent and because testosterone levels increase in response to exercise more quickly than in their response to LH, it is accepted that the exercise-associated increment in circulating testosterone is not mediated by LH. Possible mechanisms, such as hemoconcentration, reduced clearance, or increased testosterone synthesis, may be involved. If nonspecific mechanisms were responsible for the acute increase in serum testosterone levels, a similar increase would be expected for all circulating steroids.⁴³ However, timing of the testosterone increase differs from that of androstenedione and dehydroepiandrosterone,⁴⁷ suggesting that specific testicular mechanisms are involved.

In contrast to the short-term testosterone increment, suppression of serum testosterone levels occurs during and after more prolonged exercise and to some extent in the hours after intense, short-term exercise. During past decades, many investigative studies demonstrated that chronic exposure to endurance exercise training can result in a dysfunction within the reproductive-focused components of the neuroendocrine system. Most studies concentrated on women, but the effects of endurance exercise training on the male reproductive neuroendocrine system were also investigated, beginning in the 1980s.⁴⁸ Research in exercising men demonstrates the existence of a select group who, through chronic exposure to endurance exercise training, have developed alterations in their reproductive hormonal profile (i.e., persistently low basal resting testosterone concentrations).⁴⁹ Most of these men have clinically normal testosterone concentrations, but these concentrations are at the low end of the normal range or even reach subclinical status. The health consequences of such hormonal changes are increased risk of abnormal spermatogenesis, male infertility, and compromised bone mineralization.⁴⁹⁻⁵¹ The prevalence of these health problems seems to be low, but there have been few investigative studies examining this condition and its consequences.^{49,50}

The specific terminology used to refer to this condition has not been universally accepted. In 2005, Hackney and associates proposed *the exercise-hypogonadal male* as a label for this condition.⁵²

A variety of systems may influence the decrease in testosterone synthesis during and after prolonged exercise. Exercise-hypogonadal men frequently display a lack of significant elevation in basal LH that corresponds with the reduced testosterone concentration, reflecting hypogonadotropic-hypogonadal characteristics.^{48,49,53} These LH abnormalities may involve disparities in LH pulsatility (i.e., pulse frequency and amplitude), although evidence for altered LH pulsatile release is inconsistent.⁵⁴ Moreover, the gonadotropin response to gonadotropin-releasing hormone (GnRH) may be reduced or increased after prolonged, exhaustive exercise.⁵⁵

Exercise-hypogonadal men have altered basal prolactin levels.⁴⁹ At excessively low or high circulating levels, prolactin suppresses testosterone levels in men.⁵⁶ It has been speculated that the absence of prolactin at the testicle alters the ability of LH to stimulate testosterone production. This theory is based on the proposed synergistic effects of prolactin on testicular LH receptors.⁴⁸ However, not all investigators reporting low resting testosterone levels in endurance-trained men have reported the concomitant existence of low resting prolactin levels.⁵⁶ Some studies have focused on a potential relationship between high prolactin levels and low testosterone concentrations, speculating that any "stressful" situation may provoke disproportionate prolactin responses in exercise-hypogonadal men and that this may ultimately promote a reproductive axis disruption.⁵⁷

Leptin is an adipocyte-released hormone associated in part with communicating hypothalamic satiety and the status of energy reserves.⁵⁸ It is also linked to reproductive function in women and men. Acute and chronic exercise can affect resting leptin concentrations, independent of changes in body adiposity.⁵⁹ However, no studies have examined whether leptin concentrations are altered in exercise-hypogonadal men.

Ghrelin is another hormone associated with appetite regulation. Emerging evidence from animal and human experiments suggests that ghrelin may function as a metabolic modulator of the gonadotropic axis, with predominant inhibitory effects in line with its role as a signal of energy deficit.^{60,61} Acute and chronic exercise can influence ghrelin concentration levels.⁶² However, no studies have examined whether ghrelin levels in exercise-hypogonadal men are normal.

Investigations of peripheral mechanisms have focused on alterations in the testicular ability to produce and secrete testosterone and to respond to exogenous stimuli (i.e., LH or human chorionic gonadotropin [hCG]). Animal studies have demonstrated that exercise training compromises testicular enzymatic activity,⁶³ but data for exercise-hypogonadal men are contradictory. Some investigations suggest that testicular steroidogenesis is normal, whereas others indicate it is marginally impaired when challenged with exogenous stimuli.⁴⁹

Cortisol is another potentially disruptive hormone for the gonadal axis. Cumming and associates⁶⁴ demonstrated that the direct infusion of cortisol in men resulted in concurrent declines in testosterone levels. However, among the hormonal profile studies reporting the existence of low testosterone in trained men, none has reported elevated resting cortisol levels.^{48,65,66} The role of cortisol in the gonadal axis changes observed in trained men requires further study.

Female Gonadal Axis

The endocrine equilibrium that regulates female reproductive function can be affected by physical and psychological factors. Women who engage in regular, high-intensity exercise may be at risk for menstrual disturbances such as delayed menarche, oligomenorrhea, amenorrhea, and luteal-phase defects.⁶⁷ Impaired production of gonadotropins, which leads to luteal-phase deficiency and anovulation, is a common hormonal finding in women with exercise-induced menstrual disturbances, but several other hormones may also show significant alterations.⁶⁸

Although factors such as the physical or psychological stress of competition have been postulated to underlie exercise-induced reproductive disorders, accumulated evidence indicates that negative energy balance is the primary

cause of the impairment of normal reproductive function commonly observed in female athletes.⁶⁹⁻⁷² In 1939, Hans Selye reported that "the ovaries undergo atrophy and more or less permanent anestrus ensues" when young female rats are forced to exercise for prolonged periods.⁷³ Selye observed a *general adaptation syndrome* that involved hypertrophy of the adrenal glands, cessation of growth and lactation, liver shrinkage, loss of muscular tone, decreased body temperature, and disappearance of adipose tissue.⁷⁴ In 1980, Warren was the first to suggest that menstrual cycles in dancers are disrupted by an "energy drain."⁶⁹ In 1984, Winterer and colleagues hypothesized that a lack of sufficient metabolic fuels to meet the energy requirements of the brain causes an alteration in brain function that disrupts the GnRH pulse generator, through an unknown mechanism.⁷⁵ The energy availability hypothesis was supported by endocrine observations of athletes. Amenorrheic athletes have low 24-hour blood glucose levels, low 24-hour insulin levels, and high 24-hour levels of insulin-like growth factor-binding protein 1 (IGFBP1),⁷⁶ as well as loss of the leptin diurnal rhythm⁷⁷ and low T3 levels in the morning.⁷⁸ Loucks and coworkers⁷⁰ found that low energy availability reduced LH pulse frequency and increased LH pulse amplitude and that exercise stress had no suppressive effect on LH pulsatility beyond the impact of the energy cost of exercise on energy availability. LH pulsatility was disrupted regardless of whether energy availability was reduced by extreme energy restriction alone, by extreme exercise energy expenditure alone, or by a combination of moderate dietary energy restriction and moderate exercise energy expenditure. Dietary supplementation prevented the suppression of LH pulsatility by exercise energy expenditure. Later experiments on female monkeys induced amenorrhea by increasing the volume of exercise training without increasing dietary energy intake⁷⁹ and then restored ovulation by increasing dietary energy intake without moderating the exercise regimen.⁸⁰

To investigate the dose-response relationship between energy availability and LH pulsatility in exercising women, Loucks and associates⁸¹ administered balanced energy intake or one of three low-energy availabilities (45 and 10, 20, or 30 kcal/kg fat-free mass [FFM] per day, respectively) to healthy, habitually sedentary, regularly menstruating, older adolescent women for 5 days. LH pulsatility was disrupted only with energy availabilities below 30 kcal/kg FFM per day. This finding was consistent with the results of many studies of amenorrheic runners, all of which indicated disruption at energy availabilities of less than 30 kcal/kg FFM per day.⁸² Only one prospective study showed that refeeding of amenorrheic runners restored menstrual cycles by increasing energy availability from 25 to 31 kcal/kg FFM per day.⁸³

The discovery of leptin in 1994 was fundamental in clarifying the relationship between negative energy balance and reproductive dysfunction.⁸⁴ Various data sets suggest that leptin may provide the central nervous system with information on the critical amount of adipose tissue stores necessary for GnRH secretion and pubertal activation of the hypothalamic-pituitary-gonadal axis. Several unfavorable metabolic situations are associated with low levels of plasma leptin, increased secretion of hypothalamic neuropeptide Y (NPY), and hypogonadism, and a causal relationship has been suggested. Severe dietary restriction in juvenile female rats is associated with low plasma leptin concentrations and sexual immaturity. Cessation of food restriction leads to an immediate increase in plasma leptin levels followed by sexual maturation.⁸⁵ Leptin administration for the relative leptin deficiency in women with

hypothalamic amenorrhea improves reproductive, thyroid, and growth hormone (GH) axes and markers of bone formation, confirming that leptin is required for normal reproductive and neuroendocrine function.^{86,87}

HPA axis activation may be involved in the functional disruption of the gonadal axis during physical exercise. The so-called stress hypothesis proposes that exercise activates the HPA axis, which disrupts the GnRH pulse generator by another, unknown mechanism. Central and peripheral factors may be involved in this dysregulation. Amenorrheic athletes may have mildly elevated cortisol levels,^{76,88} and this observation is the basis for attributing their amenorrhea to stress. Mild hypercortisolism is also associated with amenorrhea in patients with functional hypothalamic amenorrhea and anorexia nervosa.⁸⁹ However, because cortisol is a glucoregulatory hormone activated by low blood glucose levels, the mild hypercortisolism observed in amenorrheic athletes may reflect a chronic energy deficiency rather than exercise-induced stress.⁹⁰

Some investigators think that endogenous opioid peptides and catecholestrogens are involved in provoking menstrual irregularities in women athletes.⁹¹ In basal circumstances, β -endorphin may decrease LH levels by suppressing hypothalamic GnRH; some catecholestrogens may suppress LH levels, and others seem to potentiate and induce an LH surge. The activities of β -endorphin and catecholestrogens depend on a sufficiently estrogenic environment. Endogenous opioid peptides and some of the catecholestrogens can suppress prolactin release, probably by interfering with its inhibiting factor dopamine. Increased plasma concentrations of β -endorphin, which are found after physical exercise, suggest their involvement in the common menstrual irregularities of women athletes.⁹¹

Circulating levels of testosterone, dehydroepiandrosterone, dehydroepiandrosterone sulfate, estradiol, GH, and cortisol increase in women in response to an acute bout of endurance exercise. However, only GH, estradiol, and cortisol increase after resistance exercise.⁹²

Hyperandrogenism has been suggested as an alternative mechanism underlying oligomenorrhea or amenorrhea in some female athletes with menstrual disturbances.⁹³ Sports that emphasize strength over leanness, such as swimming and rowing, are not associated with low weight and restrictive eating patterns, but athletes engaged in these sports are vulnerable to menstrual irregularities. The endocrine profile of athletes engaged in these sports is characterized by mildly elevated LH levels, elevated LH/FSH ratios, and mild hyperandrogenism rather than hypoestrogenism. Hyperandrogenic female athletes have a more anabolic body composition and higher $\dot{V}O_{2\max}$ and performance values compared with female athletes with menstrual disturbances but normal androgen concentrations.⁹³

Prolactin

Blood prolactin levels transiently increase during exercise, and this response appears proportional to exercise intensity.^{2,56} Provided the intensity is adequate, the increase in prolactin is quite rapid. Nonetheless, short-term, graded exercise may result in a peak hormonal response after the exercise ends. In some situations, excessive emotional stress can cause an anticipatory increase in prolactin levels even before exercise begins.⁹⁴

During prolonged exercise, the prolactin response is proportional to the intensity at which exercise is performed. However, extending the duration of exercise can augment the magnitude of the prolactin response.⁹⁵

The chronic effects of exercise training on basal, resting prolactin levels are unclear and need further research.

Some studies have found increases in resting levels, but others have found decreased levels.^{48,57} These contradictions reflect differences in training protocols (i.e., intensity, frequency, and duration of training sessions). McMurray and Hackney showed that the prolactin response to submaximal exercise in men was attenuated after training, but the maximal exercise response was augmented.⁹⁴ In men and women who have undergone a training program, the drug-stimulated prolactin response is enhanced.^{65,96}

The mechanisms of prolactin increase with exercise are unclear. Prolactin levels may increase when the anaerobic threshold is reached, perhaps concomitantly with a GH increase.⁹⁷ Even prolonged (i.e., 90 minutes) exercise below this threshold fails to elicit a response.⁹⁸ Prolactin increments with exercise appear to be correlated with proopiomelanocortin derivatives, ACTH, and β -endorphins.⁹⁹ Moreover, increased prolactin levels can be related to changes in body temperature and dehydration, are exaggerated by stress, are reduced with habituation and hypoxia, and are unresponsive to metabolic events.^{2,100}

Growth Hormone and Insulin-Like Growth Factor I Axis

In 1963, Roth and colleagues¹⁰¹ demonstrated that plasma levels of GH increase during exercise, and it was later shown that exercise is the most potent physiologic stimulus to GH release.¹⁰² The GH response to exercise depends on the duration and intensity of exercise, the fitness level of the exercising subject, the refractoriness of pituitary somatotroph cells to the exercise stimuli, and other environmental factors.¹⁰³⁻¹⁰⁵

Lactate and nitric oxide may provide afferent stimulation for the exercise-induced GH response.¹⁰⁶ Several investigators have demonstrated that circulating GH levels increase above the lactate/anaerobic threshold (LAT) but not below it.¹⁰³ In other reports, loads of 75% to 90% of maximal aerobic power yielded a greater GH rise than milder loads.¹⁰² Pritzlaff and coworkers¹⁰⁷ carried out tests at five exercise intensities normalized to each subject's lactate threshold. A linear dose-response relationship between exercise intensity and the GH secretory response was demonstrated, with escalating GH release across the range of exercise intensities (25% to 175% of the lactate threshold). Deconvolution analysis revealed that increased GH levels resulted from an increase in the mass of GH secreted per pulse, with no change in pulse frequency or the half-life of elimination. Later studies by the same group demonstrated that GH secretion positively correlated with the duration of exercise when intensity remained constant,¹⁰⁸ was augmented by repetitive bouts of exercise,¹⁰⁹ but was not influenced by the time of day that exercise was performed.³⁸

Given the influence of intensity of exercise, few studies have investigated the effect of duration of exercise on the GH response, although longer duration of exercise was found to increase the GH response.¹¹⁰ The exercise duration should be at least 10 minutes,¹¹¹ because exercise of shorter duration below and above the lactate threshold was not accompanied by increases in circulating GH levels.¹⁰³ The exercise-induced GH peak occurs 25 to 30 minutes after the start of exercise, regardless of exercise duration.^{103,112} When the task is brief, a peak may be reached after its cessation, but when the task is long (e.g., 45 minutes), the GH peak occurs while the individual is still exercising.^{104,113}

The interaction between duration and intensity of exercise influences GH responses to endurance-type exercise. Short-duration, high-intensity exertion (e.g., 7 minutes of

rowing races for Olympic athletes) provoked remarkable GH responses.¹¹⁴

The nature of the exercise may also influence the GH response. Whereas continuous exercise protocols may be comparable to competition events, the endurance-type training undertaken by many athletes involves intermittent or interval exertion. Comparing exercise at equivalent total workloads, GH levels are lower with continuous exercise (40% to 45% of $\dot{V}O_{2\max}$) than with interval protocols, with twice the work rate for one half of the time, reflecting the greater metabolic stress and lactate levels in the latter situation.¹¹⁵ Incremental GH responses also have been described for resistance exercise.¹¹⁶ The important determinants appear to be the relationship between load and frequency of individual repetitions. Greater GH increments have been reported after so-called hypertrophy protocols (i.e., moderate loads and high number of repetitions) than after strength protocols (i.e., heavy loads and low repetitions) in both men and women.¹¹⁰

There is conflicting evidence regarding the neuroendocrine pathways that regulate GH secretion during exercise. Mechanisms involving cholinergic, serotonergic, α -adrenergic, dopaminergic, and opioidergic pathways have been proposed.^{2,117,118} There may be interactions among the pathways, and they may operate at different exercise intensities.

In young men and boys, regular but not sporadic exercise is associated with higher GH production, and it augments GH release by GHRH.¹⁰⁹ This effect may be caused by decreased hypothalamic somatostatinergic activity and higher growth hormone pulsatility.

Fluid intake influences exercise-induced GH release. The increased rate of sweating during physical activity performed without water ingestion results in dehydration and lower GH response to exercise.¹¹⁹

Environmental elements, nutritional factors, and some pathologic states may interfere with the GH response to exercise. Cappon and associates¹²⁰ showed that a high-fat meal inhibits the magnitude of GH response to exercise, and inhibition of the exercise-induced GH response is correlated with circulating levels of somatostatin.

High ambient temperature alone may increase circulating GH levels,¹²¹ whereas low temperature attenuates GH release.¹²² Obesity and polycystic ovarian syndrome are characterized by attenuated GH response to exercise.¹²³

Gender governs the relationship between exercise intensity and GH release. For each incremental increase in exercise intensity, the fractional stimulation of GH secretion is greater in women than in men. Moreover, women have greater basal (nonpulsatile) GH secretion across all conditions, more frequent GH secretory pulses, a greater GH secretory pulse amplitude, a greater production rate, and a trend for a greater mass of GH secreted per pulse than men.¹²⁴ The more intense GH secretion in women is related to estrogens. Oral and transdermal estrogen administration increase GH release in postmenopausal women,¹²⁵ and younger women receiving oral contraceptive therapy exhibit greater GH responses to exercise than nontreated women.¹²⁶

The GH response to exercise (e.g., the 24-hour GH secretion rate) declines with age.¹¹⁸ Even those in early middle age (mean age, 42 years) had greatly attenuated GH responses to exhaustive exercise compared with younger subjects (mean age, 21 years).¹²⁷ However, it is difficult to separate the effects of aging from changes in body composition, because body fat increases with age, and GH secretory rates are reduced in overweight subjects.¹²⁸

Kelley and colleagues¹²⁹ found a significant positive correlation between $\dot{V}O_2\text{max}$ and circulating levels of GH and IGF type 1 in healthy premenopausal and postmenopausal women. They found that $\dot{V}O_2\text{max}$ and IGF1 concentrations decline with age. However, when the influence of age and fitness was analyzed using multiple regression, $\dot{V}O_2\text{max}$ remained the only independent predictor of IGF1 concentrations. The investigators concluded that the decrease in serum IGF1 levels with age is not related directly to aging but probably to an age-related decline in physical activity and fitness.

Exercise exerts acute effects on other components of the GH/IGF1 axis. The effect of exercise on circulating IGF1 has been examined by several investigators with differing results. Wilson and Horowitz¹³⁰ reported no increase in serum IGF1 levels in children after 15 minutes of a cycle ergometer exercise protocol. Hagberg and coworkers¹³¹ did not find an increase in IGF1 levels after 60 minutes of treadmill exercise at 70% of subjects' $\dot{V}O_2\text{max}$ in young and old adults. Moreover, the effect of exercise on IGF1 appears to depend on the type of exercise performed.¹⁰⁴ Schwarz and coworkers¹³² showed that IGF1 increases after 10 minutes of exercise both below and above the LAT. This study suggested that the increase in IGF1 accompanying exercise is not related to GH.

The transient nature of IGF increases suggests that hemodynamic or metabolic effects of exercise may play a role. Exercise in humans is accompanied by the rapid "hemotransfusion" of hemoconcentrated blood from the spleen into the circulation by increased blood flow to the exercising muscle and by loss of plasma water. These phenomena may explain in part an increased IGF concentration by changes in IGF flux or volume of distribution.

Longer periods of exercise training stimulate *IGF1* gene expression in both central neuroendocrine and local tissue components of the GH/IGF1 system. Zanconato and associates¹³³ found that 4 weeks of endurance training by young rats increased hepatic and muscle *IGF1* gene expression and muscle IGF1 protein levels. Eliakim and coworkers¹³⁴ showed that muscle IGF1 protein concentrations in rats increased with endurance training, despite lack of change in muscle IGF1 mRNA or serum IGF1 levels.

Few studies have investigated the response of insulin-like growth factor-binding proteins (IGFBPs) to exercise. IGFBP1 levels did not to change during 30 minutes of moderate exercise,¹¹⁰ but increased transiently after short-term exercise.¹³⁵ The physiologic role of the post-exercise increase in IGFBP1, given the IGFBP1 inhibition of IGF1's metabolic actions, may be to prevent late hypoglycemia.¹³⁵

Schwarz and colleagues¹³² demonstrated that IGFBP3 levels increased with low- and high-intensity exercise and that high-intensity exercise increased IGFBP3 proteolysis. A transient increase in IGFBP3 levels in response to short-term exercise was confirmed by Wallace and coworkers,¹³⁵ who described an immediate increase of all components of the ternary complex: IGF1, IGFBP3, and the acid-labile subunit (ALS) of the IGF-binding protein complex.

Eliakim and associates¹³⁶ correlated functional and structural indices of fitness with mean overnight GH levels, growth hormone-binding protein (GHBP), and serum IGF1 levels in late-pubertal adolescent girls. Moreover, thigh muscle volume was inversely correlated with IGFBP2 and IGFBP4.

Wallace and colleagues described an acute increase in serum GHBP in response to short-term exercise.¹³⁵ In a person at rest, GHBP dampens GH oscillation, and the study authors speculated that the postexercise increase in GHBP

levels may prolong the GH signal, increasing the GH-mediated signal for postexercise protein synthesis, tissue repair, and muscle glycogen replenishment. The increment in the serum GHBP concentration may represent increased synthesis by the liver or reduced clearance.¹³⁵

Hypothalamic-Pituitary-Thyroid Axis

Exercise has effects on thyroid function, which can be viewed as an adaptive mechanism associated with enhanced performance, possibly providing a better balance between energy consumption and expenditure. Short-term, incremental exercise (≥ 20 minutes) increases blood thyroid-stimulating hormone (TSH) levels, with a critical intensity threshold of approximately 50% or more of maximal oxygen uptake ($\dot{V}O_2\text{max}$) necessary to induce significant changes.^{94,137} Even when the TSH level is elevated, most research involving short-term exercise indicates total and free thyroxine (T_4) and triiodothyronine (T_3) are not immediately affected.⁹⁴ On the other hand, total T_4 and T_3 levels can increase after short-term exercise, although these findings are primarily linked to exercise-induced hemoconcentration.¹³⁸

The influence of prolonged, submaximal exercise (approaching 60 minutes) on thyroid hormones is controversial. Some investigations have found no effect on blood TSH levels,^{94,137} whereas others have reported that TSH, free T_3 (ft_3), or both increase progressively with high-intensity, steady-state workloads.¹³⁹ Conversely, Hackney and Gullledge¹⁴⁰ found total T_3 was unchanged but that total T_4 was increased by 60 minutes into a prolonged, steady-state, submaximal exercise session. However, Galbo¹³⁷ reported highly strenuous, prolonged exercise to exhaustion increased only circulating ft_4 levels. Some investigators reported that repeated days of stressful, demanding physical activity substantially reduced T_4 , T_3 , and TSH levels.⁹⁴ These divergent findings are difficult to interpret because of the different durations and intensities of exercise and the various blood sampling protocols employed.¹⁴¹

The effects of chronic exercise on thyroid hormone parameters have been studied in endurance athletes, with conflicting results about whether baseline hormonal levels are shifted in well-trained athletes. Regular bicycle ergometry training in recreational athletes over 6 weeks did not change the TSH or TSH response to TRH stimulation.¹⁴² Other studies indicate that intensive anaerobic exercise (e.g., cycling interval training) increases total T_4 levels for several hours after the exercise but do not affect T_3 .^{94,140} These changes appear not to depend on hemoconcentration alone, but to what extent they result from increased T_4 secretion versus a suppressed metabolic clearance rate is unclear.¹⁴¹ Research is sparse on the effects of resistance exercise, which tends to be anaerobic in nature, on the thyroid.

Several procedural limitations exist in many exercise studies. In some situations, influential factors such as environment, dietary practices, and diurnal hormonal secretion patterns are not controlled effectively and therefore cannot be separated from the influence of exercise alone.¹⁴¹ For example, variations in ambient temperature appear to alter the thyroid hormone response to exercise. TSH and ft_4 levels rose in swimmers exercising in cold (22° C) water, were unchanged at 26° C, and fell at warm (32° C) water temperatures.¹⁴³

Energy balance plays an important role in the body's thyroid hormone response to exercise. Loucks and coworkers¹⁴⁴ found a decrease in T_3 and ft_3 , along with an increase

in reverse T_3 (rT_3) in healthy women undergoing aerobic exercise testing with low caloric intake. This low- T_3 syndrome was not seen in individuals receiving a higher caloric diet. Even mild energy deficiencies may influence thyroid hormone levels. Female gymnasts with borderline energy deficit had a decrease in T_3 and increase in T_4 levels during 3 days of heavy workouts.¹⁴⁵ Energy balance has also been investigated in women runners. Those with negative energy balance had a decrease in T_3 and fT_3 but had an increase in rT_3 levels.¹⁴⁴

Overall, exercise-induced thyroid function changes are influenced by many factors. In various studies, TSH, T_4 , fT_4 , T_3 , and fT_3 levels have been unaffected, increased, or decreased, depending on the type and duration of exercise, ambient temperature, and energy intake. One of the more consistent findings is an increase in rT_3 , particularly when a caloric energy deficiency is associated with exercise.

Insulin and Glucose Metabolism

Physical activity affects the metabolism of glucose and other intermediate substrates in normal persons and in those with diabetes mellitus.¹⁴⁶ The effects of exercise on carbohydrate metabolism are complex and involve type, intensity, and duration of exercise; changes in body composition; alterations in other behaviors, such as food intake; degree of insulin deficiency; and the time course of the glucose-insulin response.¹⁴⁷

During moderate exercise, insulin levels remain unchanged over the first 40 to 60 minutes of exercise. More prolonged or strenuous exercise causes a decline in insulin levels.¹⁴⁸ Counterregulatory hormones, such as catecholamines, glucagon, GH, and cortisol, tend to increase, inducing hepatic glycogenolysis, gluconeogenesis, and lipolysis to provide increased free fatty acids for use as a metabolic fuel.

During short-term, strenuous exercise, when levels of the counterregulatory hormones increase, glucose levels may be elevated transiently. After exercise, insulin levels may rapidly return to baseline. Glucose uptake by exercising muscles is remarkably increased due to an increase in blood flow to the muscle during activity, in the number of insulin receptors, and in the number and intrinsic activity of glucose transporter proteins in the plasma membrane of skeletal muscle.¹⁴⁹ The muscle glucose uptake, which is not directly mediated by insulin, requires at least basal levels of insulin.¹⁵⁰ Increased insulin availability above basal levels has little effect on glucose transport, and the supply of glucose to the muscle is maintained during exercise despite decreased insulin levels.

Insulin also plays a role in controlling the sensitivity of hepatic glucose production.¹⁵¹ Changes in insulin and glucose levels are needed for optimal activity to occur.²

Glucagon levels increase during strenuous exercise, whereas the response varies at lesser intensities.² During prolonged, mild-intensity exercise by healthy persons, the rise in glucagon is essential for increased hepatic glucose production and increased gluconeogenesis.¹⁵² Decreasing blood glucose levels stimulate glucagon, and the glucagon response usually is blunted by preloading with glucose. Levels of glucagon usually correspond significantly with epinephrine and norepinephrine levels, although the sympathoadrenal system seems to be more important in maintaining euglycemia and enhanced hepatic production of glucose.¹⁵³

In normal individuals, major alterations in blood glucose levels usually do not occur, despite the increase in glucose use by skeletal muscle. With the onset of activity,

activation of the α -adrenergic system inhibits insulin release from the pancreas. This results in an increased rate of lipolysis in the periphery and stimulation of hepatic glucose output. As glucose levels begin to fall, glucagon levels rise, further stimulating hepatic glucose output. As the plasma glucose concentration drops toward hypoglycemic levels, epinephrine is released, further stimulating hepatic glucose production and increasing lipolysis in the periphery. The increased availability of free fatty acids for muscle metabolism helps to restrain the rate of glucose use. When one of these mechanisms fails, the others can largely compensate, avoiding hypoglycemia.¹⁴⁷

Training reduces basal insulin levels and exercise-associated changes in glucagon and insulin levels. Training increases insulin sensitivity at rest and in response to a glucose load, and it reduces the rate of insulin decline during short-term exercise.^{2,154}

Regular exercise has become an integral part of the treatment recommendations for type 2 diabetic patients, because it improves insulin sensitivity and reduces average blood glucose concentrations.¹⁵⁵ Physical training increases insulin-stimulated glucose disposal and improves glucose control in type 2 diabetes. However, the increase in insulin sensitivity is rapidly lost if exercise is not performed on a regular basis. Exercise also may be effective in delaying or preventing the development of type 2 diabetes.¹⁵⁵

USE OF PERFORMANCE-ENHANCING HORMONES

Anabolic Steroids

Anabolic-androgenic steroids (AASs) are chemically modified analogues of testosterone. First isolated in 1935, AASs have been modified many times to maximize the anabolic effects of the drug and to minimize the androgenic effects by alkylation of the 17α position or carboxylation of the 17β -hydroxyl group on the sterol D ring. These analogues are degraded much more slowly than endogenous testosterone, resulting in a higher prolonged concentration of the analogue.^{156,157} The AASs used for nontherapeutic purposes are endogenous androgens (e.g., androstenedione, dehydroepiandrosterone [DHEA]); 17 -esters of testosterone (e.g., cypionate, enanthate, heptylate, propionate, undecanoate, bucylate); 17α -alkyl derivatives of testosterone (e.g., methyltestosterone, fluoxymesterone, oxandrolone, stanozolol); 19 -nortestosterone (e.g., nandrolone); 17β -esters of 19 -nortestosterone (e.g., decanoate, phenylpropionate); 19 -norandrostenedione and 19 -norandrostenediol; and tetrahydrogestrinone. More than 100 different AASs have been developed, with most of them being used illegally, synthesized in clandestine laboratories, commercialized without medical prescription or safety controls, and sometimes unknown to the scientific world (Table 26-1).¹⁵⁷

AASs have been used in sports for more than 50 years and represent the class of substances most frequently detected in human sports doping control analyses.¹⁵⁸ Although their use is most common among weight lifters and heavy throwers, almost all types of athletes whose event requires explosive strength, including football players, swimmers, and track and field athletes, have been known to use steroids. Steroid hormones or synthetic analogues of steroid hormones promote tissue growth and masculinization; the androgenic compounds are widely used to enhance lean body mass and to improve sport performance. The anabolic-androgenic activity of each

TABLE 26-1

Performance-Enhancing Hormones**Anabolic Androgenic Steroids**

17 β -Esters of testosterone (cypionate, enanthate, heptylate, propionate, oxandrolone, bucyclate)
 17 α -Alkyl derivatives of testosterone (methyltestosterone, fluoxymesterone, oxandrolone, stanozolol)
 19-Nortestosterone (nandrolone)
 17 β -Esters of 19-nortestosterone (decanoate, phenpropionate)

steroid compound is a function of its chemical structure and metabolites, and its activity can vary considerably. These drugs may act by binding with androgen and glucocorticoid receptors, by exerting central and peripheral effects on neurotransmitters, and by interacting with IGF1 or its binding proteins in the circulation or in the muscles.¹⁵⁷

Surveys of AAS abuse by gymnasia users in the United Kingdom found that about 5% were using these drugs, whereas among people attending gyms equipped for competitive bodybuilding, the proportion of current or previous users was between 25% and 50%.^{159,160} Similar surveys indicate a high prevalence of use in the United States.¹⁶¹ Current estimates indicate that there are as many as 3 million AAS users in the United States and that 2.7% to 2.9% of U.S. young adults have taken an AAS at least once in their lives.¹⁶² Two thirds of AAS users are noncompetitive recreational body builders or nonathletes, who use these drugs for cosmetic purposes rather than to enhance sports performance.^{157,163,164}

During the past decade, careful scientific study of suprapharmacologic doses supports the anabolic efficacy of AAS regimens. Medical use of AAS for the treatment of hypogonadal men, age-related sarcopenia, and HIV-related muscle wasting has gained interest.^{163,165}

The positive effects of steroids on body composition include increased FFM, decreased total body fat, and a decrease in the percentage of body fat located in the gluteal, femoral, and triceps regions in women.^{164,166} The effects of anabolic steroids on lipolysis and skeletal muscle mass are potentiated by caloric restriction¹⁶⁶ and mechanical loading.¹⁶⁷

Skeletal muscle is a primary target tissue for the anabolic effects of AAS. The action of AAS in stimulating growth of skeletal muscles in subjects with low circulating testosterone levels, such as women and children, is undisputed. However, an early and comprehensive review of previous results concluded that there was little evidence for supraphysiologic doses of testosterone or synthetic AAS having any appreciable effect on muscle size or strength in healthy men.¹⁶⁸ Even so, many of the studies reviewed lacked adequate controls and standardization. Conclusions from later reviews suggested that the administration of AASs could consistently result in significant increases in strength if male athletes satisfied certain criteria, including the timing of doses and dietary factors.^{169,170} In 1996, Bhasin and associates¹⁶⁷ demonstrated that the administration of supraphysiologic doses of testosterone in combination with

exercise in male weight lifters increased muscle size and strength compared with exercise alone or testosterone treatment alone (i.e., the effects of combining supraphysiologic doses of testosterone with exercise are additive). Subsequent work showed that increases in FFM, muscle size, strength, and power are highly dose dependent and correlated with serum testosterone concentrations.^{171,172}

The anabolic effect of testosterone is dose dependent, and significant increases in muscle size and strength occur with doses of 300 mg per week or higher.^{171,173} Muscle size increases because of hypertrophy that results from an increase in cross-sectional area in both type I and type II muscle fibers and an increase in myonuclear number.¹⁷³

In postmenopausal women undergoing caloric restriction, administration of 30 mg of nandrolone decanoate every 2 weeks for 9 months increased FFM, decreased body fat, redistributed abdominal body fat from subcutaneous to visceral stores, and increased thigh muscle cross-sectional area compared with measurements in a control group.¹⁶⁶ Evidence of the effects of anabolic steroids on body fat distribution in young adult females has been accumulated from studies of women undergoing gender reassignment and women athletes. Women ingesting high doses of androgens experience a shift of body fat from a gynoid to an android distribution and a decrease of subcutaneous body fat in the abdomen, hip, and thigh regions.¹⁷⁴ In contrast, postmenopausal women treated with estrogens maintain a gynoid fat pattern, suggesting that fat distribution patterns are controlled by the ratio of circulating estrogens to androgens.

Investigations into the performance-enhancing effects of anabolic steroids began in the late 1960s and continued into the early 1980s. Some studies demonstrated a positive effect of steroids on strength when drug abuse was combined with resistance training, but others did not.

Since 1994, a few studies have documented the performance-enhancing effects of anabolic steroids in athletes and healthy men.^{167,175} AASs have improved exercise tolerance and the adaptability of muscle to overload by protecting against muscle fiber damage and increasing the rate of protein synthesis during recovery.¹⁷⁶ However, several issues remain unresolved regarding the use of AASs for athletic enhancement. The minimal dose of a steroid or combination of steroids needed to produce significant increases in strength and muscle mass in healthy, resistance-trained men and women are unknown. Moreover, the theory that several different anabolic steroids used concurrently can elicit a significantly greater anabolic effect than any single drug has not been evaluated in controlled studies. It has been speculated that gains in lean mass and strength acquired while using steroids are maintained indefinitely after cessation of drug treatment, but supportive studies are lacking.¹⁵⁷

The types and doses of AASs used by athletes are not easy to define, because it is difficult to obtain accurate drug-use information from athletes. In a survey conducted in Great Britain, most male anabolic steroid users reported that testosterone or nandrolone esters were the drugs of choice, whereas women preferred oxandrolone, stanozolol, and methandienone.¹⁶⁰ Testing by International Olympic Committee laboratories in 1993 revealed that the most commonly detected steroids were testosterone (32.5%), nandrolone (23.9%), stanozolol (11.4%), metandienone (10.7%), and methenolone preparations (7.7%).¹⁷⁷ Another study suggested that methyltestosterone and norethandrolone were the drugs most commonly used by athletes.¹⁷⁸

The dose of AAS used by athletes varies considerably and is often thought to exceed 10 to 40 times the

recommended therapeutic dose.¹⁷⁸ In a survey of 100 male AAS users, the drug dosages ranged from 250 to 3200 mg per week of testosterone or its equivalent.¹⁷⁹ Fifty percent of the AAS users in this sample reported using a weekly dose of at least 500 mg. To achieve these supraphysiologic doses, 88% of AAS users in this sample combined two or more types of AAS, a process known as *stacking*.

In most surveys, the duration of steroid administration (i.e., steroid cycle) lasts between 4 and 12 weeks.¹⁶³ The time interval between steroid cycles is more variable. Regular users allow a 4- to 6-week drug holiday, whereas less frequent users may remain drug free for months.¹⁶³ In one survey, approximately one half of the sample reported that their total annual AAS use was less than 6 months, whereas the other half used AASs for more than 6 months each year.¹⁷⁹ Three of the 100 AAS users surveyed admitted to continuous use of steroids for 52 weeks of the year.

The numerous side effects associated with AAS use involve multiple organ systems.^{157,164,180} With the exception of the association between hepatic dysfunction and the use of some oral AASs,¹⁸¹ many of the reports of serious side effects in otherwise healthy individuals have come from anecdotal case studies.¹⁸² Confounding factors, such as undiagnosed preexisting conditions, family history, and concurrent use of other drugs, further dampen the credibility of case reports. Moreover, because most anabolic steroids are obtained on the black market and are of dubious quality, there is potential for adverse medical events to occur independent of steroid use. However, data from larger observational studies^{179,183} suggest that most (88% to 96%) AAS users experience at least one minor subjective side effect, including acne (40% to 54%), testicular atrophy (40% to 51%), gynecomastia (10% to 34%), cutaneous striae (34%), and injection-site pain (36%) (Table 26-2). However, many of the adverse effects can be difficult to recognize without a thorough medical examination, and other damaging effects, such as the potential harmful changes in the cardiovascular system, are insidious and often unrecognized by the athletes themselves.¹⁶⁴

Dyslipidemia and cardiovascular disease have been linked with the use of AASs. In general, the ingestion of oral C17 α -alkylated anabolic steroids causes an average 30% decrease in high-density lipoprotein (HDL) cholesterol and an average 30% increase in low-density lipoprotein (LDL) cholesterol.¹⁸⁴ The mechanisms for this effect are unknown, but they apparently include increased activity of hepatic triglyceride lipase, which catabolizes HDL particles. Most studies indicate that injectable non-C17 α -alkylated anabolic steroids, such as testosterone and nandrolone esters, exert minimal adverse effects on blood lipids.^{167,184} AASs may influence platelet aggregation and the myocardium, although the relationship between these effects and cardiovascular disease is unclear.¹⁸⁵ Occasional reports of cardiomyopathies and arrhythmias associated with steroid use have been published, and several mechanisms have been proposed.¹⁸⁵ It is unclear whether the adverse changes in blood lipids as a function of testosterone use lead to an increase in the incidence of coronary artery disease.

Liver disease is a well-documented side effect of most C17 α -alkylated AASs, the exception being oxandrolone. In contrast, most non-C17 α -alkylated steroids exert minimal hepatotoxicity. Liver pathologies associated with anabolic steroids include cholestasis, peliosis hepatis, hepatocellular adenoma and carcinoma, and hepatic angiosarcoma and cholangiocarcinoma.^{163,181}

Potential effects on the reproductive system include infertility and testicular atrophy in men and menstrual and genital tract alterations in women.¹⁶³ Although all AASs

suppress the hypothalamic-pituitary axis to some extent, the resulting infertility in males usually is reversible. There are concerns about potential effects of androgens on the risk of prostate disease. The long-term effects of supraphysiologic doses of androgens on the risk of prostate cancer, benign prostatic hyperplasia, and lower urinary tract symptoms are unknown.¹⁸⁶ The effects on the prostate likely depend on the chemical structure and androgenicity of the drugs.

The effects of AAS use on fertility in women are unknown. High doses of androgens decrease circulating FSH and sex hormone-binding globulin concentrations in eugonadal women,¹⁸⁷ whereas no changes are observed in mean nadir and LH pulse amplitude and in circulating concentrations of estradiol, estrone, and adrenal steroids.¹⁸⁸

Menstruation is diminished or absent in steroid users, but ovulation may occur.¹⁸⁹

All AASs may cause some degree of acne if taken in high doses.¹⁸⁶ This is particularly true for strong androgen preparations, which may cause severe, scarring acne.

With the exception of oxandrolone and perhaps of methenolone, if used intermittently in modest doses, AAS use by most women will cause some form of permanent virilization. The degree of virilization depends on the drug, the dose, the duration of use, and the individual response. Body composition changes during steroid use are similar to those experienced in young boys during puberty. In addition to irreversible side effects, such as deepened voice, increased terminal facial hair, and a hypertrophied clitoris, some of the hypertrophic effects of anabolic steroids on skeletal muscle in women may be permanent. Balding is common in those who use AASs that undergo 5 α -reduction to potent androgens.

In some male steroid users, gynecomastia may be caused by increased circulating estrogen levels associated with the use of aromatizable androgens or hCG, or both. Decreased clearance of circulating estrogens is a result of impaired hepatic function, and a temporary state of hypotestosteronemia may occur after AAS withdrawal.¹⁶³

Ruptured tendons have been associated with AAS use on the basis of a small number of published case reports, and it has been suggested that these drugs predispose to tendon rupture by altering collagen structure.¹⁹⁰ It is possible that the rapid strength adaptations produced by AASs in skeletal muscle are not simultaneously matched by slower-adapting, less-vascular tendon structures, making tendons the weakest link in the chain.

Several studies have suggested that anabolic steroid use may lead to significant psychological morbidity. Psychological pathologies associated with anabolic steroids include anxiety, psychosis, irritability, increased aggression, and antisocial and violent behavior.¹⁹¹ In addition to behavioral problems, dependence, withdrawal symptoms, and depression have been reported during and after the nonmedical use of anabolic steroids.^{179,192}

All known AAS can be detected by urinalysis (i.e., gas chromatography–mass spectrometry) for some period after the last dose.^{193,194} The detection of these drugs depends on their chemical structures, metabolism, the form in which they were administered, pattern of dosing, and concomitant use of other drugs. Doping by testosterone can be indirectly tested by measuring the ratio of urinary testosterone to epitestosterone (T/E).¹⁹⁵ In normal, healthy individuals, testosterone and epitestosterone are produced in a ratio of 1:1. It is assumed that the urinary T/E ratio increases in athletes taking exogenous testosterone. If an athlete has a T/E of more than 4:1, the sample is submitted to further evaluations, such as gas chromatography–combustion–isotope ratio mass spectrometry. However, the T/E ratio is characterized by a larger inter-individual than intra-individual variability.¹⁹⁶ This suggests that a population-based T/E reference is not sensitive to individual variations. According to Sottas and colleagues,¹⁹⁶ the problem can be statistically defined as the detection of an outlier out of series of individual test results using a Bayesian analysis of the T/E ratio (i.e., comparing a value to a population-based reference range and a subject reference range).

Growth Hormone

GH has been used as a drug of abuse in sports since the early 1980s. The first scientific studies demonstrating a clearcut physiologic role for GH in adults were not

published in the peer-reviewed medical literature until 1989.^{197,198}

There are no well-designed scientific studies providing evidence that GH has performance-enhancing effects in normal individuals, but GH has been shown to have an important role in regulating body composition in adult humans and other species. In cattle, GH is known as a *partitioning agent*; it specifically diverts calories in food toward protein synthesis and away from fat synthesis. Animals made transgenic for GH have greatly increased lean tissues and reduced fat. Similar changes in body composition are seen in humans with acromegaly. GH-deficient adults have reduced lean body mass and increased fat mass, especially in the abdominal region. Physiologic replacement therapy with recombinant human GH (rhGH) in GH-deficient adults results in significant changes in body composition, with an average increase in lean body mass of 5 kg within the first month¹⁹⁸ and a comparable loss of 5 kg of fat.

GH-deficient adults have significantly reduced muscle mass, strength, and exercise performance.¹⁹⁹ Discontinuation of GH supplementation in patients with GH deficiency leads to a 5% reduction in isometric muscle strength and muscle size after 1 year.²⁰⁰

Investigators do not agree about whether GH replacement improves physical performance in GH-deficient patients. Exercise capacity is reported to increase in some^{197,201} but not all placebo-controlled trials enrolling hypopituitary adult patients.²⁰² Moreover, GH replacement therapy in GH-deficient patients has been shown to increase lean body mass but not aerobic capacity,²⁰³ whereas $\dot{V}O_2\text{max}$ was found to be significantly improved.^{204,205} The mechanisms through which GH acts on exercise performance are more complex than the simple increase in lean body mass. For instance, GH stimulates erythropoiesis under various conditions²⁰⁶ and exerts significant cardiovascular effects, increasing plasma volume and peripheral blood flow and enhancing left ventricular stroke volume and cardiac output.^{207,208} All these factors may contribute to improved aerobic capacity. Evidence suggests that GH therapy alone, in the absence of some form of exercise program, may increase lean body mass but not functional capacity, indicating that training may have to be combined with GH replacement in these patients to increase physical performance.²⁰³

The only controlled studies on the effects of GH on muscle function in experienced weight lifters or power athletes have not shown a significant positive effect of GH on muscular protein biosynthesis or strength.^{209–211} Only one study has demonstrated an increase in FFM and a decrease in fat mass in healthy men and women undergoing intensive exercise.²¹² Two studies in obese men²¹³ and women²¹⁴ found that GH treatment augmented fat loss in conjunction with dietary restriction or exercise, or both.

Lange and coworkers demonstrated that rhGH combined with endurance training in healthy elderly women increased the activity of muscle oxidative enzymes compared with exercise alone.²¹⁵ GH administration for 3 to 6 months to healthy elderly individuals increased IGF1 levels to those observed in younger individuals (controls); muscle mass, skin thickness, and bone mineral content significantly increased, and fat mass decreased.²¹⁶ Physiologic doses of GH given for 6 months to healthy older men with well-preserved functional abilities have improved body composition by increasing lean tissue mass and decreasing fat mass. However, functional ability was not improved, and side effects were frequently reported.²¹⁷

Two strategies have been proposed to detect GH doping in sports. Using the marker method, which focuses on

pharmacodynamic endpoints of GH use, the GH-Consortium 2000 identified biochemical parameters of the IGF system, such as IGF1, IGFBP3, and ALS, as suitable markers of GH use in combination with procollagen cleavage products, which also show a clearcut increase after GH use.^{218a} The combination of IGF1 and the procollagen type III amino-terminal extension peptide (PIIIP)²¹⁸ has been proposed to provide a set of markers that allow detection of GH abuse in athletes for up to 2 weeks after the last injection. During the initial phase of GH application, however, these pharmacodynamic markers are not expected to indicate GH abuse by athletes. The second method, known as the GH-isoform method,^{219,220} exploits the difference in isoform composition between rhGH (which consists mostly of monomeric 22-kd hGH) and a variety of GH isoforms secreted by the pituitary, including a 20-kd form lacking 14 amino acids and amidated and acylated isoforms. After peripheral injection of 22-kd rhGH, the pituitary's production of GH isoforms is reduced by negative feedback through IGF1. Subjecting serum samples to two immunoassay analyses, one that is specific for 22-kd monomeric hGH and one that recognizes most isoforms released from the pituitary, allows calculation of an isoform ratio (Fig. 26-1). This approach for the detection of GH doping has been applied since the 2004 Olympic Games, but no case of GH doping has been declared based on this method. Both strategies may be used side by side in the future, and they may primarily have their place in unannounced sampling outside of competition. The isoform test can detect GH abuse during the first 36 hours after the last injection, and the pharmacodynamic end point method provides a longer window of opportunity.

Erythropoietin and the Erythropoietin System

Erythropoietin (EPO), a glycoprotein hormone naturally produced in the kidney and liver, is an essential growth factor for the erythrocytic progenitors in the bone marrow. Tissue hypoxia is the physiologic stimulus for EPO expression and erythropoiesis. After release, EPO stimulates an increase in hemoglobin, thereby increasing the oxygen-carrying capacity of the blood.²²¹

The effects of physical exercise on circulating EPO levels have been studied in various sports, including cross-country skiing, cycling, long-distance running, and biathlon.²²¹ The results indicate that the level of EPO is not significantly affected by single bouts of strenuous exercise, although slight increases were occasionally observed a few hours after long-distance running.²²² Despite the lack of EPO response to short-term physical exercise, the number of reticulocytes may increase within 1 or 2 days after exercise.²²³ It is likely that stress hormones such as catecholamines and cortisol stimulate the release of young red blood cells from bone marrow, and sustained training is associated with increased reticulocyte counts.²²³ Hemoglobin levels and the hematocrit may nevertheless be below normal. This so-called sports anemia is a pseudoanemia, because the plasma volume is increased.²²¹

Successful cloning of the human *EPO* gene²²⁴ allowed production of recombinant human erythropoietin (rhEPO), which was later approved for treating patients with anemia. Unfortunately, some athletes and their coaches were eager to abuse rhEPO because it increases the oxygen supply to

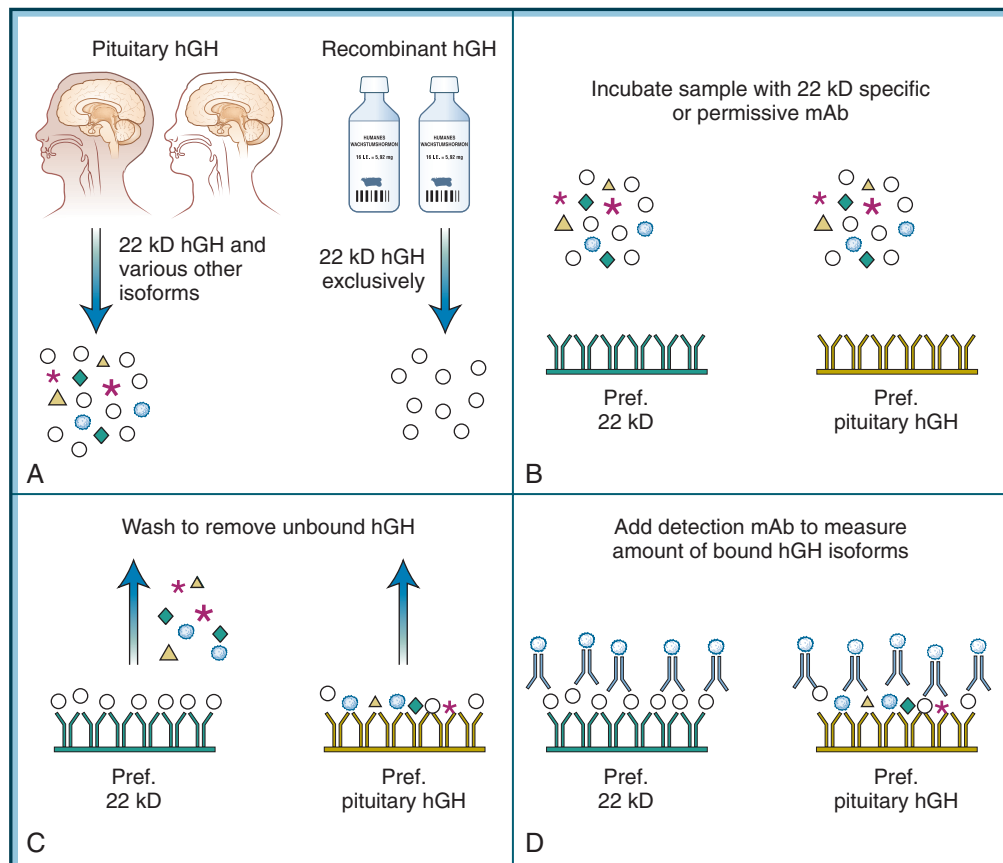

Figure 26-1 Differential immunoassays for growth hormone isoform composition. mAb, monoclonal antibody; hGH, human growth hormone.

the muscles and boosts performance in endurance sports such as skiing, running, and cycling.²²⁵

Because endurance athletes are particularly sensitive to the oxygen-carrying capacity of their blood, any substance that increases this capacity provides a tremendous aerobic advantage. This advantage is evidenced by the long-recognized practices of living at altitude and sleeping in altitude tents.¹⁵⁶ Another method of achieving this effect is through blood doping, which involves an autologous transfusion of previously donated blood after a period of hematocrit recovery or a homologous transfusion from a crossmatched donor. These transfusions artificially increase the hematocrit mass and oxygen-carrying capacity of blood.

