Contraceptive failures are reported in women taking AEDs and using the etonogestrel implant system (Implanon). Small, observational studies suggest that the levonorgestrel intrauterine system continues to be highly effective in women taking anticonvulsants.¹⁶⁰

Hormonal Contraception in Women Taking Antibiotics

Although there have been many anecdotal reports of COCP failure in women taking concomitant antibiotics, pharmacokinetic evidence of lower serum steroid levels exists only for rifampin. Women taking rifampin should not rely on oral, transdermal, vaginal ring, or implantable contraception alone for protection. Approximately 20% of pregnant women visiting family planning or abortion clinics reported concomitant COCP and antibiotic use. It is possible that individual differences in pharmacokinetic responses to

antibiotics underlie these reported contraceptive failures.¹⁶¹ In contrast to rifampin, use of ampicillin, doxycycline, fluconazole, metronidazole, miconazole, quinalones, and tetracycline have not lowered steroid levels in women using COCPs.²⁸

Hormonal Contraception in HIV-Positive Women

More than 15 million women, many of reproductive age, are infected with human immunodeficiency virus (HIV). Heterosexual intercourse is increasingly linked to HIV transmission. The role of hormonal contraception in HIV-positive women has been controversial. Studies in female sex workers suggest that some hormonal contraceptives may increase the risk of HIV acquisition, but the effect is not seen in women at low risk for HIV infection. Hormonal contraception does not interfere with antiviral drug effectiveness or disease progression in women taking antiretrovirals. However, in those not receiving antiretroviral medication, COCP use has been associated with accelerated disease progression.¹⁶² Pharmacokinetic studies have shown changes in circulating sex steroid levels in women taking antiretrovirals, but the clinical implications of these observations are unclear. All the available hormonal contraceptive methods can be used by women at risk for HIV infection and by HIV-infected women, but further studies are needed to investigate the safety and efficiency of hormonal contraception in women living with HIV infection or acquired immunodeficiency syndrome (AIDS).

The LNG-IUS appears to be safe in HIV-positive women taking antiretroviral therapy; available evidence suggests that use does not increase a woman's risk of overall complications or infection-related complications. The device may also be useful in the treatment of heavy menstrual bleeding in HIV-positive women.¹⁶³

Hormonal Contraception in Women with a History of Thromboembolism

Women with a documented history of unexplained VTE or VTE associated with pregnancy or exogenous estrogen use should not use estrogen-containing hormonal contraceptives unless they are taking anticoagulants. A COCP candidate who experienced a single episode of VTE years earlier associated with a nonrecurring risk factor (e.g., VTE occurring after immobilization after a motor vehicle accident) may not currently be at increased risk for VTE. The decision to initiate estrogen-containing contraceptives in these candidates can be individualized.²⁸

Limited data have assessed the risk of VTE associated with use of progestin-only contraceptives. A large WHO study did not find an increased VTE risk with use of progestin-only contraceptives.¹⁶⁴ A systematic review suggested increased VTE risk with use of progestin-only contraceptives, but it might reflect that higher-risk women were more likely to be prescribed progestin-only methods.¹⁶⁵

Hormonal Contraception in Women Awaiting Surgery

VTE with pulmonary embolism remains a major cause of fatalities associated with surgical (including gynecologic) procedures. Findings of a large, British, prospective, cohort study suggested that the risk of postoperative VTE was approximately twice as high ($P > .05$) in COCP users as in nonusers.¹⁶⁶ The procoagulant changes of COCPs take 6 weeks or longer to resolve after discontinuation.¹⁶⁷

The benefits associated with stopping combination contraceptives 1 month or more before major surgery should be balanced against the risks of an unintended pregnancy. If oral contraceptives are continued before major surgical procedures, heparin prophylaxis should be considered. Use of COCPs at the time of arthroscopic surgery has increased VTE risk.¹⁶⁸ Because of the low perioperative risk of VTE, it is not considered necessary to discontinue combination contraceptives before laparoscopic tubal sterilization or other brief surgical procedures not known to be associated with an elevated VTE risk.

Hormonal Contraception in Women with Hypercoagulable States

Women with familial thrombophilic syndromes, including factor V Leiden mutation, prothrombin G2010 A mutation, and protein C, protein S, or antithrombin deficiency have an elevated risk for VTE during COCP use and pregnancy and can develop VTE earlier during use than lower-risk users.¹⁶⁹ Women with factor V Leiden mutation have an increased risk of VTE of about eightfold compared with women without the mutation, and the risk is more than 30 times higher for carriers who used COCPs compared with nonusers who are not carriers of the mutation.¹⁷⁰ Approximately 5% of women of reproductive age are thought to carry the factor V Leiden mutation, but many of them will never experience a thrombotic event. In light of this, screening for factor V Leiden mutations or other thrombophilias is not considered to be cost-effective in the U.S. population considering estrogen-containing contraception in the absence of a clear family or personal history of thrombosis.¹⁷⁰ However, women with known familial thrombophilic conditions should be encouraged to use progestin-only and intrauterine contraception.

Hormonal Contraception in Women Taking Anticoagulation Therapy

The long-term risks of warfarin for reproductive-age women include heavy or prolonged menstrual bleeding and rarely include hemoperitoneum after rupture of ovarian cysts. Warfarin is a teratogen. Because COCPs can reduce menstrual blood loss and do not appear to increase the risk of recurrent thrombosis in well-anticoagulated women,¹⁷¹ some authorities recommend their use in these patients. However, no large studies address the safety of estrogen-containing contraceptives in women taking oral anticoagulation, and many experts recommend the use of progestin-only or intrauterine contraception in this setting. Because use of the copper IUD increases menstrual flow, use of the LNG-IUS is more appropriate in this situation.¹⁷² Since intramuscular injection of DMPA consistently suppresses ovulation and anecdotal experience has not revealed injection site problems such as hematoma in anticoagulated women, DMPA represents another potential contraceptive choice in this patient population.

Hormonal Contraception in Obese Women

The proportion of Americans who are obese (BMI ≥ 30) has risen to 30% (<http://www.cdc.gov/nchs/> [accessed August 2010]). Concerns about obesity and contraception include possible complications such as VTE or reduced efficacy (particularly with low-dose methods) and the increased risk of pregnancy associated with obesity. The prospect of effective contraception with weight loss may also provide a window of opportunity for obese women to achieve a

normal BMI, increase their chances of successful pregnancy, and reduce pregnancy complications. There is some evidence that obese sexually active women (and diabetic women) may be less likely to use contraception than normal-weight women.¹⁷³ Because pregnancy confers increased risks to mother and child in these pregnancies, the clinician must ensure that safe and effective contraception is provided when pregnancy is not planned.

The efficacy of COCPs, contraceptive rings, and transdermal patches primarily reflects the suppression of ovulation that results from the dose of progestin. Time to reach steady-state levels of levonorgestrel after ingestion appears to be twice as long among obese women compared with women of normal weight; the interval until hypothalamic-pituitary-ovarian activity is suppressed may be lengthened, placing obese women at higher risk for ovulation.¹⁷⁴

The true rate of contraceptive failure in overweight and obese women is unknown, because past clinical trials of efficacy routinely excluded women who weighed more than 90 kg. The failure rate among obese COCP users is estimated to be between 60% and 120% greater than among those with a normal BMI.¹⁷⁴ Despite this observation, COCPs are more effective than barrier methods in obese women.

In clinical trials of the transdermal patch, women in the highest weight decile (≥ 90 kg) had a substantially higher contraceptive failure rate.⁴² The incrementally higher rates in this setting with oral and transdermal methods should not exclude their use in overweight women motivated to use these methods in preference to less effective methods.

Obese women who are concerned about the possibility of decreased efficacy of the COCPs can consider using an IUD or implant as highly effective alternatives, especially because many obese women have hypertension and other risk factors for vascular disease that may be exacerbated by exogenous estrogen. There is relatively little high-quality information regarding the efficacy of DMPA in obese women, but in overweight women, higher pregnancy rates have not been observed with use of the 150-mg intramuscular or 106-mg subcutaneous formulations of DMPA.⁵⁶ Although DMPA does not appear to increase BMI in all women, adolescents who are already obese may gain more weight when using DMPA compared with other methods.¹⁷⁵

The health risks associated with use of estrogen-containing contraceptives may be increased in obese women. Exogenous estrogen and obesity are independent risk factors for VTE. Case-control studies suggest that higher BMI values (>25) may increase the risk of VTE by up to 10-fold in COCP users.¹⁷⁶ Because age also represents an independent risk factor for VTE, the ACOG recommends use of progestin-only and intrauterine contraceptives in obese women older than 35 years.²⁸ In helping overweight women make sound contraceptive choices, practitioners should incorporate these observations in discussions with patients. Because obese women have an elevated risk for dysfunctional uterine bleeding and endometrial neoplasia, use of the LNG-IUS may represent a particularly sound choice.

Hormonal Contraception in Women with Systemic Lupus Erythematosus

Although effective contraception is important for women with lupus, concerns about increasing disease activity and thrombosis have resulted in clinicians rarely prescribing combination estrogen-progestin oral contraceptives to women with this disease. However, level 1 data indicate that COCPs are safe in women with systemic lupus

erythematosus (SLE) if they have stable, mild disease; are seronegative for antiphospholipid antibodies; and have no history of thrombosis.¹⁷⁷ Among those with the antiphospholipid syndrome, there may be a high incidence of thrombosis in COCP users, suggesting that estrogen-containing contraceptives should be avoided.¹⁷⁸

Providing effective contraception for women with SLE is extremely important. Pregnancy carries marked maternal and fetal risks, and almost one fourth of women with SLE who conceive choose to terminate their pregnancies.¹⁷⁹ Although there are limited data regarding the safety of IUDs in women with SLE, they provide highly effective birth control and may represent a sensible option for these patients.¹⁸⁰

Hormonal Contraception in Women with Sickle Cell Disease

Similar to pregnancy in SLE patients, pregnancy in women with sickle cell disease increases maternal and fetal morbidity and mortality. The safety of hormonal contraceptives in women with homozygous sickle cell (SS) disease has been controversial. Only one small, randomized, controlled trial has addressed this issue. Twenty-five patients were randomized to three monthly DMPA or intramuscular saline placebo injections in a crossover design. DMPA users were less likely to experience painful sickle episodes (odds ratio = 0.23; 95% CI, 0.05 to 1.02).¹⁸¹ No randomized studies have addressed estrogen-containing products. These limited data suggest that DMPA is a safe contraceptive option for women with sickle cell disease. In addition to providing effective contraception, DMPA may reduce sickle pain crises.⁶⁶

No well-controlled study has assessed whether VTE risk in oral contraception users with sickle cell disease is higher than in other combination oral contraception users. However, a small, U.S., case-control study found that COCP use was associated with a nonsignificantly elevated risk of VTE.¹⁸² Cross-sectional studies of women with sickle cell disease have observed no differences in markers for platelet activation, thrombin generation, fibrinolysis, or red cell deformability between users of combination oral contraception methods, progestin-only methods, and nonusers of hormonal contraception.¹⁸³ On the basis of these observations, studies of pregnant women with sickle cell disease, and small, observational studies of women with sickle cell disease who use COCPs and on theoretical considerations, the ACOG concludes that pregnancy carries a greater risk than estrogen-containing contraceptive use.²⁸

Hormonal Contraception in Depression

Depression and mood disorders are extremely common in women of reproductive age. The issues to consider are the impact of hormonal contraceptives on mood and the potential impact of treatments for depression on contraceptive efficacy.

Data on the use of hormonal contraceptives in women with depression are limited but usually show no effect. Women with depressive disorders do not appear to suffer worsening of symptoms with use of hormonal methods of contraception. However, depression is one of the most commonly stated reasons for discontinuation of COCPs.¹⁸⁴ Unfortunately, few data help clinicians advise women with a history of anxiety or depression regarding appropriate contraceptive choices.

Prescription antidepressants do not affect the efficacy of hormonal contraceptives.²⁸ Data from randomized,

controlled trials of fluoxetine have failed to confirm any effect of COCPs on the response to fluoxetine.¹⁸⁵ However, the herbal remedy St. John's wort, a hepatic enzyme inducer, increased progestin and estrogen metabolism, breakthrough bleeding, and the likelihood of ovulation in women using COCPs.¹⁸⁶ The relationship between DMPA use and depression has been controversial, and studies have failed to identify a causal relationship between the two.⁵⁵

CHOOSING A CONTRACEPTIVE METHOD

Given the number of contraceptive options available to women, it is important that providers concentrate their efforts on helping women choose the best contraceptive method and focus on counseling that helps improve continuation. The best birth control method is one that provides the safest and most effective contraceptive for a woman and is the method she chooses to use and has access to. This approach places a strong value on medical considerations but also includes consideration of a woman's lifestyle, preferences, and level of prevention desired. Long-acting contraceptives (i.e., IUD and implant) offer women the advantages of high contraceptive efficacy and high rates of continuation. When discussing contraception, physicians should present all suitable options to their patients, including long-acting methods.

When helping women make sound contraceptive decisions, clinicians should consider the patient's age, lifestyle, and other relevant circumstances, including the recognition that contraceptive needs are likely to change during different phases of reproductive life and that the risks and benefits may alter according to age and background health factors. For those considering pregnancy in the future, contraceptive reversibility and time to return of fertility should be discussed. Affordability must be considered, because it may affect continuation rates and therefore affect efficacy.

All contraceptives have potential side effects. Discussion of these effects and other areas of patient preparation may increase acceptability. The clinician should provide information about adverse events that are individualized and provided in the context of how they compare with the effects of an unplanned pregnancy. Information about contraceptive failure and access to emergency contraception should be offered. For those at risk for sexually transmitted diseases, hormonal contraception cannot provide reliable protection. The physician should encourage consistent condom use and minimizing the number of partners, regardless of contraceptive choice. No method of contraception is perfect. Each woman must consider the advantages and disadvantages of each method in making her decision. The most effective method is likely to be the one that she can use successfully.

Testicular Disorders

ALVIN M. MATSUMOTO • WILLIAM J. BREMNER

The testes have critical physiologic roles during different stages of development. During early fetal life, production of testosterone and anti-müllerian hormone (AMH) by the fetal testis is required for the differentiation and development of normal male internal and external genitalia. During puberty, activation of the hypothalamic-pituitary-testicular axis and testosterone production by the testis are necessary for the induction of secondary (adult) male sexual characteristics, stimulation of sexual function, and initiation of sperm production. In adults, testis production of testosterone and sperm is required for the maintenance of adult male characteristics (virilization), sexual function, spermatogenesis, and fertility potential. Therefore, disorders of the testis may result in abnormalities in sexual development and function, body habitus and function, and fertility that have profound effects on health and well-being.

Disorders of the testis are common. Klinefelter's syndrome, the most common human sex chromosome abnormality and the primary testicular disorder causing testosterone deficiency and impaired spermatogenesis, affects approximately 1 in 500 to 600 men.^{1,2} Isolated disorders of sperm production are the main causes of male infertility, which affects approximately 5% to 6% of otherwise

healthy men in the reproductive age group.³ Testicular disorders resulting in testosterone deficiency may contribute to complaints of reduced libido (sexual interest and desire), erectile dysfunction, gynecomastia (benign breast enlargement), and reduced bone mass (osteoporosis), all of which are common in men, particularly as they age. Finally, disordered hypothalamic-pituitary-testicular function is commonly associated with chronic systemic illnesses, wasting syndromes, morbid obesity, chronic use of certain medications (e.g., opiates, glucocorticoids), and aging. These conditions often result in testosterone deficiency that, if severe and prolonged, may contribute to clinical manifestations and morbidity.^{4,5}

The treatment of testicular disorders usually results in significant clinical improvements in function and quality of life. In prepubertal boys and adults with severe testosterone deficiency, testosterone therapy results in dramatic transformations in body composition and function.⁶ In men with infertility and impaired spermatogenesis due to gonadotropin deficiency, gonadotropin or gonadotropin-releasing hormone (GnRH) therapy may stimulate sperm and testosterone production and effectively restore fertility. Finally, advances in assisted reproductive technology (ART) have permitted previously infertile men with testicular

disorders to have children. For example, although men with Klinefelter's syndrome and azoospermia (no spermatozoa in their ejaculate) were once thought to have untreatable infertility, testicular sperm extraction using microsurgical techniques combined with intracytoplasmic sperm injection (ICSI) may permit some of these men to father children.⁷

FUNCTIONAL ANATOMY AND HISTOLOGY

The Testis

Adult testes are paired, ovoid organs that hang from the inguinal canal by the *spermatic cord* (which is composed of a neurovascular pedicle, vas deferens, and cremasteric muscle); they are located outside the abdominal cavity within the scrotum. The left testis hangs lower in the scrotum than the right in about 60% of men, and the right testis hangs lower in approximately 30% of men. Each testis has a volume of 15 to 30 mL and measures 3.5 to 5.5 cm in length by 2.0 to 3.0 cm in width.^{8,9}

The testis comprises two structurally and functionally distinct compartments: the *seminiferous tubule compartment*, which is composed of Sertoli cells and developing germ cells at various stages of spermatogenesis and accounts for 80% to 90% of the volume of the testis, and the *interstitial compartment*, which is composed of Leydig cells that secrete testosterone, the main male sex steroid hormone, as well as peritubular myoid cells, fibroblasts, neurovascular cells, and macrophages (Fig. 19-1).¹⁰ Because germ cells constitute most of the testis volume, small testes are usually an indication of significantly impaired spermatogenesis.

Figure 19-1 Light photomicrograph of the seminiferous tubule and interstitial compartments of the human testes. The seminiferous tubule compartment makes up the majority of the testis and is composed of developing germ cells enveloped by Sertoli cells. Spermatogonia line the basal lamina of the seminiferous tubules, spermatocytes at various stages of development are present in the middle layers of the tubules, and spermatids at various steps of maturation are present in the luminal aspect of the seminiferous tubules. Within each tubule, there are germ cells at different stages of spermatogenesis. In the interstitial compartment, there are prominent clusters of Leydig cells nestled between seminiferous tubules, peritubular myoid cells within the basal lamina of the tubules, and scattered blood vessels and macrophages. (From Matsumoto AM. Spermatogenesis. In: Adashi EY, Rock JA, Rosenwaks Z, eds. *Reproductive Endocrinology, Surgery, and Technology*. Philadelphia, PA: Lippincott-Raven; 1996:359-384.)

The testis is surrounded by a fibrous capsule, the *tunica albuginea*. Fibrous septa that emanate from the tunica albuginea separate the parenchyma of the testis into lobules. The arterial blood supply of the testes is derived primarily from the testicular (internal spermatic) arteries that arise from the abdominal aorta and descend through the inguinal canal in the spermatic cord. Collateral blood supply is provided by the cremasteric and deferential arteries. This collateral supply permits survival of the testis after a testicular artery ligation associated with surgical fixation of a high undescended testis into the scrotum (orchiopexy). However, twisting of the spermatic cord, known as *testicular torsion*, results in strangulation of the blood supply to the testis and causes testicular necrosis and infarction after 6 to 8 hours, making this condition a surgical emergency.¹¹ A testis that has a *bell-clapper deformity* (i.e., is not attached to the scrotal wall) is more susceptible to testicular torsion. Lymphatic drainage from the testes follows the testicular arteries to periaortic lymph nodes; this is a common route for metastasis of testicular cancer.

A network of veins that comprise the pampiniform plexus provides venous drainage from the testes. The pampiniform plexus coalesces into the testicular (internal spermatic) vein. The right testicular vein drains into the inferior vena cava, and the left testicular vein empties at a right angle into the left renal vein. One-way valves in testicular veins prevent backflow of blood into the scrotum. Abnormal enlargement of the venous plexus draining a testicle, known as a *varicocele*, occurs if valves are defective or absent or if there is extrinsic venous compression impeding normal venous drainage.¹² Increased pressures associated with the backflow of blood and altered temperature regulation may contribute to testicular dysfunction associated with a varicocele. Ninety-eight percent of varicoceles occur in the left scrotum, possibly because of absent or defective valves in the left testicular vein. The presence of a prominent unilateral right-sided varicocele or new-onset varicocele on either side should prompt evaluation for venous obstruction by an abdominal or pelvic malignancy (e.g., renal cell carcinoma) or lymphadenopathy; a chronic right-sided varicocele may also indicate *situs inversus*. Rarely, an anatomic anomaly of the superior mesenteric artery that compresses the left renal vein causes a left-sided varicocele; this is known as the *nutcracker syndrome*.

Because the testes are located outside the abdominal cavity, they are exposed to temperatures approximately 2° C lower than core body temperature. The position of the testes within the scrotum and the testicular temperature are regulated by the cremasteric muscle. The cremasteric muscle contracts when warming is needed, resulting in shortening of the spermatic cord and drawing of the testis toward the abdomen; when cooling is needed, it relaxes, resulting in lowering of the testis into scrotum. Also, the pampiniform venous plexus provides a concurrent heat exchange mechanism to cool the testis by surrounding the testicular artery with cooler venous blood. A testis temperature slightly lower than core body temperature is important for normal spermatogenesis. Exposure of the testes to higher temperatures, such as with failure of the testes to descend normally into the scrotum (*cryptorchidism*) or excessive external heat exposure due to frequent hot tub use, impairs spermatogenesis.

Seminiferous Tubule

Seminiferous tubules contain epithelium consisting of Sertoli cells that envelop and support germ cells undergoing progressive differentiation and development into

mature spermatozoa. Once released into the lumen, mature spermatozoa are transported within seminiferous tubules, which measure up to 70 cm in length and are tightly coiled within lobules of the testis, to the rete testis, the efferent ducts, the epididymis, and, finally, the vas deferens for ultimate ejaculation. The seminiferous tubules are surrounded by a basal lamina composed of extracellular matrix that serves to separate them from the interstitial compartment, provides structural integrity to the tubules, and regulates the function of cells in contact with it. Histologic examination of a testis biopsy specimen in cross-section reveals many different seminiferous tubules surrounded by basal lamina and clusters of Leydig cells in the interstitial compartment between each tubule (see Fig. 19-1).¹⁰

Sertoli cells extend from the basal lamina to the lumen of tubules, and adjacent Sertoli cells envelop and provide a structural scaffold for germ cells as they differentiate within the tubule (Fig. 19-2).⁸ Undifferentiated spermatogenic stem cells, called *spermatogonia*, lie along the basal lamina at the periphery of tubules, interspersed between Sertoli cells. Adjacent Sertoli cells surround spermatogonia and form specialized junctional complexes or tight junctions that divide the seminiferous tubule into the *basal compartment*, in which spermatogonia reside, and the *adluminal compartment*, which is occupied by differentiating germ cells. Sertoli cell tight junctions impede the passage of large molecules, steroids, and ions into the seminiferous tubule and constitute the cytologic basis of the *blood-testis barrier*, analogous to the blood-brain barrier. In the

adluminal compartment, *spermatocytes* derived from spermatogonia in the basal compartment undergo meiosis to form *spermatids* that progressively mature (*spermiogenesis*), with the more mature germ cells occupying positions closer to the lumen, until mature spermatozoa are released into the lumen of the tubule (*spermiation*).

Because of the blood-testis barrier, only Sertoli cells and spermatogonia are directly accessible to endocrine and paracrine regulation from the circulation and cells of the interstitial compartment. Sertoli cells need to synthesize and secrete a number of products, some of which are present in circulation but not accessible to developing germ cells in the adluminal compartment, in order to nurture and regulate spermatogenesis. Sertoli cells contain receptors for follicle-stimulating hormone (FSH) and androgens, and they mediate the regulation of spermatogenesis by circulating FSH and testosterone produced locally by Leydig cells in response to stimulation from circulating luteinizing hormone (LH). Sertoli cells also produce the glycoprotein hormones—AMH, which causes regression of müllerian ducts and prevents the development of female accessory sex organs in the male fetus, and inhibin B, which participates in negative feedback suppression of FSH—and extracellular matrix components.

Spermatogenesis

In male humans, the process of spermatogenesis supports a production rate of approximately 120 million mature spermatozoa per day by the human testis (approximately

Figure 19-2 Schematic diagram of the cells in the seminiferous tubule (top). The seminiferous tubule consists of Sertoli cells that surround developing germ cells (middle). Sertoli cells extend from the basal lamina to the lumen. Tight junctions between adjoining Sertoli cells separate the seminiferous tubule into basal and adluminal compartments and are the anatomic basis for the blood-testis barrier (bottom). The basal compartment, which contains spermatogonia lining the basal lamina and peritubular myoid cells, is exposed to the interstitial compartment, which contains Leydig cells and blood vessels that deliver endocrine regulators of testis function (e.g., gonadotropins). The adluminal compartment contains developing spermatocytes, spermatids, and mature spermatozoa that are released into the lumen of the seminiferous tubule. (From Matsumoto AM. The testis. In: Felig P, Frohman LA, eds. *Endocrinology and Metabolism*, 4th ed. New York, NY: McGraw-Hill; 2001:635-705.)

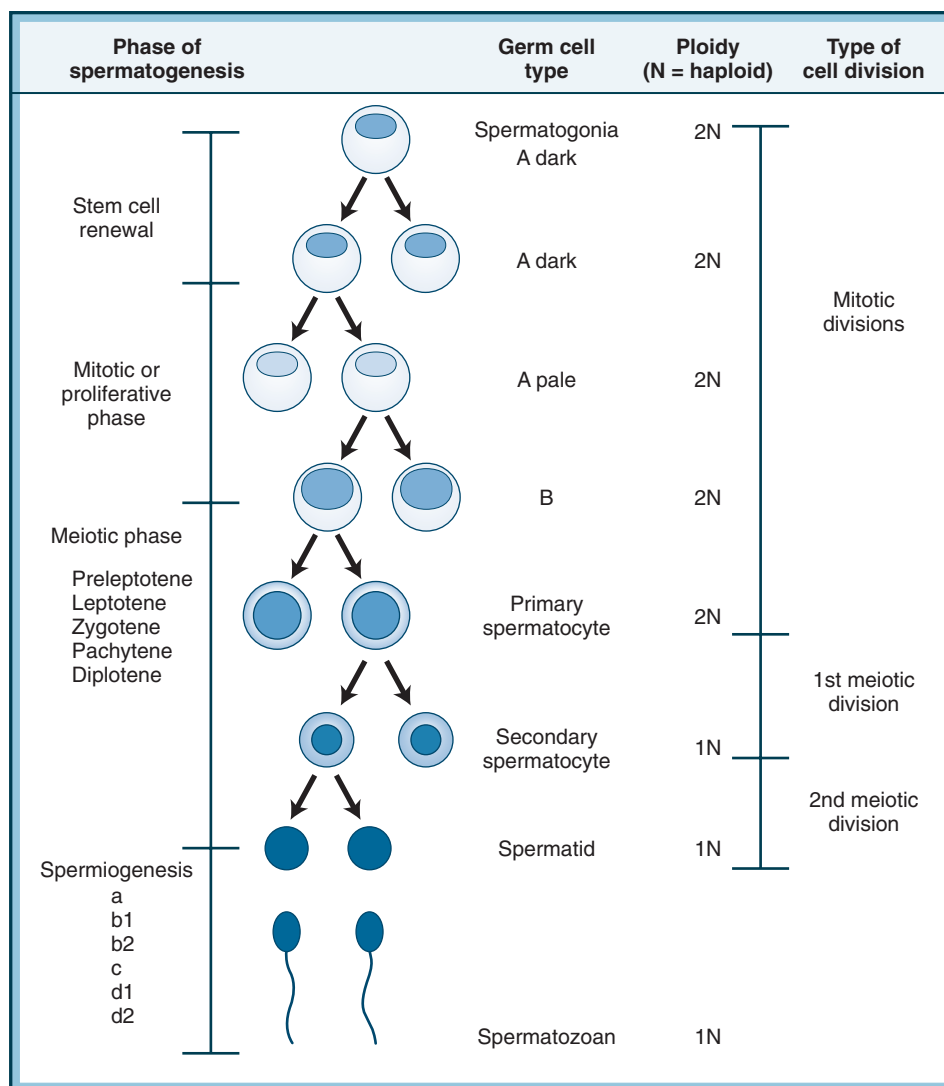

Figure 19-3 Schematic diagram of human spermatogenesis. Spermatogonial stem cells undergo self-renewal by mitotic division. At the initiation of spermatogenesis, some spermatogonia undergo differentiation into primary spermatocytes, which contain a diploid number of chromosomes ($2N = 46$ chromosomes). The primary spermatocytes then undergo two successive meiotic divisions to form spermatids, which contain a haploid number of chromosomes ($1N = 23$ chromosomes). Spermatids undergo spermiogenesis to form mature spermatozoa, which also contain a haploid number of chromosomes. (From Matsumoto AM. Spermatogenesis. In: Adashi EY, Rock JA, Rosenwaks Z, eds. *Reproductive Endocrinology, Surgery, and Technology*. Philadelphia, PA: Lippincott-Raven; 1996:359-384.)

1000 per heartbeat!).¹³ Spermatogenesis, the process by which stem cells (spermatogonia) differentiate into mature spermatozoa, proceeds in three functionally distinct phases: (1) the *mitotic or proliferative phase*, during which the majority of spermatogonia undergo mitosis to renew the stem cell pool and a minority become committed to further differentiation to produce spermatocytes; (2) the *meiotic phase*, during which spermatocytes undergo successive meiotic divisions to produce haploid germ cells (spermatids); and (3) *spermiogenesis*, during which immature, round spermatids differentiate into mature spermatozoa (Fig. 19-3).^{10,14}

Proliferative Phase

Based on chromatin staining and pattern, spermatogonia may be classified as A dark (A_d), A pale (A_p), or B spermatogonia. Because of their relatively low mitotic rate, A_d spermatogonia are thought to be the spermatogonial stem cells. A_d spermatogonia are relatively resistant to external

insults (e.g., ionizing radiation), and in response to such insults, they undergo mitotic proliferation. However, severe or complete depletion of A_d spermatogonia, such as occurs with high-dose x-irradiation or vascular compromise, results in irreversible impairment or loss of sperm production.

A small number of A_d spermatogonia undergo mitotic divisions to form A_p and then B spermatogonia. In humans, the rate of formation of B spermatogonia is low, so that only a small number of B spermatogonia are available to enter meiosis and undergo further differentiation.¹⁵ This limits the efficiency of spermatogenesis in humans. B spermatogonia are the most sensitive germ cells to the effects of ionizing radiation, and their numbers are reduced after irradiation of the testes.¹⁶

B spermatogonia that become committed to further differentiation undergo mitotic division to form *preleptotene* or *resting* spermatocytes, which enter a prolonged meiotic phase of 24 days. Spermatogonia do not completely

separate after mitosis (*incomplete cytokinesis*). Groups of spermatogonia remain connected via cytoplasmic bridges, forming a syncytium, and undergo meiosis and spermiogenesis in synchrony.

Meiotic Phase

Preleptotene primary spermatocytes contain a diploid complement of chromosomes (46 chromosomes or $2N$, where N is the number of haploid chromosomes), and they are the last germ cells to undergo DNA synthesis. Preleptotene spermatocytes undergo an initial round of meiotic division (*meiosis I*), lasting longer than 2 weeks, to form secondary spermatocytes that contain a haploid complement of chromosomes ($1N$). Secondary spermatocytes, which are present for only about 8 hours, undergo a second meiotic division (*meiosis II*) to form haploid spermatids.

Improper segregation of chromosomes (*meiotic nondisjunction*) resulting in an abnormal number of chromosomes (*aneuploidy*) occurs in 0.7% of live births and 50% of first-trimester abortuses.^{17,18} Klinefelter's syndrome, a common cause of primary hypogonadism, occurs in about 1 in 500 live births and is associated classically with a 47, XXY karyotype caused by paternal meiotic nondisjunction in 50% of cases.¹⁹ Down syndrome (trisomy 21) occurs in approximately 1 in 700 live births and is caused by paternal meiotic nondisjunction in 5% to 20% of cases.²⁰

Spermiogenesis

The final phase of spermatogenesis is the maturation of spermatids from round to elongated spermatids and then to mature spermatozoa; this process, known as spermiogenesis, is followed by release of spermatozoa into the lumen of seminiferous tubules (spermiation). The major changes that occur during spermiogenesis include formation of the sperm head with condensation of chromosomes (DNA and nucleoproteins) and formation of the *acrosomal cap*, which contains proteolytic enzymes needed for sperm penetration of the ovum; formation of the sperm tail or *flagellum* (pointing into the lumen), which permits motility; phagocytic removal of excess spermatid cytoplasm (known as the *residual body*) by Sertoli cells; and release of mature spermatozoa into the lumen. Progressive maturation of spermatids is accompanied by progressive movement of more mature spermatids toward the lumen of the seminiferous tubule. Spermiogenesis is directed by the Sertoli cells that sustain and support developing spermatids and by the major endocrine regulators of Sertoli cells, FSH and testosterone.

Germ Cell Loss

Compared to most other species, the efficiency of spermatogenesis in humans is relatively poor, and the germ cell degeneration and loss that occurs predominantly during mitosis and meiosis is a major contributor to the low efficiency of sperm production.²¹ Significant degrees of germ cell degeneration occurring during meiosis account for a decrease of approximately 40% in the ratio of the number of spermatids to preleptotene spermatocytes. This ratio is reduced further as men age, resulting in a reduction of daily sperm production in elderly men. It is hypothesized that germ cell degeneration prevents abnormal germ cells from further development, thereby serving an important quality control function.

Organization of Spermatogenesis

Histologic examination of a human testis in cross-section reveals that germ cells at particular phases of development cluster in six cellular associations, referred to as *stages*,

which together constitute a complete *cycle* of spermatogenesis. In most mammals, stages are organized sequentially along the longitudinal axis of the tubules, so that all of the germ cells present in a cross-section of a tubule are in the same stage of spermatogenesis.^{22,23} In contrast, three or more different stages of a cycle may variably be present in a cross-section of human testis. Although some have proposed a helical pattern of stages along the tubule to explain this seemingly chaotic arrangement, this has not been confirmed by others.

In humans, the duration of spermatogenesis from A_p spermatogonia to release of mature spermatozoa is 74 ± 4 days.²⁴ The epididymal transit time of spermatozoa is approximately 12 to 21 days.²⁵ Therefore, external insults to the testis (e.g., ionizing radiation) or induction of gonadotropin deficiency (e.g., by male contraceptive regimens) that affects early germ cell development and reduces spermatogenesis may not be reflected in reduced sperm counts in the ejaculate until months later.

Sperm Transport and Fertilization

Mature spermatozoa released into the lumen of the seminiferous tubule are transported to the rete testis, to the efferent ducts of the testis, and then to the caput epididymis primarily by peristaltic contractions and intratubular fluid flow. In the epididymis, sperm undergo functional modifications that result in the capacity for sustained forward motility. After ejaculation from the vas deferens and penis into the female reproductive tract, human sperm undergo *capacitation* in the uterus; the resulting biochemical alterations in the acrosomal cap increase the fluidity and hyperactivated motility induced by uterine secretory products so that the spermatozoa acquire the capacity to fertilize an ovum.^{26,27} After capacitation, as the spermatozoon meets an ovum in the ampulla of the fallopian tube, the sperm binds to the egg and releases hyaluronidase to penetrate the zona pellucida that surrounds the ovum, a process known as the *acrosome reaction*. Fertilization then occurs as the plasma membranes of sperm and ovum fuse.

Spermatozoa

Morphologically, most ejaculated human spermatozoa are composed of an oval-shaped head that contains condensed chromatin and nucleoproteins; an acrosomal cap that covers approximately the anterior two thirds of the head; a short neck that contains centrioles important for attachment of the tail and cleavage of the zygote after fertilization; a middle piece that consists of axial filaments surrounded by a spiral of mitochondria containing oxidative enzymes that provide energy for motility; and a long tail or flagellum that permits normal progressive forward motility of the spermatozoa (Fig. 19-4).¹⁰ The flagellum consists of a microtubule-based cytoskeleton, the *axoneme*, which has a characteristic structure composed of two central microtubules surrounded by nine microtubule doublets ($9 \times 2 + 2$ pattern) that serves as a scaffold for motor protein complexes (i.e., *dynein arms*).²⁸

In humans, the normal sperm concentration in the ejaculate is greater than 15 million/mL, with 4% or more having normal morphology by strict criteria ($\geq 30\%$ by previous criteria) and 40% or more having total motility, according to the most recent World Health Organization criteria.^{29,30} Men with infertility may exhibit abnormal morphology of the sperm head (tapered, amorphous, or double-headed forms) or of the tail (coiled forms) and reduced or absent motility. Alterations in the structural or

Figure 19-4 Light photomicrograph of an ejaculated mature human spermatozoon, composed of a head, neck, mid-piece, and tail (principal piece and end piece). (From Matsumoto AM. Spermatogenesis. In: Adashi EY, Rock JA, Rosenwaks Z, eds. *Reproductive Endocrinology, Surgery, and Technology*. Philadelphia, PA: Lippincott-Raven; 1996:359-384.)

functional components of the axoneme (e.g., absence of dynein arms) result in altered motility, and deficiency of dynein adenosine triphosphatase (ATPase) results in primary ciliary dyskinesia or immotile cilia syndrome.³¹

Interstitial

The interstitial compartment of the testis contains clusters of Leydig cells, the primary sex steroid-producing cells of the testis, which comprise only about 5% of testis volume (see Fig. 19-1).^{23,32} Leydig cells produce testosterone, which acts as a paracrine regulator within the seminiferous tubules of the testis on Sertoli cells in close proximity to stimulate spermatogenesis. Testosterone is secreted into adjacent testicular capillaries and then into the general circulation to act as an endocrine signal on androgen target organs throughout the body. Leydig cells also produce *insulin-like factor 3 (INSL3)*, a peptide hormone in the relaxin-insulin family, which plays an important role in the first phase of testicular descent from the abdomen into the scrotum during development.³³ INSL3 also may be an important autocrine regulator of Leydig cells and a paracrine regulator of germ cells directly.³⁴

Peritubular myoid cells, which surround the seminiferous tubules, are contractile, smooth, muscle-like cells that serve to facilitate forward transport of spermatozoa and testicular fluid within the tubular lumen, provide structural integrity to the tubule, secrete extracellular matrix components and putative regulatory factors such as growth factors, and are involved in retinol metabolism.^{23,35} These cells contain androgen receptors (ARs) and are thought to mediate some of the paracrine effects of testosterone on Sertoli cells within the seminiferous tubules, although

their precise role in human testicular physiology remains unclear.

The interstitial compartment also contains macrophages that may regulate Leydig cell steroidogenesis by secretion of cytokines and may play a role in phagocytosis of degenerating cells and necrotic debris. The interstitium contains arterioles and a rich network of capillaries that permit secretion of testosterone and other products into the circulation and delivery of the main endocrine regulators of testis function, the gonadotropins LH and FSH.

TESTIS DEVELOPMENT

Fetal Development

During embryogenesis, the Y chromosome directs the development of the testis from an undifferentiated anlage that has the potential to develop into either a testis or an ovary.³⁶ The *SRY* (*sex-determining region of the Y chromosome*) gene, located on the pseudoautosomal region of the Y chromosome, encodes a transcription factor that increases the expression of SRY-box 9 (*SOX9*), which in turn drives the formation of Sertoli cells and testis differentiation. *SRY* gene expression is activated by a number of factors, including steroidogenic factor 1 (SF1) and the binding protein GATA4.³⁷ *SRY*-independent *SOX9* expression may also be driven by SF1. *SOX9* directs the expression of other genes that are essential in testis differentiation, such as fibroblast growth factor 9 (*FGF9*) and *AMH*, and in repression of ovarian differentiation, such as *WNT4* and *DAX1* (now designated *NROB1*). In the absence of *SRY* or *SRY* action, *SOX9* is repressed by a number of factors, including β -catenin, and development of the follicular cells and ovaries follows.

Primordial germ cells originate in the yolk sac and migrate to the genital ridges. Together with celomic epithelial and mesenchymal cells that eventually differentiate, respectively, into Sertoli cells and interstitial cells (Leydig and peritubular myoid cells), they form the *genital blastema* by 6 weeks of gestation. Primordial germ cells that fail to migrate normally explain the location of extragonadal germ cell cancers in men. Under the influence of gene products activated by *SRY*, primordial germ cells become surrounded by primitive Sertoli cells to form seminiferous or sex cords that eventually develop into seminiferous tubules.

Leydig cells begin to form at 8 weeks of gestation. Then, under the influence of maternal human chorionic gonadotropin (hCG) initially and later LH and FSH from the fetal pituitary gland, immature Leydig cells, Sertoli cells, and germ cells undergo differentiation, proliferation, and organization. Testosterone production from fetal Leydig cells increases progressively and induces development of the epididymis, vas deferens, and seminal vesicles from wolffian or mesonephric ducts. Conversion of testosterone to 5 α -dihydrotestosterone (5 α -DHT) in the urogenital tract leads to the formation of the prostate from the urogenital sinus, the penis from the genital tubercles and folds, and the scrotum from the urogenital swelling.³⁸ In the absence of testosterone production or action, female internal and external genitalia develop. *AMH* secretion from the fetal Sertoli cells causes regression of the müllerian or paramesonephric ducts and prevents the formation of a uterus and fallopian tubes.

Male phenotypic development is complete by about 15 weeks of gestation, after which the proliferation of Sertoli

and germ cells arrests and Leydig cells involute until gonadotropin secretion increases at the time of puberty.

Testis Descent

The developing testis is attached to the diaphragm by the cranosuspensory ligament and anchored to the inguinal region by a caudal ligament known as the *gubernaculum*. Descent of the testis occurs in two phases.³³ During the initial *transabdominal phase*, the testis descends within the abdomen to the inguinal region; this occurs between 10 and 23 weeks of gestation. Studies in animals suggest that testis descent during this phase depends on two processes: (1) regression of the cranosuspensory ligament, induced by testosterone, which frees the testes to descend, and (2) thickening of the gubernaculum, which is controlled by INSL3 produced by Leydig cells and its cognate receptor, relaxin family peptide receptor 2 (RXFP2, also known as leucine-rich repeat-containing G protein-coupled receptor 8 [LGR8] or G protein-coupled receptor affecting testis descent [GREAT]). During the *inguinoscrotal phase*, which begins at 26 to 28 weeks of gestation, the testis descends into the scrotum; this process is largely controlled by the effects of testosterone on gubernacular shortening and contractions. The effects of testosterone may be mediated in part by the neurotransmitter, calcitonin gene-related peptide (CGRP), which is released by the genitofemoral nerve. The importance of testosterone, gonadotropins, and INSL3 in testis descent in humans is suggested by the occurrence of undescended testes (cryptorchidism) associated with fetal androgen deficiency or resistance, gonadotropin deficiency, and *INSL3* or *RXFP2* mutations.³⁴

Testis descent is usually complete, with the testes entirely within the scrotum, by 7 months of gestation to birth. During testis descent, a herniation of the abdominal cavity, the *processus vaginalis*, develops along the course of the gubernaculum, forming the inguinal ring and canal and descending with the testis into the scrotum. As the abdominal wall and muscles develop, the inguinal rings close, and the processus vaginalis obliterates to form the *tunica vaginalis*, which covers the anterior and lateral portion of the testes. Incomplete closure of the inguinal ring predisposes an individual to *inguinal hernia*, and incomplete obliteration of the processus vaginalis with accumulation of serous fluid results in a *hydrocele*; either of these conditions can manifest as a scrotal mass.

Postnatal Development

During late gestational life, the male fetus is exposed to high concentrations of estrogens from the placenta. With the decline in estrogen levels after birth, the hypothalamic-pituitary-testicular axis is released from negative feedback suppression, resulting in a postnatal surge of gonadotropin that stimulates the testes to produce testosterone and inhibin B.

LH and testosterone levels begin to increase at about 1 week of life and peak 1 to 2 months later, reaching the equivalent of adolescent levels in association with an increase in the number of Leydig cells; they then decline to prepubertal levels by about 6 months of age. Infants with complete androgen insensitivity who lack androgen action due to an AR mutation (see later discussion) do not demonstrate a postnatal gonadotropin surge and have low or undetectable LH and testosterone levels postnatally, suggesting that AR expression is required for the surge.³⁹ In humans, there is no evidence that the postnatal surge of LH and testosterone has an effect on adult Leydig cell

function. However, in infants with hypogonadotropic hypogonadism, lack of a surge in testosterone may play a role in the development of micropenis or cryptorchidism, suggesting a role in postnatal development.^{40,41} In infants with micropenis, postnatal hormone testing may permit early identification and possible treatment of isolated hypogonadotropic hypogonadism or hypopituitarism.

FSH and inhibin B levels also begin to rise at 1 week of life, in association with an increase in proliferation of Sertoli cells, and peak at 3 months. FSH then declines to prepubertal levels by 9 months of age. Inhibin B declines more slowly and plateaus at approximately 15 months of age, probably reflecting ongoing Sertoli cell proliferation. Because Sertoli cell number determines spermatogenic potential, the postnatal gonadotropin surge may be important for sperm production in adults. The postnatal testosterone surge also increases the formation of *A_s* spermatogonia (spermatogonial stem cells) from gonocytes during the first 3 months and increases testis size and seminiferous tubule length during the first year of life, providing further evidence for the importance of the gonadotropin surge on future spermatogenesis and possibly fertility. In men with gonadotropin deficiency, inadequate postnatal gonadotropin stimulation results in inadequate numbers of Sertoli cells and spermatogonia, and this may contribute to the failure of gonadotropin therapy to quantitatively stimulate normal sperm production in men with Kallmann's syndrome who are treated as adults.

Pubertal Development

At the onset of puberty, reactivation of hypothalamic GnRH secretion stimulates pituitary LH and testicular Leydig cell testosterone secretion, initially only during the evening (Fig. 19-5) and subsequently throughout the day with FSH secretion.^{42,43} Progressive increase in testosterone levels during puberty induces male secondary sexual characteristics and, together with increasing FSH levels, stimulates Sertoli cells to initiate the first wave of spermatogenesis. With increasing germ cell numbers and expansion of seminiferous tubules, testis size increases progressively. Increase in testis size is the first clinical sign of puberty. Also, with the release of mature spermatozoa into the lumen of seminiferous tubules and transport of sperm to the genitourinary tract, sperm begin to appear in the urine (*spermarche*) during early puberty (usually at 12 to 15 years of age).⁴⁴

ADULT PHYSIOLOGY

Hypothalamic-Pituitary-Testicular Axis

The testis is controlled by classic positive feed-forward and negative feedback mechanisms (Fig. 19-6). The major positive regulators of testis function are the gonadotropins LH and FSH, which are synthesized and secreted from the anterior pituitary gland. Secretion of LH and, to a lesser extent, FSH is pulsatile and is driven primarily by episodic release of GnRH from neurons in the hypothalamus.⁴⁵ GnRH stimulates gonadotropin-producing cells of the anterior pituitary (gonadotrophs) to secrete both LH and FSH.

LH acts on Leydig cells of the testes to stimulate production of testosterone, the main sex steroid hormone in males. In concert with FSH, testosterone acts locally on Sertoli cells within the seminiferous tubules of the testes to initiate and maintain spermatogenesis. Testosterone secreted into the circulation acts to mediate and promote

Figure 19-5 Sleep-associated secretion of luteinizing hormone (LH) (middle) and testosterone (bottom) related to sleep stage (top) in a prepubertal boy entering puberty. REM, rapid-eye-movement sleep. (From Boyar RM, Rosenfeld RS, Kapen S, et al. Human puberty: simultaneous augmented secretion of luteinizing hormone and testosterone during sleep. *J Clin Invest.* 1974;54:609-618.)

androgen action on almost every tissue in the body, including negative feedback inhibition of pituitary LH and FSH secretion (primarily via conversion to estradiol) and suppression of GnRH production by the hypothalamus. FSH also stimulates Sertoli cells to produce inhibin B, a peptide hormone that causes negative feedback inhibition of FSH secretion by the anterior pituitary.

Knowledge of the hypothalamic-pituitary-testicular axis is essential in understanding the causes, classification, differential diagnosis, clinical consequences, and treatment of testicular disorders.

Central Nervous System Regulation of Gonadotropin-Releasing Hormone Secretion

The brain plays a vital role in regulation of the testis and of reproductive function through production of the decapeptide, GnRH, by a relatively small number of neurons located primarily in the arcuate nucleus of the medial basal hypothalamus. GnRH is released episodically from axon terminals in the median eminence into capillaries of the hypothalamic hypophyseal portal system, through which it is carried to the anterior pituitary to stimulate synthesis and release of LH and FSH. Because the amount of GnRH

in portal blood is low, GnRH concentrations in peripheral blood are very low and cannot be measured reliably for clinical purposes (e.g., to diagnose GnRH deficiency).

The precise mechanism of synchronous episodic release of GnRH from a number of separate GnRH neurons into the hypophyseal portal system to provide pulsatile stimulation of pituitary gonadotrophs is not clear. There is evidence that pulse generation is a direct consequence of intrinsic periodicity of GnRH or other neurons that synapse on GnRH neurons within the medial basal hypothalamus, such as neurons containing kisspeptin or excitatory or inhibitory neurotransmitters.

The frequency of pulsatile GnRH secretion is temporally coupled with the episodic release of LH, free α -subunit (cosecreted with intact gonadotropins), and FSH.⁴⁶ Because the half-lives of LH and free α -subunit in circulation are shorter than that of FSH, levels of LH and α -subunit demonstrate discrete pulses, which are evident with frequent blood sampling (e.g., every 10 minutes for 12 to 24 hours), whereas FSH pulses are not as apparent. The frequency of LH or free α -subunit pulses reflects GnRH pulse frequency and serves as an indicator of synchronous GnRH neuronal activity (pulse generation) in the brain. The amplitude of LH or free α -subunit pulses reflects both the amplitude of GnRH pulses and the responsiveness of the gonadotrophs to GnRH stimulation. Normal men usually demonstrate 12

Figure 19-6 Schematic diagram of the hypothalamic-pituitary-testicular axis. Hypothalamic gonadotropin-releasing hormone (GnRH) stimulates the pituitary to produce luteinizing hormone (LH) and follicle-stimulating hormone (FSH). LH stimulates Leydig cells of the testes to produce testosterone (T), which is actively metabolized to estradiol (E₂) and dihydrotestosterone (DHT), resulting in a number of direct and indirect androgen actions. FSH stimulates Sertoli cells of the testes, which together with LH-stimulated testosterone, increases spermatogenesis. LH-stimulated testosterone and E₂ exert negative feedback suppression of GnRH production at the hypothalamus and LH and FSH production at the pituitary, and FSH-stimulated inhibin B exerts negative feedback suppression on FSH secretion by the pituitary. (From Matsumoto AM. The testis. In: Felig P, Frohman LA, eds. *Endocrinology and Metabolism*, 4th ed. New York, NY: McGraw-Hill; 2001:635-705.)

to 16 LH pulses of varying amplitude over 24 hours (Fig. 19-7). In men with GnRH deficiency (idiopathic hypogonadotropic hypogonadism [IHH] or Kallmann's syndrome), there is an absence of LH pulses (most commonly) or abnormalities in LH pulsatility.⁴⁷

Treatment of men who have GnRH deficiency with low-dose pulsatile GnRH normalizes LH and FSH secretion and testicular function. In contrast, continuous low-dose GnRH administration does not stimulate normal gonadotropin secretion in these men.⁴⁸ Administration of potent GnRH receptor agonists providing continuous, high-dose GnRH stimulation of the pituitary initially stimulates but then downregulates and profoundly suppresses gonadotropin secretion and testosterone production. This effect has been the basis for the use of potent GnRH agonists to produce medical castration (androgen deprivation therapy) in the men with advanced prostate cancer. These findings underscore the critical importance of pulsatile GnRH control of reproductive function in men.

GnRH neurons receive a number of excitatory and inhibitory inputs from other brain regions as well as

feedback signals from the testes and other circulating endocrine signals. Therefore, the GnRH neuronal system serves an important integrative role in regulation of reproductive and testis function. A large and complex ensemble of neuroregulators mediates GnRH secretion, acting directly on GnRH neurons themselves or indirectly on other neurons that in turn regulate GnRH neurons to stimulate or inhibit GnRH secretion. These central nervous system (CNS) neuromodulatory systems, together with peripheral endocrine regulators, provide the means by which GnRH secretion and testicular function may be altered by environmental factors such as stress (e.g., via corticotropin-releasing hormone, glucocorticoids), nutritional compromise (e.g., via leptin), and medications (e.g., opiate drugs).

During embryogenesis, GnRH and olfactory neurons originate outside the CNS in the olfactory placode and migrate together along olfactory axons through the cribriform plate of the ethmoid bone to the olfactory bulb, where GnRH neurons diverge and continue to migrate to the medial basal hypothalamus.⁴⁹ Abnormalities in the migration of these neurons explain the association between

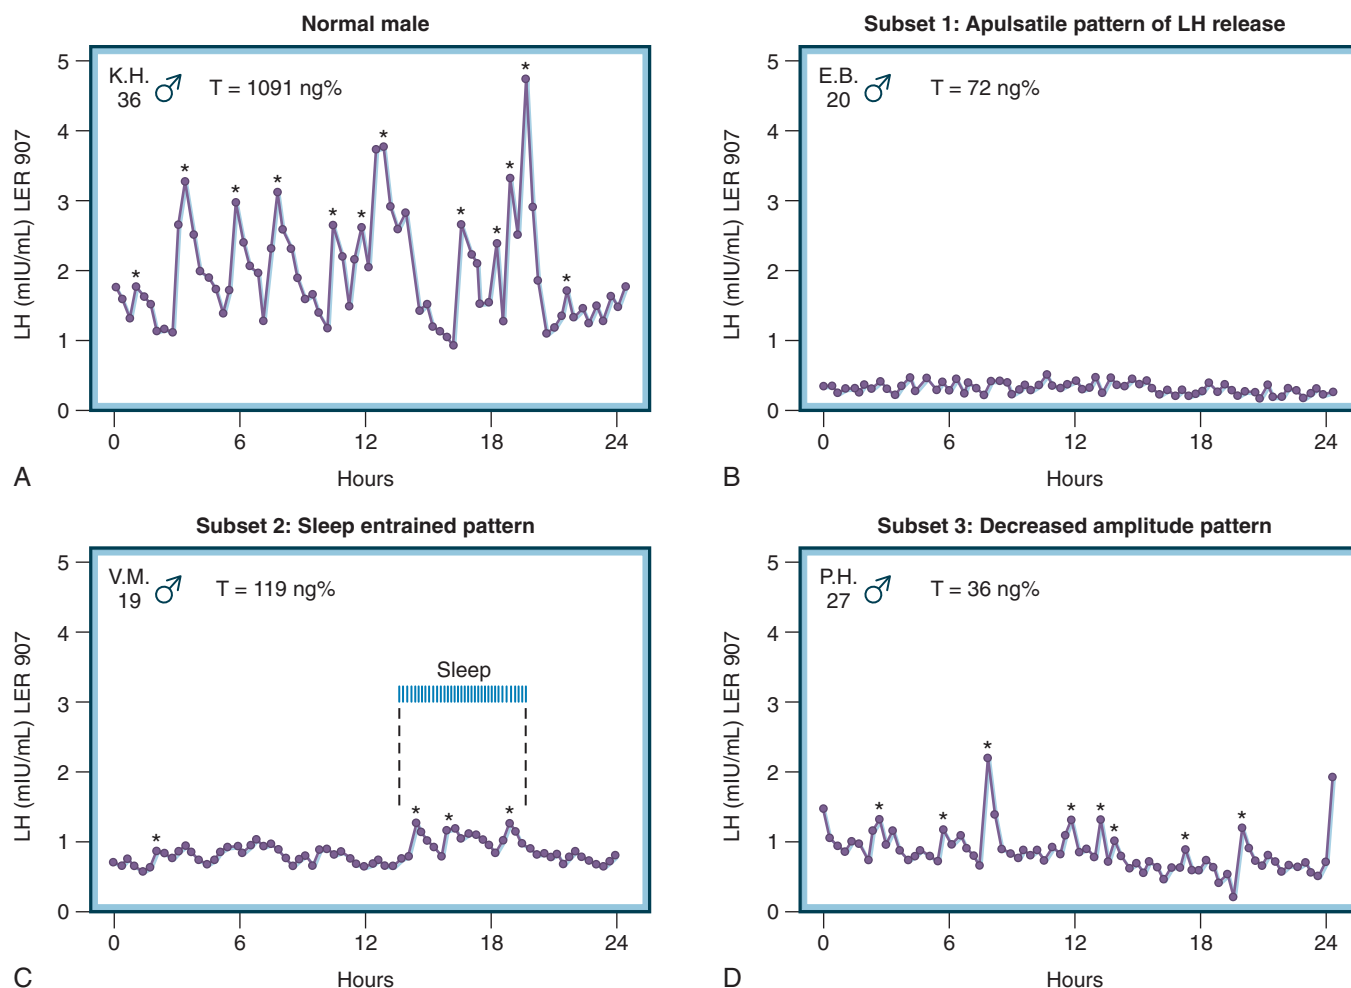

Figure 19-7 Endogenous pulsatile secretion of luteinizing hormone (LH) in a normal man (**A**) and in men with idiopathic hypogonadotropic hypogonadism (**B** through **D**), assessed by blood sampling every 20 minutes for 24 hours. In normal men (**A**), discrete pulses (*) of LH occur approximately every 2 hours, reflecting pulsatile release of gonadotropin-releasing hormone (GnRH) from the hypothalamus, and stimulate normal adult levels of testosterone (T). Most men with idiopathic hypogonadotropic hypogonadism (**B**) demonstrate no detectable LH pulses and have prepubertal testosterone concentrations. Others exhibit primarily sleep-entrained LH pulses of reduced amplitude without significant LH pulsatility during the waking hours (**C**) or LH pulses of reduced amplitude throughout sleep and waking hours (**D**) with pubertal or prepubertal testosterone levels, respectively. (From Santoro N, Filicori M, Crowley WF Jr: Hypogonadotropic disorders in men and women: diagnosis and therapy with pulsatile gonadotropin-releasing hormone. *Endocr Rev*. 1986;7:11-23.)

IHH due to GnRH deficiency and the loss or impairment of the sense of smell (anosmia or hyposmia, respectively) that occurs in patients with Kallmann's syndrome. Loss-of-function mutations occur in genes that play important roles in the migration and embryologic development of GnRH neurons, such as the genes for Kallmann's syndrome 1 (*KAL1*), *KAL2* (now called *fibroblast growth factor receptor 1* [*FGFR1*]), and prokineticin receptor 2 (*PROKR2*) and its ligand, prokineticin 2 (*PROK2*). Similarly, genes that are important in the regulation of GnRH neurons may sustain loss-of-function mutations; examples include the genes for kisspeptin 1 receptor (*KISS1R* [formerly *GPR54*]) and its ligand, kisspeptin 1 (*KISS1*), also called metastin; the neurokinin B (tachykinin 3) receptor (*TACR3*) and its ligand (*TAC3*); and the GnRH receptor (*GNRHR*) and its ligand (*GNRH*). All of these result in isolated GnRH deficiency associated with impaired pubertal development, often in combination with anosmia or hyposmia or other morphologic defects.⁵⁰

Gonadotropin-Releasing Hormone Regulation of Gonadotropin Secretion

GnRH released from the hypothalamus into the hypophyseal portal system binds to G protein-coupled GnRH receptors on anterior pituitary gonadotrophs.⁵¹ In humans, GnRH receptors are coupled primarily to $G_{q/11}$ proteins, which activate phospholipase C- β to produce 1,2-diacylglycerol (DAG) and inositol 1,4,5-triphosphate (IP3). DAG activates protein kinase C (PKC), and IP3 mobilizes intracellular calcium, which binds to the calcium-binding protein, calmodulin. Both PKC and calcium phosphorylate and activate a number of transcription factors, resulting in increased synthesis of the gonadotropin subunits LH β , FSH β , and the common α -subunit and release of intact LH and FSH and free α -subunits into the circulation. The GnRH receptor may also be coupled to G_s protein, which activates protein kinase A (PKA), resulting in synthesis and release of gonadotrophs.

LH and FSH, together with another anterior pituitary hormone, thyroid-stimulating hormone (TSH), and a placental hormone, hCG, are members of the glycoprotein hormone family. Glycoprotein hormones are heterodimers in which two common α -subunits are each linked to a unique β -subunit; this structure confers their ability to bind to their cognate receptors and their biologic specificity. In the pituitary gonadotroph, the common α -subunit and the LH β - and FSH β -subunits are products of different genes that are synthesized and regulated differentially.⁵² After the subunits are synthesized, an α -subunit combines noncovalently with either an LH β - or an FSH β -subunit. After translation, the heterodimer undergoes variable glycosylation wherein oligosaccharide chains (glycans) are attached covalently to specific amino acids, resulting in LH and FSH molecules with a high degree of microheterogeneity (i.e., a large number of LH and FSH isoforms characterized by different glycosylation patterns). The gonadotropin α -subunit is produced in excess relative to the LH β - and FSH β -subunits; it too is glycosylated, and free α -subunit is cosecreted into the circulation with LH and FSH. Many nonfunctional and gonadotropin-secreting pituitary adenomas secrete excessive amounts of free α -subunit into the circulation.⁵³

The degree of glycosylation of gonadotropins and other glycoprotein hormones alters their clearance rate from circulation and their signal transduction after receptor binding, thereby affecting their biologic activity in vivo. The half-life in circulation of gonadotropins increases with greater degrees of glycosylation: hCG > FSH > LH > free α -subunit. In humans, the initial half-life of disappearance for LH is about 40 minutes, and the secondary half-life of disappearance is about 120 minutes; for FSH, these periods are approximately 4 and 70 hours, respectively.^{54,55} Variations in glycosylation of LH and FSH result in substantial microheterogeneity among circulating gonadotropin isoforms, which vary in half-life and biologic activity and may be altered by particular physiologic conditions, such as during puberty, with aging, and with androgen deprivation.

Clinically, serum LH and FSH levels are measured with rapid, nonradioactive, highly sensitive immunoassays that use monoclonal antibodies recognizing two separate epitopes on the gonadotropin molecule. Gonadotropin measurements are essential in the evaluation of men with hypogonadism to distinguish those who have a primary testicular disorder (*primary hypogonadism*, in which gonadotropins are high) from those who have a secondary hypothalamic or a pituitary disorder (*secondary hypogonadism*, in which gonadotropins are low or normal). Specific immunoassays for free α -subunit are used to diagnose and monitor patients with nonfunctional and gonadotropin-secreting pituitary adenomas.

Gonadotropin Control of Testicular Function

Luteinizing Hormone Regulation of Leydig Cells

Circulating LH binds to the G protein-coupled receptor for LH and hCG (termed *LHCGR*) on the surface of Leydig cells, resulting in receptor aggregation and a conformational change that activates G_s protein. G_s protein, in turn, results primarily in cyclic adenosine monophosphate (cAMP)-dependent activation of PKA.⁵⁶ Activated PKA increases the production of proteins that regulate steroidogenesis and testosterone biosynthesis (Fig. 19-8). The main proteins regulated by LH-stimulated PKA are

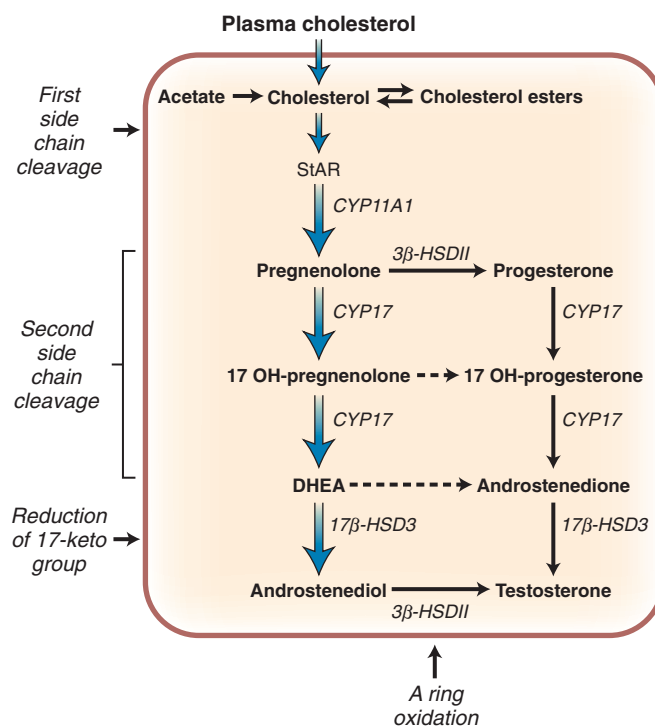

Figure 19-8 Testosterone biosynthetic pathways in the Leydig cell of the human testis. Cholesterol may be synthesized *de novo* from acetate within the Leydig cell or derived from hydrolysis of cholesterol esters or circulating cholesterol. Cholesterol is transported into the inner mitochondrial membrane by steroidogenic acute regulatory protein (StAR); there it is converted to pregnenolone by the cholesterol side-chain cleavage enzyme (CYP11A1). Biosynthesis of testosterone in the human testis proceeds predominantly through the Δ^5 pathway, in which pregnenolone is converted to 17-hydroxypregnenolone and then to dehydroepiandrosterone (DHEA), both by 17 α -hydroxylase/17,20 lyase (CYP17), which is converted to androstenedione by 17 β -hydroxysteroid dehydrogenase type 3 (17 β -HSD3 or HSD17B3) and then to testosterone by 3 β -hydroxysteroid dehydrogenase type II (3 β -HSDII or HSD3B2). In the Δ^4 pathway, pregnenolone is converted successively to 17-hydroxyprogesterone, androstenedione, and testosterone. (From Bhasin S. Testicular disorders. In: Kronenberg HM, Melmed S, Polonsky KS, et al., eds. *Williams Textbook of Endocrinology*, 11th ed. Philadelphia, PA: Elsevier; 2008:645-698.)

1. *Steroidogenic acute regulatory protein (StAR)*, a transport protein that regulates transfer of cholesterol from the outer to the inner mitochondrial membrane—the rate-limiting step for steroid production
2. *Cytochrome P450 isoenzyme 11a1 (CYP11A1)*, also called cholesterol side-chain cleavage enzyme, within the inner mitochondrial membrane, which catalyzes the conversion of cholesterol delivered by StAR protein to pregnenolone—the first and rate-limiting enzymatic step in steroidogenesis
3. *CYP17A1*, also called 17 α -hydroxylase, which catalyzes the conversion of pregnenolone to 17 α -hydroxypregnenolone—the second enzymatic step in testosterone biosynthesis.⁵⁷

In humans, cholesterol is synthesized within Leydig cells from acetate by *3-hydroxy-3-methyl-glutaryl-coenzyme A (HMG-CoA) reductase*, or it is derived from circulating low-density lipoprotein (LDL) cholesterol.

Clinically, rare inactivating mutations of the LHCGR cause Leydig hypoplasia, resulting in impaired male genital development and male pseudohermaphroditism due to insufficient testosterone production during fetal development.⁵⁸ (Male pseudohermaphroditism is now classified as

a 46,XY disorder of sex development [DSD]; see Chapter 23.) Rare LH β mutations cause failure of normal male pubertal development with normal genital development at birth, evidence that normal endogenous LH secretion is not required for male sexual differentiation during fetal development and that hCG stimulation of testosterone production by fetal Leydig cells is the main driver.⁵⁹ Activating mutations of the LHCGR have been found in boys with familial precocious puberty (*testotoxicosis*).⁶⁰ Inhibitors of HMG-CoA reductase (statins) used to treat hypercholesterolemia do not affect serum testosterone levels.

Leydig Cell Production of Testosterone and Insulin-Like Factor 3

In the human testis, LH-stimulated transport of cholesterol into the inner mitochondrial membrane is followed by conversion of cholesterol to pregnenolone by CYP11A1 and conversion of pregnenolone to 17 α -hydroxypregnenolone by CYP17A1. Testosterone biosynthesis then proceeds via a series of further enzymatic steps initially within the Δ^5 steroid biosynthesis pathway (see Fig. 19-8).^{57,61}

CYP17A1 also has 17,20-lyase (*desmolase*) activity and catalyzes the further conversion of 17 α -hydroxypregnenolone to dehydroepiandrosterone (DHEA). DHEA then is converted to Δ^5 -androstenediol by 17 β -hydroxysteroid dehydrogenase 3 (17 β -HSD3 or HSD17B3). DHEA and Δ^5 -androstenediol are converted to the Δ^4 steroids, Δ^4 -androstenedione and testosterone, respectively, by the enzyme 3 β -HSD/ Δ^5 -4 isomerase (HSD3B1).

The early steroid precursors, pregnenolone and 17 α -hydroxypregnenolone, also may be converted to progesterone and 17 α -progesterone, respectively, by HSD3B1 and then proceed down the Δ^4 pathway to testosterone synthesis. However, in the human testis, the Δ^5 pathway is the predominant early steroid biosynthetic pathway for testosterone production. Testosterone may be converted in the testes to the active metabolites, estradiol (E₂) and DHT, by the enzymes *aromatase* (CYP19A1) and *steroid 5 α -reductase type 1* (SRD5A1, the predominant isoform found in the testis), respectively.