Although few studies on the ergogenic potential of rhEPO have been done, some investigations have come to conclusions similar to those achieved in studies of blood doping. Birkeland and coworkers²²⁶ performed a double-blind, placebo-controlled study for 4 weeks of rhEPO supplementation using a cycle ergometer to measure effects. The investigators reported that in rhEPO subjects, hematocrit increased from 42.7% to 50.8%. The $\dot{V}O_2$ max significantly increased from 63.6 to 68.1 mL/kg per minute, a 7% increase. Neither outcome measure showed a significant increase in the placebo group. Similar results were found by Ekblom and Berglund.²²⁷ They reported a 6% to 11% increase in hematocrit and increases in $\dot{V}O_2$ max in time to exhaustion after 7 weeks of rhEPO administration.

Williams and Branch²²⁸ reported that an increase of 1 g/dL of hemoglobin in an athlete with an exercise cardiac output of 25 L/min would increase oxygen transport by 335 mL, which extrapolates to an 8% increase for a normal $\dot{V}O_2$ max of 4000 mL of oxygen per minute. In male endurance athletes, the treatment with rhEPO ($3 \times 50 \text{ IU} \cdot \text{kg}^{-1} \cdot \text{wk}^{-1}$ for 4 weeks, followed by $3 \times 20 \text{ IU} \cdot \text{kg}^{-1} \cdot \text{wk}^{-1}$ for 2 weeks) increased aerobic physical fitness and perceived physical strength scores.²²⁹

Apart from rhEPO, several other erythropoiesis-stimulating agents (ESAs) have been developed. Darbepoetin alfa is an rhEPO glycosylation analogue that was approved for use in 2002 in the European Union and United States. It has the same mechanism of action as rhEPO—binding and activation of the EPO receptor—but it has a longer serum half-life and increased in vivo potency.²²⁵ Additional ESAs are in various stages of clinical development and may appear in the athletic arena. They include polyethylene glycol (PEG)-conjugated epoetin beta and an EPO mimetic peptide, hemateide. PEG epoetin beta has been approved by regulators in the European Union.²²⁵ ESAs include the EPO fusion proteins: rhEPO-IL3, EPO albumin, rhEPO-PAI1, rhEPO-Fc, and rhEPO dimers.²²⁵

Artificially raising hemoglobin levels can have dangerous consequences. In 1987, the first year of EPO release in Europe, five Dutch cyclists died of unexplained causes. Between 1997 and 2000, 18 cyclists died of stroke, myocardial infarction, or pulmonary embolism.¹⁵⁶ In contrast to the effect of endurance training, which increases plasma volume, the administration of rhEPO produces a selective increase in red cell mass. If the hematocrit exceeds 0.50, blood viscosity and cardiac afterload increase significantly. The main risks of erythrocytosis with a hematocrit greater than 0.55 include heart failure, myocardial infarction, seizures, peripheral thromboembolic events, and pulmonary embolism.²²¹

Since the 1996 Atlanta Olympic Games, gas chromatography-mass spectrometry evaluations have been used for screening exogenous EPO in the urine.¹⁵⁶ High-performance liquid chromatography has also been

used to detect subtle peptides in the urine.¹⁹⁴ Despite these advances, exogenous EPO remains a particularly difficult substance to detect through tests.

Two teams of scientists developed tests for EPO that were used at the 2000 Sydney Olympic Games. Parisotto and coworkers developed an indirect test based on the measurement of five blood parameters, including reticulocyte hematocrit, serum EPO, hematocrit, soluble transferrin receptor, and the percentage of macrocytes.²³⁰ Two models were developed: the *on model* used all parameters to detect recent use of EPO, whereas the *off model* used three parameters to detect EPO use over a longer period. The *on model* was used as a screening test at the Sydney Olympics. Confirmation of rhEPO use was accomplished with an isoelectric focusing/immunoblotting/chemiluminescence technique that was able to detect the different glycoforms of recombinant versus native EPO.²³¹ This method can also detect the use of the novel erythropoiesis-stimulating drug darbepoetin alfa.²³² The limitation of this technique is that it allows detection of EPO for only a few days after use. In Sydney, both tests were required to be positive to confirm EPO use, and no positive cases were detected.

Despite the availability of a test for rhEPO, numerous questions remain. Additional rhEPO products may have different and indistinguishable glycoforms and isoforms. Other approaches to improving oxygen transport can be envisioned, including polymerized and cross-linked hemoglobins (i.e., hemoglobin-based oxygen carriers), blood substitutes such as perfluorohydrocarbons, and 2,3-diphosphoglycerate (2,3-DPG) mimetics. The latter group, including efaproxiral (RSR13), shift the oxygen saturation curve to the left and deliver more oxygen to the tissue per molecule of hemoglobin.²³³ Advances in science related to doping require further research.

Endocrinology and Aging

STEVEN W. J. LAMBERTS

The average length of human life has increased to 75 to 78 years, and to almost 85 years for Japanese women.¹ The data indicate that the linear climb of recorded life expectancy will continue in the next decade.¹ It is not clear, however, whether these additional years will be satisfactory.

Most data indicate a modest gain in the number of healthy years lived but a far greater increase in years of compromised physical, mental, and social function.² The number of days with restricted activity and admissions to hospitals and nursing homes increase sharply after 70 years of age.³ The compression-of-morbidity hypothesis⁴ suggests that it may be possible to reduce cumulative lifetime morbidity. Because chronic illness and disability usually occur late in life, cumulative lifetime disability could be reduced if primary prevention measures postponed the onset of chronic illness. Smoking, body mass index (BMI), and exercise patterns in midlife and late adulthood are important predictors of subsequent disability.⁵ Persons with better health habits live longer, with disability postponed and compressed into fewer years at the end of life.

AGING AND PHYSICAL FRAILTY

Throughout adult life, all physiologic functions decline gradually.⁶ A diminished capacity for cellular protein synthesis, a decline in immune function, an increase in fat

mass, a loss of muscle mass and strength, and a decrease in bone mineral density contribute to declining health status.⁶ Most older adults die of atherosclerosis, cancer, or dementia, but in an increasing number of the “healthy” oldest old, loss of muscle strength is the limiting factor that determines their chances of an independent life until death.

Age-related disability is characterized by generalized weakness, impaired mobility and balance, and poor endurance. In the oldest old, this state is called *physical frailty*, defined as a state of reduced physiologic reserves associated with increased susceptibility to disability.⁷ Clinical correlates of physical frailty include falls, fractures, impairment in activities of daily living, and loss of independence. Falls contribute to 40% of admissions to nursing homes.⁸

Loss of muscle strength is an important factor in the development of frailty. Muscle weakness can be caused by aging of muscle fibers and their innervation, osteoarthritis, or chronic debilitating diseases.⁹ However, a sedentary lifestyle, decreased physical activity, and disuse are also important determinants of the decline in muscle strength.

In a study of 100 frail nursing home residents (average age, 87 years), lower-extremity muscle mass and strength were closely related.¹⁰ Supervised resistance exercise training (45 minutes three times per week for 10 weeks) doubled muscle strength and significantly increased gait velocity and stair-climbing power. This finding demonstrates that frailty in the elderly population is not an irreversible effect

of aging and disease but can be influenced and perhaps prevented.¹⁰ In nondisabled elderly persons living in the community, objective measures of lower-extremity function are highly predictive of subsequent disability.¹¹ Prevention of frailty can be achieved only through work (i.e., training). However, exercise is difficult to implement in the daily routine of the aging population, and the number of dropouts from exercise programs is very high.

Part of the aging process involving body composition—that is, loss of muscle (strength) and bone and increase in fat mass—may also be related to changes in the endocrine system.⁶ Current knowledge has shed light on the effects of long-term hormonal replacement therapy on body composition and on atherosclerosis, cancer formation, and cognitive function.

ENDOCRINOLOGY OF AGING

The two most important clinical changes in endocrine activity during aging involve the pancreas and the thyroid gland. Approximately 40% of individuals between the ages of 65 and 74 years and 50% of those older than 80 years have impaired glucose tolerance or diabetes mellitus, and in almost 50% of elderly adults with diabetes the disease is undiagnosed.¹² These adults are at risk for secondary, mainly macrovascular complications occurring at an accelerated rate. Pancreatic, insulin receptor, and postreceptor changes associated with aging are critical components of the endocrinology of aging. Apart from relatively decreased insulin secretion by the beta cells, peripheral insulin resistance related to poor diet, physical inactivity, increased abdominal fat mass, and decreased lean body mass contribute to the deterioration of glucose metabolism.¹² Dietary management, exercise, oral hypoglycemic agents, and insulin are the four components of treatment for these patients, whose medical care is costly and intensive (see Chapter 27).

Age-related thyroid dysfunction is common.¹³ Lowered plasma thyroxine (T_4) and increased thyrotropin concentrations occur in 5% to 10% of elderly women.¹³ These abnormalities are primarily caused by autoimmunity and are an expression of age-associated disease rather than a consequence of the aging process. Normal aging is accompanied by a slight decrease in pituitary thyrotropin release and especially by decreased peripheral degradation of T_4 , which results in a gradual age-dependent decline in serum triiodothyronine (T_3) concentrations without changes in T_4 levels.¹³ This slight decrease in plasma T_3 concentrations occurs largely within the broad normal range of the healthy elderly population and has not been convincingly related to functional changes during the aging process.

The detrimental effects of overt thyroid dysfunction in elderly individuals are clearly recognized, but the clinical relevance of mild forms of hypothyroidism and hyperthyroidism are a matter of debate. Subclinical hypothyroidism is present in about 4% to 8.5% of adults in the United States who are without known thyroid disease.¹⁴ Subtle thyroid dysfunction often affects the oldest-old fraction of the elderly population (i.e., those >85 years). In 85-year-old healthy individuals, hypothyroidism was in the subsequent 4 years associated with lower all-cause and cardiovascular mortality rates compared with euthyroid individuals.¹⁵ In a group of 400 men with a mean age of 78 years, Van den Beld and colleagues¹⁶ showed that low serum levels of free T_4 and T_3 (with normal reverse T_3 [rT_3]) concentrations were associated with better physical performance and 4-year survival, whereas subjects with low serum levels of T_3 and high rT_3 concentrations (i.e.,

fulfilling the criteria for the low T_3 syndrome) did not show a survival advantage and had lower levels of physical activity. These two studies support the concept that some degree of physiologically decreased thyroid activity at the tissue level may have favorable effects in the oldest-old subjects, but caution should be exercised when interpreting the predictive value of thyroid dysfunction in the elderly, which may produce contradictory results if not considered in the appropriate context.^{17,18}

Three other hormonal systems exhibit lowered circulating hormone concentrations during normal aging, and these changes have been considered mainly physiologic (Figs. 27-1 and 27-2). Hormone replacement strategies have

Figure 27-1 During aging, declines in the activities of a number of hormonal systems occur. Left, A decrease in growth hormone (GH) release by the pituitary gland causes a decrease in the production of insulin-like growth factor type I (IGF-I) by the liver and other organs (somatopause). Middle, A decrease in release of the gonadotropins luteinizing hormone (LH) and follicle-stimulating hormone (FSH) results in menopause, and decreased secretion at the gonadal level from the ovaries, decreased estradiol (E_2) from the testicle, and decreased testosterone (T) cause andropause. (Immediately after the initiation of menopause, serum LH and FSH levels increase sharply.) Right, The adrenocortical cells responsible for the production of dehydroepiandrosterone (DHEA) decrease in activity (adrenopause) without clinically evident changes in the secretion of corticotropin (ACTH) and cortisol. A central pacemaker in the hypothalamus or higher brain areas (or both) is hypothesized, which together with changes in the peripheral organs (ovaries, testicles, and adrenal cortex) regulates the aging process of these endocrine axes. PRL, prolactin; T_4 , thyroxine; TSH, thyrotropin.

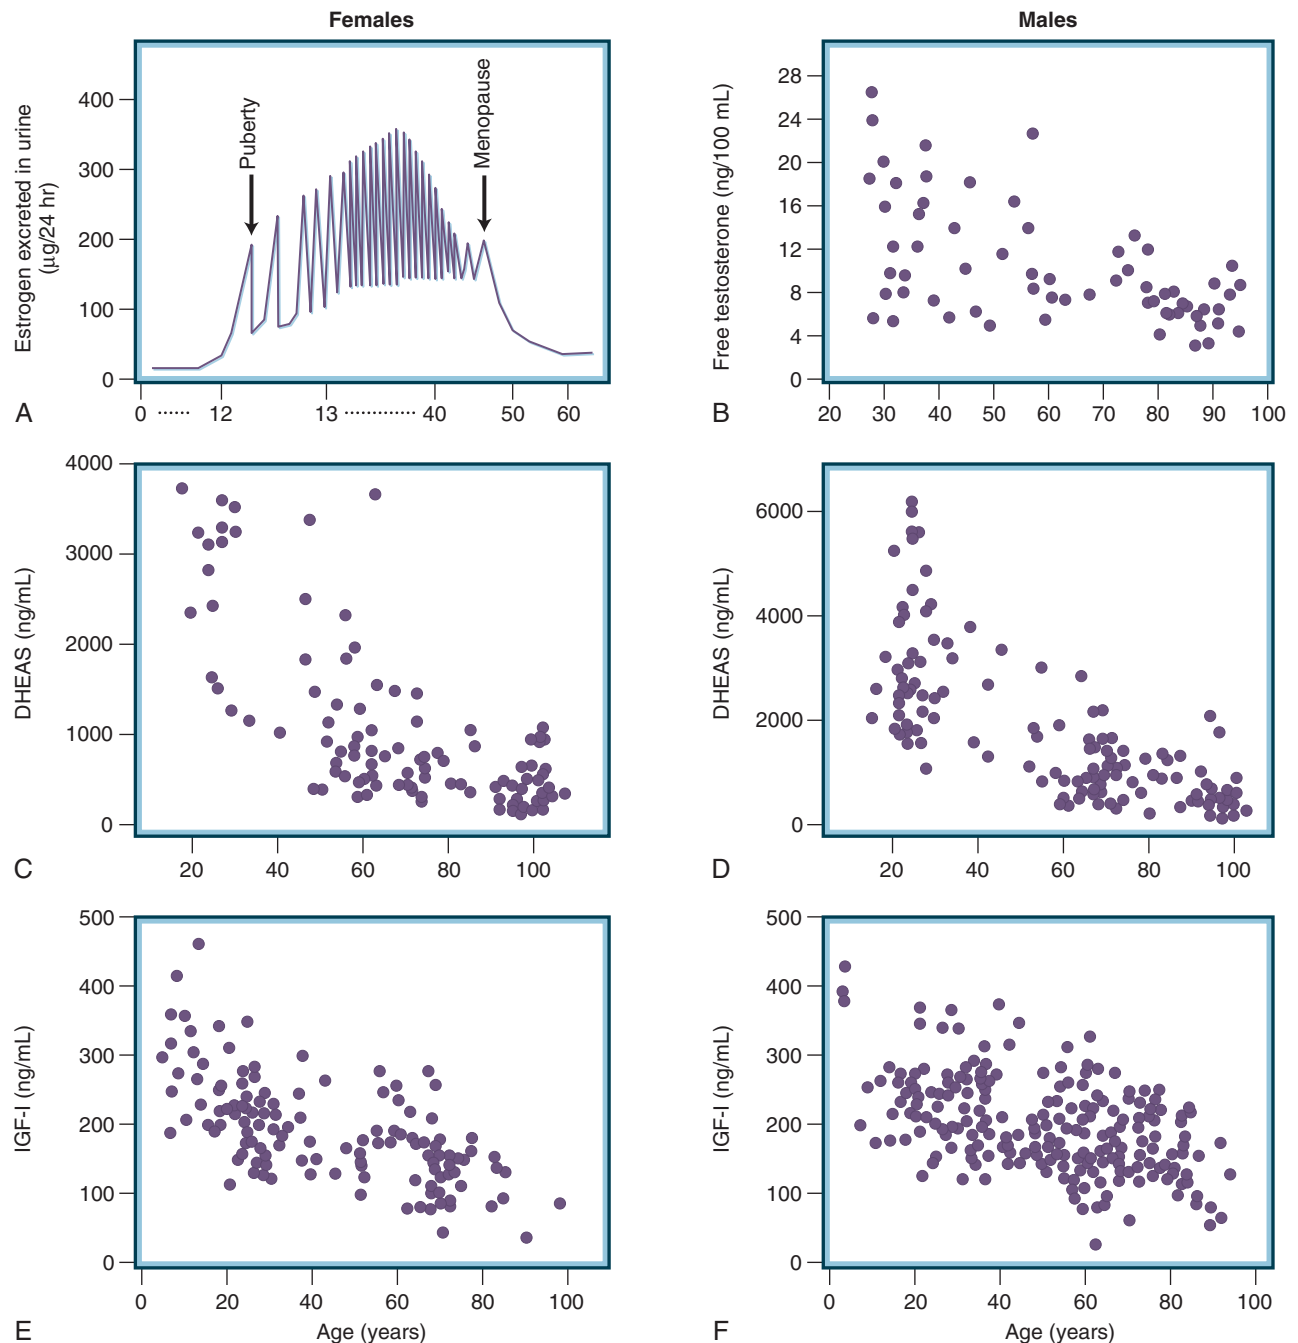

Figure 27-2 Changes in the hormone levels of normal women (left) and men (right) during the aging process. **A**, Estrogen secretion throughout an individual normal woman's life (expressed as urinary estrogen excretion). **B**, Mean free testosterone (T) index (ratio of serum total T to sex hormone-binding globulin levels) during the life span of healthy men. (From Guyton A. *Textbook of Medical Physiology*, 8th ed. Philadelphia, PA: Saunders; 1991:899.) Serum dehydroepiandrosterone sulfate (DHEAS) concentrations in 114 healthy women (**C**) and 163 healthy men (**D**) during aging. (Adapted from Ravaglia G, Forti P, Maioli F, et al. The relationship of dehydroepiandrosterone sulfate (DHEAS) to endocrine-metabolic parameters and functional status in the oldest-old: results from an Italian study on healthy free-living over-ninety-year-olds. *J Clin Endocrinol Metab*. 81:1173, 1996.) The course of serum insulin-like growth factor I (IGF-I) concentrations in 131 healthy women (**E**) and 223 healthy men (**F**) during aging. Note the difference in the distribution of ages in the different panels. (Adapted from Corpas E, Harman SM, Blackman MR. Human growth hormone and human aging. *Endocr Rev*. 14:20, 1993.)

been developed, but many aspects remain controversial, and replenishing blood hormone levels to those found in 30- to 50-year-old patients has not uniformly proved beneficial and safe.

The most dramatic and rapidly occurring change in women at about the age of 50 years is *menopause*.¹⁹ Cycling estradiol production during the reproductive years is

replaced by very low, constant estradiol levels. For many years, the prevailing view was that menopause resulted from exhaustion of ovarian follicles. An alternative perspective is that age-related changes in the central nervous system and the hypothalamic-pituitary unit initiate the menopausal transition. Evidence that both ovary and brain are key pacemakers in menopause is compelling.¹⁹

Changes in the activity of the hypothalamic-pituitary-gonadal axis in men are slower and more subtle. During aging, a gradual decline in serum total and free testosterone levels occurs.²⁰ *Andropause* is characterized by a decrease in testicular Leydig cell numbers and their secretory capacity and by an age-related decrease in episodic and stimulated gonadotropin secretion.^{21,22} The primary site of the aging effect appears to be the Leydig cell's ability to respond to luteinizing hormone (LH) with increased testosterone production.

The second demonstration of age-related changes in a hormonal system is *adrenopause*, a term that describes the gradual decline in circulating levels of dehydroepiandrosterone (DHEA) and its sulfate (DHEAS).^{23,24} Adrenal secretion of DHEA gradually decreases over time, while corticotropin secretion, which is physiologically linked to plasma cortisol levels, remains largely unchanged. The decline in DHEA and DHEAS levels in both sexes contrasts with the maintenance of plasma cortisol levels and seems to be caused by a selective decrease in the number of functional zona reticularis cells in the adrenal cortex rather than regulation by a central (hypothalamic) pacemaker of aging.²⁵

The third endocrine system that gradually declines in activity during aging is the growth hormone (GH)–insulin-like growth factor type 1 (IGF1) axis (see Fig. 27-2).^{6,26} Mean pulse amplitude and duration and the fraction of GH secreted, but not pulse frequency, gradually decrease during aging. In parallel, a progressive drop in circulating IGF1 levels occurs in both sexes.^{26,27} There is no evidence for a peripheral factor in this process of *somatopause*, and its triggering pacemaker seems to be localized mainly in the hypothalamus, because pituitary somatotropes, even of the oldest old, can be restored to their youthful secretory capacity by treatment with GH-releasing peptides (discussed later).

It is unclear whether changes in gonadal function (e.g., menopause, andropause) are interrelated with the processes of adrenopause and somatopause, which occur in both sexes. Functional correlates, such as decrease in muscle size and function, decrease in fat and bone mass, progression of atherosclerosis, and decline of cognitive function, have not been directly causally related to these changes in endocrine activity. However, several effects of normal aging closely resemble features of (isolated) hormonal deficiency (e.g., hypogonadism, GH deficiency), which in subjects in middle adulthood are successfully reversed by replacement of the appropriate hormone.^{28,29} Although aging does not simply result from a variety of hormone deficiency states, medical intervention in the processes of menopause, andropause, adrenopause, or somatopause may prevent or delay some aspects of the aging process.

MENOPAUSE

Menopause is the permanent cessation of menstruation that results from the loss of ovarian follicular function. It is diagnosed retrospectively after 12 months of amenorrhea.

In most women, vasomotor reactions, depressed mood, and urogenital complaints accompany this period of estrogen decline. In subsequent years, the loss of estrogens is followed by a high incidence of cardiovascular disease, loss of bone mass, and cognitive impairment. The average age at menopause (51.4 years) has not changed over time and seems to be largely determined by genetic factors.

Perimenopausal Use of Hormone Therapy

Typical symptoms that result from the sudden decrease in estrogen production around menopause are menstrual cycle disorders, vasomotor changes (e.g., hot flashes, night sweats), and urogenital complications (e.g., atrophic vaginal irritation and dryness, dyspareunia, atrophic urethral epithelium leading to micturition disorders). Additional symptoms include irritability, mood swings, joint pain, and sleep disturbances. Frequency, severity, onset, and duration of symptoms vary widely among individuals and ethnic groups. About 75% of women in Western societies experience so few troublesome symptoms during the menopausal transition that hormone therapy (HT) is not needed or requested.³⁰

HT quickly alleviates the symptoms of menopause. Hot flashes, vasomotor instability, and symptoms of urogenital atrophy rapidly disappear with the start of HT.

Long-Term Hormone Replacement Therapy

Because life expectancy is increasing, the time a woman spends after menopause constitutes more than one third of her life. Until recently, long-term use of HT (5 to 10 years) was considered to offer advantages with regard to prevention of the three chronic disorders most common in the elderly: cardiovascular diseases, osteoporosis, and dementia. In the early 1990s, a number of cross-sectional and prospective studies demonstrated a statistically significant reduction in coronary heart disease in menopausal women taking HT. Grady and colleagues³¹ presented a meta-analysis of published observational studies and reported that HT was associated with one-third less fatal coronary heart disease. A meta-analysis of 25 observational studies conducted between 1976 and 1996 showed that the relative risk for coronary heart disease in women who had ever used HT compared with never-users was 0.70.³²

The Nurse's Health Study was a comprehensive investigation conducted in 121,700 female nurses between the ages of 30 and 55 years. In the 2000 report, compiled with data from 70,533 postmenopausal nurses followed for 20 years, the overall risk of coronary heart disease in current users of HT was found to be reduced, with a relative risk of 0.61.³³

Over the past 10 years, findings from a number of prospective, randomized, controlled trials have radically changed the attitudes concerning benefits and harms of HT. The Women's Health Initiative (WHI) trial comprised two large, randomized, placebo-controlled clinical trials, including estrogen-only and combined estrogen-progestin studies in more than 161,000 healthy postmenopausal women between the ages of 50 and 79 years.³⁴ The WHI was expected to definitively answer whether estrogen was cardioprotective. However, the estrogen-progestin versus placebo trial, which involved more than 16,000 women, was discontinued early because of an increase in cardiovascular complications (i.e., coronary heart disease, stroke, and venous thromboembolism) and an increased incidence of breast cancer in the treatment group.³⁴ Although important benefits were also seen (i.e., risk reduction for fractures and colon cancer), there was concern that the risks of combined estrogen-progestin therapy outweighed the benefits. The estrogen-only versus placebo trial included almost 11,000 women who had undergone hysterectomy and therefore did not require a progestin. This trial was also stopped early because a small increase in the risk of breast cancer and coronary heart disease risk was seen, but hip fracture risk was reduced.³⁵

Three other randomized, controlled trials supported the absence of benefit of HT for prevention of coronary heart disease and ischemic stroke.³⁶⁻³⁸ These studies were carried out in postmenopausal women with documented ischemic stroke or transient ischemic attack,³⁶ in women after documented myocardial infarction,³⁷ or in women with documented coronary heart disease.³⁸

Taken together, the WHI, which studied women presumed healthy at recruitment, and the three other trials enrolling women with documented cardiovascular disorders argued strongly against the earlier assumptions made on the basis of observational studies that estrogen users had a 30% to 40% reduced risk of coronary heart disease mortality and morbidity relative to nonusers.

A series of commentaries has addressed the differences in outcome between the observational studies and the randomized trials.^{39,40} Healthy user bias, the age at which study participants started HT, and the different estrogen and progestin preparations and doses have been mentioned as possible confounders.

Subsequently, reassessment of the data from the WHI and other studies has led to a different interpretation of the data, that groups of perimenopausal and early postmenopausal women may derive cardiovascular benefits from HRT. In this regard, much interest has focused on the timing hypothesis, which states that estrogens are atheroprotective if used in an early phase of atherosclerosis development. In an arm of the WHI in which 50- to 59-year-old women were treated with conjugated estrogens, only coronary artery calcium scores were significantly lower than in nontreated controls.⁴¹

Several studies have confirmed the risk of breast cancer, which increases with longer duration of HT.⁴²⁻⁴⁴ In the Million Women Study, current users of estrogen had an increased risk of incident invasive breast cancer of 30%, whereas in women using estrogen plus progestin, this risk had doubled. Breast cancer risk was unchanged in both the older and younger women with a prior hysterectomy treated with estrogen only. Past users of HT had also no increased risk.⁴⁵

The earlier expectations from observational studies that estrogen use might prevent cognitive decline were not confirmed by randomized, placebo-controlled trials. Estrogen therapy alone did not reduce dementia or mild cognitive impairment in women 65 years old or older, and the estrogen-progestin combination resulted in slightly increased risks for both end points.⁴⁶ The efficacy of HT in the prevention of osteoporotic fractures remains undisputed in regard to hip and other fractures (see Table 27-1).⁴⁷

The findings of the WHI trial are so important and have been so broadly publicized that they have created the perception that HT always carries risks that exceed its benefits. Given the described uncertainties, HT is only recommended in the perimenopausal period for women suffering from menopausal symptoms. HT is highly effective in alleviating hot flashes and night sweats. An association between endometrial cancer and estrogen use was observed many years ago. Ten years of unopposed estrogen use increases the risk for endometrial cancer 10-fold.³¹ For that reason, the HT regimens were supplemented with progestagens, which almost completely prevented this excess risk of endometrial cancer.

Currently advised doses of estrogen were originally designed to prevent bone loss, and opposing progestagen regimens were added to prevent endometrial cancer. Several estrogen and progestagen preparations are available for HT.³⁰ Components of available preparations vary in their effects on various target tissues. Commercial preparations

TABLE 27-1

Clinical Event Risks and Benefits of Hormone Therapy with Estrogen-Progestin or Estrogen Only in the Women's Health Initiative Trial*

Health Event	ESTROGEN-PROGESTIN THERAPY		ESTROGEN THERAPY	
	Risk	Benefit	Risk	Benefit
Coronary heart disease	8	—	—	3
Stroke	8	—	11	—

differ in their clinical effect by design, and individual women differ in their responses. HT can be administered orally, transdermally, topically, intranasally, or as subcutaneous implants.

Although HT in the perimenopausal state can cause some symptoms (e.g., vaginal discharge, uterine bleeding, breast tenderness), it relieves many others, including hot flashes and the severity of night sweats.⁴⁸ Grady estimated that about one serious adverse event will occur among every 1000 50-year-old women using HT for 1 year. The HT regimen used in the WHI trial combined 0.625 mg/day of conjugated equine estrogen and 2.5 mg/day of medroxyprogesterone acetate.³¹ However, the dose of estrogen necessary to diminish perimenopausal symptoms can be lower in many women. A dose of 0.3 or 0.45 mg/day of conjugated equine estrogen is effective at diminishing the number and intensity of hot flashes.⁴⁹

Selective Estrogen Receptor Modulators

In the search for optimal HT during menopause, it was observed that tamoxifen has variable antiestrogenic and estrogenic actions in different tissues.^{50,51} Tamoxifen suppresses the growth of estrogen receptor–positive breast cancer cells. Long-term treatment of breast cancer in menopausal patients with tamoxifen also lowered the incidence of new (contralateral) breast cancer by 40%. The number of cardiovascular incidents decreased by 70%, and the age-related decrease in bone mineral density was partially prevented.⁵²

These initially puzzling observations were explained by the fact that tamoxifen and other compounds such as raloxifene have selective estrogen receptor–modulating effects, exerting antiestrogenic actions on normal and cancerous breast tissue but agonistic actions on bone, lipids, and the blood vessel walls.⁵³ The effects of tamoxifen and raloxifene may be explained by differential stabilization of the conformation of the estrogen receptor, which facilitates interactions with coactivator or corepressor proteins and subsequently initiates or suppresses transcription of target genes. These specific interactions in the target cell lead to tissue-selective actions.⁵⁴

The efficacy and safety of raloxifene for the prevention of osteoporosis in postmenopausal women were demonstrated in a study that found a 2.5% increase in bone mineral density in the lumbar spine and hip in a group of postmenopausal, non-osteoporotic women treated with raloxifene for 2 years.⁵⁵ A significant reduction of vertebral fracture risk by raloxifene was subsequently demonstrated.⁵⁶ A total of 7705 postmenopausal women with existing osteoporosis were studied. After 36 months, bone mineral density at the hip and spine increased in the women treated with 60 mg of raloxifene by 2.1% and 2.6%, respectively, compared with those receiving placebo. At 36 months, 7.4% of women had at least one new vertebral fracture, including 10.1% of women receiving placebo and 6.6% of those receiving raloxifene at 60 mg/day. Compared with the placebo group, those receiving 60 mg of raloxifene had a relative risk for fracture of 0.7 ($P < .001$). Forty-six subjects needed raloxifene at 60 mg for 3 years to prevent one vertebral fracture in menopausal women without an existing fracture; for those with an existing fracture, 16 subjects required treatment. A meta-analysis confirmed the effects of raloxifene treatment on reduction of vertebral fracture risk in postmenopausal women without an effect on nonvertebral fracture risk.⁵⁷

In a placebo-controlled clinical trial of 10,000 postmenopausal women with an increased risk of coronary heart disease who were monitored for 5 to 6 years, raloxifene had an overall neutral effect on the incidence of cardiovascular events.⁵⁸ The incidence of all strokes was not different in the raloxifene- and the placebo-treated groups. However, among raloxifene-treated individuals, there was a higher incidence of fatal stroke, especially in smokers (incidence rates per 100 women-years, 0.22 versus 0.15 [$P < .0499$]), and a higher incidence of venous thromboembolic events (0.39 versus 0.27 incidents per 100 women-years [$P = .02$]).⁵⁹

Raloxifene, in contrast to tamoxifen and estrogen, does not stimulate endometrial thickness or vaginal bleeding.⁵⁵ With regard to side effects, raloxifene causes an increased incidence of leg cramps and hot flashes.⁶⁰

Endocrine approaches to breast cancer prevention have become increasingly successful. Four trials of tamoxifen administration for 5 years or longer in women at increased risk for breast cancer showed an approximately 50% reduction in breast cancer, but only for estrogen receptor-positive disease.⁶¹ (See Fig. 27-3.) Follow-up indicates that there was a carryover effect of tamoxifen after completion of treatment at 5 years so that the preventive effect at 10 years was significantly greater than at 5 years.

Raloxifene has been compared with placebo in three trials: one in women with osteoporosis,^{56,62} one in women with or at risk for cardiac disease,⁵⁸ and one in which raloxifene was compared with tamoxifen in women at high risk for breast cancer.⁶³ Reductions of 66%, 44%, and 50% in breast cancer risk were observed after 4 to 5 years of raloxifene therapy, respectively. The last trial showed that raloxifene was as effective as tamoxifen.⁶³ As with the previous tamoxifen studies, raloxifene reduced the risk only of estrogen receptor α -positive tumors.

In the United States, the 60-mg dose of raloxifene is indicated for the treatment and prevention of osteoporosis in postmenopausal women and for reduction in the risk of invasive breast cancer in postmenopausal women with osteoporosis, and in postmenopausal women at high risk for invasive breast cancer.^{64,65}

Tibolone is a compound that regulates estrogen activity selectively in different tissues. It has a high efficacy in the treatment of climacteric symptoms and the prevention

Figure 27-3 Effect of raloxifene administration (60 to 120 mg/day) on the cumulative incidence of breast cancer in 7705 postmenopausal women (mean age, 66.5 years) with osteoporosis. Statistical significance of the difference between the groups was $P < .001$. (From Cummings SR, Eckert S, Krueger KA, et al. The effect of raloxifene on risk of breast cancer in postmenopausal women: results from the MORE randomized trial. Multiple Outcomes of Raloxifene Evaluation. *JAMA*. 281:2189, 1999.)

of bone loss. The compound is approved in many countries but not in the United States. In a 5-year trial, tibolone (1.5 mg/day) was associated with a 45% decrease in vertebral fractures, a 26% decrease in nonvertebral fractures, a 68% decrease in invasive breast cancer, and a 69% decreased risk of colon cancer.⁶⁶ However, the tibolone-treated group had an increased risk of stroke (relative hazard = 2.19; $P = .02$).

Androgen Replacement

In premenopausal women, androgen production originates equally from the adrenal glands and the ovaries. Androgen production in women declines with age. After menopause, circulating androgen levels decrease by more than 50%.

There is increasing awareness of the effect of low androgen levels on the emotional and sexual well-being of perimenopausal women. No single androgen level is predictive of low female sexual function, and in one study, most of 1423 women between the ages of 18 and 75 years with low DHEAS levels were found to have normal sexual function.⁶⁷

The efficacy and safety of testosterone treatment for hypoactive sexual desire disorder in postmenopausal women was studied in a double-blind, placebo-controlled, 52-week trial in which more than 800 women participated.⁶⁸ Treatment with a patch delivering 300 μ g of testosterone per day resulted in a modest but meaningful improvement in sexual function. The long-term effects of testosterone, including effect on the breast, remain uncertain.

Hormone Therapy, Selective Estrogen Receptor Modulators, or No Treatment

The issue of HT in postmenopausal women is controversial, and many aspects remain unresolved. The idea that HT is a global risk reduction strategy has been abandoned. Although the general benefits of HT in the short term during and after the menopausal transition are evident in women suffering from estrogen-withdrawal symptoms, the balance of the effects of long-term HT after menopause points to a negative outcome, with more harm than benefit. Evolution of the association of HT and cardiovascular risk, from protection to harm and now to possible protection again, has resulted in controversy and confusion.^{69,70}

HT is usually prescribed for women between the ages of 45 and 60 years who are experiencing vasomotor symptoms. HT is not indicated for cardioprotection for women in their 70s or for women who do not suffer from vasomotor symptoms or urogenital atrophy. Data clearly demonstrate, however, that clinicians can prescribe and women can use low-dose HT confidently during the time when therapy is most needed. The debate regarding the potential benefits of HT on cardiovascular risk and mortality for women who start therapy close to the menopausal transition is not resolved. The benefit and risk of any therapy, including HT, should be reassessed periodically for each individual based on future scientific evidence.⁷⁰

A vast armamentarium of other pharmacologic treatments to reduce cardiovascular and bone risks is available. Agents include cholesterol-lowering statins, β -blockers, selective estrogen receptor modulators (SERMs), and bisphosphonates. An optimal choice of these different lifestyle drugs for menopausal women requires individualization of the treatment decision. Coronary artery disease, for example, is a complex disorder resulting from an interaction of genetic predisposition and environmental factors. Risk factor modification (e.g., diet, smoking, physical activity) should be advised. Secondary prevention of coronary artery disease and atherosclerosis includes the use of lipid-lowering drugs, aspirin, nitrates, and β -blockers.⁷¹

For women with existing osteoporosis, HT is effective. However, SERMs and especially bisphosphonates come close or are better in their fracture-reducing effects. Recognition of an increased risk of breast cancer in menopausal women is an important consideration in the choice of SERMs. Chemoprevention of breast cancer with raloxifene has become a major consideration in the pharmacologic choice for risk reduction in the long-term preventive treatment of postmenopausal women.

ANDROPAUSE AND PARTIAL ANDROGEN DEFICIENCY

Role of Testosterone during Aging

Age-associated hypogonadism does not develop as clearly in men at andropause as in women at menopause. The key difference is the gradual, often subtle change in androgen levels in men compared with the precipitate fall of estrogen production in women. As men age, there is a decline in serum total testosterone concentrations that begins after the age of 40 years. In cross-sectional studies, the annual decline in total and free testosterone is 1.0%, and 1.2%, respectively. The higher decline in free testosterone levels is related to the increase in the levels of sex hormone-binding globulin (SHBG) with age.^{20,72}

It remains unclear whether the well-known biologic changes that occur during aging in men (e.g., reduced sexual activity, muscle mass and strength, skeletal mineralization) are causally related to the changes in testosterone bioactivity. The decline in testosterone levels, when associated with signs and symptoms of androgen deficiency, has been called *andropause*, but this term may be better replaced by (partial) androgen deficiency of the aging male, or (P)ADAM, because androgen production in the elderly male does not cease, but instead gradually decreases.

There has been major disagreement on how to define androgen deficiency in the elderly man. Investigators have initially taken two different approaches; one is purely biochemical, the other clinical. The biochemical approach consists of defining (partial) androgen deficiency by

measuring morning serum total testosterone levels or determining, by additionally measuring SHBG levels, a “free” testosterone concentration. Most elderly men have testosterone levels within the normal range; prevalence estimates of low serum testosterone concentrations (<10.4 nmol/L or <300 ng/dL) are usually between 10% and 25%.^{73,74} Most men with low testosterone levels do not come to clinical attention, because testosterone levels are not routinely measured in clinical practice.⁷⁵ An important problem with a biochemical approach to the diagnosis of (P)ADAM is that men with low testosterone may not exhibit clinically significant symptoms, raising the possibility that large numbers of men may be diagnosed as needing testosterone replacement therapy simply by virtue of falling below an arbitrary threshold.

The clinical approach to the diagnosis of (P)ADAM has important drawbacks.⁷⁶ All symptoms and signs of androgen deficiency are nonspecific and readily accounted for by comorbidities. Lethargy, reduced concentration, sleep disturbance, irritability, and depressed mood may relate to physical illness (and side effects of treatment), obesity, or lack of physical exercise and other lifestyle issues (e.g., alcohol or drug use); relationship difficulties; or occupational or financial stresses. Existing screening tools for androgen deficiency lack adequate specificity and sensitivity to be reliably employed in directing clinical diagnosis and treatment.

Araujo and coworkers⁷⁵ defined the prevalence of symptomatic androgen deficiency in men by studying the association between symptoms of androgen deficiency (i.e., low libido, erectile dysfunction, osteoporosis or fracture, or two of the following symptoms: sleep disturbance, depressed mood, lethargy, or diminished physical performance) and low serum total testosterone (<10.4 nmol/L or <300 ng/dL) and free testosterone (<0.17 nmol/L or <5 ng/dL) concentrations. Applying these criteria to almost 1500 men 30 to 79 years old, they found 24% with total testosterone levels and 11% with low free testosterone levels. Symptoms included low libido (12% prevalence), erectile dysfunction (16%), osteoporosis or fracture (1%), and two or more of the nonspecific symptoms (20%). Although low testosterone levels were associated with symptoms, many men with low testosterone levels were asymptomatic (e.g., 47.6% of men older than 50 years). In Figure 27-4 the interrelationships are shown; symptomatic androgen deficiency with low serum testosterone (<10.4 nmol/L) was observed in 4.2% of men younger than 50 years old and in 8.4% of men older than 50 years. This prevalence rapidly increases with age, reaching 18.4% among 70-year-olds.

Low testosterone concentrations are especially prevalent among obese men.⁷⁷ Although much of the effect of obesity was explained by a decrease in SHBG, the serum free testosterone concentration was especially lower in men with a BMI of 30 kg/m² or greater. Lower total testosterone levels are associated with comorbidities, including the presence and degree of atherosclerosis.⁷⁸ In line with these observations, men with total testosterone levels in the lowest quartile had a 40% increased risk of death during the next 20 years after testing, independent of multiple risk factors and several preexisting health conditions.⁷⁹

Testosterone Replacement Therapy

Many persuasive reports in the literature demonstrate that testosterone replacement in young, adult, and old men with clear clinical and severe biochemical hypogonadism instantly reverses vasomotor activity (i.e., flashes and sweats); improves libido, sexual activity, and mood;

Figure 27-4 Venn diagrams showing the interrelationships among symptoms, low total testosterone (total T < 10.4 nmol/L or < 300 ng/dL), and low free testosterone (free T < 0.17 nmol/L or < 5 ng/dL) among men younger than 50 years (left) and 50 years or older (right). Circles for the Venn diagrams are proportional within age strata. Numbers displayed are percentages observed within each area. Positive symptom reports and low total T and free T levels were more common among older men. The presence of symptoms was related more strongly to T levels in older than in younger men, as indicated by a greater degree of overlap between symptom presence and low T levels among older subjects (52.4% of men with low total T or free T had symptoms) compared with younger ones (43.1% of men with low total T or free T had symptoms). The intersection of symptoms and low total T and free T levels was more common in older men: prevalence of symptomatic androgen deficiency was 4.2% among men younger than 50 years of age and 8.4% among men 50 years or older. (From Araujo AB, Esche GR, Kupelian V, et al. Prevalence of symptomatic androgen deficiency in men. *J Clin Endocrinol Metab*. 92:4241, 2007.)

increases muscle mass, strength, and bone mineralization; prevents fractures; decreases fat mass; and decreases fatigue and poor concentration.^{28,72,80} Treatment of normal adult men with supraphysiologic doses of testosterone, especially when combined with resistance exercise training, increased fat-free mass and muscle size and strength.⁸¹

Many studies reporting the results of androgen therapy in older men have been small, short-term, not controlled, and without uniform end points. The results of a large, randomized study in healthy elderly men were published in 1999 and seem to be representative for effects expected of androgen therapy.^{82,83} Ninety-six men (mean age, 73 years) wore a testosterone patch on their scrotum (6 mg of testosterone/24 hours) or a placebo patch for 36 months. Mean serum testosterone concentrations in the men treated with testosterone increased from 12.7 ± 2.9 nmol/L (367 ± 7.9 ng/dL) before treatment to 21.7 ± 8.6 nmol/L (625 ± 249 ng/dL, $P < .001$) after 6 months of treatment and remained at that level for the duration of the study. The decrease in fat mass (-3.0 ± 0.5 kg) in the testosterone-treated men during the 36 months of treatment was significantly different from the decrease in the placebo-treated men (-0.7 ± 0.5 kg; $P < .001$) (Fig. 27-5). The increase in lean mass (1.9 ± 0.3 kg) with testosterone treatment was also significantly different from that observed with placebo (0.2 ± 0.2 kg, $P < .001$).

Changes in knee extension and flexion strength, hand grip, walking speed, and other parameters of muscle strength and function were not significantly different in the two groups. Bone mineral density in the lumbar spine increased in both groups ($4.2\% \pm 0.8\%$ and $2.5\% \pm 0.6\%$, respectively), but mean changes did not differ between groups (see Fig. 27-5). However, the lower the pretreatment serum testosterone concentration, the greater the effects of testosterone treatment on lumbar spine bone density after

36 months ($P = .02$). A minimal effect ($0.9 \pm 1.0\%$) of testosterone treatment on bone mineral density was observed in men with a pretreatment serum testosterone concentration of 13.9 nmol/L (400 ng/dL), but an increase of $5.9\% \pm 2.2\%$ was found in men with a pretreatment testosterone concentration of 6.9 nmol/L (200 ng/dL).

The subjective perception of physical functioning decreased significantly during the 36 months of treatment

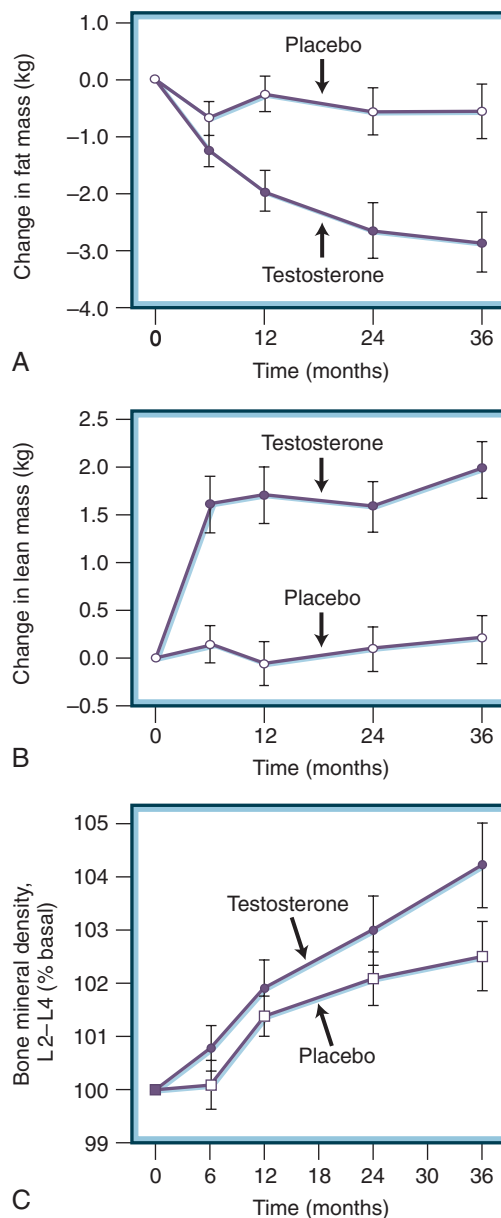

Figure 27-5 A through C, Mean (\pm standard error) changes from baseline in fat mass, lean mass, and bone mineral density of the lumbar spine (L2 to L4) as determined by dual-energy x-ray absorptiometry in 108 men older than 65 years who were treated with either testosterone or placebo (54 men each). The decrease in fat mass ($P < .005$) and the increase in lean mass ($P < .01$) in the testosterone-treated subjects were significantly different from those in placebo-treated subjects at 36 months. Bone mineral density increased significantly in both groups. (A and B from Snyder PJ, Peachey H, Hannoush P, et al. Effect of testosterone treatment on bone mineral density in men over 65 years of age. *J Clin Endocrinol Metab*. 84:1966, 1999. C from Snyder PJ, Peachey H, Hannoush P, et al. Effect of testosterone treatment on body composition and muscle strength in men over 65 years of age. *J Clin Endocrinol Metab*. 84:2647, 1999.)

in the placebo-treated ($P < .001$) but not in the testosterone-treated group. The effect of testosterone treatment on the perception of physical functioning varied inversely with the pretreatment serum testosterone concentration ($P < .01$). There was no significant difference between the two treatment groups with regard to the subjective perception of energy or sexual function.

With regard to the potential adverse effects of testosterone treatment in healthy elderly men, the study by Snyder and colleagues⁸² seems representative. The mean serum prostate-specific antigen (PSA) concentration did not change during the 36 months of treatment in the placebo-treated group, but it increased by a relatively small but statistically significant ($P < .001$) amount by 6 months of treatment in the testosterone-treated group and remained relatively stable for the remainder of the study. The urine flow rate, volume of urine in the bladder after voiding, and number of clinically significant prostate events during the 3 years of the study were similar in the two groups. Hemoglobin and hematocrit levels did not change in the placebo-treated group during treatment, but both increased significantly ($P < .001$) in the testosterone-treated group within 6 months and remained relatively stable for the remainder of the study. Three men treated with testosterone developed persistent erythrocytosis (hemoglobin > 17.5 g/dL; hematocrit $> 52\%$) during treatment.

Numerous studies of large populations of healthy men have shown a marked rise in the incidence of impotence to more than 50% in men 60 to 70 years old.⁸⁴ Although this increased rate occurs in the same age group who show a clear decline in serum (free) testosterone levels, no causal relationships have been demonstrated. A systematic review and meta-analysis of randomized, placebo-controlled trials concluded that testosterone use in normal men is associated with a small improvement in satisfaction with erectile function and moderate improvements in libido.⁸⁵ Other factors, such as atherosclerosis, alcohol consumption, smoking, and the quality of personal relationships, seem to be more important.^{86,87} Only in the case of clear hypogonadism is the decrease in libido and potency restored by testosterone therapy.^{28,80}

An Endocrine Society Clinical Practice Guideline on testosterone therapy in adult men with androgen deficiency syndromes summarized the observed effects of randomized, placebo-controlled trials of testosterone administration with 1- to 3-year-old duration in older men with low-normal to low testosterone concentrations.⁸⁸ There was a moderate effect on lumbar bone mineral density but no reports on bone fracture rate; a significant increase in lean body mass (+2.7 kg on average) and a reduction in fat mass (−2.0 kg) without a change in body weight; a greater improvement in grip strength than placebo (3.3 kg), without consistent effects on lower extremity muscle strength and unequivocal effects on physical function; and inconsistent or insignificant effects on sexual function, quality of life, depression, and cognition.

In the Guidelines, all reported adverse outcomes with testosterone therapy in elderly men were summarized⁸⁸ from a systematic review of 19 randomized trials,⁸⁹ and the combined rate of all prostate events was significantly greater in testosterone-treated men than in placebo-treated men (odds ratio = 1.78; 95% confidence level [CI], 1.07 to 2.95). Rates of prostate cancer, PSA greater than 4 ng/mL, and prostate biopsies were not significantly higher for the testosterone group than the placebo group. Testosterone-treated men were almost four times more likely than placebo-treated men to have hematocrits greater than 50% (odds ratio = 3.69; 95% CI, 1.82 to 7.51). The frequency of

cardiovascular events, sleep apnea, or death did not differ significantly between groups. Nonsignificant changes in lipids were observed. Compared with placebo, testosterone therapy for older men was associated with a higher risk of detecting prostate events and a hematocrit greater than 50%.

Which Elderly Men Should Be Treated?

A key lesson from the Heart and Estrogen/Progestin Replacement and WHI studies was that conventional medical use of these agents should not precede substantiation with reliable clinical evidence of safety and efficacy.⁹⁰ Androgen replacement in older men is the male counterpart of HT in postmenopausal women, but it differs crucially in that a clear syndrome of androgen deficiency is lacking. On the basis of a number of suggestive clinical features collected from the history, symptoms, or signs of an elderly man, the biochemical confirmation of androgen deficiency is sought.

In previous discussions of testosterone replacement in older men,^{86,91} it was suggested that the biochemical diagnosis of true hypogonadism seems certain if the serum total testosterone concentration is less than 6.9 nmol/L (200 ng/dL). This cutoff remains arbitrary and does not answer the question of whether healthy elderly men with testosterone levels between 6.9 and 10.4 nmol/L are hypogonadal and would benefit from replacement therapy with testosterone. Intercurrent diseases frequently result in a transient, sharp drop in serum testosterone concentrations,⁹² whereas frail, elderly men tend to have testosterone levels 10% to 15% lower than those of healthy, age-matched control subjects.⁹³ When a serum testosterone concentration is below 6.9 nmol/L (200 ng/dL), an additional evaluation with measurements of serum gonadotropins and prolactin is mandatory to exclude pituitary pathology.

The current recommendation⁸⁸ is not to treat asymptomatic older men with age-related decline in testosterone levels. If the decision is made to start testosterone replacement, the major goal of therapy is to return testosterone levels to values as close to physiologic levels in age-matched controls as possible. The dose should be titrated according to serum levels. Considerations concerning the choice of testosterone preparation and the route of administration (i.e., oral, injectable, implantable, or transdermal) are discussed in Chapter 8.