Mutations in testosterone biosynthetic enzymes result in abnormalities of sexual differentiation and varying degrees of male pseudohermaphroditism, depending on the severity of androgen deficiency.⁶²

Testosterone is the major androgen produced by the testis. In humans, the average secretion rate of testosterone is approximately 7000 μ g/day. The testes also secrete significant but quantitatively smaller amounts of 17 α -progesterone, pregnenolone, Δ^4 -androstenedione, and progesterone. Very little estradiol (about 10 μ g/day) or DHT (about 69 μ g/day) is secreted by the testis (Fig. 19-9).^{8,63}

In response to pulsatile LH stimulation, testosterone is secreted episodically into the spermatic vein and then into the general circulation. However, testosterone pulses are less discrete, relatively in low amplitude, and concordant with LH pulses only after a lag time of 80 to 120 minutes, suggesting a relatively sluggish response of Leydig cells to LH stimulation.⁴⁵ In addition to this ultradian variation, testosterone levels in young men exhibit a circadian variation characterized by a maximum excursion of 140 ng/dL, with peak testosterone levels occurring at approximately 8 a.m. and nadir levels at 8 p.m.⁶⁴ The circadian variation in testosterone levels is blunted but still present in older men, with a maximum excursion of 60 ng/dL. The testosterone response to hCG (LH-like) stimulation is greater in the morning than in the evening, suggesting that diurnal

Figure 19-9 Relative steroid hormone secretion rates from the human testis. Secretion rates were calculated from arteriovenous (AV) differences across the testis of testosterone and other steroids, assuming a testosterone secretion rate of 7000 μ g per 24 hours and using the following formula: Secretion rate (SR) = Assumed testosterone SR/testosterone AV difference \times AV difference of steroid in question. Testosterone (T) is the main steroid secreted by the testis; much lower amounts of 17-hydroxypregesterone (17-OHP), pregnenolone (Δ_5 P), androstenedione (Δ_4 A), progesterone (P), and dihydrotestosterone (DHT) are also secreted. (From Hammond GL, Ruokonen A, Kontturi M, et al. The simultaneous radioimmunoassay of seven steroids in human spermatic and peripheral venous blood. *J Clin Endocrinol Metab.* 1977;45:16-24.)

variation in Leydig cell responsiveness may contribute to the circadian variation in testosterone concentrations.⁶⁵ Both the ultradian and the circadian variation in testosterone levels contribute to the variability in testosterone measurements within an individual; together with assay variability, this underscores the importance of repeating testosterone measurements during the clinical evaluation of patients with clinical manifestations of male hypogonadism.

INSL3 is a peptide hormone in the relaxin-insulin family that is produced by Leydig cells and secreted into circulation.⁶⁶ Serum levels of INSL3 reflect the number and differentiation status of Leydig cells. During puberty, LH induces proliferation and differentiation of Leydig cells and production of INSL3. Serum INSL3 levels increase progressively during puberty, reaching adult levels at about 18 years of age and remaining stable until 35 to 40 years of age, after which they decline steadily with age.

Men with anorchia and bilateral orchidectomy, in whom Leydig cells are absent, and men with chronic gonadotropin suppression induced by GnRH analogues or androgens have undetectable or very low levels of INSL3. In men with hypogonadotropic hypogonadism, INSL3 levels are undetectable; in these patients, hCG (LH-like) stimulation increases serum testosterone levels within 72 to 96 hours but has no stimulatory effect on INSL3 levels. However, chronic hCG treatment, presumably because of induction of Leydig cell differentiation by longer-term LH-like stimulation, increases both testosterone and INSL3 levels in these men.⁶⁷ In men with unilateral orchidectomy, INSL3 levels are intermediate between those in men with bilateral orchidectomy and those in normal men, but testosterone

levels are normal, supporting the importance of Leydig cell number for circulating INSL3 concentrations.

Follicle-Stimulating Hormone and Testosterone Regulation of Sertoli Cells

Circulating FSH binds to G protein-coupled FSH receptors on the surface of Sertoli cells, activating G_s protein, which in turn activates cAMP.⁶⁸ cAMP then activates PKA and other signal-transduction proteins (e.g., phosphatidylinositol 3-kinase, phospholipase A_2 , calcium channel proteins, mitogen-activated protein kinase [MAPK]). Activated PKA activates a number of proteins, including the transcription factor, *cAMP response element-binding protein* (CREB); these proteins, in turn, regulate gene expression and production of Sertoli cell proteins that play important roles in supporting and regulating spermatogenesis within the seminiferous tubules. In rodents, the expression of FSH receptors in Sertoli cells varies cyclically with the stage of spermatogenesis, being highest in stages XIII through I and lowest in stages VII through VIII.⁶⁹ The precise roles of Sertoli cell products in human spermatogenesis are poorly understood and derive from studies using Sertoli cells obtained primarily from immature animals, mostly rodents.

Testosterone produced locally by Leydig cells binds to intracellular ARs in the cytoplasm of Sertoli cells; ligand-bound AR translocates to the nucleus, where it binds to androgen response elements (AREs) and interacts with coregulator proteins to regulate gene expression and production of Sertoli cell proteins that play vital roles in supporting and regulating spermatogenesis. The expression of the AR also varies cyclically with the stage of spermatogenesis, being highest in stage VII, when FSH receptor expression is the lowest.⁷⁰

The major functions of Sertoli cells^{71,72} are (1) to maintain seminiferous tubule structure and compartmentalization; (2) to provide nutrients and growth factors to developing germ cells and spermatozoa; (3) to translocate, sculpt, and release developing germ cells; (4) to secrete seminiferous tubule fluid; and (5) to produce reproductive hormones.

Maintenance of Seminiferous Tubule Structure and Compartmentalization. The blood-testis barrier is formed by basal tight junctions between adjacent Sertoli cells; these serve to compartmentalize the seminiferous tubule into basal and adluminal compartments. Compartmentalization provides an environment in which developing germ cells are protected from external insults and the immune system.

Sertoli cells produce a number of junctional complex, structural, and extracellular matrix proteins such as cell adhesion molecules (e.g., claudin 3, which is particularly important for the integrity of Sertoli cell tight junctions), cadherins, laminins, type I and type IV collagen, and proteoglycans including chondroitin and heparin. These proteins are important in maintaining the structural integrity and support for developing germ cells, forming the blood-testis barrier, mediating cell-to-cell interactions, and maintaining polarized secretion of products by Sertoli cells.

Provision of Nutrients and Growth Factors to Developing Germ Cells and Spermatozoa. Although it is protective, the blood-testis barrier also isolates developing germ cells from nutrients, hormones, and growth factors that are present in the systemic circulation. The Sertoli cell has an essential role in producing vital nutrients, cofactors, and proteins that are needed for the normal progression of

spermatogenesis and support of spermatozoa being transported within the seminiferous tubule lumen.

Sertoli cells produce pyruvate and contain lactate dehydrogenase, which catalyzes the conversion of pyruvate to lactate, the preferred energy substrate of germ cells.

Most of the proteins produced by Sertoli cells are binding or transport proteins for substances (e.g., metals, vitamins, sphingolipids, androgens, hormones, growth factors) that serve as cofactors and regulators of germ cell development within the seminiferous tubule. Binding proteins produced by Sertoli cells include transferrin, an iron-binding protein; ceruloplasmin, a copper-binding protein; glycosphingolipid-binding protein; sulfated glycoprotein 2 (SGP-2), also called clusterin, a lipid-binding protein with other biologic activities; *androgen-binding protein* (ABP); α_2 -macroglobulin, which serves as a binding protein for inhibin and activin; follistatin, a potent binding protein for activin; and insulin-like growth factor-binding proteins (IGFBPs), which bind insulin-like growth factor type 1 (IGF1).

ABP is a testicular homologue of the major circulating androgen-binding protein, *sex hormone-binding globulin* (SHBG), which is synthesized by the liver and encoded by the same gene.⁷³ Based on studies in rodents, ABP is thought to play a role in regulating local testosterone concentrations in the seminiferous tubule and epididymis. However, one study reported that human SHBG is expressed in germ cells but not in Sertoli cells and that a smaller isoform of SHBG is located between the outer acrosomal membrane and the sperm plasma membrane and is released during capacitation.⁷⁴ These findings suggest a potentially different role of SHBG/ABP in humans and rodents and underscore the hazard of extrapolating results from animal studies.

The Sertoli cell also produces a number of growth factors, such as IGF1, basic fibroblast growth factor, activin A, transforming growth factor- α (TGF- α) and TGF- β , interleukin-1 α (IL-1 α) and IL-6, stem cell factor (SCF, the KIT ligand), glial cell-derived neurotrophic factor (GDNF), and polyamines (putrescine, spermine, and spermidine), that act both as paracrine regulators of stem cell renewal, germ cell development, and Leydig cell and peritubular myoid cell function and as autocrine regulators.

Translocation, Sculpting, and Release of Developing Germ Cells. Sertoli cells actively move developing germ cells from the basal compartment through the adluminal compartment and release spermatozoa from the seminiferous epithelium into the lumen (spermiation). During translocation, Sertoli cells remove degenerating germ cells, residual cytoplasm from late elongated spermatids (residual body), and seminiferous tubule fluid and contents by phagocytosis and pinocytosis.

The Sertoli cell produces proteases and protease inhibitors (e.g., testibumin or SGP-1, tissue plasminogen activators, type IV collagenase, cystatin, α_2 -macroglobulin) that are involved in germ cell translocation, removal of degenerating germ cells, and spermiation.

Secretion of Seminiferous Tubule Fluid. Seminiferous tubule fluid serves important roles in the delivery of nutrients to developing germ cells within the seminiferous epithelium, transportation of regulatory factors and nutrients within the seminiferous tubule lumen, and transportation of spermatozoa released into the seminiferous tubule lumen to the rete testis, efferent ducts, and epididymis.

Production of Reproductive Hormones. Sertoli cells produce hormones that are important in male reproductive

differentiation and function. These include AMH, which causes regression of the müllerian ducts, preventing uterine and fallopian tube formation during embryogenesis; inhibin B and activin A, peptide hormones that, respectively, participate in negative feedback regulation of FSH secretion and potentially act as a paracrine regulator of spermatogenesis; and estradiol, a potent estrogen that is produced via aromatization of testosterone in immature Sertoli cells.

FSH acts directly and testosterone (secreted by Leydig cells in response to LH) acts directly and also indirectly (e.g., by stimulating peritubular myoid cells) to control Sertoli cell function and regulate spermatogenesis. Gene expression profiling studies using microarray analysis in rat Sertoli cells treated with FSH, in Sertoli cell-specific AR mutant mice, and in GnRH mutant mice treated with testosterone have provided insight into specific Sertoli cell genes that are regulated directly by FSH and testosterone.⁷⁵ However, similar studies in humans investigating the regulation of Sertoli cell gene expression, specifically by FSH and testosterone, have yet to be performed.

Paracrine and Autocrine Regulation of Testis Function

As described earlier, gonadotropins, LH, and FSH secreted by the pituitary are the major endocrine regulators, and testosterone produced by Leydig cells in response to LH stimulation is the main paracrine regulator, of testicular function. However, there is evidence, mostly from studies in experimental animals and in vitro studies using isolated testis cell types from animals, that Leydig, Sertoli, and peritubular myoid cells and macrophages in the testis secrete other paracrine and autocrine factors that may be important modulators of testosterone and sperm production.

One of the most important examples of paracrine regulation within the testis is the effect of testosterone, produced locally by Leydig cells, on Sertoli cell function and spermatogenesis. There is evidence that testosterone has both a direct effect on Sertoli cell function and spermatogenesis and an indirect effect (acting through androgen action) on peritubular myoid cells. In GnRH- and gonadotropin-deficient *hpg* mice in which the AR has been knocked out specifically in Sertoli cells, DHT treatment is not able to stimulate spermatogenesis, suggesting that direct androgen action on Sertoli cells is needed to stimulate spermatogenesis.⁷⁶ Animals with a peritubular myoid cell-specific AR knockout demonstrate impaired Sertoli function (i.e., reduced seminiferous tubule fluid and Sertoli cell androgen-dependent gene expression), azoospermia, and infertility not explained by alterations in testosterone, LH, and FSH levels.⁷⁷ These findings suggest that the paracrine effect of Leydig cell-produced testosterone on Sertoli cell function and regulation of spermatogenesis is mediated in part by androgen-driven interactions between peritubular myoid cells and Sertoli cells. Whether these stromal-epithelial cell interactions occur in humans is not known. At present, the roles of paracrine and autocrine factors other than testosterone in the regulation of human testis function are not clear.

Hormonal Control of Spermatogenesis

FSH and LH are the main hormonal regulators of spermatogenesis in humans. The effect of FSH on spermatogenesis is mediated by a direct endocrine action on Sertoli cells, whereas that of LH is mediated by an action on Leydig cells to produce testosterone, which in turn acts locally within

the testes in a paracrine manner, with direct effects on Sertoli cells and possibly indirect effects through peritubular myoid cell regulation of Sertoli cells. The gonadotropin requirements necessary for the initiation of spermatogenesis at the time of puberty differ from those needed for the maintenance of sperm production, once initiated, in adults.^{10,78}

Initiation of Spermatogenesis. Usually, both FSH and LH are required to initiate spermatogenesis at the time of puberty. In men with prepubertal gonadotropin deficiency (e.g., IHH), treatment with LH (hCG) is needed to stimulate intratesticular testosterone production sufficient to support spermatogenesis and seminal fluid production by accessory sex glands (seminal vesicles and prostate gland). However, most such patients also require FSH treatment to initiate and complete the first wave of spermatogenesis and to produce sperm in the ejaculate.⁷⁹ In some men with incomplete gonadotropin deficiency (usually with evidence of endogenous FSH secretion, such as larger testes volume), LH treatment alone is sufficient to initiate and complete spermatogenesis. FSH treatment without LH (hCG) does not stimulate sperm production in men with prepubertal gonadotropin deficiency.

Natural inactivating mutations of gonadotropin β -subunits and receptors provide some insight into the roles of LH and FSH in initiating spermatogenesis. Men with inactivating mutations of LH β usually have a lack of pubertal development and arrested spermatogenesis or azoospermia and infertility.⁵⁹ Recently, however, a man with an LH β mutation resulting in a partially active LH molecule (as evidenced by expression of steroidogenic enzymes in a few mature Leydig cells and low intratesticular testosterone concentrations) was reported to have complete and quantitatively normal spermatogenesis.⁸⁰ This finding suggests that complete spermatogenesis may be initiated by low concentrations of LH and intratesticular testosterone in the presence of high serum FSH levels, as were present in this case.

Men with inactivating LH receptor mutations present with varying degrees of impaired sexual differentiation or male pseudohermaphroditism (ranging from ambiguous genitalia to perineoscrotal hypospadias) and azoospermia, although defects in sperm production are confounded by the presence of cryptorchidism in many of these men.⁵⁸ Recently, a man with a partially inactivating mutation of the LH receptor was reported to have micropenis, delayed puberty, low serum testosterone concentrations, and normal FSH levels but bilaterally normal-sized, descended testes and normal sperm production, albeit with low sperm concentration (oligozoospermia).⁸¹ This finding suggests that spermatogenesis may be initiated by very low LH activity in presence of normal FSH levels.

Men with inactivating mutations of FSH β have been found generally to have azoospermia with low or low-normal testosterone and high LH levels.⁸²⁻⁸⁵ In contrast, men with inactivating FSH receptor mutations have been reported to have moderate to severely reduced sperm counts (but not azoospermia) with normal testosterone and normal to high LH levels.^{58,86} The reason for the apparent discrepancy in degree of spermatogenic impairment exhibited by men with FSH β versus FSH receptor mutations is not clear. It is possible that residual receptor function in men with FSH receptor mutations results in persistent small amounts of FSH activity or that men with FSH β mutations have greater Leydig cell dysfunction, as evidenced by lower serum concentrations of LH and intratesticular testosterone.

In summary, findings from the small number of reports of men with inactivating mutations of gonadotropin β -subunits and receptors suggest that initiation of the first wave of spermatogenesis may require only very low levels or activity of either LH (intratesticular testosterone) or FSH. Clinically, however, most men with prepubertal gonadotropin deficiency require treatment with both LH and FSH to initiate spermatogenesis during puberty. Because FSH stimulates Sertoli cell proliferation and number during testis development, it plays an important role in determining the capacity for quantitatively normal spermatogenesis.

Maintenance of Spermatogenesis. In men with prepubertal gonadotropin deficiency (e.g., IHH), once spermatogenesis has been initiated with LH (hCG) and FSH treatment, sperm production may be maintained with LH treatment alone without continued FSH administration.⁷⁹ However, spermatogenesis is not stimulated by administration of FSH in combination with testosterone (to maintain normal levels of serum testosterone but continued low LH and intratesticular testosterone levels) in men with IHH. Spermatogenesis may be reinitiated with LH (hCG) alone in men with IHH after a period of gonadotropin deficiency associated with exogenous testosterone replacement therapy. Furthermore, in men with gonadotropin deficiency and azoospermia acquired as an adult (e.g., secondary to a pituitary adenoma), spermatogenesis may be reinitiated and maintained with LH (hCG) treatment alone.⁷⁹

In normal men with experimental gonadotropin deficiency induced by high-dose testosterone administration, spermatogenesis may be reinitiated and maintained by either LH or hCG alone, despite markedly suppressed FSH levels, or by FSH alone, despite severely suppressed LH (and presumably low intratesticular testosterone) concentrations. However, sperm production was not stimulated by either LH or FSH alone to the baseline levels that existed before experimental gonadotropin suppression.⁸⁷ In this model of gonadotropin deficiency, treatment with both LH (hCG) and FSH restored sperm counts fully to baseline values. Finally, in support of the ability of FSH alone to stimulate sperm production, spermatogenesis was maintained despite undetectable serum gonadotropin levels in a hypophysectomized man who had an activating FSH receptor mutation.⁸⁸

Together, these findings suggest that a normal concentration of either FSH or LH is sufficient for maintenance of qualitatively normal sperm production, but both gonadotropins are necessary for quantitatively normal spermatogenesis in male humans.

The effect of gonadotropins on specific stages of spermatogenesis has been studied in normal men with experimental gonadotropin suppression induced by administration of high-dose progestin and testosterone. In these gonadotropin-deficient men, selective replacement of either FSH or LH (increasing intratesticular testosterone) supported all stages of spermatogenesis, including spermatogonial maturation, meiosis, spermiogenesis, and spermiation, but each agent had predominant actions on specific stages.⁸⁹ FSH exerts a relatively greater effect on maturation of spermatogonia (conversion of spermatogonia A_p to spermatogonia B), early meiosis, and maintenance of pachytene spermatocytes (conversion of spermatogonia to pachytene spermatocytes). LH (stimulating intratesticular testosterone) has predominant effects on the completion of meiosis (conversion of pachytene spermatocytes to round spermatids) and on spermiation (release of mature spermatozoa). FSH and LH (intratesticular

testosterone) exert similar effects on spermiogenesis (conversion of round to elongated spermatids).

In normal men, LH stimulates intratesticular testosterone concentrations that are approximately 100- to 200-fold higher than serum testosterone levels and correlate with circulating LH levels. Administration of various combinations of exogenous testosterone, progestin, and GnRH antagonist to induce gonadotropin deficiency in male contraception trials suppressed intratesticular testosterone by 98%, to concentrations comparable to those in serum, and reduced sperm production, producing severe oligozoospermia or azoospermia.⁹⁰ Short-term administration of hCG (LH-like activity) in normal men with experimental gonadotropin deficiency resulted in a dose-dependent increase in intratesticular testosterone.⁹¹

Testosterone replacement therapy in gonadotropin-deficient men does not increase intratesticular testosterone sufficiently to support spermatogenesis. In fact, testosterone treatment suppresses endogenous gonadotropin levels and may suppress sperm production. However, this cannot be assumed to occur in all testosterone-treated gonadotropin-deficient men, especially if testosterone replacement is not adequate. In one study involving a small number of men with acquired hypogonadotropic hypogonadism due to hypothalamic-pituitary disease, half had detectable sperm counts ranging from very low (1 million/mL) to normal (120 million/mL) on testosterone replacement therapy, mostly because of incomplete gonadotropin suppression associated with an inadequate testosterone regimen (200 to 250 mg given intramuscularly [IM] every 3 to 4 weeks).⁹²

Spermatogenesis is maintained with intratesticular testosterone concentrations that are 10% of normal, but the minimum concentration needed to support sperm production is not known. Intratesticular testosterone is converted within the testes to its active metabolites, estradiol and DHT, by CYP19A1 (aromatase) and 5 α -reductase (SRD5A1), respectively. As with testosterone, intratesticular concentrations of estradiol are about 100-fold higher than serum estradiol levels; however, intratesticular concentrations of DHT are only approximately 15-fold higher than levels in circulation.⁹³ The roles of these relative high concentrations of estradiol and DHT within the testes in the maintenance of spermatogenesis are not clear.

Negative Feedback Regulation of Gonadotropin Secretion

As described earlier, the feed-forward regulation of testicular function involves hypothalamic GnRH stimulation of pituitary gonadotropin secretion, which in turn stimulates the testes to secrete testosterone and increase sperm production (see Fig. 19-6). An important aspect of hypothalamic-pituitary-testicular axis regulation is the negative feedback suppression of hypothalamic GnRH and pituitary gonadotropin secretion by steroid and peptide hormones produced by the testes. Testosterone, produced by Leydig cells of the testis, and estradiol, its active metabolite, act at both the hypothalamus and the pituitary gland to inhibit GnRH and gonadotropin secretion. Inhibin B, produced by Sertoli cells within seminiferous tubules of the testis, acts primarily on the pituitary to suppress FSH secretion.

Recently, in a series of elegant prospective studies, normal men and GnRH-deficient men with IHH treated with physiologic doses of pulsatile GnRH (via a GnRH clamp) underwent medical castration and aromatase inhibition induced by high-dose ketoconazole plus physiologic doses of testosterone or estradiol. The effects of these

interventions on production of FSH and LH were measured. These studies have helped to define the relative roles of testosterone and estradiol in regulating gonadotropin secretion and the sites of negative feedback by these steroids.^{94,95} It appears that both testosterone and estradiol derived from aromatization of testosterone exert negative feedback effects at the hypothalamus to suppress pulsatile GnRH secretion. These studies also demonstrated that negative feedback inhibition of pituitary LH and FSH secretion by testosterone requires aromatization of testosterone to estradiol. The suppression of FSH by estradiol is modest when inhibin B levels are normal and testes are normal, suggesting that inhibin B is the main physiologic negative feedback regulator of FSH secretion.⁹⁶ When inhibin B levels are low, as in men with seminiferous tubule failure or anorchia, the negative feedback effect of estradiol derived from testosterone assumes a greater role in suppressing FSH.

Although active metabolism of testosterone to estradiol is important in the negative feedback actions of testosterone, conversion of testosterone to DHT by 5 α -reductase types 1 and 2 does not play a major role in steroid feedback. Men with mutations in *SRD5A2* exhibit only modest elevations in gonadotropins and increases in LH pulse amplitude but not frequency.⁹⁷ Men with benign prostatic hyperplasia (BPH) and normal men treated with finasteride (an *SRD5A2* inhibitor) or dutasteride (an *SRD5A1* and *SRD5A2* inhibitor) do not demonstrate increases in serum LH and FSH levels.⁹⁸ These findings suggest a relatively minor role for DHT in physiologic negative feedback regulation of gonadotropins. However, administration of supraphysiologic amounts of DHT does suppress concentrations of LH (by 30% to 60%) and FSH (by 15% to 30%).⁹⁹

The pituitary gonadotrophs contain estrogen receptor α (ER α), but GnRH neurons appear to lack both ER α and AR. The negative feedback actions of testosterone and estradiol are thought to be mediated indirectly by other neuronal systems that relay steroid feedback signals to GnRH neurons. Studies in animals suggest that neurons that produce *kisspeptin*, a 54-amino-acid peptide product of the *KISS1* gene, may be candidate mediators of steroid negative feedback.¹⁰⁰ These neurons interact directly with GnRH neurons in the medial basal hypothalamus, the majority of which contain the kisspeptin receptor, *KISS1R*, and release kisspeptin, thereby stimulating GnRH secretion. Kisspeptin neurons may also interact with other neurons (e.g., γ -aminobutyric acid [GABA] neurons) to indirectly regulate GnRH secretion. Kisspeptin neurons contain both AR and ER α . In experimental animals, castration increases kisspeptin expression, coinciding with an increase in GnRH and gonadotropin secretion; sex steroid treatment with testosterone, estradiol, or DHT reverses these changes, and kisspeptin antagonists block the postcastration increase in LH secretion. In humans, mutations in *KISS1* or *KISS1R* cause hypogonadotropic hypogonadism and impaired pubertal development,¹⁰¹ and there is accumulating evidence in animals that kisspeptin may have an important role in the initiation of puberty.

Inhibins are heterodimeric glycoproteins belonging to the TGF- β superfamily of proteins, which includes activins, inhibins, TGF- β , bone morphogenetic proteins (BMPs), and growth and differentiation factors (GDFs) such as AMH and myostatin.¹⁰² Inhibins are composed of an α -subunit connected by a disulfide bridge to either a β_A or a β_B subunit to form inhibin A or inhibin B, respectively. *Inhibin B* (α - β_B heterodimer) is the physiologically relevant inhibin species in humans. Unlike most proteins in the TGF- β family, which act as local paracrine or autocrine regulators of diverse cellular functions, inhibin B acts as a circulating

hormone. Inhibin B is produced by the Sertoli cell in response to FSH stimulation. It binds to a coreceptor composed of the type III TGF- β receptor (TGFBR3 or betaglycan) and the type IIB activin receptor (ACVR2B) and is thought to be the main endocrine negative feedback suppressor of FSH secretion by pituitary gonadotrophs.

In humans, inhibin B levels rise progressively at the time of puberty, correlating with FSH levels and FSH-stimulated Sertoli cell proliferation.¹⁰² Adult levels are reached by mid-puberty. At that time, Sertoli cell function becomes intimately linked to the onset of spermatogenesis, and inhibin B levels assume an inverse relationship with FSH levels as the inhibin B-mediated negative feedback regulation becomes activated. For example, in boys with Sertoli cell-only syndrome, inhibin B levels are normal before puberty as a function of Sertoli cell proliferation but become undetectable at the time of puberty, reflecting the absence of germ cells and Sertoli cell dysfunction. In adults, inhibin B levels are inversely related to the degree of germ cell damage or loss and Sertoli cell dysfunction. This relationship suggests that germ cells regulate Sertoli cell function, although the precise cellular and molecular mechanisms underlying this regulation are not clear. Inhibin B levels have been used as biomarkers of spermatogenesis and Sertoli cell function in research and by some practitioners, but they have not yet been used in routine clinical practice.

Activins include homodimers consisting of two β_A subunits (activin A) or two β_B subunits (activin B) and a heterodimer of one β_A and one β_B subunit (activin AB).^{102,103} Activins are produced by gonadotrophs and bind to ACVR2B receptors. They act primarily as autocrine regulators to stimulate FSH β synthesis and sensitize gonadotrophs to GnRH stimulation, resulting in increased FSH secretion. Inhibin B acts as a selective antagonist of activins in gonadotrophs by binding to ACVR2B receptors. *Follistatins* are glycoproteins produced by gonadotrophs and by folliculostellate cells of the pituitary gland that bind and antagonize the actions of activin. They act as autocrine and paracrine regulators of FSH secretion. Activins and follistatins are also produced in Sertoli cells and germ cells and may act as autocrine and paracrine regulators of testis function.

Negative feedback suppression of gonadotropin production, by pharmacologic doses of androgens or combinations of androgens and progestins or by GnRH antagonists, that is sufficient to result in suppression of sperm production has been the basis for male hormonal contraceptive development strategies.¹⁰⁴

Testosterone Transport, Metabolism, and Actions

Circulating Testosterone

Like other steroid and thyroid hormones, testosterone secreted into the circulation by Leydig cells is mostly bound to plasma proteins, primarily to SHBG and albumin. In the circulation, *total testosterone* is composed of 0.5% to 3.0% *free testosterone* unbound to plasma proteins, 30% to 44% SHBG-bound testosterone, and 54% to 68% albumin-bound testosterone (Fig. 19-10).^{105,106}

Clinically, biologic actions of testosterone, like those of other steroid hormones, are thought to conform to the free hormone hypothesis; that is, the biologic activity of testosterone is mediated only by its free (unbound) concentration or the concentration that is easily dissociable from plasma proteins in circulation.^{106,107} Testosterone is tightly

Figure 19-10 Fractions of circulating testosterone in blood. The majority of circulating testosterone (T) is bound to serum proteins: approximately 54% is weakly bound to albumin, and 44% is tightly bound to sex hormone-binding protein (SHBG). Only about 2% of circulating T is free of protein binding. The combination of free and weakly bound (albumin-bound) T is referred to as bioavailable testosterone.

bound to SHBG with such high affinity (1.6×10^{-9} mol/L) that it is not easily dissociable and available to target tissues for biologic action. In contrast, testosterone is loosely bound to albumin, with a binding affinity (1.0×10^{-4} mol/L) that is several orders of magnitude less than that of SHBG binding. Therefore, albumin-bound testosterone is dissociable and available to target tissues for action. Together, free and albumin-bound testosterone are referred to as *bioavailable testosterone*, because these fractions are available to diffuse into target tissues, bind AR, and affect gene transcription, resulting in androgen action in those tissues.

SHBG, which is synthesized by hepatocytes of the liver, is a homodimeric β -globulin protein composed of a heavy and a light subunit that are identical in peptide sequence and encoded by a single gene but differ in their degree of glycosylation.⁷³ The *SHBG* gene is also expressed in the testes, and in most mammals, Sertoli cells produce a homologue of SHBG (ABP) under the control of FSH. In the human testis, however, *SHBG* appears to be expressed in germ cells rather than Sertoli cells and to produce a truncated form of SHBG that localizes to the acrosome of spermatozoa.⁷⁴ SHBG has a single competitive binding site per molecule; this site binds DHT and testosterone with high affinity and estradiol less avidly. Glycosylation of SHBG is not involved in steroid binding but may prolong the plasma half-life of the protein in circulation. SHBG production by the liver is increased under the influence of estrogens and thyroid and decreased by androgens and insulin.

Counter to the free hormone hypothesis, there is evidence that testosterone bound to SHBG may affect androgen action in some target tissues. In some tissues such as the human prostate, SHBG may bind to a cell surface receptor; testosterone then binds to the SHBG-receptor complex, activating cAMP and affecting target organ function.¹⁰⁸ Glycosylation of SHBG may be important for the interaction of steroid-SHBG complexes with plasma membranes. *Megalin* is a member of the LDL receptor superfamily of proteins that serve as endocytic proteins facilitating the entry of steroids into cells (most notably 25-hydroxyvitamin D into proximal tubule cells of the kidney). Megalin is found in the kidney and also in the epididymides, prostate, ovaries, and uterus. In vitro studies in cells that expressed megalin but no other endocytic receptors found that testosterone, DHT, and estradiol bound to SHBG were endocytosed into cells and activated AR-mediated transcription; these effects were blocked by a megalin antagonist.¹⁰⁹

Furthermore, megalin knockout mice demonstrated impaired testicular descent, an androgen-mediated process. These findings suggest that megalin may be important in mediating cellular uptake of androgens into some tissues. However, the importance of testosterone bound to SHBG or endocytic proteins such as megalin in human physiology remains to be determined.

In normal men with an intact hypothalamic-pituitary-testicular axis, alterations in SHBG concentrations and testosterone bound to SHBG do not have an effect on the physiology and action of androgens at steady state. Any acute effects on free testosterone concentration caused by changes in SHBG would alter the negative feedback regulation of gonadotropins, resulting in normalization of free testosterone levels. For example, an acute increase in SHBG levels may transiently decrease free testosterone levels, but the consequent decrease in testosterone negative feedback increases pituitary LH secretion, which increases testosterone production by the testes to restore normal free testosterone levels. In contrast, alterations in SHBG levels may alter free testosterone levels in men with reproductive disorders who have impaired negative feedback regulation or are receiving testosterone replacement therapy.

SHBG concentrations may be decreased or increased in a variety of commonly encountered clinical conditions.¹¹⁰ Clinically, alterations in SHBG are extremely important to consider in the diagnosis of male hypogonadism (see later discussion). Because serum total testosterone measurements are affected by changes in SHBG levels, accurate measurements of free or bioavailable testosterone are needed to assess the adequacy of Leydig cell function, to determine whether a patient is hypogonadal, and to monitor testosterone replacement in patients with alterations in circulating SHBG concentrations.

Active Metabolism and Catabolism of Testosterone

An important aspect of the effects of testosterone action on target tissues is its active metabolism to *17 β -estradiol* (estradiol) by CYP19A1 and to *DHT* by SRD5A1 and SRD5A2; these are the most potent of the endogenous estrogens and androgens (Fig. 19-11).⁸ Many of the biologic actions of testosterone are mediated by these active metabolites, acting through mechanisms that are dependent on ER α and ER β (estradiol) or on AR (DHT). These active metabolites are formed and act locally as paracrine or autocrine regulators, and they also are secreted and act as endocrine regulators of target tissue function.

Aromatization of Testosterone to Estradiol. Aromatase catalyzes the conversion of testosterone to estradiol as well as the conversion of the weaker androgen, Δ^4 -androstenedione, to the weaker estrogen, estrone. These conversions occur predominantly in adipose tissue but also in other tissues, including brain, bone, breast, liver, blood vessels, and testes (Sertoli cells and Leydig cells). Approximately 40 to 50 μ g of estradiol is produced daily, primarily by extratesticular aromatization of testosterone to estradiol and of Δ^4 -androstenedione to estrone (which is then converted to estradiol by various isoforms of the enzyme, 17 β -HSD). Approximately 15% to 25% of circulating estradiol is produced by the testes, primarily by Leydig cells.¹¹¹

Aromatization of testosterone to estradiol mediates the effects of testosterone on epiphyseal closure at the time of puberty, inhibition of bone resorption and maintenance of bone mineral density (BMD), negative feedback suppression of hypothalamic GnRH secretion and pituitary gonadotropin secretion, increases in high-density lipoprotein (HDL) cholesterol levels, and possibly some aspects of brain

Figure 19-11 Active metabolism of testosterone. Testosterone may be converted to the potent estrogen, 17 β -estradiol, by the enzyme aromatase (CYP19) or to the more potent androgen, dihydrotestosterone (DHT), by the enzyme 5 α -reductase. The effects of testosterone on prostatic growth, skin, and hair follicles in androgen-sensitive areas require 5 α -reduction of testosterone to DHT. The effects of testosterone on prevention of bone resorption, epiphyseal fusion, sexual differentiation of the brain, some aspects of behavior and brain function, plasma lipids (high-density lipoprotein cholesterol), and atherosclerosis progression require aromatization of testosterone to estradiol. (From Bhasin S. Testicular disorders. In: Kronenberg HM, Melmed S, Polonsky KS, et al., eds. *Williams Textbook of Endocrinology*, 11th ed. Philadelphia, PA: Elsevier; 2008:645-698.)

function (e.g., sexual function, mood, cognitive function).^{112,113} In men, circulating estradiol is regulated primarily by the amount of androgen substrates, testosterone and Δ^4 -androstenedione, and by aromatase activity in Leydig cells is controlled primarily by LH. Stimulation of aromatase activity in gonadotropin-deficient men treated with hCG may result in relatively higher concentrations of serum estradiol compared with testosterone and may contribute to benign breast tenderness and enlargement (gynecomastia) during treatment. As in women, men with ER-positive breast cancer may be treated with aromatase inhibitors to reduce estrogen synthesis.

The few men reported with inactivating mutations of the aromatase gene (CYP19A1) have demonstrated tall stature, persistent linear growth after puberty, eunuchoidal body proportion, delayed bone age, osteopenia or osteoporosis and progressive *genu valgum*, and variable impairments in glucose and lipid metabolism, including insulin resistance, elevated triglyceride and low HDL-cholesterol levels, abnormal liver enzymes and fatty liver, variable low sperm counts and infertility, and undetectable estradiol levels with normal to elevated serum testosterone and gonadotropin levels.¹¹⁴ Furthermore, estradiol treatment results in closure of the epiphyses, increased BMD, and increased bone age. Men with a rare inactivating mutation of ER α had a similar phenotype, but in contrast to men with aromatase deficiency, they had high serum estradiol, testosterone, and gonadotropin concentrations, consistent with estrogen resistance.¹¹² These findings support potentially important roles of estradiol in bone, glucose, and

lipid metabolism; liver function; and pituitary and testis function.

5 α -Reduction of Testosterone to Dihydrotestosterone. Testosterone is converted to DHT, an androgen that is 2.5 to 3 times more potent than testosterone, by SRD5A1 and SRD5A2. These two isoenzymes of 5 α -reductase differ in the optimal pH for their activity and in their expression patterns.¹¹⁵ SRD5A2 is expressed most highly in prostate, epididymis, seminal vesicles, genital skin, and liver and at lower levels in other tissues such as certain brain regions, nongenital skin, testis, and kidney. SRD5A1 is expressed most highly in nongenital skin (hair follicles), liver, and certain brain regions and at lower levels in prostate, epididymis, seminal vesicles, genital skin, testis, adrenal, and kidney. Approximately 200 to 300 μ g of DHT is produced daily, mostly from 5 α -reduction of testosterone in peripheral tissues (predominantly skin and liver). The prostate and testis contribute relatively little to concentrations of DHT in blood.

Men with inactivating mutations of SRD5A2 are born with severe male pseudohermaphroditism (46,XY DSD) with ambiguous genitalia (clitoris-like phallus, bifid scrotum, pseudovaginal hypospadias, and rudimentary prostate gland) but normal wolffian duct differentiation (normal seminal vesicles, epididymides, and vas deferens) and no müllerian duct structures, supporting the vital role of DHT in external genital differentiation and prostate development.¹¹⁶ Individuals with SRD5A2 deficiency are usually raised as girls. With the onset of puberty and increase in testosterone to adult male levels, the phallus

grows, the scrotum develops, libido and erections are stimulated, and the gender role may change from female to male. Cryptorchidism is common but not invariable and is associated with oligozoospermia or azoospermia. Testes may descend at the time of puberty. Normal sperm counts may occur in individuals with descended testes, and fertility has been reported in men with SRD5A2 deficiency. However, in adults, the prostate remains underdeveloped and is not palpable, facial and body hair are diminished, sebum is not produced, and male-pattern baldness does not occur, supporting the importance of normal SRD5A2 activity and DHT for hair growth, sebaceous function, and prostate development. Serum DHT concentrations are low, testosterone levels are normal to slightly elevated, and gonadotropin concentrations are modestly elevated.

Within the prostate gland, conversion of testosterone to DHT produces concentrations of DHT that are approximately 10-fold higher than those in serum, serving to amplify androgen activity in the prostate. Intraprostatic androgen concentrations may contribute to prostate pathology, such as BPH or prostate cancer.¹¹⁷

Inhibitors of SRD5A2 (finasteride) or of both SRD5A1 and SRD5A2 (dutasteride) are used to treat lower urinary tract symptoms, improve urinary flow, and prevent complications related to BPH, as well as to treat male-pattern baldness and androgenic alopecia.¹¹⁸ Treatment with finasteride or dutasteride reduces, respectively, the prevalence or the incidence of prostate cancer found on biopsy but is possibly associated with a greater number of cancers with high Gleason grade.^{119,120} An important aspect of the effect of androgens on the prostate is that intraprostatic androgen concentrations are not reflected in serum levels, underscoring the importance of local paracrine and autocrine actions of androgens in the physiology and pathology of the prostate and probably other androgen target tissues.

Catabolism of Testosterone. The primary site of catabolism of circulating testosterone and 5 α -DHT is the liver.¹²¹ Testosterone and 5 α -DHT are taken up in the liver, and testosterone is converted to an inactive metabolite, 5 β -DHT, by the enzyme 5 β -reductase. Both 5 α - and 5 β -DHT then undergo 3 α -reduction by the enzyme 3 α -HSD to form 3 α ,5 α -androstenediol (also called 3 α -diol) and 3 α ,5 β -androstenediol, respectively; this is followed by 17 β -reduction by the enzyme 17 β -HSD to form androstosterone and etiocholanolone as catabolic products. In peripheral tissues such as skin, 5 α -DHT may also be converted to 3 α -diol, which is further metabolized in the liver.

In the liver, testosterone, DHT, 3 α -androstenediols, androstosterone, and etiocholanolone undergo glucuronidation and, to a lesser degree, sulfation to form more hydrophilic conjugates that are released into circulation and excreted in urine and bile. Metabolic inactivation of testosterone primarily involves its conversion to metabolites such as testosterone (about 50%), androstosterone (20%), and etiocholanolone (20%) glucuronides (as well as sulfates) and lesser conversion to 3 α -diol glucuronides. Because 3 α -diol comes mostly from skin, blood and urine measurements of 3 α -diol glucuronide (3 α -diol G) has been used as a marker of peripheral androgen action.¹²¹ In men with 5 α -reductase deficiency, 3 α -diol G concentrations are reduced. The amount of body hair and acne correlates with 3 α -diol G levels.

Epitestosterone (17 α -hydroxy-4-androsten-3-one) is a biologically inactive 17 α -hydroxy epimer of testosterone (17 β -hydroxy-4-androsten-3-one) that is produced by the testes in response to LH.¹²² The production rate of epitestosterone is about 3% that of testosterone, but its clearance

rate is 33% that of testosterone, and there is no interconversion of epitestosterone and testosterone. Similar to testosterone, epitestosterone is conjugated in the liver, primarily to glucuronides and sulfates, and excreted in the urine. Because epitestosterone conjugates are rapidly cleared in the urine, excretion rates of testosterone and epitestosterone are similar, and the ratio of urinary testosterone to epitestosterone (T/E ratio) is approximately 1:1.

Measurements of the T/E ratio and other metabolites in urine by sensitive gas chromatography/mass spectrometry methods are used to detect androgenic anabolic steroid doping by competitive athletes.¹²² Administration of androgenic anabolic steroids suppresses the production and clearance of epitestosterone relative to testosterone, resulting in an elevated T/E ratio in urine. The World and United States Anti-Doping Agencies have set a threshold T/E ratio of greater than 4:1 as suspicious for anabolic steroid doping.

Testosterone is glucuronidated primarily by the enzyme uridine diphosphate glucuronyl transferase 2B17 (UGT2B17), whereas epitestosterone is glucuronidated mostly by another UGT isoform, UGT2B7. Although testosterone may be glucuronidated by other UGT isoforms (e.g., UGT2B15), individuals with an inactivating genetic polymorphism of UGT2B17 (common in Asian populations) have reduced testosterone glucuronidation and clearance, resulting in lower T/E ratios that do not reach threshold levels with androgen administration.^{121,123,124} Realization that there were populations with naturally low T/E led to a reduction in the T/E ratio cutoff from the previous threshold for suspicion of doping of (>6:1) to the present one (>4:1). Also, there are individuals with a naturally high T/E ratios, perhaps because of other genetic polymorphisms or environmental factors such as excessive alcohol consumption that may increase T/E ratio transiently.¹²⁵ In the absence of environmental perturbations, the T/E ratio in a single individual is remarkably stable over time, and longitudinal measurements of urinary T/E ratio may be used to detect illicit androgen use. Coadministration of epitestosterone with testosterone has been used by athletes to avoid detection.

If a urinary T/E ratio is suspicious for doping, exogenous androgen use is confirmed by gas chromatography combustion isotope ratio mass spectrometry (GC/C/IRMS), which can detect small differences in the ratio of carbon 13 to carbon 12 (¹³C/¹²C) isotopes of testosterone or its metabolites.¹²² Because synthetic androgens are synthesized from plant sources (yams or soy), their ¹³C/¹²C ratio is lower than that of endogenously produced testosterone and other steroids that reflect an animal source or dietary ingestion of both animal and plant products. However, ¹³C/¹²C IRMS will not detect doping by administration of hCG or LH-like activity to stimulate endogenous testosterone production or administration of androgens derived from animal sources that have a ¹³C/¹²C ratio similar to that of endogenous testosterone.

Mechanisms of Androgen Action

In androgen target tissues, testosterone and DHT in circulation diffuse through the plasma membrane and bind to intracellular ARs.¹²⁶ Binding of androgen to the AR induces a conformational change in the AR that causes dissociation of heat shock proteins bound to AR, permitting translocation into the nucleus, induction of phosphorylation and homodimerization, and interaction with DNA, specifically on AREs located in regulatory sites of target genes. The AR dimer actively recruits tissue-specific coregulators

Figure 19-12 Schematic diagram of the structure of the human androgen receptor (AR) gene and homology to other steroid hormone receptors: progesterone receptor (PR), glucocorticoid receptor (GR), mineralocorticoid receptor (MR), estrogen receptor- α (ER α), and estrogen receptor- β (ER β). The AR is a 919-amino-acid protein that is composed of three functional domains: a ligand-binding domain (LBD), a DNA-binding domain (DBD), and an N-terminal transactivation domain (NTD). The DBD shares the greatest degree of homology (>51% versus AR) and the NTD the least degree of homology (<15% versus AR) among steroid hormone receptors. (From Li J, Al-Azzawi F. Mechanism of androgen receptor action. *Maturitas*. 2009;63:142-148.)

(coactivators and corepressors) to form the transcriptional apparatus necessary to control androgen-regulated gene transcription and subsequent protein synthesis.

The AR gene is located on the long arm of the X chromosome (Xq11-12). AR is organized into functional domains (Fig. 19-12)¹²⁶: (1) an *N-terminal domain* (NTD) comprising two transactivation domains (AF1 and AF2) that mediate the majority of AR transcriptional activity and coregulator interaction and two trinucleotide repeat segments (CAG and GGN, encoding polyglutamine and polyglycine tracts, respectively) of varying number that modify AR transactivation; (2) a *DNA-binding domain* (DBD) comprising two finger motifs, the first mediating DNA recognition and binding and the second stabilizing DNA interaction and mediating dimerization of AR; (3) a small *hinge region* (H); and (4) a *ligand-binding domain* (LBD) that mediates high-affinity binding of androgen to the AR and also contains another transactivation domain (AF2).

AR is a member of the nuclear receptor superfamily that includes other steroid hormone receptors. It shares approximately 80% sequence homology in the DBD, and 50% in the LBD, with its most closely related steroid receptors, the progesterone receptor (PR), the glucocorticoid receptor (GR), and the mineralocorticoid receptor (MR).¹²⁶ This may explain why, for example, some progestins (e.g., medroxyprogesterone acetate) have AR agonist activity, others (e.g., cyproterone acetate) have AR antagonist activity, and a mineralocorticoid antagonist, spironolactone, has AR antagonist activity. Compared with the binding of testosterone, DHT binds to AR with higher affinity, greater stability, and a slower rate of dissociation, conferring greater androgen activity to DHT, the most potent endogenous androgen in humans.

Inactivating mutations of the AR may cause qualitative or quantitative abnormalities of receptor function, resulting in variably impaired androgen action.¹²⁷ AR mutations manifest phenotypic variability, ranging from that of a male who is phenotypically female with normal female external genitalia and breast development (*complete testicular feminization*), which occurs in individuals with complete androgen insensitivity or resistance, to that of an otherwise normal male with incomplete hypospadias, mild undervirilization, or infertility.

In a normal population, the number of trinucleotide CAG repeats in the first exon of the AR gene varies from 11 to 35. In general, the number of CAG repeats appears to correlate inversely with AR function and action, both in vitro and in vivo, in transgenic mice and humans.

Kennedy's disease, or *X-linked spinal and bulbar muscular atrophy* (SBMA), is a rare adult-onset neurodegenerative disease of motor neurons that results in progressive muscle weakness; it is associated with a markedly expanded number of CAG repeats, varying from 40 to 62, which does not overlap with the normal population.¹²⁸ Neurodegeneration in this disorder is thought to be caused by toxicity from intracellular aggregation of the AR and associated cofactors that is worsened by androgen binding to the mutant AR and translocation into the nucleus.

Most men with Kennedy's disease also manifest clinical findings of partial androgen resistance, including gynecomastia, reduced libido, erectile dysfunction, decreased facial hair, testicular atrophy, and oligozoospermia or azoospermia in association with high testosterone and high or normal gonadotropin levels.¹²⁹ The severity of the latter biochemical indices of androgen insensitivity is directly related to CAG repeat length. Although it is not found consistently, some studies have reported an association between CAG repeat number and manifestations of androgen action in normal men.¹³⁰ In these studies, a low number of CAG repeats within the normal range was associated with higher androgenicity (e.g., earlier onset of prostate cancer, male pattern baldness, lower HDL-cholesterol), and a high number of repeats within the normal range was associated with lower androgenicity (e.g., gynecomastia, impaired spermatogenesis, lower bone density, depressive symptoms). CAG repeat number also seems to be associated with the clinical manifestations of men with androgen deficiency due to Klinefelter's disease and their response to testosterone treatment, the latter suggesting a possible pharmacogenetic influence of this AR polymorphism.

Studies in vitro and in experimental animals suggest that some actions of androgens may occur within seconds to minutes, too rapidly to be caused by classic genomic effects of androgens acting through the AR on gene transcription and subsequent protein synthesis, which usually take hours to produce effects.¹³¹ Rapid, nongenomic effects of androgens may be mediated by cell surface interactions and receptors and by the activation of conventional signal transduction mechanisms, including activation of PKA and PKC, which increase intracellular calcium and MAPK pathways. Binding of androgen to intracellular AR may also activate coregulators that do not require gene transcription to signal, such as the tyrosine kinase, steroid receptor coactivator (SRC). Nongenomic actions of androgens have been described in testis (Sertoli cells), brain, muscle, cardiovascular tissues, prostate, and immune cells. In humans,

the rapid vasodilatory effect of testosterone on myocardial ischemia in patients with coronary artery disease is attributed to a direct nongenomic effect of androgens on vascular cells.

Androgen Effects at Various Stages of Sexual Development

Levels of testosterone and its actions differ at various stages of sexual development (Fig. 19-13).¹³² During *fetal life*, testosterone is secreted by the fetal testis beginning at 7 weeks of gestation.³⁶ Testosterone secretion is primarily under the control of hCG, initially, and then LH secreted by the fetal pituitary. During this time, testosterone concentrations increase to almost adult male levels, and testosterone and its conversion to DHT are critical for normal male internal and external genital differentiation (e.g., development of primary sexual characteristics). Testosterone concentrations remain elevated through most of the second trimester, after which they decline.

Shortly after birth, during *neonatal life*, LH secretion increases and stimulates a second rise in testosterone levels, almost to adolescent concentrations, between 3 to 6 months of age; this is followed by a fall to low prepubertal levels.¹³³ The neonatal surge in testosterone levels may have a role in development of normal phallus size and completion of testicular descent. The neonatal increase in testosterone and FSH levels at this time also stimulates Sertoli cell proliferation and spermatogonial development, which may play a role in determining spermatogenic capacity.

During *puberty*, testosterone concentrations increase to adult male levels in response to activation of hypothalamic GnRH secretion and its stimulation of pituitary gonadotropin secretion.^{43,134} The progressive increase in testosterone and its active metabolites, estradiol and DHT, is responsible for the development of secondary sexual characteristics (*virilization* or *masculinization*) and other changes. Pubertal

changes induced by testosterone may be categorized as those related to body, brain, and sexual function. *Body function changes* include the following:

- Growth and development of the penis and scrotum and the appearance of rugal folds and pigmentation in scrotal skin
- Enlargement of the prostate and seminal vesicles and production of accessory sexual gland secretion and seminal fluid
- Androgen-dependent hair growth and development of a male hair distribution—facial (moustache and beard), external auditory canal, chest, axillary, pubic and lower abdomen (male escutcheon), perianal, inner thigh, and leg and arm hair growth and frontal scalp hair recession
- Increase in sebum production
- Stimulation of IGF1 production together with that of growth hormone (GH)
- Long bone growth and eventually closure of long bone epiphyses resulting in cessation of growth
- Increase in BMD and stimulation of peak bone mass
- Increase in skeletal muscle mass and strength, especially in shoulder and pectoral muscles
- Decrease and redistribution of body fat
- Enlargement of the larynx and thickening of vocal cords, resulting in a lower-pitched voice
- Stimulation of erythropoiesis resulting in an increase in hematocrit, primarily by direct bone marrow induction of erythroid differentiation and stimulation of erythropoietin secretion
- Suppression of HDL-cholesterol.

Brain function changes include stimulation of libido (sexual interest, desire, and motivation); increase in motivation, initiative, and social aggressiveness; and increase in aspects of cognitive function (e.g., visuospatial abilities). *Sexual function changes* include initiation of spermatogenesis and acquisition of fertility potential and increase in spontaneous erections.

Figure 19-13 Schematic diagram of changes in serum testosterone concentration and sperm production during different phases of life. During fetal life, testosterone levels increase almost to adult male levels, peaking during the first trimester and remaining elevated throughout the second trimester; after which they decline. During neonatal life, testosterone increases almost to adolescent levels at 3 to 6 months of age, then declines to prepubertal levels. During puberty, testosterone concentrations and sperm production increase to adult male levels over several years. With aging, there is a variable, gradual, and progressive decline in serum testosterone levels and sperm production, beginning at age 40 years. (From Griffin JE, Wilson JD. The testis. In: Bondy PK, Rosenberg LE, eds. *Metabolic Control and Disease*, 8th ed. Philadelphia, PA: WB Saunders; 1980:1535-7158.)

In *adult life*, normal adult male levels of testosterone serve to maintain many of the changes induced during puberty. This includes maintenance of body function changes such as normal amounts of androgen-dependent hair and male hair distribution, sebum production, BMD, muscle mass and strength, hematocrit in the male range (higher than the female range), and HDL-cholesterol in the male range (lower than the female range); brain function changes such as libido, motivation, initiative, social aggressiveness, energy and vitality, mood, and possibly some aspects of cognitive function; and sexual function changes such as sperm production and fertility potential and spontaneous erections. Some of the masculinizing changes induced by testosterone during puberty are permanent. Once they are developed, testosterone is not necessary for maintenance of penis size, scrotal development, linear growth, laryngeal size, vocal cord thickness, or voice pitch.¹¹⁰

With *aging*, there is a gradual and progressive decline in serum testosterone concentrations associated with reductions in muscle mass and strength, BMD, libido, energy and vitality, mood, aspects of cognitive function, sperm production and fertility, and erections.¹³⁵

MALE HYPOGONADISM

The two major functions of the testis are to produce sufficient amounts of testosterone and of sperm to support the development and maintenance of male sexual function, body function, and fertility. *Male hypogonadism* is a clinical syndrome that results from a failure of the testes to produce adequate amounts of testosterone; this is almost always associated with impaired sperm production (*androgen deficiency and impairment of sperm production*) or with an *isolated impairment of sperm production or function* with normal testosterone production. Hypogonadism is the most common disorder of testis function encountered in clinical practice.

Because testis function is controlled by the hypothalamus and the pituitary, male hypogonadism may be caused by a primary disorder of the testis (*primary hypogonadism*); it may be secondary to a disorder of the pituitary or hypothalamus (*secondary hypogonadism*); or, in some instances, there may be defects at both levels (*combined primary and secondary hypogonadism*).

Identifying men with secondary hypogonadism has important clinical implications that may affect management.¹¹⁰ For example, secondary hypogonadism can be caused by a pituitary adenoma that may be associated with clinical manifestations related to tumor mass (e.g., headaches, visual field defects); to deficiency or excessive secretion of other anterior pituitary hormones; or to diabetes insipidus resulting from hypothalamic antidiuretic hormone deficiency. Such patients require management of the primary disorder in addition to testosterone replacement therapy. Secondary hypogonadism may be reversible with treatment of the underlying condition (e.g., nutritional deficiency) or discontinuation of an offending medication (e.g., glucocorticoids, opiates), or it may be associated with a chronic systemic illness that is not curable, such as chronic kidney disease (CKD). Impaired spermatogenesis and infertility caused by gonadotropin deficiency in men with secondary hypogonadism may be treated with gonadotropin or GnRH therapy, and sperm production and fertility may be restored. In contrast, infertility caused by primary testicular disease is usually not treatable with hormone therapy and requires

other fertility options, such as the use of donor sperm, ART (e.g., ICSI), or adoption.

Clinical Manifestations

Because testosterone has different roles during sexual life, the manifestations of androgen deficiency differ depending on the stage of sexual development.^{8,110}

Androgen Deficiency and Impairment in Sperm Production

Fetal Androgen Deficiency. During fetal development, testosterone and its conversion to DHT have vital roles in directing male internal and external genital differentiation and development. Fetal androgen deficiency (e.g., from congenital defects in testosterone biosynthesis enzymes) or androgen resistance (e.g., from AR mutations or 5 α -reductase deficiency) manifests at birth with varying degrees of ambiguous genitalia and DSDs (i.e., male pseudohermaphroditism) (Table 19-1).^{36,62} Depending on the severity of androgen deficiency or resistance, the phenotype of individuals with these disorders may range from that of a normal female to that of an otherwise normal male with microphallus, pseudovaginal perineoscrotal hypospadias, bifid scrotum, and cryptorchidism of varying severity. These disorders are described in greater detail in Chapter 23.

Prepubertal Androgen Deficiency. The increase in testosterone levels that occurs at the time of puberty is responsible for development of secondary sexual characteristics; an increase in muscle mass and reduction and redistribution of body fat; long bone growth and eventually closure of epiphyses resulting in cessation of growth; stimulation of sexual interest (libido), erections, and sexual activity; and initiation of spermatogenesis and seminal fluid production.¹³⁶ Prepubertal androgen deficiency causes *eunuchoidism* (Fig. 19-14; see Table 19-1),¹³⁶ which is characterized most notably by infantile genitalia with a small penis and a poorly developed scrotum that lacks rugal folds and pigmentation. The testes are small, usually less than 2 cm in length and from 2 mL to less than 4 mL in volume. Hair is thin and fine, and there is a lack of androgen-dependent hair growth (i.e., absence of a male hair pattern in all body areas) and no temporal hair recession. The pubic hair pattern is more typical of females, with the shape of an inverted triangle in the pubic area (female escutcheon) rather than a diamond shape with hair extending from the pubic area to the umbilicus (male escutcheon), and there is little hair extending to the thighs. Acne does not develop because sebum production is not stimulated by androgens.

Eunuchoidism is typified by a distinctive body habitus, characterized by poor muscle mass development (especially in the shoulders and chest), prepubertal fat distribution (predominantly in the face, chest, and hips), and excessively long arms and legs relative to height. Arm span exceeds height, and the distance from the crown of the head to the symphysis pubis exceeds that from the symphysis to the floor, both differences being greater than 5 cm. The voice is high-pitched in the absence of androgen-dependent laryngeal enlargement and vocal cord thickening. Relatively long arms and legs result from a failure of long bone epiphyses to close; epiphyseal closure is mediated normally by increased estradiol derived from aromatization of the increased testosterone produced at the time of puberty.

TABLE 19-1

Clinical Manifestations of Androgen Deficiency

FETAL ANDROGEN DEFICIENCY	
Symptoms	Signs
Ambiguous genitalia	Ambiguous genitalia (47,XY DSD) Normal female genitalia Microphallus (resembling clitoromegaly) Pseudovaginal perineoscrotal hypospadias Bifid scrotum Cryptorchidism
PREPUBERTAL ANDROGEN DEFICIENCY	
Symptoms	Signs
Delayed puberty	Eunuchoidism
Lack of sexual interest or desire (libido)	Infantile genitalia
Reduced nighttime or morning spontaneous erections	Small testes
Breast enlargement and tenderness	Lack of male hair pattern growth, no acne
Reduced motivation and initiative	Disproportionately long arms and legs relative to height
Diminished strength and physical performance	Pubertal fat distribution
No ejaculate or ejaculation (spermarche)	Poorly developed muscle mass
Inability to father children (infertility)	High-pitched voice Reduced peak bone mass, osteopenia or osteoporosis Gynecomastia Small prostate gland Aspermia, severe oligozoospermia or azoospermia
ADULT ANDROGEN DEFICIENCY	
Symptoms	Signs
Incomplete sexual development	Eunuchoidism
Lack of sexual interest or desire (libido)	Small or shrinking testes
Reduced nighttime or morning spontaneous erections	Loss of male hair (axillary and pubic hair)
Breast enlargement and tenderness	Gynecomastia
Inability to father children (infertility)	Aspermia or azoospermia or severe oligozoospermia
Height loss, history of minimal-trauma fracture	Low bone mineral density (osteopenia or osteoporosis)
Hot flushes, sweats	Height loss, minimal-trauma or vertebral compression fracture
Reduced shaving frequency	Unexplained reduction in prostate size or PSA
Less Specific Symptoms	Less Specific Signs
Decreased energy, vitality	Mild normocytic, normochromic anemia (normal female range)
Decreased motivation, self-confidence	Depressed mood, mild depression or dysthymia
Feeling sad or blue, irritability	Reduced muscle bulk and strength
Weakness, decreased physical or work performance	Increased body fat or body mass index
Poor concentration and memory	Fine facial skin wrinkling (lateral to orbits and mouth)
Increased sleepiness	

DSD, disorders of sex development; PSA, prostate-specific antigen.

Prepubertal androgen deficiency may not be recognized or diagnosed until adulthood. Compromise in peak bone mass accrual due to androgen deficiency may manifest as low BMD for age, and prolonged severe androgen deficiency increases the risk of osteoporosis and fractures as these men become older. Despite the absence of pubertal development, these individuals may develop gynecomastia (benign breast enlargement) that is caused by androgen deficiency rather than by the relatively high ratio of estradiol to testosterone levels associated with pubertal gynecomastia. Motivation and initiative are reduced and, together with poor muscle mass and strength, may contribute to poor physical performance (e.g., in athletics or the military). These men have reduced sexual interest or desire (libido) and have spontaneous erections at night or on awakening in the morning. Hematocrit remains in the female range due to inadequate androgen stimulation of erythropoiesis. The prostate and seminal vesicles remain small without androgen stimulation, and seminal fluid production is absent, resulting in aspermia (lack of ejaculate) and failure to undergo spermarche (first ejaculation). Seminal fluid may be present in men with partial prepubertal androgen deficiency or in those treated with androgens. However, these men usually have severe oligozoospermia or azoospermia, and most are infertile.

Adult Androgen Deficiency. Some individuals with prepubertal androgen deficiency who are not diagnosed or are inadequately treated as boys present as adults with features of eunuchoidism and other manifestations of prepubertal androgen deficiency (see Table 19-1). Their condition is usually clinically obvious because of inadequate sexual development for chronologic age.

In adults, testosterone is needed to maintain sexual function, some secondary sexual characteristics, muscle and bone mass, and sperm production. Clinical manifestations of androgen deficiency are nonspecific and may be modified by the severity and duration of androgen deficiency, the presence of comorbid illnesses, previous testosterone treatment, or variations in target-organ sensitivity to androgens. Therefore, the clinical diagnosis of androgen deficiency acquired as an adult can be challenging, particularly in older men.¹¹⁰

Some clinical symptoms and signs are suggestive of androgen deficiency. Adults most commonly present with *sexual dysfunction* (diminished libido as manifested by reduced sexual interest or desire, reduced spontaneous and sexually evoked erections, and erectile dysfunction); *gynecomastia* (benign breast enlargement that may be accompanied by tenderness); and *infertility* (inability to father children despite unprotected intercourse) associated with oligozoospermia or azoospermia and small or shrinking testes with severe impairment in spermatogenesis. Secondary sexual characteristics do not regress to a prepubertal state; however, with long-standing, severe androgen deficiency, there may be loss of androgen-dependent hair, such as reduced facial hair associated with reduced shaving frequency and loss of axillary and pubic hair (Fig. 19-15). Men with rapid and profound decreases in testosterone levels (e.g., from GnRH treatment of prostate cancer) may have hot flushes and sweats due to vasomotor instability, similar to those experienced by menopausal women. Because testosterone and its active metabolite, estradiol, have an important role in the maintenance of bone mass, men with chronic androgen deficiency may present with osteopenia or osteoporosis on BMD measurement (e.g., by dual energy x-ray absorptiometry [DEXA] scan) or with a minimum-trauma bone or vertebral compression fracture that may be

Figure 19-14 A 19-year-old patient with prepubertal androgen deficiency caused by congenital anorchia before (A, C, and E) and after (B, D, and F) 5 years of testosterone treatment, which ended when he was 19 years old. Before testosterone treatment, the patient had features of eunuchoidism, characterized by infantile genitalia (small penis and poorly developed scrotum); lack of chest, pubic, and facial hair; long arms and legs relative to height; and poorly developed muscle mass in the upper body with accumulation of fat in the face, chest, and hips. After testosterone treatment, there was an increase in penis size; an increase in chest, pubic, and facial hair with scalp recession and development of acne; an increase in muscle mass, particularly in the upper body; and loss of fat in the face, chest, and hips. (From Matsumoto AM. The testis. In: Felig P, Frohman LA, eds. *Endocrinology and Metabolism*, 4th ed. New York, NY: McGraw-Hill; 2001:635-705.)

Figure 19-15 A 54-year-old man with adult androgen deficiency caused by hypopituitarism who presented with sexual dysfunction (reduced libido and erectile dysfunction); loss of chest, axillary, and pubic hair (A, B, and C); and gynecomastia (A). His penis and testes were normal in size (B). He had normal facial hair (C), but his shaving frequency was less.

associated with height loss. An unexplained reduction in prostate size or in the level of prostate-specific antigen (PSA) is uncommon but may occur as a result of acquired androgen deficiency.

Other symptoms and signs are much less specific for androgen deficiency but may occur, commonly in conjunction with clinical manifestations described previously that are more suggestive of androgen deficiency. Men with low testosterone concentrations often complain of diminished energy and *joie de vivre* (vitality), poor motivation and social aggressiveness, depressed mood and irritability that may be diagnosed as subsyndromal depression (mild depression or dysthymia), increased sleepiness, or poor concentration and memory. Men with severe androgen deficiency may have a mild hypoproliferative normocytic, normochromic anemia within the female range in the absence of androgen stimulation of erythropoiesis. With long-standing deficiency, reduced muscle bulk and strength associated with weakness and reduced physical and work performance occur. The latter symptoms may occur in conjunction with an increase in body fat, but androgen deficiency is not a cause of clinically obvious obesity per se. Skin changes and reduced sebum production with severe, long-standing androgen deficiency may be associated with fine facial wrinkling that is particularly noticeable on the lateral corners of the orbits (lateral canthus) and mouth. Testis size may be small, especially with severe impairment of spermatogenesis, but in most men with acquired adult androgen deficiency, testis size is normal to slightly reduced.

Because clinical manifestations are nonspecific, older men may have a number of medical conditions or comorbidities and medications that contribute to symptoms and signs that are consistent with androgen deficiency, presenting a particular diagnostic challenge (Fig. 19-16). Symptoms and signs of comorbid illnesses may mask, mimic, or contribute to clinical manifestations of androgen deficiency in older men. Elderly men may present with muscle

loss and mobility impairment, fragility fracture or osteoporosis, and reduced vitality and depressed mood. On close examination, however, older men with severe, long-standing androgen deficiency usually manifest objective evidence of androgen deficiency.

Isolated Impairment of Sperm Production or Function

Most men with male infertility have hypogonadism manifested by an isolated impairment of sperm production with normal androgen production. These men present as adults with infertility and demonstrate oligozoospermia or azoospermia, sperm with abnormal morphology (*teratospermia*) or reduced or absent motility (*asthenospermia*), or a combination of abnormalities on seminal fluid analysis. They do not have manifestations of androgen deficiency, and serum testosterone concentrations are normal. Testes may be small (if spermatogenesis is severely impaired) or normal-sized. Testes may not be palpable if cryptorchidism or anorchia is present.

History and Physical Examination

Clinical evaluation of male hypogonadism involves a careful history and physical examination directed at determining whether there are symptoms and signs of androgen deficiency or isolated impairment of sperm production and at identifying potential common etiologies of hypogonadism.⁸ Because adults with androgen deficiency present commonly with sexual dysfunction, gynecomastia, and infertility, the differential diagnosis of these conditions and causes other than hypogonadism of these presenting complaints should be considered. Laboratory evaluation of serum testosterone, gonadotropins, and seminal fluid (in men who are concerned with infertility) are performed to confirm the diagnosis of hypogonadism and to determine

Figure 19-16 A 70-year-old man with severe androgen deficiency caused by Kallmann's syndrome (hypogonadotropic hypogonadism and anosmia) who presented to a geriatric evaluation and management unit with functional and mobility disability caused by upper (A) and lower muscle wasting and severe back pain from multiple vertebral compression fractures (B) due to osteoporosis. He was noted to have gynecomastia and absence of chest, axillary, and pubic hair.

whether there is predominantly primary or secondary hypogonadism.

The history should include inquiry regarding symptoms of androgen deficiency. These may be grouped as relating to several areas:

1. *Development*: genital abnormalities and the potential need for surgical correction (e.g., hypospadias, microphallus, cryptorchidism); delayed sexual development or growth and need for hormone therapy; family history of delayed puberty or reproductive disorders; psychological impact of delayed puberty or growth; difficulty in school or learning disability; inability or reduced ability to smell
2. *Sexual function*: poor erections; reduced spontaneous, nighttime, or morning erections; inability to perform sexually; decreased sexual activity; inability to father children despite unprotected sexual relations (>1 year); small or shrinking testes
3. *Brain function*: poor general well-being; reduced sexual desire, interest, and motivation (libido); poor energy and vitality and excessive fatigue; poor motivation and initiative, passivity, low self-confidence, and low self-esteem; depressed mood and irritability; difficulty sleeping; hot flushes and sweats; poor concentration and memory
4. *Body function*: decreased muscle bulk and strength; reduced physical activity or performance; breast enlargement or tenderness, especially if recent in onset; height loss, history of low-trauma or vertebral compression fractures, osteopenia, or osteoporosis; body hair loss (chest, axillary, or pubic); reduced beard growth and shaving frequency.