The recommended duration of testosterone administration is uncertain. Control of prostate size, PSA levels, and hematocrit is mandatory. The identification of elderly men who may benefit most from testosterone treatment remains uncertain, and the risks to the prostate and increased blood viscosity require further study. The development of androgenic compounds with variable biologic action in different organs (i.e., selective androgen receptor modulation) is being pursued.⁹⁴

Testosterone's effects are mediated through the androgen receptor, and the considerable variation in testosterone responsiveness that is observed between aging men receiving therapy may be related to variations in the androgen receptor gene. A candidate for this variability is the CAG repeat polymorphism in exon 1 of the androgen receptor gene, which is located on the X chromosome.⁹⁵ The CAG repeat encodes for a polyglutamine tract in the androgen receptor protein, and ranges normally form about 6 to 37 repeats, with an average of between 20 and 22. The number of CAG repeats is inversely associated with the transcriptional activity in testosterone target genes.⁹⁵ Krithivas and associates⁹⁶ demonstrated that the CAG repeat in the

androgen receptor gene is associated with the age-related decline in serum testosterone levels in men; the lower the number of repeats, the sharper the decline in serum testosterone concentrations. The lower the number of CAG repeats in normal healthy men, the earlier and higher the degree of prostate hyperplasia during the aging process.⁹⁷ For testosterone substitution in hypogonadal adult men for 36 months with a fixed dose, prostate size increased significantly more if the number of CAG repeats in the androgen receptor gene was lower.⁹⁵ This first pharmacogenetic study demonstrating that the effect of androgen replacement therapy on prostate growth in hypogonadal men is greatly influenced by the genetic background has important implications for its use in otherwise healthy elderly men. It is assumed that androgen sensitivity as determined by variations in the androgen receptor gene in muscle, fat, brain, vessel walls, and prostate will be similar within one individual. In future selection of aging men for testosterone therapy, the genetic background should probably be taken into account. The same applies to the androgen dose prescribed. Correlation of the CAG repeat in the androgen receptor with the serum testosterone level was confirmed in a population survey involving almost 3000 men.⁹⁸ Weaker transcriptional activity of the androgen receptor with longer CAG-encoded polyglutamine repeats appeared to be compensated for by higher testosterone levels. The investigators suggested that the phenotypic correlations may reflect differences in estrogen levels or actions after aromatization of the higher testosterone levels.⁹⁸

ADRENOPAUSE

Role of Dehydroepiandrosterone during Aging

Humans are unique among primates and rodents because the human adrenal cortex secretes large amounts of the steroid precursor DHEA and its sulfate derivative DHEAS.⁹⁹ Serum DHEAS concentrations in adult men and women are 100 to 500 times higher than those of testosterone and 1000 to 10,000 times higher than those of estradiol. In normal subjects, serum concentrations of DHEA and DHEAS are highest in the third decade of life, after which the concentrations of both gradually decrease, and by age 70 to 80 years, the values are about 20% of peak values in men and 30% of peak values in women (see Fig. 27-2).²⁴

DHEA and DHEAS seem to be inactive precursors that are transformed within human tissues by a complicated network of enzymes into androgens or estrogens, or both (Fig. 27-6). The key enzymes are aromatase, steroid sulfatase, 3 β -hydroxysteroid dehydrogenases (3 β -HSD1 and 3 β -HSD2), and at least seven organ-specific 17 β -hydroxysteroid dehydrogenases (17 β -HSD1 to 17 β -HSD7). Labrie and colleagues⁹⁹ introduced the term *intracrinology* to describe this synthesis of active steroids in peripheral target tissues in which the action is exerted in the same cells in which synthesis takes place and without release into the extracellular space and general circulation.

In postmenopausal women, almost 100% of sex steroids are synthesized in peripheral tissues from precursors of adrenal origin, except for a small contribution from ovarian or adrenal testosterone and androstenedione. In postmenopausal women, virtually all active sex steroids are made in target tissues by an intracrine mechanism. In elderly men, the intracrine production of androgens is also important; less than 50% of the androgen supply is derived from testicular production.

Figure 27-6 Human steroidogenic enzymes in peripheral intracrine tissues. DHEA, dehydroepiandrosterone; DHEA-S, DHEA sulfate; DHT, dihydrotestosterone; 5-DIOL, androsterone-5-ene-3 β ,17 β -diol; 4-DIONE, androstenedione; E₁, estrone; E₂, estradiol; 3 β -HSD, 3 β -hydroxysteroid dehydrogenase; 17 β -HSD, 17 β -hydroxysteroid dehydrogenase; S, sulphate; testo, testosterone. (Modified and adapted from Labrie F, Luu-The V, Lin SX, et al. Intracrinology: role of the family of 17 beta-hydroxysteroid dehydrogenases in human physiology and disease. *J Mol Endocrinol*. 25:1, 2000.)

The high secretion rate of adrenal precursor sex steroids in men and women differs from that in laboratory animal models, in which the secretion of sex steroids occurs exclusively in the gonads. In rats and mice, long-term administration of DHEA prevented obesity, diabetes mellitus, cancer, and heart disease and enhanced immune function.^{23,25,100}

These experimental animal data have been used to argue that DHEA administration in adult or elderly individuals prolongs the life span and may be an “elixir of youth.” Supportive data in humans are few, however, and highly controversial. Epidemiologic studies point to a mild cardioprotective effect of higher DHEAS levels in men and women.¹⁰¹ Functional parameters of activities of daily living in men older than 90 years were lowest in those with the lowest serum DHEAS concentrations,²⁴ and in healthy elderly individuals, there was an association between the ratio of cortisol to DHEAS levels and cognitive impairment.¹⁰²

CYP3A7, expressed in the human fetal liver and normally silenced after birth, plays a major role in the 16 α -hydroxylation of DHEA, DHEAS, and estrone. A common polymorphism in the *CYP3A7* gene (*CYP3A7*1C*) causes persistence of the enzymatic activity encoded by the gene during adult life. Between 6% and 8% of the population are heterozygous carriers of this polymorphism, resulting in almost 50% lower DHEAS levels compared with homozygous carriers of the reference allele.¹⁰³ No evidence was found that such lowered levels are associated with an acceleration of the aging process.

Dehydroepiandrosterone Replacement Therapy

A physiologic functional role of DHEA in women was ascertained in a carefully designed, double-blind study. In women with adrenal insufficiency,¹⁰⁴ DHEA administration (50 mg/day) normalized serum concentrations of DHEA, DHEAS, androstenedione, and testosterone. DHEA significantly improved overall well-being, the scores for depression and anxiety, and the frequency of sexual thoughts, sexual interest, and satisfaction with both mental and physical aspects of sexuality.

A number of short-duration, controlled trials with DHEA in small groups of elderly individuals provided ambiguous results.^{105,106} A 2-year placebo-controlled trial showed no effect of the oral administration of DHEA (at a dose of 75 mg/day in men and 50 mg/day in women) on body composition, muscle strength, or insulin sensitivity compared with placebo.¹⁰⁷ In this study involving 87 elderly men with low levels of DHEAS and bioavailable testosterone and 57 elderly women with low levels of DHEAS, DHEA levels increased in both sexes during DHEA administration by about 9.5 $\mu\text{mol/L}$.

These results are in line with those of a previous study¹⁰⁸ of 280 healthy subjects between 60 and 79 years old, in whom 50 mg of DHEA daily for 1 year did not improve body composition or muscle strength, whereas an increase in libido was observed in women. A double-blind, randomized, controlled trial with 50 mg of DHEA each day for 36 weeks in 50 elderly men 70 years old or older with low scores on muscle strength tests did not improve isometric grip strength, leg extensor power, or physical performance.¹⁰⁹

With regard to one beneficial effect of DHEA administration, the results seem rather consistently positive: Increases in bone mineral density were repeatedly reported.^{107,108,110} These positive effects, however, were very small and not more than approximately one half of those observed with current osteoporosis therapies, such as estrogens and bisphosphonates. They are therefore unlikely to have a significant effect on the risk of fracture.¹⁰⁷

Conclusions and Recommendations

DHEAS is a universal precursor for peripheral local production and action of estrogens and androgens in target tissues such as brain, bone, skin, and adipose tissue. However, the importance of these pathways remains undefined, particularly in men, who have a relatively much higher production of testosterone from testicular origin. DHEA administration in the elderly, compared with placebo, increases serum DHEAS, testosterone, free testosterone, estrone, estradiol, and IGF1 concentrations and lowers SHBG levels.^{107,109,110} It is not known whether this increase in sex steroid levels induced by DHEA administration in the long-term is safe with regard to the development or growth of ovarian, prostate, or other types of steroid-dependent cancers. The addition of DHEA (50 mg/day) to the existing large pool of DHEA and DHEAS in elderly individuals, even if they have been selected on the basis of low circulating levels of these steroids, has very limited or no clinically meaningful effects.

DHEA, which is available as a dietary supplement, is widely used within the United States as an unapproved preventive treatment against aging. There are no convincing arguments to recommend the routine use of DHEA for delaying or preventing the physiologic consequences of aging, and its safety is unknown.^{111,112}

SOMATOPAUSE

Role of Growth Hormone and Insulin-Like Growth Factor Type I during Aging

Elderly men and women secrete GH less frequently and at lower amplitude than do young people.²¹ GH secretion declines approximately 14% per decade in normal individuals.^{113,114} In parallel, serum levels of IGF1 (see Fig. 27-2) are 20% to 80% lower in healthy elderly individuals than in healthy young adults.¹¹⁵ The concept that the decline in GH and IGF1 secretion contributes to the decline of functional capacity in elderly people (i.e., somatopause) is mainly derived from studies in which GH replacement therapy in GH-deficient adults increased muscle mass, muscle strength, bone mass, and quality of life. A beneficial effect on the lipid profile and an important decrease in fat mass were also observed in these patients.^{29,116,117} As in hypogonadal individuals, adult GH deficiency can be considered a model of normal aging because a number of catabolic processes that are central in the biology of aging can be reversed by GH replacement.

Growth Hormone Replacement Therapy

Rudman and colleagues,¹¹⁸ after a groundbreaking, randomized, controlled trial enrolling healthy men 61 to 81 years old with serum IGF1 concentrations in the lower third for their age, reported in 1990 that GH treatment (30 $\mu\text{g/kg}$ three times weekly for 6 months) restored the men's IGF1 levels to normal. In the treatment group, lean body mass rose by 8.8%, and lumbar vertebral density increased by 1.6%. The magnitudes of these initial changes were equivalent to a reversal of the age-related changes by 10 to 20 years. However, during continuation of this study to 12 months, the significant positive effect on bone mineral density at any site was lost.¹¹⁹

In the subsequent years, it became clear that GH administration in healthy elderly individuals frequently caused acute adverse effects, such as carpal tunnel syndrome, gynecomastia, fluid retention, and hyperglycemia, which were severe enough for an appreciable number of individuals to drop out of these studies. The most disappointing aspect, however, was that no positive effects of GH administration were observed on muscle strength, maximal oxygen consumption, or functional capacity. In contrast, when GH was administered in combination with resistance exercise training, a significant positive effect on muscle mass and muscle strength was recorded that did not differ from that seen with placebo treatment, which suggests that GH does not add to the beneficial effects of exercise.^{120,121} A representative sample from a well-controlled study¹²² of GH administration in unselected elderly men is given in Table 27-2.

In a systematic study of 31 articles describing 18 unique, well-defined study populations the safety and efficacy of GH in the healthy elderly were reviewed.¹²³ A total of 220 participants who received GH for 107 person-years completed their studies. The mean age was 69 years, and they were overweight (mean BMI, 28 kg/m^2). Initial daily GH dose (mean, 14 $\mu\text{g/kg}$ of body weight), and treatment duration (mean, 27 weeks) varied. Overall fat mass decreased by 2.1 kg, and lean body mass increased by 2.1 kg in those treated with GH; total cholesterol levels decreased by 0.29 mmol/L. Disappointingly, no consistent changes in muscle strength, physical activity, or psychosocial outcomes were observed.

TABLE 27-2

Effects of Growth Hormone (GH) Administration in Healthy Older Men with Low Levels of Insulin-Like Growth Factor Type I (IGF1)*

Parameter	MEAN CHANGE IN VARIABLE		P Value
	GH (n = 26)	Placebo (n = 26)	
IGF1 (ng/mL)	119.2	7.6	<.0001
Body Weight and Composition			
Weight (kg)	0.5	1.0	>.2
Lean mass (%)	4.3	-0.1	<.001
Fat mass (%)	-13.1	-0.3	<.001
Bone mineral content (%)	0.9	-0.1	.05
Skin thickness (%)	13.4	1.1	.09
Muscle Strength (%)			
Knee extension	3.8	1.3	>.2
Knee flexion	10.0	8.2	>.2
Hand grip	-1.5	3.8	.11
Maximum Oxygen Consumption (%)	2.5	-2.0	>.2

*GH, 30 µg/kg three times a week, was administered for 6 months to 52 healthy 69-year-old men with well-preserved functional ability but low levels of IGF1. (From Papadakis MA, Grady D, Black D, et al. Growth hormone replacement in healthy older men improves body composition but not functional ability. *Ann Intern Med.* 1996;124:708-716.)

GH is associated with substantial adverse effects.¹²³ To obtain insights into what can be expected, the details of one particularly well-conducted, placebo-controlled study enrolling healthy women ($n = 57$) and men ($n = 74$) aged 65 to 88 years is described here¹²⁴: GH administered subcutaneously at an initial dose of 30 µg/kg three times per week and then reduced to 20 µg/kg for 26 weeks was associated with carpal tunnel syndrome in 38% of women (versus 7% for placebo) and in 24% of men (0% for placebo); edema in 39% of women (0% for placebo) and 30% of men (12% for placebo); and arthralgias in 46% of women (7% for placebo) and 41% of men (0% for placebo). Eighteen men treated with GH developed glucose intolerance or diabetes, compared with only seven men in the nontreatment group.¹²⁴

Blackman and colleagues¹²⁴ studied in a randomized, controlled trial the synergistic effects of a combination of GH and sex steroids in healthy elderly women and men. A slight increase in lean body mass and muscle strength was observed in elderly men treated with GH and testosterone, but the effects were not seen in women who received GH and estrogen. In a study in healthy elderly men, coadministration of low-dose GH with testosterone resulted in slightly beneficial changes (e.g., muscle strength, quality of life), compared with GH or testosterone alone.¹²⁵

Earlier studies demonstrated that pharmacologic doses of GH prevent the *autocannibalistic* effects of acute diseases on muscle mass.¹²⁶ Confirmation is needed, however, before GH can gain a place in the treatment of acute catabolic states in frail elderly people.

Other components in the regulation of the GH-IGF1 axis are effective in activating GH and IGF1 secretion. Long-acting derivatives of the hypothalamic peptide growth hormone-releasing hormone (GHRH), given twice daily subcutaneously for 14 days to healthy 70-year-old

men, increased GH and IGF1 levels to those encountered in 35-year-olds.²⁶ These studies suggest that somatopause is driven primarily by the hypothalamus and that pituitary somatotropes retain their capacity to synthesize and secrete high levels of GH.

Two ghrelin-mimetic GH secretagogues (GHSs) can restore levels of GH and IGF1 in elderly individuals to levels seen in young adults.^{127,128} Ghrelin, an octanoylated 28-amino-acid peptide, stimulates GH secretion through a distinct, endogenous GHS receptor, but it also has appetite-stimulating activity.¹²⁹

In a 2-year, double-blind, randomized, placebo-controlled, modified-crossover clinical trial enrolling 65 healthy adults aged 60 to 81 years, the orally active GHS and ghrelin mimetic MK-677 increased GH and IGF1 levels to those of healthy young adults, with a slightly increased fat-free mass but without changing fat mass, muscle strength and function, or quality of life. No important adverse effects were observed, apart from a transient increase in appetite and slight decrease in insulin sensitivity.¹³⁰ In a preliminary report of 12-month data from a multicenter study that used a different orally active GHS, capromorelin, in older persons with mild functional decline, dose-responsive increases in IGF1 and changes in body composition were accompanied by small but significant improvements in some measures of physical function (Fig. 27-7).¹³¹ Capromorelin-treated subjects exhibited greater increases in appetite (14 versus 4.9%), insomnia (30.3 versus 17.3%), and higher fasting glucose concentrations at 12 months (+5.4 versus +0.8 mg/dL). Although these results support the hypothesis that endogenous stimulation of GH release may benefit physical performance and delay functional decline in older adults, the magnitude of improvement observed was modest.¹³¹ Stair climbing is a sensitive measure of lower extremity power. In one exercise trial enrolling frail nursing home residents, stair climbing improved by 23% to 34% after 10 weeks of high-intensity resistance training,¹⁰ but only a modest 7% improvement in stair climbing was seen after 2 years of treatment with capromorelin (see Fig. 27-7).

Figure 27-7 Change in power stair climb in elderly individuals (aged 65 to 84 years) with mild functional limitations after 6 and 12 months of therapy with placebo or one of four doses of the oral growth hormone secretagogue/ghrelin mimetic, capromorelin. *, $P < .05$ in comparison with placebo group. (Reproduced from White HK, Petrie CD, Landschulz W, et al. Effects of an oral growth hormone secretagogue in older adults. *J Clin Endocrinol Metab.* 94:1198, 2009.)

The long-term safety of activating GH and IGF1 levels in older people has become a concern because of reports of an association between serum IGF1 concentrations and cancer risk. Individuals with high IGF1 levels (or low IGF-binding protein 3 levels) within the broad normal range have an increased risk of prostate, colon, and breast cancer.¹³²⁻¹³⁴ These epidemiologic studies together with experimental data suggest that the IGF1 system is involved in tumor development and progression. However, no causal relationship between IGF1 levels and cancer risk has been established, and possible medical intervention directed at increasing IGF1 bioactivity in elderly people will in most instances be given toward the end of life, presumably not allowing enough time to affect tumor development or progression.

Conclusions and Recommendations

During the aging process, GH-IGF1 axis activity declines. It is unclear whether changes in body composition and functional capacity are directly related. GH administration in older adults causes an increase in lean body mass and an appreciable loss of fat mass. However, GH treatment does not improve muscle strength and functional capacity in elderly people, despite restoration of circulating IGF1 concentrations to young adult levels. Most dose regimens of GH cause appreciable adverse effects, and long-term safety with regard to tumor development and progression remains uncertain. Oral ghrelin mimetics are also capable of restoring GH and IGF1 levels in the elderly population, together with an increase in appetite. Modest functional improvement was observed in one study after 2 years' administration.

In the near future, clinical trials of orally active molecules in frail elderly people or in elderly individuals with clearly lowered IGF1 levels, or both, should be able to delineate the precise role of the GH-IGF1 axis in the aging process. In these trials, safety must be emphasized. There is no evidence to support recommending medical intervention in the GH-IGF1 axis as an anti-aging effort, to prolong life, or to rejuvenate healthy elderly people.^{135,136} Only elderly patients with GH deficiency caused by organic diseases, such as pituitary adenomas, benefit from GH replacement therapy.¹³⁷

CONCEPT OF SUCCESSFUL AGING

There is considerable variation in the effects of aging on healthy individuals, with some people exhibiting greater, and others few or no, age-related alterations in physiologic functions. It may be useful to distinguish between usual and successful patterns of aging.¹³⁸ Genetic factors, lifestyle, and societal investments in a safe and healthful environment are important aspects of successful aging.¹³⁹

Traditionally, the aging process, including the development of physical frailty toward the end of life, has been considered physiologic and unavoidable, but it may not be necessary to accept the grim stereotype of aging as an unalterable process of decline and loss.¹³⁸ As life expectancy increases during the coming decades, the overarching goal should be "an increase in years of healthy life with a full range of functional capacity at each stage of life."¹⁴⁰ Compression of morbidity can be achieved by adapting healthy lifestyle measures, and several aspects of the aging process of the endocrine system invite the development of routine medical intervention programs offering long-term replacement therapy with one or more hormones to delay

the aging process and to allow humans to live for a longer period in a relatively intact state.¹⁴¹ However, current hormonal interventions with sex steroids, DHEA, GH, and oral ghrelin agonists have had very limited effects on physical capacity in elderly individuals but often produced considerable adverse effects.

MINERAL METABOLISM: BASIC BIOLOGY AND ROLES OF THE MINERAL IONS

Calcium (Ca) and phosphorus (P) are the principal constituents of bone, and together they comprise 65% of its weight. Bone, in turn, contains almost all of the calcium and phosphorus and more than half of the magnesium in the human body. The quantitatively minor amounts of each of these ions in the extracellular fluid (ECF) and within cells play crucial roles in normal physiology (Fig. 28-1).

Ninety-nine percent of total body calcium resides in bone, of which 99% is located within the crystal structure of the mineral phase. The remaining 1% of bone calcium is rapidly exchangeable with extracellular calcium; this calcium is equally distributed between the intracellular and extracellular fluids. Extracellular calcium is the principal substrate for the mineralization of cartilage and bone. It also serves as a cofactor for many extracellular enzymes, most notably the enzymes of the coagulation cascade, and as a source of calcium ions that function as signaling

molecules for a great diversity of intracellular processes. These processes include automaticity of nerve and muscle; contraction of cardiac, skeletal, and smooth muscle; neurotransmitter release; and various forms of endocrine and exocrine secretion.

In blood, approximately 50% of total calcium is bound to proteins, mainly albumin and globulins. The ionized calcium concentration in serum is approximately 1.2 mmol/L (5 mg/dL), and this ionized fraction is biologically active and tightly controlled by hormonal mechanisms. Because intracellular cytosolic free calcium concentrations typically are in the range of only 100 nmol/L, a very large chemical gradient (i.e., 10,000:1), augmented by the large negative electrical potential, favors calcium entry into cells through calcium channels. This gradient is maintained by the limited conductance of resting calcium channels and by the energy-dependent extrusion of calcium into the ECF via high-affinity Ca^{2+} - and H^{+} -adenosine triphosphatases (ATPases) and low-affinity sodium-calcium ($\text{Na}^{+}/\text{Ca}^{2+}$) exchangers.

More than 99% of intracellular calcium exists in the form of complexes within the mitochondrial compartment,

Figure 28-1 Distribution and function of calcium and phosphate. Note the remarkable difference between intracellular and extracellular concentrations of calcium ion and the dramatically different functions of calcium and phosphate inside cells.

bound to the inner plasma membrane, or associated with the inner membranes of the endoplasmic reticulum and other compartments. Release of calcium from membrane-bound compartments transduces cellular signals and is tightly regulated. The mechanisms responsible for translocations of intracellular calcium between the cytosol and these sequestered regions have become better understood with the identification of specific receptors for calcitropic signaling molecules such as the inositol triphosphate (IP_3) receptor and the ryanodine receptors.

Phosphate is more widely distributed to non-osseous tissues than is calcium. Eighty-five percent of body phosphate is in the mineral phase of bone, and the remainder is located in inorganic or organic form throughout the extracellular and intracellular compartments. In human serum, inorganic phosphate (P_i) is present at a concentration of approximately 1 mmol/L and exists almost entirely in ionized form as either $H_2PO_4^-$ or HPO_4^{2-} . Only 12% of serum phosphate is protein bound, and an additional small fraction is loosely complexed with calcium, magnesium, and other cations. Intracellular free phosphate concentrations are comparable to those in the ECF (i.e., 1 to 2 mmol/L), although the inside-negative electrical potential of the cell creates a significant energy requirement for translocation of phosphate into cells. This process generally is accomplished through sodium-phosphate ($NaPi$) cotransport driven by the transmembrane sodium gradient. A number of $NaPi$ cotransporters have been cloned; various cells and tissues employ different species of such transporters with distinctive regulatory characteristics.

Organic phosphate is a key component of almost all classes of structural, informational, and effector molecules that are essential for normal genetic, developmental, and physiologic processes. Phosphate is an integral constituent of nucleic acids; phospholipids; complex carbohydrates; glycolytic intermediates; structural, signaling, and enzymatic phosphoproteins; and nucleotide cofactors for enzymes and G proteins. The need for the large amounts of phosphate incorporated into cellular constituents during cell proliferation explains why phosphate levels in the blood are regulated by insulin-like growth factor 1, in addition to regulation by hormones of bone mineralization. Of particular importance are the high-energy phosphate ester bonds present in molecules such as ATP, diphosphoglycerate, and creatine phosphate that store chemical energy.

Phosphate plays a particularly prominent role as the key substrate or recognition site in numerous kinase and phosphatase regulatory cascades. Cytosolic phosphate per se also directly regulates a number of crucial intracellular reactions, including those involved in glucose transport, lactate production, and synthesis of ATP. In light of these diverse roles, it is not surprising that disorders of phosphate homeostasis associated with severe depletion of intracellular phosphate lead to profound and global impairment of organ function. (Note that none of these roles for intracellular phosphate involve actions of intracellular calcium; the reason we are discussing these together solely results from their intimate relationship in regulating bone mineralization outside of cells.)

Magnesium is the fourth most abundant cation in the body. Roughly half is found in bone and half in muscle and other soft tissues. As much as half of the magnesium in bone is not sequestered in the mineral phase but is freely exchangeable with the ECF and, therefore, may serve as a buffer against changes in extracellular magnesium concentration. Less than 1% of all magnesium in the body is present in the ECF, where the magnesium concentration is approximately 0.5 mmol/L. The concentration of magnesium in serum normally is 0.7 to 1.0 mmol/L, of which roughly one third is protein bound, 15% is loosely complexed with phosphate or other anions, and 55% is present as the free ion. More than 95% of intracellular magnesium is bound to other molecules, most notably ATP, the concentration of which is approximately 5 mmol/L. The intracellular cytosolic free magnesium concentration is approximately 0.5 mmol/L (i.e., 1000-fold higher than that of calcium) and is maintained by an active sodium-magnesium antiporter. The mechanisms whereby magnesium enters cells, presumably down a favorable electrochemical gradient, are unknown, although some evidence for regulated channels has been obtained.¹

Intracellular magnesium, like phosphate, is necessary for a wide range of cellular functions. It is an essential cofactor in enzymatic reactions, including most of the same glycolytic, kinase, and phosphatase pathways that also involve phosphate. Magnesium serves to directly stabilize the structures of a variety of macromolecules and complexes, including deoxyribonucleic acid (DNA), ribonucleic acid (RNA), and ribosomes; it is also a key activator of the many ATPase-coupled ion transporters and plays a direct role in mitochondrial oxidative metabolism. As a result, magnesium is critical for energy metabolism and the maintenance of a normal intracellular environment. Extracellular magnesium is crucial for normal neuromuscular excitability and nerve conduction, and many of the clinical consequences of magnesium deficiency or excess reflect abnormalities in this sphere.

The levels of extracellular calcium and phosphate are regulated in a coordinated way that reflects the roles of calcium and phosphate in mineralization of bone. The concentrations of these ions in body fluids are, together, close to the concentrations that could lead to spontaneous precipitation in soft tissues. In fact, elaborate mechanisms, most poorly understood, have evolved to prevent precipitation of calcium phosphate in tissues and yet allow the controlled deposition of calcium and phosphate in bone.² The importance of the mineral ions for normal cellular physiology as well as skeletal integrity is reflected in the powerful endocrine control mechanisms that have evolved to maintain their extracellular concentrations within relatively narrow limits. The following sections describe the structures, secretory controls, actions, and interactions of parathyroid hormone (PTH), calcitonin, $1,25(OH)_2D_3$

Figure 28-2 Parathyroid hormone (PTH)-calcium feedback loop that controls calcium homeostasis. Four organs—the parathyroid glands, intestine, kidney, and bone—together determine the parameters of calcium homeostasis. +, positive effect; −, negative effect; 1,25 D, 1,25-dihydroxyvitamin D₃; ECF, extracellular fluid.

(1,25-dihydroxyvitamin D or calcitriol), and fibroblast growth factor 23 (FGF23)—the major hormones involved in mineral ion homeostasis. Subsequent sections cover the wide variety of clinical disorders that accompany abnormalities in this hormonal network.

PARATHYROID HORMONE

PTH is the peptide hormone that controls the minute-to-minute level of ionized calcium in the blood and ECF. PTH binds to cell surface receptors in bone and kidney, triggering responses that increase blood calcium (Fig. 28-2). PTH also increases renal synthesis of calcitriol, the hormonally active form of vitamin D, which then acts on the intestine to augment absorption of dietary calcium, in addition to promoting calcium fluxes into blood from bone and kidney. The resulting increase in blood calcium (and in

calcitriol) feeds back on the parathyroid glands to decrease the secretion of PTH. The parathyroid glands, bones, kidney, and gut are thus the crucial organs that participate in PTH-mediated calcium homeostasis.

Parathyroid Gland Biology

Parathyroid glands first appeared in evolutionary history with the exit of amphibians from the sea and a switch from dependence on gills to sole dependence on bone, intestine, and kidney to maintain extracellular calcium homeostasis. Reptiles, birds, and mammals all have parathyroid glands that develop as epithelial specializations from the endoderm of the pharyngeal pouches. Although fish have no discrete parathyroid glands, they do synthesize PTH.³ The physiologic role of this PTH in fish is not yet defined.

Parathyroid chief cells have three properties that are vital to their homeostatic function. First, they rapidly secrete hormone in response to changes in blood calcium. Second, they can synthesize, process, and store large amounts of PTH in a regulated manner. Third, parathyroid cells replicate when chronically stimulated. These functional attributes allow, respectively, for short-term, intermediate-term, and long-term adaptation to changes in calcium availability.

Parathyroid Hormone Biosynthesis

PTH, a protein of 84 amino acids in mammals, is synthesized as a larger precursor, called pre-proparathyroid hormone (pre-pro-PTH); the gene has been sequenced in 11 species ranging from fish to humans.⁴ Figure 28-3 illustrates representative pre-pro-PTH sequences. These sequences share a 25-residue “pre” or signal sequence and a 6-residue “pro” sequence. The signal sequence, along with the short pro sequence, functions to direct the protein into the secretory pathway (Fig. 28-4). During transit across the membrane of the endoplasmic reticulum, the signal sequence is cleaved off and rapidly degraded. The importance of the signal sequence for normal secretion of PTH is illustrated by the hypoparathyroidism inherited in families that carry mutations in the signal sequence of pre-pro-PTH.^{5,6}

The role of the short pro sequence is not completely understood; it may help the signal sequence to work

Figure 28-3 Sequences of pre-proparathyroid hormone from six species. Completely conserved residues are in boldface. Arrows indicate the sites of signal sequence (“pre”) and “pro” sequence cleavage. Numbers start at residue +1 of mature parathyroid hormone (PTH); because of gaps, the numbers correspond only to the mammalian and not to the chicken sequence. Amino acids are indicated by single-letter codes: A, Ala; R, Arg; N, Asn; D, Asp; C, Cys; Q, Gln; E, Glu; G, Gly; H, His; I, Ile; L, Leu; K, Lys; M, Met; F, Phe; P, Pro; S, Ser; T, Thr; V, Trp; Y, Tyr; V, Val.

Figure 28-4 Intracellular processing of pre-proparathyroid hormone (pre-pro-PTH). Diagonal arrows indicate sites of cleavage by enzymes that generate pro-PTH in the rough endoplasmic reticulum (ER), PTH in the Golgi apparatus, and carboxy-terminal fragments of PTH in the secretory granule.

efficiently and ensure accurate cleavage of the precursor.⁷ After cleavage of the pro sequence, the mature PTH(1-34) is concentrated in secretory vesicles and granules. One morphologically distinct subtype of granule contains both PTH and the proteases cathepsin B and cathepsin H. This co-localization of proteases and PTH in secretory granules probably explains the observation that a portion of the PTH secreted from parathyroid glands consists of carboxy-terminal PTH fragments. No amino-terminal fragments of PTH are secreted. Although the possible functions of carboxy-terminal fragments of PTH are still poorly characterized, they do not activate the receptor for PTH and parathyroid hormone-related protein (PTHrP) and may even block bone resorption (see later discussion).⁸ The intracellular degradation of newly synthesized PTH therefore provides an important regulatory mechanism. Under conditions of hypercalcemia, the secretion of PTH is substantially decreased, and most of what is secreted consists of carboxy-terminal fragments.⁹

Parathyroid Hormone Secretion

Although catecholamines, magnesium, and other stimuli can affect PTH secretion, the major regulator of PTH secretion is the concentration of ionized calcium in blood. Increased serum ionized calcium leads to a decrease in PTH secretion (Fig. 28-5A). The shape of the dose-response curve is sigmoid. Properties of the parathyroid cell determine the conformation of the sigmoidal curve but do not alone determine the point on the curve that represents a physiologic steady state for an individual. This point, which is usually between the midpoint and the bottom of the curve, is determined by how vigorously target organs respond to PTH.¹⁰ Figure 28-5C (solid line) shows how an individual's calcium level rises in response to increases in PTH; the parathyroid gland's sigmoidal curve is the dotted line. In the steady state, the blood levels of PTH and calcium are represented by the intersection of the two lines.

The sigmoidal curve reveals several important physiologic properties of the parathyroid gland. The minimal secretory rate is low, but not zero. The maximal secretory rate represents the reserve of the parathyroid's capacity to respond to hypocalcemia. Because values from normal persons in the steady state are located in the lower portion of the sigmoidal curve, the system seems designed to respond more dramatically to hypocalcemia than to hypercalcemia.

Physiologic studies in humans have confirmed this sigmoidal relationship and have also revealed that the parathyroid cell responds both to the absolute level of blood calcium and to the rate of fall of the calcium level. For example, PTH levels briefly rise higher during a sudden drop in blood calcium than they do during a more gradual fall in calcium. This property of the parathyroid cell offers an additional protection against sudden hypocalcemia.

The biochemical and cellular determinants of the parathyroid gland's sigmoidal response curve are beginning to be defined. A parathyroid calcium-sensing receptor (CASR)¹¹ on the parathyroid cell surface is a member of the G protein-coupled family of receptors. The sequence of the receptor suggests that it spans the plasma membrane seven times, like other receptors in the G protein-linked receptor family (Fig. 28-6). A large extracellular domain resembles similar domains in brain metabotropic glutamate receptors as well as bacterial periplasmic proteins designed to bind small ligands, including cations. The receptor is expressed in a number of cell types and has been shown to activate phospholipase C and to block stimulation of cyclic adenosine monophosphate (cAMP) production, just as it does in normal parathyroid cells.

The most convincing proof of the identity of the parathyroid CASR has been the observation that mutations in the receptor gene cause characteristic human diseases. Inactivating mutations cause familial hypocalciuric hypercalcemia (FHH), a disease of defective calcium sensing (see later discussion),¹² whereas activating mutations cause familial hypoparathyroidism with hypercalciuria.¹³ Furthermore, mice that have been genetically engineered to have only one functioning copy of the CASR gene also have the expected defects in parathyroid calcium sensing. Of importance, calcimimetic compounds that activate the cloned CASR have been shown to inhibit PTH secretion in humans and are useful in the treatment of secondary hyperparathyroidism.^{14,15} Despite the enormous increase in understanding of how extracellular calcium activates the parathyroid CASR, the mechanism by which this activation leads to a decrease in PTH secretion is poorly understood.

The CASR is expressed widely. Expression in the renal tubules and in the calcitonin-producing cells of the thyroid contributes to calcium homeostasis, whereas expression in organs such as the brain points to multiple roles for calcium signaling. The observation that the CASR also responds to physiologic levels of certain amino acids¹⁶ suggests that its expression in the gut, parathyroid, and other sites may facilitate the assimilation of multiple nutrients.

Regulation of the Parathyroid Hormone Gene

The minute-to-minute regulation of PTH blood levels can be explained by the two mechanisms already discussed: regulation of PTH secretion by the CASR and amplification of this regulation by intracellular degradation of stored hormone. Over a longer time frame, the parathyroid cell regulates the expression of the PTH gene as well.

Although calcitriol, the active form of vitamin D, has no direct effect on PTH secretion, it dramatically suppresses PTH gene transcription.¹⁷ This suppression of transcription does not occur when calcitriol is administered to chronically hypocalcemic animals, however, perhaps because hypocalcemia leads to a fall in the number of parathyroid cell vitamin D receptors (VDRs) or because hypocalcemia increases the expression of calcitriol in the parathyroid.¹⁸ The capability of hypocalcemia to override the effects of high levels of calcitriol represents an important defense, because it provides a way for the parathyroid cell to

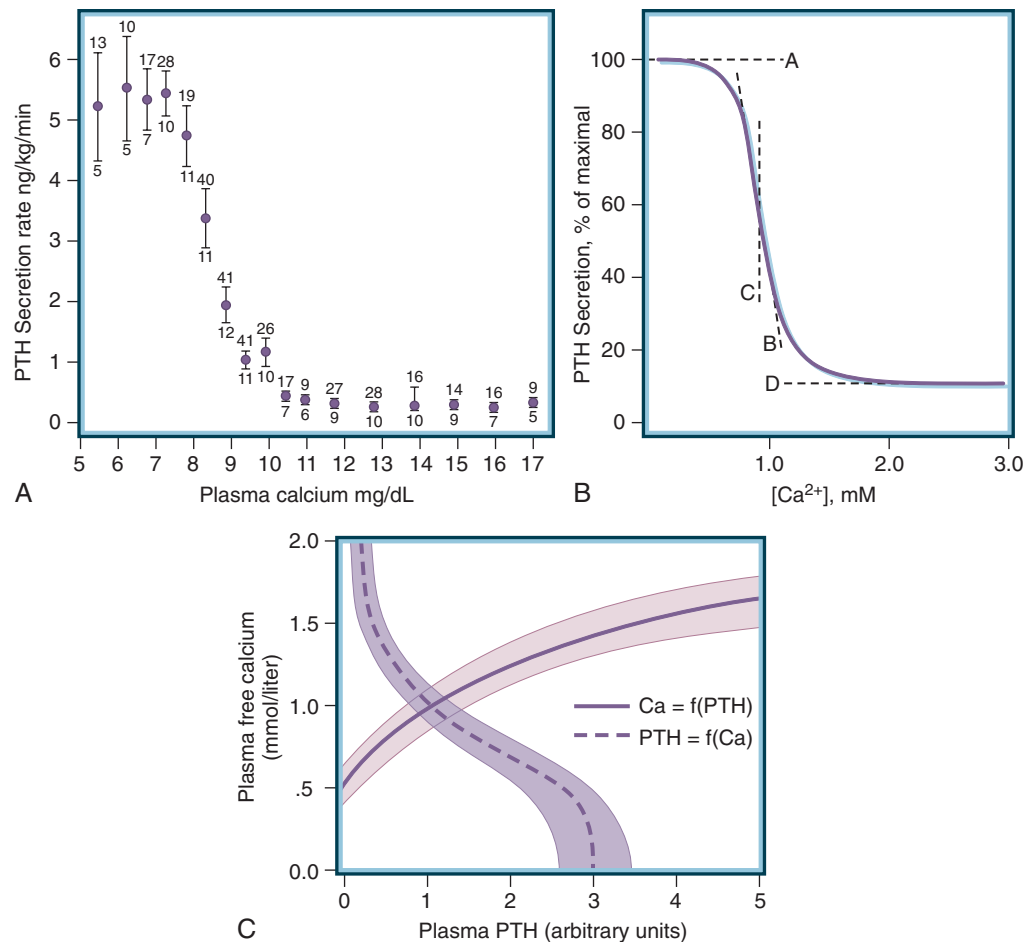

Figure 28-5 Parathyroid hormone (PTH) secretion. **A**, Secretory response of bovine parathyroid glands to induced alterations of plasma calcium concentration. Calves were infused with calcium chloride or ethylenediaminetetra-acetic acid (EDTA), and PTH secretion was assessed by measuring PTH levels in the parathyroid venous effluent. The circles and vertical bars indicate the secretory rate (mean \pm SE) in calcium concentration ranges of 1.0 or 0.5 mg/100 mL. The number of calves and samples are indicated, respectively, by numbers below and above the bars. (From Mayer GR, Hurst JG. Sigmoidal relationship between parathyroid hormone secretion rate and plasma calcium concentration in calves. *Endocrinology*. 1978;10:1037-1042.) **B**, Sigmoidal curve generated by the equation $Y = \{[A - D]/[1 + (X/C)^B]\} + D$. Such a curve can be defined by four parameters: the maximal secretory rate (A), the slope of the curve at its midpoint (B), the level of calcium at the midpoint (often called the setpoint) (C), and the minimal secretory rate (D). The significance of A, B, C, and D is described in the text. (Modified from Brown EM. Four-parameter model of the sigmoidal relationship between parathyroid hormone release and extracellular calcium concentration in normal and abnormal parathyroid tissue. *J Clin Endocrinol Metab*. 1983;56:572-581.) **C**, Relationships between calcium and PTH levels when each in turn is treated as an independent variable. The dashed line represents the sigmoidal relationship between calcium and PTH when calcium is the independent variable. This curve is the same as that in **A** and **B**, but it is turned on its side, because the axes are reversed. The solid line represents the relationship between calcium and PTH when PTH is considered the independent variable; values for this curve result from measurements made during PTH infusion into parathyroidectomized animals. Actual data are limited, so the curves should be viewed as illustrative. (From Parfitt AM. Calcium homeostasis. In Mundy GR, Martin TJ, eds. *Physiology and Pharmacology of Bone: Handbook of Experimental Pharmacology*, vol 107. Berlin: Springer-Verlag; 1993:1-65.)

synthesize large amounts of PTH and calcitriol at the same time, when both are needed.

Calcium also regulates the biosynthesis of PTH. In vivo studies show that acute hypocalcemia in rats leads, within 1 hour, to an increase in PTH messenger RNA (mRNA). In contrast, hypercalcemia leads to little or no change in PTH mRNA. Therefore, under normal conditions, the inhibition by calcium of PTH biosynthesis already is almost maximal, just as it is for PTH secretion. The parathyroid gland is poised to respond to a fall in calcium much more readily than to a rise. The mechanism for the increase in PTH mRNA in response to hypocalcemia is uncertain; differing experimental paradigms suggest regulation at the levels of gene transcription, mRNA translation, and mRNA stability. The latter mechanism is the one best understood at the molecular level.^{19,20} In the parathyroid cell, the

peptidyl-prolyl isomerase Pin1 binds to and leads to the activation of K-homology splicing regulator protein (KSRP), an RNA-binding protein that destabilizes PTH mRNA. Mice without Pin1 have high PTH and PTH mRNA levels, and hypocalcemic rats and rats with chronic kidney disease have low levels of Pin1. Therefore, Pin1 and KSRP regulate PTH mRNA levels in normal physiology and disease.

For decades it has been known that phosphate elevation stimulates PTH secretion, largely by lowering the levels of blood calcium and calcitriol. More recently, a series of studies in vitro^{21,22} and in vivo²³ demonstrated that phosphate can increase PTH secretion directly, independent of effects on blood calcium and calcitriol. Phosphate increases PTH secretion acutely only after a delay, and it probably works largely through regulation of PTH mRNA levels. The mechanisms that phosphate uses to regulate parathyroid

Figure 28-6 Signaling by the calcium-sensing receptor. Numerous agonists activate the calcium-sensing receptor (CaR) and trigger intracellular pathways. AA, arachidonic acid; AC, adenylate cyclase; cAMP, cyclic adenosine monophosphate; cPLA₂, cytosolic phospholipase A₂; DAG, diacylglycerol; Giα and Gqα, α-subunits of the i- and q-type heterotrimeric G proteins, respectively; Ins(1,4,5)P₃, inositol-1,4,5-trisphosphate; Ins(1,4,5)P₃R, inositol-1,4,5-trisphosphate receptor; JNK, Jun amino-terminal kinase; MAPK, mitogen-activated protein kinase; MEK, MAPK kinase; PI4K, phosphatidylinositol 4-kinase; PKC, protein kinase C; PLC, phospholipase C; PtdIns(4,5)P₂, phosphatidylinositol-4,5-bisphosphate; ERK, extracellular-signal-regulated kinase. cells are unknown. It is intriguing to speculate that these mechanisms may interact with the pathways regulated by FGF23²⁴ and Klotho,²⁵ mediators of phosphate action in other settings, and act directly on parathyroid cells (see later discussion of FGF23).

The regulation of the PTH gene has particular clinical relevance in patients with renal failure. Hypocalcemia, low levels of calcitriol, hyperphosphatemia, FGF23 (see later discussion) and, possibly, uremic toxins disrupt normal calcium homeostasis in this setting. Therapy with calcitriol and calcium increases calcium absorption and also inhibits PTH synthesis by direct effects on the parathyroid gland. Cinacalcet, an activator of the CASR, lowers PTH secretion and thereby lowers both calcium and phosphorus levels.¹⁴ (In renal failure, the role of PTH to increase release of phosphorus from bone dominates over any action of PTH to increase phosphaturia.) Prevention of hyperphosphatemia avoids the direct and indirect actions of phosphate in stimulating PTH secretion.

Regulation of Parathyroid Cell Number

Parathyroid cells divide during the growth of young animals but replicate little in adulthood.²⁶ Parathyroid cell number can dramatically increase, however, in the setting of hypocalcemia, low levels of calcitriol, hyperphosphatemia, or uremia and during neoplastic growth.

Calcium, acting through the parathyroid CASR, restrains parathyroid proliferation. This effect has been demonstrated clinically in patients who lack both copies of the CASR gene. These neonates exhibit severe primary hyperparathyroidism with large, diffusely hyperplastic glands that presumably have developed because of insufficient activation of the parathyroid CASR by extracellular calcium. Furthermore, administration of the calcimimetic compound NPS R-568, which activates the CASR directly, prevents parathyroid cell proliferation in experimental uremia.

The role of calcitriol, independent of blood calcium, in regulating parathyroid cell proliferation is less well established than that of calcium. That calcitriol can dramatically affect parathyroid cell number has been shown in vivo in many settings, but such studies cannot rigorously eliminate effects of transient changes in blood calcium. The suppression of proliferation of cultured parathyroid cells by calcitriol²⁷ suggests that it can directly inhibit parathyroid cell replication. In experimental renal failure, the action of calcitriol to decrease parathyroid cell expression of transforming growth factor may partly explain the dampening of parathyroid cell proliferation.²⁸ Nevertheless, vitamin D action through the VDR is not essential for control of parathyroid cell number, because calcium alone can prevent parathyroid cell hyperplasia in mice engineered to lack VDRs.²⁹

Although the ability to increase parathyroid cell number in response to physiologic challenge represents an important defense against hypocalcemia, it is a slow response that is not easily reversible. When the need for an increased number of parathyroid cells disappears (e.g., after renal transplantation for uremia), persistent hyperparathyroidism can cause vexing clinical problems for months and years afterward. The mechanisms for decreasing parathyroid cell number, if they exist, are poorly understood. Apoptosis of normal parathyroid cells in response to experimental manipulation has not been demonstrated.

Parathyroid Gland Development

Genes involved in making parathyroid cells during development may also regulate PTH synthesis and parathyroid cell number throughout life; therefore, understanding of parathyroid cell development could have broad clinical implications. Although the genetic mechanisms used to generate parathyroid chief cells during development are

largely unknown, the importance of several specific genes has become clear.

Studies of gene knockout mice have shown that the *hoxa3*,³⁰ *pax1*,³¹ *pax9*,³² and *Eya1*³³ transcription factors are needed to form parathyroid glands, as are many other pharyngeal pouch derivatives, such as the thymus (reviewed by Liu and colleagues³⁴). Another transcription factor, *Tbx1*, which is regulated by the developmental paracrine factor, sonic hedgehog, is expressed early in parathyroid development and is essential for parathyroid cell development. In humans and mice, haploinsufficiency for the transcription factor *Tbx1* is likely to be responsible for many of the abnormalities found in DiGeorge syndrome, including hypoparathyroidism.³⁵ Whereas these transcription factors together are essential for the early generation of parathyroid cells, another transcription factor, called “glial cell missing” or *GCM2*, is needed for the continuing survival of parathyroid cells.³⁴ Furthermore, mice or humans³⁶ missing this gene have no parathyroid glands. In both species, deletion of the gene is very specific for controlling parathyroid development, because no abnormalities in other tissues have been noted. Mice, which have only two parathyroid glands normally, still make PTH in a small number of cells in the thymus after *Gcm2* gene ablation, and they secrete this PTH into the circulation. Humans without *GCM2* have little detectable circulating PTH at birth and low levels of PTH several years later.

Studies of human hypoparathyroidism have led to the discovery of the likely roles of other transcription factors in parathyroid development. *Sox3* is a transcription factor expressed in the pharyngeal pouches that give rise to parathyroid cells. Humans with X-linked hypoparathyroidism manifest a deletion-insertion near the end of the *SOX3* gene, a finding that suggests an important role for *Sox3* in parathyroid development.³⁷ People with mutations in the gene encoding the transcription factor *GATA3* exhibit a syndrome of hypoparathyroidism, sensorineural deafness, and renal anomalies when only one copy of the gene is mutated.³⁸

Metabolism of Parathyroid Hormone

The earliest radioimmunoassays for PTH demonstrated that the molecular forms of PTH in the circulation differ from those in the parathyroid gland. Characterization of the metabolism of PTH and its fragments has clarified the origins and significance of immunoreactive PTH molecules in the bloodstream.³⁹ As noted previously, both PTH(1-84) and carboxy-terminal fragments of PTH are secreted from the parathyroid gland; the ratio of inactive PTH to active PTH secretion increases with increasing blood calcium. Secreted intact PTH(1-84) is extensively metabolized by liver (70%) and kidney (20%) and disappears from the circulation with a half-life of 2 minutes. This rapid peripheral metabolism of PTH is unaffected by widely varying levels of blood calcium or calcitriol. Less than 1% of the secreted hormone finds its way to PTH receptors on physiologic target organs. These features of PTH metabolism ensure that the blood level of PTH is determined principally by the activity of the parathyroid glands and that the PTH level can respond rapidly to small changes in the rate of secretion of the hormone.

In the liver, a small amount of PTH binds to physiologically relevant PTH receptors, but most of the intact PTH is cleaved, initially after residues 33 and 36, probably by cathepsins. In the kidney, a small amount of intact PTH binds to physiologic PTH receptors, but most of the intact PTH is filtered at the glomerulus and subsequently bound

by a large, membrane-bound luminal protein, megalin.⁴⁰ This binding leads to internalization and degradation of PTH by the tubules.⁴¹ Carboxy-terminal fragments are also cleared efficiently by glomerular filtration. In fact, the kidney is the only known site of clearance of carboxy-terminal PTH fragments, and these fragments accumulate dramatically when the glomerular filtration rate (GFR) falls. Even in the presence of normal renal function, the half-life of carboxy-terminal fragments of PTH exceeds that of PTH¹⁻⁸⁴ by several-fold. Consequently, the concentration of carboxy-terminal fragments in the circulation exceeds that of intact PTH, even though intact PTH usually is the major form of PTH secreted from the parathyroid gland.

Careful analysis of PTH fragments using high-performance liquid chromatography (HPLC) and immunologic methods has revealed almost full-length PTH fragments that are missing the first several amino acids of the hormone but contain most or all of the remaining hormone sequence.⁴² These still incompletely characterized fragments are both secreted from the parathyroid gland and generated by peripheral metabolism of the hormone. Because they are missing the amino-terminal portion of PTH, they cannot stimulate cAMP production by the PTH/PTHrP receptor, and they circulate in small amounts except in renal failure. Nevertheless, the possible biologic activity of these and other PTH fragments, possibly through novel receptors, remains an area of active investigation. Experiments with PTH(7-84) suggest that such extended carboxyl fragments may exert potent effects *in vivo*, opposing those of intact PTH (see later discussion).^{8,43,44}

Actions of Parathyroid Hormone

Actions of Parathyroid Hormone on the Kidney

Stimulation of Calcium Reabsorption. Almost all of the calcium in the initial glomerular filtrate is reabsorbed by the renal tubules. Sixty-five percent or more is reabsorbed by the proximal convoluted and straight tubules via a passive, paracellular route.⁴⁵ Changes in the transepithelial voltage gradient, determined largely by the rate of sodium reabsorption, control the rate of calcium transport in the proximal tubule, and PTH does little to affect calcium flux in this region. The remaining calcium is largely reabsorbed more distally—20% of the initial filtrate in the cortical thick ascending limb (cTAL) of Henle's loop and 10% in the distal convoluted and connecting tubules.