The initial history may also include inquiry concerning the potential etiology of hypogonadism. With *primary hypogonadism*, there may be a history of mumps involving the testes; testicular trauma, irradiation, or surgery; medication use (spironolactone, ketoconazole, cytotoxic agents); or chronic liver or kidney failure. With *secondary hypogonadism*, headaches; visual complaints or reduced peripheral vision; history of pituitary disease; chronic lung disease or chronic heart failure (CHF); wasting conditions (e.g., AIDS, cancer); nutritional deficiencies; recent acute illness; morbid obesity; or use of certain medications (e.g., opiates, CNS-active drugs, glucocorticoids, anabolic steroids, megestrol acetate, medroxyprogesterone acetate, nutritional supplements) may be noted.

The patient should be questioned regarding conditions that are relative or absolute contraindications to testosterone treatment, including a history of severe BPH and lower urinary tract symptoms as measured by the American Urological Association (AUA) symptom score or International Prostate Symptom Score (IPSS); history of prostate or breast cancer; history or symptoms of untreated obstructive sleep apnea syndrome (daytime sleepiness, snoring with sleep disruption, witnessed apnea episodes); history of severe congestive heart failure; and polycythemia or hyperviscosity.

In patients with suspected prepubertal androgen deficiency, total arm span, height, and the distances from the crown of the head to the symphysis pubis and from the symphysis pubis to the floor should be measured (see Fig. 19-14). Eunuchoidal body proportions are characterized by an arm span that is at least 5 cm greater than height and a crown-to-symphysis distance that is at least 5 cm greater than the symphysis-to-floor distance; such proportions are indicative of prepubertal androgen deficiency. Men with Klinefelter's syndrome may have disproportionately long legs relative to arms and a greater ratio of

lower- to upper-body segment measurements but a relatively normal ratio of arm span to height. Eunuchoidism is also characterized by infantile genitalia (micropenis or small penis, unrugated and nonpigmented scrotum); small testes or, rarely, absence of the testes; cryptorchidism; sparse or absent facial, axillary, chest, extremity, and pubic hair; poorly developed upper body musculature; fat predominance in the face, chest, and hips; and gynecomastia. Patients with Kallmann's syndrome may have anosmia or hyposmia that may be tested with an odor identification and threshold test using readily identifiable, common household odorants (e.g., alcohol swab, peppermint, cinnamon, cocoa, coffee, cigarette, orange, soap) or more formally, such as with the University of Pennsylvania scratch and sniff test.

The physical findings of androgen deficiency acquired in adulthood are usually more subtle than those of prepubertal androgen deficiency (see Fig. 19-15). In patients with severe, long-standing adult androgen deficiency, there may be loss of androgen-dependent facial, axillary, chest, extremity, and pubic hair; however, there are ethnic variations in body hair in androgen-dependent areas (e.g., less in Asians and Hispanics). The skin may be dry, and there may be fine wrinkling lateral to orbits or mouth in patients with severe, long-standing androgen deficiency. Patients should be carefully examined for the presence of palpable breast tissue or gynecomastia; presence, size, and consistency of the testes; and palpable abnormalities in the scrotum, such as varicocele, epididymal enlargement, or tenderness or absence of the vas deferens. A digital rectal examination (DRE) should be performed to primarily determine whether there are palpable abnormalities, such as a prostate nodule or induration, and also to assess the size of the prostate. Careful examination for kyphosis and measurement of height are useful for detecting significant height loss (>5 cm) associated with osteoporotic vertebral compression fractures that may be asymptomatic.

Proper technique is needed to examine the male breast. The thumb and index finger are used to grasp and gently pinch the periareolar area of the breast and to palpate glandular breast tissue, which is rubbery in consistency and firmer than the surrounding adipose tissue (Fig. 19-17). With this technique, gynecomastia can usually be distinguished from excessive breast adipose tissue, called *pseudo-gynecomastia*, which is often associated with generalized obesity. Gynecomastia is usually bilateral and relatively symmetric, but occasionally it is asymmetric and more prominent on one side. If present, asymmetric gynecomastia may suggest breast carcinoma, which is usually rock-hard and irregular and may be associated with skin dimpling (*peau d'orange*), nipple retraction or discharge, and axillary lymphadenopathy. The diameter of palpable breast tissue is used as an objective measure of gynecomastia. Gynecomastia of recent onset is usually tender on palpation, and men usually complain of nipple irritation associated with rubbing against clothing.

Examination of the testes and scrotum may be performed with the patient either lying on his back or standing, but the latter position is preferred because it relaxes the scrotum, making some abnormalities (e.g., varicocele) more easily detected. In patients with retractile testes positioned high in the scrotum, it may be possible to palpate the testes only after placing the scrotum in warm water, after a warm bath, or by having the patient assume a squatting position. The testes may be very difficult to examine and palpate in morbidly obese men who have excessive folds of fat overlying the scrotum, in the presence of a large hydrocele, if the testis is tender (e.g., with

Figure 19-17 The proper method of examining the male breast is to use the thumb and index finger to grasp the periareolar area of the breast and to gently pinch the thumb and index finger together on either side of the breast toward the nipple. Glandular breast tissue feels like a rubbery disc of tissue that extends concentrically from under the nipple and subareolar area and is firmer than the surrounding adipose tissue. The size of gynecomastia is estimated by measurement of the diameter of palpable breast tissue. (From Matsumoto AM. The testis. In: Felig P, Frohman LA, eds. *Endocrinology and Metabolism*, 4th ed. New York, NY: McGraw-Hill; 2001:635-705.)

epididymo-orchitis or testicular torsion), or occasionally in some men who are sensitive to palpation for unclear reasons. In these instances, testicular ultrasound may be required to confirm the presence of the testis, estimate its size, and detect abnormalities.

Although ultrasonographic size estimates are more accurate, testis size can be estimated by measuring length and width with a ruler or calipers or by comparing testis volume with that of ellipsoid models of known volume (Prader orchidometer) (Fig. 19-18). Normal testis size varies with age and ethnicity. Normal prepubertal testis size is approximately 1.6 to 2.9 cm in length and 1.0 to 1.8 cm in width, or 1 to 4 mL in volume. Testis size greater than 4 mL suggests the onset of puberty. In adults, normal testes usually measure 3.5 to 5.5 cm in length and 2.0 to 3.0 cm in width, or 15 to 30 mL in volume.^{9,137} In addition to size, testes should be palpated for consistency or firmness and for presence of a mass representing a benign or malignant testicular tumor. The testicular examination in men with Klinefelter's syndrome is notable for very small (usually <3 mL), firm testes.

Differential Diagnosis

Because sexual dysfunction, gynecomastia, and infertility are often presenting complaints in adults with androgen deficiency, it is important to consider the differential diagnosis and to be familiar with other common causes of these manifestations when evaluating men who present with these complaints.

Sexual Dysfunction

Normal sexual function requires successive, coordinated physiologic events—libido, erection, ejaculation, orgasm, and detumescence—that occur in a defined sequence and require normal psychological, CNS, peripheral nerve, vascular, and genital function.¹³⁸

Sexual dysfunction may involve specific disorders of libido or sexual desire, erectile dysfunction, ejaculatory disorders, orgasmic dysfunction, or failure of detumescence. These may occur in isolation, but specific disorders of sexual function commonly occur together because these processes are interrelated and because a specific etiology (e.g., androgen deficiency) can affect more than one of the physiologic processes that mediate normal sexual function. Male sexual dysfunction is detailed in Chapter 20. Men with androgen deficiency often present with sexual dysfunction, and it is important to consider the differential diagnosis of this complaint in the evaluation.

Androgen deficiency often results in reduced libido or sexual desire (hypoactive sexual desire disorder), loss or reduction of spontaneous evening and morning or sexually stimulated erections (erectile dysfunction), and, if severe, reduced or absent ejaculation. In many men with androgen deficiency, erectile response to intense erotic stimuli (and, occasionally, spontaneous erections) may be preserved, suggesting that the androgen requirement for sexual function is variable.¹³⁹ However, persistent erectile dysfunction may cause performance anxiety, and, together with hypoactive sexual desire and depressed mood associated with androgen deficiency, this may contribute to the eventual loss of erotically stimulated erections and, secondarily, to orgasmic dysfunction. Androgen deficiency may also affect nitric oxide production and maximal smooth muscle relaxation and vasodilatation within the penis, reducing the ability to produce an erection that is sufficient to satisfactorily complete sexual intercourse and further contributing to the severity of erectile dysfunction.^{140,141}

Clinically, men with androgen deficiency most commonly present with hypoactive sexual desire disorder and erectile dysfunction. Severely androgen-deficient men may

Figure 19-18 The assessment of testis size using a Prader orchidometer in a normal man (A), who has a right testis size of 20 mL, and in a man with Kallmann's syndrome (B), who has a right testis size of 5 mL. Care must be taken not to include the head of the epididymis when estimating testis size. (From Matsumoto AM. The testis. In: Felig P, Frohman LA, eds. *Endocrinology and Metabolism*, 4th ed. New York, NY: McGraw-Hill; 2001:635-705.)

present with reduced ejaculation, but these individuals usually also complain of hypoactive sexual desire disorder and erectile dysfunction.

Hypoactive Sexual Desire Disorder and Erectile Dysfunction. Libido, the desire or drive for sexual activity, is generated by external visual, auditory, and tactile stimuli as well as internal psychic stimuli acting on cortical and subcortical brain regions such as the limbic system (amygdala, hippocampus, anterior thalamic nuclei, and prefrontal cortex) and the temporal lobe. Stimuli from these areas are relayed to the medial preoptic area, which serves to integrate central inputs and sends impulses to the paraventricular nuclei; these, in turn, send projections to the thoracolumbar and sacral spinal cord centers that regulate penile erection. This neural pathway explains why brain disorders that cause hypoactive sexual desire disorder are usually accompanied by varying degrees of erectile dysfunction (see later discussion).¹³⁸ In particular, there is a loss of the spontaneous evening and morning erections that are associated with brain activation of sexual neural pathways during rapid-eye-movement (REM) sleep and dreaming. Clinically, libido may be influenced by previous or recent sexual activity and by experiences, psychosocial background, overall state of general health, androgen sufficiency, and brain function.

The neurotransmitter systems that regulate the physiology of normal libido are not known precisely. However, there is evidence that central dopamine neurotransmission may be important in mediating CNS regulation of sexual desire and erections. In humans, treatment with dopamine receptor agonists (e.g., bromocriptine, pergolide) may stimulate spontaneous erections, and in 20% to 30% of men with Parkinson's disease, levodopa therapy is associated with stimulation of libido and spontaneous erections. The use of pharmacologic agents with dopamine receptor antagonist activity is frequently associated with reduced libido and erectile dysfunction. However, these agents also affect a number of other neurotransmitter systems. Dopamine antagonism (e.g., by neuroleptic agents) results in elevated prolactin levels that suppress endogenous gonadotropin and testosterone secretion and may contribute to reduced libido and erectile dysfunction.

Hypoactive sexual desire disorder is defined as persistent or recurrent deficiency or absence of desire for sexual activity resulting in marked personal distress or interpersonal difficulty or both.^{138,142} It is estimated to affect more than 15% of men. The causes of hypoactive sexual desire disorder are primarily disorders that affect normal brain function and are usually associated with erectile dysfunction, in particular loss of spontaneous evening or morning erections (Table 19-2). *Erectile dysfunction* is defined as the inability to achieve or maintain penile erection that is adequate for completion of satisfactory sexual intercourse or activity.¹⁴³ Erectile dysfunction is a common condition that increases with aging. It is estimated to affect fewer than 10% of men younger than 40 years of age but approximately 50% of men between 40 and 70 years of age, with 35% of men in the latter age group having moderate or complete erectile dysfunction.

Hypoactive Sexual Desire Disorder and Erectile Dysfunction Due to Brain Disorders. *Psychogenic disorders* commonly cause hypoactive sexual desire and erectile dysfunction; these disorders include stress or preoccupation associated with life circumstances or situations, illness, marital discord, or underlying maternal transference or gender identity issues; performance anxiety associated with fear of failure or preoccupation with the adequacy of

TABLE 19-2

Causes of Hypoactive Sexual Desire Disorder and Erectile Dysfunction

Cause	Examples
BRAIN DISORDERS	
Psychogenic disorders	Stress or preoccupation, performance anxiety, depression, major psychiatric illness
Chronic systemic illness	Heart, respiratory, kidney, or liver failure; cancer
CNS-active drugs	Alcohol; antihypertensive, narcotic, sedative-hypnotic, anticonvulsant, antidepressant, antipsychotic medications
Structural brain disease	Temporal lobe or limbic system disorders, Parkinson's or other neurodegenerative brain disease, vascular brain disorders
Androgen deficiency	Primary and secondary hypogonadism
Other endocrine disorders	Hyperprolactinemia, Cushing's syndrome, hyperthyroidism, hypothyroidism
SPINAL CORD AND PERIPHERAL DISORDERS	
Spinal cord disorders	Trauma, vascular compromise, spinal stenosis, epidural abscess, tumor; transverse myelitis, multiple sclerosis, other spinal cord lesions
Peripheral nerve disorders	Diabetes mellitus; pelvic, prostate, or retroperitoneal surgery or damage; other causes of peripheral neuropathy
PNS-active drugs	Anticholinergic, antihistamine, antidepressant, sympathomimetic, α -adrenergic agonist, β -adrenergic antagonist medications
Peripheral vascular disease	Aorto-iliac atherosclerosis, diabetes mellitus, trauma, surgery, vasculitis, venous incompetence (venous leakage), smoking
Antihypertensive drugs	Diuretics, α - and β -adrenergic antagonists, ACE inhibitors, calcium channel antagonists
Penile abnormalities	Peyronie's disease, chordee, micropenis, trauma, priapism, phimosis

ACE, angiotensin-converting enzyme; CNS, central nervous system; PNS, peripheral nervous system.

erections during sexual intercourse; major depression or dysthymia (moderate or complete erectile dysfunction occurs in 60% to 90% of men with moderate to severe depression); and major psychiatric illness such as psychotic or personality disorders.^{138,142,143}

Chronic systemic illness (chronic heart, respiratory, kidney, or liver failure or cancer) and poor general health are usually associated with reduced libido and spontaneous erections.^{138,142,143} A number of *CNS-active medications* may cause hypoactive sexual desire disorder and erectile dysfunction, including alcohol, centrally acting antihypertensive medications, narcotics, sedative-hypnotic drugs, anticonvulsants, antidepressants, and antipsychotic medications. In addition to their direct effects on brain neurotransmitter function, both chronic illness and CNS-active medications may also be associated with androgen deficiency. *Structural brain disease*, such as infiltrative or destructive lesions of the temporal lobe or limbic system, Parkinson's or other neurodegenerative brain disease, or vascular brain disorders such as stroke or vasculitis, may reduce libido and spontaneous erections.

Androgen deficiency is commonly associated with reduction or loss of libido and spontaneous erections.^{144,145} Sexual dysfunction is usually a prominent presenting complaint in young, severely androgen-deficient men and in older men who are treated with medical therapies (e.g., GnRH agonist treatment) or surgical castration for advanced prostate cancer. In contrast, older men with less severe androgen deficiency may have sexual dysfunction that is also related to underlying chronic systemic illness or use of certain medications.¹⁴⁶ Comorbid conditions contribute to the nonspecificity of presenting complaints of androgen deficiency (e.g., sexual dysfunction) as men age. Testosterone treatment of severe androgen deficiency in young men usually improves sexual desire, interest, and thoughts; attentiveness to erotic stimuli; and the frequency, duration, and rigidity of spontaneous evening and morning erections.^{145,147}

Other endocrine disorders can cause hypoactive sexual desire disorder and erectile dysfunction; examples include hyperprolactinemia, Cushing's syndrome (glucocorticoid excess), hyperthyroidism, and hypothyroidism. In addition to their direct effects on brain function, hyperprolactinemia and glucocorticoid excess also suppress GnRH and gonadotropin secretion and induce androgen deficiency that contributes to sexual dysfunction. Anecdotally, some men with androgen deficiency due to severe hyperprolactinemia who are treated with testosterone treatment alone do not fully recover sexual function and may require additional therapy with dopamine receptor agonists, but this has not been demonstrated conclusively. Dopamine receptor agonists lower elevated prolactin levels and may also have direct effects in the brain to activate neuronal systems involved in stimulating libido and erections.

Erectile Dysfunction Due to Spinal Cord or Peripheral Disorders. External and internal erotic stimuli from the brain are relayed via descending neural pathways in the lateral spinal columns to stimulate the parasympathetic sacral (S2-4) spinal erection center, resulting in *psychogenic erections*. Efferent parasympathetic nervous system stimulation from the sacral center travels via the nervi erigentes (pelvic splanchnic nerve) and the pelvic plexus and enters the penis via the cavernosal nerve. This stimulation causes relaxation of the smooth muscles that form sponge-like interconnected trabecular spaces within the corpora cavernosa of the penis and vasodilation of the cavernosal arterioles and vascular sinusoids. As a result, blood flow and pressure into the trabecular spaces within the corpora increase several-fold and causes engorgement of the penis (tumescence). Expansion of the trabecular spaces against the thick fibrous sheath (tunica albuginea) surrounding the corpora compresses subtunical venules and impedes venous outflow, resulting in sustained penile tumescence (i.e., an erection).^{138,143}

Afferent somatic (via the pudendal nerve) and parasympathetic impulses in response to sensory stimulation of the penis with sexual intercourse or masturbation also act to stimulate erections via a reflex arc through the sacral spinal erection center, resulting in *reflexogenic erections*. Pudendal nerve stimulation also triggers the reflex contraction of the ischiocavernosus and bulbocavernosus muscles, resulting in vascular compression at the base of the penis, further increasing cavernosal blood pressure and maximal penile rigidity, leading to the plateau phase of erection.

The primary neurotransmitter that mediates penile smooth muscle relaxation and erection is nitric oxide (NO). In response to parasympathetic cholinergic (acetylcholine-mediated) stimulation, NO is synthesized from its precursor, L-arginine, by the enzyme nitric oxide

synthase (NOS) and is released by corporal sinusoidal endothelial cells and postganglionic noncholinergic, nonadrenergic nerve terminals. NO then enters adjacent smooth muscle cells, where it activates guanylate cyclase and increases intracellular cyclic guanosine monophosphate (cGMP). cGMP activates cGMP-dependent protein kinase, which phosphorylates a number of proteins, including myosin light chains and ion channels that ultimately decrease intracellular calcium concentrations, causing smooth muscle relaxation, increase in penile blood flow, and erection. cGMP is hydrolyzed and inactivated by the enzyme, phosphodiesterase type 5 (PDE5). In addition to cGMP, other neurotransmitters induce cavernosal smooth muscle relaxation, including prostaglandin E₁ (PGE₁), which activates adenylate cyclase and increases cAMP and cAMP-dependent protein kinase.

Knowledge of the neurotransmitter systems that control erections has been used to design pharmacologic treatments for erectile dysfunction (detailed in Chapter 20).^{143,148,149} The most commonly used treatments are oral PDE5 inhibitors, such as sildenafil, vardenafil, and tadalafil, which act to inhibit the breakdown of cGMP, resulting in more sustained smooth muscle relaxation and improved penile erection after erotic stimulation. Injection of intracavernosal PGE₁ or insertion of intraurethral PGE₁ pellets acts to increase cavernosal cAMP concentrations and induce smooth muscle relaxation and penile erection even in the absence of sexual stimulation. Intracavernosal injections of papaverine, a nonspecific phosphodiesterase inhibitor (which inhibits the breakdown of both cGMP and cAMP), combined with phentolamine, an α_1 - and α_2 -adrenergic receptor antagonist vasodilator (bi-mix), or the two combined together with PGE₁ (tri-mix), are also used to induce smooth muscle relaxation and erection.

Studies in experimental animals and in vitro have found that androgen deficiency impairs penile nerve, trabecular smooth muscle, vascular endothelial, and tunica albuginea structure and function; reduces both endothelial and neuronal NOS synthesis and activity; and causes accumulation of adipocytes in the subtunical region of the corpora cavernosa.¹⁴¹ These changes are reversed with androgen administration, suggesting a direct penile effect of androgens in addition to their central role in maintaining penile erections. In humans, ARs are expressed in the corpora cavernosa tissue. However, there is no conclusive evidence to support the notion that androgen treatment has a direct effect in the penis to enhance the response to PDE5 inhibitor therapy in androgen-deficient men with erectile dysfunction. In practice, symptomatic men with androgen deficiency and sexual dysfunction are usually treated with testosterone replacement; if erectile dysfunction does not improve, they are given additional therapy for erectile dysfunction (e.g., a PDE5 inhibitor).

In addition to the brain disorders that cause hypoactive sexual desire disorder and erectile dysfunction, spinal cord and peripheral disorders (e.g., peripheral nervous system disorders, peripheral vascular disease, medications that affect peripheral nerve and vascular function, penile abnormalities) may also cause erectile dysfunction that is usually not associated with hypoactive sexual desire (see Table 19-2). However, long-standing, severe erectile dysfunction may cause performance anxiety or depression, which may secondarily reduce libido. Furthermore, peripheral disorders that cause erectile dysfunction may also affect brain function and alter sexual interest and drive, contributing to erectile dysfunction. Tricyclic antidepressants may affect both peripheral and CNS function.

Spinal cord disorders, such as spinal cord injury due to trauma, vascular compromise, spinal stenosis, epidural abscess, tumor, transverse myelitis, multiple sclerosis, or other spinal cord lesions, usually cause erectile dysfunction. In general, the severity of erectile dysfunction associated with spinal cord injury and the response to treatment vary with the cord level involved, the severity of the lesion (i.e., complete versus incomplete), and the time since the injury. *Peripheral nerve disorders*, particularly those that affect the autonomic nervous system, may disrupt the normal regulation of penile erectile tissue and cause erectile dysfunction. For example, erectile dysfunction may be caused by diabetes mellitus or other causes of peripheral neuropathy (e.g., amyloidosis, vasculitis, heavy metal toxicity, renal failure, multiple system atrophy, acute intermittent porphyria) or by pelvic, prostate, or retroperitoneal surgery or damage (e.g., abdominoperineal resection of the rectum, pelvic lymph node dissection, prostatectomy, aorto-iliac bypass, lumbar sympathectomy). Peripheral nervous system medications, including anticholinergic agents, antihistamines, antidepressants, sympathomimetic medications, α -adrenergic agonists, and β -adrenergic antagonists, often impair erectile function by affecting peripheral nervous system regulation of erectile tissue of the penis, and many also cause erectile dysfunction by altering neurotransmitter function in the CNS.

The blood supply of the penis is derived from the internal iliac (hypogastric) artery, a branch of the common iliac artery that bifurcates from the aorta.¹³⁸ The internal iliac artery gives rise to the internal pudendal artery, which branches into the dorsal penile, bulbourethral, and cavernosal arteries. The cavernosal arteries run through the middle of the corpora cavernosa and give off corkscrew-shaped branches, the helicine arteries, that open directly into the lacunar spaces. Smooth muscle relaxation of lacunar spaces increases blood flow into the corpora cavernosa, resulting in penile tumescence. Blood from the lacunar spaces or cavernosal sinusoids collects in the subtunical plexus and is delivered via emissary veins to the deep dorsal vein, which ultimately drains into the internal and common internal iliac veins and then into the inferior vena cava. With filling of the lacunar spaces of the corpora cavernosa and penile tumescence against the fibrous tunica albuginea, venous outflow from the subtunical venous plexus is impeded, and sustained tumescence or erection ensues. Disorders of arterial inflow or venous output may cause erectile dysfunction.

Peripheral vascular disease due to aorto-iliac atherosclerosis is probably the most common cause of erectile dysfunction in aging men.^{138,143} These men usually have absent or severely diminished femoral artery pulses, and some present clinically with Leriche syndrome (absent femoral pulses, buttock or leg claudication, and erectile dysfunction). Other men with iliac atherosclerosis may be able to achieve an erection, but with penetration and use of the hip muscles for thrusting during sexual intercourse, blood is diverted from the penis to the hips, resulting in premature detumescence and loss of erection; this is known as the *pelvic steal syndrome*. Atherosclerotic large- and small-vessel disease may contribute to erectile dysfunction in men with diabetes mellitus, hypertension, CKD, smoking, and other atherosclerotic risk factors. Erectile dysfunction occurs in about 50% of men with diabetes mellitus. Smoking, specifically nicotine, also causes direct vasoconstriction of the corpora cavernosum and erectile dysfunction. Other conditions that compromise aorto-iliac circulation, such as pelvic trauma, irradiation, and vasculitis, are less common causes of erectile dysfunction.

Chronic pressure on the pudendal artery from bicycle riding, especially with some bicycle seats, may cause penile ischemia and erectile dysfunction; in addition, pressure on the pudendal nerve may cause penile numbness and contribute to sexual dysfunction. *Penile venous incompetence* (venous leakage) may cause premature loss of erections and inability to maintain erections sufficient to complete intercourse.

Many *antihypertensive medications*, including diuretics, α - and β -adrenergic antagonists, angiotensin-converting enzyme inhibitors, and calcium channel antagonists, have been implicated as causes of erectile dysfunction. *Penile abnormalities*, such as Peyronie's disease or chordee (fibrosis or scarring of the tunica albuginea resulting in bending of the penis), micropenis or microphallus, penile trauma, phimosis (inability to retract the foreskin over the penis), and priapism (painful extended erections) may also cause erectile dysfunction.

Evaluation of Erectile Dysfunction. The etiology of erectile dysfunction is usually strongly suspected on the basis of a careful medical, psychiatric, and medication history and physical examination.^{138,143} Erectile dysfunction of psychogenic origin usually occurs abruptly, is transient, is intermittent or associated with a stressful situation, or occurs with only some partners but not with others or not with masturbation. Spontaneous evening and morning erections are usually maintained in psychogenic erectile dysfunction but lost with organic causes. Spontaneous erections may be detected by formal measurements of nocturnal penile tumescence (NPT) in a sleep laboratory or by breakage of wires of different tensile strength in a snap gauge (RigiScan), but these assessments are not routinely performed in practice and usually are not necessary.

Patients with nonpsychogenic brain disorders, spinal cord or peripheral nervous system disorders, vascular disorders, or penile abnormalities that cause organic erectile dysfunction usually exhibit clinical manifestations of the underlying disorder, and offending drugs that impair erectile function are revealed with a careful review of medications. Androgen deficiency is a cause of reduced libido and erectile dysfunction and occurs in 15% to 20% of men who complain of sexual dysfunction in a general medical clinic.¹⁵⁰ Therefore, evaluation of men who present with sexual dysfunction should include inquiry regarding other symptoms of androgen deficiency, examination for signs such as small testis size and gynecomastia, and confirmation of androgen deficiency by measurement of serum testosterone levels (see later discussion).

Peripheral pulses, in particular the presence of femoral pulses, should be tested to assess for peripheral vascular disease. Diagnosis of penile vascular insufficiency may be suspected by Doppler ultrasound measurement of the ratio of penile to brachial systolic blood pressure (penile/brachial index). A penile/brachial index greater than 0.75 is normal, whereas an index of less than 0.60 is suggestive of vascular erectile dysfunction. If there is a clinical suspicion of spinal cord disease, perineal and penile sensation should be assessed. A cremasteric reflex (stroking of the inner thigh associated with contraction of the ipsilateral cremasteric muscle and pulling up of the scrotum and testis) and a bulbocavernosus reflex (squeezing of the glans penis associated with contraction of the anal sphincter) should be elicited to assess spinal cord levels L1-2 and S2-4, respectively. Finally, the penis should be examined for abnormalities, such as penile plaques, angulation, or tight, unretractable foreskin.

Ejaculatory Disorders and Orgasmic Dysfunction. After the plateau phase of erection is achieved, sympathetic nervous system stimulation from the thoracolumbar (T10-L2) spinal erection center travels via the hypogastric nerve and pelvic plexus, enters the penis via the cavernosal nerve, and causes α -adrenergic receptor-mediated contraction of the cauda epididymis, vas deferens, accessory sex glands (the bulbourethral or Cowper's glands and the urethral glands or glands of Littre), prostate, seminal vesicles, and ejaculatory ducts to move sperm and semen to the posterior urethra (*emission*). It also stimulates closure of the internal urethral sphincter to prevent retrograde ejaculation of sperm into the bladder.¹³⁸ After emission, continued sensory stimulation of the penis with sexual intercourse or masturbation stimulates reflex rhythmic contractions of the ischiocavernosus and bulbocavernosus muscles, resulting in expulsion of semen from the urethra (*ejaculation*).¹³⁸

Like erection, ejaculation is under considerable control by higher brain centers, with both voluntary and involuntary regulation.¹³⁸ *Premature ejaculation* is ejaculation that occurs before or shortly after vaginal penetration during sexual intercourse and is followed by a rapid loss of erection.¹⁵¹ The etiology of premature ejaculation is usually a psychological disturbance such as performance anxiety; it is rarely the result of an organic cause. There is evidence that serotonergic neurotransmission inhibits sexual function and ejaculation. Selective serotonin reuptake inhibitors retard ejaculation, an effect that is used therapeutically to treat premature ejaculation.¹⁵² Other men with psychological disorders such as excessive anxiety may have *retarded ejaculation* (inability to ejaculate), either in isolation or in combination with impaired libido and erections. The ejaculate is composed of spermatozoa (10%) and seminal fluid (90%), the latter derived mostly from the seminal vesicles (65%) and the prostate gland (30%). Because secretions from these accessory sex glands are androgen dependent, severe androgen deficiency may result in *absent or reduced ejaculation*. Absent or reduced ejaculation may also be caused by urethral abnormalities. Autonomic neuropathy, such as that caused by diabetes mellitus, sympatholytic drugs, thoracolumbar sympathectomy, extensive retroperitoneal or pelvic surgery, or bladder neck surgery, may be associated with absent or reduced ejaculation by causing *retrograde ejaculation* into the bladder.

Orgasm, the pleasurable sensation associated with ejaculation, usually occurs simultaneously with ejaculation and is mediated by CNS activation via ascending pathways from the spinal cord erection centers to regions of the temporal lobe and limbic system.¹³⁸ Because of impaired libido and erectile dysfunction, men with androgen deficiency may also fail to achieve an orgasm. Isolated absence of orgasm in the presence of normal libido, erections, and ejaculation is relatively rare and is almost always caused by a psychological disorder.

Disorders of Detumescence. After ejaculation, the thoracolumbar sympathetic outflow acts via α -adrenergic receptor stimulation to cause contraction of trabecular smooth muscle, which results in collapse of lacunar spaces, vasoconstriction of arterioles of the corpora cavernosa (reducing blood flow into the penis), and decompression of subtunical venules, leading to an increase in venous outflow and a flaccid penis (*detumescence*).¹³⁸ Premature detumescence may contribute to erectile dysfunction, such as that caused by penile venous incompetence. Intracorporal injection of an α -adrenergic receptor antagonist, phenolamine, together with papaverine and PGE₁, causes

sustained lacunar smooth muscle relaxation, arteriole vasodilatation, and penile tumescence and is used to treat erectile dysfunction caused by premature detumescence.

Priapism is failure of detumescence with persistence of erection lasting for longer than 4 hours that is unrelated to sexual stimulation and is usually painful.¹³⁸ An erection that persists for more than 4 hours is an emergency and may be complicated by ischemia, thrombosis, and vascular damage that contribute further to erectile dysfunction; if ischemia is severe, it can cause gangrene and eventual loss of the penis. Priapism may be idiopathic, or it may be caused by medications (e.g., intracavernosal injection therapy for erectile dysfunction, phenothiazines, trazodone, cocaine); by hematologic disorders such as sickle cell disease or chronic myelogenous leukemia; by neurologic disorders such as spinal cord injury; or by infiltrative diseases such as amyloidosis. The initial treatment is administration of the α -adrenergic receptor agonist, pseudoephedrine; if this is unsuccessful, aspiration of blood from the corpora cavernosa is performed with local anesthesia.

Gynecomastia

Gynecomastia is benign enlargement of the male breast caused by proliferation of glandular breast tissue.¹⁵³⁻¹⁵⁵ On inspection, it is difficult to distinguish gynecomastia from increased adipose tissue deposition within the breast in the absence of glandular proliferation (pseudogynecomastia), which is commonly present in obese men and boys. Detection of glandular breast tissue requires a careful and properly performed physical examination (see earlier discussion), feeling for a firm, rubbery, finely lobular, freely mobile disc of tissue that extends concentrically from under the nipple and areola. Initially, gynecomastia of relatively recent and rapid onset may be painful and associated with tenderness. With time, glandular tissue is replaced by fibrous tissue and tenderness resolves, although palpable tissue remains. In contrast, pseudogynecomastia is soft, nondiscrete, and irregularly lobular, similar to subcutaneous fat in the abdomen.

Gynecomastia is usually present bilaterally but may be asymmetric in size and symptoms. If palpable breast tissue is present unilaterally, the major concern is male breast cancer. Breast cancer is usually rock-hard and indurated, eccentrically located from the nipple and areola, and fixed to underlying tissue; it may be associated with skin dimpling with retraction of hair follicles (*peau d'orange*), nipple retraction, nipple bleeding or discharge, or axillary lymphadenopathy.¹⁵⁶ Other chest wall tumors may cause unilateral breast enlargement, including lipomas, sebaceous or dermoid cysts, hematomas, fat necrosis, lymphangiomas, neurofibromas, and lymphomas.

The primary hormones that regulate breast tissue development are estrogens, which stimulate the growth and differentiation of breast epithelium to form ducts (ductal hyperplasia), and progesterone, which controls acinar development and the formation of glandular buds (glandular formation).¹⁵⁵ Growth hormone, IGF1, insulin, thyroid hormone, and cortisol play permissive roles in breast development. Androgens inhibit the growth and differentiation of breast tissue. Prolactin stimulates differentiated breast acinar cells to produce milk, but high progesterone levels inhibit lactogenesis. Therefore, milk production requires a reduction in high progesterone levels in the presence of high prolactin levels, as occurs in the first few days after delivery. Milk production (galactorrhea) is rarely seen in men with hyperprolactinemia and gynecomastia, because progesterone levels are not usually high

enough for breast acinar development to occur, and they do not decline in the presence of high prolactin levels to stimulate lactogenesis.

Gynecomastia develops in clinical situations in which the levels or activity of estrogens is relatively high in comparison with androgens (i.e., high estrogen-to-androgen ratio). This hormonal milieu may result from high estrogen or low androgen concentrations or activity. Androgen deficiency, because it decreases the inhibitory influence of androgens on breast development, is a major cause of gynecomastia. However, the differential diagnosis of other causes of gynecomastia should be considered in patients who present with breast enlargement with or without tenderness.

Causes of Gynecomastia. *Physiologic gynecomastia* occurs normally in neonatal and pubertal boys. Transient gynecomastia (neonatal gynecomastia) occurs in 60% to 90% of neonatal boys as a result of exposure in utero to high concentrations of maternal estrogens; it resolves within several weeks after delivery (Table 19-3).¹⁵³⁻¹⁵⁵ At the time of puberty, breast enlargement greater than 0.5 cm in diameter, which is often tender, initially occurs in 60% to 70% of boys by 14 years of age and then regresses within 1 to 2 years. This pubertal gynecomastia is thought to be caused by a transient rise in serum concentrations of estrogen relative to testosterone during puberty.

Pathologic gynecomastia may result from excessive estrogen levels or action or from androgen deficiency or resistance in isolation. In some conditions, both estrogen excess and androgen deficiency contribute to proliferation of glandular breast tissue.¹⁵³⁻¹⁵⁵ For example, in most conditions that cause gynecomastia as a result of excessive estrogen exposure, high circulating estrogen concentrations inhibit endogenous gonadotropin and testosterone secretion and cause secondary hypogonadism, which also contributes to the growth of breast tissue. Also, some disorders of the testes that cause androgen deficiency (i.e., primary hypogonadism), such as Klinefelter's syndrome, result in high circulating LH levels that stimulate aromatase activity in Leydig cells, leading to higher levels of estradiol relative to testosterone and contributing to the pathogenesis of gynecomastia.

Estrogen excess disorders that cause gynecomastia include exposure to exogenous estrogens (e.g., diethylstilbestrol treatment of prostate cancer, contact with an estrogen-containing cream or cosmetic, accidental occupational exposure to estrogens, ingestion of estrogen-containing nutritional supplements or excessive amounts of phytoestrogens) and exposure to estrogen receptor (ER) agonists such as marijuana smoke (unidentified phenolic components but not active cannabinoids¹⁵⁷) or digitoxin. Ingestion of normal dietary amounts of phytoestrogens (e.g., soybean isoflavones) does not usually cause gynecomastia.¹⁵⁸ Uncommonly, administration of testosterone or other aromatizable androgens, usually to prepubertal boys or men with long-standing, severe androgen deficiency, induces or worsens gynecomastia by initially causing relatively higher estradiol than testosterone levels.

Increased peripheral aromatase activity with increased conversion of androgens to estrogens in excessive amounts of adipose tissue is thought to cause mild to moderate gynecomastia in men with obesity.¹⁵³⁻¹⁵⁵ Also, increased aromatization of androgens to estrogens with increasing amounts of adipose tissue (including that within the breast) probably contributes substantially to the increased prevalence of gynecomastia with aging, which occurs in up to 65% of men 50 to 80 years of age.¹⁵³⁻¹⁵⁵ Familial gynecomastia, an

TABLE 19-3

Causes of Gynecomastia

Cause	Examples
PHYSIOLOGIC CAUSES	
Maternal estrogen exposure	Neonatal gynecomastia
Transient increase in estrogen to androgen concentrations	Pubertal gynecomastia
ESTROGEN EXCESS	
Estrogens or estrogen receptor agonists	Estrogens, marijuana smoke, digitoxin, testosterone or other aromatizable androgens
Increased peripheral aromatase activity	Obesity, aging, familial
Estrogen-secreting tumors	Adrenal carcinoma, Leydig or Sertoli cell tumor
hCG-secreting tumors	Germ cell, lung, hepatic carcinoma
hCG treatment	
ANDROGEN DEFICIENCY OR RESISTANCE	
Androgen deficiency	Primary or secondary hypogonadism
Hyperprolactinemia causing androgen deficiency	
Androgen resistance disorders	Congenital and acquired androgen resistance
Drugs that interfere with androgen action	Spiroglactone, androgen receptor antagonists, marijuana, 5 α -reductase inhibitors, histamine 2 receptor antagonists
SYSTEMIC DISORDERS	
Organ failure	Hepatic cirrhosis, chronic kidney disease
Endocrine disorders	Hyperthyroidism, acromegaly, growth hormone treatment, Cushing's syndrome
Nutritional disorders	Refeeding, recovery from chronic illness (hemodialysis, insulin, isoniazid, antituberculous medications, HAART)
IDIOPATHIC CAUSES	
Drugs Adult-onset idiopathic gynecomastia	HAART, calcium channel antagonists, amiodarone, antidepressants (SSRIs, tricyclic antidepressants), alcohol, amphetamines, penicillamine, sulindac, phenytoin, omeprazole, theophylline
Persistent prepubertal macromastia	

HAART, highly active antiretroviral therapy; hCG, human chorionic gonadotropin; SSRIs, selective serotonin reuptake inhibitors.

autosomal dominant or X-linked genetic disorder caused by constitutive activation of the *CYP19A1* (aromatase) gene that results in increased peripheral conversion of androgen to estrogen, is a very rare cause of gynecomastia that manifests as prepubertal gynecomastia persisting into adulthood.

Estrogen-secreting tumors of the adrenal gland or testis are uncommon causes of gynecomastia. Feminizing adrenal tumors are usually malignant and large, manifesting with a palpable abdominal mass. In contrast, estrogen-secreting Leydig or Sertoli tumors are usually small and benign. Feminizing Sertoli tumors (in particular, the large-cell calcifying variety) may occur in isolation or in association with autosomal dominant disorders such as Peutz-Jeghers syndrome (multiple intestinal polyps and mucocutaneous

pigmented macules) or the Carney complex (cardiac or cutaneous myxomas, pigmented skin lesions, and endocrinopathy, including functioning endocrine tumors of the adrenal and testis). *hCG-secreting tumors* (e.g., germ cell, lung, gastric, renal cell, or hepatic carcinomas in adults; hepatoblastomas in boys) or *hCG treatment* of gonadotropin deficiency increases aromatase activity in Leydig cells and stimulates excessive secretion of estradiol relative to testosterone, causing relative rapid onset of symptomatic gynecomastia.

Disorders and drugs that cause *androgen deficiency*, such as conditions that cause either primary or secondary hypogonadism (including medications such as cytotoxic agents) or androgen resistance, are major causes of gynecomastia.¹⁵³⁻¹⁵⁵ Although prolactin acts on the breast to facilitate milk production in developed glandular tissue, the major mechanism by which hyperprolactinemia causes gynecomastia is inhibition of endogenous gonadotropin and testosterone production (inducing androgen deficiency), which acts indirectly to stimulate breast development by reducing the inhibitory influence of androgens on the breast. Hyperprolactinemia is a main reason that a number of CNS-active medications, such as antipsychotics, antidepressants, and sedatives, are associated with gynecomastia. Drugs that interfere with androgen action, such as spironolactone (in contrast to eplerenone, a selective aldosterone receptor antagonist that does not cause gynecomastia), AR antagonists (e.g., flutamide, bicalutamide, nilutamide), marijuana, and histamine 2 (H₂) receptor antagonists, may cause gynecomastia.

Androgen deficiency contributes to the pathogenesis of gynecomastia in *systemic disorders* such as major organ failure—and, in particular, in hepatic cirrhosis and CKD, which are commonly associated with combined primary and secondary hypogonadism—and in *endocrine disorders* such as acromegaly and Cushing's syndrome, which may be associated with secondary hypogonadism.¹⁵³⁻¹⁵⁵ In hepatic cirrhosis, there is reduced catabolism of Δ^4 -androstenedione, resulting in increased peripheral conversion of Δ^4 -androstenedione to estrone and increased circulating estrogen levels. Also, in both hepatic cirrhosis and hyperthyroidism, increased serum concentrations of SHBG, which binds testosterone with greater affinity than estradiol, result in relatively higher free estradiol compared with free testosterone levels and thereby contribute to stimulation of breast tissue and development of gynecomastia. LH levels are often elevated in men with hyperthyroidism, which stimulates relatively more estradiol than testosterone secretion by Leydig cells of the testes. Excessive GH with acromegaly or GH treatment and excessive cortisol with Cushing's syndrome directly stimulate breast tissue growth in addition to causing secondary hypogonadism, both of which contribute to the pathogenesis of gynecomastia.

Gynecomastia often accompanies *nutritional disorders*, in particular during nutritional repletion after a period of starvation and weight loss (refeeding gynecomastia) and analogously during recovery from chronic illness.¹⁵³⁻¹⁵⁵ In both starvation and severe chronic illness that is commonly associated with anorexia and weight loss, central GnRH production and concomitant gonadotropin and testosterone secretion are markedly suppressed. With refeeding or restitution of appetite and weight gain, there is activation of the hypothalamic-pituitary-testicular axis and restoration of gonadal function, similar to what occurs during puberty but more rapid (a "second puberty"), resulting in transiently higher levels of estrogen relative to androgen and inducing gynecomastia. Refeeding

gynecomastia was described initially in World War II prisoners who developed painful gynecomastia after liberation and nutritional repletion. Analogously, refeeding-like gynecomastia may occur in stage 5 CKD with the initiation of hemodialysis, in type 1 diabetes mellitus (T1DM) with insulin therapy, in tuberculosis with antituberculosis medications, and in human immunodeficiency virus (HIV) infection or AIDS with highly active antiretroviral treatment (HAART). As mentioned, these chronic systemic disorders also cause androgen deficiency that may contribute to the pathogenesis of gynecomastia. HAART also may cause lipohypertrophy and fat accumulation in the breast (pseudogynecomastia), and efavirenz has estrogenic activity.

The mechanisms of gynecomastia associated with a number of *drugs* are not entirely clear, and these cases are usually classified as idiopathic. Such drugs include HAART, calcium channel blockers (e.g., nifedipine, verapamil), amiodarone, antidepressants (selective serotonin reuptake inhibitors, tricyclic antidepressants), alcohol, amphetamines, penicillamine, sulindac, phenytoin, omeprazole (much less commonly than H₂-receptor antagonists), and theophylline.^{153-155,159}

In a number of cases of adult-onset gynecomastia, the etiology remains idiopathic. Most of these cases are probably caused by increased aromatization of androgens to estrogens associated with increased peripheral adiposity, enhanced breast production of estrogens, enhanced sensitivity to estrogens, or some combination of these factors. Rarely, boys may develop severe pubertal gynecomastia (female size breast development, Tanner stage III through V) that persists to adulthood (persistent pubertal macromastia). This disorder is not associated with specific hormonal or receptor abnormalities and remains idiopathic.

Evaluation. Most gynecomastia is asymptomatic and of mild degree but can be appreciated on a properly performed, careful physical examination (as described earlier). Mild, asymptomatic gynecomastia found incidentally on examination and in isolation does not warrant evaluation. However, breast enlargement that is recent and rapid in onset, large (>5 cm in obese men, >2 cm in lean men), symptomatic (i.e., associated with breast pain, tenderness, or galactorrhea), asymmetric, or suspicious for malignancy (eccentrically located, rock-hard, fixed to overlying or underlying tissues, or associated with bloody nipple discharge or lymphadenopathy) should trigger further evaluation.

A careful history, including medication history, and physical examination usually identify potential predisposing conditions or medications causing gynecomastia that in older men may be multifactorial.¹⁵³⁻¹⁵⁵ Clinical evaluation should focus on evidence of androgen deficiency; assessment of prescription and over-the-counter medications, substance abuse, herbal or nutritional supplement intake, cosmetic use, and usual dietary intake; symptoms and signs of systemic illness (e.g., hepatic or renal disease), malignancy, or endocrine disorders (e.g., thyroid, GH, cortisol excess); and history of recent recovery from malnutrition, severe weight loss, or chronic illness. At a minimum, the initial laboratory evaluation comprises serum testosterone, LH, FSH, TSH, and renal and liver function tests. Evaluation also usually includes measurements of estradiol, prolactin, and β -hCG, although elevations of these hormones usually affect testosterone and gonadotropin concentrations. Breast enlargement suspicious for malignancy should be evaluated by mammography and biopsy.

Treatment. Pubertal gynecomastia usually regresses spontaneously without treatment in 1 to 2 years and by age 17 in about 90% of cases. In adults, spontaneous regression of symptoms (breast pain and tenderness, nipple sensitivity) associated with inflammatory glandular proliferation usually occurs within 6 months, after which progressive stromal fibrosis causes more or less permanent palpable breast tissue and only partial regression of gynecomastia by 1 year.

Initial treatment of gynecomastia is directed at correction of the underlying cause of breast enlargement or discontinuation or replacement of a potentially offending medication.¹⁶⁰ Testosterone replacement therapy in androgen-deficient men may result in partial regression of gynecomastia, especially if breast enlargement is of recent onset. Prophylactic low-dose breast irradiation (10 to 15 Gy over 1 to 3 days) may be used before androgen deprivation therapy in men with prostate cancer to prevent the development of gynecomastia; this is more common in surgical orchiectomy and in AR antagonist monotherapy rather than combined therapy with a GnRH agonist or antagonist. ER antagonists (tamoxifen, 10 to 20 mg daily, or raloxifene, 60 mg daily) are effective in treating pubertal and adult gynecomastia and preventing gynecomastia induced by androgen deprivation therapy. For unclear reasons, aromatase inhibitors (e.g., anastrozole) are not effective. Although tamoxifen is not approved for treatment of gynecomastia, it has been shown to be effective in the treatment of idiopathic gynecomastia, resulting in partial regression in approximately 80% and complete regression in about 60% of cases. A gel formulation of DHT, a nonaromatizable androgen, is used to treat gynecomastia in some countries outside the United States.

Gynecomastia of recent onset, during the initial phase of ductal proliferation, periductal inflammation and edema, and subareolar fat accumulation, is usually responsive to medical therapy (e.g., androgen replacement in hypogonadal men, ER antagonist therapy). With longstanding gynecomastia (>1 year), there is progressive stromal fibrosis of the breast that is not responsive to medical treatment. In these cases, surgical reduction mastoplasty (i.e., removal of breast tissue [subcutaneous mastectomy] with or without periareolar adipose tissue [liposuction]) is necessary, especially if breast enlargement is severe, painful, socially embarrassing, or disfiguring.

Infertility

Infertility is defined as the inability of a sexually active couple to achieve conception despite 1 year of unprotected intercourse. The probability of conception in a sexually active couple is approximately 85% by 1 year. Approximately 15% of couples in the reproductive age group are infertile, and a male factor contributes to the cause (either in isolation or in combination with a female factor) in about half of the cases. Therefore, male infertility is a common condition, affecting approximately 7% of men.¹⁶¹

Causes of Male Infertility. In about 80% to 90% of infertile men, infertility is caused by primary or secondary hypogonadism, manifested mostly by an isolated impairment of sperm production or function, much less commonly by androgen deficiency and impaired spermatogenesis, and rarely by androgen resistance (Table 19-4).^{162,163} The evaluation and specific causes of hypogonadism are discussed in detail in subsequent sections. Most men with isolated impairment in sperm production have a primary disorder of the testes that is idiopathic in 60% to 70% of cases (if one includes both idiopathic oligozoospermia or

TABLE 19-4

Causes of Male Infertility

Cause	Examples
HYPOGONADISM	
Isolated impairment of sperm production or function	
Androgen deficiency and impaired sperm production Androgen resistance	
DISORDERS OF SPERM TRANSPORT	
Genital tract obstruction	Congenital bilateral absence of the vas deferens, cystic fibrosis, other congenital defects, vasectomy, postinfectious fibrosis, Young syndrome
Accessory gland dysfunction	Androgen deficiency or resistance, infection or inflammation, anti-sperm antibodies (immunologic)
Sympathetic nervous system dysfunction	Autonomic neuropathy, sympatholytic drugs, sympathectomy, retroperitoneal or abdominopelvic surgery, spinal cord injury or disease, vasovasoostomy
EJACULATORY DYSFUNCTION	
Premature or retarded ejaculation	
Retrograde ejaculation	Prostatectomy, bladder neck surgery, autonomic neuropathy, SNS dysfunction
Reduced ejaculation	Androgen deficiency or resistance, SNS dysfunction, ureteral abnormalities
COITAL DISORDERS	
Erectile dysfunction	
Defects in coital technique	Infrequent intercourse, excessive intercourse or masturbation, poor timing in relation to ovulation, premature withdrawal of penis

SNS, sympathetic nervous system.

azoospermia and varicocele, although their relationship to the pathogenesis of infertility is unclear). If isolated impairment of spermatogenesis is severe in men with primary hypogonadism, serum FSH levels may be selectively elevated as a result of reduced negative feedback by inhibin B from Sertoli cells of the testis. In men with less severely impaired spermatogenesis, serum gonadotropin levels are normal, but this is still classified with disorders of primary hypogonadism because gonadotropin treatment has not been demonstrated to improve fertility.

Disorders of spermatogenesis caused by primary hypogonadism may be associated with chromosomal or genetic disorders. There is an 8- to 10-fold increase in the prevalence of chromosomal abnormalities among infertile men with impaired spermatogenesis—specifically, sex chromosomal aneuploidy (e.g., Klinefelter's syndrome) or robertsonian translocations of two nonhomologous chromosomes, most commonly involving chromosomes 13 and 14 or chromosomes 14 and 21.¹⁶⁴ The long arm of the Y chromosome (Yq), specifically the azoospermia factor (AZF) region (Yq11), contains a number of genes that encode for proteins that have important roles in spermatogenesis. This region contains highly homologous palindromic DNA repeat sequences that are susceptible to

rearrangement and deletions. Small deletions in the *AZF* region (*Y chromosome microdeletions*) are the most common genetic cause of impaired sperm production and male infertility; they are found in 5% to 10% of men with azoospermia or severe oligozoospermia (sperm concentration <5 million/mL).¹⁶⁴ *Y chromosome microdeletions* have been identified in three regions: in the *AZF_a* region, microdeletions are uncommon but are usually associated with azoospermia and Sertoli cell-only histology; in the *AZF_b* region, they are usually associated with severe oligozoospermia and germ cell arrest at the pachytene primary spermatocyte stage; and in the *AZF_c* region, where the majority of *Y chromosome microdeletions* reside, they are usually associated with germ cell arrest at the spermatid stage or hypospermatogenesis with some mature spermatids present. Occasionally, microdeletions in the *AZF_b* and *AZF_c* regions are associated with azoospermia and Sertoli cell-only histology. Genes encoding a number of candidate proteins for male infertility include *DDX3Y* (DEAD box *Y*, an ATP-dependent RNA helicase), *RBMY* (RNA-binding motif *Y*-linked, an RNA-binding protein), and *DAZ* (deleted in azoospermia, another RNA-binding protein) in the *AZF_a*, *AZF_b*, and *AZF_c* regions, respectively.^{164,165}

Approximately 15% to 20% of male infertility is caused by *disorders of sperm transport* from the testes to the urethra, most commonly by genital tract obstruction. *Congenital bilateral absence of the vas deferens* (CBAVD) is present in 1% to 2% of men with infertility.^{164,166,167} Seventy-five percent of men with CBAVD are heterozygous for the cystic fibrosis transmembrane conductance regulator gene (*CFTR*), which encodes for an epithelial chloride channel, or carry compound heterozygous mutations of *CFTR*. They do not have obvious clinical manifestations of cystic fibrosis, although some manifest abnormalities on sweat chloride testing and sinopulmonary infections. Conversely, almost all men with cystic fibrosis have CBAVD. CBAVD is also commonly associated with absence of the seminal vesicles, ejaculatory ducts, and epididymides due to fetal atrophy of these wolffian duct derivatives; in 10% of cases, there is also renal agenesis or hypoplasia.

Other causes of genital tract obstruction include other congenital defects of the epididymides and vas deferens (e.g., epididymal cysts associated with prenatal diethylstilbestrol exposure); vasectomy (surgical ligation of the vas deferens); postinfectious fibrosis (e.g., associated with gonorrhea, *Chlamydia* infection, other sexually transmitted diseases; tuberculosis; leprosy); and Young syndrome, a rare, congenital primary ciliary dyskinesia syndrome characterized by bronchiectasis, recurrent sinopulmonary infections, and obstructive azoospermia caused by thickened, inspissated mucous secretions obstructing the epididymides.

Although a causal link to infertility has not been clearly established, other genital tract abnormalities may contribute to impaired sperm transport and the pathogenesis of infertility in some men. *Accessory gland dysfunction*, such as reduced seminal vesicle and prostate secretions associated with disorders that cause severe androgen deficiency or resistance, may contribute to reduced fertility, although the main effects of these disorders are to impair spermatogenesis and cause sexual dysfunction. *Infection or inflammation* of the epididymides, seminal vesicles, or prostate gland may affect fertility directly by impairing sperm maturation or function or secondarily by causing scarring of the genital tract or induction of *anti-sperm antibodies* in semen (resulting in sperm agglutination and impaired sperm function).^{168,169} *Sympathetic nervous system dysfunction* (e.g., associated with autonomic neuropathy, sympatholytic

drugs, sympathectomy, retroperitoneal or abdominopelvic surgery, spinal cord injury or disease, vasovasostomy) may contribute to impaired sperm transport and male infertility.

Ejaculatory dysfunction may cause or contribute to male infertility by preventing normal or efficient deposition of sperm into the vagina and female genital tract. Premature or retarded ejaculation may contribute to infertility if ejaculation occurs during arousal or foreplay before vaginal penetration or after withdrawal from the vagina. Retrograde ejaculation of semen into the bladder rather than the urethra occurs with neuromuscular failure of normal bladder sphincter contraction during ejaculation. Retrograde ejaculation may be associated with prostatectomy or bladder neck surgery (e.g., transurethral resection of the prostate [TURP]), autonomic neuropathy (e.g., complicating diabetes mellitus), or sympathetic nervous system dysfunction, and in particular with sympatholytic drugs (e.g., α -adrenergic receptor antagonists such as prazosin or terazosin), retroperitoneal or abdominopelvic surgery (e.g., retroperitoneal lymph node dissection), and spinal cord injury or disease. Reduced ejaculation caused by androgen deficiency or resistance, sympathetic nervous system dysfunction, or urethral abnormalities may contribute to reduced sperm delivery to the female genital tract.

Erectile dysfunction may contribute to male infertility by causing unsuccessful completion of intercourse. Coital disorders are uncommon causes of male infertility, but they are potentially correctable with proper education. Infrequent sexual intercourse, excessive intercourse with other partners or masturbation, intercourse during menses rather than just before or around the time of ovulation, and premature withdrawal of the penis during intercourse may contribute to reduced fertility.

Evaluation. Because a coexisting female factor contributes to infertility in 30% of cases, it is important for the female partner to undergo evaluation for ovulation (menstrual periods, androgenization) and for cervical disorders (postcoital testing) and uterine and tubal disorders (hysterosalpingogram, pelvic ultrasound). In men, the history and physical examination are usually able to identify the potential etiology of male infertility.¹⁶²⁻¹⁶⁴

In addition to an assessment of general health and medical comorbidities, the initial clinical evaluation should focus on the following:

- Symptoms and signs of androgen deficiency or resistance (as detailed elsewhere in this chapter)
- Scrotal examination for presence of a varicocele, presence and size of the testes, and presence or absence of firm, fibrous cords of the vas deferens
- Family history or evidence of cystic fibrosis
- Previous vasectomy or vasovasostomy
- History or manifestations of genitourinary infections
- Medications, particularly ones that cause androgen deficiency or resistance and sympatholytic agents
- Ejaculatory problems, in particular absent or reduced ejaculate
- Autonomic neuropathy (e.g., complicating diabetes mellitus)
- Retroperitoneal or abdominopelvic surgery
- Spinal cord injury or disease
- Erectile dysfunction
- Coital practices and techniques.

The initial laboratory evaluation of male infertility should begin with at least two or three seminal fluid analyses performed over a period of a few months (see later

discussion) to assess semen volume, sperm count and concentration, and sperm motility and morphology, with the aim of identifying men who have impaired sperm production or function, the major cause of male infertility. The presence of leukocytes in semen ($>10^6/\text{mL}$, termed *leukospermia* or *pyospermia*) may suggest a genitourinary inflammation or infection, but routine cultures are not usually helpful in guiding treatment. Agglutination of spermatozoa in semen (i.e., sticking of motile sperm to each other) suggests the presence of *anti-sperm antibodies*, which can be measured in semen and in serum and may indicate an immunologic cause of male infertility.

Seminal fluid fructose is derived mostly from the seminal vesicles (60%) and to a lesser extent from the prostate gland (30%). Absent or low seminal fluid fructose and low semen volume suggest either congenital absence of the vas deferens and seminal vesicles or obstruction of the ejaculatory ducts. Dilated seminal vesicles may be detected on transrectal ultrasonography to confirm the presence of ejaculatory duct obstruction. In men who have little or no ejaculate, a postejaculatory urine specimen should be collected and examined for the presence of sperm, indicating retrograde ejaculation.

If there are clinical manifestations of androgen deficiency, serum testosterone levels should be measured on at least two occasions to confirm androgen deficiency, and measurements of LH and FSH should be performed to determine whether the patient has primary or secondary hypogonadism (see later discussion). Identification of infertile men with secondary hypogonadism potentially has important therapeutic implications. In men with impaired sperm production due to gonadotropin deficiency, spermatogenesis may be stimulated and fertility restored with the use of gonadotropin or GnRH therapy. Secondary hypogonadism is one of few treatable causes of male infertility. Elevated levels of testosterone, LH, and FSH suggest androgen resistance.

Measurements of FSH levels specifically as a marker of Sertoli cell and seminiferous tubule function are useful in identifying men with severe defects in spermatogenesis and impairment of seminiferous tubule and Sertoli cell function; such patients often demonstrate selective elevation in serum FSH concentrations with normal or high-normal LH levels due to loss of negative feedback inhibition of pituitary FSH secretion by inhibin B.¹⁷⁰ However, men with less severe seminiferous tubule dysfunction and impairment of spermatogenesis and those with azoospermia due to genital tract obstruction (obstructive azoospermia) have normal serum FSH levels.

Genetic disorders make up a small but significant proportion of the causes of male infertility. Because ART, and specifically ICSI, which involves direct injection of spermatozoa into the cytoplasm of an ovum (discussed later), is commonly used to treat male infertility, the potential exists for transmission of genetic defects to offspring. Therefore, genetic testing and counseling should be undertaken for men who are considering ICSI, particularly for those with severe oligozoospermia or azoospermia.¹⁶²⁻¹⁶⁴

Men in whom bilateral congenital absence of the vas or genital tract obstruction is suspected (i.e., those with low semen volume, low fructose level, and nonpalpable vas deferens in the scrotum) and those who have unexplained obstructive azoospermia should undergo genetic testing for *CFTR* mutations and genetic counseling before ICSI. In men with severe oligozoospermia (sperm concentration <5 million/mL) or azoospermia, testing for Y chromosome microdeletions in the *AZF* region should routinely be performed. There is a high prevalence of sex chromosome and

autosomal chromosome defects, often in the absence of other phenotypic abnormalities, in men with moderately impaired spermatogenesis and infertility. Therefore, karyotyping is recommended before ICSI for infertile men with impaired sperm production, and in particular for those with a sperm concentration of less than 10 million/mL.

In azoospermic men with normal semen volume, a normal fructose level, and a normal FSH level in whom it is unclear whether azoospermia is caused by germ cell failure, genital tract obstruction, or both, surgical exploration of the scrotum and testis biopsy are needed. Biopsy is also used to harvest sperm for ICSI, even in men with known severe impairment in spermatogenesis, such as those with Klinefelter's syndrome.^{162,163,171}

Specialized tests of in vitro sperm function, such as detailed examination of sperm motility using computer-assisted semen analysis (CASA), cervical mucus penetration tests, acrosome reaction, and human zona pellucida binding tests, may be useful in some men who are considering intrauterine insemination or in vitro fertilization. However, these tests should be performed only in highly specialized laboratories that have demonstrated excellent quality control. Even in such laboratories, there is a high rate of clinical false-positive and false-negative results, limiting the clinical utility of these tests.

Treatment. In men with infertility caused by primary hypogonadism (whether due to androgen deficiency and impairment of sperm production or to isolated impairment of sperm production or function), defects in sperm production are not treatable, although spontaneous recovery of spermatogenesis may occur at variable times after discontinuation of cytotoxic drugs or ionizing radiation. Because intratesticular testosterone concentrations are normally approximately 100-fold higher than serum levels, exogenous testosterone treatment of men with androgen deficiency cannot deliver sufficient amounts of testosterone to support sperm production in the testis.

In men with secondary hypogonadism, on the other hand, sperm production can be stimulated with gonadotropin or GnRH treatment, or spermatogenesis may recover sufficiently to restore fertility after discontinuation of drugs that suppress gonadotropins, such as androgenic anabolic steroids, progestins, glucocorticoids, and drugs causing hyperprolactinemia.

Most men with a varicocele and infertility have abnormal seminal fluid. However, varicocele repair has not been demonstrated to be effective in restoring fertility to these men. Therefore, unless a varicocele is very large or symptomatic, surgical repair is not recommended.¹² Although the efficacy of treatment is unclear, infertile men with leukospermia or sperm agglutination are usually treated empirically with a 14-day course of antibiotics, such as doxycycline, trimethoprim-sulfamethoxazole, or a fluoroquinolone. Although high-dose prednisone (40 to 60 mg for several months) has been shown to be effective in treating infertile men with anti-sperm antibodies, the risks of high-dose glucocorticoid treatment are substantial, and this therapy cannot be recommended given the safer alternative of ICSI.

Although ICSI is costly, it is used increasingly to treat male infertility, and it dramatically improves the prognosis for men with impaired sperm production regardless of the cause.¹⁷² Spermatozoa that are ejaculated or obtained by testicular biopsy (*testicular sperm extraction [TESE]*) or from the epididymis (*microsurgical epididymal sperm aspiration [MESA]*) are used for ICSI and other ARTs. With ICSI, fertilization rates of about 60% and pregnancy rates of

approximately 20% are achieved, irrespective of the etiology of male infertility or source of spermatozoa. ICSI after TESE using microsurgical testis biopsy or fine-needle aspiration to retrieve sperm has been successful in restoring fertility to men with primary hypogonadism who had severe impairments in spermatogenesis and azoospermia that were previously thought to be untreatable (e.g., Klinefelter's syndrome, prolonged azoospermia after chemotherapy).¹⁷³ Because of the potential for chromosomal abnormalities and transmission of Y chromosome microdeletions and *CFTR* mutations that cause infertility in male offspring, genetic testing and counseling should be conducted if ICSI is being considered (see earlier discussion).¹⁶⁴

Obstruction of the epididymides or the ejaculatory ducts can be corrected surgically, such as with end-to-end anastomosis of the epididymides or transurethral resection of the ejaculatory ducts. More commonly, MESA is used to obtain spermatozoa that can be incubated with ova in vitro (*in vitro fertilization [IVF]*) or directly injected into an ovum (ICSI), and this is more successful in restoring fertility than surgical options. In contrast, microsurgical reanastomosis of the vas (vasovasostomy) to reverse vasectomy is less costly and more successful in restoring fertility than MESA followed by IVF or ICSI. Return of sperm in the ejaculate occurs in approximately 90% of men who undergo vasectomy reversal, but restoration of fertility occurs in only about 50%, probably because of stenosis or blockage of the previous vasovasostomy, epididymal blockage, or the development of anti-sperm antibodies in response to the vasectomy.¹⁷⁴

In men with retrograde ejaculation, collection of spermatozoa in alkalized postejaculation urine, followed by extensive washing and *intrauterine insemination (IUI)* or ICSI, has been used successfully to treat infertility. With proper education, coital disorders that contribute to infertility may be corrected. Also, the timing of intercourse may be optimized to occur a few days before ovulation (the period of highest probability for conception) based on basal body temperature measurements or, more accurately, on commercially available rapid urinary LH kits to estimate the timing of ovulation in the female partner.

If the treatment options described previously are not available or affordable to infertile couples who desire children, artificial insemination with donor sperm or adoption may be considered.

Diagnosis of Male Hypogonadism

Clinical Manifestations of Androgen Deficiency

The diagnosis of male hypogonadism requires clinical manifestations consistent with androgen deficiency and unequivocally low serum testosterone levels. In community-dwelling middle-aged to older men, the crude prevalence of symptomatic androgen deficiency is 2% to 9%, depending on the constellation of symptoms and signs and the biochemical definition of androgen deficiency used.¹⁷⁵⁻¹⁷⁷ This prevalence increases with age and is much higher in a primary care setting.¹⁷⁸ In community populations, the prevalence of low testosterone levels alone, without consideration of symptoms and signs of androgen deficiency, is much higher than that of clinical androgen deficiency. This underscores the importance of making a diagnosis of hypogonadism only in men who have clinical manifestations and consistently low testosterone levels. Both the clinical and the biochemical diagnosis of androgen deficiency can be challenging, especially in older adults.

Although the manifestations of fetal androgen deficiency or resistance (ambiguous genitalia and DSDs) and those of prepubertal androgen deficiency (eunuchoidism) are usually clinically obvious, the clinical diagnosis of androgen deficiency in adults is more difficult. As described previously, the symptoms and signs of androgen deficiency are nonspecific and have a broad differential diagnosis. Moreover, clinical manifestations may be modified by a number of factors, such as the severity and duration of androgen deficiency, age, comorbid illnesses, medications, previous testosterone treatment, and individual variations in androgen sensitivity, all of which contribute to variability in clinical presentation that may confound the diagnosis.¹¹⁰

The degree and duration of androgen deficiency have impressive effects on clinical manifestations. The severe and relatively rapid suppression of testosterone levels in men with prostate cancer treated with a GnRH agonist or orchidectomy results in prominent clinical manifestations with notable reductions in erectile function, libido, energy, and mood; hot flushes and sleep disturbances; infertility; decreases in muscle mass and strength, BMD (associated with an increase in fracture risk), and body hair; gynecomastia; increases in body fat; anemia; and possibly increases in the risks for diabetes mellitus and for cardiovascular events.^{179,180} In contrast, men with mild androgen deficiency may have few or no referable manifestations; such patients have "subclinical" androgen deficiency that may or may not be associated with clinically significant outcomes. The latter situation is analogous to that observed in other endocrine disorders such as subclinical hypothyroidism or asymptomatic primary hyperparathyroidism.

Aging is associated with alterations in body functions, such as declines in sexual function, muscle mass and strength, and BMD, that result in clinical manifestations similar to those of androgen deficiency.¹³⁵ These alterations associated with aging may also be caused in part by age-related androgen deficiency. To add to the clinical complexity in older men, age-associated comorbid illnesses and medications used to treat these illnesses may modify the symptoms and signs of androgen deficiency, and in many instances, they may also contribute to the etiology of androgen deficiency. Therefore, it is understandable why the diagnosis of clinical androgen deficiency is challenging in older men, and particularly in frail elderly men who have multiple comorbidities and are taking numerous medications.