In the cTAL, calcium reabsorption also is mainly passive and paracellular, although some transcellular, active calcium transport may occur as well. Efficient paracellular calcium and magnesium movement requires expression of a unique tight-junction protein, paracellin-1; mutant paracellin-1 genes underlie a rare renal calcium- and magnesium-wasting disorder.⁴⁶ Because paracellular cation transport in the cTAL is driven by the lumen-positive transepithelial voltage gradient that is established by active sodium reabsorption, calcium reabsorption there is strongly inhibited by loop diuretics such as furosemide. The CASR, initially characterized in the parathyroid, also is expressed in the cTAL. When activated by high blood levels of calcium or magnesium, this receptor inhibits Na/K/Cl₂ reabsorption in the cTAL and, consequently, paracellular calcium reabsorption as well. This provides a parathyroid-independent mechanism for controlling renal calcium handling in direct response to changes in blood calcium concentration.

Although PTH modestly stimulates paracellular calcium reabsorption in the cTAL, the primary site for hormonal

regulation of renal calcium reabsorption is the distal nephron, which normally reabsorbs almost all of the remaining 10% of filtered calcium by a unique transcellular active transport mechanism. As depicted in Figure 28-1, the intracellular level of calcium is extremely low, about 150 nmol/L, compared with the millimolar levels in the glomerular filtrate and the blood. Calcium enters distal tubular cells from the tubular lumen down a highly favorable electrochemical gradient via selective Ca^{2+} channels (TRPV5 and TRPV6) that are present on the apical membrane of cells in the distal convoluted tubule and connecting tubule. Intracellular calcium inhibits the activity of these channels, but this is minimized by the avid binding of calcium to calbindin-D28K, which effectively buffers cytosolic calcium and transports it to the basolateral membrane. There, calcium is ejected via active processes involving mainly the sodium-calcium exchanger NCX1 and an ATP-driven calcium pump (PMCA).⁴⁷ PTH stimulates active calcium transport in the distal convoluted tubule and connecting tubule by upregulating several of these components, including TRPV5, calbindin-D28K and NCX1, both directly and indirectly, via increased synthesis of calcitriol.^{47,48}

The amount of calcium in the final urine reflects all of the tubular reabsorption processes just enumerated but also depends crucially on the initial filtered load of calcium. All of PTH's actions serve to raise the blood calcium level, so the filtered load of calcium is high in states of PTH excess. In that setting, even though the rate of distal tubular calcium reabsorption is increased by PTH, the total amount of calcium in the final urine is likely to be high, because of the high initial filtered load.

Inhibition of Phosphate Transport. Phosphate reabsorption occurs mainly in the proximal renal tubules, which reclaim roughly 80% of the filtered load. Some additional phosphate (8% to 10%) is reabsorbed in the distal tubule (but not in Henle's loop), leaving about 10% to 12% for excretion in the urine. The normal overall fractional tubular reabsorption of phosphate (TRP), therefore, is about 90%, although a more reliable measure of renal phosphate handling is the *phosphate threshold* ($\text{Tm}_{\text{PO}_4}/\text{GFR}$), which can be derived from the TRP through the use of a nomogram (Fig. 28-7) based on studies of experimental phosphate infusions in healthy persons and in patients with a variety of diseases that affect phosphate excretion.⁴⁹

Phosphate reabsorption in both proximal and distal tubules is strongly inhibited by PTH, although the proximal effect is quantitatively more important. Phosphate is reabsorbed by a transepithelial route. Transport from the glomerular filtrate into the cell is mediated by specific NaPi cotransporters, several types of which have been cloned and extensively characterized.⁵⁰ The low level of sodium within the cell drives the cotransport of sodium and phosphate, even though the phosphate travels up an electrochemical gradient. In response to PTH, the maximum velocity (V_{max}) for NaPi cotransport decreases because NaPi cotransporters (both NaPi-IIa and NaPi-IIc) are rapidly (15 minutes) sequestered within subapical endocytic vesicles, after which they are delivered to lysosomes and undergo proteolysis.⁵¹ This response to PTH is dependent on Na^+/H^+ exchange regulatory factors (NHERFs) that physically interact with both the PTH/PTHrP receptor and the NaPi type II cotransporters and control the pattern of PTH receptor signaling.⁵² Conversely, in hypoparathyroidism, expression of NaPi protein and mRNA is strongly upregulated.

Dietary intake of phosphate also reciprocally regulates the expression and activity of NaPi cotransporters and,

Figure 28-7 Nomogram for determining renal threshold phosphate concentration ($\text{Tm}_{\text{PO}_4}/\text{GFR}$) from the plasma phosphate concentration $[\text{PO}_4]$ and the fractional reabsorption of filtered phosphate (TRP) or fractional excretion of filtered phosphate ($1 - \text{TRP}$, or $\text{C}_{\text{PO}_4}/\text{C}_{\text{creat}}$). Because the blood level of phosphate influences the renal handling of phosphate, the $\text{Tm}_{\text{PO}_4}/\text{GFR}$ best separates normal from abnormal renal phosphate handling. C, clearance; creat, creatinine; GFR, glomerular filtration rate; TRP, tubular resorption of phosphate. (From Walton RJ, Bijvoet OLM. Nomogram of derivation of renal threshold phosphate concentration. *Lancet*. 1975;2:309-310.)

consequently, the proximal tubular absorption of phosphate by a mechanism that is independent of PTH. Dietary deprivation of phosphate, for example, leads to a stimulation of phosphate reabsorption that can override the effects of PTH on the proximal tubule. It is likely that this dietary regulation of NaPi expression is mediated by FGF23⁵³ (see later discussion).

Other Renal Effects of Parathyroid Hormone. PTH stimulates the synthesis of $1,25(\text{OH})_2\text{D}_3$ (calcitriol) in the proximal tubule by rapidly inducing transcription of the $25(\text{OH})\text{D}$ 1α -hydroxylase gene, an effect that can be overridden by hypercalcemia or by calcitriol. The interactions of calcitriol and PTH in regulating the $25(\text{OH})\text{D}$ 1α -hydroxylase gene involve both protein kinase A-mediated phosphorylation of an activating transcription factor and protein kinase C-mediated demethylation of DNA upstream of the $25(\text{OH})\text{D}$ 1α -hydroxylase gene.⁵⁴ PTH inhibits proximal tubular transcription of the $25(\text{OH})\text{D}$ 24-hydroxylase gene and antagonizes the upregulation of 24-hydroxylase activity by calcitriol (see "Vitamin D Metabolism"). PTH inhibits proximal tubular sodium, water, and bicarbonate reabsorption, mainly via inhibition of the apical Na^+/H^+ exchanger (NHE3) and the basolateral Na^+/K^+ -ATPase. PTH also stimulates proximal tubular gluconeogenesis and acts directly on glomerular podocytes to decrease both the single-nephron and the whole-kidney GFR.

Actions of Parathyroid Hormone on Bone

The actions of PTH on bone are complicated because PTH acts on a number of cell types, both directly and indirectly. For years, the release of calcium from bone through stimulation of bone resorption has been considered to be the major action of PTH on bone. This is only part of the story,

however. In fact, PTH administration by any route increases both bone resorption and bone formation. Which action dominates depends on the dose of PTH and the route of administration. When PTH is administered continuously, the effect of PTH on bone resorption dominates, and the net result is release of calcium from bone and a decrease in bone mass. This action of PTH therefore contributes to the increase in blood calcium seen on administration of PTH. In contrast, administration of low doses of PTH or of active, amino-terminal fragments of PTH by once-daily subcutaneous injection leads to a net increase in bone mass, with only transient effects on the blood calcium level. Mechanisms for these divergent effects of PTH are incompletely understood but certainly reflect the variety of cell types in bone that respond directly to PTH, the varying time courses of these responses, and the indirect effects caused by autocrine and paracrine responses to PTH.⁵⁵

Figure 28-8 illustrates the cells of the osteoblast lineage (see also Chapter 29). Osteoblasts are probably derived from pluripotent mesenchymal stem cells that, at least in vitro, can differentiate into chondrocytes, adipocytes, osteoblasts, and other cell types.⁵⁶ Perivascular cells within human bone can reconstitute bone that supports hematopoiesis after subcutaneous transplantation in mice⁵⁷; these cells may well represent one group of osteoblast stem cells in vivo. Within the osteoblast lineage, committed osteoprogenitor cells divide, become preosteoblastic stromal cells (which can divide further), and then become osteoblasts. Osteoblasts no longer divide and are cuboidal cells found on the bone surface actively laying down new bone. When these cells become surrounded by bone, they become stellate osteocytes. If, instead, osteoblasts stop synthesizing matrix and remain on the bone surface, they flatten out as bone lining cells. Not all preosteoblasts and osteoblasts mature; a variable number die by apoptotic, programmed cell death.⁵⁸

Figure 28-8 Osteoblast lineage. All precursors of osteoblasts can proliferate; osteoblasts are transformed to osteocytes and lining cells without further proliferation. Some data suggest that lining cells may revert to osteoblast function after parathyroid hormone stimulation. At each stage in the lineage, apoptotic cell death is probably an alternative fate.

PTH administration can influence movement of cells through the osteoblast lineage.⁵⁵ PTH administration in vivo, whether administered continuously or intermittently, increases osteoblast surface and number and the rate of bone formation. With intermittent PTH administration, the number of bone lining cells decreases as the number of active osteoblasts increases, without an increase in the percentage of osteoblasts incorporating precursors into DNA; these observations suggest that lining cells might be converted to osteoblasts in response to PTH.⁵⁹ An alternative, and not mutually exclusive, explanation for the increase in osteoblast number after intermittent PTH administration is the observed decrease in the rate of osteoblast apoptosis after PTH administration.⁵⁸ PTH administration in vivo also probably increases the number of early osteoblast precursors. For example, both the number of total stromal cell colonies (CFU-F) generated and the number of CFU-F expressing alkaline phosphatase, were increased when bone marrow cells were plated in vitro after treatment of rats with PTH(1-34) intermittently.⁶⁰ This increase in osteoblast precursors may correlate with the in vivo phenomenon of "osteofibrosis," with large numbers of alkaline phosphatase-positive fibroblastic cells present in marrow after prolonged, continuous activation of the PTH receptor in vivo.⁶¹ The effect of PTH administration on osteoblast differentiation after plating of calvarial or marrow cells in vitro has also been studied extensively. For example, when PTH is administered to calvarial cells plated in vitro, bone nodule formation is suppressed, probably by late actions that slow the conversion of preosteoblasts to mature osteoblasts.⁶² The precise timing of the addition of PTH in this system has disparate effects, partly through activation of distinct second messenger pathways and stimulation of secretion of other signaling molecules. These in vivo and in vitro studies therefore suggest effects of PTH on movement through the osteoblast lineage at multiple steps.

In addition to changing osteoblast numbers, PTH changes the activity of mature osteoblasts by a variety of mechanisms. When PTH is added to calvariae in vitro, the osteoblasts decrease their synthesis of collagen I and other matrix proteins. This action may reflect, in part, the action of PTH to steer the essential osteoblast transcription factor Runx2 toward proteosomal destruction.⁶³ In vivo, however, the most obvious effects of PTH are to increase bone formation by osteoblasts, probably by indirect actions of PTH on autocrine and paracrine pathways. PTH stimulation of osteoblastic cells leads to the release of growth factors such as insulin-like growth factor 1, FGF2, and amphiregulin from these cells.⁶⁴ PTH also decreases the synthesis of dickkopf-1⁶⁵ and SOST,⁶⁶ inhibitors of Wnt signaling⁶⁷; these actions are expected to increase the anabolic actions of Wnt proteins on osteoblasts. These paracrine actions of PTH may not only stimulate osteoblastic cells with PTH receptors but might well activate, indirectly, osteoblast precursors that are too immature to express PTH receptors. Further, because bone matrix is a rich source of osteoblast growth factors, the release of these growth factors from this matrix after PTH-induced bone resorption may increase bone formation and bring osteoblastic cells to sites of bone formation.⁶⁸ Therefore, a variety of both direct and indirect actions of PTH can lead to the increased production of bone.

Surprisingly, osteoclasts, the bone-resorbing cells derived from hematopoietic precursors, have no PTH receptors on their surfaces. Instead, preosteoblasts and osteoblasts signal to osteoclast precursors to cause them to fuse and form mature osteoclasts. This signaling also serves to stimulate mature osteoclasts to resorb bone and to avoid apoptosis (Fig. 28-9). Two osteoblast surface proteins, macrophage

Figure 28-9 Stromal cell control of osteoclastogenesis and osteoclast activity. Parathyroid hormone (PTH) acts on PTH/PTH-related protein (PTHrP) receptors on precursors of osteoblasts to increase the production of macrophage colony-stimulating factor (M-CSF) and receptor activator for nuclear factor κ B (RANK) ligand and to decrease the production of osteoprotegerin (OPG). M-CSF and RANK ligand stimulate the production of osteoclasts and increase the activity of mature osteoclasts by binding to the receptor RANK. OPG blocks the interaction of RANK ligand and RANK.

colony-stimulating factor and receptor activator for nuclear factor κ B (RANK) ligand, or RANKL, are essential for stimulation of osteoclastogenesis,⁶⁹ and RANKL is essential for the activation of mature osteoclasts. Macrophage colony-stimulating factor, a growth factor encoded by *CSF1*, is expressed both as a secreted protein and as a cell surface protein; the production of both forms is stimulated by PTH.⁷⁰ RANKL—also called osteoprotegerin (OPG) ligand, osteoclast-differentiating factor, and TRANCE—is a membrane-bound member of the tumor necrosis factor (TNF) family; its synthesis is also increased by PTH. RANKL binds to its receptor, RANK, a member of the TNF receptor family. RANK is found on both osteoclast precursors and mature osteoclasts. The binding of RANKL to RANK can be blocked by osteoprotegerin (OPG), another member of the TNF receptor family. OPG (also called OCIF, TR1, or TNFRSF11B) circulates and is also secreted by cells of the osteoblastic lineage. PTH decreases the synthesis and secretion of OPG from these cells. Therefore, PTH, by increasing RANK and decreasing OPG locally in bone, serves to increase bone resorption.

Because PTH can both increase bone formation and increase resorption, the net effect of PTH on bone mass varies from one part of bone to another and also varies strikingly according to whether PTH is administered continuously or intermittently. Intermittent administration of low doses of PTH causes dramatic net increase in trabecular bone mass with little effect on cortical bone mass in humans. Continuous administration of PTH, in contrast, leads to a decrease in cortical bone mass; the net effect of PTH on trabecular bone depends on the dose. In mild primary hyperparathyroidism, there is little net effect of PTH on trabecular bone and a decrease in cortical bone. In all of these settings, the rate of bone formation is increased; the varying rate of osteoclastic resorption determines the net effect of PTH on bone mass.

Molecular Basis of Parathyroid Hormone Action

Ever since the discovery that PTH stimulates the secretion of cAMP into the urine,⁷¹ PTH has been thought to act by triggering a cascade of intracellular second messengers. This guiding hypothesis, in its current form, postulates that all of the actions of PTH result from binding of the hormone

to a receptor on the plasma membrane of target tissues. This receptor is a member of a large family of G protein-linked receptors that span the plasma membrane seven times (Fig. 28-10). The binding of hormone on the outside of the membrane causes conformational changes in the disposition of the seven transmembrane helices that activate the receptor's ability to release guanosine diphosphate (GDP) from the α -subunit of a G protein bound to the receptor. The G protein then binds guanosine triphosphate (GTP) in place of GDP. The GTP-binding α -subunit of the G protein then separates from the $\beta\gamma$ -subunits, and the separate subunits of the G protein modulate the activity of enzymes and channels, affecting proteins further downstream and eventually leading to the physiologic responses of bone and kidney cells.

Parathyroid Hormone and Parathyroid Hormone-Related Protein Receptors. DNA encoding a PTH/PTHrP receptor has been isolated from rat, opossum, human, pig, *Xenopus* (toad), and zebrafish cells and tissues.⁷² The receptor mediates actions of both PTH and PTHrP (see discussion of PTHrP later in this chapter). The predicted amino acid sequence of the receptor and direct mapping of inserted epitopes suggest that the receptor spans the plasma membrane seven times, but the sequence does not closely resemble those of most known G protein-linked receptors. Instead, it is a member of a distinct subfamily of closely related receptors. Most of these receptors bind peptides that are 30 to 40 amino acids long. Known members include receptors for the secretin family of peptides (secretin, vasoactive intestinal peptide VIP, glucagon, glucagon-like peptide, growth hormone-releasing hormone, pituitary adenylate cyclase-activating peptide, gastric inhibitory peptide), corticotropin-releasing hormone, calcitonin, and insect diuretic hormones related to corticotropin-releasing hormone. The PTH/PTHrP receptor most closely resembles receptors of the secretin group. The gene encoding the PTH/PTHrP receptor has a complicated structure, with 13 introns interrupting the coding sequence.

Figure 28-10 Parathyroid hormone (PTH)/PTH-related protein (PTHrP) receptors act as nucleotide exchangers. PTH binding to the receptor leads to exchange of guanosine triphosphate (GTP) for guanosine diphosphate (GDP) bound to stimulatory G protein (G_s) α -subunits. G_s α -subunits bound to GTP are released from the receptor and from the $\beta\gamma$ -subunits and then activate effectors. G_s α activates adenylate cyclase (AC), leading to the formation of cyclic adenosine monophosphate (cAMP), which then activates protein kinase A (PKA). G_q α and related α -subunits activate phospholipase C (PLC). PLC hydrolyzes phosphatidylinositol 1,4,5-trisphosphate to generate diacylglycerol (DAG) and inositol 1,4,5-trisphosphate (IP_3). The DAG then activates protein kinase C (PKC), and the IP_3 activates a receptor on microsomal vesicles that directs the movement of calcium (Ca^{2+}) from microsomal vesicles into the cytosol.

The cloned PTH/PTHrP receptor binds amino-terminal fragments of PTH and PTHrP with equal affinity. The receptor is expressed at high levels in kidney and in osteoblasts of bone but is also expressed in many other tissues, including smooth muscle, brain, and a variety of fetal tissues, which are thought to be target tissues more for PTHrP than for PTH. The interactions of the PTH/PTHrP receptor with its two ligands are similar but do differ in ways that have physiologic significance.⁷³ After binding to the receptor, PTH continues to interact with the receptor for much longer than does PTHrP.⁷⁴ This more stable binding mode of PTH involves interactions with the receptor that allow the ligand to remain receptor bound even when G molecules are not interacting with the receptor. More stable binding results in a different intracellular fate for PTH compared with PTHrP and leads to more prolonged activation of the receptor by PTH.⁷⁵ In response to binding of PTH or PTHrP, the receptor activates several G proteins, including G_s , G_q , G_{11} , G_i , G_{12} , and G_{13} .

The PTH/PTHrP receptor mediates many of the actions of PTH and PTHrP. The ligand-binding and signaling properties of the receptor, the pattern of expression of the receptor, and the consequences of mutation of the receptor sequence (see later discussion) are persuasive evidence in this regard. Nevertheless, the scheme of PTH action illustrated in Figure 28-10 should be considered a simplified outline. It is unlikely that all of the actions of PTH can be explained by interactions with the cloned PTH/PTHrP receptor. Fragments of PTH that seem not to bind the receptor may be biologically active,⁷⁶ and some cells respond to PTH in ways not mimicked by the cloned receptor.⁷⁷ Furthermore, the carboxyl-terminal portion of PTH(1-84) binds a cell surface protein distinct from the PTH/PTHrP receptor.

A second PTH receptor, which can be activated by PTH but not by PTHrP, has been cloned; it is called the PTH2 receptor (PTH2R). This receptor is expressed in multiple tissues, including brain, vascular endothelium and smooth muscle, endocrine cells of the gastrointestinal tract, and sperm. Expression is not seen in osteoblasts or renal tubules, however. Although PTH activates the human PTH2R well, PTH only poorly activates PTH2R in the rat and other species. Furthermore, a novel ligand called TIP39 has been characterized and shown to be a potent activator of PTH2R. TIP39 bears only a weak resemblance to PTH or PTHrP and is likely to be a physiologically relevant activator of the PTH2. The functional role of the PTH2R is unknown, but it appears to mediate many actions of TIP39 in the brain and testis; studies of knockout mice implicate TIP39 in regulation of anxiety reactions⁷⁸ and germ cell development.⁷⁹ The two cloned PTH receptors, as well as distinct receptors for fragments of PTHrP (see later discussion), probably are part of a complex network of ligands and receptors (Fig. 28-11).

Functional Implications of Parathyroid Hormone Structure. Amino-terminal fragments of PTH as short as the PTH(1-34) peptide have potency at least as great as that of the full-length PTH(1-84). Several discrete portions of PTH(1-34) interact with the receptor. The first several residues of PTH are particularly important for triggering the conformational change in the receptor that results in activation of G_s and adenylate cyclase. Sequences responsible for transmembrane activation of G_s make up most of the first 13 residues of PTH; it is these residues that are highly conserved between PTH and PTHrP. At high concentrations, PTH(1-14) by itself can activate the PTH/PTHrP receptor. This activation domain interacts with the receptor's

Figure 28-11 Network of parathyroid hormone (PTH) ligands and receptors (R). PTH and PTH-related protein (PTHrP) closely resemble each other at the amino-terminal region; TIP39 is more distantly related. Although only the PTH/PTHrP receptor and the PTH2 receptor have been cloned, biologic actions suggest that there are receptors specific for the carboxy-terminal portion of PTH, as well as distinct receptors for the midregion of PTHrP and for a more distal region of PTHrP. PTHrP is also found in nuclei and may act directly there.

transmembrane domains and extracellular loops. When the first nine residues of PTH are covalently linked to the receptor's transmembrane domains and extracellular loops, they can activate the receptor. An analogue of PTH(1-14) can trigger G_q activation, thus activating phospholipase C.⁸⁰ These data, plus the observation that a PTH analogue modified at position 1 selectively loses its ability to activate phospholipase C,⁸¹ demonstrate that the amino-terminal portion of PTH is essential for activation of both G_s and G_q . More distal regions of PTH(1-34) can activate protein kinase C and can raise intracellular calcium levels by mechanisms that have not been fully clarified. Remarkably, a PTH analogue that is missing the first six residues and cannot activate G proteins can still activate the PTH/PTHrP receptor and increase bone mass in vivo.⁸² This analogue can activate mitogen-activated protein kinase (MAPK) signaling through interactions of the receptor with β -arrestin. These studies illustrate how the PTH/PTHrP receptor can signal intracellularly without activating G proteins.

The more carboxy-terminal portions of PTH(1-34) contribute importantly to the specificity and tight binding of PTH to the PTH/PTHrP receptor, at least partly through interactions with the receptor's amino-terminal extracellular domain (Fig. 28-12). A variety of studies of genetically altered receptors, biochemical studies using photoactivated cross-links between PTH and the receptor, and studies of co-crystals of the receptor's amino-terminal domain and PTH/PTHrP fragments^{73,83} have reinforced each other and show that the carboxy-terminal portion of PTH makes multiple contacts with the amino-terminal extension of the receptor and with its extracellular loops. This interaction of PTH with the amino-terminal portion of the receptor occurs extremely rapidly, with a time constant of 140 milliseconds.⁸⁴ In contrast, the subsequent interaction of the amino-terminal portion of PTH with the so-called J domain of the receptor (the transmembrane domains and associated extracellular loops) occurs more slowly, with a time constant of 1 second. Presumably, this extra time is needed for the amino-terminus of PTH to form a helix and for the receptor to attain an optimal conformation for binding. When this slow interaction occurs, the receptor changes the relationships of its transmembrane domains and activates G proteins.⁸⁵

Studies of the structure of PTH by nuclear magnetic resonance spectroscopy suggest that the activation domain and

Figure 28-12 Binding of the PTH(1-34) peptide of the parathyroid hormone (PTH) to the PTH/PTH-related protein (PTHrP) receptor. The amino-terminal extracellular domain of the receptor binds rapidly to the carboxy-terminal portion of the ligand. The “J domain” of the receptor, containing the transmembrane domains and associated loops, binds to the amino-terminal domain of the ligand. This binding is slower and may require conformational changes in both the ligand and the receptor. These changes then trigger G protein activation, receptor internalization, and other actions. (Courtesy of Tom Gardella.)

the carboxy-terminal domain are discrete entities dominated by α -helices separated by a flexible loop of variable size, depending on the hydrophobicity of the solvent. In the crystal structure of human PTH(1-34), the flexible loop is entirely replaced by a helical structure.⁸⁶ Taken together, these studies suggest that the carboxy-terminal portion of PTH(1-34) makes multiple contacts with the receptor that allow high-affinity binding and positioning of the amino-terminal portion of PTH to activate the receptor through contacts with transmembrane domains and associated loops.

Activation of Second Messengers. Precisely how binding of PTH to the extracellular domains of the PTH/PTHrP receptor leads to activation of G proteins is not understood. The crystal structure of rhodopsin, another member of the seven-transmembrane receptor family, as well as the behavior of certain mutant PTH/PTHrP receptors,^{87,88} suggest that the seven transmembrane domains of the PTH/PTHrP receptors form a ring, with the seventh transmembrane domain adjacent to the first and second domains. Presumably, binding of PTH to several different regions of the receptor changes the relationships of the transmembrane domains⁸⁵ such that the receptor's three intracellular loops and carboxy-terminal tail interact with G proteins in an altered way.

Receptors with certain point mutations in the second, sixth, and seventh transmembrane domains can activate G_s even without stimulation by hormone. These mutant receptors were discovered by analyzing the PTH/PTHrP receptors in patients with Jansen's metaphyseal chondrodystrophy.⁸⁹ Patients with this disorder have signs of parathyroid overactivity (hypercalcemia, hypophosphatemia, high levels of calcitriol, and urinary cAMP) but low PTH and PTHrP levels. The mutations must change the conformation of the intracellular face of the receptor in a way that resembles the effect of binding of PTH to the normal receptor. The observation that inappropriate activation of

the PTH/PTHrP receptor in Jansen's chondrodystrophy leads to all of the metabolic abnormalities found in primary hyperparathyroidism is one of the most persuasive pieces of evidence that the cloned PTH/PTHrP receptor does, in fact, mediate the actions of PTH in bone and kidney in humans *in vivo*.

Second Messengers and Distal Effects of Parathyroid Hormone. The activation of multiple G proteins by PTH raises questions about the individual roles of each second messenger and their possible interactions. The importance of cAMP as a mediator of the physiologic actions of PTH has been demonstrated by studies *in vivo*⁷¹ and *in vitro*.⁹⁰ Furthermore, patients with pseudohypoparathyroidism type I, who cannot increase urinary cAMP levels in response to PTH, show clear renal resistance to PTH (see later discussion).

Activation of phospholipase C, with concomitant activation of protein kinase C and synthesis of IP_3 , may also contribute to physiologic actions of PTH such as inhibition of NaPi cotransport⁹¹ and stimulation of the renal 25(OH) D 1 α -hydroxylase.⁹² Mice with mutant PTH/PTHrP receptors that cannot activate phospholipase C have a mild delay in bone development⁹³ and abnormalities of phosphate handling by the kidney when challenged with a low-calcium diet.⁹⁴ Some actions of PTH may require activation of both adenylate cyclase and phospholipase C for optimal activity.

The stimulation of one G protein or another by the PTH/PTHrP receptor can vary in different types of cells and even in differing regions of the same cell.⁹¹ In some settings, this choice may be influenced by the interactions of the PTH/PTHrP receptor with intracellular scaffolding proteins such as NHERF1 and NHERF2. Binding of the PTH/PTHrP receptor to NHERFs is directed by the last four amino acids in the receptor sequence. This binding, which is particularly prominent, for example, at the apical surface of the proximal tubular cells of the kidney, may change the G protein activated by the PTH/PTHrP receptor from predominantly G_s to predominantly G_i .⁹⁵

Target Cell Responsiveness to Parathyroid Hormone. Physiologic responses to PTH depend not only on the concentration of PTH in blood but also on the responsiveness of target cells to PTH. This responsiveness can be modified by previous exposure to PTH or by exposure to a variety of other hormones and paracrine factors. Responsiveness can be changed by alterations at virtually every step in the cellular response to PTH.

Major regulators of PTH/PTHrP receptor gene expression include, not surprisingly, PTH and calcitriol, both of which can decrease PTH/PTHrP receptor mRNA in certain target cells. In some settings, PTH decreases the amount of immunoreactive and functional receptor on the cell surface without changing the levels of PTH/PTHrP receptor mRNA. This decrease reflects ligand-induced internalization and degradation of receptors. Internalization of receptor is stimulated by PTH binding, which leads to phosphorylation of specific serines found in the receptor's cytoplasmic tail and subsequent internalization directed by binding of arrestin to the receptor.^{96,97} Even without a change in receptor number, the binding of arrestin to the PTH/PTHrP receptor decreases the efficiency of activation of G proteins (desensitization).

Parathyroid Hormone-Related Protein

PTHrP was discovered because its secretion by a wide variety of tumors contributes to the humoral hypercalcemia of

malignancy. For this reason, the initial studies of PTHrP in humans and animals stressed the PTH-like structure and properties of the molecule. However, subsequent studies soon showed that PTHrP, unlike PTH, is made by a wide variety of tissues, in which it acts locally in ways that may have little relevance to the control of blood calcium.

Gene and Protein Structure

PTHrP sequences from 10 species, ranging from fish to humans, have been identified (Fig. 28-13).⁴ In humans, alternative RNA splicing yields transcripts that encode three distinct proteins, of 139, 141, and 173 residues, which differ only after residue 139.

Inspection of these sequences suggests that PTHrP has several functionally distinct domains. Eight or nine of the first 13 residues of PTHrP are identical to those in known mammalian PTH sequences. These sequences encompass the known "activation" domain of PTH (see earlier discussion) and are instrumental in the ability of PTHrP to activate PTH/PTHrP receptors. The conserved histidine at position 5 of all PTHrP molecules (except those of fish) differs from the hydrophobic residue found at the corresponding position of all PTHs and allows PTHrP to activate the PTH/PTHrP receptor but not the PTH2 receptor.

The sequences in PTHrP(14-34) are also highly conserved. Although these sequences little resemble the corresponding region of PTH, they can displace PTH from the PTH/PTHrP receptor. Studies of the secondary and tertiary structures of PTHrP(1-34) and PTH(1-37) suggest that they have similar structures dominated by α -helices connected by a flexible hinge.

The remaining portion of the PTHrP molecule bears no resemblance to corresponding sequences in PTH. Nevertheless, residues 35 to 111 of PTHrP are strikingly well conserved, with only nine residues differing between mammalian and chicken PTHrP sequences. This sequence conservation is considerably greater than that found in the carboxyl-terminal portion of PTH, suggesting that this region of PTHrP has unique and important functions. After

residue 111, the PTHrP sequences vary considerably from species to species.

Interspersed within the PTHrP sequences are multiple sites containing one or several basic residues that might serve as post-translational cleavage sites⁹⁸ (see Fig. 28-13). Extensive analysis of PTHrP fragments in tumors, cell lines, and transfected cells has shown that several of these sites are, in fact, functional cleavage signals. PTHrP is cleaved⁹⁹ after the arginine at residue 37; this cleavage, followed by carboxypeptidase cleavage, generates a PTH-like PTHrP(1-36) fragment as well as the fragments PTHrP(38-94) amide, PTHrP(38-95), and PTHrP(38-101). More carboxy-terminal fragments of PTHrP have been detected in cells as well.

In the blood of patients with humoral hypercalcemia of malignancy, multiple immunoreactive species of PTHrP have been found that may well correspond to the fragments of PTHrP in cells and tissue culture media, although precise characterization of these various immunoreactive species is incomplete (see later discussion). Full-length PTHrP may not circulate, because an amino-terminal-specific immunoaffinity column was unable to extract carboxy-terminal immunoreactivity from the serum of patients with malignant hypercalcemia.¹⁰⁰

Functions of Parathyroid Hormone-Related Protein

The first actions of PTHrP to be defined were the PTH-like actions associated with the humoral hypercalcemia of malignancy. In this pathologic entity, PTHrP acts as a hormone; it is secreted from the tumor into the bloodstream and then acts on bone and kidney to raise calcium levels (see "Hypercalcemia of Malignancy").¹⁰¹ Whether PTHrP circulates at high enough levels in normal adults to contribute to normal calcium homeostasis is an unanswered question. With metastases of breast cancer to bone, locally produced PTHrP can raise serum calcium without necessarily raising blood levels of PTHrP.

Figure 28-13 Sequences of parathyroid hormone-related protein (PTHrP) from five species. Completely conserved residues are in boldface. Note the high level of conservation through residue 111. Arrows indicate sites of internal cleavage after residues 37 and 95, which lead to generation of PTHrP(38-94) amide and PTHrP(38-95). Another site of cleavage, generating PTHrP(38-101) and, perhaps, PTHrP(107-139), is not shown.⁹⁸ The three human sequences represent proteins synthesized from alternatively spliced messenger RNAs and differ only after residue 139. Amino acids are indicated by single letter codes (see Figure 28-3).

PTHrP acts as a calciotropic hormone during fetal life and in lactation. Fetal mice missing the PTHrP gene transport calcium ^{45}Ca across the placenta inefficiently. This action of PTHrP requires only the midregion of PTHrP and probably involves a receptor distinct from the PTH/PTHrP receptor. Amino-terminal portions of PTHrP and PTH may also be able to increase placental calcium transport, because PTH(1-84) can increase placental calcium transport in mice missing the PTH gene.¹⁰²

The second setting for humoral actions of PTHrP is lactation. In mice, secretion of PTHrP from the breast into the bloodstream leads to an increase in bone resorption.¹⁰³ Calcium then activates the CASR in breast tissue, increases the movement of calcium into milk, and downregulates expression of PTHrP in the breast.¹⁰⁴ PTHrP, therefore, probably contributes to the dramatic but largely reversible bone loss that occurs during lactation in humans, which is only minimally affected by calcium supplementation.¹⁰⁵ An exaggeration of this lactational role of PTHrP may explain the rare presentation of hypercalcemia and high PTHrP levels in pregnant and lactating women.¹⁰⁶ Large amounts of PTHrP are also secreted into breast milk, although the role of PTHrP in milk is unknown.

Most of the actions of PTHrP are likely to be paracrine or autocrine.¹⁰⁷ PTHrP is synthesized at one time or another during fetal life in virtually every tissue. Its role in the development of fetal bone has been demonstrated through the striking abnormalities found in genetically engineered mice missing the PTHrP gene. These abnormalities suggest that PTHrP normally keeps chondrocytes proliferating in orderly columns, thereby delaying chondrocyte differentiation.¹⁰⁸ The role of PTHrP in many other fetal tissues may analogously involve regulation of proliferation and differentiation. The widespread expression of PTHrP in fetal life probably underlies the expression of PTHrP in a wide variety of malignancies. As is often the case in malignancy, the expression of PTHrP represents the re-initiation of a fetal pattern of gene expression.

PTHrP is synthesized by many adult tissues. In tissues such as skin, hair, and breast, it is likely that PTHrP regulates cell proliferation and differentiation. PTHrP is also synthesized in response to stretch in the smooth muscle of blood vessels, gastrointestinal tract, uterus, and bladder, and it acts in an autocrine fashion to relax the smooth muscle.¹⁰⁹ PTHrP is also widely expressed in neurons of the central nervous system; its function in the brain is

unknown, but it may protect neurons from excitotoxicity by decreasing flux through voltage-gated calcium channels. An analogous mechanism may explain the role of PTHrP in smooth muscle relaxation.

Many of the actions of PTHrP are mediated by the PTH/PTHrP receptor. Others, such as the activation of placental calcium transport, are probably mediated in part by a distinct receptor, and other actions on bone cells probably involve yet another receptor responsive to more distal portions of PTHrP. Increasing evidence also suggests that some actions of PTHrP involve direct nuclear actions of PTHrP.¹¹⁰ Therefore, both PTH and PTHrP are likely to use multiple mechanisms to stimulate cells (see Fig. 28-11).

CALCITONIN

Calcitonin has an important role in regulating blood calcium in fish and a demonstrable role in rodents; however, the importance of calcitonin in human calcium homeostasis remains uncertain.

The existence of a second calcium-regulating hormone, in addition to PTH, was first demonstrated during perfusion studies of the thyroid/parathyroid glands of dogs.¹¹¹ High calcium perfusion resulted in a rapid decrease in plasma calcium, even more rapid than after parathyroidectomy. This suggested that calcium had stimulated the secretion of a hormone that lowered blood calcium. It was subsequently demonstrated that this missing hormone, named calcitonin for its role in regulating the “tone” or level of calcium, was elaborated by the thyroid gland, not the parathyroids. Calcitonin is found in the nonfollicular cells of the thyroid, called C cells, which originate from the neural crest.

In fish, the location of the C cells in discrete organs led to the rapid isolation of calcitonin from these ultimobranchial bodies in dogfish, salmon, and several other species. The identification of the glandular origin of calcitonin enabled the isolation of sufficient quantities of calcitonin for sequence analysis and studies of its structure and biologic function.

Synthesis and Secretion

Calcitonin consists of a 32-amino-acid polypeptide with an intrachain disulfide bond provided by the cysteines at positions 1 and 7 (Fig. 28-14). These two cysteine residues,

Figure 28-14 The amino acid sequences of calcitonin (CT), calcitonin gene-related peptide (CGRP), amylin, adrenomedullin (ADM), intermedin (IDM), and calcitonin receptor-stimulating proteins (CRSP) from selected species. The letters “C” in boldface represent the cysteine residues that form the disulfide linkages critical for the secondary structure of these peptides. The other conserved residues are indicated by a dashed line (see Figure 28-3 for the single-letter amino acid codes).

Figure 28-15 Tissue-specific expression of the calcitonin gene. Splicing of alternative exons leads to two different messenger RNAs (mRNAs). The mRNA encoding calcitonin is found predominantly in the thyroid C cell; the mRNA encoding calcitonin gene-related peptide (CGRP) is found predominantly in the hypothalamus and other nervous tissue. aa, amino acids; CCP, calcitonin carboxy-terminal peptide. (From Amara SG, Jonas V, Rosenfeld MG, et al. Alternative RNA processing in calcitonin gene expression generates mRNAs encoding different polypeptide products. *Nature*. 1982;298:240-244.)

along with the carboxy-terminal proline-amide and six additional residues, are the only amino acids conserved among the calcitonins isolated from various species. The disulfide linkage and proline-amide residues are important for the function of the molecule, although biologically active analogues lacking disulfide bonds have been developed.

Interestingly, fish calcitonin is more potent in mammals than the mammalian hormone itself. The mature peptide is derived from the middle of a 136-amino-acid precursor. The human calcitonin gene, located on the short arm of chromosome 11, contains six exons which are alternatively spliced in a tissue-specific manner to yield the mRNAs encoding calcitonin or calcitonin gene-related peptide (CGRP) (Fig. 28-15). The mRNA encoding calcitonin is derived by splicing together the first four exons, and it represents more than 95% of mature transcripts in the thyroid C cells. The splicing of the first three exons to exons 5 and 6 results in an mRNA that encodes the 37-amino-acid α -CGRP peptide. The mRNA encoding α -CGRP is expressed in multiple tissues and is the only mature transcript of the calcitonin gene detected in neural

tissue. A second CGRP gene encodes the closely related β -CGRP. In humans, the predicted sequence of the mature peptide differs from that of α -CGRP by only three amino acids (see Fig. 28-14). The β -CGRP gene is also found on chromosome 11, and its tissue distribution is the same as that of α -CGRP.

The synthesis and secretion of calcitonin are tightly regulated. Studies in a porcine model revealed a linear relationship between the secretion of calcitonin and ambient calcium levels. Cell culture studies with calcium ionophores and calcium channel blockers demonstrated that the calcium ion concentration within the C cell determines this secretion rate. The CASR cloned from parathyroid cells is also expressed in C cells and contributes to the regulation of calcitonin secretion.¹¹² Other calcitonin secretagogues include glucocorticoids, CGRP, glucagon, enteroglucagon, gastrin, pentagastrin, pancreozymin, and β -adrenergic agents.¹¹³ The physiologic role of the gastrointestinal hormones in regulating calcitonin remains unclear; however, they have been postulated to play a role in the regulation of postprandial hypercalcemia. The secretion of calcitonin is inhibited by somatostatin, which is

also secreted by the thyroïdal C cells. In vivo and in vitro studies have demonstrated that calcitriol decreases calcitonin mRNA levels by a transcriptional mechanism.

Calcitonin, when administered acutely, decreases tubular reabsorption of calcium¹¹⁴ and impairs osteoclast-mediated bone resorption by a direct action on osteoclasts.¹¹⁵ In rodents, calcitonin has been shown to play a role in the regulation of postprandial hypercalcemia.¹¹⁶ Studies in calcitonin/CGRP knockout mice revealed a doubling of the bone formation rate in the absence of hormone, accompanied by resistance to ovariectomy-induced bone loss.¹¹⁷ A similar increase in bone formation was found in mice heterozygous for ablation of the calcitonin receptor.¹¹⁸ Recent studies have emphasized a dramatic increase in bone resorption caused by the knockout of calcitonin/CGRP, demonstrating an important physiologic role for calcitonin in normally suppressing osteoclast activity.¹¹⁹

The physiologic role of calcitonin in humans, however, remains elusive. The effect of calcitonin on bone density was examined in patients with long-term hypercalcitoninemia secondary to medullary carcinoma of the thyroid and in patients with subtotal thyroidectomy resulting in lack of calcitonin secretory reserve.¹²⁰ Bone density at the lumbar spine and distal radius were not influenced by the abnormal calcitonin levels. Furthermore, no physiologic abnormalities have been reported with long-term, high-dose administration of exogenous calcitonin.

Many of the effects of calcitonin are mediated by a G protein-coupled cell surface receptor in the PTH/secretin receptor family.¹²¹ The mRNA encoding this receptor has been found in multiple tissues including kidney, brain, and osteoclasts. The coupling of this receptor to different G proteins results in the activation of either adenylate cyclase or phospholipase C; in some settings, this action is cell cycle dependent.¹²²

Calcitonin Family: Calcitonin Gene-Related Peptide, Amylin, Adrenomedullin, and Intermedin

CGRP, amylin, adrenomedullin, calcitonin receptor-stimulating peptide 1 (CRSP1), and intermedin have all been shown to have high-affinity binding sites on cell membranes, and displacement studies suggest that several receptor subtypes for these related ligands are present. However, cloning of specific receptors for these ligands has proved difficult, because the functional receptors consist of heterodimers between G protein-coupled receptors and single transmembrane proteins of the RAMP (receptor activity-modifying proteins) family.¹²³ Interaction of the calcitonin receptor-like receptor, a relative of the calcitonin receptor, with RAMP1 results in a CGRP receptor, whereas RAMP2 and RAMP3 interactions with the same calcitonin receptor-like receptor generate adrenomedullin receptors. Interaction of RAMP1 with the calcitonin receptor creates an amylin receptor.¹²⁴

CGRP is thought to act as a neurotransmitter and vasodilator rather than as a hormone. In support of this hypothesis, mice lacking α -CGRP have been shown to have an increase in mean arterial pressure.¹²⁵ Immunohistochemical studies of CGRP in the brain and in the peripheral nervous system suggest that this neuropeptide also plays an important role in sensory and integrative motor functions.

Three structurally related peptides have been isolated from porcine brain (see Fig. 28-14). These CRSPs, found in many mammals but not in primates,¹²⁶ are also expressed in the thyroid gland. CRSP1, which is 60% homologous to

α -CGRP at the amino acid level, binds to the calcitonin receptor and dose-dependently stimulates cAMP production. Consistent with this observation, administration of CRSP1, like that of calcitonin, results in a decrease in serum calcium. The receptors for CRSP2 and CRSP3 have not been identified.

Amylin is highly homologous to CGRP and calcitonin (see Fig. 28-14). Although amylin has been shown to have skeletal actions, the presence of amylin in the pancreas of patients with type 2 diabetes mellitus suggests an etiologic role for this peptide in this disorder.¹²⁷ Analogues of this peptide are currently being explored as therapeutic agents for type 1 diabetes in children.¹²⁸ Amylin administration inhibits bone loss associated with ovariectomy and streptozotocin-induced diabetes mellitus in rats. Targeted ablation of amylin in mice results in low bone mass due to an increase in bone resorption.¹¹⁸ Amylin has also been shown to decrease food intake and inhibit gastric acid secretion, protecting against ulcer development in numerous models.

Adrenomedullin (see Fig. 28-14) has vasodilatory effects similar to those of CGRP. In addition to activating CGRP receptors, adrenomedullin binds to specific receptors in the vascular system. Mice that lack the DNA coding adrenomedullin die in midgestation.¹²⁹ The physiologic roles of adrenomedullin in adults remain to be clarified.

Intermedin, the newest member of this family (see Fig. 28-14), was identified by homology screening of expressed sequence tags. It is expressed primarily in the pituitary and the gastrointestinal tract. Intermedin is able to signal through CGRP receptors and competes with CGRP for receptor binding.¹³⁰ However, unlike CGRP and adrenomedullin, intermedin is a nonselective agonist for the RAMP coreceptors.

Calcitonin in Human Disease

Calcitonin is secreted by several endocrine malignancies and, therefore, can serve as a tumor marker. Basal and pentagastrin-stimulated calcitonin levels have been used to identify and monitor patients who are at risk for, or affected by, medullary carcinoma of the thyroid (see Chapter 41), although abnormal basal and stimulated levels may be observed in patients undergoing chronic hemodialysis. Calcitonin may also be ectopically secreted by other tumors, including insulinomas, VIPomas, and lung cancers. Severely ill patients, including those with burn inhalation injury, toxic shock syndrome, or pancreatitis may also have elevated calcitonin levels.

Therapeutic Uses

The observation that calcitonin inhibits osteoclastic bone resorption has led to its therapeutic use for the treatment of several disorders associated with excess bone resorption, including osteoporosis and Paget's disease (see Chapter 29). Calcitonin has also been used for its analgesic effect, in the treatment of patients with vertebral crush fractures, osteolytic metastases, or phantom limb.

VITAMIN D

Metabolism of Vitamin D

Vitamin D is not a true vitamin, because nutritional supplementation is not required in humans who have adequate sun exposure. When exposed to ultraviolet irradiation,

Figure 28-16 Vitamin D precursors and alternative reaction products. The numbering system for vitamin D carbons and the distinct structures of vitamin D_2 (ergocalciferol) and D_3 (cholecalciferol) are noted, as is the structure of dihydrotachysterol, a synthetic product not produced in vivo. Note that the 3-hydroxyl group of dihydrotachysterol is in a pseudo-1-hydroxyl configuration. This may explain the relatively high potency of dihydrotachysterol in conditions associated with low 1α -hydroxylase activity.

the cutaneous precursor of vitamin D, 7-dehydrocholesterol, undergoes photochemical cleavage of the carbon bond between carbons 9 and 10 of the steroid ring (Fig. 28-16). The resultant product, previtamin D, is thermally labile and over a period of 48 hours undergoes a temperature-dependent molecular rearrangement that results in the production of vitamin D. Alternatively, this thermally labile product can isomerize to two biologically inert products, luminosterol and tachysterol. This alternative photoisomerization prevents production of excessive amounts of vitamin D with prolonged sun exposure. The degree of skin pigmentation, which increases in response to solar exposure, also regulates the conversion of 7-dehydrocholesterol to vitamin D by blocking the penetration of ultraviolet rays.

The alternative source of vitamin D is dietary. Elderly people, institutionalized individuals, and those living in northern climates probably obtain most of their vitamin D from dietary sources. However, with increasing avoidance of sun exposure by the general population, ensuring adequate dietary intake of vitamin D has become important for the population at large. Vitamin D deficiency is prevalent and has been shown to contribute significantly to osteopenia and fracture risk. The major dietary sources of

vitamin D are fortified dairy products, although lack of monitoring of this supplementation results in marked variation in the amount of vitamin D provided.¹³¹ Other dietary sources include egg yolks, fish oils, and fortified cereal products. Vitamin D provided by plant sources is in the form of vitamin D_2 , whereas that provided by animal sources is in the form of vitamin D_3 (see Fig. 28-16). These two forms have equivalent biologic potencies and are activated equally efficiently by the hydroxylases in humans.

Vitamin D is absorbed into the lymphatics and enters the circulation bound primarily to vitamin D-binding protein (VDBP), although a fraction of vitamin D circulates bound to albumin. The human VDBP is a 52-kd α -globulin that is synthesized in the liver. The protein has a high affinity for 25(OH)D (25-hydroxyvitamin D) but also binds vitamin D and calcitriol. Approximately 88% of 25(OH)D circulates bound to the VDBP, 0.03% is free, and the rest circulates bound to albumin. In contrast, 85% of circulating calcitriol is bound to the VDBP, 0.4% is free, and the rest is bound to albumin. Mice lacking the vitamin D-binding protein have increased susceptibility to calcitriol toxicity and to dietary vitamin D deficiency.¹³² Therefore, the role of VDBP is to maintain a serum reservoir and to modulate the activity of vitamin D metabolites. Studies in megalin-null mice suggest that vitamin D-binding protein is filtered by the glomerulus and reabsorbed by a megalin-dependent pathway in the proximal renal tubule.¹³³ Further investigations will be required to determine the importance of this pathway in vitamin D metabolism and the tissues in which megalin-dependent endocytosis plays an important role.¹³⁴

In the liver, vitamin D undergoes 25-hydroxylation by a cytochrome P450-like enzyme present in the mitochondria and microsomes. The half-life of 25(OH)D is approximately 2 to 3 weeks. The 25-hydroxylation of vitamin D is not tightly regulated; therefore, the blood levels of 25(OH)D reflect the amount of vitamin D entering the circulation. When levels of VDBP are low, such as in nephrotic syndrome, circulating levels of 25(OH)D are also reduced. The half-life of 25(OH)D is shortened by increases in levels of its active metabolite, calcitriol.

The final step in the production of the active hormone is the renal 1α -hydroxylation of 25(OH)D to $1,25(\text{OH})_2\text{D}_3$ (calcitriol). The half-life of this hormone is approximately 6 to 8 hours. Like the 25-hydroxylase, the 1α -hydroxylase in the proximal convoluted tubule is a cytochrome P450-like mixed-function oxidase, but unlike the 25-hydroxylase, the 1α -hydroxylase is tightly regulated. PTH and hypophosphatemia are the major inducers of this microsomal enzyme, whereas calcium and the enzyme's product, calcitriol, repress it.¹³⁵ FGF23 (see later discussion) also represses 1α -hydroxylase mRNA production.¹³⁶ In animal models and in vitro studies, other hormones such as estrogen, calcitonin, growth hormone, and prolactin have been shown to increase 1α -hydroxylase activity; however, the clinical importance of these observations has not been established. Ketoconazole has been shown to decrease levels of calcitriol in a dose-dependent manner, presumably by interfering with 1α -hydroxylase activity.

The 1α -hydroxylase enzyme is also expressed in keratinocytes, in the trophoblastic layer of the placenta, and in the activated macrophages that are present in granulomata, including sarcoid granulomata, among many other tissues. In granulomatous tissue, the 1α -hydroxylase gene that is expressed is identical to that expressed in the kidney but is not regulated by PTH, phosphate, calcium, or vitamin D metabolites in these cells. However, activation of macrophages with interferon- γ ¹³⁷ or with ligands that activate

the heterodimer of toll-like receptors 1 and 2¹³⁸ increases expression of the 1 α -hydroxylase in macrophages, whereas treatment of sarcoidosis-associated hypercalcemia with glucocorticoids, ketoconazole,¹³⁹ or chloroquine¹⁴⁰ has been shown to lower serum calcitriol levels. Activation of the VDR in human macrophages induces the antimicrobial peptide, cathelicidin, and increases killing of intracellular *Mycobacterium tuberculosis*.¹³⁸ Therefore, the pathologic excess of calcitriol in sarcoidosis may represent an exaggeration of a healthy paracrine response of tissue macrophages. This action can be viewed as a paradigm for many other actions of vitamin D that are mediated more by the local production of calcitriol than by circulating calcitriol.

Both 25(OH)D and calcitriol can also be hydroxylated by the vitamin D 24-hydroxylase that is present in most tissues, including kidney, cartilage, and intestine. Calcitriol increases the activity of 24-hydroxylase, thereby inducing its own metabolism. The 24-hydroxylated vitamin D metabolites, 24,25(OH)₂D₃ and 1,24,25(OH)₃D₃, are not thought to play major biologic roles. Mice null for the 24-hydroxylase gene demonstrate hypercalcemia, hypercalciuria, and nephrocalcinosis due to vitamin D toxicity.¹⁴¹ Although 24,25(OH)₂D₃ has been shown to have unique actions in a number of biologic systems,¹⁴² no unique receptor for this metabolite has been identified, and the physiologic role of 24,25(OH)₂D₃ is unclear.

Calcitriol is also metabolized to several inactive products by 23- or 26-hydroxylation and side chain oxidation and cleavage. This latter side chain cleavage, resulting in the formation of calcitric acid, occurs in the liver and intestine, whereas inactivation of calcitriol by 24-hydroxylation occurs in a wide variety of target tissues. In addition, polar metabolites of calcitriol are excreted in the bile. Some of these metabolites are deconjugated in the intestine and reabsorbed into the enterohepatic circulation.

Actions of Vitamin D

Vitamin D Receptors

Calcitriol exerts its biologic functions by binding to a nuclear receptor, which then regulates transcription of DNA into RNA. Among the other nuclear receptors, the VDR most closely resembles the retinoic acid, triiodothyronine, and retinoid-X receptors (RXRs). The affinity of the receptor for calcitriol is approximately three orders of magnitude greater than that for other vitamin D metabolites (Fig. 28-17). Although 25(OH)D is less potent on a molar basis, its concentration in the serum is approximately three orders of magnitude greater than that of calcitriol. However, its free concentration is only two orders of magnitude greater. Therefore, under normal circumstances it is unlikely that 25(OH)D contributes importantly to calcium homeostasis. As a substrate for local 1 α -hydroxylases in many tissues, however, 25(OH)D may contribute to local tissue homeostasis.

Because the affinity of the VDBP for 25(OH)D is greater than for calcitriol, in states of vitamin D intoxication (with its associated high levels of 25(OH)D), the free levels of calcitriol increase¹⁴³ because 25(OH)D displaces it from the VDBP. Therefore, 25(OH)D may play a role in the clinical syndrome of vitamin D intoxication both by its direct biologic effects, when it is present at toxic levels, and by increasing the free levels of calcitriol.

The VDR acts by forming a heterodimer with the RXR, binding to DNA elements, and recruiting coactivators in a ligand-dependent fashion. These coactivators link the receptor complex to the basal transcription apparatus, thereby regulating transcription of target genes. In most cases, the upregulatory response elements for vitamin D contain hexameric repeats separated by three bases (Fig. 28-18). However, vitamin D also promotes the DNA-protein interactions of other transcription factors, such as SP1 and NF- κ B, in genes lacking classic response elements, by

Figure 28-17 Relative potency of analogues of 1,25(OH)₂D₃ (calcitriol) in competitive binding to vitamin D receptors of chick intestinal mucosa. Slopes are plotted (left to right) for 1,25(OH)₂D₃ (1,25-dihydroxyvitamin D₃); 3-deoxy-1,25(OH)₂D₃ (3-deoxy-1,25-dihydroxyvitamin D₃); 25-OH-DHT₃ (25-hydroxydihydroxyvitamin D₃); 25-OH-5,6-trans-D₃ (25-hydroxy-5,6-transvitamin D₃); 25-OH-D₃ (25-hydroxyvitamin D₃); 1- α -OH-D₃ (1 α -hydroxyvitamin D₃); 24,25-OH₂-D₃ (24,25-dihydroxyvitamin D₃); and 3-deoxy-1 α -OH-D₃ (3-deoxy-1 α -hydroxyvitamin D₃). D₃, vitamin D₃; DHT₃, dihydroxyvitamin D₃. (From Prosser DA, Okamura WH, Norman AW. Structural requirements for the interaction of 1 α ,25-(OH)₂-vitamin D₃ with its chick intestinal system. *J Biol Chem*. 1975;250:8382-8388.)

Figure 28-18 Transcriptional activation by $1,25(\text{OH})_2\text{D}_3$ (1,25-dihydroxyvitamin D_3 or calcitriol). A heterodimer of retinoid-X receptor (RXR) and vitamin D receptor (VDR) binds to a pair of hexameric sequences separated by three intervening bases (ATG). Arrows indicate that the hexamers found in the upregulated rat osteocalcin gene are variants of a consensus sequence, repeated here with identical orientations (direct repeats). On binding to DNA, the RXR-VDR heterodimer facilitates formation of a transcription initiation complex, which binds to DNA at and near the TATA sequence.

uncertain mechanisms.¹⁴⁴ The mechanism of transcriptional repression by vitamin D is varied. For example, VDR-RXR heterodimers repress the 1α -hydroxylase and renin genes by blocking the function of other transcription factors,^{145,146} whereas interaction of the VDR with the Ku antigen, acting as a transcription factor, is required for transcriptional repression of the human PTHrP gene.¹⁴⁷

Glucocorticoids have been shown to decrease the expression of the VDR gene in osteosarcoma cell lines, whereas calcitriol increases its expression in many cells. In the renal proximal convoluted tubule, however, calcitriol decreases the VDR levels. This decrease has been postulated to lead to decreased activation of the renal 24-hydroxylase by calcitriol, thereby protecting the newly synthesized calcitriol from local inactivation.¹⁴⁸

Calcitriol also has some biologic effects which occur too rapidly for transcriptional mechanisms to be implicated. These “nongenomic actions,” including a rapid increase in intracellular calcium, activation of phospholipase C, and opening of calcium channels, are observed in several cell types within minutes of exposure to calcitriol. Additional data supporting the hypothesis that nongenomic actions are not dependent on the classic receptor include the identification of specific binding sites for calcitriol on the anti-luminal surface of intestinal cells¹⁴⁹ and a disparity between the affinity of the various vitamin D analogues for the nuclear receptor and their potency in these nongenomic actions. However, both the rapid intracellular accumulation of cyclic guanosine monophosphate in association with the VDR and the rapid increase in intracellular calcium in response to calcitriol depend on the presence of an intact nuclear receptor, because these effects are not observed in cells derived from patients and mice with VDR mutations.¹⁵⁰ The physiologic importance of the nongenomic actions of vitamin D metabolites has not yet been established.

The VDR is expressed in most tissues and has been shown to regulate cellular differentiation and function in many cell types. Nevertheless, the most dramatic physiologic effects of vitamin D, acting through the VDR, involve regulation of intestinal calcium transport. This is most clearly demonstrated by the phenotype of patients and mice with mutant VDRs (hereditary vitamin D-resistant rickets)^{151,152}; dramatic abnormalities in bone mineralization can be reversed by bypassing the defect in intestinal calcium absorption.¹⁵³⁻¹⁵⁵

Intestinal Calcium Absorption

Under normal dietary conditions, calcium intake is in the range of 700 to 900 mg daily. Approximately 30% to 35% of this calcium is absorbed; however, losses from intestinal

secretion of calcium lead to a net daily uptake of approximately 200 mg. Although vitamin D is the major hormonal determinant of intestinal calcium absorption, the bioavailability of mineral ions in the intestinal lumen may be affected by a number of local factors and dietary constituents. Absorption of calcium and magnesium is impaired by bile salt deficiency, unabsorbed free fatty acids in steatorrheic states, and high dietary content of fiber or phytate. Gastric acid is needed to promote dissociation of calcium from anionic components of food or therapeutic preparations of calcium salts. Administration of calcium salts with meals, especially in achlorhydric, and use of divided doses or more soluble salts such as calcium citrate are commonly employed strategies to increase calcium bioavailability.

Calcium is thought to be absorbed by three pathways: the transcellular route, vesicular calcium transport, and paracellular transport. The first two pathways have been shown to be dependent on calcitriol. Although the necessity of vitamin D for paracellular calcium absorption remains controversial, substantial evidence exists that the hormone enhances this pathway as well.¹⁵⁶ Notably, the expression of claudin 2 and claudin 12, which contribute to intestinal calcium absorption and are thought to form paracellular channels between neighboring cells, has been shown to be induced by calcitriol.¹⁵⁷

The most extensively studied mechanism of intestinal calcium absorption is the transcellular route. This pathway is thought to involve three steps: entry of calcium into the enterocyte (which is the rate-limiting step), transport across the cell, and extrusion across the basolateral membrane.

Entry into the Enterocyte. A number of brush border proteins, including the intestinal membrane calcium-binding protein, brush border alkaline phosphatase, and low-affinity $\text{Ca}^{2+}, \text{Mg}^{2+}$ -ATPase have been shown to be induced by calcitriol. The activity of these proteins correlates with active calcium transport; however, a causal relationship remains to be established. Two calcium channels, TRPV5 and TRPV6, members of the transient receptor potential vanilloid receptor subfamily containing six membrane-spanning domains, are expressed in the duodenum, the jejunum, and the kidney as well as other tissues. TRPV6 is thought to play a critical role in intestinal calcium absorption, and its expression is increased by calcitriol, as is that of TRPV5.¹⁵⁸ Studies in mice lacking TRPV5 demonstrate that this channel is primarily responsible for renal calcium reabsorption; mice lacking TRPV5 have enhanced, rather than impaired, intestinal calcium absorption, because of their high circulating levels of calcitriol.¹⁵⁹ In contrast, mice missing TRPV6 do exhibit a decrease in intestinal calcium transport and the stimulation of this transport by vitamin D. Nevertheless, these knockout mice retain some responsiveness of intestinal calcium transport to calcitriol, emphasizing our still incomplete understanding of this process.¹⁶⁰

On entering the enterocyte, calcium binds to components of the brush border complex subjacent to the plasma membrane. Calmodulin is redistributed to the brush border in response to calcitriol and may play a role in this process, as may the calcitriol-inducible calcium-binding protein, calbindin-D9K.

Transcellular Transport. The best-studied effect of vitamin D on the enterocyte is the induction of synthesis of the intestinal calcium-binding protein, calbindin-D9K. This protein has an EF hand structure, which permits the

binding of two calcium ions per molecule. The affinity of calbindin for calcium is approximately four times that of the brush border calcium-binding components, so calcium is preferentially transferred to calbindin. Calbindin serves to buffer the intracellular free calcium concentration during calcium absorption. It associates with microtubules and may play a role in the transport of calcium across the enterocyte. Nevertheless, mice without calbindin-D9K exhibit normal vitamin D-mediated intestinal calcium transport; this demonstrates that the role of calbindin-D9K is not rate-limiting for this activity.¹⁶⁰ Organelles such as the mitochondria, Golgi apparatus, and endoplasmic reticulum also serve as repositories for intracellular calcium.

Exit from the Enterocyte. The transport of calcium across the antiluminal surface of the enterocyte, the final process involved in intestinal calcium absorption, is dependent on calcitriol. The main mechanism of calcium extrusion is the calcitriol-inducible, ATP-dependent plasma membrane Ca^{2+} pump (PMCA1b). The affinity of the pump for calcium is approximately 2.5 times that of calbindin. With high calcium intake, a calcitriol-independent $\text{Na}^+/\text{Ca}^{2+}$ exchanger may also play a role in the transfer of calcium across the basolateral membrane.

Actions on the Parathyroid Gland

Calcitriol has been shown to regulate gene transcription and cell proliferation in the parathyroids. The hormone also inhibits the proliferation of dispersed parathyroid cells in culture, although the relative contributions of calcium and calcitriol in the regulation of parathyroid cell proliferation in vivo have not been established. Normocalcemic mice lacking functional VDRs have normal serum PTH levels and normal-sized parathyroid glands, demonstrating that the genomic actions of calcitriol are not essential for parathyroid cellular homeostasis.¹⁵⁵ However, calcitriol has been shown to decrease transcription of the PTH gene both in vivo and in vitro. This action has been exploited in the use of calcitriol for treatment of the secondary hyperparathyroidism associated with chronic renal failure (see “Parathyroid Hormone Biosynthesis” and “Vitamin D Deficiency”). Nevertheless, the VDR in parathyroid cells has a modest role in normal physiology. When the receptor is removed specifically from parathyroid cells in genetically manipulated mice, the resultant mice have modest decreases in the levels of CASRs in their parathyroids, accompanied by modest elevations of blood PTH levels and evidence of increased resorption of bone.¹⁶¹

Actions on Bone

The effects of calcitriol on bone are numerous. Calcitriol is a major transcriptional regulator of the two most abundant bone matrix proteins: it represses the synthesis of type I collagen and induces the synthesis of osteocalcin. Calcitriol promotes the differentiation of osteoclasts from monocyte-macrophage stem cell precursors in vitro and also increases osteoclastic bone resorption in high doses in vivo, by stimulating production of RANKL (osteoclast-differentiating factor) by osteoblasts.¹⁶² Despite the multiple effects of calcitriol on the biology of bone in vitro, in vivo studies in calcitriol-deficient rats and in mice lacking functional VDRs^{152,153} suggest that the major osseous consequences of hormone and receptor deficiency can be reversed after mineral ion homeostasis is normalized. In addition, parenteral calcium infusions have been shown to heal the osteomalacic lesions in children with mutant VDRs.¹⁵⁴ These observations suggest that the major role of calcitriol in bone is to provide the proper microenvironment for

bone mineralization through stimulation of the intestinal absorption of calcium and phosphate.

Other Actions of Vitamin D

The effects of calcitriol on phosphate transport are less well studied than the effects on calcium transport. However, vitamin D has been shown to promote the already efficient intestinal phosphate absorption. Importantly, calcitriol also induces expression of the phosphaturic hormone FGF23.⁵³

One of the striking clinical features of profound vitamin D deficiency that is poorly understood is severe proximal myopathy. Muscle cells express VDRs, and calcitriol has nongenomic effects on muscle. Further, calcitriol increases amino acid uptake and alters phospholipid metabolism in vitro in muscle cells. Vitamin D administration has been shown to increase the concentration of troponin C, a calcium-binding protein that plays a role in excitation coupling and increases the rate of uptake of calcium by the sarcoplasmic reticulum. VDR knockout mice demonstrate a delay in myoblast differentiation.¹⁶³ However, little is known regarding the direct role of vitamin D in normal muscle physiology. The myopathy that accompanies vitamin D deficiency is characterized by normal levels of creatine phosphokinase, a myopathic electromyogram, and biopsy findings of loss of myofibrils, fatty infiltration, and interstitial fibrosis. The myopathy resolves within days to weeks on vitamin D replacement and is not related to normalization of mineral ion homeostasis.

Vitamin D Analogues

The recognition that calcitriol promotes cellular differentiation and inhibits cellular proliferation has led to efforts directed at producing new analogues that retain these effects but do not cause hypercalcemia. Several analogues have been shown to have antiproliferative effects on normal and malignant cells in vitro and in xenografts in immunosuppressed mice.¹⁶⁴ In addition, analogues of vitamin D have been shown to synergize with cyclosporine in preventing rejection of transplanted islet cells in a murine model.¹⁶⁵ One nonhypercalcemic analogue, 22-oxacalcitriol, has been shown to suppress PTH synthesis and secretion in rats,¹⁶⁶ at doses that stimulate intestinal calcium absorption less than calcitriol does. This suggests that such analogues may be useful in the prevention and treatment of hyperparathyroidism. The antiproliferative effects of vitamin D have been exploited clinically in the treatment of psoriasis.¹⁶⁷ Although analogues with reduced calcemic activity are predominantly used, hypercalcemic crisis can occur after excessive topical use of such compounds.

The physiology underlying the various biologic effects of these analogues is not completely understood. Altered affinity for VDBP, metabolism by target tissues,¹⁶⁸ and effects on recruitment of coactivators by the VDR may contribute to the unique properties of vitamin D analogues.¹⁶⁹

FIBROBLAST GROWTH FACTOR 23

FGF23 in Human Disease

A new era in the understanding of phosphate metabolism was ushered in with the identification of the molecular basis for the human disorder, autosomal dominant hypophosphatemic rickets (ADHR).¹⁷⁰ Linkage analyses of

affected kindreds identified mutation of the gene encoding FGF23 as the basis for ADHR. The mutation in affected individuals abolishes an RXXR protease recognition motif that is thought to be responsible for the cleavage and inactivation of FGF23.^{171,172} The complementary DNA encoding FGF23 predicts a peptide of 251 amino acids, the first 24 of which comprise a signal peptide. Studies using recombinant FGF23 demonstrate that the full-length mature peptide is required for its biologic activity and that mutation of the cleavage site in the patients with ADHR is responsible for its inactivation. Cleavage of FGF23 is inhibited by furin inhibition, suggesting that the enzyme responsible is a subtilisin-like proprotein convertase.

Analyses of tumors isolated from patients with tumor-induced osteomalacia revealed a dramatic increase in levels of mRNA encoding FGF23.¹⁷³ Serum levels of FGF23 are elevated in patients with tumor-induced osteomalacia and have been shown to normalize after removal of the tumor, correlating with resolution of the hypophosphatemia that characterizes this disorder.¹⁷⁴⁻¹⁷⁶ Conversely, patients with the rare syndrome known as tumoral calcinosis present with hyperphosphatemia and soft tissue calcium phosphate deposits. Some of these patients have point mutations in the FGF23 gene that cause abnormal processing of the protein, with low serum levels of the active hormone and high levels of inactive fragments.¹⁷⁷⁻¹⁷⁹ Yet others have mutations in the FGF23 coreceptor Klotho or in GALNT3 which normally O-glycosylates FGF23.^{180,181} Therefore, human diseases of both increased and decreased FGF23 activity suggest that this “new” factor represents an important regulator of phosphate metabolism.

Actions of FGF23

Evidence that FGF23 is a novel hormone that plays a key role in normal phosphate homeostasis has been obtained in murine models of overexpression and ablation. Overexpression of FGF23 or administration of FGF23 to animals results in the development of hypophosphatemia¹⁷² and impaired 1 α -hydroxylation of 25(OH)D,^{136,182} recapitulating the findings observed in patients affected by tumor-induced osteomalacia. Investigations in mice with targeted ablation of FGF23 have proven that endogenous production of this hormone is critical for normal phosphate homeostasis and the regulation of vitamin D metabolism.^{183,184} Absence of FGF23 results in impaired renal phosphate excretion, leading to the development of hyperphosphatemia within the first 2 weeks of life. Affected mice also develop hypercalcemia due to high levels of calcitriol, a result of the lack of the normal suppressive effect of FGF23 on the renal 25(OH)D 1 α -hydroxylase.¹³⁶ Ablation of FGF23 results in premature death associated with ectopic mineralization of soft tissues, including the kidney. Impairing calcitriol action in these animals prevents the development of hypercalcemia and improves survival, suggesting that the premature death is a direct consequence of impaired mineral ion homeostasis rather than a specific developmental or maturational effect of FGF23.¹⁸⁵

FGF23 impairs Na⁺-dependent phosphate transport in both intestinal and renal brush border membrane vesicles.¹⁸⁶ It has been shown to decrease the levels of type IIa, IIb, and IIc NaPi transporters, thereby regulating both intestinal and renal phosphate transport.¹⁸⁷⁻¹⁸⁹ FGF23 decreases circulating levels of calcitriol, both by decreasing mRNA levels for the renal 25(OH)D 1 α -hydroxylase and by increasing expression of 24-hydroxylase, the key enzyme involved in inactivation of calcitriol.¹³⁶ FGF23 activates FGF receptor 1 in the presence of Klotho, a single-pass

transmembrane protein that acts as a coreceptor.¹⁹⁰ Klotho knockout mice exhibit the same hyperphosphatemia and high calcitriol levels seen in FGF23 knockout mice,¹⁹¹ demonstrating that Klotho plays a critical role in mediating the actions of FGF23.

Regulation of FGF23

Circulating FGF23 levels are increased by dietary phosphorus, serum phosphorus and calcitriol.^{53,192,193} Precisely how phosphate is sensed to regulate FGF23 production is unknown. Studies in mice with mutations in the *PheX* or *Dmp1* gene suggest that these genes are upstream of FGF23 and suppress its expression.^{184,194} The products of these genes, as well as FGF23 itself, are synthesized primarily by osteocytes, cells derived from osteoblasts, that reside in the bone matrix. Interestingly, studies in mice with chondrocyte-specific ablation of the VDR suggest that this receptor regulates a factor elaborated by chondrocytes that suppresses FGF23 production.¹⁹⁵ In patients with chronic renal failure, an increase in FGF23 levels has been shown to antedate the development of secondary hyperparathyroidism and thus may be beneficial in predicting which individuals will develop this disorder.¹⁹⁶

Treatment of dialysis patients with sevelamer hydrochloride and calcium carbonate decreases levels of phosphate and FGF23 in parallel, implicating increases in serum phosphate or in intestinal absorption of phosphate as the pathophysiologic basis for the increased FGF23 levels in this population.¹⁹⁷ Thus, FGF23 has emerged as an essential regulator of normal phosphate and calcitriol homeostasis. Phosphate and calcitriol increase FGF23 levels; this FGF23 then acts on the renal proximal tubule to suppress synthesis of calcitriol and decrease the reabsorption of phosphate.

CALCIUM AND PHOSPHATE HOMEOSTASIS

The cytosolic concentrations of intracellular calcium, phosphorus, and magnesium differ markedly, as reviewed previously, and their physiologic roles within cells are diverse and largely unrelated (see Fig. 28-1). In contrast, the concentrations of these mineral ions in ECF are quite comparable (i.e., 1 to 2 mmol/L), and it is here that they exert important interactions, both with cells and with one another, that are critical for bone mineralization, neuromuscular function, and normal mineral ion homeostasis. Extracellular calcium and phosphate, in particular, exist so close to the limits of their mutual solubility that stringent regulation of their concentrations is required to avoid diffuse precipitation of calcium phosphate crystals in tissues.

Serum concentrations and total body balances of the mineral ions are maintained within narrow limits by powerful, interactive homeostatic mechanisms. PTH, calcitriol, and FGF23 regulate mineral ion levels; mineral ion levels, in turn, regulate PTH, calcitriol, and FGF23 secretion, and these hormones may regulate the production of one another. Calcium sensors in the parathyroid glands control PTH secretion by monitoring the blood concentration of ionized calcium, whereas those in the kidney act to adjust tubular calcium reabsorption independently of PTH or calcitriol. However, the mechanisms of phosphate sensing needed for normal homeostasis are not understood. The operation of these homeostatic mechanisms can be

Figure 28-19 Homeostatic responses to variations in dietary calcium content. Major homeostatic responses to dietary calcium deprivation or loading are depicted. Arrow thickness indicates relative activity of transport or secretory mechanisms, and the amounts of hormones or transported ions are indicated by the size of their notations. Parentheses indicate an inhibitory regulation. Note that the extracellular calcium concentration is well maintained, although different underlying mechanisms are involved in the two circumstances (see text for details). 1,25 D, calcitriol; PTH, parathyroid hormone.

appreciated by considering the following examples of how the organism adapts to changes in calcium loads (Fig. 28-19).

Dietary calcium restriction leads to an increase in the efficiency of intestinal calcium absorption. This increased efficiency results from a sequence of homeostatic responses in which the lowered concentration of ionized calcium in blood activates secretion of PTH, PTH augments synthesis of calcitriol by the proximal tubules of the kidney, and calcitriol then acts directly on enterocytes to increase active transcellular transport of calcium. Enhanced intestinal calcium absorption is quantitatively the most important response to calcium deprivation, but a series of other homeostatic events also occur that limit the impact of this stress. Renal tubular calcium reabsorption is increased by PTH, an effect that is enhanced by increased calcitriol-stimulated expression of calbindin-D28K in the distal tubules. Calcium reabsorption is also enhanced directly by any tendency to hypocalcemia, which is detected by CASRs in Henle's loop (and possibly also in the distal nephron) that control trans epithelial calcium movements independent of PTH or calcitriol.

The impact of dietary calcium deprivation is reduced by approximately 15% through release of calcium from bone in response to PTH and calcitriol. The concomitant increase in net bone resorption causes release of phosphate as well as calcium into the ECF. Intestinal phosphate absorption also is increased by calcitriol. These phosphate loads are problematic, in that phosphate directly lowers ionized calcium in ECF, suppresses renal synthesis of calcitriol, and directly inhibits bone resorption. These potentially negative effects of phosphate are obviated by the powerful phosphaturic actions of PTH and FGF23, the secretion of which is promoted by phosphate, calcium and calcitriol.

Finally, the possibility of unrestrained secretion of PTH, which would lead to excessive bone resorption and severe hypophosphatemia, is prevented by the effects of calcium on PTH secretion and by the direct suppressive effect of calcitriol on the synthesis of PTH and PTH receptors. As a result of these homeostatic responses, calcium-deprived people maintain near-normal serum calcium and phosphate concentrations but display increased intestinal calcium absorption, increased bone resorption and

progressive osteopenia, increased renal tubular calcium reabsorption, decreased renal TRP, low urinary calcium excretion, elevated urinary phosphate excretion, and high serum concentrations of PTH and calcitriol.

Calcium loads induce an opposite series of adaptations: parathyroid suppression, inhibition of renal calcitriol synthesis, decreased intestinal active transport of calcium, increased renal excretion of calcium and decreased renal excretion of phosphate (secondary to functional hypoparathyroidism), and decreased bone resorption sufficient to allow a positive skeletal calcium balance. The decline in intestinal calcium absorption is the major safeguard against calcium overload, although this mechanism may be overridden with extraordinarily high intakes of calcium because of the persistence of the passive, non-vitamin D-dependent mode of calcium absorption. Moreover, nonenteral sources of calcium, such as intravenous calcium infusion or excessive net bone resorption (as from immobilization or malignancy), may readily overwhelm the limited homeostatic adaptations that remain once the capacity of suppressed intestinal calcium absorption is exceeded. In such situations, the kidney rather than the intestine becomes the principal defense against hypercalcemia, and calcium homeostasis becomes critically dependent on adequate renal function. If renal function is impaired in these settings, as frequently occurs clinically, severe hypercalcemia and pathologic calcium deposition in extraskeletal sites may ensue.

LABORATORY ASSESSMENT OF MINERAL METABOLISM

Parathyroid Hormone

The major challenges in the measurement of blood PTH have been the low levels of circulating PTH and the presence of inactive PTH fragments in far greater abundance than the intact, biologically active PTH molecule. The measurement of inactive fragments would not be a concern if the ratio of inactive to active PTH molecules remained constant. However, this ratio changes in response to changes in GFR or in parathyroid gland secretory activity

(see “Parathyroid Hormone Secretion” and “Metabolism of Parathyroid Hormone”). Consequently, radioimmunoassays of PTH have suffered from lack of sensitivity and from inability to measure the biologically active hormone directly.

For these reasons, two-site assays, which require the presence of amino-terminal and carboxy-terminal sequences of full-length PTH(1-84) on the same molecule, have replaced older radioimmunoassays.¹⁹⁸ The assays are sensitive enough to detect PTH in all normal persons. The assays have demonstrated modest circadian variation in PTH levels and some pulsatility in PTH secretion, but these variations have not interfered with the diagnostic usefulness of randomly drawn PTH measurements. Some studies have reported modest increases in PTH levels with age, although others have not. Unlike older radioimmunoassays, the two-site assays demonstrate virtually no overlap in PTH levels between patients with primary hyperparathyroidism and those with nonparathyroid hypercalcemia (Fig. 28-20). Because this distinction represents the most important challenge in the clinical setting, the use of the two-site assay has dramatically facilitated the clinician's task.

This straightforward picture has been complicated by the realization that most two-site assays detect small amounts of PTH fragments that are large but do not extend to the hormone's amino-terminus.¹⁹⁹ These fragments accumulate in significant amounts in patients with renal failure. These observations have prompted the development of two-site PTH assays that use antibodies specific for the first four amino acids of PTH and therefore do not detect large fragments of PTH. Although it seems plausible that such assays might prove particularly useful in some

clinical situations, their role is presently unclear. They offer no advantage over older two-site assays, for example, in diagnosing primary hyperparathyroidism.²⁰⁰

Parathyroid Hormone–Related Protein

The measurement of PTHrP in serum presents a series of challenges. The concentration of PTHrP in the bloodstream, even in some patients with PTHrP-mediated malignant hypercalcemia, is not high, and the molecular definition of circulating, biologically active fragments is incomplete. Despite these problems, several groups of investigators have developed assays for PTHrP that can be helpful in the evaluation of hypercalcemia in a subset of patients. Radioimmunoassays for amino-terminal portions of PTHrP and two-site assays for amino-terminal and midregion PTHrP²⁰¹ separate healthy persons and patients with nonmalignant hypercalcemia from most patients with the humoral hypercalcemia of malignancy (Fig. 28-21). When measured with the most recently developed assays, PTHrP levels are found to be elevated in almost all patients with malignant hypercalcemia without bone metastases and in most patients with hypercalcemia and bone metastases.

Occasionally, the PTHrP assay has helped distinguish an occult malignancy from other causes of non-PTH-dependent hypercalcemia. Nevertheless, because the diagnosis of malignancy as the cause of hypercalcemia is usually clinically obvious and the PTH assay can be used to diagnose primary hyperparathyroidism, the role of PTHrP assays in clinical practice is limited.²⁰²

Calcitonin

Several assays for measuring serum calcitonin are commercially available. The measurements are based on single- or double-antibody radioimmunoassays or enzyme immunoassays, several of which are sufficiently sensitive to detect calcitonin deficiency.^{203,204} The calcitonin monomer is thought to be the biologically active molecule; therefore, some investigators believe that extraction of the multimeric forms before radioimmunoassay provides a more sensitive and more specific measurement of serum calcitonin levels. However, the double-antibody radioimmunoassay is thought by others to provide the same information with less sample manipulation. The only clinical use of the calcitonin assay is as a tumor marker, primarily in medullary carcinoma of the thyroid.

Vitamin D Metabolites

The radioligand assays for determining the levels of vitamin D metabolites require fractionation and extraction of the hormone from serum proteins by HPLC or silica cartridges. These assays are sufficiently sensitive to detect subnormal values. Because the assays measure both protein-bound and unbound vitamin D metabolites, results may not always reflect the levels of biologically relevant (“free”) metabolites. This limitation may lead to misleading results in patients with nephrotic syndrome or vitamin D intoxication. With the move away from using radioligand-based assays, other methods for measuring vitamin D metabolites, including chemiluminescent assays, have been pioneered.²⁰⁵ Although these assays have not withstood the test of time, they have been proven to be as accurate as the currently available radioimmunoassay. Mass spectrometry is being increasingly used for measuring levels of 25(OH) D. Regardless of the method used, it has been recognized

Figure 28-20 Intact immunoreactive parathyroid hormone (PTH) determined using a two-site immunoradiometric assay in normal subjects and in three different patient groups. Note that there is some overlap between normal people and patients with primary hyperparathyroidism but no overlap between hypercalcemic patients with primary hyperparathyroidism and those with hypercalcemia of malignancy. (From Segre GV. Advances in techniques for measurement of parathyroid hormone: current applications in clinical medicine and directions for future research. *Trends Endocrinol Metab.* 1990;1:243-247.)

Figure 28-21 Plasma PTHrP(1-74) determined by two-site immunoradiometric assay in selected patient groups and normal subjects. Also shown are concentrations of PTHrP in human milk (filled circles) and in bovine milk (open circles). Two normocalcemic patients with cancer (filled triangles) subsequently became hypercalcemic. The number of samples in each category is shown in parentheses. Hatched area denotes levels too low to detect with this assay. PTHrP, parathyroid hormone-related protein. (Adapted from Burtis WJ, Brady TG, Orloff JJ, et al. Immunochemical characterization of circulating parathyroid hormone-related protein in patients with humoral hypercalcemia of cancer. *N Engl J Med.* 1990;322:1106-1112.)

that a central repository for uniform standards is required for validation of these assays and of the laboratories performing them. The National Institute of Standards and Technology in the United States has developed standard reference materials for this purpose.²⁰⁶

The levels of 25(OH)D correlate better with the clinical signs and symptoms of vitamin D deficiency than do the levels of calcitriol. Because the 25-hydroxylation of vitamin D is not tightly regulated, measurements of 25(OH)D more accurately reflect body stores of vitamin D. Measurement of this metabolite should, therefore, be performed if vitamin D deficiency is suspected.

Measurements of calcitriol should be reserved for cases in which excessive or impaired 1α -hydroxylation is suspected. High calcitriol levels can be seen in sarcoidosis, lymphomas, Williams' syndrome, and intoxication with 1α -hydroxylated metabolites (see "[Parathyroid-Independent Hypercalcemia](#)"). Impaired 1α -hydroxylation can contribute to the hypocalcemia of patients with renal dysfunction, increased FGF23 levels, or hereditary defects of vitamin D metabolism (see "[Hypocalcemic Disorders](#)").

Fibroblast Growth Factor 23

Currently, two types of immunoassays are available for the measurement of serum FGF23 in humans. An assay using two polyclonal antibodies directed against carboxyl-terminal epitopes²⁰⁷ detects most, if not all, circulating forms of FGF23 but does not discriminate between the intact active hormone and the cleaved fragment, which is not thought to have biologic activity. One assay for the intact hormone is a classic sandwich assay with antibodies directed against both the amino- and the carboxyl-terminus of the hormone.²⁰⁸ This assay has been shown to be more

useful than others for studying the effects of dietary phosphate on FGF23 levels in humans thought to provide a more precise determination of the biologically active levels of the hormone in the circulation, particularly when such levels may be changing.²⁰⁹

HYPERCALCEMIC DISORDERS

Parathyroid-Dependent Hypercalcemia

It is useful to delineate two categories of hypercalcemia: that associated with dysfunction of the parathyroid cell and that in which hypercalcemia occurs despite appropriate suppression of PTH secretion by the parathyroid. This distinction is particularly useful clinically because it emphasizes the centrality of the PTH assay in the diagnostic approach to the patient with hypercalcemia. Abnormal parathyroid glands are associated with hypercalcemia in three settings: primary hyperparathyroidism, familial hypocalciuric hypercalcemia (FHH), and lithium-induced hypercalcemia.

Primary Hyperparathyroidism

In primary hyperparathyroidism, a primary abnormality of parathyroid tissue leads to inappropriate secretion of PTH. In contrast, increased secretion of PTH that is an appropriate response to hypocalcemia is called *secondary hyperparathyroidism*. The inappropriately high serum concentration of PTH in primary hyperparathyroidism sustains excessive renal calcium reabsorption, phosphaturia, and calcitriol synthesis, as well as increased bone resorption. These actions of PTH produce the characteristic biochemical phenotype of hypercalcemia and hypophosphatemia, loss of

cortical bone, hypercalciuria, and the various clinical sequelae of chronic hypercalcemia.

Primary hyperparathyroidism results most often (75% to 80%) from the occurrence of one or more adenomas in previously normal parathyroid glands; in 20% of cases diffuse hyperplasia of all parathyroid glands may be present, and, rarely, parathyroid carcinoma may be found (<1% to 2%).²¹⁰⁻²¹³

Classic Primary Hyperparathyroidism. The bone disease called osteitis fibrosa cystica was first described by von Recklinghausen in 1891, but the etiologic link between this disease and parathyroid neoplasms was not established until 1925, when Mandl observed clinical improvement after removal of a parathyroid adenoma from a young man with severe bone disease. In early clinical descriptions of primary hyperparathyroidism, the disease emerged as a distinctly uncommon disorder, with significant morbidity and mortality, in which almost all affected patients manifested radiographically significant or symptomatic skeletal or renal involvement, or both.

The skeletal involvement seen in classic primary hyperparathyroidism reflects a striking and generalized increase in osteoclastic bone resorption, which is accompanied by fibrovascular marrow replacement and increased osteoblastic activity. The radiographic appearance (Fig. 28-22) is characterized by the following features:

- Generalized demineralization of bone, with coarsening of the trabecular pattern (due to osteoclastic resorption of the smaller trabeculae)
- Subperiosteal resorption, often most evident in the phalanges of the hands, which gives an irregular, serrated appearance to the outer, subperiosteal cortex and may progress to extensive cortical resorption
- Bone cysts, usually multiple, which contain a brownish serous or mucoid fluid; tend to occur in the central medullary portions of the shafts of the metacarpals, ribs, or pelvis; and may expand into and disrupt the overlying cortex
- Osteoclastomas, or “brown tumors,” composed of numerous multinucleated osteoclasts (“giant cells”) admixed with stromal cells and matrix, which are found most often in trabecular portions of the jaw, long bones, and ribs
- Pathologic fractures

The skull may exhibit a finely mottled, salt-and-pepper radiographic appearance, with loss of definition of the inner and outer cortices. Dental radiographs typically show erosion or disappearance of the lamina dura due to subperiosteal resorption, often with extension into the adjacent mandibular bone. The erosion and demineralization of cortical bone may lead to radiographic disappearance of some bones, most notably the tufts of the distal phalanges of the hands, the inferolateral cortex of the distal third of the clavicles, the distal ulna, the inferior margin of the femoral neck and pubis, and the medial aspect of the proximal tibia. The clinical correlates of these changes may include aching bone pain and tenderness, “bowing” of the shoulders, kyphosis and loss of height, and collapse of lateral ribs and pelvis with “pigeon breast” and triradiate deformities, respectively.

The renal manifestations of classic severe primary hyperparathyroidism include recurrent calcium nephrolithiasis, nephrocalcinosis, and renal functional abnormalities that range from impaired concentrating ability to end-stage renal failure. Associated signs and symptoms include recurrent flank pain, polyuria, and polydipsia. No unique features of the stone disease seen in primary hyperparathyroidism serve to distinguish it from that associated with other, more common causes of calcium kidney stones. It may more often be recurrent and severe, and in some patients the stones may be composed entirely of calcium phosphate, instead of the pure oxalate or mixed oxalate and phosphate stones more commonly encountered in other disorders. In patients diagnosed before 1965, the frequency with which nephrolithiasis complicated primary hyperparathyroidism was reportedly as high as 60% to 80% (currently, it is less than 25%), yet in studies of unselected patients conducted throughout the past 50 years, primary hyperparathyroidism has accounted for fewer than 5% of all calcium kidney stones.

Other clinical features that have been reported in association with classic severe primary hyperparathyroidism are conjunctival calcifications, band keratopathy, hypertension (50%), gastrointestinal signs and symptoms (anorexia, nausea, vomiting, constipation, or abdominal pain), peptic ulcer disease, and acute or chronic pancreatitis. The issue of whether primary hyperparathyroidism increases the risk for peptic ulcer disease and pancreatitis remains controversial. Although hyperparathyroidism is associated with a higher risk of hypertension, successful parathyroidectomy has not been shown to correct the hypertension.

Signs and symptoms in primary hyperparathyroidism may result from the involvement of bone (fracture, bone

Figure 28-22 Radiograph of the hand of a patient with severe primary hyperparathyroidism. Note the dramatic remodeling associated with the intense region of high bone turnover in the third metacarpal and the widespread evidence of subperiosteal, endosteal, and trabecular resorption. (Courtesy of Fuller Albright Collection, Massachusetts General Hospital.)

pain) or kidneys (renal colic, renal failure), peptic ulcer disease, pancreatitis, or hypercalcemia per se (weakness, apathy, depression, polyuria, constipation, coma). The presence and severity of neuropsychiatric symptoms, in particular, correlate poorly with the serum calcium concentration, although few patients with severe hypercalcemia are entirely asymptomatic. Elderly persons are most likely to exhibit such symptoms. A peculiar neuromuscular syndrome, first described in 1949 but rarely encountered now, includes symmetric proximal weakness and gait disturbance, with muscle atrophy, characteristic electromyographic abnormalities, generalized hyperreflexia and tongue fasciculations.²¹⁴

Contemporary Primary Hyperparathyroidism. The clinical spectrum of primary hyperparathyroidism was changed dramatically in the early 1970s by the introduction of routine multichannel serum chemistry screening, which unearthed a large population of patients with previously unsuspected, asymptomatic disease. In Rochester, Minnesota, for example, the annual incidence of the disease increased abruptly, from 0.15 to 1.12 per 1000 persons, between the prescreening era (1965-1974) and 1975, the year after routine screening was introduced.²¹⁵ The peak incidence occurs in the sixth decade of life, and the disease rarely is encountered in patients younger than 15 years of age. It is twofold to threefold more common in women, who also tend to be slightly older at diagnosis than men.

Annual incidence rates were widely reported to be 0.1 to 0.3 per 1000 persons in the wake of this surge of ascertainment in Europe and the United States, but they appear to have declined substantially since then, to levels as low as 0.04 per 1000.²¹⁵ This may represent a true decline in disease incidence or simply the residual effect of "sweeping" the population of prevalent subclinical disease over the previous 3 decades. Ascertainment of mild or asymptomatic disease may decline even further in the future because of prevalent economic disincentives to routine serum chemistry screening in the primary care setting.

On the other hand, insistence on overt hypercalcemia as a diagnostic criterion may underestimate the true incidence of the disease. For example, when serum calcium and immunoreactive PTH (iPTH) were measured in a large population of Swedish women undergoing routine mammographic screening, the prevalence of unsuspected primary hyperparathyroidism, defined by criteria that included the combination of high-normal serum calcium plus elevated or high-normal iPTH, was 2.1%.²¹⁶ Two thirds of these women (72/109) were normocalcemic (10.0 to 10.4 mg/dL), yet bone density was reduced in the group as a whole, and the disease was confirmed histologically in 98% of the 61 who had surgery. Furthermore, the widespread practice of evaluating PTH levels in patients with osteoporosis has led to the identification of patients with high PTH levels and normocalcemia.²¹⁷ Many of these patients become hypercalcemic during follow-up.

Not surprisingly, given that primary hyperparathyroidism now usually is diagnosed incidentally, few patients are found to have overt signs or symptoms of the classic disease, and most therefore are considered to be "asymptomatic." For example, only 2% of patients with primary hyperparathyroidism residing in Olmsted County, Minnesota, and only 17% of 121 patients studied at an academic referral center in New York City had classic disease symptoms^{215,218}; in most of cases, the relevant symptom was urolithiasis. Many clinicians argue, however, that most of the patients who are regarded as having asymptomatic primary hyperparathyroidism and who have only minimally elevated

serum calcium actually suffer from various neuropsychiatric or other symptoms that may improve after curative surgery.²¹⁹ Nonetheless, these symptoms—which include fatigability, weakness, forgetfulness, depression, somatization, polydipsia, polyuria, and bone and joint pain—are also common in otherwise normal persons.

In the small randomized studies of surgery for primary hyperparathyroidism (discussed later), the effects of surgery on measures of quality of life have been conflicting.^{217,220-222} This remains a critical issue, because the advent of less invasive operative approaches and concerns regarding fracture, cancer, and mortality risk have lowered the threshold for consideration of surgery in many patients with the disease (see later discussion). Throughout this chapter, the term *asymptomatic primary hyperparathyroidism* refers to patients who lack signs or symptoms of the classic disease, whether or not they experience any of the subtle symptoms mentioned previously.

The natural history of untreated asymptomatic primary hyperparathyroidism, as currently detected, remains incompletely understood. Few patients seem to experience progression of the disease, as measured by extreme elevations of serum or urinary calcium or by the advent of renal dysfunction, nephrocalcinosis, or worsening osteopenia over many years of observation.²¹⁸ On the other hand, late cortical bone loss observed at the femoral neck and distal radius in a small number of patients who were observed without surgery for 15 years points to the potential importance of continued monitoring in such patients.²²⁶ Also, an excess risk of mortality, mainly from cardiovascular disease, has been noted during extended follow-up of large cohorts of patients with chronic hypercalcemia (and presumed primary hyperparathyroidism) identified by population health screening in Sweden,²²³ and similar observations have been made during extended follow-up of postsurgical patients with hyperparathyroidism.²²⁴ Associations of hypertension, hyperuricemia, and glucose intolerance with primary hyperparathyroidism have been implicated, together with hypercalcemia per se, as contributors to this elevated risk.²²⁵

Abnormal cardiac calcification and left ventricular hypertrophy (reversible by successful parathyroidectomy) have also been reported in primary hyperparathyroidism.²²⁷ Increased cardiovascular mortality may be a feature only of severe hyperparathyroidism, because it was restricted to those in the highest quartile of serum calcium in the Olmsted County study, which otherwise showed an overall decreased risk of death.²²⁸ A 40% excess risk of malignancy also was reported among 4163 Swedish patients who had undergone surgery more than a year earlier for (presumably symptomatic) primary hyperparathyroidism.²²⁹ It has been argued that these increased risks for mortality and malignancy, even if confirmed, may apply only to those with primary hyperparathyroidism that is more severe than the "asymptomatic" version typically encountered today.²²⁵

Abnormalities of bone in modern, mild primary hyperparathyroidism are far subtler than those associated with the classic disease. Histologically, the rate at which new bone remodeling cycles are activated is increased. Because the phase of restorative bone formation at each remodeling site takes much more time than does the initial resorptive phase, such an increase in remodeling rate inevitably increases the ambient volume of the "remodeling space" and, thus, the porosity of bone. Depending on the rate and extent of the accompanying increase in osteoblastic activity and the resulting local balance between net bone formation and resorption, mineralized bone volume may decrease

Figure 28-23 Iliac crest biopsy specimens from a patient with primary hyperparathyroidism (left) and a normal control (right), viewed by scanning electron microscopy. Note the thin cortices and contrasting maintenance of trabecular bone in the patient. (From Parisien M, Silverberg SJ, Shane E, et al. The histomorphometry of bone in primary hyperparathyroidism: preservation of cancellous bone structure. *J Clin Endocrinol Metab.* 1990;70:930-938.)

further, remain stable, or even increase (despite an increased remodeling space). For reasons not yet understood, the balance achieved between increased resorption and formation of bone in primary hyperparathyroidism depends not only on the severity of the hyperparathyroidism but also on skeletal location: Net resorption of endosteal bone may predominate in cortical sites, whereas net apposition of mineral may occur in trabecular bone (Fig. 28-23).²³⁰

In mild primary hyperparathyroidism, osteopenia usually is not evident radiographically, although bone mineral density may be reduced by as much as 10% to 20%, particularly at sites of predominantly cortical bone such as the midradius.²³¹ The mass of trabecular or cancellous bone, as represented in the vertebral bodies, is preferentially preserved and often is normal.²³² Curiously, the reduced cortical bone density at the forearm is not improved by successful parathyroidectomy, whereas density at trabecular-rich sites such as the hip and spine may increase by 10% to 15% over several years postoperatively.²¹⁸

The critical issue of whether fracture risk is increased in patients with primary hyperparathyroidism was addressed by a retrospective analysis of fracture incidence within a cohort of 407 residents of Rochester, Minnesota, who were diagnosed with the disease between 1965 and 1992.²³³ Compared to the expected age- and sex-adjusted rates of incident fractures in that community, the relative risk among those with hyperparathyroidism was significantly elevated at the vertebrae (3.2-fold), distal forearm (2.2-fold) and ribs (2.7-fold), although not at the hip (1.4-fold). Overall risk of fracture at any site was significantly increased as well (1.3-fold) and was as high in those diagnosed incidentally, after the institution of automated chemistry screening in 1974, as in those diagnosed before that time. Similar findings were reported in 674 Danish patients who were scheduled to undergo parathyroidectomy.²³⁴ These results are consistent with those of several previous studies involving smaller cohorts of patients and, absent data from

an appropriately controlled prospective study, strongly support the conclusion that patients with primary hyperparathyroidism should be considered to be at increased risk for fracture. This presumably is true in both symptomatic and asymptomatic disease, because less than 10% of the post-screening Rochester cohort had symptoms or complications of primary hyperparathyroidism.²¹⁵ What is not yet known is whether fracture risk is reduced by successful parathyroidectomy, although in the Danish series the risk for vertebral and lower-extremity fractures was no longer increased postoperatively.²³⁴

Kidney stones now are reported in only 10% to 25% of patients with primary hyperparathyroidism, although some degree of renal dysfunction—either a significant reduction in creatinine clearance (Cl_{Cr}) or impaired concentrating or acidifying ability—may be found in up to one third of those with asymptomatic disease. These renal abnormalities are not progressive in the majority of affected patients.^{218,235} The association of kidney stones with primary hyperparathyroidism generally is viewed as an indication for parathyroidectomy, however, because successful surgery usually prevents further symptomatic stone disease.^{218,224} On the other hand, it is not possible at present to confidently predict, from biochemical measurements in blood or urine, which asymptomatic patients with hyperparathyroidism will go on to develop new stone disease. Stone-formers are more likely to be hypercalciuric than not, but fewer than one third of hypercalciuric patients with hyperparathyroidism actually develop stones.

Etiology and Pathogenesis. Parathyroid adenomas are caused by mutations in the DNA of parathyroid cells; these mutations confer a proliferative or survival advantage for affected cells compared with their normal neighbors.^{236,237} As a consequence of this advantage, the descendants of one particular parathyroid cell, a clone of cells, undergo clonal expansion to produce an adenoma.

Multiple chromosomal regions are missing in the parathyroid cells of individual parathyroid adenomas, probably reflecting the deletion of tumor suppressor genes. These chromosomal loci include portions of chromosome 1p-pter (in 40% of adenomas), 6q (in 32% of adenomas), 15q (in 30% of adenomas), and 11q (in 25% to 30% of adenomas). Many of the 11q deletions are associated, in the undelleted chromosome 11, with mutations in the gene encoding the transcription factor *menin*, the gene that is mutated in multiple endocrine neoplasia type 1 (MEN1). This gene is also commonly involved in somatic mutations in patients with sporadic parathyroid adenomas. Somatic mutations have also been found in the mitochondrial genomes of a fraction of chief cell adenomas and have been found even more frequently in so-called oxyphil adenomas, which are known to exhibit mitochondria with abnormal morphology.²³⁸ The widespread presence of somatic mutations in sporadic parathyroid adenomas, which are detectable only because large numbers of cells in any one tumor contain the same deletion, constitutes the strongest evidence that parathyroid adenomas are clonal expansions of mutant cells.

One parathyroid proto-oncogene has been identified: the cyclin D1 gene (*CCND1*, also called parathyroid adenomatous 1 or *PRAD1*).²³⁹ This gene was discovered at the breakpoint of an inversion on chromosome 11 in a parathyroid adenoma. This inversion led to juxtaposition of the PTH gene's regulatory region and the DNA encoding cyclin D1. As a consequence, the cyclin D1 gene was overexpressed. Cyclin D1 is an important regulator of the transition from the G₁ phase of the cell cycle (which follows mitosis) to the S phase (associated with DNA synthesis), and it is mutated or amplified in a wide variety of malignancies. Cyclin D1 is overexpressed in about 20% of parathyroid adenomas, although cyclin D1 gene rearrangements have been documented in only 5% of adenomas. Overexpression of cyclin D1 in the parathyroids of transgenic mice leads to formation of parathyroid adenomas and hypercalcemia over many months.²⁴⁰ The phenotype of these mice demonstrates that cyclin D1 overexpression can cause primary hyperparathyroidism.

As expected for a disease caused by mutations in DNA, parathyroid adenomas occur more frequently in patients who underwent neck irradiation decades earlier, with greater radiation exposure leading to higher risk. Most patients have no definite history of exposure to specific mutagens, however. An intriguing clue that abnormalities of vitamin D physiology may predispose to primary hyperparathyroidism has come from the observation that patients with parathyroid adenomas are more likely than others to have inherited a particular allele of the VDR gene.²⁴¹ These patients have tumors with particularly low levels of mRNA encoding the VDR. Nevertheless, no mutations in the coding regions of the gene encoding the VDR have been found in parathyroid adenomas.²⁴²

The cause of sporadic primary parathyroid hyperplasia is unknown. The known stimulus for parathyroid cell proliferation—low levels of blood calcium or calcitriol—is not present in this disease. Presumably, some other stimulus outside the parathyroid glands, or a genetic abnormality present in all four parathyroid glands, leads to inappropriate cell proliferation. Such abnormalities have been found in several inherited forms of parathyroid hyperplasia (see later discussion), but most cases of parathyroid hyperplasia do not occur as part of familial clusters.

The theoretical distinction between adenoma as a clonal proliferation and hyperplasia as a polyclonal growth is

clearcut. In some settings, however, clonal expansion can occur in the context of preexisting nonclonal proliferation. The clearest example of this complication has been found in the large parathyroid glands associated with severe renal failure. In many such glands removed surgically because of hypercalcemia or severe parathyroid-dependent bone disease, evidence for clonal proliferation complicating secondary hyperplasia has been found. Interestingly, the pattern of chromosomal abnormalities in these clonal tumors differs from that found in parathyroid adenomas in patients without renal failure.²⁴³ Analogous mechanisms may be operative in a number of settings associated with stimuli to parathyroid cell proliferation, such as X-linked hypophosphatemia and long-term lithium therapy. Furthermore, just as clonal tumors can arise in the setting of secondary parathyroid hyperplasia, they can also arise in the setting of sporadic primary parathyroid hyperplasia²⁴⁴ and in MEN1.²⁴⁵

The distinction between adenoma and hyperplasia is clinically important, because removal of the one gland that is abnormal can be expected to cure a parathyroid adenoma, whereas removal of multiple glands is required to cure parathyroid hyperplasia. However, differentiating adenoma from hyperplasia and from normal parathyroid tissue at pathologic examination is not straightforward. Pathologists distinguish normal from abnormal parathyroid glands by the increase in size and the paucity of fat in abnormal glands. Attempts have been made to distinguish an adenoma from an individual hyperplastic gland on the basis of morphologic features, but no criteria have proved completely reliable.²⁴⁶ The formation of clonal neoplasms in originally hyperplastic tumors may explain some of the difficulty encountered in pathologic diagnosis.