Previous testosterone treatment that has been discontinued may affect the clinical manifestations of androgen deficiency, depending on the duration of therapy and the time since discontinuation. It is also likely that clinical manifestations of androgen deficiency are affected by individual variations in androgen action on specific target organs. Alterations in androgen sensitivity may result from individual or tissue-specific differences in the activity of the AR or the ER and associated coregulators or from differences in active metabolism or inactivation of testosterone.

In men with clinical manifestations suggestive of androgen deficiency, the diagnosis of hypogonadism is confirmed biochemically by measurement of consistently low serum testosterone concentrations (Fig. 19-19).¹¹⁰

Testosterone Measurements

As with the clinical manifestations, the biochemical confirmation of androgen deficiency presents its own difficulties. Testosterone levels exhibit both biologic and assay variability. Total testosterone concentrations are affected

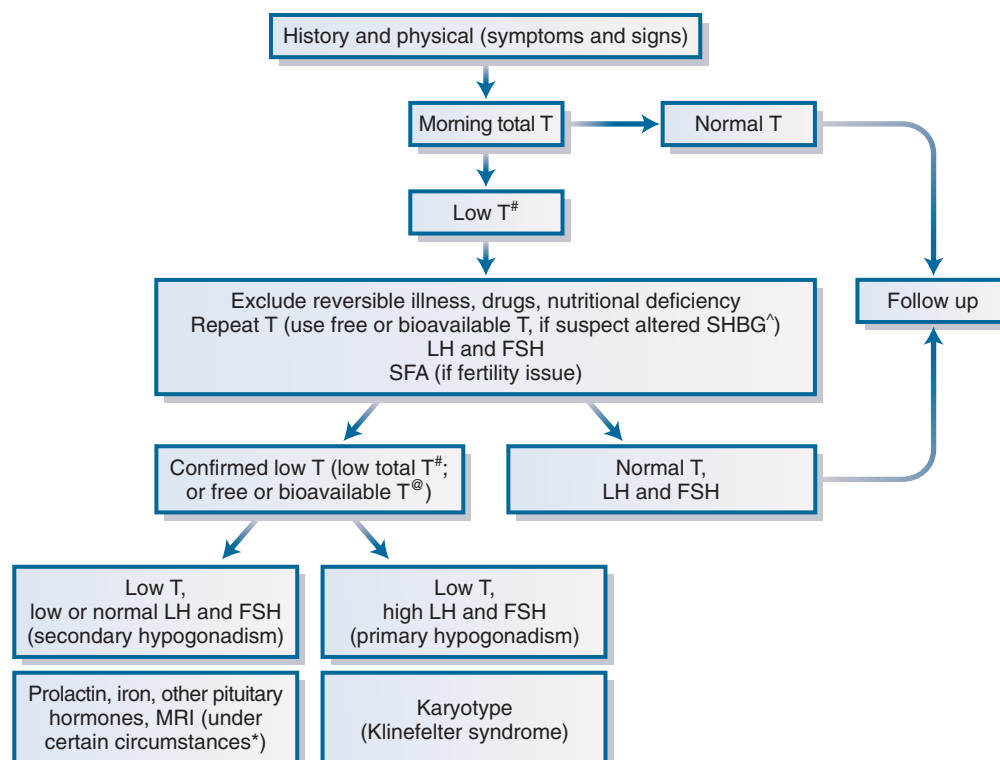

Figure 19-19 Algorithm for the diagnosis and evaluation of suspected androgen deficiency. In men with clinical manifestations (symptoms and signs) consistent with androgen deficiency, a morning serum total testosterone (T) measurement should be obtained. [#]The normal range for total T in healthy young men varies in different laboratories, but the lower limit of normal for most reliable assays is 280 to 300 ng/dL (9.8 to 10.4 nmol/L). If the initial total T concentration is low, the measurement should be repeated to confirm the presence of biochemical androgen deficiency. Reversible illnesses, drugs, or nutritional deficiencies that can transiently lower T levels should be ruled out before making a diagnosis of male hypogonadism. ^{*}If a condition is present that could cause an alteration in the level of sex hormone-binding globulin (SHBG), an accurate measurement of free or bioavailable T (instead of total T) should be obtained to confirm the presence of biochemical androgen deficiency. [@]The normal range for accurate measurements of free testosterone (free T by equilibrium dialysis and calculated free T) in healthy young men varies in different laboratories but is usually 5 to 6 ng/dL (0.17 to 0.31 nmol/L). Levels of luteinizing hormone (LH) and follicle-stimulating hormone (FSH) should be obtained with T to determine whether androgen deficiency is caused by secondary hypogonadism (low T with low or normal LH and FSH) or by primary hypogonadism (low T with high LH and FSH). ^{*}In men with secondary hypogonadism, assessment of serum prolactin, serum iron, and other pituitary hormones, with or without magnetic resonance imaging (MRI), should be considered for further evaluation. In men with primary hypogonadism and consistent clinical features (e.g., very small testes), a karyotype should be considered to confirm the diagnosis of Klinefelter's syndrome. SFA, seminal fluid analysis. (From Bhasin S, Cunningham GR, Hayes FJ, et al. Testosterone therapy in men with androgen deficiency syndromes: an Endocrine Society clinical practice guideline. *J Clin Endocrinol Metab*. 2010;95:2536-2559.)

by alterations in SHBG, and testosterone levels may be suppressed transiently with illness, certain medications, and some nutritional deficiencies.¹¹⁰ Therefore, the biochemical diagnosis of androgen deficiency requires demonstration of consistently and unequivocally low serum testosterone levels on at least two occasions and preferably measured in the morning. In men who have conditions that alter SHBG, accurate and reliable free or bioavailable testosterone measurements are needed to confirm the diagnosis of hypogonadism. Finally, the diagnosis of hypogonadism should not be made during acute or subacute illness.

The threshold level of circulating total or free testosterone below which symptoms and signs of androgen deficiency occur and for which testosterone treatment will improve clinical manifestations is not known. However, the concept of a single threshold testosterone level is probably not valid, nor is it clinically useful, because thresholds vary with the specific symptom and the androgen target organ or tissue. In general, symptoms and signs of androgen deficiency are more likely to occur with a total testosterone level that is below the lower limit of the normal range for young healthy men (approximately 280 to 300 ng/dL or 2.8 to 3.0 ng/mL [9.7 to 10.4 nmol/L], when

using an accurate and reliable assay). The likelihood and severity of clinical manifestations of androgen deficiency increases with a greater decline in testosterone level below normal.

Variability in Testosterone Levels. Because serum testosterone levels exhibit both biologic and assay variability, a single measurement is not a reliable indicator of an individual's average concentration. Serum testosterone levels exhibit both ultradian and circadian variation, providing physiologic sources of biologic variability. Ultradian fluctuations in serum testosterone levels, characterized by peaks of incremental amplitude that average approximately 240 ng/dL (40% fractional amplitude) with a 95-minute duration,⁴⁵ have been reported in a small number of young men; more chaotic peaks with lower amplitude have been reported in older men.¹⁸¹ As described previously, the circadian variation in serum testosterone peaks at about 8 a.m. and has a maximum excursion averaging 140 ng/dL.⁶⁴ The circadian variation in testosterone is blunted but still present in older men, with a maximum excursion averaging 60 ng/dL. In young men, serum testosterone levels are 20% to 25% lower at 4 p.m. than at 8 a.m. (i.e., over the course of usual clinic hours).¹⁸² This difference decreases

with age: in 70-year-old men, testosterone levels are 10% lower at 4 p.m. than at 8 a.m. Most importantly, many young and old men who have testosterone concentrations that are below normal in the afternoon have consistently normal levels in the morning. Given these findings and the fact that normal ranges of testosterone concentration are usually based on morning blood samples, testosterone measurements to confirm the diagnosis of hypogonadism should preferably be performed in the morning.

There is also substantial day-to-day variation in serum testosterone concentrations, underscoring the need to repeat the measurement to confirm low levels, particularly if the first result was only moderately below normal. Among men with serum testosterone levels of less than 300 ng/dL on an initial test, 30% were found to have a normal level on repeat testing.¹⁸³ Among community-dwelling middle-aged to older men who had an initial serum testosterone concentration of less than 250 ng/dL, 20% were found to have an average testosterone level higher than 300 ng/dL (i.e., within the normal range) when six samples were drawn over the subsequent 6 months.¹⁸⁴ However, none of the subjects who had an initial average serum testosterone concentration of less than 250 ng/dL on two separate samples obtained 1 to 3 days apart had an average level higher than 300 ng/dL in six samples drawn over the next 6 months. These findings support the need to measure testosterone on at least two occasions to confirm the diagnosis of androgen deficiency.

Total Testosterone Assays. Total testosterone assays are performed in most local laboratories and are readily available to clinicians. Therefore, total testosterone is recommended as the initial measurement for the assessment of androgen deficiency. In local clinical laboratories, total testosterone is usually measured by automated platform-based immunoassays. However, there is substantial variability in results from different assays, mostly because the accreditation of laboratories has been based on the reproducibility of results in comparison to other laboratories using the same method or kit, rather than on the accuracy of results. For example, when identical quality control samples were assayed by different methods or kits, the reported measured values ranged from 160 to 508 ng/dL. Moreover, the lower limit of the normal range in some assays was as low as 132 to 210 ng/dL (clearly in the hypogonadal range for most conventional assays).¹⁸⁵ In contrast, the lower limit of the normal range based on conventional radioimmunoassays is approximately 280 to 300 ng/dL.

Most commercial laboratories now measure testosterone by liquid chromatography tandem mass spectrometry methods that have the potential to be more accurate than immunoassays. To address the problems in the quality control of testosterone assays, the U.S. Centers for Disease Control and Prevention (CDC) has initiated a program to standardize and harmonize testosterone assays using accuracy-based quality control standards.¹⁸⁶

The prevalence of low testosterone concentrations is high in a number of clinical conditions, namely presence of a pituitary or sellar mass; irradiation; disease; use of certain medications, such as opiates or high-dose glucocorticoids; HIV disease with weight loss; late-stage CKD, especially with hemodialysis; moderate to severe chronic lung disease; infertility; BMD levels that reveal osteoporosis or low-trauma fracture; and type 2 diabetes mellitus (T2DM). If clinical manifestations consistent with androgen deficiency are present in men with these conditions, testosterone measurements should be performed.¹¹⁰

TABLE 19-5

Conditions Associated with Alterations in SHBG Concentrations

Decreased SHBG Concentrations	Increased SHBG Concentrations
Moderate obesity, type 2 diabetes mellitus	Aging
Nephrotic syndrome	Hepatic cirrhosis and hepatitis
Glucocorticoids, progestins, and androgens	Estrogens
Hypothyroidism	Hyperthyroidism
Acromegaly	Anticonvulsants
Familial SHBG deficiency	HIV disease

HIV, human immunodeficiency virus; SHBG, sex hormone-binding globulin.
(From Bhasin S, Cunningham GR, Hayes FJ et al. Testosterone therapy in men with androgen deficiency syndromes; an Endocrine Society clinical practice guideline. *J Clin Endocrinol Metab*. 2010;95:2536-2559.)

Total Testosterone Affected by Alterations in Sex Hormone-Binding Globulin. Because a substantial proportion (30% to 40%) of circulating testosterone is bound tightly to SHBG, alterations in SHBG concentration may affect total testosterone levels without altering free or bioavailable testosterone. Conditions that suppress SHBG levels (even within the broad normal range) lower total testosterone (sometimes to below the normal range) without affecting circulating free or bioavailable testosterone levels (Table 19-5).¹¹⁰ Common conditions that lower SHBG concentrations include moderate obesity, often associated with T2DM; protein-losing states, such as nephrotic syndrome; administration of glucocorticoids, progestins, or androgens; hypothyroidism; acromegaly; and familial SHBG deficiency. SHBG concentrations are increased with increasing age; hepatic cirrhosis and inflammation (hepatitis of any cause); estrogens; hyperthyroidism; anticonvulsants; and HIV disease.

If conditions that affect SHBG concentration are present in a patient or if total testosterone concentrations are close to the lower limit of the normal range, serum free or bioavailable testosterone measurements should be obtained to confirm androgen deficiency. Unfortunately, accurate and reliable assays for free or bioavailable testosterone are not performed routinely in most local clinical laboratories. Although direct free testosterone assays using automated platform-based analog immunoassay methods are available, these assays are inaccurate and are affected by alterations in SHBG, so they offer no advantage over total testosterone measurements and are not recommended.¹⁸⁷⁻¹⁸⁹

The gold standard method for measurement of free testosterone levels is equilibrium dialysis or centrifugal ultrafiltration. Free testosterone concentrations may be calculated accurately from measurements of total testosterone, SHBG, and albumin using affinity constants for binding of testosterone to its binding proteins and published formulas. Calculated free testosterone values are comparable to those measured by equilibrium dialysis.¹⁸⁸ However, calculated values depend on the specific testosterone and SHBG assays employed and the formula used to estimate free testosterone.¹⁹⁰ Bioavailable testosterone is measured by ammonium sulfate precipitation of SHBG-bound testosterone and measurement of free and albumin-bound testosterone in the supernatant. Bioavailable testosterone levels may also be calculated from measurements of total testosterone, SHBG, and albumin. These

accurate and reliable measurements of free and bioavailable testosterone are available in commercial laboratories and should be used to confirm androgen deficiency in men who have conditions that affect SHBG and in those with total testosterone levels near the lower limit of the normal range.

Transient Suppression of Testosterone. In evaluating men for a diagnosis of male hypogonadism, it is important to recognize that serum testosterone levels may be suppressed transiently during acute (particularly critical) and subacute illness and recovery; with the short-term use of certain medications, such as opiates, high-dose glucocorticoids, and CNS-active medications or recreational drugs that affect gonadotropin and testosterone production; and during transient malnutrition, such as that associated with illness, eating disorders, or excessive or prolonged strenuous exercise. In such situations, measurement of serum testosterone should be delayed until the patient is completely recovered from the illness, the offending drugs are discontinued, the malnutrition is corrected, or the excessive exercise is stopped.¹¹⁰

Case-Finding in Androgen Deficiency

In the absence of evidence for long-term clinical benefits greater than risks for testosterone treatment of androgen deficiency, screening for androgen deficiency in the general population or in all elderly men is not indicated. Existing case-finding instruments lack sufficient specificity and sensitivity to be clinically useful. In certain clinical conditions, there is a high prevalence of low testosterone concentrations, and measurement of serum testosterone should be performed. These conditions include hypothalamic-pituitary mass, disease, surgery, or radiation therapy; medications that suppress testosterone production (e.g., opiates, glucocorticoids); HIV-associated weight loss and other wasting syndromes; and osteoporosis or minimal-trauma fragility fracture, especially in young men. In patients with a chronic disease in which low testosterone is common (e.g., T2DM, CKD, chronic obstructive pulmonary disease [COPD]), serum testosterone should be measured if symptoms or signs indicative of androgen deficiency (e.g., sexual dysfunction, weakness) are present.¹¹⁰

Seminal Fluid Analysis

If infertility is a main complaint, whether or not androgen deficiency is also present, seminal fluid analysis should be performed to determine the presence and degree of impairment of sperm production. Seminal fluid analyses are performed on ejaculated semen samples obtained by masturbation after a standardized period (usually 48 hours) of abstinence from ejaculation. Semen collection after withdrawal of the penis from the partner just before ejaculation during sexual intercourse (coitus interruptus) is usually incomplete and is not recommended, but it may be an option if masturbation is not possible or is not permitted for personal or religious reasons. Seminal fluid analyses should be performed in a specialized laboratory that employs standardized procedures, such as those outlined by the World Health Organization (WHO), and is certified and qualified to carry out these procedures.²⁹

According to recently revised WHO criteria based on approximately 1800 to 1900 men from 14 countries whose partners became pregnant in 12 months or less (Table 19-6), the lower limit of normal sperm concentration is 15 million/mL; semen volume is 1.5 mL; total sperm count is 39 million per ejaculate; total sperm motility (both progressive and nonprogressive) is 40% and progressive sperm

TABLE 19-6

Normal Seminal Fluid Analysis

Parameter	Normal Value
Sperm concentration	≥15 million/mL
Semen volume	≥1.5 mL
Sperm count	≥39 million per ejaculate
Sperm motility	≥40% (progressive sperm motility >32%)
Sperm morphology	≥4% normal forms (by strict criteria excluding sperm with mild abnormalities)

From WHO Laboratory Manual for the Examination and Processing of Human Semen, 5th ed. Geneva, Switzerland: World Health Organization, 2010.

motility is 32%; and sperm morphology (percentage of normal forms) using strict criteria to eliminate spermatozoa with even mild abnormalities is 4%.²⁹ Values below these lower limits may be classified as falling into the subfertile range, and such values are found in independent (unscreened) populations. In another study, the subfertile ranges were defined as follows: sperm concentration, less than 13.5 million/mL; motility, less than 32%; and strict morphology, less than 9%. The respective fertile ranges were higher than 48 million/mL for sperm concentration, 63% for motility, and 12% for strict morphology. Values between these ranges indicated indeterminate fertility.¹⁹¹

Sperm counts and concentrations exhibit extreme variability (Fig. 19-20)⁸ for a number of reasons, including variations in sexual activity and abstinence, completeness of collection, recent illness (especially febrile illness) that may suppress spermatogenesis, and lifestyle factors such as frequent hot tub use. Therefore, at least two or three seminal fluid analyses, separated by at least 2 weeks, should be performed to assess sperm production adequately. Also, to assess motility, freshly collected semen (within 1 hour of ejaculation) should be used, necessitating collection at or near the laboratory in which the analysis is to be performed.

Gonadotropin Measurements

Androgen Deficiency and Impaired Sperm Production. The diagnosis of hypogonadism is confirmed in men with symptoms and signs consistent with androgen deficiency if low testosterone levels are found on at least two occasions in the absence of acute illness, medication use, or nutritional deficiency that could transiently lower testosterone, provided that an accurate assay of low free or bioavailable testosterone is performed for men who have conditions that alter SHBG or a total testosterone level near the lower limit of normal. Measurements of serum gonadotropins, LH, and FSH should be obtained to distinguish primary from secondary hypogonadism (see Fig. 19-19).¹¹⁰

Men with primary hypogonadism caused by a disorder of the testis have low serum testosterone in association with elevated LH and FSH levels as a result of reduced negative feedback suppression of gonadotropin secretion by testosterone and inhibin B (Fig. 19-21).⁸ In contrast, men with secondary hypogonadism caused by a disorder of the pituitary or the hypothalamus (or both) have low testosterone in association with low gonadotropin levels or inappropriately normal LH and FSH given the presence of the low testosterone level (Fig. 19-22).⁸ In most local clinical laboratories, LH and FSH are measured by newer-generation, nonradioactive immunoassays that have sufficient sensitivity to distinguish between normal and low concentrations.

Figure 19-20 Normal variation in sperm concentration (millions of spermatozoa per milliliter of ejaculate) in a healthy young man: results of frequent sampling over a period of 210 weeks. At several times during this period, sperm concentrations dropped below the normal range (15 million/mL). (From Matsumoto AM. The testis. In: Felig P, Frohman LA, eds. *Endocrinology and Metabolism*, 4th ed. New York, NY: McGraw-Hill; 2001:635-705.)

Aging, some systemic illnesses (e.g., hemochromatosis), and certain medications (e.g., glucocorticoids) may cause defects in both the testes and the hypothalamus or pituitary, resulting in combined primary and secondary hypogonadism. In most cases, a hormonal pattern consistent with either primary or secondary hypogonadism predomi-

nates. For example, men with hemochromatosis have defects in both the pituitary and the testis due to iron overload, but they usually have low testosterone and gonadotropin levels, consistent mostly with secondary hypogonadism. Men with late-stage CKD have both testis and hypothalamic-pituitary dysfunction but usually have

Figure 19-21 Schematic diagram of alterations in the hypothalamic-pituitary-testicular axis with primary hypogonadism due to testicular disease, which results in both androgen deficiency and impairment of sperm production and elevated luteinizing hormone (LH) and follicle-stimulating hormone (FSH) levels (hypergonadotropic hypogonadism) due to loss of negative feedback regulation of gonadotropins. GnRH, gonadotropin-releasing hormone; T, testosterone. (From Matsumoto AM. The testis. In: Felig P, Frohman LA, eds. *Endocrinology and Metabolism*, 4th ed. New York, NY: McGraw-Hill; 2001:635-705.)

Figure 19-22 Schematic diagram of alterations in the hypothalamic-pituitary-testicular axis with secondary hypogonadism due to hypothalamic and/or pituitary disease, which results in both androgen deficiency and impairment of sperm production and inappropriately normal or low luteinizing hormone (LH) and follicle-stimulating hormone (FSH) levels (hypogonadotropic hypogonadism). GnRH, gonadotropin-releasing hormone; T, testosterone. (From Matsumoto AM. The testis. In: Felig P, Frohman LA, eds. *Endocrinology and Metabolism*, 4th ed. New York, NY: McGraw-Hill; 2001:635-705.)

low testosterone and elevated LH and FSH concentrations, the latter mostly due to reduced clearance of gonadotropins by the kidney. Some men have more than one disorder influencing the gonadal axis, one affecting the testis and another affecting the hypothalamus or pituitary. This may result in a hormonal pattern that is predominantly consistent with either primary or secondary hypogonadism or in a combined pattern (e.g., very low testosterone levels with only slightly elevated or high-normal gonadotropin levels that are lower than expected given the presence of very low testosterone concentrations).

Distinguishing primary from secondary hypogonadism helps to define the specific etiology of hypogonadism and has important clinical and therapeutic implications.⁸ Secondary hypogonadism may be caused by a destructive process in the pituitary or hypothalamus, such as a pituitary adenoma. A large pituitary adenoma (macroadenoma) may cause space-occupying tumor mass effects such as headaches, visual field defects, hydrocephalus, or cerebrospinal fluid rhinorrhea, or it may result in impaired or excessive secretion of some anterior pituitary hormones, leading to clinical manifestations and therapeutic implications beyond the treatment of androgen deficiency alone. Secondary hypogonadism may be caused by disorders that are transient, such as an acute illness, certain medications (e.g., opiates, glucocorticoids), or malnutrition associated with illness. In such cases, androgen deficiency may resolve with treatment of and recovery from the illness or malnutrition or discontinuation of the offending medication. Finally, in men with secondary hypogonadism who have gonadotropin deficiency but otherwise normal testes, gonadotropin or GnRH treatment may be used to stimulate

spermatogenesis and androgen production and to restore fertility in men who wish to father children. In contrast, infertility in men with primary hypogonadism is not treatable with hormone therapy.

Isolated Impairment of Sperm Production or Function. Most men with isolated impairment of sperm production have low sperm counts or abnormalities in sperm motility or morphology (or both) but no clinical manifestations of androgen deficiency and normal levels of testosterone and gonadotropins. Most men with isolated impairment of sperm production or function are classified as having primary hypogonadism with an isolated defect in the seminiferous tubule compartment of the testes (Table 19-7); in such cases, there is no response to gonadotropin treatment, as there is in secondary hypogonadism. Men with severe seminiferous tubule failure and azoospermia or severe oligozoospermia may demonstrate a selective elevation in FSH levels as a result in reduced negative feedback from inhibin B with normal LH levels (Fig. 19-23).⁸ Occasionally, isolated impairment in sperm production is caused by gonadotropin deficiency (i.e., secondary hypogonadism) (Table 19-8); this may occur in men who are taking high doses of testosterone and in those who have androgen-secreting tumors, congenital adrenal hyperplasia, or, rarely, isolated FSH deficiency.

Men with nonfunctioning or gonadotropin-secreting pituitary tumors often have secondary hypogonadism with clinical manifestations of androgen deficiency and low testosterone levels.⁵³ Many of these men secrete excessive amounts of intact FSH and biologically inactive free α -,

Figure 19-23 Schematic diagram of alterations in the hypothalamic-pituitary-testicular axis with primary hypogonadism due to an isolated seminiferous tubule defect, which results in isolated impairment of sperm production and/or function and elevation of follicle-stimulating hormone (FSH) levels with normal luteinizing hormone (LH) levels. With less severe seminiferous tubule defects, both FSH and LH levels are normal. GnRH, gonadotropin-releasing hormone; T, testosterone. (From Matsumoto AM. The testis. In: Felig P, Frohman LA, eds. *Endocrinology and Metabolism*, 4th ed. New York, NY: McGraw-Hill; 2001:635-705.)

FSH β -, and LH β -subunits but rarely intact LH. Therefore, a gonadotropin-secreting pituitary tumor should be suspected in a man who has clinical manifestations of androgen deficiency, low testosterone, and elevated FSH but normal or low LH (or, rarely, elevated LH but normal FSH), which is an atypical gonadotropin pattern for men with androgen deficiency.

Rarely, disorders of androgen action or androgen resistance manifest in adults (Table 19-9). These men usually present with clinical manifestations similar to those of men with mild androgen deficiency, usually with an almost

normal male phenotype and frequently with varying degrees of hypospadias, cryptorchidism, scrotal abnormalities, or impairment in sperm production. Usually, both serum testosterone and gonadotropin levels are elevated (Fig. 19-24).⁸

Further Evaluation

Testosterone measurements and assessment of sperm production, combined with measurement of gonadotropin levels, allow classification of the causes of male hypogonadism into primary or secondary hypogonadism and subclassification of the latter into disorders causing androgen deficiency and impairment in sperm production and those causing isolated impairment of sperm production or function (see Tables 19-7 and 19-8).

Once hypogonadism has been classified, further evaluation includes a history (including medication review), physical examination, and laboratory testing to identify a specific etiology. For example, in men with primary hypogonadism and suggestive clinical manifestations such as very small testes and gynecomastia, low or low-normal testosterone, azoospermia, and markedly elevated gonadotropins, a karyotype may be obtained to confirm the diagnosis of Klinefelter's syndrome.

In men with secondary hypogonadism, further evaluation may include measurements of serum prolactin (in almost all cases) to exclude hyperprolactinemia; iron saturation to screen for hereditary hemochromatosis, especially in men with other manifestations of iron overload (e.g., liver failure, diabetes, CHF) and in young men with unexplained selective gonadotropin deficiency; further testing to exclude excessive secretion or deficiency of anterior pituitary hormones; and magnetic resonance imaging

AR, androgen receptor.

(MRI) of the sella turcica to exclude a pituitary or hypothalamic tumor or infiltrative disease. Computed tomography of the sella turcica usually detects a pituitary macroadenoma but is less sensitive than sella MRI in detecting smaller tumors and infiltrative disease.¹¹⁰

It is not cost-effective to perform sella MRI in all men with secondary hypogonadism. This modality should be reserved for men with severe androgen deficiency (e.g., serum testosterone <150 ng/dL) due to secondary hypogonadism, particularly with distinctly low gonadotropin levels^{192,193}; discordant LH and FSH levels associated with androgen deficiency; hyperprolactinemia (especially with prolactin levels >100 to 200 ng/mL); clinical and biochemical evidence of excessive secretion of other pituitary hormones (e.g., free α -subunit secretion, Cushing's syndrome, acromegaly), panhypopituitarism, or diabetes insipidus; and tumor mass effects, such as severe headache, visual field defects, or visual impairment.

In men who have severe androgen deficiency caused by primary or secondary hypogonadism or who have sustained a low-trauma or fragility fracture, DEXA scanning to assess BMD should be performed to exclude osteopenia or osteoporosis.¹¹⁰

Causes of Primary Hypogonadism

Androgen Deficiency and Impairment in Sperm Production

Congenital or Developmental Disorders

Klinefelter's Syndrome. Classically, Klinefelter's syndrome is characterized by very small, firm testes; azoospermia and infertility; varying degrees of androgen deficiency and eunuchoidism; and uniformly elevated gonadotropin levels.¹⁹⁴⁻¹⁹⁶ It is the most common sex chromosome abnormality and the most common cause of primary

hypogonadism resulting in androgen deficiency and impaired sperm production. It occurs prenatally and neonatally in 1 of every 500 to 700 males, and the prevalence in adults is 1 in 2500.^{1,2} Because the syndrome does not cause premature mortality in boys, the low adult prevalence indicates that Klinefelter's syndrome is often overlooked and underdiagnosed in men. This is surprising, given the almost uniform finding of extremely small testes and other phenotypic abnormalities in these men. The risk of having a child with Klinefelter's syndrome increases with both maternal and paternal age.

The fundamental chromosomal abnormality in Klinefelter's syndrome is the presence of one or more extra X chromosomes due to maternal meiotic nondisjunction (mostly in meiosis I) in approximately 50% of the cases or paternal meiotic nondisjunction in the remaining cases.¹⁹⁴⁻¹⁹⁶ The principal karyotype in 90% of men with Klinefelter's syndrome is 47,XXY. Most of the remaining 10% have mosaic Klinefelter's syndrome (47,XXY/46,XY), in which there is a 47,XXY karyotype in some tissues and a normal 46,XY karyotype in other tissues. Mosaicism occurs as a result of postfertilization mitotic nondisjunction. Men with mosaic Klinefelter's syndrome usually demonstrate a variable and less severe phenotype that depends on the specific tissues in which an extra X chromosome is present. Some men with mosaicism have a normal karyotype in the testis with intact spermatogenesis and fertility. Rarely, men with Klinefelter's syndrome have more than one extra X chromosome (e.g., 48,XXX, 49,XXXXY). Men with these variants manifest a more severe phenotype than is seen in classic Klinefelter's syndrome.

Infants with Klinefelter's syndrome may manifest micropenis, hypospadias, cryptorchidism, or developmental delay.¹⁹⁷ During childhood, boys with the syndrome commonly have small testes and reduced penile length relative

Figure 19-24 Schematic diagram of alterations in the hypothalamic-pituitary-testicular axis with androgen resistance due to impaired androgen action (e.g., androgen receptor mutation), which results in high testosterone (T) levels but reduced androgen action. This leads to manifestations of androgen deficiency, impaired sperm production, and elevated luteinizing hormone (LH) and follicle-stimulating hormone (FSH) levels due to impaired androgen-mediated negative feedback regulation of gonadotropins. GnRH, gonadotropin-releasing hormone. (From Matsumoto AM. The testis. In: Felig P, Frohman LA, eds. *Endocrinology and Metabolism*, 4th ed. New York, NY: McGraw-Hill; 2001:635-705.)

to age-matched normal individuals and may manifest relatively tall stature, clinodactyly, hypertelorism, gynecomastia, elbow dysplasia, high-arched palate, hypotonia, language delay or learning and reading disabilities requiring therapy, and behavioral problems. However, these manifestations may be mild and are often missed. Fewer than 10% of boys with Klinefelter's syndrome (usually those with the most severe phenotype) are diagnosed before puberty. At puberty, the testes fail to increase in size and become firm due to a progressive loss of germ cells and seminiferous tubule hyalinization and fibrosis; Sertoli cell products, inhibin B, and AMH decline to very low or undetectable levels; testosterone levels increase but to less than normal levels in some boys, resulting in varying degrees of eunuchoidism and gynecomastia; and FSH levels are disproportionately elevated relative to LH levels.

In adults, the most prominent and consistent clinical feature of Klinefelter's syndrome is very small testes, <4 mL (<2.5 cm) in length; this feature is easily detected on examination and should alert the clinician to possibility of Klinefelter's syndrome (Fig. 19-25).^{9,198} Men with this syndrome may present with a complaint of infertility and subsequently be found to have azoospermia and very small testes.¹⁹⁹ Other manifestations include varying degrees of androgen deficiency, eunuchoidism, and gynecomastia (Fig. 19-26).¹⁹⁶ In contrast to the classic long arms and legs of eunuchoidism seen in patients with prepubertal androgen deficiency, Klinefelter's syndrome results in a disproportionate increase in lower- compared with upper-extremity long bone growth. Gynecomastia occurs in 50% to 80% of men with the syndrome and may be quite prominent and embarrassing. Learning and developmental disabilities occur in about 70% of men with Klinefelter's syndrome. Character and personality disorders and behavioral problems occur commonly, possibly in part because of the psychosocial consequences of androgen deficiency. Men with Klinefelter's syndrome have intelligence quotient (IQ) scores that are reduced by 10 to 15 points but not into the intellectual disability range. Taurodontism, characterized by enlarged molar teeth resulting from enlargement and extension of the pulp chamber, is present in 40% of men with Klinefelter's syndrome.

As described previously, the *AR* gene is located on the X chromosome, and the length of the highly polymorphic CAG repeat in exon 1 of the *AR* gene is inversely related to AR activity. In Klinefelter's syndrome, the X

Figure 19-25 Testis size in a man with classic 47,XXY Klinefelter's syndrome is characteristically very small (e.g., 2 mL).

Figure 19-26 Variability in the degree of androgen deficiency manifested in men with Klinefelter's syndrome. The man on the left, who has classic 47,XXY Klinefelter's syndrome, demonstrates prepubertal androgen deficiency with eunuchoidal body proportions, small penis, sparse chest and pubic hair, poor muscle development, prepubertal fat distribution, and very small testes (2 mL bilaterally). The man on the right, who has mosaic 47,XXY/46,XY Klinefelter's syndrome, demonstrates normal body proportions, penis size, and body hair but small testis size (8 mL bilaterally). (From Smyth CM, Bremner WJ. Klinefelter syndrome. *Arch Intern Med*. 1998;158:1309-1314.)

chromosome carrying the *AR* gene with a short CAG repeat length (i.e., greater AR activity) undergoes inactivation preferentially.¹³⁰ Klinefelter's syndrome patients with short CAG repeat lengths were found to have more stable relationships, higher educational levels, and greater responses to testosterone treatment. In contrast, men with long CAG repeat length (i.e., reduced AR activity) had longer arms and legs, smaller testes, a greater degree of gynecomastia, and lower BMD. Therefore, skewed inactivation of the X chromosome resulting in preferential activity of the long CAG repeat may contribute to phenotypic severity and variability of Klinefelter's syndrome.

Most men with mosaic Klinefelter's syndrome exhibit less severe clinical manifestations than those with the classic syndrome. Men with more than two extra X chromosomes have more severe manifestations and a higher incidence of intellectual disability and somatic abnormalities such as hypospadias, cryptorchidism, and radioulnar synostosis. Very rarely, some phenotypic males with a 46,XX karyotype exhibit typical clinical manifestations of Klinefelter's syndrome except that they have shorter stature and a greater incidence of cryptorchidism, gynecomastia, and androgen deficiency.²⁰⁰ In most of these cases, there has been a translocation of an SRY-containing segment of the Y chromosome onto an X chromosome.