An increase in cell number is not the only abnormality in primary hyperparathyroidism. The ability of the normal parathyroid cell to suppress PTH secretion in response to hypercalcemia might be expected to protect an individual from sustained hypercalcemia even if the number of parathyroid cells increases moderately. However, parathyroid cells in parathyroid adenomas usually demonstrate abnormalities in their responsiveness to calcium, with a shift in setpoint to the right (Fig. 28-24). This setpoint shift, combined with the nonsuppressible component of PTH secretion, leads to a new steady state in which both the PTH level and the blood calcium level are higher than normal.

The molecular underpinning of the abnormal parathyroid cell responsiveness is beginning to be understood. Parathyroid cells from adenomas respond to changes in extracellular calcium with smaller than normal increases in intracellular calcium, and the amount of CASR protein on the cell surface is reduced.²⁴⁷ Perhaps surprisingly, no mutations in the gene encoding the CASR have been found in parathyroid adenomas. In the experimental model in which overexpression of cyclin D1 results in primary hyperparathyroidism,²⁴⁰ reduced expression of the CASR occurs only after cell proliferation has been increased for some time. Therefore, the decreased expression of the CASR in parathyroid adenomas is likely to be a secondary response that occurs during tumor formation. One demonstrated regulator of expression of the CASR gene in parathyroid cells is the developmental regulator, GCM2.²⁴⁸

Inherited Primary Hyperparathyroidism. Although inherited forms of primary hyperparathyroidism are uncommon, they are clinically important for several reasons. Management of the parathyroid tumors found in familial parathyroid syndromes often differs from that of sporadic primary hyperparathyroidism. Furthermore,

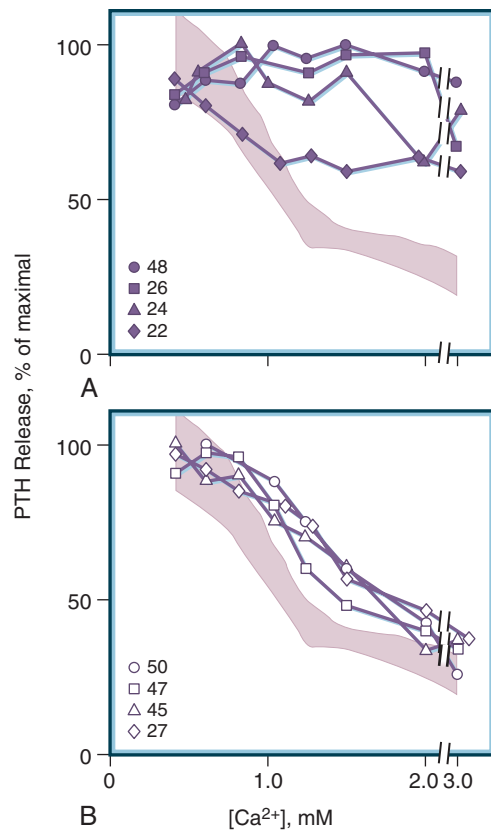

Figure 28-24 Abnormal patterns of parathyroid hormone (PTH) secretion from cells prepared from adenomatous glands and stimulated with varying levels of calcium in tissue culture. The shaded area shows the pattern of PTH release (± 1 standard deviation) from normal human parathyroid cells. Panel **A** illustrates the pattern from four patients with little suppression of PTH secretion by calcium. Panel **B** illustrates the pattern from four patients with relatively intact mechanisms of suppression of PTH secretion by calcium. Even in this group, the setpoint for calcium suppression is shifted to the right. (From Brown EM. Calcium-regulated parathyroid hormone release in primary hyperparathyroidism: studies in vitro with dispersed parathyroid cells. *Am J Med.* 1979;66:923-931.)

extraparathyroidal manifestations of inherited syndromes may need treatment, and awareness of familial clustering should prompt systematic family screening.

Multiple Endocrine Neoplasia Type 1. MEN1 (see also Chapter 41) is caused by inactivating mutations in the tumor suppressor gene encoding menin.²⁴⁹ Menin is a ubiquitously expressed transcription factor that is part of a complex that targets histone H₃ for methylation²⁵⁰ and thereby leads to expression of cell cycle inhibitors in pancreatic islets and other tissues.²⁵¹ Rarely, mutations in genes encoding cyclin-dependent kinase inhibitors such as p27 (CDKN1B) are found in MEN1 patients without menin mutations.²⁵² Although MEN1 includes tumors of the parathyroid, anterior pituitary, and pancreatic islets, the parathyroid tumors are far more prevalent than the others; 95% of affected patients eventually develop hyperparathyroidism. Most of the parathyroid tumors harbor mutations in both copies of the menin gene; one mutation is inherited, and the second occurs in the parathyroid cell whose progeny form the tumor.

The onset of hypercalcemia occurs in the second and third decades of life, although occasionally a patient presents in the first decade. Hypercalcemia never manifests at

birth or in infancy. The disease involves all four parathyroid glands, although the involvement can be asymmetric and apparently asynchronous. Apart from the earlier age at diagnosis, the presenting clinical picture resembles that of sporadic primary hyperparathyroidism, perhaps with somewhat greater loss of bone density.²⁵³ One common complicating feature of hypercalcemia is that it can dramatically increase the gastrin levels and symptomatology in those patients who also have gastrinomas. Treatment of the parathyroid disease in this setting can greatly simplify management of the gastric hyperacidity.

After parathyroid surgery, hypoparathyroidism and recurrent hyperparathyroidism are more common than in other forms of hyperparathyroidism.²⁵⁴ The timing and type of surgery are therefore more complicated issues than in sporadic primary hyperparathyroidism. Most authorities agree that parathyroid disease recurs eventually, particularly if fewer than three glands are removed. Some surgeons prefer subtotal parathyroidectomy, whereas others prefer total parathyroidectomy with forearm implantation of a small amount of parathyroid tissue.

Multiple Endocrine Neoplasia Type 2a. Parathyroid disease is usually a late and infrequent (5% to 20%) occurrence in patients with MEN type 2a (see also Chapter 41), a disease defined by the clustering of medullary carcinoma of the thyroid, pheochromocytoma, and hyperparathyroidism. In some families, hyperparathyroidism is more common; however, these families have the same mutations in the *RET* proto-oncogene that are found in families without frequent hyperparathyroidism. Both parathyroid hyperplasia and adenoma have been noted at surgery. Because asymptomatic parathyroid hyperplasia has been observed at the time of thyroid surgery, a progression from hyperplasia to adenoma in MEN2a has been suggested. The approach to diagnosis and treatment of hyperparathyroidism is similar to that for sporadic primary hyperparathyroidism, but hyperplasia is more frequently the underlying disorder. The pathogenesis of the hyperparathyroidism is uncertain, but the *RET* gene, which is mutated in almost all cases of MEN2a, is expressed in parathyroid cells,²⁵⁵ so abnormal *RET* expression in parathyroid cells may directly cause parathyroid tumor formation. Hyperparathyroidism does not occur in MEN2b, the variant associated with mucosal neuromas.

Hyperparathyroidism–Jaw Tumor Syndrome. Patients with hereditary hyperparathyroidism–jaw tumor syndrome²⁵⁶ present with parathyroid adenomas that can be multiple and are usually cystic. These tumors are often but not invariably associated with fibrous jaw tumors that are unrelated to the hyperparathyroidism. Importantly, the parathyroid tumors are frequently malignant, in contrast to the findings in MEN1 and MEN2a. Wilms' tumor and polycystic renal disease also have occurred in affected families. The gene mutated in this syndrome, *HRPT2* (now called *CDC73*), encodes the nuclear protein, parafibromin.²⁵⁷ Parafibromin is part of the evolutionarily highly conserved PAF complex, which binds RNA polymerase II, regulates chromatin structure, and regulates gene expression.²⁵⁸⁻²⁶⁰ Parafibromin binds β -catenin and can mediate Wnt pathway signaling and Notch signaling, although it is not known whether these properties of parafibromin are related to its tumor suppressor function.²⁶¹ Inactivating mutations in parafibromin are found in a high number of patients with apparently sporadic parathyroid cancer.²⁶² Because some of these patients have subsequently proved to be members of families with inherited *CDC73* mutations, perhaps all patients with parathyroid cancer should be screened for germline mutations in *CDC73*.

Management of Primary Hyperparathyroidism. The strategy for management of primary hyperparathyroidism has evolved in parallel with the changing presentation of the disease. The only opportunity for permanent cure is surgical removal of the abnormal gland or glands, an approach that clearly was appropriate for virtually all patients in whom the classic, severe form of the disease was diagnosed 4 to 5 decades ago and that still is the treatment of choice for those patients who do present with recurrent kidney stones, nephrocalcinosis, clinically overt bone disease, or severe hypercalcemia.

In contrast, the choice of surgical versus medical management for patients with asymptomatic primary hyperparathyroidism remains an open and hotly debated question. Those who favor surgery point to the expected improvement in bone mineral density (at the hip and spine) and left ventricular hypertrophy after successful surgical intervention; evidence of increased risk for fracture, cardiovascular mortality, malignancy, and neuropsychiatric symptoms associated with primary hyperparathyroidism; and the recent successful development of effective minimally invasive surgical procedures (discussed later). Those who favor an observational approach emphasize the evidence for lack of disease progression in most asymptomatic patients; the small but finite risk of surgical failure and postoperative complications; the probability that excess mortality and cancer risks documented in patients with relatively severe disease may not apply to those with mild, asymptomatic primary hyperparathyroidism; the difficulty in assigning vague neuropsychiatric symptoms to the parathyroid disorder; the lack of evidence (or negative evidence) that hypertension and increased risk of cancer, fracture, or cardiovascular mortality, even if present, are improved by successful parathyroidectomy; and the availability of sensitive techniques for monitoring disease status in patients who do not undergo surgery.²²⁵

No large prospective studies powered to compare clinical outcomes in patients with asymptomatic primary hyperparathyroidism randomly assigned to surgery versus medical management have been conducted. Nevertheless, three valuable smaller, randomized controlled trials of surgery versus observation have been conducted that allow some conclusions about surrogate markers of disease.²²⁰⁻²²² All three trials demonstrated increased bone density in the spine and hip in those treated surgically; the increases were similar to those produced with bisphosphonate therapy in patients with primary hyperparathyroidism (see later discussion). Two of the three studies showed modest improvements in some quality-of-life measures, although the unblinded nature of the studies limits interpretation of these findings. All of the findings reported so far have been after 2 years or less. As useful as these studies have been, their limitations have forced the field to tap observational studies to draw tentative recommendations based on limited data.

Such provisional recommendations have emanated from a series of conferences. A Consensus Conference sponsored by the National Institutes of Health (NIH) was held in 1990, followed by a more informal update in 2002 and, most recently, in 2008.²⁶³ The major conclusion of that group was that, although surgery is indicated for symptomatic hyperparathyroidism and always should be considered an appropriate option in patients with asymptomatic hyperparathyroidism, many patients with asymptomatic disease can be safely monitored without surgery. Those suitable for medical observation should have no evidence of significant compromise of skeletal integrity or renal function and no history of urolithiasis or gastrointestinal

TABLE 28-1

Indications for Surgery in Primary Hyperparathyroidism

Overt clinical manifestations of disease
Kidney stones or nephrocalcinosis
Fractures or classic radiographic findings of osteitis fibrosa
Classic neuromuscular disease
Symptomatic or life-threatening hypercalcemia
Serum calcium >1 mg/dL above the upper limit of normal
Creatinine clearance <60 mL/min
Bone mineral density low (T score ≤−2.5) at any site*
History of fragility fracture
Young age (<50 yr)
Uncertain prospects for adequate medical monitoring

*Z score ≤−2.5 in premenopausal women and in men <50 years old.

Modified from Bilezikian JP, Khan AA, Potts JT Jr: Third International Workshop on the Management of Asymptomatic Primary Hyperparathyroidism. Guidelines for the management of asymptomatic primary hyperparathyroidism: summary statement from the Third International Workshop. *J Clin Endocrinol Metab.* 2009;94:335-339. Based on recommendations of the 2008 National Institutes of Health-sponsored "Workshop on the Management of Asymptomatic Primary Hyperparathyroidism.")

or neuropsychiatric symptoms, and they should meet the criteria listed in Table 28-1. Such patients comprise at least 50% of those who currently present with primary hyperparathyroidism.

On the other hand, the conferences concluded, surgery may be preferable if the patient desires surgery even when asymptomatic, if the probability of consistent monitoring seems low, if concomitant illness seems likely to complicate management or obscure significant disease progression, or if the patient is relatively young (less than 50 years of age). The last recommendation reflects the absence of reliable information about the natural history of the disease over many decades of follow-up; the cumulative cost of medical monitoring, which begins to exceed that of surgery by 5 to 10 years; and some data suggesting that young people are more likely than others to have progressive disease.²⁶⁴ However, age alone is not viewed as a contraindication to parathyroidectomy, because the procedure has been accomplished with excellent results, with a perioperative mortality rate of 1% to 3%, in large numbers of appropriately selected patients older than 75 years of age. Because hypertension is not thought to be a feature of mild primary hyperparathyroidism, and because hypertension generally is not improved by parathyroidectomy, hypertension is not viewed as an indication for surgery.

Although the Consensus Conference recommendations and subsequent modifications provide a useful framework for decision-making, supporting data from large clinical trials are lacking. In a series of 52 asymptomatic patients who were selected for nonoperative management mainly on the basis of the 1990 Consensus Conference criteria and whose course was followed for 10 years, approximately 25% developed one or more new indications for surgery.²¹⁸ Patients who do not meet the Consensus Conference criteria for surgery may nevertheless experience the same postsurgical increase in bone density as those who do.²⁶⁵ Some have emphasized that evidence of baseline vertebral osteopenia, an unusual finding in primary hyperparathyroidism, should be considered among the criteria for surgery²³² and that surgery also should be considered for postmenopausal women who exhibit vertebral bone loss in the setting of primary hyperparathyroidism.^{218,225}

A common dilemma is the inability to ascertain whether vague but troublesome symptoms such as fatigue, lethargy,

weakness (without objective muscle weakness), or depression are caused by the hyperparathyroidism and therefore qualify as “significant” in the context of considering the decision for surgery. Most clinicians do not routinely recommend parathyroidectomy on the basis of such symptoms alone, although dramatic responses to surgery are occasionally seen. With the availability of improved, minimally invasive surgical approaches, the threshold for considering surgery in patients who are significantly disabled by such symptoms clearly is lower now than in the past. Some have advocated, in selected cases, a limited trial of medical therapy (i.e., calcimimetics) to reduce serum calcium levels (see later discussion) and thereby attempt to predict the symptomatic response to surgical cure.

Medical Monitoring of Primary Hyperparathyroidism. The updated NIH Consensus Conference recommendations suggest that patients not treated surgically should be monitored carefully, with annual measurement of serum calcium and calculation of Cl_{Cr} and serial determinations of bone mineral density at 1- to 2-year intervals. The most appropriate bone densitometric site is considered to be one that reflects mainly changes in cortical bone (e.g., distal forearm), although the importance of monitoring vertebral bone density as well has been emphasized,²¹⁸ and current criteria acknowledge the importance of significant bone loss at any site.²⁶³

Patients undergoing nonoperative medical management must be cautioned to maintain adequate hydration, to avoid diuretics and prolonged immobilization, and to seek prompt medical attention in the event of illnesses accompanied by significant vomiting or diarrhea. Dietary calcium should not be restricted.

The goal of an effective pharmacologic therapy for primary hyperparathyroidism remains elusive, although study of sex hormones and selective estrogen receptor modulators, bisphosphonates, and calcimimetics continue. Estrogens and progestins may reduce serum calcium and phosphorus, urinary calcium and hydroxyproline, and histologic evidence of active bone resorption in women with primary hyperparathyroidism, although safety concerns have limited these therapeutic options in postmenopausal women. Limited data with raloxifene suggest that this drug may be useful in controlling serum calcium and lowering bone turnover in women with primary hyperparathyroidism.²⁶⁶

Intravenous bisphosphonates have been employed successfully in the urgent treatment of hypercalcemia caused by primary hyperparathyroidism, and several trials have shown that treatment with oral alendronate for 1 year or longer improves bone density at the spine and hip, with only transient effects on serum calcium and PTH.^{267,268} The calcimimetics represent a new class of agents that, by sensitizing the CASR to extracellular calcium, can reduce PTH secretion. Cinacalcet, the first calcimimetic approved for control of secondary hyperparathyroidism in renal disease, was shown to lower serum calcium and PTH in patients with primary hyperparathyroidism (and in some patients with parathyroid carcinoma), although improvement in bone density has not been documented in this population.²⁶⁹ Therefore, in patients for whom surgery for asymptomatic primary hyperparathyroidism is not an option, therapy with oral bisphosphonates can improve bone density without worsening other features of the disease, at least over 2 years of follow-up. Whether this or any other medical therapy offers a beneficial long-term alternative to surgery is unknown.

Surgical Treatment of Primary Hyperparathyroidism. Parathyroidectomy is a safe and highly effective approach

for definitive treatment of primary hyperparathyroidism. The most serious potential complications of parathyroid surgery are vocal cord paralysis and permanent hypoparathyroidism, which occur after fewer than 1% and 4%, respectively, of procedures performed by highly skilled surgeons, although these rates can be much higher in less experienced hands. Such complications occur most often in patients who require subtotal parathyroid resections for hyperplasia or resection of carcinoma. The surgical cure rate for primary hyperparathyroidism in the best hands is at least 95%.^{270,271}

Apart from operator inexperience, the usual cause of initial surgical failure (“persistent disease”) is the presence of either unrecognized (often very asymmetric) parathyroid hyperplasia or ectopic parathyroid tissue (i.e., intrathyroidal, undescended, retroesophageal, or mediastinal glands) (Fig. 28-25).²⁷² Up to one in five parathyroid glands may be located ectopically, and this is especially true of supernumerary glands. Recurrent disease, defined as that occurring after an interval of at least 6 to 12 months of normocalcemia, varies in incidence from 2% to 16%. Recurrent hyperparathyroidism usually arises in unresected hyperplastic glands, but rarely it may be caused by parathyroid carcinoma, a second adenoma, or a multicentric or miliary “parathyromatosis” engendered by inadvertent local seeding of parathyroid tissue (usually hyperplastic) into the neck during previous parathyroid surgery.^{210,273}

In the past, there was broad agreement that the best approach is a bilateral neck exploration in which all four parathyroids are identified and all enlarged glands are removed. With this procedure, preoperative parathyroid localization studies before initial cervical exploration are superfluous, because the positive predictive value of even the best current technique (i.e., technetium 99m [^{99m}Tc]-sestamibi scanning) falls well short of the success rate of experienced surgeons unaided by prior imaging.^{210,274}

Figure 28-25 Sites of ectopic location of 104 parathyroid glands found at reoperation for primary hyperparathyroidism. (From Wang C-A. A clinical and pathological study of 112 cases. *Ann Surg.* 1977;186:140-145.)

Preoperative ^{99m}Tc -sestamibi scanning, however, can accurately localize 80% to 90% of the single adenomas that account for 75% to 85% of cases, and since it became available there has been renewed interest in the performance of directed unilateral explorations, which reduce operative and recovery room time, minimize the number of frozen sections required, are associated with significantly fewer postoperative complications, and can more readily be performed using minimally invasive techniques (including local anesthesia and intravenous sedation), enabling same-day discharge.²⁷⁵ Sestamibi scanning also can identify the occasional mediastinal adenoma, allowing the surgeon to avoid an unnecessary neck exploration. On the other hand, the sensitivity and positive predictive value of sestamibi scanning is poor (<50%) in the presence of multiglandular disease (hyperplasia or double adenomas), so the test may frequently miss the presence of bilateral disease.²⁷¹ To reduce this failure rate, which is unacceptably high in comparison to bilateral exploration, supplemental preoperative ultrasonic imaging (with or without needle biopsy) is often employed, and rapid intraoperative PTH assays have been developed to verify successful excision.²⁷⁶ Because the half-life of intact PTH in blood is very short (<2 min), a decline of 50% or more from baseline within approximately 10 minutes can signal successful removal of all hyperfunctioning parathyroid tissue. This approach has functioned well in patients with single adenomas but can be misleading in those with multiglandular disease unless more stringent criteria for cure are applied (i.e., >90% decline, or even normalization, of iPTH).²⁷⁷

At present, preoperative imaging enables consideration of a minimally invasive unilateral parathyroidectomy in approximately 70% of those patients thought preoperatively to have sporadic primary hyperparathyroidism due to a solitary adenoma. Surgical cure rates in appropriately selected patients are comparable to those achieved after bilateral neck exploration (i.e., 95% to 97%).²⁷¹ although a recent study in which all patients selected for minimally invasive surgery were also subjected to immediate bilateral neck dissection demonstrated a failure to recognize multiglandular disease in 16% of the subjects.²⁷⁸ Patients with known or suspected multiglandular disease, such as those with MEN1 and those younger than 30 years of age, should undergo bilateral neck exploration.²⁷⁹ Options for patients with hyperplasia include resection limited to visibly abnormal glands, subtotal parathyroidectomy with cryopreservation of tissue, and total parathyroidectomy with immediate autotransplantation (i.e., in the forearm) of some excised tissue. In patients with MEN1, considerations of the rate (30% to 50% or higher with long-term follow-up) and the timing of recurrences versus the potential morbidity of surgical hypoparathyroidism tend to favor subtotal parathyroidectomy as the preferred approach at present.

The incidence of parathyroid carcinoma in primary hyperparathyroidism is less than 1%,²¹³ but this possibility should be strongly considered in patients with unusually severe hyperparathyroidism, a palpable neck mass, hoarseness, evidence of local invasion at surgery, or recurrent hypercalcemia.²⁸⁰ Even so, parathyroid carcinoma rarely is suspected preoperatively and often eludes diagnosis at the time of initial surgery. When the disease is recognized, vigorous attempts should be made to remove the tumor en bloc. The incidence of local recurrence approaches 50%, however, and distant metastases, particularly to lung, may be heralded by recurrent, severe hyperparathyroidism.²⁸¹ Because apparently sporadic and isolated parathyroid cancer can occur in families with parafibromin mutations,

a search for such mutations in all patients with parathyroid cancer can facilitate family counseling.²⁶²

The immediate postoperative management of parathyroidectomy focuses on establishing the success of the surgery and monitoring the patient closely for symptomatic hypocalcemia and for uncommon but potentially serious acute complications such as bleeding, vocal cord paralysis, and laryngospasm. After successful resection of a parathyroid adenoma, serum levels of intact PTH decline rapidly, often to undetectable concentrations, with a disappearance half-time of about 2 minutes. Serum calcium typically reaches a nadir between 24 and 36 hours after surgery. Serum PTH returns to the normal range within 30 hours, although measurements of the parathyroid secretory response to hypocalcemia suggest that it does not fully normalize for at least several weeks.²⁸²

In the past, patients usually were maintained on a low-calcium diet until normalization of serum calcium was clearly documented. Ampoules of injectable calcium and other seizure precautions were maintained at the bedside, serum calcium was measured at least every 12 hours until stable, and symptomatic hypocalcemia was promptly treated with calcium, either intravenously (90-mg bolus, then 50 to 100 mg/hour) or orally (1.5 to 3.0 g/day). This approach is no longer appropriate for most patients, who are discharged within a few hours after limited surgery. Instead, oral calcium supplements routinely are provided as soon as oral intake is reestablished. Moderate doses of calcitriol (0.5 to 1.0 μg daily) are added for those with large adenomas and severe hyperparathyroidism and for those in whom alkaline phosphatase had been elevated preoperatively—that is, patients in whom an impressive calcium requirement can be anticipated, often for many weeks postoperatively, as they remineralize their skeletons. This so-called hungry bone syndrome is associated with hypocalcemia, hypophosphatemia, and low urinary calcium excretion.

Serum calcium should be checked at intervals of several days initially to guide adjustment of calcium and vitamin D therapy as needed to achieve a stable result. In those in whom hypocalcemia persists for more than several days, serum PTH should be measured to exclude the possibility of postoperative hypoparathyroidism. Given evidence that bone mineral density continues to increase for at least 1 year after successful parathyroidectomy,²¹⁸ it is prudent to continue calcium supplementation for at least that long.

The approach to patients with persistent or recurrent hyperparathyroidism is informed by the recognition that parathyroid hyperplasia or carcinoma, ectopic or supernumerary parathyroid tissue, and postoperative hypoparathyroidism and other complications of further surgery all are more common in this population.^{272,274} The first issue to address is whether surgery is indicated. If a presumed adenoma was not identified initially, the original indications for surgery usually still exist, although some patients may not be suitable candidates for more extensive surgery (e.g., median sternotomy) because of concurrent medical illness. Patients with parathyroid hyperplasia may have experienced significant clinical improvement, even after incomplete parathyroidectomy, although those with MEN1 are very likely to experience further progression of their disease.

Preoperative localization studies are recommended for patients with persistent or recurrent disease after a first operation. Scanning with ^{99m}Tc -sestamibi offers the highest sensitivity and accuracy, although other studies (ultrasonography, computed tomography [CT], magnetic resonance imaging) may provide additional or confirmatory

Figure 28-26 Technetium 99m (^{99m}Tc) sestamibi, iodine 123 (^{123}I) subtraction scanning of a patient with persistent hyperparathyroidism after two previous unsuccessful operations. The arrow points to parathyroid adenoma, shown as increased tracer uptake in the aortopulmonary window. (From Thule P, Thakore K, Vansant J, et al. Preoperative localization of parathyroid tissue with technetium-99m sestamibi 123I subtraction scanning. *J Clin Endocrinol Metab.* 1994;78:77-82.)

information.²⁸³ Sestamibi does localize to thyroid nodules, which may accompany parathyroid disease in 20% to 40% of patients, although it tends to wash out from thyroid tissue much more rapidly than from parathyroids. ^{99m}Tc -sestamibi can be combined with iodine 123 (^{123}I) scanning to improve distinction of parathyroids from thyroid nodules or with single-photon emission computed tomographic (SPECT) imaging to achieve accuracy in localization not possible with planar imaging (Fig. 28-26). On the other hand, sestamibi scanning may fail to reveal small glands (uptake is related to gland size and PTH levels²⁸⁴) or to demonstrate multiple abnormal glands in cases of parathyroid hyperplasia, the most common cause of persistent postoperative hyperparathyroidism.^{271,285} Recently, the use of so-called four-dimensional CT with synchronous contrast-enhanced multiplanar anatomic reconstruction was shown in one study to provide sensitivity superior to sestamibi scanning alone for localizing functioning parathyroid tissue in candidates for reoperation.²⁸⁶

More invasive techniques have been used, including angiography and selective venous sampling for measurement of PTH.^{287,288} Ultrasound- or CT-guided fine-needle aspiration of suspected parathyroid tissue may be used to obtain cytologic or immunochemical confirmation before surgery, and intraoperative ultrasonography has been useful in some cases to locate cervical or intrathyroidal glands.²⁷⁴ Video-assisted thoracoscopic resection of documented mediastinal lesions has been successful^{262,289} and offers a less invasive alternative to median sternotomy for this relatively common cause of persistent hyperparathyroidism.

The need for these procedures depends on the experience of the original surgeon and the confidence that the neck was adequately explored initially. For example, among reoperations at one center, more than half of the “missed” hyperplastic parathyroid glands in cases previously explored by a highly experienced parathyroid surgeon were found in the mediastinum or another ectopic location, whereas more than 90% of cases referred by less experienced surgeons were discovered in a normal anatomic location in the neck.²¹⁰

After successful surgery for primary hyperparathyroidism, bone mass typically improves by as much as 5% to 10% during the first year at sites rich in trabecular bone (spine, femoral neck), whereas improvement at cortical sites (distal radius) is less predictable.^{218,290} Increases at trabecular sites may continue for several years, to as much as 12% to 15% after 10 years, although normal bone mineral density may not be achieved. This improvement, which is most apparent in those with the greatest preoperative reductions in bone mass, may be related in part to rapid remineralization of the previously enlarged bone remodeling volume,²⁶⁵ but the continued improvement over years suggests a more sustained increase in net bone formation and total bone volume as well.²¹⁸

Familial Hypocalciuric Hypercalcemia

FHH, also appropriately called *familial benign hypercalcemia*, is, in most families, a disorder of autosomal dominant inheritance caused by mutations of the CASR gene found in parathyroid glands, kidney, and other organs (see earlier discussion of calcium sensing). The mutations, which cause complete or partial loss of function of the CASR, lead to a shift in the parathyroid cell's setpoint for calcium.²⁹¹ As a consequence, higher than normal levels of blood calcium are needed to suppress PTH secretion. Furthermore, abnormal function of the CASR in the renal thick ascending limb leads to increased PTH-independent calcium reabsorption and consequent hypocalciuria.

The presence of one normal sensing receptor gene with the abnormal one usually leads to a very mild clinical disorder, although the receptor functions as a dimer, and certain mutations can worsen the function of the normal allele. Rare patients who inherit mutant CASR genes from both parents present at birth with severe, life-threatening, primary hyperparathyroidism and almost always require immediate parathyroid surgery. In another genetic variation, a familial form of CASR-dependent hypercalcemia has been described in association with other autoimmune disorders such as Hashimoto's hypothyroidism and celiac sprue, in which autoantibodies directed against the sensor apparently antagonize calcium recognition by the parathyroids and renal tubules.^{292,293}

FHH is manifested at birth by hypercalcemia. Although some controversy exists, most observers have concluded that the condition is asymptomatic and that apparent symptoms represent ascertainment bias. Possible exceptions include the occurrence of chondrocalcinosis and perhaps pancreatitis. The blood calcium level is usually less than 12 mg/dL but can be higher. Phosphate measurements are low, as in primary hyperparathyroidism. Blood magnesium levels are high-normal or slightly elevated. PTH levels are inappropriately normal for the degree of hypercalcemia and are occasionally modestly elevated. Urine calcium is usually low, although one novel mutation in the receptor's intracellular tail has been associated with hypercalciuria, possibly because of only mild dysfunction in the kidney.²⁹⁴

When patients present as adults, the distinction between FHH and mild primary hyperparathyroidism can be

Figure 28-27 Index of urinary excretion rate for calcium as a function of creatinine clearance. Each point represents the mean of multiple determinations for a hypercalcemic patient with either familial hypocalciuric hypercalcemia (filled circles) or typical primary hyperparathyroidism (open circles). The data are based on average 24-hour urinary excretion values and average fasting serum samples. (From Marx SJ, Attie MF, Levine M, et al. The hypocalciuric or benign variant of familial hypercalcemia: clinical and biochemical features in fifteen kindreds. *Medicine [Baltimore]*. 1981;60:397-412.)

difficult. However, this distinction is crucial. Young patients with primary hyperparathyroidism are usually treated surgically and cured. In contrast, hypercalcemia always recurs after surgery for FHH, unless the patient is rendered hypoparathyroid by the removal of all parathyroid tissue. Therefore, surgery is contraindicated as therapy for FHH, except in the very rare patient with severe, symptomatic hypercalcemia. No blood or urine measurements are completely reliable for distinguishing between the two conditions, although the ratio of calcium clearance (Cl_{Ca}) to Cl_{Cr} differentiates most patients with FHH from those with primary hyperparathyroidism.²⁹⁵ However, although this ratio separates the two groups with modest overlap (Fig. 28-27), primary hyperparathyroidism is much more common than FHH, so most patients with values near the cutoff Cl_{Ca}/Cl_{Cr} ratio of 0.01 have primary hyperparathyroidism and not FHH. Consequently, a case can be made²⁹⁶ that many such patients, particularly before parathyroid surgery, should undergo sequencing of their CASR gene, a procedure that is now available commercially. The most helpful diagnostic information is the presence of hypercalcemia in an infant relative; such early hypercalcemia does not occur in MEN1. Furthermore, a past history of clearly normal blood calcium concentrations, considerably lower than current measurements, makes FHH unlikely in the absence of another reason for a change in blood calcium levels.

Lithium Toxicity

Treatment of bipolar affective disorders with lithium commonly leads to mild, persistent increases in blood calcium,²⁹⁷ occasionally out of the normal range, in affected persons. After several years of therapy, clear elevations of PTH levels and modest increases in parathyroid gland size, detected

by ultrasonography, often occur. Usually, after lithium therapy is stopped, the blood calcium and PTH levels normalize within several months. Uncommonly, substantial hypercalcemia and clear hyperparathyroidism ensue. At surgery, both single-gland and multigland disease are found, with a higher fraction of multigland disease than in patients who have primary hyperparathyroidism not associated with lithium therapy.²⁹⁸

The management of mild, lithium-induced hypercalcemia is somewhat complicated. Like patients with mild primary hyperparathyroidism, patients taking lithium usually tolerate mild hypercalcemia without obvious symptoms. They can be monitored with protocols similar to those for patients with asymptomatic primary hyperparathyroidism. Close attention must be paid to urine-concentrating ability in these patients, however, because the nephrogenic diabetes insipidus associated with lithium therapy can lead to dehydration and sudden worsening of hypercalcemia. Substantial hypercalcemia should lead to withdrawal of lithium therapy, if possible, with substitution of newer psychopharmacologic agents. If hypercalcemia persists after withdrawal of lithium, decisions about surgery should follow the same guidelines as for those patients with primary hyperparathyroidism.

Lithium increases the setpoint for PTH secretion when it is added to isolated parathyroid cells in vitro, and the setpoint for PTH secretion in vivo is shifted to the right in patients who have received lithium for several years. A corresponding shift in the concentration of extracellular calcium needed to raise intracellular calcium levels²⁹⁹ suggests that lithium interferes with the action of the parathyroid CASR.

Parathyroid-Independent Hypercalcemia

In parathyroid-independent hypercalcemia, PTH secretion is appropriately suppressed. PTH levels, measured with the use of two-site assays, are invariably lower than 25 pg/mL and are usually lower than normal or undetectable. Most affected patients have malignant hypercalcemia, although parathyroid-independent hypercalcemia occurs in a number of other settings as well.³⁰⁰

Hypercalcemia of Malignancy

The presentation of malignant hypercalcemia is seldom a subtle one.¹⁰¹ Most malignancies produce hypercalcemia only when they are far advanced; the diagnosis becomes evident after routine studies, guided by the history and physical examination. Patients with malignant hypercalcemia usually die within 1 or 2 months after hypercalcemia is discovered. Patients present with the classic signs and symptoms of hypercalcemia: confusion, polydipsia, polyuria, constipation, nausea, and vomiting. Perhaps because of the acuteness of the hypercalcemia and the elderly patient population involved, dramatic changes in mental status, culminating in coma, are relatively common. The diagnosis can be missed because the manifestations often overlap those of the underlying malignancy and because low blood albumin may lead to an apparently normal total blood calcium value despite an elevated blood ionized calcium concentration. Even though the overall prognosis is grim, the diagnosis of malignant hypercalcemia is important to make.

Treatment is usually simple and effective in the short term; such treatment can importantly reverse the patient's symptoms for several weeks and can even provide time for a fundamental attack on the underlying tumor, if it is treatable. Only effective treatment of the underlying neoplasm

can significantly influence the long-term prognosis for patients with malignant hypercalcemia.

Although mechanisms in a given patient may be multiple, it is still useful to distinguish hypercalcemia associated with local involvement of bone from that caused by humoral mechanisms. In all cases, resorption of bone plays a pivotal role in the pathogenesis.

Local Osteolytic Hypercalcemia. Hypercalcemia resulting from tumors invading bone occurs most clearly in multiple myeloma and in some cases of breast cancer. There is little evidence that the tumor cells themselves resorb bone. Instead, active osteoclasts found near the tumor cells are thought to be the proximate mediators of bone resorption.³⁰¹ Myeloma cells and marrow cells associated with myeloma cells secrete numerous cytokines and chemokines that are capable of stimulating bone resorption, including MIP1, lymphotoxin (TNF- β), and interleukins 1 β , 3, and 6. These factors lead to increased expression of RANKL (see Fig. 28-9) on the surface of marrow stromal cells and to stimulation of osteoclast formation and activity. RANKL is also found on the surface of myeloma cells, so these cells may directly stimulate the production and activity of osteoclasts. The increased bone resorption not only releases calcium into the circulation but also weakens the bone structurally. Bone is further weakened by the suppression of bone formation resulting from secretion of dickkopf-1, an inhibitor of Wnt signaling, by myeloma cells.^{302,303} In patients with myeloma, treatment with intermittent intravenous bisphosphonates inhibits bone resorption and reduces the incidence of bone pain, fracture, and hypercalcemia.

The pathogenesis of hypercalcemia in breast cancer is not completely understood. Extensive metastases to bone are detected in most patients with hypercalcemia and breast cancer; this finding suggests that factors produced in bone by the metastatic tumor cells may be important. Breast cancer cells make a host of cytokines that are capable of resorbing bone. The role of tumor-produced PTHrP may be particularly important.³⁰³ A majority of breast cancer patients with hypercalcemia have elevated blood levels of PTHrP. This circulating PTHrP, as well as PTHrP produced in bone by metastatic tumor cells, may generate the hypercalcemia. Primary breast tumors that stain for PTHrP are more likely to result in bone metastases than are those that do not stain for PTHrP; this PTHrP may be instrumental in the establishment of lytic metastases. Animal models indicate that transforming growth factor- β , released from bone matrix by PTHrP-stimulated osteoclastic resorption, may augment PTHrP secretion by the tumor cells. The latter may be further promoted by estrogen, which may explain the occasional occurrence of hypercalcemia after institution of estrogen or tamoxifen therapy in this disease.³⁰⁴

Humoral Hypercalcemia of Malignancy. Albright, in 1941, was the first to propose that a PTH-like humoral factor caused the hypercalcemia observed in patients with malignancy but few or no bone metastases.³⁰⁵ Four decades later, biochemical analysis demonstrated that such patients have high blood calcium levels, low blood phosphate levels, and high urinary cAMP levels, similar to those found in primary hyperparathyroidism, but no elevation in iPTH levels.³⁰⁶ The stimulation of cAMP production was used as an assay to eventually purify PTHrP from human tumors associated with the humoral hypercalcemia of malignancy.³⁰⁷

The evidence that PTHrP mediates the humoral hypercalcemia of malignancy in most patients is substantial. As

noted previously, PTHrP binds to the PTH/PTHrP receptor and mimics all of the actions of amino-terminal fragments of PTH. Blood levels of PTHrP are elevated in most patients with solid tumors and hypercalcemia. In animal models of the humoral hypercalcemia of malignancy, antibodies against PTHrP can reverse the hypercalcemia.³⁰⁸

The acute actions of PTHrP cannot explain all of the findings in patients with the hypercalcemia of malignancy, however. Acutely administered PTHrP increases blood levels of calcitriol by stimulating the renal 1 α -hydroxylase, although the stimulation is less than that induced by PTH.³⁰⁹ Nevertheless, patients with the humoral hypercalcemia of malignancy usually have low levels of calcitriol.³⁰⁶ This finding is particularly puzzling, because human tumors associated with low calcitriol levels stimulate calcitriol synthesis after they are transplanted into nude mice.³¹⁰ Possible explanations for the low calcitriol levels observed in patients include the weak activation of the renal 1 α -hydroxylase in humans by PTHrP, combined with inhibition of the 1 α -hydroxylase by hypercalcemia³¹¹ or by tumor products.

A second disparity between the acute actions of PTHrP and the findings in patients with malignant hypercalcemia involves the rate of bone formation. Acutely, PTHrP infused in rats, like PTH, leads to increased bone formation.³¹² However, in patients with malignant hypercalcemia, bone formation is markedly lower than normal. The explanation for this effect may well lie in the action of other cytokines, immobilization, or particular fragments of PTHrP with novel properties.

The tumors most commonly associated with humoral hypercalcemia include squamous cell cancers of the lung, head and neck, esophagus, cervix, vulva, and skin; breast cancer; renal cell cancer; and bladder cancer. Benign or malignant pheochromocytomas, islet cell tumors, and carcinoids can also overproduce PTHrP, causing hypercalcemia. The aggressive T-cell lymphoma associated with human T-cell lymphotropic virus 1 (HTLV-1) infection is the only hematologic malignancy commonly associated with PTHrP overproduction and hypercalcemia.

It is unlikely that PTHrP is the sole cause of the humoral hypercalcemia of malignancy. As noted previously, many cytokines produced by tumors can stimulate bone resorption. The actions of these cytokines have been shown to synergize with those of PTHrP in a number of experimental models. Furthermore, in hypercalcemic patients with non-Hodgkin's lymphoma, blood levels of calcitriol were found to be higher than otherwise expected,³¹³ and such patients show abnormal sensitivity to 25(OH)D administration.³¹⁴ In these hypercalcemic patients, the relative importance of calcitriol cytokines, PTHrP, and immobilization needs to be clarified.

In a few reported cases, malignant tumors secrete PTH and not PTHrP.¹⁰¹ Although this phenomenon has now been well documented, it should be stressed that in almost all patients with cancer and high PTH levels, concurrent primary hyperparathyroidism, not ectopic PTH production, is the cause of the hyperparathyroidism.

Vitamin D Intoxication

Because the synthesis of calcitriol is so tightly regulated, extremely large doses of vitamin D, on the order of 100,000 units per day, are required to cause hypercalcemia. Such doses are available in the United States only by prescription; therefore, most cases of vitamin D intoxication are iatrogenic. Occasionally, inadvertent ingestion occurs. Patients present with nausea, vomiting, weakness, and altered level of consciousness. Hypercalcemia can be severe

and prolonged because of the storage of vitamin D in fat. As expected, PTH levels are suppressed, and levels of 25(OH)D, which are poorly regulated and reflect levels of ingested vitamin D, are dramatically elevated. In contrast, the levels of calcitriol are only modestly elevated, and they can be normal or even low. The modest changes in calcitriol levels result from downregulation of the renal 1 α -hydroxylase by low levels of PTH and high levels of phosphate, calcium, FGF23, and calcitriol itself. The cause of the hypercalcemia, when it occurs in the face of normal levels of calcitriol, is uncertain but may reflect the direct action of 25(OH)D and possibly other vitamin D metabolites that are capable of binding the calcitriol receptor weakly or that may be locally 1 α -hydroxylated by nonrenal 1 α -hydroxylases. Also, the weaker vitamin D metabolites may displace calcitriol from the circulating VDBP and increase the concentration of active, free calcitriol.^{143,315}

The hypercalcemia of vitamin D intoxication results from both increased intestinal absorption of calcium and the direct effect of calcitriol to increase resorption of bone. Therefore, in severe cases, bisphosphonate therapy can be usefully added to the therapeutic regimen of hydration and omission of dietary calcium.

Sarcoidosis and Other Granulomatous Diseases

Sarcoidosis may be associated with hypercalcemia and, even more commonly, with hypercalciuria.³¹⁶ Hypercalcemic patients have high levels of calcitriol; this probably causes the hypercalcemia, although overproduction of bone-resorbing cytokines and PTHrP may contribute in some patients. As expected in calcitriol-dependent hypercalcemia, intestinal absorption of calcium is increased and PTH levels are suppressed. The hypercalcemia and the high levels of calcitriol fall after treatment with glucocorticoids. The unregulated synthesis of calcitriol, found even in anephric patients, occurs not in the kidney but rather in the sarcoid granulomas. Removal of a large amount of granulomatous tissue can reverse hypercalcemia. Furthermore, isolated sarcoid macrophages can synthesize calcitriol from 25(OH)D, as can normal macrophages after stimulation with interferon- γ or after activation of toll-like receptors. Such macrophages express the gene encoding the identical 25(OH)D 1 α -hydroxylase found in the kidney. Local synthesis of calcitriol by activated macrophages and activation of VDRs in those cells represents a paracrine system that activates antibacterial mechanisms as part of the normal action of macrophages.¹³⁸

The unusual increase in the numbers of activated macrophages in sarcoidosis leads to elevations of blood calcium. These patients have unusual sensitivity to vitamin D and can become hypercalcemic in response to ultraviolet radiation or oral vitamin D intake. Abnormalities in calcium metabolism are usually found only in patients with active disease and large, clinically obvious total-body burdens of granulomas. Nevertheless, hypercalcemia can manifest in patients without obvious pulmonary disease. Furthermore, subtle abnormalities of vitamin D metabolism can be demonstrated even in patients with only mildly active sarcoidosis.

Hypercalcemia is also associated with other granulomatous diseases, such as tuberculosis, fungal infections, and berylliosis, and has been reported in Wegener's granulomatosis, in acquired immunodeficiency syndrome (AIDS)-related *Pneumocystis jiroveci* (*Pneumocystis carinii*) infection, in fat necrosis of the newborn,³¹⁷ and even in association with extensive granulomatous foreign-body reactions.³⁰⁰ Patients with Crohn's disease occasionally have hypercalcemia with elevations of calcitriol, but often they have

elevated calcitriol levels with normal calcium levels and low bone mass, associated with increased production of calcitriol in intestinal macrophages.³¹⁸

Hyperthyroidism

Mild hypercalcemia can result from thyrotoxicosis.³¹⁹ Blood calcium levels seldom exceed 11 mg/dL, but mild elevations are found in a quarter of patients. Patients have low PTH levels, low calcitriol levels, and hypercalciuria. The hypercalcemia is caused by a direct action of thyroid hormone to stimulate bone resorption.³²⁰ β -Adrenergic blocking agents can reverse the hypercalcemia.³²¹

Vitamin A Intoxication

Excess ingestion of vitamin A (retinol) results in a syndrome of dry skin, pruritus, headache from pseudotumor cerebri, bone pain, and, occasionally, hypercalcemia. Hypercalcemia occurs only with the ingestion of 10 times the Recommended Dietary Allowance (RDA) of 5000 IU/day. The identical syndrome can result from ingestion of the vitamin A derivatives isotretinoin (13-*cis*-retinoic acid [Accutane]) and tretinoin (all-*trans*-retinoic acid [Retin-A]), which are used to treat acne and acute promyelocytic leukemia.^{322,323} Bones can show characteristic periosteal calcification on radiographs. The hypercalcemia is probably caused by the action of retinoids to stimulate bone resorption. The diagnosis is made by association of a history of excess ingestion of retinoids with the characteristic syndrome and abnormal results of liver function tests; elevated vitamin A levels confirm the diagnosis. Treatment involves hydration and, if necessary, glucocorticoids or bisphosphonates.

Adrenal Insufficiency

Hypercalcemia occurs in the setting of adrenal insufficiency. Blood calcium is elevated partly as a result of hemoconcentration and increased albumin levels, but the level of ionized calcium can also be increased.³²⁴ PTH and calcitriol levels are low to low-normal.³²⁵ The hypercalcemia in this study resulted from a combination of influx of calcium into the vascular space, probably from bone, and low renal clearance.

Thiazide Diuretics

Thiazide diuretics do not cause hypercalcemia by themselves, but they can exacerbate the hypercalcemia of primary hyperparathyroidism or any other cause of increased input of calcium into the bloodstream that is not suppressed by hypercalcemia. The mechanism of the hypercalcemia may involve the action of thiazide diuretics to increase proximal tubular calcium reabsorption as a secondary consequence of direct action of thiazides on the distal tubule.³²⁶ Decreased renal clearance of calcium alone would be expected to raise blood calcium in the normal human only transiently because the transient hypercalcemia should suppress PTH secretion and lead to return of the blood calcium to normal. However, in the presence of primary hyperparathyroidism, sarcoidosis, excess calcium intake, or any other cause of high, fixed calcium load, thiazide administration will increase the level of calcium in blood.

As predicted by this model, thiazide administration leads to chronic hypercalcemia in patients with abnormal parathyroid physiology but not in normal individuals.³²⁷ In primary hyperparathyroidism, thiazide administration exacerbates the hypercalcemia; in hypoparathyroidism, thiazide administration facilitates the maintenance of normocalcemia when given in conjunction with calcitriol and calcium.

Milk-Alkali Syndrome

The triad of hypercalcemia, metabolic alkalosis, and renal failure can be the consequence of massive ingestion of calcium and absorbable alkali. This syndrome was first described when milk and sodium bicarbonate were used in large amounts to treat peptic ulcer disease. With the change in ulcer treatment to nonabsorbable antacids and suppression of acid secretion, milk-alkali syndrome became rare. In the last several years, however, the increased use of calcium carbonate to treat dyspepsia and osteoporosis has led to the reappearance of milk-alkali syndrome.³²⁸ In most cases, a history of ingestion of several grams per day of calcium in the form of calcium carbonate can be elicited. The pathogenesis of the syndrome is not understood in detail but may well involve a vicious circle in which alkalosis decreases renal calcium clearance and hypercalcemia helps maintain alkalosis. Nephrocalcinosis, nephrogenic diabetes insipidus, decreased GFR associated with hypercalcemia, and hypovolemia from vomiting all lead to renal failure, which can be severe. PTH levels, measured with currently available two-site assays, are invariably low in hypercalcemic patients, as are levels of calcitriol. After clearance of the calcium by hydration or by dialysis, if necessary, renal function usually returns to normal, unless the disorder has been severe and long-standing.

Immobilization

Immobilization can lead to bone resorption sufficient to cause hypercalcemia. The immobilization is usually caused by spinal cord injury or extensive casting after fractures, although it can occur in settings such as Parkinson's disease.³²⁹ Hypercalcemia of immobilization occurs predominantly in the young and in patients with other reasons for a high rate of bone turnover, such as Paget's disease or extensive fractures. Hypercalciuria and substantial bone loss are more common than hypercalcemia. After spinal cord injury, the hypercalciuria is maximal at 4 months and can persist for longer than 1 year. PTH and calcitriol levels are suppressed, and bone biopsies show increased resorption and decreased formation of bone. Osteocytes are essential mediators of the bone loss associated with immobilization.³³⁰ Bisphosphonates have been used to reverse the hypercalcemia and hypercalciuria of spinal cord injury.

Renal Failure

After rhabdomyolysis, during the oliguric phase of acute renal failure, severe hypocalcemia can result from acute hyperphosphatemia and calcium deposition in muscle.³³¹ PTH levels are high. In the diuretic phase that follows, hypercalcemia can occur. The hypercalcemia results from the high calcitriol levels observed in some patients and from mobilization of the calcium deposits.³³²

In chronic renal failure, hypercalcemia can result from tertiary hyperparathyroidism, or it may appear during therapy for aplastic bone disease associated with low PTH levels and sometimes with aluminum toxicity.

Williams' Syndrome

Williams' syndrome is a developmental disorder in which supravalvular aortic stenosis is associated with elfin facies and mental retardation.³³³ Hypercalcemia can occur transiently in the first 4 years of life. Affected hypercalcemic infants have been found to have increased intestinal absorption of calcium and associated elevations of calcitriol that fall to normal as the blood calcium level normalizes.³³⁴ Levels of 25(OH)D are normal. The hypercalcemia

can usually be controlled by dietary manipulation and, if needed, bisphosphonates.³³⁵

Molecular analysis has clarified the origin of the connective tissue component of Williams' syndrome. Isolated supravalvular aortic stenosis is associated with deletion or translocation of the distal portion of the elastin gene. Williams' syndrome, with more protean connective tissue abnormalities and mental retardation, is associated with large deletions that include the elastin gene and a gene encoding the protein kinase, LIM-kinase 1. A gene within the Williams' syndrome deletion region encodes a nuclear protein, Williams' syndrome transcription factor, that is part of a large chromatin-remodeling complex that can bind the VDR and influence the transcription of VDR-responsive genes.³³⁶ This makes the gene a strong candidate for the gene associated with transient hypercalcemia in this disorder. However, genetic proof that this gene is responsible for the hypercalcemia is still lacking.

Jansen's Metaphyseal Chondrodysplasia

Jansen's metaphyseal chondrodysplasia is a rare disease in which affected persons present in childhood with short stature and hypercalcemia (Fig. 28-28). Blood chemistry studies suggest hyperparathyroidism, with high calcium, low-normal phosphate, high calcitriol, high alkaline phosphatase, and high urinary hydroxyproline, but PTH levels are suppressed.³³⁷ A generalized defect in endochondral bone formation results from abnormally organized chondrocytes in growth plates. Metaphyses appear disordered and rachitic on radiographs. The bones may show signs of osteitis fibrosa cystica. Constitutive activation of the PTH/PTHrP receptor, caused by point mutations in the transmembrane domains of the receptor, explains the findings in this disorder.^{89,338} The abnormalities on serum chemistry studies result from PTH-like actions of the receptor in bone and kidney. The growth plate disorder results from PTHrP-like actions of the receptor on the growth plate.

Figure 28-28 A patient with Jansen's metaphyseal chondrodysplasia at ages 5 years and 22 years. Note the short stature, characteristic facies, and misshapen metaphyseal region of long bones. (From Frame B, Poznanski AK. Conditions that may be confused with rickets. In DeLuca HF, Anastas CS, eds. *Pediatric Diseases Related to Calcium*. New York: Elsevier; 1980:269-289.)

Approach to the Hypercalcemic Patient

The diagnostic approach to the hypercalcemic patient is strongly influenced by the clinical setting and the knowledge that primary hyperparathyroidism is at least twice as common as all other causes combined (Table 28-2). These considerations are particularly significant in the patient who seems otherwise well and in whom the hypercalcemia is detected incidentally or is mild, stable, or known to be of long duration (i.e., years). Among outpatients referred to endocrinologists for evaluation of hypercalcemia, more than 90% are found to have primary hyperparathyroidism. Among ill or hospitalized patients, malignant disease is the cause in more than 50% of cases. The differential diagnosis is seldom complicated, however, because malignant hypercalcemia usually manifests in the context of advanced, clinically obvious disease.

Because hypercalcemia usually is first detected as an elevation of total serum calcium, it is important to distinguish hemoconcentration or rare instances of calcium-binding paraproteinemia or thrombocythemia-associated hypercalcemia (due to release of intracellular calcium in vitro) from a true increase in serum ionized calcium (Fig. 28-29). The presence of hypercalcemia should be confirmed by direct measurement of ionized calcium, and the total calcium measurement should be repeated, together with albumin, globulin electrolytes, blood urea nitrogen, creatinine, and phosphate. Especially when hypercalcemia is mild, it is prudent to repeat the serum total or ionized calcium measurement at least twice, preferably fasting and without venous occlusion, before proceeding with more costly studies directed at its etiology.

A careful history and physical examination, combined with efforts to assess chronicity by seeking prior results of

routine multichannel serum chemistry determinations, most often will point to the likely diagnosis. Serum phosphate is frequently low in hyperparathyroidism, but this often is true also of PTHrP-secreting malignancies, so the presence of hypophosphatemia is not helpful in distinguishing these two possibilities. If serum phosphate is normal or high despite correction of dehydration, the possibility of PTH- or PTHrP-independent hypercalcemia should be considered more strongly. Elevations in serum chloride and alkaline phosphatase, often observed in primary hyperparathyroidism, cannot be reliably employed in the differential diagnosis of hypercalcemia. Important elements in the medical history of hypercalcemic patients include inquiries about kidney stones or fractures; weight loss; back or bone pain; fatigue or weakness; cough or dyspnea; ulcer disease or pancreatitis; ingestion of vitamins, calcium preparations, lithium, or thiazides; dates of most recent mammograms and chest radiographs; and a family history of hypercalcemia, kidney stones, ulcer disease, endocrinopathy, or tumors of the head or neck. Because malignancy is a common cause of hypercalcemia and may occur concomitantly with primary hyperparathyroidism, clinical findings strongly suggestive of malignancy should be acted upon by proceeding directly to a search for an underlying tumor, regardless of serum PTH.

The single most important test in the differential diagnosis of hypercalcemia is the measurement of serum PTH, preferably in a two-site assay specific for the intact, biologically active molecule (see Fig. 28-20). New PTH assays have been introduced that ignore long circulating fragments of the hormone, which lack the amino-terminal residues required for activity at the PTH/PTHrP receptor, but whether these will be more useful than standard “intact PTH” assays remains to be established.^{339,340} A consistently elevated serum PTH in the presence of true hypercalcemia always is abnormal and almost always indicates the presence of primary hyperparathyroidism. The exceptions that also can be associated with elevated PTH levels are FHH, autonomous parathyroid secretion complicating secondary hyperparathyroidism (so-called tertiary hyperparathyroidism), lithium-associated hyperparathyroidism, and, very rarely, ectopic PTH secretion by a malignant neoplasm or the presence of antagonizing autoantibodies directed against the CASR in patients with another autoimmune disease—an acquired condition that mimics FHH.^{341,342}

Diagnosis of primary hyperparathyroidism is complicated by the fact that some patients fail to exhibit both hypercalcemia and elevated iPTH. In up to 10% of patients with hypercalcemia and primary hyperparathyroidism, PTH levels fall within the high-normal range with current PTH assays. However, in the face of hypercalcemia, such PTH levels are inappropriate and support the diagnosis of PTH-dependent hypercalcemia. In fact, many such patients will manifest frankly elevated serum PTH if retested, especially if dietary calcium is restricted beforehand. As noted earlier, some patients present with serum calcium in the high-normal range (>10.0 mg/dL) and an elevated or high-normal PTH. This may be discovered incidentally in an otherwise asymptomatic patient or in the course of evaluation of recurrent urolithiasis or osteopenia. Those with persistently high-normal serum calcium and high-normal iPTH should be retested at intervals and, meanwhile, given a provisional diagnosis of hyperparathyroidism and evaluated accordingly.

In patients with PTH-dependent hypercalcemia (Fig. 28-30), calcium and creatinine should be measured in a 24-hour urine collection with a simultaneous serum sample to determine total urinary calcium output (milligrams per

day) and the clearance rates of calcium and creatinine (Cl_{Ca} and Cl_{Cr} , respectively). A calcium excretion rate of less than 100 mg/day or a Cl_{Ca}/Cl_{Cr} ratio of less than 0.01 should prompt consideration of FHH, especially in patients who are younger than 40 years of age, have a family history of FHH, or have serum iPTH levels within the normal range. A urinary calcium excretion rate greater than 4 mg/kg per day or a Cl_{Ca}/Cl_{Cr} ratio greater than 0.02 effectively excludes FHH. In FHH, serum phosphate is normal or slightly low, serum magnesium may be slightly high, and serum calcitriol is normal or low (unlike in primary hyperparathyroidism).

A definite diagnosis of FHH, as in the MEN syndromes, may be provided by confirming the presence of mutations in the relevant genes; however, such studies are not invariably informative, presumably because of mutations in introns and other unchecked regions, and they are usually unnecessary. The identification of *RET* gene mutations is now an essential part of the management in families with MEN2, because this information most effectively guides the decision for preventive thyroidectomy to prevent medullary cancer of the thyroid. In contrast, the identification of mutations in the *menin* gene has not yet led to any effective preventive strategies, so genetic analysis may be useful only for genetic counseling in families with MEN1. Even for this purpose, however, the incomplete ascertainment of mutations limits the effectiveness of such analysis.

In patients with suspected lithium-induced hyperparathyroidism, a trial off lithium, if feasible clinically, may

confirm the diagnosis or indicate the presence of persistent primary hyperparathyroidism. Patients with primary hyperparathyroidism should undergo bone densitometry, preferably at both cortical- and trabecular-rich sites (i.e., forearm or hip and lumbar spine, respectively) to assist in the decision about surgery. Those who are younger than 40 years of age or have a family history of hypercalcemia (or other MEN manifestations) should be evaluated for these syndromes as well. Patients not meeting criteria for parathyroidectomy should be monitored medically, as should those with FHH. In the rare patients with CASR-blocking autoantibodies, hypercalcemia may respond to glucocorticoids.³⁴²

A low or undetectable serum PTH level signifies the presence of nonparathyroid hypercalcemia and should prompt a detailed evaluation for malignancy or other causes of PTH-independent hypercalcemia (see Table 28-2). Breast and lung cancers alone account for more than 50% of all cases of malignancy-associated hypercalcemia. Mammography, chest radiography with or without CT, abdominal CT, and serum and urinary immunoelectrophoresis are among the more useful tests for detecting the cause of nonparathyroid hypercalcemia. Although humoral mechanisms, especially secretion of PTHrP, are implicated in the pathogenesis of most cancer-associated hypercalcemias, bone metastases are common, particularly in breast cancer. Technetium 99m bone scanning is useful for detecting this syndrome and identifying bones vulnerable to fracture. The utility of serum PTHrP measurements probably is limited to the unusual situation in which serum PTH is

suppressed but an underlying malignancy cannot readily be demonstrated. PTHrP-associated hypercalcemia can occur rarely during pregnancy and lactation, via secretion from benign neoplasms or in association with lymphoid hyperplasia in patients with lupus erythematosus or human immunodeficiency virus (HIV) infection.³⁴³

In the absence of evident malignancy, unusual causes of hypercalcemia should be sought.³⁴³ Intoxication with vitamin D and vitamin A can be excluded by measurement of serum 25(OH)D and retinoids, respectively. Elevated calcitriol and hypercalcemia may occur in several settings, including sarcoidosis and other granulomatous diseases, B-cell and T-cell lymphomas (including AIDS-associated lymphomas), and, uncommonly, Crohn's disease, neonatal subcutaneous fat necrosis syndrome, and epithelial neoplasms such as lung cancer. Very rarely, patients with severe idiopathic hypercalciuria and excessive absorption of dietary calcium may manifest mild, dietary-dependent hypercalcemia. Overtreatment of hypoparathyroidism or other conditions with oral calcitriol or topical use of analogues of the active metabolite in psoriasis should be obvious from the history. Because hypercalcemia and hypercalciuria are observed in up to 10% and 30%, respectively, of patients with thyrotoxicosis, measurement of serum thyroid-stimulating hormone may be helpful, especially in older patients, who may be less overtly symptomatic. Adrenal insufficiency and pheochromocytoma usually are accompanied by characteristic clinical features, but a definite diagnosis may be sought with appropriate studies. Granulomatous diseases are among

the more common disorders that underlie initially unexplained hypercalcemia.

Management of Severe Hypercalcemia

Causes of Severe Hypercalcemia

The need for urgent treatment of acute, severe hypercalcemia, usually defined as a serum calcium concentration greater than 14 mg/dL (3.5 mmol/L), is unusual. This is because most patients with hypercalcemia have primary hyperparathyroidism, in which hypercalcemia is typically chronic and mild. Episodes of acute, severe hypercalcemia may occur occasionally in primary hyperparathyroidism ("parathyroid crisis"), usually in patients with large parathyroid adenomas and very high PTH levels. The severe hypercalcemia in this setting may be triggered by dehydration resulting from diarrheal illness, protracted vomiting, or diuretic therapy; recovery from major surgery; immobilization; ingestion of large amounts of oral calcium salts; hemorrhage or rupture of a cystic parathyroid neoplasm; or parathyroid carcinoma.

Most often, acute, severe hypercalcemia is encountered in patients with underlying malignancy, in whom accelerated bone resorption dramatically increases the filtered load of calcium. The ensuing profound hypercalciuria impairs renal tubular sodium reabsorption, which induces progressive extracellular volume depletion, reduces GFR, impairs renal calcium clearance, and further aggravates the hypercalcemia. In many such patients, elevated circulating levels of PTHrP compound the problem by mimicking the

action of PTH to enhance distal tubular calcium reabsorption.

Clinical Features of Severe Hypercalcemia

The indications for urgent treatment of hypercalcemia usually relate more to the presence of clinical symptoms of hypercalcemia than to the absolute level of serum calcium, although few clinicians would hesitate to treat patients in whom total serum calcium exceeded 14 mg/dL (3.5 mmol/L). Many patients with previously mild hypercalcemia become symptomatic when serum calcium concentrations exceed 12 mg/dL (3.0 mmol/L). It is important to remember that hypoalbuminemia can mask significant elevations of ionized calcium. The most common symptoms of severe hypercalcemia are referable to disturbances of nervous system and gastrointestinal function: fatigue, weakness, lethargy, confusion, coma (rarely), anorexia, nausea, abdominal pain (rarely due to pancreatitis), and constipation. Polyuria, nocturia, and polydipsia commonly are present also.

Bone pain is often present but is usually a result of the underlying metastatic disease. Cardiac arrhythmias may occur, particularly bradyarrhythmias or heart block; digitalis toxicity may be potentiated, and ST-segment elevation responsive to treatment of the hypercalcemia may be seen. Patients who suffer a fatal outcome from acute severe hypercalcemia may manifest coma, hypotension, acute pancreatitis, acute renal failure, widespread soft tissue calcification, heart failure, or venous thrombosis, particularly of the renal veins.

Treatment of Severe Hypercalcemia

The first decision to be made in the management of acute, severe hypercalcemia is whether to treat the problem at all. This may become an issue for the patient with an untreatable, widely disseminated malignancy if all other approaches to controlling the neoplasm have been exhausted and the patient has chosen not to have complications treated. Otherwise, as noted earlier, patients who are symptomatic or have serum calcium levels greater than 14 mg/dL ordinarily should be treated aggressively. Treatment most often entails rehydration and administration of a bisphosphonate intravenously (Table 28-3). Calcitonin can be useful as a temporary measure early in therapy, and glucocorticoids or dialysis may be indicated in some patients.³⁴⁴

Volume Repletion. When treatment is indicated, the first priority is to correct the extracellular volume depletion that almost invariably is present, usually by infusing isotonic saline at a rate of 2 to 4 L/day. The aggressiveness with which the individual patient is rehydrated must be considered in relation to both the patient's volume status

and the risk of precipitating or aggravating congestive heart failure or ascites. Diuretics, particularly thiazides, should be discontinued. The use of furosemide or other potent loop diuretics to promote calciuresis may exacerbate extracellular volume depletion if used too early in the course of treatment. In light of the availability of highly effective alternatives for the treatment of hypercalcemia, such drugs probably are best avoided, except in circumstances in which vigorous rehydration fails to improve severe hypercalcemia or might precipitate congestive heart failure. In any case, prolonged use of saline-induced calciuresis without the early introduction of an effective antiresorptive agent is ill-advised and ultimately futile.

Bisphosphonates. Intravenous bisphosphonates rapidly inhibit bone resorption and currently are the agents of first choice in managing severe hypercalcemia that is known or suspected to be driven mainly by osteoclastic bone resorption.³⁴⁴ Bisphosphonates should not be used in patients with milk-alkali syndrome, in whom they are likely to induce post-treatment hypocalcemia.³⁴⁵ Pamidronate and zoledronate are approved by the U.S. Food and Drug Administration for treatment of malignant hypercalcemia and are the most widely used agents in the United States, although ibandronate and clodronate have been successfully deployed elsewhere. These drugs generally are well tolerated, although local pain or swelling at the infusion site, low-grade fever lasting 1 to 2 days after the infusion, transient lymphopenia, and mild hypophosphatemia or hypomagnesemia may occur. Serum calcium usually declines within 24 hours and reaches a nadir within 1 week after a single infusion, at which point calcium levels may be normal in 70% to 90% of treated patients. Intravenous bisphosphonates may be nephrotoxic, but clinical data to guide their use in patients with renal insufficiency are not yet available. Most clinicians employ the standard dose (see Table 28-3), perhaps at half or less of the usual rate of administration, in patients with moderate renal insufficiency (GFR >30 mL/min), which is common in the setting of severe hypercalcemia. In patients with more severe renal insufficiency, bisphosphonates probably are best avoided, and dialysis may be a more appropriate alternative (see later discussion). The duration of the response to intravenous bisphosphonate treatment is quite variable, ranging from a week or two to several months. Depending on the clinical circumstances, repeated courses of therapy may be indicated and effective.

Calcitonin. Calcitonin, which directly inhibits osteoclast function, may be used with other antiresorptive agents to achieve more rapid control of severe hypercalcemia. However, calcitonin rarely produces a decline in serum calcium of more than 1 to 2 mg/dL, and its efficacy typically is limited to a few days at most, possibly because of receptor downregulation in target cells of bone and kidney. Its major advantages are a more rapid onset of action than bisphosphonates (several hours) and the potential to augment renal calcium excretion directly. Calcitonin usually is well tolerated, although transient nausea, vomiting, abdominal cramps, flushing, and local skin reactions may occur.

Other Approaches to Treatment of Severe Hypercalcemia. Because of their potential toxicity, other antiresorptive agents such as gallium nitrate, plicamycin (mithramycin), and intravenous phosphate (in patients with severe hypophosphatemia) have largely been abandoned in the treatment of severe hypercalcemia, although

TABLE 28-3

Management of Severe Hypercalcemia

Therapy	Usual Dose	Frequency
Rehydration	2-4 L/day of 0.9% NaCl IV	qd × 1-5 days
Furosemide	20-40 mg IV (after rehydration)	q12-24hr
Pamidronate	60-90 mg IV over 2-4 hr	Once
Zoledronate	4 mg IV over 15-30 min	Once
Calcitonin	4-8 IU/kg SC	q12-24hr
Gallium nitrate	200 mg/m ² IV over 24 hr	qd × 5 days
Glucocorticoids	200-300 mg hydrocortisone IV 40-60 mg prednisone PO	qd × 3-5 days qd × 3-5 days
Dialysis		

a recent randomized trial demonstrated that gallium nitrate may be more effective than bisphosphonate in controlling hypercalcemia of malignancy.³⁴⁶ Oral or enteral phosphate repletion is appropriate for patients with significant hypophosphatemia (<2.5 mg/dL), provided that serum phosphate and renal function are closely monitored. Intravenous or oral glucocorticoids should be considered early in patients with suspected vitamin D-dependent hypercalcemia, including those with lymphoma or granulomatous disease. The response to glucocorticoids may be more delayed than that to bisphosphonates. Successful treatment of hypercalcemia in Crohn's disease with infliximab has been reported.³⁴⁷

In patients with severe renal insufficiency with or without complicating heart disease, in whom saline rehydration and associated calciuresis may not be feasible and bisphosphonates probably are best avoided, dialytic therapy against a low- or zero-calcium dialysate may be the most appropriate tactic. In patients with known primary hyperparathyroidism and intercurrent severe hypercalcemia ("parathyroid storm"), urgent parathyroidectomy (after initial medical stabilization) should be considered.

Novel approaches to the treatment of severe hypercalcemia are in development. One available therapy for parathyroid carcinoma is the calcimimetic cinacalcet, which may be effective in some patients.³⁴⁸ Monoclonal antibodies directed against PTHrP could prove useful in controlling PTHrP-dependent hypercalcemia,³⁴⁹ and other novel anti-resorptives (monoclonal antibodies against the osteoclastogenic factor RANKL or recombinant OPG, which neutralizes RANKL) are on the horizon.

HYPOCALCEMIC DISORDERS

Clinical Presentation

The predominant clinical symptoms and signs of hypocalcemia are those of neuromuscular irritability, including perioral paresthesias, tingling of the fingers and toes, and spontaneous or latent tetany. Tetany can be elicited by percussion of the facial nerve below the zygoma, resulting in ipsilateral contractions of the facial muscle (Chvostek's sign), or by 3 minutes of occlusive pressure with a blood pressure cuff resulting in carpal spasm, which on occasion can be very painful (Trousseau's sign) (Fig. 28-31). The usefulness of these signs in diagnosing hypocalcemia and in monitoring therapeutic responses cannot be overemphasized.

Electrocardiographic abnormalities also result from hypocalcemia, including prolonged QT intervals and marked QRS and ST-segment changes that may mimic acute myocardial infarction or conduction abnormalities. Ventricular arrhythmias are a rare complication of hypocalcemia, although congestive heart failure, corrected by normalization of serum calcium, has been reported.

In profound hypocalcemia or during acute falls in serum calcium, grand mal seizures or laryngospasm also may be observed. Chronic hypocalcemia is associated with milder symptoms and signs of neuromuscular irritability and may even be asymptomatic. Long-standing hypocalcemia associated with hyperphosphatemia (observed in PTH deficiency or resistance) may lead to calcification of the basal ganglia and occasional extrapyramidal disorders. In addition, mineral ion deposits in the lens may lead to cataract formation.

Chronic hypocalcemia, particularly when associated with hypophosphatemia as in vitamin D deficiency, is associated with growth plate abnormalities in children (rickets)

Figure 28-31 Trousseau's sign. (From Burnside JW, McGlynn TJ. *Physical Diagnosis*, 17th ed. Baltimore: Williams & Wilkins; 1987:63.)

and defects in the mineralization of new bone (osteomalacia) (see Chapter 29). Severe symptomatic hypocalcemia constitutes an emergency that requires immediate attention to prevent seizures and death from laryngospasm or cardiac causes.

Total calcium in serum includes both the free (biologically active) and the protein-bound components; the major binding protein is albumin (see earlier discussion). Therefore, measurements of total calcium cannot be interpreted without concurrent measurement of albumin. Studies of hypoalbuminemic patients with cirrhosis have led to a formula for correction of total calcium based on concurrent albumin levels: Calcium is decreased by 0.8 mg/dL for every 1 g/dL decrease in albumin. However, no formula has proved accurate for assessment of calcium in acutely ill patients. This probably relates to the variety of factors that can increase protein binding and decrease the fraction of total calcium present as the free ion, including alkalosis, elevated circulating free fatty acids, and lipid infusions. Consequently, ionized calcium should be measured when the diagnosis of hypocalcemia is considered in the setting of acute illness or severe hypoalbuminemia.

Chronic hypocalcemia is most often caused by deficiency of PTH or calcitriol or by resistance to the biologic effects of these calcium-regulating hormones (Table 28-4).

Parathyroid-Related Disorders

Hypocalcemia associated with parathyroid dysfunction can be differentiated from other causes of hypocalcemia by routine laboratory tests. Serum calcium is low due to lack of PTH-mediated bone resorption and urinary calcium reabsorption. Serum phosphate is increased owing to impaired renal clearance. Serum calcitriol is low because PTH and hypophosphatemia stimulate the renal 25(OH)D 1 α -hydroxylase. Consequently, calcitriol-mediated intestinal calcium absorption is markedly decreased, further exacerbating the hypocalcemia. PTH levels as measured by sensitive two-site PTH assays (see Fig. 28-20) are usually low or undetectable but may be inappropriately normal if some degree of PTH production is preserved. Elevated levels of PTH are found in syndromes associated with resistance to the biologic effects of PTH.

TABLE 28-4

Causes of Hypocalcemia**Parathyroid-Related Disorders****Absence of the Parathyroid Glands or of PTH**

Congenital

- DiGeorge's syndrome
- X-linked or autosomally inherited hypoparathyroidism
- Autoimmune polyglandular syndrome type I
- PTH gene mutations

Postsurgical hypoparathyroidism

Infiltrative disorders

- Hemochromatosis
- Wilson's disease
- Metastases

Hypoparathyroidism following radioactive iodine thyroid ablation

Impaired Secretion of PTH

Hypomagnesemia

Respiratory alkalosis

Activating mutations of the calcium sensor

Target Organ Resistance

Hypomagnesemia

Pseudohypoparathyroidism

- Type I
- Type 2

Vitamin D–Related Disorders

Vitamin D deficiency

- Dietary absence
- Malabsorption

Accelerated loss

- Impaired enterohepatic recirculation
- Anticonvulsant medications

Impaired 25-hydroxylation

- Liver disease
- Isoniazid

Impaired 1 α -hydroxylation

- Renal failure

Vitamin D–dependent rickets type I

Oncogenic osteomalacia

Target organ resistance

- Vitamin D–dependent rickets type II
- Phenytoin

Other Causes

Excessive deposition into the skeleton

- Osteoblastic malignancies
- Hungry bone syndrome

Chelation

- Foscarnet
- Phosphate infusion
- Infusion of citrated blood products
- Infusion of EDTA-containing contrast reagents
- Fluoride

Neonatal hypocalcemia

- Prematurity
- Asphyxia
- Diabetic mother
- Hyperparathyroid mother

HIV infection

- Drug therapy
- Vitamin D deficiency
- Hypomagnesemia
- Impaired PTH responsiveness

Critical illness

- Pancreatitis
- Toxic shock syndrome
- Intensive care unit patients

EDTA, ethylenediaminetetra-acetic acid; HIV, human immunodeficiency virus; PTH, parathyroid hormone.

Congenital or Inherited Parathyroid Disorders

Several rare syndromes associated with congenital or inherited hypoparathyroidism appear sporadically or in a variety of inheritance patterns suggesting multiple etiologies. Mutation of the transcription factor GCM2 (chromosome 6p23), which is expressed in the PTH-secreting cells of the developing parathyroids, has been shown to be a cause of familial hypoparathyroidism in humans and mice.³⁶ Although it is usually inherited in an autosomal recessive fashion, GCM2-associated hypoparathyroidism can be autosomal dominant through expression of a dominant-negative mutant GCM2 gene.⁵⁵¹ The genetic abnormality responsible for X-linked, recessive hypoparathyroidism has been identified as a deletion/insertion of DNA near the SOX3 gene at Xq26-q27.³⁷

In a number of diseases, hypoparathyroidism is associated with multiple abnormalities in embryonic development in the neck and chest region. DiGeorge's syndrome occurs sporadically and is associated with an embryologic defect in the formation of the third, fourth, and fifth branchial pouches, resulting in the absence of parathyroid glands. DiGeorge's syndrome may, in fact, be a neurocristopathy, because ablation of the premigratory cephalic neural crest in chick embryos produces the same phenotype.³⁵⁰ The contribution of homeobox genes to parathyroid development and their potential relationship to DiGeorge's syndrome is also demonstrated by the absence of thymic and parathyroid tissue, accompanied by cardiac and craniofacial abnormalities, in mice lacking the homeobox gene *Hoxa3*.³⁵¹ DiGeorge's syndrome is often associated with other congenital abnormalities in a syndrome referred to by the acronym CATCH 22 (cardiac defects, abnormal facies, thymic hypoplasia, cleft palate, hypocalcemia, and 22q11 deletions).³⁵² Microdeletion of 22q11.21-q11.23³⁵³ and a t(2;22)(q14;q11) balanced translocation suggest that a gene at chromosome 22q11 may be pathogenetic in this syndrome.³⁵⁴ Hypoparathyroidism also has been reported in two patients with a 22q11 deletion.³⁵⁵ Although deletion of the *TBX1* gene has been shown to be responsible for the cardiovascular defects in this syndrome,³⁵⁶ the molecular basis for impaired parathyroid gland development has not yet been elucidated. A number of cases of DiGeorge's syndrome and velocardiofacial syndrome have been shown to have no detectable abnormality at 22q11, but rather terminal 10p deletions or interstitial 10p13/10p14 deletions, suggesting that two loci may be critical for the development of branchial pouch structures.³⁵⁷ Terminal deletions of 10p accompanied by hypoparathyroidism can be further subdivided into the second DiGeorge critical region (10p13-p14) and a more telomeric region (10p14-10pter). In the latter region, mutation of the transcription factor GATA3 causes the HDR syndrome (hypoparathyroidism, sensorineural deafness, and renal anomaly).³⁵⁸ The genetic basis for HDR (hypoparathyroidism, retardation, dysmorphism) or the related disorder known as Kenny-Caffey syndrome, which is additionally associated with recurrent bacterial infections, has been shown to be linked to 1q43-q44; it involves mutations in the chaperone protein, TBCE, which is required for the proper folding of α -tubulin and formation of $\alpha\beta$ -tubulin heterodimers.³⁵⁹

Familial hypoparathyroidism is seen in conjunction with mucocutaneous candidiasis, Addison's disease, and other immune disorders in autosomal recessive autoimmune polyglandular syndrome type 1, which is caused by mutations in the autoimmune regulatory gene, *AIRE*.^{360,361} NALP5 (encoded by *NLRP5*) has been identified as a parathyroid-specific antigen in affected patients.³⁶²

Hypoparathyroidism may also be observed in association with mitochondrial myopathies such as mitochondrial trifunctional protein deficiency³⁶³ and the Kearns-Sayre syndrome.³⁶⁴ Other inherited forms of hypoparathyroidism may be observed as isolated defects³⁶⁵ or in association with other features such as lymphedema, dysmorphism, and renal and cardiac abnormalities.^{366,367}

Abnormalities in the Parathyroid Hormone Gene

Specific defects have been found in the PTH gene in a small number of kindreds affected by congenital hypoparathyroidism. These include point mutations in the signal peptide^{368,369} and in an intron border, leading to aberrant splicing.³⁷⁰ No abnormalities in the sequences encoding PTH¹⁻⁸⁴ have been discovered in familial hypoparathyroidism.

Destruction of the Parathyroid Glands

The most common cause of chronic hypocalcemia is post-surgical hypoparathyroidism. This may occur after removal of all parathyroid tissue during thyroidectomy and radical neck dissection for malignancies, or after inadvertent interruption of the blood supply to the parathyroid glands during head and neck surgery. Transient hypoparathyroidism, attributed to reversible damage to the remaining normal glands, is common after parathyroidectomy; permanent hypoparathyroidism may occur after vascular or surgical injury or inadvertent removal of all parathyroid tissue. Rarely, transient hypoparathyroidism may follow spontaneous infarction of autonomous tissue in primary hyperparathyroidism.³⁷¹ Hypoparathyroidism is a rare complication of radioactive iodine ablation of the thyroid gland in patients with Graves' disease.³⁷²

Hypoparathyroidism also can occur as a result of infiltrative diseases of the parathyroids. This is seen in diseases of iron overload such as hemochromatosis and in patients with thalassemia major who have been heavily transfused.³⁷³ Copper deposition in Wilson's disease³⁷⁴ may also cause parathyroid dysfunction. Metastatic disease to the parathyroids can cause hypoparathyroidism, but rarely, presumably because of the need for four-gland involvement before significant hypoparathyroidism is observed.

Impaired Parathyroid Hormone Secretion

Impaired secretion of PTH from the parathyroid glands can lead to functional hypoparathyroidism. This is commonly seen in profound hypomagnesemia,³⁷⁵ in which target organ resistance to PTH can also occur. Both of these abnormalities are reversible on magnesium repletion (see "Disorders of Magnesium Metabolism").^{376,377}

Chronic respiratory alkalosis leads to hyperphosphatemia and decreased ionized calcium levels accompanied by

impaired renal calcium resorption and inappropriately normal PTH levels.³⁷⁸ This biochemical phenotype suggests both an abnormality of PTH secretion and renal resistance to PTH. Acute alkalosis in dogs also suppresses PTH secretion.³⁷⁹

Activating mutations in the CASR cause autosomal dominant hypocalcemia associated with inappropriately normal PTH levels. The clinical syndrome is variable; patients present with hypocalcemia and seizures, but their affected relatives may be only later diagnosed with asymptomatic hypocalcemia.³⁸⁰ Unlike patients with inactivating mutations of the CASR, homozygously affected individuals do not appear to have a more severe phenotype.³⁸¹ The presence of hypercalciuria in these patients makes medical management uniquely challenging. Treatment with vitamin D metabolites often results in a marked increase in renal calcium excretion, associated with renal calcification and resultant renal impairment. Based on these observations, it has been suggested that asymptomatic individuals should be left untreated and that the goal of therapy in patients with symptomatic hypocalcemia should be solely to relieve symptoms, not to achieve normocalcemia. Treatment with calcium and vitamin D metabolites should be accompanied by the use of thiazide diuretics to decrease urinary calcium excretion and ensure a urinary volume that is adequate to decrease the urinary calcium concentration.

Pseudohypoparathyroidism

The idiopathic and inherited forms of PTH resistance are referred to as pseudohypoparathyroidism (PHP). The first cases of documented PTH resistance were described by Albright in 1942.³⁸² The patients were hypocalcemic and hyperphosphatemic and they also exhibited a number of features that are characteristic of the disorder now called *Albright's hereditary osteodystrophy* (AHO). These features include short stature, rounded face, foreshortened fourth and other metacarpals, obesity, and subcutaneous calcifications (Figs. 28-32 and 28-33).

PTH administration to these patients failed to provoke a phosphate diuresis or an increase in serum calcium. It was subsequently demonstrated that hypocalcemic patients with features of AHO had elevated PTH levels and that PTH infusions failed to stimulate renal production of cAMP. Failure of stimulation of cAMP production suggested a defect in the PTH receptor or in its cAMP-mediated signal transduction.³⁸³ The measurement of cAMP in the urine after an infusion of synthetic PTH¹⁻³⁴ is now used to establish the diagnosis of PTH resistance.³⁸⁴

The variable presence of AHO and renal resistance to PTH in PHP has led to subclassification of PHP (Table 28-5). PHP type 1A is characterized by AHO and diminished activity (approximately 50% of normal) of G_sα, the α-subunit of

TABLE 28-5

Types of Pseudohypoparathyroidism (PHP)

Disorder	Urinary cAMP Response to PTH	Urinary PO ₄ Response to PTH	Other Hormonal Resistance	AHO	Pathophysiology
PHP type 1A	Decreased	Decreased	Yes	Yes	G _s α mutation
Pseudo-PHP	Normal	Normal	No	Yes	G _s α mutation
PHP type 1B	Decreased	Decreased	No	No	GNAS1 imprinting mutations
PHP type 1C	Decreased	Decreased	Yes	Yes	G _s α activity normal
PHP type 2	Normal	Decreased	No	No	Vitamin D deficiency or myotonic dystrophy in some cases

AHO, Albright's hereditary osteodystrophy; cAMP, cyclic adenosine monophosphate; GNAS1, portion of the GNAS complex locus encoding G_sα; G_sα, α-subunit of the stimulatory G protein; PO₄, phosphate; PTH, parathyroid hormone.

Figure 28-32 Daughter (left) and mother (right) with pseudohypoparathyroidism and Albright's hereditary osteodystrophy.

Figure 28-33 Radiograph of hand from a patient with pseudohypoparathyroidism and Albright's hereditary osteodystrophy. Note the shortened fourth metacarpal.

of the stimulatory G protein, G_s . These patients have mutations that inactivate one allele of the $G_s\alpha$ gene, through a variety of mechanisms, including missense mutations, chain-terminating mutations, changes that induce abnormal splicing, small insertions, deletions, and inversions.³⁸⁵ The resultant diminished $G_s\alpha$ activity has been demonstrated in several tissues, including kidney, fibroblasts, transformed lymphocytes, platelets, and erythrocytes.

Impaired mentation is seen in approximately half of patients with PHP-1A and appears to be related to the $G_s\alpha$ deficiency rather than to chronic hypocalcemia, because patients with other forms of PHP and hypocalcemia have normal mentation. The $G_s\alpha$ deficiency in PHP-1A may be associated not only with PTH resistance but also with resistance to other hormones such as thyroid-stimulating hormone, glucagon, and gonadotropins, resulting in thyroidal and gonadal dysfunction. Paradoxically, two unrelated male patients with both PHP-1A and gonadotropin-independent precocious puberty have been described. The $G_s\alpha$ point mutation found in these individuals is thought to lead to a protein that is unstable at 37° C and, therefore, to confer renal resistance to PTH. In the testes, however, the temperature is lower and the protein is not degraded. In this setting, the stable but mutated protein is constitutively active and stimulates the Leydig cell, in a manner similar to the skeletal effects of the G_s mutations in McCune-Albright syndrome (see Chapter 25).³⁸⁶

The term *pseudo-pseudohypoparathyroidism*, or pseudo-PHP, is used to refer to individuals with the phenotype of AHO who are without evidence of PTH resistance. Patients with pseudo-PHP often are found in the same kindreds as those with PHP-1A, and they invariably inherit the same abnormal $G_s\alpha$ gene found in their PTH-resistant relatives.³⁸⁷ People who inherit the mutant $G_s\alpha$ gene from their father exhibit pseudo-PHP, whereas those who inherit it from their mother exhibit PHP.^{388,389} This pattern, in which the renal hormone resistance phenotype depends on the parent of origin, is considered a form of tissue-specific genetic imprinting. Mice with targeted ablation of the gene

that encodes $G_s\alpha$ (*Gnas1*) also display such imprinting.³⁹⁰ Notably, mice with targeted ablation of one *Gnas1* gene fail to express $G_s\alpha$ mRNA in the renal cortex when the mutant gene is inherited from the mother but have normal expression in the cortex when it is inherited from the father. No such imprinting pattern is seen in the inner medulla. This correlates with the findings in mice (and patients) exhibiting resistance to PTH but not to vasopressin³⁹⁰ and emphasizes the cell type-specific nature of the imprinting. The parental origin of the $G_s\alpha$ mutation affects certain other features of the clinical presentation of these patients: obesity is often seen in patients with PHP-1A and not in those with pseudo-PHP.³⁹¹ In a mouse model of PHP-1A, this obesity was traced to imprinting of *Gnas* in the hypothalamus.³⁹² Further, whereas subcutaneous ossification is seen in patients with both PHP-1A and pseudo-PHP, extension of this ossification deep into muscle (called *progressive osseous heteroplasia*) is seen almost exclusively in patients with pseudo-PHP.³⁹³

Pseudohypoparathyroidism type 1B (PHB-1B) manifests with hypocalcemia, high PTH levels, and failure of PTH infusions to increase urinary cAMP production. However, PHP-1B is not accompanied by any of the clinical features of AHO, nor is it associated with abnormal $G_s\alpha$ levels in fibroblasts. As in PHP-1A, mild resistance to thyroid-stimulating hormone has been reported.³⁹⁴⁻³⁹⁶ The PTH target organ manifestations of PHP-1B are variable, with some affected individuals having manifestations of PTH overactivity in bone and PTH resistance in kidney, a pattern that resembles PHP-1A. Cultured osteoblast-like cells from a patient with PHP-1B demonstrated normal cAMP responsiveness to PTH despite the lack of renal responsiveness.³⁹⁷

When inherited, PHP-1B has been found to map to chromosome 20q13.3,³⁹⁸ the same region that contains the *GNAS1* gene. Although the disease is inherited with the imprinting characteristics of PHP-1A, mapping studies suggest that the disease-causing mutations are close to, but distinct from, the $G_s\alpha$ coding region. Affected individuals have imprinting abnormalities of the *GNAS* complex locus that lead to abnormal patterns of expression of $G_s\alpha$ without effects on the $G_s\alpha$ coding sequence.^{395,399,400} The discovery that PHP-1B is a disease of imprinting may explain why these patients exhibit PTH resistance but not AHO: Presumably, the normal structure of the $G_s\alpha$ gene allows normal expression of $G_s\alpha$ in most tissues, which do not exhibit tissue-specific imprinting. In the renal proximal tubule, where $G_s\alpha$ is expressed only from the maternal allele, abnormal imprinting leads to no expression of $G_s\alpha$ and to PTH resistance in those cells.

Figure 28-34 The *GNAS* complex locus and the adjacent syntaxin (*STX16*) locus. A schematic representation of the *GNAS* complex locus is shown, with the black boxes indicating exons for *STX16*, neuroendocrine secretory protein 55 (*NESP*), the antisense *NESP55* transcript (*A/S*), the $G_s\alpha$ isoforms *XL* (α), loss-of-methylation locus *A/B*, and $G_s\alpha$ (*GS*). The start site and the direction of transcription (sense versus antisense) are indicated by the arrows. Genes that are maternally transcribed are indicated by arrows above the relevant exons, whereas those that are paternally transcribed are indicated below. The expression of *XL*, *A/B*, and *A/S* is through the paternal allele, whereas it is the maternal *NESP55* transcript that is expressed. Expression of *STX16* is biallelic. The arrowhead below the *GS* locus indicates that only the maternal allele is expressed in certain tissues (e.g., the renal tubules). $G_s\alpha$, α -subunit of the stimulatory G protein.

The *GNAS* complex locus gives rise to multiple transcripts (Fig. 28-34), including $G_s\alpha$. $G_s\alpha$ is biallelically expressed in most tissues, but only the maternal transcript is expressed in the renal proximal tubules, thyroid, gonads, and pituitary. In contrast, the *XL*, *A/B*, and antisense (*A/S*) transcripts are expressed only paternally, and the (*NESP55*) transcript only maternally. These patterns of expression involve differential methylation of DNA sequences associated with each transcript. All patients with PHP-1B exhibit loss of methylation at exon *A/B*, which results in biallelic expression of the transcript. This abnormality may play a role in the hormone resistance observed.⁴⁰⁰ The methylation defect in exon *A/B*, when found in families with PHP-1B, is most often caused by 3-kilobase deletions of DNA—not in exon *A/B* but instead 200 kilobases upstream of *GNAS*.^{401,402} How these deletions lead to methylation abnormalities in exon *A/B* is unknown. In sporadic cases of PHP-1B, deletions within *GNAS* also cause abnormal methylation of exon *A/B* and an abnormal expression pattern of $G_s\alpha$.

Several patients with AHO and PTH resistance have been found to have normal $G_s\alpha$ activity, and this subgroup of the disorder has been designated pseudohypoparathyroidism type 1C (PHP-1C). Biochemical characterization in one case⁴⁰³ revealed a significant decrease in the manganese-stimulated adenylate cyclase activity in fibroblast membranes, raising the possibility that a second defect in the cAMP pathway may lead to the phenotype of PHP-1C. Another PHP-1C patient, studied after $G_s\alpha$ sequencing became easier, was found to have a short deletion at the carboxy-terminus of G_s , which resulted in normal levels of G_s activity when assayed in erythrocytes but defective activation by receptors.⁴⁰⁴

In pseudohypoparathyroidism type 2 (PHP-2), PTH infusions increase urinary cAMP normally, but PTH does not elicit a phosphaturic response.⁴⁰⁵ Patients with this syndrome, like those with PHP-1B, lack signs of AHO or resistance to other hormones, but PHP-2, unlike PHP-1B, is not familial in origin. The age at onset of patients with this disorder is variable, ranging from infancy to senescence, suggesting that it is an acquired defect or that the biochemical phenotype may be unmasked by intercurrent abnormalities. A subset of patients with myotonic dystrophy display the biochemical features of PHP-2, with the degree of PTH resistance correlating with the degree of expansion of the pathogenetic CTG repeats in the myotonin protein kinase gene.⁴⁰⁶ A similar biochemical phenotype can also be observed in vitamin D deficiency,⁴⁰⁷ and some authors have suggested that PHP-2 is a manifestation of vitamin D deficiency rather than a distinct clinical entity.⁴⁰⁸ Minagawa and colleagues reported on three neonates who had no signs of rickets and normal levels of vitamin D but presented with transient PHP-2 that resolved at about 6 months of age.⁴⁰⁹ They postulated that PTH responsiveness is subject to maturation during fetal and neonatal development. PHP-2, therefore, seems to reflect a heterogeneous clinical disorder associated with defects in PTH responsiveness distal to cAMP or involving a separate signal transduction pathway.⁴¹⁰

The specificity of PTH resistance for the proximal tubule has implications for the management of PHP. Because bone is not resistant to PTH, hyperparathyroid bone disease may occur.^{411,412} Patients with PHP have lower bone density than normal subjects or hypoparathyroid controls. Basal urinary hydroxyproline excretion in patients with PHP is twice that of hypoparathyroid controls, and they have similar increases in response to parathyroid extract.⁴¹³ Further, the renal resistance to PTH is limited to the

proximal tubule, where the 1α -hydroxylase activates 25(OH)D, and the normal distal tubular reabsorption of calcium keeps the urinary calcium excretion low in comparison to that in patients with primary hypoparathyroidism.⁴¹⁴ Therefore, therapy with calcitriol can be used, with the goal of normalizing PTH levels to avoid bone disease, with less concern that urinary calcium excretion might be excessive.

Vitamin D–Related Disorders

Hypocalcemia secondary to vitamin D deficiency or resistance to the biologic effects of calcitriol is easily differentiated from the hypocalcemia of hypoparathyroidism by routine clinical and laboratory evaluations. The primary cause of hypocalcemia in vitamin D deficiency is decreased intestinal absorption of calcium. In the setting of normal renal function, the hypocalcemia of vitamin D deficiency, unlike that of hypoparathyroidism, is accompanied by hypophosphatemia and increased renal phosphate clearance. This increase in phosphate clearance is a direct result of compensatory (secondary) hyperparathyroidism. The hyperparathyroidism is a consequence of the hypocalcemic stimulus to PTH secretion and the stimulation of PTH gene expression and parathyroid cell proliferation caused by hypocalcemia (see “Parathyroid Hormone Biosynthesis”). Therefore, measurements of serum phosphate and PTH are very useful in distinguishing these disorders from hypoparathyroidism. The secondary hyperparathyroidism results in increased calcium mobilization from the skeleton, increased renal reabsorption of calcium, and increased renal 1α -hydroxylation of 25(OH)D. In severe vitamin D deficiency, the increased levels of PTH no longer lead to increased bone resorption, perhaps because osteoclasts appear not to resorb unmineralized osteoid.

In profound vitamin D deficiency, the level of calcitriol is usually low; in moderate vitamin D deficiency, the stimulation of the renal 1α -hydroxylase by PTH can result in a normal or even elevated calcitriol level. These high levels of calcitriol reflect the action of PTH on the renal 1α -hydroxylase. The ineffectiveness of the high levels of total calcitriol in normalizing serum calcium may be explained by increased binding of this metabolite to VDBP when the levels of 25(OH)D are very low.

Vitamin D Deficiency

Because the two sources of vitamin D are the diet and cutaneous synthesis after ultraviolet irradiation, lack of solar irradiation and decreased intake or impaired absorption of vitamin D can lead to vitamin D deficiency. As the population has become increasingly educated about the risks of skin cancer from solar irradiation, the avoidance of long periods of intense sun exposure and the use of sun blocks with high solar protective factor (SPF) values have resulted in increased reliance on dietary sources of vitamin D. The RDA for vitamin D is 400 IU; however, this level of intake is lower than that required to prevent vitamin D deficiency in the absence of solar exposure especially in elderly or housebound individuals.⁴¹⁵

Vitamin D is present in many food sources, both vegetable and animal. In addition, many prepared foods, especially cereal products, are fortified with vitamin D. Although dairy products have been fortified with vitamin D as well, the actual amount of vitamin D provided does not correlate well with the purported content.¹³¹ The vitamin D derived from vegetable sources is vitamin D₂, and that derived from animal sources is vitamin D₃. These two forms of vitamin D are metabolized identically and have

equivalent biologic potency in humans. Both forms have been used to fortify foods.

Early vitamin D deficiency can be detected when the serum level of 25(OH)D falls to less than 15 ng/dL, because this level has been shown to be associated with the development of secondary hyperparathyroidism. Although elderly, homebound individuals in particular are at high risk, several studies have demonstrated that vitamin D deficiency is prevalent in the general population (reviewed by Thomas and associates in 2000⁴¹⁶). The clinical relevance of this vitamin D deficiency was confirmed by a study demonstrating that administration of vitamin D (800 IU/day) to an ambulatory elderly population decreased serum PTH levels as well as the incidence of hip fracture.⁴¹⁷

Malabsorption also remains an important cause of vitamin D deficiency in all age groups. Because vitamin D is a fat-soluble vitamin, its absorption depends on emulsification by bile acids. Any cause of fat malabsorption or short-bowel syndrome can result in vitamin D deficiency; therefore, malabsorption should be ruled out in patients with very low 25(OH)D levels (<8 ng/dL).

Accelerated Loss of Vitamin D

Both 25(OH)D and calcitriol are secreted with bile salts and undergo enterohepatic circulation; therefore, intestinal disease may also result in vitamin D deficiency due to excessive losses. Increased metabolism of vitamin D, leading to low blood levels of 25(OH)D, is seen in individuals given anticonvulsant medications or anti-tuberculosis therapy. Phenobarbital, primidone, phenytoin,⁴¹⁸ rifampin, and glutethimide⁴¹⁹ have all been reported to accelerate the hepatic inactivation of vitamin D.

Impaired 25-Hydroxylation of Vitamin D

The vitamin D that is absorbed undergoes 25-hydroxylation in the liver; therefore, severe hepatic parenchymal damage can result in 25(OH)D deficiency. Clinically, severe vitamin D deficiency as a consequence of liver disease is rare, because the degree of hepatic destruction necessary to impair 25-hydroxylation is incompatible with long-term survival. However, isoniazid has been shown to decrease the 25-hydroxylation of vitamin D.⁴²⁰ Two kindreds have been described in whom the clinical and biochemical presentations and therapeutic responses suggest an inherited 25-hydroxylation defect.⁴²¹

Impaired 1α -Hydroxylation of 25-Hydroxyvitamin D

The final step in the activation of vitamin D is hydroxylation of 25(OH)D by the renal 1α -hydroxylase to yield 1,25(OH)₂D₃ (calcitriol). Renal parenchymal damage, therefore, can result in deficiency of the active metabolite of vitamin D. Impaired 1α -hydroxylation is observed once the creatinine clearance decreases to approximately 30 to 40 mL/minute. In contrast to the situation with liver failure, dialysis permits long-term survival of patients with renal failure; therefore, deficiency of calcitriol as a result of impaired renal 1α -hydroxylation is a common and important clinical entity.

The metabolic consequences of chronic renal failure on the parathyroid glands and the skeleton are complex (see Chapter 29). Impaired renal 1α -hydroxylation leads to decreased intestinal absorption of calcium, resulting in hypocalcemia. The diminished phosphate clearance associated with renal failure leads to elevated levels of blood phosphate and, consequently, increases in circulating FGF23; this, in turn, further lowers levels of calcitriol and

calcium. The resultant secondary hyperparathyroidism increases the release of calcium and phosphate from bone; however, because of the renal insufficiency, PTH does not have a phosphaturic effect. As a result, the increased serum phosphate level rises further.

Oral phosphate binders are used to lower blood phosphate. Calcium-containing antacids, which replaced the more toxic aluminum-containing antacids (see Chapter 29), are being supplemented or replaced with the phosphate-binding exchange resin, sevelamer. Calcium administration also attenuates the hypocalcemic stimulus to parathyroid secretion. Calcitriol therapy is critical for the absorption of this calcium and should be administered early in the course of renal failure (when the Cl_{Cr} falls to less than 30 to 40 mL/minute), to avoid the development of secondary hyperparathyroidism, and with careful monitoring to avoid hypercalcemia. Once secondary hyperparathyroidism has developed, pharmacologic doses of intravenous or oral calcitriol or calcimimetics⁴²² may be required to suppress PTH gene transcription and parathyroid cellular proliferation. Efforts are currently under way to develop nonhypercalcemic analogues of calcitriol that maintain their PTH-suppressing and antiproliferative effects. Such analogues would be invaluable for the prevention and treatment of secondary hyperparathyroidism in the setting of chronic renal failure and perhaps in the treatment of malignancies whose proliferation may be inhibited by pharmacologic doses of calcitriol.

Decreased levels of calcitriol may also be observed in patients taking ketoconazole¹³⁹ and those with X-linked hypophosphatemia or tumor-induced osteomalacia, diseases associated with high levels of FGF23 (see Chapter 29).¹³⁶

A rare heritable defect of vitamin D activation has been described in several kindreds. Biochemically, pseudo-vitamin D deficiency rickets is characterized by hypocalcemia and secondary hyperparathyroidism. The only metabolic abnormalities that differentiate it from dietary vitamin D deficiency are the presence of normal or elevated levels of vitamin D and 25(OH)D accompanied by low levels of calcitriol.^{423,424} The disease is inherited in an autosomal recessive fashion and manifests in infancy with rickets, osteomalacia, and seizures. Cloning of the 1α -hydroxylase gene has confirmed that mutation of this gene is the molecular basis for the disorder^{425,426} and that, as expected, physiologic replacement doses of 1α -hydroxylated metabolites of vitamin D results in clinical remission.⁴²⁷

Target Organ Resistance to 1,25-Dihydroxyvitamin D₃

A second rare inherited disorder, characterized by resistance to the biologic actions of calcitriol, has been described in several kindreds. This disorder, referred to as hereditary vitamin D-resistant rickets (HVDRR), is also characterized by autosomal recessive inheritance. Its biochemical presentation, with hypocalcemia, hypophosphatemia, and secondary hyperparathyroidism, resembles that of vitamin D deficiency, but it is accompanied by elevated levels of calcitriol. The molecular basis for this disease is mutation of the VDR gene, which results in impaired target organ responsiveness. Most of the mutations that have been described involve the DNA-binding domain of the receptor. These mutations cause a decreased affinity of the receptor for its response elements on target genes, leading to impaired regulation of these genes. Mutations in the hormone-binding and nuclear receptor coactivator-binding

domains of the receptor have also been described in kindreds with HVDRR.⁴²⁸

The clinical presentation of HVDRR is variable; however, most patients present in infancy with rickets, hypophosphatemia, and seizures, although presentation in late adolescence has also been described. Alopecia totalis, developing in the first 2 years of life, is present in some kindreds.⁴²⁹ The finding of alopecia in mice with VDR mutations^{150,152} confirms the association of alopecia with disruption of the VDR gene.

Because of target organ resistance to the active metabolite of vitamin D, there is no ideal treatment for HVDRR. Pharmacologic doses of vitamin D, 25(OH)D, 24,25(OH)₂D₃, and 1,25(OH)₂D₃ (calcitriol) have been administered in an attempt to overcome this target organ resistance,⁴³⁰ with variable effects. For those patients in whom the hypocalcemia and osteomalacia are resistant to such therapeutic interventions, parenteral calcium infusions have been used to heal osteomalacic lesions.¹⁵⁴ Studies in VDR-ablated mice have demonstrated that maintenance of normal mineral ion homeostasis prevents all the complications of VDR ablation except alopecia.^{153,155} Based on these observations, patients with VDR mutations should be treated early and aggressively to prevent skeletal abnormalities and parathyroid hyperplasia. Lifelong therapy is usually required, although spontaneous remissions off therapy have been described.⁴³¹ The pathophysiology of the spontaneous remissions is not well understood, because the underlying genetic defect still exists. It is likely that these "remissions" reflect compensated calcium homeostasis once the needs of the growing skeleton are met. In support of this hypothesis is a report of a relapse in a pregnant woman, followed by a postpartum remission.⁴³²

Phenytoin causes target organ resistance to the biologic effects of calcitriol, in addition to its acceleration of the hepatic catabolism of vitamin D metabolites. Phenytoin has been shown to impair intestinal calcium absorption in vivo in rats⁴³³ and to impair PTH- and calcitriol-mediated bone resorption in vitro. Combination chemotherapy with 5-fluorouracil and low-dose leucovorin has been reported to cause hypocalcemia in 65% of patients, associated with an acute decrease in plasma calcitriol levels.⁴³⁴

Other Causes of Hypocalcemia

Excessive Deposition into the Skeleton

Excessive deposition of calcium into the skeleton can occur in association with osteoblastic metastases, with chondrosarcomas,⁴³⁵ or in the hungry bone syndrome. This last syndrome manifests with prolonged hypocalcemia, hypocalciuria, and hypophosphatemia after parathyroidectomy for primary hyperparathyroidism (see "Primary Hyperparathyroidism"). The hypocalcemia is a consequence of remineralization of a skeleton that has been subjected to the bone-resorbing effects of PTH for a prolonged period. Hungry bone syndrome can also be observed after treatment of other diseases that are associated with excessive bone resorption. It has been described after radioactive iodine treatment of a patient with Graves' disease.⁴³⁶

Chelation

Decreases in ionized calcium have been reported with fos-carnet, a pyrophosphate analogue that is used as an antiviral agent,⁴³⁷ perhaps because of the formation of complexes between ionized calcium and the drug.

Hyperphosphatemia caused by phosphate administration or rapid destruction of soft tissue (e.g., rhabdomyolysis,

chemotherapy for hematologic malignancies) may produce profound hypocalcemia by directly complexing and precipitating calcium in bone or soft tissues, by inhibiting bone resorption, and by blocking renal synthesis of calcitriol (see "Hyperphosphatemia").

Massive infusions of citrated blood products may cause hypocalcemia, presumably because citrate complexes with calcium in the recipient's plasma.⁴³⁸ Large doses of ethylenediaminetetra-acetic acid (EDTA)-containing radiographic contrast dyes have also been reported to cause hypocalcemia.

Hypocalcemia resulting from complexes of calcium and fluoride has been reported with hydrofluoric acid burns⁴³⁹ or ingestion.⁴⁴⁰

Neonatal Hypocalcemia

Neonatal hypocalcemia is seen in infants of hyperparathyroid mothers, infants of diabetic mothers, premature infants, and infants with birth asphyxia. The cause of hypocalcemia in infants of diabetic mothers is likely multifactorial. Prematurity per se does not account for the higher incidence.⁴⁴¹ The response of premature infants and infants of diabetic mothers to exogenous PTH suggests that functional hypoparathyroidism may, in part, account for the increased hypocalcemia in these two populations.^{441,442} The hypocalcemia in infants of hyperparathyroid mothers is presumably secondary to the maternal hypercalcemia that, in turn, suppresses fetal parathyroid function.⁴⁴³

Human Immunodeficiency Virus Infection

Hypocalcemia is sixfold more prevalent in HIV-infected patients than in the general population.⁴⁴⁴ Although hypocalcemia is often a consequence of antiretroviral and antibiotic/antimycotic therapy, vitamin D deficiency and hypomagnesemia are also common in patients with AIDS. Impaired parathyroid responsiveness to hypocalcemia has also been documented (see Chapter 38).

Critical Illness

Hypocalcemia is commonly seen in critically ill patients and is thought to be a reflection of parathyroid gland suppression, failure to activate vitamin D, calcium chelation or sequestration, hypomagnesemia, or some combination of these. However, an increased basal level and secretory response of PTH to lowering of serum calcium has been observed in some septic and nonseptic patients in intensive care units, emphasizing the multifactorial origin of the hypocalcemia.⁴⁴⁵ There was a correlation between cytokine levels and hypocalcemia in this study, as in others, suggesting that these inflammatory agents may play a role in redistribution of calcium to the intracellular or other pools. Interleukins 1 and 6 have been shown to increase the expression of the CASR on parathyroid cells and to lower PTH secretion and blood calcium levels in rats injected with the cytokine.^{446,447}

Severe acute pancreatitis is often associated with hypocalcemia, and this association is a negative prognostic indicator. The hypocalcemia occurs shortly after the onset of the pancreatitis and is associated with an increase in PTH levels, suggesting that parathyroid function is normal. It has long been thought that this hypocalcemia is secondary to the deposition of "calcium soaps" consisting of calcium and fatty acids. Supporting this hypothesis, studies in a patient with a pancreatic fistula demonstrated hypocalcemia (4.3 mg/dL) in the setting of high levels of calcium (26 mg/dL) and fatty acids in ascitic fluid.⁴⁴⁸ Subsequent studies in a rat model supported this finding and demonstrated that oleate has a high binding capacity for

calcium.⁴⁴⁹ However, other investigations in a porcine model of experimental pancreatitis demonstrated that hypocalcemia does not occur if the animals are subjected to thyroidectomy before the induction of pancreatitis.⁴⁵⁰ This finding suggests a role for calcitonin in the development of hypocalcemia with acute pancreatitis, although several clinical studies have documented normal calcitonin levels in hypocalcemic individuals with pancreatitis.⁴⁵¹

Severe hypocalcemia with hypercalcitoninemia and hypophosphatemia has been reported in the patients with toxic shock syndrome sepsis and in critically ill patients.⁴⁵² As in acute pancreatitis, this hypocalcemia is usually accompanied by increased serum levels of PTH, and the degree of hypocalcemia is a negative prognostic indicator. The mechanism of hypocalcemia in these patients is likely to be heterogeneous and has not been clearly defined.

Treatment of Hypocalcemia

Acute hypocalcemia is an emergency that requires prompt attention. If symptoms of neuromuscular irritability are present and carpopedal spasm is elicited on physical examination, treatment with intravenous calcium is indicated until the signs and symptoms of hypocalcemia subside. Approximately 100 mg of elemental calcium should be infused over a period of 10 to 20 minutes (Table 28-6). If this is not sufficient to alleviate the clinical findings of hypocalcemia, an infusion of 100 mg/hour can be given to adults for several hours, with close monitoring of calcium levels. In hypocalcemia associated with hypomagnesemia, magnesium replacement also is required. Magnesium should be given intravenously, 100 mEq over 24 hours in the acute setting. Because most of the parenteral magnesium is excreted in the urine, oral magnesium oxide should be instituted as soon as possible to replete body stores. Special caution and reduced doses are necessary when administering magnesium to patients in renal failure (see "Disorders of Magnesium Metabolism").

The treatment of hypocalcemia should be directed at the underlying disorder. In all cases, replacement with exogenous calcium (1 to 3 g of elemental calcium daily, given orally) should be instituted. Calcium carbonate is the least expensive formulation, but it requires acidification for efficient absorption. This becomes important for patients with achlorhydria and for those in whom gastric acid production is being suppressed with pharmacologic agents. Notable in this respect is the acid-buffering capacity of calcium carbonate. It is recommended that patients take their calcium carbonate supplements in divided doses of 1 g or less. The calcium should be taken with food or citrus drinks to promote maximal absorption.

In cases of vitamin D deficiency or resistance, the metabolite of vitamin D chosen depends on the underlying disorder. If impaired renal 1 α hydroxylation is present, such as in renal failure, hypoparathyroidism (or PTH resistance), or the vitamin D-dependent rickets syndromes, metabolites that do not require this modification should be administered (calcitriol 0.25 to 1 μ g/day or dihydroxycholesterol 0.2 to 1 mg/day). If decreased intake or increased losses are the problem, vitamin D should be administered and the treatment directed at the underlying disorder. Initial repletion of stores can be undertaken with 50,000 IU of vitamin D daily for 2 to 3 weeks, followed by weekly or bimonthly administration until the underlying disorder has been treated. In patients with resistance to vitamin D, such as those taking phenytoin, high doses (50,000 IU one to three times weekly) should be used as maintenance therapy. In other patients, once treatment of

Na/K phosphate (neutral)				Capsule	250 mg	8.1 mmol						
K phosphate (neutral)				Capsule	250 mg	8.1 mmol	soln	94 mg/mL	3.0 mmol/mL			
Na phosphate (neutral)							soln	94 mg/mL	3.0 mmol/mL			

*Molecular weights (MW) shown are for the usual chemical form, including water molecules (e.g., $\text{MgSO}_4 \cdot 7 \text{H}_2\text{O}$).

[†]Other formulations exist. Those shown are among those approved in the United States.

[‡]Phosphate preparations contain buffered mixtures of monobasic (H_2PO_4^-) and dibasic (HPO_4^{2-}) ions; the phosphorus content therefore is specified in millimoles. Oral phosphates contain 7 mEq sodium and potassium per capsule (Na/K form) or 14 mEq potassium per capsule (K form). Parenteral solutions typically contain 4 mEq of sodium or potassium per milliliter.

MW, molecular weight; soln, solution.

Data from *Drug Facts and Comparisons*, 1995 ed. St. Louis: Facts and Comparisons.

the underlying disorder and repletion of body stores have been addressed, two multivitamins (i.e., 800 IU) per day should provide sufficient maintenance therapy. In cases of severe malabsorption, vitamin D can be administered parenterally.

Patients should be monitored closely, both to assess response to therapy and to prevent therapeutic complications. Serum calcium should be monitored frequently (daily in profound hypocalcemia, weekly in moderate hypocalcemia) for the first month of therapy. Concomitant with resolution of the hypocalcemia, a decline in serum PTH should be observed as the secondary hyperparathyroidism resolves. Measurement of serum PTH and assessment of 24-hour urinary calcium excretion should be performed within 2 to 4 weeks after institution of therapy. The urinary calcium measurement reflects the effect of therapy on the patient's ability to absorb calcium and the net uptake of calcium by bone. A low urine calcium concentration indicates poor adherence to a regimen, poor absorption of calcium, or increased uptake by bone. In addition, the urine calcium level provides important information on which to base therapeutic modifications to avoid nephrolithiasis.

Once normalization of serum and urinary calcium and a decrease in PTH levels have been observed, a transition from aggressive replacement therapy to maintenance therapy should be undertaken to prevent hypercalcemia and nephrolithiasis. These same parameters should be monitored at 1 and 3 months after a dose change to assess

the effect of the therapeutic intervention. Monitoring of the alkaline phosphatase concentration can also be performed at this time. Alkaline phosphatase levels may actually increase soon after treatment is started, because of healing of the osteomalacic lesions; however, by 3 to 4 months after institution of therapy, a clear downward trend should be observed. Alkaline phosphatase and PTH values may remain elevated for 6 to 12 months after therapy begins; this should not be a cause for alarm, provided that the levels are declining and that monitoring of the other parameters indicates that therapy is effective.

The treatment of hypoparathyroidism is similar to that of vitamin D deficiency, with the exception that these patients have impaired renal 1α hydroxylation of $25(\text{OH})\text{D}$ and therefore require treatment with 1α -hydroxylated metabolites. PTH has been used experimentally for the treatment of hypoparathyroidism, with twice-daily injections providing a better result than once-daily administration.⁴⁵³ This therapy controls hypocalcemia with lower urine calcium excretion compared with calcium and calcitriol therapy, but it is expensive and requires parenteral administration. Therefore, oral calcium and 1α -hydroxylated vitamin D metabolites remain the mainstay of therapy. Monitoring of serum and urinary calcium should be performed as in the treatment of vitamin D deficiency.

Therapy in these patients is lifelong, and careful monitoring is required to avoid renal or hypercalcemic complications. The aim of therapy should be to maintain serum calcium in the low-normal range without causing frank

hypercalciuria, to avoid nephrolithiasis and decrease in GFR. Because PTH plays an important role in renal calcium reabsorption, difficulties are often encountered in attaining these therapeutic goals. In such cases, renal calcium losses can be minimized by the addition of a thiazide diuretic to the treatment regimen. As stated earlier, in patients with PHP, the intact distal tubular reabsorption of calcium leads less often to hypercalciuria and allows more aggressive treatment aimed at normalizing PTH levels, to protect bones from the hyperparathyroid bone disease sometimes seen in PHP.

One of the frustrations often encountered in treating patients with hypoparathyroidism is the fluctuating response to a seemingly stable therapeutic regimen. Episodes of hypercalcemia are occasionally observed without any discernible cause. Because of this, serum calcium should be monitored every 3 months to permit temporary withdrawal of calcitriol, should a hypercalcemic trend be observed. The half-life of this metabolite is short, so that discontinuation for a few days to 1 week, with subsequent resumption at a lower dose, is usually efficacious.

All patients receiving vitamin D metabolites and calcium need to be aware of potential therapeutic complications. Importantly, the mild symptoms of hypercalcemia should be emphasized to the patient. It is essential that these patients be aware that their calcium level should be monitored more frequently during intercurrent illnesses that may affect their absorption of calcium or their hydration status, and also on introduction of drugs such as thiazides or loop diuretics that might change the dosing requirement, to prevent the development of hypocalcemia or severe hypercalcemia.

DISORDERS OF PHOSPHATE METABOLISM

Hyperphosphatemia

Serum phosphate levels are controlled primarily by the rate of proximal renal phosphate reabsorption, which is due, in turn, to the integrated activity of the major sodium-dependent cotransporters (NaPi-IIa and NaPi-IIc). This activity is strongly downregulated by PTH and FGF23, both of which are stimulated by phosphate. Therefore, absent extraordinary filtered loads of phosphate, the capacity of normal kidneys to excrete phosphate is not easily exceeded. Consequently, the occurrence of hyperphosphatemia usually signifies impaired renal function, hypoparathyroidism, defective FGF23 action, a huge flux of phosphate into the ECF, or some combination of these factors (Table 28-7).

The most common cause of hyperphosphatemia is acute or chronic renal failure in which the GFR is so reduced that the usual daily load of phosphate cannot be excreted at a normal level of serum phosphate, despite maximal inhibition of phosphate reabsorption in the remaining functional nephrons. In hypoparathyroidism (or PHP), the serum phosphate level may rise to as high as 6 to 8 mg/dL because of loss of the tonic inhibitory effect of PTH on phosphate reabsorption, although increased FGF23 levels may prevent even further increases in serum phosphate.⁴⁵⁴ The hyperphosphatemia of hypoparathyroidism is only partly caused by the absence of PTH per se. Hypocalcemia may further impair phosphate clearance in this setting, and correction of hypocalcemia by treatment with vitamin D metabolites and oral calcium may reduce serum phosphate even if PTH levels remain low.⁴⁵⁵

TABLE 28-7

Causes of Hyperphosphatemia

Impaired Renal Phosphate Excretion

Renal insufficiency
Familial tumoral calcinosis
Endocrinopathies
 Acromegaly
 Hypoparathyroidism
 Pseudohypoparathyroidism
Heparin

Increased Extracellular Phosphate

Rapid Administration of Phosphate (Intravenous, Oral, Rectal)

Phosphate salts
Fosphenytoin
Liposomal amphotericin B

Rapid Cellular Catabolism or Lysis

Catabolic states
Tissue injury
 Hyperthermia
 Crush injuries
 Fulminant hepatitis
Cellular lysis
 Hemolytic anemia
 Rhabdomyolysis
 Tumor lysis syndrome

Transcellular Shifts of Phosphate

Metabolic acidosis
Respiratory acidosis

Other circumstances in which renal tubular phosphate excretion is decreased, in the absence of renal failure, include acromegaly,⁴⁵⁶ chronic therapy with heparin, and familial tumoral calcinosis.⁴⁵⁷ Familial tumoral calcinosis can result from inactivating mutations in either FGF23 or the O-linked glycosyl transferase GALNT3, which may glycosylate and activate FGF23.^{458,459} The choice of FGF23 assay is important, because the responsible FGF23 mutations may render the molecule more susceptible to proteolytic degradation, such that the blood levels of (inactive) carboxyl fragments may be quite high in contrast to low levels of (bioactive) intact FGF23.⁴⁵⁸ Affected patients may display focal hyperostosis; large, lobulated periarticular ectopic calcifications, especially around the shoulders or hips; hyperphosphatemia due to increased renal TRP; increased serum calcitriol despite normal or low serum PTH; and increased intestinal calcium absorption, consistent with the elevated serum calcitriol concentration. The disorder may manifest in childhood or adulthood, is more common among blacks, and is lifelong, with a tendency for the tumoral calcifications to progress at affected sites. In contrast to the elevated serum calcitriol, hyperphosphatemia is not a constant feature of tumoral calcinosis, although it tends to be most severe in those with prominent calcifications. Despite their chronic hyperphosphatemia, secondary hyperparathyroidism does not develop in these patients, presumably because of the high levels of calcitriol and intestinal hyperabsorption of calcium. Treatment is problematic, although some success has been reported with phosphate-binding antacids, calcium deprivation, and calcitonin therapy.

Hyperphosphatemia may result from overly rapid administration of therapeutic phosphate preparations or phosphate-rich drugs (fosphenytoin, liposomal amphotericin B), especially if renal function is compromised,⁴⁶⁰ or from rapid shifts of phosphate out of cells, most often provoked by mechanical injury or metabolic insult. Most

cases of hyperphosphatemia associated with intestinal phosphate loads have involved children who received phosphate-containing laxatives or enemas or older adults with impaired renal function receiving phosphate-based cathartics in preparation for colonoscopy.⁴⁶¹ Hyperphosphatemia due to cytolytic release of intracellular phosphate can be quite dramatic, with serum phosphate concentrations up to or exceeding 20 mg/dL. This was described initially as a complication of rapid induction chemotherapy for certain hematologic malignancies (“tumor lysis syndrome”), although it also may occur from cellular injury associated with trauma, hyperthermia, overwhelming infection, hemolysis, rhabdomyolysis, or metabolic acidosis.⁴⁶² Rarely, apparent hyperphosphatemia reflects measurement artifact caused by paraproteins in myeloma.⁴⁶³

Most often, hyperphosphatemia is mild and asymptomatic, although chronic hyperphosphatemia is an important factor in the development of secondary hyperparathyroidism in progressive renal failure. The clinical manifestations of acute, severe hyperphosphatemia are related mainly to those of the accompanying hypocalcemia, caused by formation of insoluble calcium phosphate precipitates. Tetany, muscle cramps, paresthesias, and seizures may occur, and these may be compounded by other metabolic disturbances (e.g., hyperkalemia, acidosis, hyperuricemia) that frequently coexist. Generalized precipitation of calcium phosphate into soft tissues may produce organ dysfunction, notably renal failure.⁴⁶¹

Therapeutic options for hyperphosphatemia are limited. Volume expansion may be helpful to improve GFR in acute syndromes. Identification and removal of any exogenous sources of phosphate is important, and phosphate-binding

aluminum hydroxide antacids may be useful in limiting intestinal phosphate absorption and chelating phosphate secreted into the intestine. Hemodialysis is the most effective approach and should be considered early in severe hyperphosphatemia, especially in the tumor lysis syndrome and particularly if symptomatic hypocalcemia cannot be adequately treated for fear of inducing widespread soft tissue calcification.

Hypophosphatemia

Etiology

Hypophosphatemia may result from one or more of three general mechanisms (Table 28-8): increased urinary losses due to decreased net renal TRP; rapid shifts of phosphate from ECF into the intracellular space or the mineral phase of bone; or, rarely, severe and selective deprivation of dietary phosphate, as may occur with chronic ingestion of large amounts of nonabsorbable aluminum-containing antacids. Fasting or starvation does not lead directly to hypophosphatemia, apparently because phosphate is mobilized from catabolized bone and soft tissue in amounts sufficient to maintain serum phosphate, even during prolonged caloric deprivation.⁴⁶⁴ Starvation does induce phosphate deficiency and, therefore, predisposes to subsequent hypophosphatemia.⁴⁶⁵

Chronic hypophosphatemia usually can be traced to ongoing renal phosphate wasting. Elevation of serum PTH for any reason (other than renal failure), as in primary hyperparathyroidism or secondary hyperparathyroidism due to vitamin D or calcium deficiency, results in inhibition of TRP and fasting hypophosphatemia. Phosphate

TABLE 28-8

Causes of Hypophosphatemia

Reduced Renal Tubular Phosphate Reabsorption

Excess PTH or PTHrP

Primary hyperparathyroidism
PTHrP-dependent hypercalcemia of malignancy
Secondary hyperparathyroidism
Vitamin D deficiency/resistance
Calcium starvation or malabsorption
Imatinib
Rapid, selective correction of severe hypomagnesemia

Excess FGF23 or Other “Phosphatonins”

Familial hypophosphatemic rickets (XLH)
Autosomal dominant hypophosphatemic rickets (ADHR)
Autosomal recessive hypophosphatemia (ARHP)
Tumor-induced osteomalacia syndrome (TIO)
McCune-Albright syndrome (fibrous dysplasia)
Epidermal nevus syndrome
Idiopathic hypercalciuria

Intrinsic Renal Disease

Fanconi syndromes, other renal tubular disorders
Cystinosis
Amyloidosis
Hemolytic uremic syndrome
Magnesium deficiency
NaPi-IIa mutations
NaPi-IIc mutations (HHRH)

Wilson's disease
Multiple myeloma
Heavy metal toxicity
Rewarming or hyperthermia

Other

Poorly controlled diabetes, alcoholism
Hyperaldosteronism
Post-partial hepatectomy

Post-renal transplantation

Drugs or toxins

Ethanol	High-dose estrogens
Acetazolamide, other diuretics	Ifosfamide
High-dose glucocorticoids	Cisplatin
Bicarbonate	Suramin
Toluene	Foscarnet
Heavy metals (Pb, Cd)	N-methyl formamide
Calcitonin	Bisphosphonates
Tenofovir	Paraquat

Shifts of Extracellular Phosphate into Cells or Bone

Acute Intracellular Shifts

Intravenous glucose, fructose, glycerol
Insulin therapy for hyperglycemia, diabetic ketoacidosis
Catecholamines (epinephrine, albuterol, terbutaline, dopamine)
Thyrotoxic periodic paralysis
Acute respiratory alkalosis, salicylate intoxication, acute gout
Gram-negative sepsis, toxic shock syndrome
Recovery from acidosis, starvation, anorexia nervosa, hepatic failure
Rapid cellular proliferation
Leukemic blast crisis
Intensive erythropoietin, G-CSF therapy

Accelerated Net Bone Formation

Post-parathyroidectomy
Osteoblastic metastases
Treatment of vitamin D deficiency
Antiresorptive therapy for severe Paget's disease

Impaired Intestinal Phosphate Absorption

Aluminum-containing antacids

clearance also is increased in PTHrP-associated hypercalcemia of malignancy, although when such patients develop severe hypercalcemia, hypophosphatemia may be masked initially by underlying volume depletion and compromised GFR. Therapy with the tyrosine kinase inhibitor imatinib appears to cause hypophosphatemia, at least in part by inhibiting bone turnover, lowering serum calcium, and stimulating secondary hyperparathyroidism.⁴⁶⁶ When PTH secretion is compromised by severe hypomagnesemia, rapid intravenous administration of magnesium alone, without concurrent attention to coexisting hypocalcemia, can provoke massive phosphaturia and hypophosphatemia in patients with underlying phosphate depletion.

The discovery that gain-of-function mutations in FGF23 cause rickets (i.e., ADHR) inaugurated a new era in the understanding of phosphate homeostasis.⁴⁶⁷⁻⁴⁶⁹ Elevated FGF23 also occurs in autosomal recessive hypophosphatemia, which is caused by mutations in the gene encoding dentin matrix protein-1 (DMP1). DMP1 is expressed in osteocytes and presumably regulates local production of FGF23.⁴⁷⁰ Immunoassays for FGF23⁴⁷¹ have pointed to elevated circulating FGF23 as at least one “phosphatonin” responsible for the reduction of phosphate reabsorption and serum calcitriol levels observed in the more common disorder, X-linked hypophosphatemic rickets, in the rare but distinctive tumor-induced osteomalacia and epidermal nevus syndromes, and in the approximately 50% of patients with McCune-Albright syndrome (fibrous dysplasia of bone) who manifest hypophosphatemia.^{467-469,472-474} These disorders share a common biochemical phenotype, which may include a more generalized proximal tubular dysfunction, with modest proteinuria and aminoaciduria. Serum calcium usually is normal or low-normal, urinary calcium often is low, PTH is normal or only slightly elevated, and calcitriol is inappropriately normal. The clinical picture is dominated by weakness, bone pain, and other features attributable to the associated rickets or osteomalacia (see Chapter 29). Increased FGF23 also may play a role in impaired phosphate reabsorption, which is seen in the 20% or so of patients with calcium kidney stones and idiopathic hypercalciuria who exhibit fasting hypophosphatemia,⁴⁷⁵ although a few such patients may harbor mutations in the NaPi-IIa cotransporter.⁴⁷⁶

Renal phosphate clearance may be impaired in the context of a more generalized renal tubular disorder such as the Fanconi syndromes or others associated with systemic diseases such as amyloidosis, Wilson's disease, or cystinosis (see Table 28-8). In addition to NaPi-IIa mutations, inactivating mutations in the NaPi-IIc cotransporter, also expressed in the proximal tubule and known to be regulated by both PTH and FGF23, have been shown to account for the rare disorder known as hereditary hypophosphatemic rickets with hypercalciuria, in which primary renal tubular phosphate wasting causes appropriate elevation of serum calcitriol and resulting hypercalciuria.^{477,478} Other causes of impaired renal TRP include the osmotic diuresis associated with poorly controlled diabetes, alcoholism, hyperaldosteronism, or exposure to any of a wide variety of drugs or toxins (see Table 28-8). The pathogenesis of phosphate wasting that often follows partial hepatectomy or renal transplantation remains unclear, but humoral mechanisms seem to be involved.^{479,480}

Rapid egress of extracellular phosphate into cells is the cause of the hypophosphatemia that develops acutely during administration of intravenous glucose, insulin therapy for hyperglycemia, administration of catecholamines (pressors or bronchodilators), thyrotoxic periodic paralysis, profound respiratory alkalosis, refeeding

syndrome in the wake of severe acidosis or starvation, recovery from acute hepatic failure (in which hypophosphatemia is a recognized favorable prognostic factor⁴⁸¹), or other circumstances involving rapid cellular proliferation, such as leukemic blast crisis or responsiveness to hematopoietic growth factors. Hypophosphatemia in these situations is most pronounced when there is underlying phosphate depletion, as in hyperparathyroidism or vitamin D deficiency, or after prolonged malnutrition, alcoholism, or glycosuria. Accelerated uptake of phosphate into cells is particularly common in patients who have experienced surgery, burns, or trauma, in whom it may be promoted by high levels of circulating catecholamines and exacerbated by concurrent respiratory alkalosis, fever, volume expansion, sepsis, and hypokalemia. Situations of greatly accelerated net bone formation—such as in hungry bone syndrome occurring immediately after parathyroidectomy for primary or tertiary hyperparathyroidism; during initial treatment of severe vitamin D deficiency or Paget's disease; or occasionally in patients with extensive osteoblastic bone metastases—may manifest hypophosphatemia as well as hypocalcemia.

Clinical Features

The clinical significance of hypophosphatemia depends on the presence and severity of underlying phosphate depletion. The status of the total-body phosphorus pool, and more particularly the critical intracellular pool, is reflected only indirectly by the concentration of phosphate in the ECF, which contains less than 0.5% of body phosphorus. Therefore, although serum phosphate concentrations generally are used to characterize hypophosphatemia as severe (<1 to 1.5 mg/dL or <0.3 to 0.5 mmol/L), moderate (1.5 to 2.2 mg/dL or 0.5 to 0.7 mmol/L), or mild (2.2 to 3.0 mg/dL or 0.75 to 1.0 mmol/L), serum phosphate may be normal or even high (depending on renal function) in the presence of profound intracellular phosphate deficiency. Conversely, it may be low when intracellular phosphate is relatively normal, such as after a sudden movement of extracellular phosphate into cells.

The prevalence of severe hypophosphatemia among hospitalized patients overall is less than 1%, whereas mild or moderate hypophosphatemia may be detected in 2% to 5% of these patients.⁴⁸² Hypophosphatemia is recognized most often in critically ill patients, alcoholics or other malnourished individuals, decompensated diabetics, and those with acute infectious or pulmonary disorders.⁴⁸²

The clinical manifestations of severe hypophosphatemia are protean. Among the most common are various neuromuscular symptoms, ranging from progressive lethargy, muscle weakness, and paresthesias to paralysis, coma, and even death, depending on the severity of the phosphate depletion. Confusion, profound weakness, paralysis, seizures, and other major sequelae usually are limited to those patients with serum phosphate concentrations lower than 0.8 to 1.0 mg/dL.⁴⁸³ Biochemical evidence of muscle injury is observed within 1 to 2 days in more than one third of patients whose serum phosphate concentrations fall to less than 2 mg/dL.⁴⁸⁴ Overt rhabdomyolysis also may occur, especially in the setting of chronic alcoholism with underlying malnutrition and phosphate depletion.^{485,486} However, by the time this is recognized, the serum phosphate level often has been raised by the large amounts of cellular phosphate released from damaged muscle. Reversible respiratory failure due to respiratory muscle weakness may preclude successful weaning from ventilatory support.^{487,488} Left ventricular dysfunction, heart failure, and ventricular arrhythmias may result from profound hypophosphatemia but may

not be significant if the serum phosphate concentration is greater than 1.5 mg/dL.⁴⁸⁹ Correction of moderate hypophosphatemia (<2 mg/dL) in patients with septic shock led to a significant increase in blood pressure as well as left ventricular function and arterial pH.⁴⁸⁹ Hematologic sequelae of severe hypophosphatemia include hemolysis, platelet dysfunction with bleeding, and impaired leukocyte function (phagocytosis and killing).⁴⁹⁰ Erythrocytes demonstrate increased fragility; altered membrane composition, rigidity, and microspherocytosis; and reduced levels of ATP and 2,3-diphosphoglycerate.⁴⁹⁰ The reduction in erythrocyte 2,3-diphosphoglycerate impairs oxyhemoglobin dissociation and may thereby reduce oxygen delivery to tissues. This problem, together with accelerated hemolysis, may provoke a substantial increase in cardiac output. The blockade in cellular glycolysis becomes demonstrable at levels of serum phosphate between 1 and 2 mg/dL.⁴⁹¹ Glucose intolerance and insulin resistance also have been demonstrated in these patients.⁴⁹²

Treatment

Hypophosphatemia appears most often in acutely or critically ill individuals. Accordingly, it often is difficult to discern whether hypophosphatemia is responsible for features of the multiple organ dysfunction commonly encountered in this population. For example, although depression of intracellular high-energy organophosphates has been demonstrated during treatment of diabetic ketoacidosis and phosphate repletion leads to more rapid recovery of erythrocyte 2,3-diphosphoglycerate concentrations, opinion is divided as to whether phosphate therapy in this setting hastens recovery, prevents complications, or improves mortality.^{493,494} Nevertheless, because severe hypophosphatemia has been associated, in a variety of clinical settings, with serious neuromuscular, cardiovascular, and hematologic dysfunction that is at least partially reversible with phosphate repletion, most now agree that a relatively low threshold for treatment should be adopted.⁴⁸⁹

The decision to correct hypophosphatemia urgently should be guided by the estimated severity of the cellular phosphate deficit, the presence of signs or symptoms suggestive of phosphate depletion, and the overall clinical status of the patient. The presence of renal insufficiency (a risk for iatrogenic hyperphosphatemia), concomitant administration of intravenous glucose (alone or as a component of hyperalimentation solutions), and the potential for aggravating coexistent hypocalcemia also should be considered.

Limited data are available from clinical trials to predict the appropriate dose and rate of phosphate administration. In patients without severe renal insufficiency or hypocalcemia, administration of intravenous phosphate at rates of 2 to 8 mmol/hour of elemental phosphorus over 4 to 8 hours frequently corrects hypophosphatemia without provoking hyperphosphatemia or hypocalcemia.^{482,495-497} Suggested guidelines based on serum phosphate are shown in Table 28-9. It is essential that serum calcium and phosphate be monitored every 6 to 12 hours during and after phosphate therapy, both to detect untoward consequences and because many patients require additional infusions for recurrent hypophosphatemia within 24 to 48 hours after apparently successful repletion.⁴⁹⁶ Less acute or severe hypophosphatemia should be managed with oral (or enteral) phosphate supplements if possible, usually given as a total of 1.0 to 2.0 g/day (as elemental phosphate) of neutral sodium or potassium phosphate in divided doses three to four times a day (see Table 28-6). In many patients, however, oral phosphate therapy is limited by gastrointestinal symptoms such as nausea or diarrhea.

TABLE 28-9

Guidelines for Urgent Treatment of Hypophosphatemia*

Serum PO ₄ (mg/dL)	Rate of Infusion (mmol/hr)	Duration (hr)	Total PO ₄ (mmol)
<2.5	2.0	6	12
<1.5	4.0	6	24
<1.0	8.0	6	48

*Rates shown are normalized for a 70-kg person. Most formulations available in the United States provide 3 mmol/mL of sodium or potassium phosphate. The following factors should be considered: severity of hypophosphatemia, likelihood of underlying phosphate depletion, clinical condition of the patient, renal function, serum calcium, and concurrent parenteral therapy (glucose, hyperalimentation).

DISORDERS OF MAGNESIUM METABOLISM

The fourth most abundant extracellular cation, magnesium, like calcium, plays a critical physiologic role, particularly in neuromuscular function but also as a component of the mineral phase of bone. Intracellular magnesium is crucial for normal energy metabolism, as a cofactor for ATP and numerous enzymes and transporters, and this is reflected in the rather global clinical effects that accompany disorders of magnesium homeostasis. Hypomagnesemia and hypermagnesemia are among the most common electrolyte disturbances; one or the other of these abnormalities is observed in as many as 20% of hospitalized patients and even more frequently (30% to 40%) among those admitted to intensive care units.⁴⁹⁸

Hypermagnesemia

Magnesium homeostasis is achieved mainly through highly efficient regulation of tubular magnesium reabsorption in the loop of Henle.¹ Because normal kidneys can readily excrete even large amounts of magnesium (i.e., 500 mEq/day), high filtered loads of magnesium rarely cause hypermagnesemia except in patients with significant renal insufficiency.⁴⁹⁹ Increased magnesium loads in such cases may arise from ingestion of large amounts of oral magnesium salts, typically given as cathartics or antacids, or from extensive soft tissue ischemia or necrosis in patients with trauma, sepsis, cardiopulmonary arrest, burns, or shock (Table 28-10).⁴⁹⁹ Hypermagnesemia may result from parenteral administration of magnesium salts, such as when magnesium is used to treat preeclampsia or as a tocolytic.⁵⁰⁰ The infants of such hypermagnesemic mothers may manifest transient hypermagnesemia as well, along with parathyroid suppression and neurobehavioral symptoms.^{501,502} The use of oral magnesium preparations as laxatives may lead to hypermagnesemia if absorption is increased by intestinal ileus, obstruction, or perforation.⁵⁰³

The most prominent clinical manifestations of hypermagnesemia are vasodilatation and neuromuscular blockade, which may involve both presynaptic and postsynaptic inhibition of neuromuscular transmission.⁵⁰⁴ Signs and symptoms usually do not appear unless the serum magnesium concentration exceeds 4 mEq/L.⁴⁹⁹ Hypotension, often refractory to pressors and volume expansion, may be one of the earliest signs of progressive hypermagnesemia.^{504,505} Lethargy, nausea, and weakness, accompanied by reduction or loss of deep tendon reflexes, may progress to stupor or coma with respiratory insufficiency or

quadripareisis at serum concentrations in excess of 8 to 10 mEq/L. Gastrointestinal hypomotility or ileus is common. Facial flushing and pupillary dilatation may be observed. Hypotension may be complicated by a paradoxical relative bradycardia, and other cardiac effects may be evident, including prolongation of the PR, QRS, and QTc intervals, appearance of heart block, and, ultimately, asystole as serum concentrations approach 20 mEq/L.

Hypermagnesemia activates CASRs in the parathyroids, thereby suppressing PTH secretion,⁵⁰⁶ and in the renal distal tubules, thereby reducing tubular calcium and magnesium reabsorption. Severe hypocalcemia opposes the effect of hypermagnesemia on PTH secretion, so that serum PTH may remain within the normal range but still be inappropriate for the level of serum calcium.⁵⁰⁷

Successful treatment of hypermagnesemia requires identification and interruption of the source of magnesium and measures to increase clearance of magnesium from the ECF. Use of magnesium-free cathartics or enemas to accelerate clearance of ingested magnesium from the gastrointestinal tract, together with vigorous intravenous hydration, usually is successful in reversing hypermagnesemia. Refractory cases, especially those with advanced renal insufficiency, may require hemodialysis. Infusions of intravenous calcium (100 to 200 mg) have been advocated as an effective antidote to hypermagnesemia, and there are examples in which this therapy has apparently been successful, at least in the short run.^{499,504,508}

Hypomagnesemia

Hypomagnesemia may occur because of impaired intestinal magnesium absorption or, more commonly, because of excessive gastrointestinal losses due to diarrhea, preprocedural bowel preparation, or prolonged drainage. Most often, hypomagnesemia reflects defective renal tubular reabsorption of magnesium, although rapid shifts into cells, other extrarenal losses, or incorporation into new bone may occur (Table 28-11). Because only 1% of the body's magnesium content is present in ECF, measurements of serum total or ionized magnesium may not adequately reflect total-body magnesium or the magnesium status of the intracellular compartment in critical tissues

such as muscle.⁵⁰⁹ Therefore, patients with deficiency of tissue magnesium may fail to manifest overt hypomagnesemia⁵¹⁰ while exhibiting abnormal retention (i.e., >50% in 24 hours) of infused magnesium, a maneuver that may be employed to assess magnesium status.⁵¹¹

Etiology

Intestinal Causes of Hypomagnesemia. Selective dietary magnesium deficiency does not occur, and in fact it is remarkably difficult to induce magnesium depletion experimentally by feeding magnesium-deficient diets, probably because renal magnesium conservation is so efficient. Large amounts of magnesium may be lost in chronic diarrheal states (this fluid may contain more than 10 mEq/L of magnesium) or via intestinal fistulae or prolonged gastrointestinal drainage.⁵¹² More commonly, magnesium becomes trapped within fatty acid soaps in disorders associated with chronic malabsorption.⁵¹³ Investigation of a rare autosomal recessive disorder, hypomagnesemia with secondary hypocalcemia, has led to identification of the transient receptor potential channel protein TRPM6, in the form of a heterooligomer with the closely related channel protein TRPM7, as a key molecular mediator of intestinal (and renal tubular) transepithelial magnesium transport.⁵¹⁴

Renal Causes of Hypomagnesemia. Roughly 60% of renal magnesium reabsorption occurs in the thick ascending limb of Henle's loop, and another 5% to 10% is reabsorbed in the distal tubules.¹ Investigations of the pathogenesis of several genetic disorders associated with renal magnesium wasting have identified key pathways of magnesium reabsorption at these sites (see Table 28-11).

In familial hypomagnesemia with hypercalciuria and nephrocalcinosis, loss-of-function mutations in the claudin 16 gene (*CLDN16*) that encodes the paracellin-1 protein, a component of the tight junctions between adjacent epithelial cells (or in the related gene, *CLDN19*), selectively impair paracellular reabsorption of magnesium (and calcium) in response to the (lumen-positive) transepithelial voltage gradient.^{515,516}

In Bartter's syndromes, inactivating mutations in any of several transporters involved in sodium chloride reabsorption in the ascending limb cause salt wasting, compromise the voltage gradient, and similarly impair paracellular magnesium and calcium reabsorption.⁵¹⁷⁻⁵¹⁹ In autosomal dominant hypocalcemia, mutations causing increased sensitivity of CASRs to cationic agonists may cause hypomagnesemia, as well as hypocalcemia, through inappropriate CASR-dependent suppression of PTH secretion and of renal tubular cation reabsorption.⁵²⁰

In Gitelman's syndrome, inactivating mutations in the gene encoding the luminal thiazide-sensitive sodium-chloride cotransporter (NCC), which is expressed in the distal convoluted tubules, leads to sodium chloride and magnesium wasting, in this case with hypocalciuria.^{517-519,521}

The mechanisms by which impaired NCC activity compromises (transcellular) magnesium reabsorption in this segment are unclear, although NCC-knockout mice (or normal mice treated with thiazides) display reduced distal tubular expression of the TRPM6 channel protein required for normal magnesium transport across the apical membrane.³²⁹

Mutations in the FXD2 γ -subunit of the distal tubular basolateral Na⁺,K⁺-ATPase similarly impair salt and magnesium reabsorption at that site and account for some, but not all, cases of isolated renal magnesium wasting.^{522,523} An autosomal recessive form of renal hypomagnesemia is caused by inactivating mutations in the epidermal growth factor gene; this likely also explains why hypomagnesemia

may complicate the use of cetuximab, a monoclonal antibody directed against the epidermal growth factor receptor.⁵²⁴ Another genetic syndrome that, like Gitelman's syndrome, features renal magnesium wasting and hypocalciuria (and therefore presumably a defect in distal tubular function) in association with hypertension and hypercholesterolemia, is linked to a mutation in mitochondrial transfer RNA DNA.⁵²⁵

Most often, renal magnesium wasting is attributable to an acquired abnormality in tubular magnesium reabsorption. In normal subjects, magnesium reabsorption is virtually complete within several days after institution of experimental dietary magnesium deficiency, even before the serum magnesium level has declined substantially.⁵²⁶ Therefore, the finding of more than 1 mEq/day of urinary magnesium in a frankly hypomagnesemic patient indicates a defect in renal tubular magnesium reabsorption. The causes of acquired primary tubular magnesium wasting include various tubulointerstitial disorders, recovery from acute tubular necrosis or obstruction, renal transplantation, various endocrinopathies, alcoholism, and exposure to certain drugs (see Table 28-11).

Hypomagnesemia or magnesium depletion due to subnormal renal reabsorption may complicate a variety of endocrinopathies, including hyperaldosteronism, hyperthyroidism, and disorders associated with hypercalcemia, hypercalciuria, or phosphate depletion.⁵¹¹ In primary hyperparathyroidism, PTH stimulates increased tubular magnesium reabsorption, but this is opposed by a direct tubular effect of hypercalcemia. As a result, the serum magnesium level in patients with primary hyperparathyroidism usually is normal or only slightly reduced.⁵²⁷ In hypoparathyroidism, serum and urinary magnesium concentrations are low. The magnesium depletion in hypoparathyroidism is consistent with loss of both the magnesium-retaining renal action of PTH and the stimulatory effect of calcitriol on intestinal magnesium absorption.⁵²⁸

Diabetes is among the disorders most commonly associated with hypomagnesemia.^{529,530} The severity of the hypomagnesemia in diabetics correlates with indices of glycosuria and poor glycemic control,⁵³¹ suggesting that urinary losses of magnesium on the basis of glycosuria may partly explain the magnesium depletion. Rapid correction of hyperglycemia with insulin therapy causes magnesium

to enter cells and may further lower the extracellular magnesium concentration during treatment.

Alcoholism is another very common clinical setting in which hypomagnesemia occurs. Magnesium depletion in alcoholism may result in part from nutritional deficiency of magnesium, overall caloric starvation and ketosis, and gastrointestinal losses due to vomiting or diarrhea, but an acute magnesuric effect of alcohol ingestion most likely plays the major role.⁵³² This effect of alcohol is most evident during the rising limb of the blood ethanol curve and may be related to transient suppression of PTH secretion.⁵³² Other factors that may contribute to hypomagnesemia in alcoholism include pancreatitis, malabsorption, secondary hyperaldosteronism, respiratory alkalosis, and elevated plasma catecholamines, which increase intracellular sequestration of magnesium.⁵¹¹

A number of drugs have been identified as causes of defective renal tubular magnesium reabsorption and hypomagnesemia.⁵¹¹ These include diuretics (especially loop diuretics), digoxin, cisplatin, cetuximab, pentamidine, cyclosporine, tacrolimus, interleukin 2, aminoglycosides, foscarnet, and amphotericin B. Most often, drug-induced hypomagnesemia is mild and reversible, particularly when it is associated with diuretic therapy. In more than half of patients treated with cisplatin, hypomagnesemia occurs within days or weeks, and roughly half of those who develop it exhibit persistent hypomagnesemia many months or even years later. The median duration of hypomagnesemia in cisplatin-treated patients is about 2 months, but recovery has been observed for up to 2 years after treatment.⁵³³ Cisplatin may induce a more global nephropathy and azotemic renal failure, but the magnesium wasting appears to be an isolated functional abnormality.

Other Causes of Hypomagnesemia. Magnesium, like phosphate, is a major intracellular ion, and significant shifts of magnesium from the extracellular compartment may occur during recovery from chronic respiratory acidosis or acute ketoacidosis, refeeding, or administration of hyperalimentation solutions and in response to elevations of circulating catecholamines.⁵¹¹ Other rapid losses of extracellular magnesium may occur during periods of greatly accelerated net bone formation (after parathyroidectomy, during recovery from vitamin D deficiency, or with osteoblastic metastases) or with large losses due to pancreatitis, cardiopulmonary bypass surgery,⁵³⁴ massive transfusion,⁵³⁵ extensive burns, excessive sweating, or pregnancy or lactation.

Consequences of Hypomagnesemia

Most of the signs and symptoms of hypomagnesemia reflect alterations in neuromuscular function: tetany, hyperreflexia, positive Chvostek and Trousseau signs, tremors, fasciculations, seizures, ataxia, nystagmus, vertigo, choreoathetosis, muscle weakness, apathy, depression, irritability, delirium, and psychosis.⁵¹¹ Patients usually are not symptomatic unless the serum magnesium concentration falls to less than 1 mEq/L, although the occurrence of symptoms, like the intracellular magnesium concentration, may not correlate well with serum magnesium levels. Atrial or ventricular arrhythmias may occur, as may various electrocardiographic abnormalities such as prolonged PR or QT intervals, T-wave flattening or inversion, and ST-segment straightening.⁵¹¹ Hypomagnesemia also increases myocardial sensitivity to digitalis intoxication.⁵³⁶

Hypomagnesemia evokes important alterations in mineral ion and potassium homeostasis that frequently aggravate the clinical syndrome. Magnesium-deprived

humans or animals develop hypocalcemia, hypocalciuria, hypokalemia (due to impaired tubular reabsorption of potassium), and positive calcium and sodium balances.^{526,537} Sustained correction of hypocalcemia or hypokalemia cannot be achieved by administration of calcium or potassium alone, but both abnormalities respond to administration of magnesium.^{513,538}

The mechanism of hypocalcemia in this setting may be multifactorial. Inappropriately normal or low serum PTH, despite hypocalcemia, is common and indicates a defect in PTH secretion⁵³⁹ that is caused by augmented signaling by CASR-associated G proteins (normally inhibited by magnesium) within the parathyroid cell.⁵⁴⁰ Other evidence indicates that hypomagnesemia also may impair PTH action on target cells in bone and kidney, although some have observed normal responsiveness, and the issue remains controversial.^{375,376,538,539,541}

Vitamin D resistance also is a feature of hypomagnesemic states.^{542,543} This appears to be caused mainly by impaired renal 1α -hydroxylation of 25(OH)D, although tissue resistance to calcitriol also may play a role.^{528,544} The serum calcitriol concentration usually is low during hypomagnesemia; this may result from magnesium depletion per se, from parathyroid insufficiency, or from coexistent vitamin D deficiency.⁵⁴⁵⁻⁵⁴⁷ Deficiency of calcitriol probably is not the main cause of hypocalcemia in these patients, however, because hypocalcemia can be rapidly corrected (within hours to days) by magnesium therapy alone, well in advance of any increase in the serum calcitriol concentration.^{545,546}

Therapy of Hypomagnesemia

Patients with mild, asymptomatic hypomagnesemia may be treated with oral magnesium salts—MgCl₂, MgO, or Mg(OH)₂—usually given in divided doses totaling 40 to 60 mEq (480 to 720 mg) per day (see Table 28-6). Diarrhea sometimes occurs with larger doses but usually is not a problem. The gluconate form (54 mg magnesium per gram) is said to cause less diarrhea.⁵¹¹ Patients with malabsorption or ongoing urinary magnesium losses may require chronic oral therapy to avoid recurrent magnesium depletion. Although intestinal magnesium absorption is severely impaired in renal failure,⁵⁴⁸ oral magnesium must be administered with great caution in this setting, especially in patients receiving concomitant therapy with calcitriol.

Symptomatic or severe (<1 mEq/L) hypomagnesemia, especially if complicated by hypocalcemia, usually signifies magnesium deficits of at least 1 to 2 mEq/kg and is best treated promptly with parenteral magnesium salts. The use of intramuscular MgSO₄ is to be discouraged, because the injections are painful and provide relatively little magnesium (e.g., 2 mL of 50% MgSO₄ supplies only 8 mEq of magnesium, compared with typical magnesium deficits in excess of 100 mEq). Moreover, because unretained sulfate ions also may increase urinary calcium excretion, intravenous magnesium chloride or gluconate probably is the most logical initial parenteral therapy for patients who also may be hypocalcemic. In adult hypomagnesemic patients with normal renal function, rates of infusion of 2 to 4 mEq/hour (50 to 100 mEq/day) usually are needed to maintain serum magnesium in the range of 2 to 3 mEq/L.^{513,545,549} Up to 100 mEq/day for 2 days can be safely administered without elevating the serum magnesium concentration above 4 mEq/L, whereas doses of 200 mEq/day may increase serum magnesium to 4.5 to 5.5 mEq/L and therefore are excessive.⁵⁴⁹ In patients with active seizures or other urgent indications, the infusion may be preceded by

a slowly administered bolus of 10 to 20 mEq, followed by a higher rate of infusion (10 to 15 mEq/hour) for the first 1 to 2 hours only. Patients with normal renal function can readily excrete more than 400 mEq/day of magnesium in the urine without becoming hypermagnesemic, but even mild renal failure may greatly limit magnesium excretion. Therefore, doses of magnesium supplements should be reduced twofold to threefold, and careful serial monitoring of serum magnesium should be performed in patients with compromised renal function.

It is important to appreciate that a large fraction of parenterally administered magnesium may be excreted in the urine, even in patients with profound magnesium deficiency. Many such patients excrete as much as 50% to 75% of infused magnesium, and in normal subjects excretion approaches 100%.⁵¹³ Moreover, because equilibration of the intracellular and extracellular magnesium pools is relatively slow, it is usually necessary to continue magnesium therapy for 3 to 5 days to achieve adequate repletion of the typical 1 to 2 mEq/kg deficit. Because serum magnesium may become normal well before tissue stores are repleted, monitoring of urinary magnesium excretion is a more reliable measure of the approach to full repletion, especially after patients are switched to oral therapy.

The need for calcium, potassium, and phosphate supplementation should be considered in the usual clinical setting of hypomagnesemia. Vitamin D deficiency also frequently coexists and should be treated with oral or parenteral vitamin D or 25(OH)D. Use of calcitriol is not necessary, does not hasten recovery, and may actually worsen hypomagnesemia by suppressing PTH secretion and thereby promoting renal magnesium excretion.⁵⁵⁰ Initial parenteral magnesium therapy in hypocalcemic patients may produce a dramatic hypophosphatemia via the rapid stimulation of PTH secretion. This is most likely to be problematic in those patients with underlying phosphate depletion (e.g., malabsorption, alcoholism, diabetes), in whom it may provoke acute neuromuscular dysfunction, and it may be avoided by concomitant intravenous calcium therapy.