In addition to infertility, variable androgen deficiency, and gynecomastia, patients with Klinefelter's syndrome have an approximately 20-fold increased risk in breast cancer compared with normal men (although the absolute lifetime risk of <1% is low); such patients account for approximately 4% of all cases of male breast cancer.²⁰¹ Klinefelter's syndrome is also associated with increased risk for mitral valve prolapse; lower-extremity varicose veins,

venous stasis ulcers, deep vein thrombosis, and pulmonary embolism; autoimmune diseases such as systemic lupus erythematosus, rheumatoid arthritis, and Sjögren's syndrome; other cancers such as extragonadal germ cell cancer and non-Hodgkin's lymphoma; T2DM and the metabolic syndrome; and psychiatric illnesses such as depression and schizophrenia. There is a minimal reduction in life expectancy of approximately 2 years in men with Klinefelter's syndrome, associated with excess deaths due to a variety of common causes.^{202,203}

Azoospermia is present in more than 95% of men with classic Klinefelter's syndrome, and infertility in more than 99%. Serum total testosterone levels are usually low but may fall in the low-normal to mid-normal range in 40% to 50% of cases (Fig. 19-27).^{195,196} Relative to normal men, men with Klinefelter's syndrome have elevated serum estradiol levels, which probably contributes to the development of gynecomastia, and increased SHBG concentrations. Increased SHBG levels provide a partial explanation for normal total testosterone levels in the presence of low concentrations of free testosterone. Serum FSH levels are almost always elevated; serum LH levels are usually elevated but may fall into the high-normal range in some men (see Fig. 19-27).^{195,196}

A *Barr body analysis* may be used as a rapid and reliable screening test for Klinefelter's syndrome. In a normal female with two X chromosomes, one X chromosome is inactivated and may be detected as sex chromatin (Barr body) on staining of the nucleus in epithelial cells obtained from a scraping of the buccal mucosa (buccal smear). In a normal 46,XY male, the single X chromosome is not inactivated, and no Barr body is present. In contrast, X inactivation occurs in a 47,XXY man with Klinefelter's syndrome, resulting in a detectable Barr body. Men with variant syndromes characterized by more than two extra X chromosomes may exhibit more than one Barr body per nucleus; the number of Barr bodies is one less than the number of extra X chromosomes. Although Barr body analysis may be helpful in screening for Klinefelter's syndrome, it is

subject to false-negative and false-positive results and is no longer performed commonly.

The diagnosis of Klinefelter's syndrome is confirmed by *karyotype analysis*, which is usually performed on cultured peripheral blood lymphocytes. Occasionally, karyotype analysis is performed on cultured skin fibroblasts and testis tissue if mosaicism is suspected. If a fetus is diagnosed on prenatal testing with 47,XY Klinefelter's syndrome, genetic counseling should be provided. Despite a reasonably good prognosis, 75% of couples choose termination of a fetus with a prenatal diagnosis of Klinefelter's syndrome.

Treatment of Klinefelter's syndrome is directed at correction of androgen deficiency. Infants with micropenis may benefit from topical testosterone treatment. For boys with Klinefelter's syndrome, early intervention with speech and reading therapy is important if speech delay and dyslexia are present. At puberty, testosterone treatment may be needed for adequate development of secondary sexual characteristics; peak bone mass and BMD; muscle mass and strength; and energy, motivation, mood, and behavior. Adults with Klinefelter's syndrome who have clinical manifestations of androgen deficiency and consistently low levels of serum total or free testosterone (or both) should receive testosterone replacement therapy. Also, men who have symptoms and signs of androgen deficiency but normal total and free testosterone levels should be offered a trial of testosterone treatment.

Although azoospermia and infertility are irreversible, TESE permits identification of the relatively few seminiferous tubules that contain active spermatogenesis and harvesting of sperm from the small testes of men with Klinefelter's syndrome for use in ICSI; this approach results in live birth rates of approximately 45% in specialized centers.⁷ Because there is an increased risk of sex chromosome and autosomal aneuploidy, genetic counseling and prenatal or preimplantation testing should be provided to couples who undergo ICSI.

Prominent gynecomastia does not resolve with testosterone treatment and requires reduction mammoplasty.

Figure 19-27 Serum levels of follicle-stimulating hormone (FSH, left), luteinizing hormone (LH, middle) and total testosterone (T, right) in men with Klinefelter's syndrome (dots) compared with normal men (normal range depicted by shaded boxes). A substantial proportion of men with Klinefelter's syndrome have total testosterone levels within the normal range, but almost all have elevated LH and FSH levels. (From Smyth CM, Bremner WJ. Klinefelter syndrome. *Arch Intern Med.* 1998;158:1309-1314.)

Psychological counseling for patients and spouses and participation in support groups may be extremely helpful for men with Klinefelter's syndrome.

Myotonic Dystrophy. Myotonic dystrophy is an autosomal dominant, multisystem disorder that is characterized by progressive muscle weakness and wasting (particularly in the lower legs, hands, neck, and face) and results in physical disability; myotonia (involuntary sustained contraction of muscles); cataracts; cardiac conduction defects; respiratory insufficiency; dysphagia; testicular atrophy, impaired spermatogenesis, infertility, and androgen deficiency; premature frontal balding; and intellectual disability.²⁰⁴ Features of the disease usually develop in young adults but can occur at any age, and their severity varies widely among affected individuals. There are two types of myotonic dystrophy, caused by expansion of CTG trinucleotide repeats in two different genes. Myotonic dystrophy type 1 has more severe clinical features and is caused by CTG repeat expansion in the dystrophin myotonia protein kinase gene (*DMPK*); it accounts for 98% of cases. Myotonic dystrophy type 2 is less severe and is caused by CTG repeat expansion in the CCHC-type zinc finger, nucleic acid-binding protein gene (*CNBP*).

Primary hypogonadism occurs in approximately 80% of young to middle-aged men with myotonic dystrophy.^{205,206} Most of these men have isolated impairment of sperm production or function with testicular atrophy, oligozoospermia or azoospermia, moderate to severe testicular damage on testis biopsy, infertility, and disproportionately elevated FSH compared with LH levels. Approximately 20% to 40% of men with myotonic dystrophy have variable degrees of androgen deficiency with low testosterone levels and elevated LH and FSH; testosterone replacement therapy is appropriate for these men. High-dose testosterone therapy has been demonstrated to improve muscle mass but did not affect muscle strength.²⁰⁷ Infertility is irreversible, and patients who desire children need to pursue ART or other options; genetic counseling and preimplantation or prenatal testing should be provided, given the autosomal dominant nature of the disease.

Cryptorchidism. Cryptorchidism is the failure of one or both testes to descend normally from within the abdomen through the inguinal canal into the scrotum. It is the most common congenital disorder of the male genital tract in children, affecting 2% to 4% of full-term male births.^{208,209} It is more common in premature, low-birth-weight, and small-for-gestational-age infants. Spontaneous descent of the testis occurs during the first year in most infants (probably induced by the neonatal surge of gonadotropins and testosterone), so the prevalence of cryptorchidism in boys and adults is lower, approximately 0.3% to 1.0%. Because a patent processus vaginalis is usually also present, inguinal hernia is found in conjunction with cryptorchidism in 50% to 80% of cases. Both unilateral and bilateral cryptorchidism are associated with impaired sperm production and infertility and an increased risk of testicular cancer.

In contrast to cryptorchidism, *ectopic testes* are located outside the normal path of testicular descent.²¹⁰ Ectopic testes may be located anywhere in the perineum or in the femoral or superficial inguinal regions. It is also important to distinguish cryptorchidism from *retractile testes* (pseudocryptorchidism). Retractable testes are located in the scrotum but withdraw into the inguinal canal or abdomen with minimal stimulation due to a hyperactive cremasteric reflex; they are not usually associated with impaired sperm production, infertility, or increased risk of testicular cancer. However, impaired spermatogenesis and fertility have been

reported in men with bilateral retractile testes located high in the inguinal canal or, sometimes, in the abdomen.

Bilateral cryptorchidism may be associated with a number of disorders causing primary hypogonadism (including Klinefelter's syndrome variants and Noonan syndrome), secondary hypogonadism (including IHH, Kallmann's syndrome, and complex genetic disorders associated with multiple congenital anomalies or defects, such as Prader-Labhart-Willi syndrome or Laurence-Moon-Biedl syndrome), and androgen resistance syndromes (e.g., Reifenstein syndrome).²¹¹ Cryptorchidism may also be caused by mutations of the Leydig cell product, INSL3, which controls growth of the gubernaculum, or of its receptor (RXFP2) in up to 5% of cases.

Unilateral or bilateral cryptorchidism that is not related to known causes of hypogonadism or androgen resistance usually results in primary hypogonadism, causing isolated impairment of sperm production associated with low sperm counts, normal testosterone concentrations, a selective elevation in FSH levels, and, occasionally, high LH levels as well.^{208,209} Rarely, cryptorchidism causes Leydig cell failure and androgen deficiency (e.g., in adults with uncorrected bilateral cryptorchidism), producing low serum testosterone with high LH and FSH levels.^{212,213} Azoospermia occurs in 50% to 60% and oligozoospermia in 75% to 100% of men with bilateral cryptorchidism; among men with unilateral cryptorchidism, these figures are, respectively, 15% to 20% and 20% to 40%. This suggests that the function of both testes is compromised in unilateral cryptorchidism. An underlying developmental or environmental disorder affecting both testes (*testicular dysgenesis*) may contribute to impaired spermatogenesis in these individuals.^{208,209} The formation of A_d spermatogonia from neonatal gonocytes is inhibited in undescended testes. Uncommonly, normal testicular descent is impeded by an anatomic abnormality such as a large external inguinal hernia. In this instance, both testes function normally, and correction of the anatomic abnormality with orchiopexy before puberty usually preserves spermatogenesis and fertility.

The risk of testicular cancer in an undescended testis is 2.5- to 8-fold greater than in a scrotal testis, and the risk remains higher even after the testis is surgically relocated into the scrotum, supporting the notion that cryptorchidism is a manifestation of a underlying testicular disorder (i.e., testicular dysgenesis).²⁰⁸⁻²¹¹ Even though the incidence of testicular cancer is only 1 or 2 per 100,000 males, the lifetime risk of malignancy in a cryptorchid testis is substantial. The prevalence of testicular carcinoma in situ, which is thought to precede testicular cancer, is about 3% in the cryptorchid testis. Testicular cancer usually occurs in men 20 to 40 years of age.

A careful physical examination should be performed to assess the location of testes within the scrotum or inguinal canal; the presence of an inguinal hernia, hydrocele, or other scrotal mass; the cremasteric reflex induced by stroking of the upper medial thigh; and penile size and the position of the urethral meatus. The examination should be performed with the patient standing, squatting, or supine with legs abducted. Scrotal examination may be difficult in a morbidly obese man with a large abdominal panniculus. Techniques that may be helpful in the detection of retractile testes include examination during a Valsalva maneuver, with pressure applied to the lower abdomen, or after scrotal warming or a hot bath to facilitate testicular descent. Also, elicitation of the cremasteric reflex may cause a localized puckering of the scrotal skin if a retractile testis is present in the scrotum. Often, a low undescended testis may be confirmed by pushing with one

hand on the lower abdomen, with firm strokes from the anterior superior iliac spine through the groin and to the pubis, toward and into the scrotum, and then grasping the testis with the other hand. After the testis has been held in the scrotum until the cremasteric muscle fatigues, it is released. If the testis then retracts, it is considered a retractile testis; a low cryptorchid testis returns to its undescended position after release. Absence of a palpable testis in the scrotum after repeated examinations may be a result of cryptorchidism, an extremely atrophic testis, or anorchia (absent testis). Up to 50% of men with a unilateral, nonpalpable testis in the scrotum have a severely atrophic or absent testis rather than cryptorchidism; in these instances, the contralateral testis may be relatively large (by about 2 mL). High-resolution ultrasonography or MRI may help to localize testes that are not palpable.

Treatment for persistent cryptorchidism should be started before puberty, when greater germ cell degeneration occurs.^{208,209} The exact timing of treatment is controversial, but recent recommendations suggest that treatment should be instituted between 6 to 12 months or up to 24 months of age. Hormonal treatment with hCG or GnRH in prepubertal boys is effective in stimulating descent of a cryptorchid testis in approximately 10% to 20% of cases. A trial of hormonal therapy may be attempted in the hope of avoiding surgery. If hormonal treatment is unsuccessful or not attempted, an orchiopexy (surgical relocation and fixation of the testis into the scrotum with ligation of the hernia sac at the external or internal inguinal ring) should be performed to allow examination of the testes (e.g., as in monitoring for malignancy) and preservation of remaining testis function. Despite orchiopexy, spermatogenesis remains impaired and fertility rates are reduced, particularly with bilateral cryptorchidism (65% paternity rate after orchiopexy). If orchiopexy is performed before puberty, the risk of testicular cancer is reduced but is still increased twofold to threefold. In patients with a history of unilateral cryptorchidism, the risk of malignancy in the contralateral testis is also increased, by about 70%. Because the risk of malignancy is two to six times higher in men who underwent orchiopexy after puberty and the fertility potential is poor, some clinicians recommend orchidectomy for men with cryptorchidism discovered after puberty. The majority of testis cancers found in persistently cryptorchid testes are seminomas, whereas those in cryptorchid testes after orchiopexy are mostly non-seminoma testicular cancers.

Noonan Syndrome. Noonan syndrome is an autosomal dominant or occasional sporadic genetic disorder that is characterized by short stature; unusual facial features (hypertelorism, downward-slanting eyes, ptosis, strabismus, low-set ears with thickened helices, high nasal bridge, micrognathia and triangular-shaped face, high-arched palate, low hairline, dental malocclusion); short, webbed neck; shield-like chest, pectus excavatum or carinatum, scoliosis, cubitus valgus, and joint laxity; intellectual disability; cardiac disease (pulmonic stenosis, hypertrophic cardiomyopathy); hepatosplenomegaly; lymphedema; and cryptorchidism.^{214,215}

Because a number of these clinical features resemble those of females with Turner syndrome, Noonan syndrome was previously called male Turner syndrome. However, the karyotype in these men is normal. Noonan syndrome affects approximately 1 in 1000 to 2500 live births and is caused by mutations in genes in the Ras-MAPK signaling pathway.^{214,215} Approximately 50% of men with Noonan syndrome have mutations in the *PTPN11* (the protein tyrosine phosphatase nonreceptor type 11) gene, and the

remainder have mutations in the *SOS1* (son of sevenless homolog 1), *RAF1*, or *KRAS* genes.

Men with Noonan syndrome may demonstrate primary hypogonadism characterized by androgen deficiency and impaired sperm production with elevated gonadotropin levels; they usually present with delayed puberty.²¹⁶ Cryptorchidism is present in more than 50% of men with the syndrome and contributes to the etiology of hypogonadism.

Bilateral Congenital Anorchia. Congenital anorchia (also known as functional prepubertal castrate or vanishing testis syndrome) is a rare condition in which one or both testes are absent in a phenotypically and genotypically normal male.^{217,218} Normal fetal testes function is needed for normal male internal and external genital differentiation and development during early gestation. The presence of otherwise normal male internal and external genitalia without müllerian duct-derived structures or descent of the spermatic cord structures (e.g., vas deferens, blood vessels) into the scrotum implies that normally functioning testes must have been present during the first 16 weeks of gestation and subsequently lost during fetal or neonatal life. The prevalence of bilateral congenital anorchia is 1 in 20,000, and that of unilateral congenital anorchia is 1 in 5000 males. The etiology is not known but is probably heterogeneous. It is hypothesized that congenital anorchia may be caused by spermatic vascular compromise due to torsion or trauma during or after testicular descent.

Infants with bilateral anorchia present with micropenis in almost 50% of cases, supporting a prenatal origin of the disorder.^{217,218} Males with congenital anorchia usually present with prepubertal primary hypogonadism with delayed puberty and eunuchoidism (see Fig. 19-14), very low testosterone levels in the castrate range, and elevated gonadotropin levels. On examination, palpable testes are absent but blind-ending spermatic cords and epididymides are usually present. Normal testosterone and gonadotropin concentrations in pubertal or adult patients with absent testes exclude the diagnosis of congenital anorchia and should raise the possibility of bilateral cryptorchidism, which carries an increased risk for testicular malignancy.

An hCG stimulation test may be performed to distinguish congenital anorchia from bilateral cryptorchidism. In patients with congenital anorchia, serum testosterone concentrations do not increase in response to prolonged hCG administration (e.g., 1000 to 2000 IU three times weekly for 2 weeks), whereas most patients with bilateral cryptorchidism respond to hCG. However, lack of testosterone response to hCG administration for 6 weeks has been reported in men with bilateral cryptorchidism.²¹⁹ Serum AMH concentrations are usually undetectable in patients with congenital anorchia.²²⁰ Measurements of AMH levels are more sensitive than those of testosterone concentrations but equally specific. If clinical examination and endocrine biochemical tests do not distinguish bilateral anorchia from cryptorchidism, imaging studies (e.g., MRI) and laparoscopy or surgical abdominal exploration may be necessary to confirm the diagnosis.

Treatment of bilateral congenital anorchia consists of testosterone replacement to stimulate penile length in patients with micropenis and to induce and maintain sexual development in boys with delayed puberty and eunuchoidism. Implantation of testicular prostheses in the scrotum may be of psychological and cosmetic value.

Autoimmune Polyglandular Syndrome. Autoimmune polyglandular syndromes are characterized by a clustering of organ-specific autoimmune disorders that involve a number of endocrine and nonendocrine tissues and are

associated with circulating autoantibodies to components of these tissues. Autoimmune polyglandular syndrome type 1, also called autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy (APECED), is a rare autosomal recessive disorder that is caused by a mutation in the autoimmune regulator (*AIRE*) gene.²²¹ Its main features are mucocutaneous candidiasis, hypoparathyroidism, primary adrenal insufficiency, and the presence of autoimmune disorders including primary hypogonadism. The prevalence of primary hypogonadism is much more common in females than in males. In females, hypogonadism is manifested as premature ovarian failure and is present in 35% to 70% of cases, whereas in males, it is present in 8% to 28% of cases and is manifested by either androgen deficiency and impairment in sperm production or isolated impairment in sperm production (azoospermia) with elevated gonadotropin levels.

Autoimmune polyglandular syndrome type 2 is a common polygenic disorder associated with the genes for human leukocyte antigens (HLA) DR3 and DR4.²²² It is characterized by autoimmune primary adrenal insufficiency, thyroid disease (Hashimoto's or Graves' disease), and T1DM in addition to other autoimmune disorders including primary hypogonadism (again, more common in females than in males). In autoimmune polyglandular syndrome type 2, primary hypogonadism is associated with circulating steroid-producing cell autoantibodies (SCA) and with specific autoantibodies to CYP11A1 and 17 α -hydroxylase.

Defects in Testosterone Biosynthetic Enzymes. Males with uncommon defects in 17,20-lyase/17 α -hydroxylase, 17 β -HSD/17-ketoreductase, or 3 β -HSD, resulting from mutations in the *CYP17*, *HSD17B3*, and *HSD3B3* genes, respectively, usually present at birth as phenotypic females with partial virilization or with ambiguous genitalia. However, patients with incomplete defects in these enzymes may present as phenotypic males with hypospadias, gynecomastia, and primary hypogonadism with androgen deficiency manifested by delayed puberty.

Because 17,20-lyase and 17 α -hydroxylase activities reside in the same enzyme, mutations in *CYP17* usually cause deficiencies in both activities, leading to elevated levels of progesterone, corticosterone, and deoxycorticosterone (DOC).²²³ Rarely, males exhibiting isolated 17,20-lyase deficiency with elevated 17-hydroxyprogesterone levels have been reported.²²⁴ Patients with 17 α -hydroxylase deficiency may have hypertension and hypokalemia due to excessive production of the aldosterone precursor DOC, which has potent mineralocorticoid activity, but this is relatively uncommon in males compared with females. Patients with this deficiency usually do not manifest adrenal insufficiency because of increased production of the cortisol precursor, corticosterone, which has glucocorticoid activity. Males with either 17,20-lyase/17 α -hydroxylase deficiency or isolated 17,20-lyase deficiency have primary hypogonadism with low testosterone and elevated LH and FSH levels; they require testosterone treatment at the time of puberty.

Patients with 17 β -HSD/17-ketoreductase deficiency may have ambiguous genitalia and be raised as females, but at puberty, their testosterone levels increase sufficiently to induce virilization, resulting in gender reassignment (similar to individuals with androgen resistance due to 5 α -reductase deficiency).²²⁵ Serum testosterone levels are low to normal, but androstenedione and gonadotropin levels are increased.

Incomplete deficiency of 3 β -HSD is a rare disorder that may manifest in adolescents with mild ambiguous

genitalia, delayed virilization, gynecomastia, low testosterone levels, and elevated LH and FSH levels.²²⁶ Levels of pregnenolone, 17-hydroxypregnenolone, and DHEA are elevated. Spontaneous virilization and puberty due to direct effects of high levels of the weak androgen DHEA or conversion of DHEA to testosterone (or both) has been reported. A eugonadal male with partial 3 β -HSD deficiency who presented with gynecomastia has also been reported.²²⁷

Congenital Adrenal Hyperplasia. Adolescent and adult male patients with congenital adrenal hyperplasia due to 21-hydroxylase deficiency may develop *testicular adrenal rest tumors* that resemble Leydig cell tumors but do not contain intracytoplasmic Reinke crystalloids, which are commonly found (approximately 40%) on histologic analysis in the latter.²²⁸⁻²³⁰ Testicular adrenal rest tumors may be large and easily palpable, or they may be detectable only on testicular ultrasonography. These tumors are thought to originate embryologically from aberrant adrenal tissue, and they are responsive to adrenocorticotrophic hormone (ACTH). They regress with adequate glucocorticoid therapy for congenital adrenal hyperplasia and suppression of ACTH, and they grow with inadequate glucocorticoid treatment.

21-Hydroxylase deficiency is an autosomal recessive condition caused by a mutation in the *CYP21* gene. It is the most common enzymatic defect causing congenital adrenal hyperplasia. 21-Hydroxylase deficiency produces an accumulation of steroid substrates (17-hydroxyprogesterone and progesterone) that results in excessive production of adrenal androgens (androstenedione and DHEA), which are subsequently converted to testosterone. In addition, 21-hydroxylase deficiency causes reduced production of cortisol and aldosterone, resulting in deficiency of glucocorticoid and mineralocorticoid, respectively, and increased ACTH secretion (due to reduced cortisol negative feedback). Elevated ACTH secretion stimulates adrenal gland growth, resulting in adrenal hyperplasia. Glucocorticoid treatment suppresses ACTH secretion, reduces excessive adrenal androgen production, treats clinical adrenal insufficiency, and prevents excessive adrenal hyperplasia.

Excessive adrenal androgen production due to untreated or inadequate glucocorticoid therapy for 21-hydroxylase deficiency suppresses gonadotropin secretion by sex steroid negative feedback regulation and causes secondary hypogonadism. Because androgen levels are maintained by excessive adrenal production, men with 21-hydroxylase deficiency may not have clinical androgen deficiency. However, they usually have isolated impairment of sperm production due to gonadotropin deficiency. Adequate glucocorticoid therapy reduces excessive adrenal androgen production and usually restores gonadotropin secretion and normalizes testis function. Adequate and early glucocorticoid treatment also causes regression of adrenal rest tumors, which otherwise may affect testicular function directly or cause mechanical obstruction of seminiferous tubules.²²⁸⁻²³⁰

If testicular adrenal rest tumors are present, inadequate glucocorticoid treatment stimulates their growth, often resulting in very large tumors that can cause irreversible testicular damage.²²⁸⁻²³⁰ In this circumstance, although adequate glucocorticoid therapy reduces tumor size, the patient will manifest primary hypogonadism with androgen deficiency due to loss of Leydig cells and impaired sperm production due to loss of seminiferous tubules. On adequate glucocorticoid treatment, tumors may regress completely, but testis size usually remains small, serum

testosterone levels and sperm counts low, and gonadotropin levels elevated.

Complex Genetic Syndromes. Primary hypogonadism resulting in androgen deficiency and impaired sperm production or in isolated impairment in sperm production or function may occur as a manifestation of complex genetic syndromes, usually in association with a number of congenital anomalies or defects and distinct morphologic developmental manifestations.²³¹ Examples include the Alström, ataxia telangiectasia, H-, Marinesco-Sjögren, Robinow, Rothmund-Thomson, Sohval-Soffer, Weinstein, Werner, and Wolfram syndromes.²³²⁻²⁴¹ Primary hypogonadism may also occur in some patients with Prader-Labhart-Willi syndrome (associated with cryptorchidism), Laurence-Moon-Bardet-Biedl syndrome, and Alström syndrome, disorders that are more commonly associated with secondary hypogonadism.²⁴²⁻²⁴⁴

Down Syndrome. Down syndrome, or trisomy 21, is a chromosomal disorder in which all or part of an extra chromosome 21 is present.²⁴⁵ It affects 1 of every 700 to 800 infants and is the most common cause of intellectual disability in children. Down syndrome is characterized by moderate to severe intellectual disability, spontaneous warm and cheerful personality, short stature, characteristic mongoloid facial features (most notably round facies with microgenia, upward-slanting and almond-shaped eyes resulting from bilateral epicanthal folds, macroglossia, and flat nasal bridge), congenital heart defects, hypothyroidism, and defects affecting most other body systems. Males with Down syndrome usually manifest primary hypogonadism, most commonly characterized by isolated impairment in sperm production with normal or selective elevation of FSH levels. Histologically, they may manifest hypospermatogenesis (moderate to severe reduction in all germ cell types), maturation arrest, or Sertoli cell-only syndrome with loss of all germ cells. Less commonly, they demonstrate mild to moderate androgen deficiency with low or low-normal testosterone and elevated LH and FSH levels.

Luteinizing Hormone Receptor Mutations. Inactivating mutations of the LH receptor in males usually cause Leydig cell aplasia or hypoplasia. These patients present with DSDs involving a female phenotype without breast development at puberty (Leydig cell aplasia) or genital ambiguity (hypoplasia) and cryptorchidism.⁵⁸ Rarely, partially inactivating LH receptor mutations lead to presentation of a male with micropenis, hypospadias, delayed sexual development, undervirilization, low testosterone, impaired sperm production, and high LH levels, consistent with primary hypogonadism. However, they usually have normal FSH levels. An individual with an LH receptor mutation was reported to exhibit normal levels of testosterone and spermatogenesis after hCG stimulation, suggesting that hCG action via the LH receptor may be dissociated from that of LH.²⁴⁶

Acquired Disorders

Bilateral Surgical Castration and Trauma. Bilateral surgical castration causes a rapid and profound decline in testosterone levels within hours, resulting in severe clinical manifestations of androgen deficiency, including hot flashes. Severe blunt trauma to the testes and associated vascular compromise may result in testicular atrophy and loss of testes function, including androgen deficiency and impaired spermatogenesis or isolated impairment in sperm production or function.

Drugs and Ionizing Radiation. Certain drugs that affect androgen production may cause androgen deficiency. The

antifungal agent, ketoconazole, inhibits 17,20-lyase and 17 α -hydroxylase activity at high doses (>400 mg daily) and has been used, in conjunction with other agents, to lower both adrenal and testicular androgen production in the treatment of prostate cancer.^{247,248} Spironolactone, a non-specific aldosterone antagonist, acts mainly as a competitive AR antagonist and inhibits androgen action.²⁴⁹ However, it also inhibits 17,20-lyase and 17 α -hydroxylase activity and testosterone biosynthesis at high doses. Excessive intake of alcohol inhibits testosterone production, but it may also suppress gonadotropins; it may be associated with nutritional deficiency or chronic liver disease, which may contribute to androgen deficiency and impairment in sperm production.^{250,251}

In general, because spermatogenesis involves active cell replication, the germ cell compartment is much more sensitive to external or environmental influences (e.g., chemotherapy agents, ionizing radiation) than are Leydig cells. Exposure to such agents often results in primary hypogonadism characterized by an isolated impairment in sperm production or function and elevated gonadotropins. However, severe testis damage induced by these agents may cause Leydig cell dysfunction or damage, resulting in both androgen deficiency and impairment of sperm production.

Combination chemotherapy regimens that include alkylating agents (e.g., cyclophosphamide, ifosfamide, procarbazine, busulfan, chlorambucil), such as those used for the treatment of Hodgkin's and non-Hodgkin's lymphoma and leukemia, are particularly toxic to the testes and may result in androgen deficiency in up to 20% of patients.^{16,252-254} High-dose chemotherapy and total body irradiation before bone marrow transplantation may also cause androgen deficiency in a substantial proportion of men. In contrast, men with testicular cancer who undergo combination chemotherapy that includes platinum drugs (together with unilateral orchiectomy and, often, radiation therapy) have a relatively low prevalence of usually mild androgen deficiency with slightly low to low-normal testosterone levels and elevated LH levels.²⁵⁵

Exposure of testes to ionizing irradiation commonly suppresses spermatogenesis in a dose-dependent manner, and doses greater than 600 to 800 cGy may compromise Leydig cell function and reduce testosterone production.^{252,253}

Orchitis. Viral infection of the testes may result in testicular atrophy, impaired sperm production, and, in severe cases, androgen deficiency. *Mumps orchitis* was common before the introduction of the measles/mumps/rubella (MMR) vaccine in 1968, after which rates of mumps infection decreased profoundly.^{256,257} Because of worldwide shortage of the MMR vaccine approximately 15 years ago, there has been a resurgence of mumps infection and orchitis in adolescents and young adults. Prepubertal mumps orchitis is very uncommon and is not associated with subsequent testicular dysfunction. Orchitis is the most common complication of mumps infection in pubertal boys and adults; it usually causes permanent seminiferous tubule damage, impaired spermatogenesis, and, in severe cases, Leydig cell failure and androgen deficiency.

Mumps infection usually manifests with headache, fever, and malaise followed by unilateral or bilateral parotid swelling due to parotiditis.^{256,257} Testis pain and swelling due to orchitis occurs in about 10 days or up to 6 weeks after the onset of parotiditis and may be subclinical in up to 50% of cases. Epididymitis accompanies orchitis in 85% of cases. Mumps orchitis is usually unilateral but may be bilateral in 15% of cases in adolescents and in 30% of cases

in young adults. Even if orchitis is clinically unilateral, degenerative changes may occur in the apparently unaffected testis. Germ cell sloughing occurs as a result of acute infection, inflammation, and ischemia resulting from pressure induced by swelling of the testes within the tunica albuginea. The acute phase is followed by seminiferous tubule fibrosis and then testicular atrophy (30% to 50% of cases) for the next several months, resulting in impaired spermatogenesis in 25% to 40% of cases. In severe cases, prednisone may be used to reduce inflammation and swelling associated with mumps orchitis, but it does not prevent testis damage.

HIV infection usually causes gonadotropin suppression and secondary hypogonadism. However in 20% to 30% of cases, HIV infection causes primary hypogonadism characterized by low testosterone and elevated gonadotropin levels. The etiology of primary hypogonadism is orchitis that is caused by HIV infection of the testis or occurs secondary to opportunistic infection (e.g., by cytomegalovirus [CMV], *Mycobacterium avium intracellulare*, *Toxoplasma gondii*) associated with the patient's immunocompromised state.^{258,259}

Other causes of infectious orchitis usually associated with epididymitis include echovirus, arbovirus, or lymphocytic choriomeningitis infection; gonorrhea or *Chlamydia* infection in young adults and urinary pathogens such as *Escherichia coli* in older men; leprosy and tuberculosis; brucellosis, glanders, and syphilis; and parasitic infections such as filariasis and bilharziasis.^{258,260}

Systemic Disorders. Low serum testosterone levels associated with symptoms and signs consistent with androgen deficiency are commonly associated with chronic diseases affecting the liver, kidney, heart, and lungs.^{4,5} The underlying cause of both clinical and biochemical hypogonadism in these conditions is complex and multifactorial. The illness itself, associated complications, nutritional compromise, and medications used to treat the illness may contribute to or confound the clinical manifestations of androgen deficiency and also may suppress gonadotropin and testosterone production, thereby playing an etiologic role. Chronic systemic diseases usually have effects both on testis and hypothalamic-pituitary function and cause combined primary and secondary hypogonadism. Clinically, however, measurements of gonadotropin levels usually suggest predominantly primary hypogonadism (i.e., elevated gonadotropins) or secondary hypogonadism (i.e., normal or low gonadotropins). The benefits and risks of testosterone therapy in patients with these systemic disorders have not been evaluated in long-term randomized, controlled outcome studies.

Chronic Liver Disease. In men with chronic liver disease of any etiology (and particularly in those with hepatic cirrhosis or liver failure), sexual dysfunction, gynecomastia, and testicular atrophy resulting in impaired androgen and sperm production occur commonly, affecting 50% to 75% of these patients.^{4,5,261-263} Total testosterone levels may be low but are often normal or high-normal, because SHBG levels are increased substantially with cirrhosis and chronic active hepatitis. Therefore, measurements of free or bioavailable testosterone using accurate assay methods should be used to assess androgen deficiency. Free and bioavailable testosterone levels are usually low, and LH levels are usually elevated or in the high-normal range in patients with mild to moderate hepatic cirrhosis (Child-Pugh class A or B).

Estrogen (estrone and estradiol) levels are usually high due to increased production (e.g., induced by alcohol

excess) and reduced clearance of adrenal androgens (e.g., androstenedione), which provide increased substrates for aromatization of androgens to estrogens. High estrogen levels contribute to the development of gynecomastia (high estrogen-to-androgen ratio), palmar erythema and spider angiomas, and increased prolactin levels. Treatment of ascites and edema with spironolactone may further lower testosterone levels and block androgen action, contributing to gynecomastia and other manifestations of androgen deficiency. High LH levels may be suppressed by high estrogen and prolactin levels and by the malnutrition that occur commonly in men with hepatic cirrhosis and liver failure. Oligozoospermia or azoospermia associated with abnormalities in sperm motility and morphology occurs in approximately 30% to 50% of men with chronic liver disease.

Testosterone treatment of androgen deficiency is usually well tolerated but occasionally may worsen gynecomastia and rarely may increase edema and ascites by causing fluid retention. Because immunosuppressive medications such as prednisone and cyclosporine are used to prevent rejection, liver transplantation only partially reverses hypogonadism associated with chronic liver disease.^{261,262}

Chronic Kidney Disease. Late-stage CKD commonly causes combined primary and secondary hypogonadism, resulting in androgen deficiency and impairment in sperm production in 50% to 60% of these patients.^{4,5,264} Serum testosterone levels are low, and LH and FSH levels are high, in large part because of markedly reduced renal clearance of gonadotropins as well as increased secretion resulting from reduced negative feedback. SHBG levels are usually not affected by CKD unless nephrotic syndrome is present, in which case levels of SHBG and, consequently, total testosterone may be low. In the latter situation, free or bioavailable testosterone measurements should be performed to assess androgen deficiency. Sperm production is impaired, and sperm motility and the percentage of sperm with normal morphology are reduced. The Leydig cell response to hCG administration is reduced, consistent with primary testicular dysfunction. The frequency and amplitude of pulsatile LH secretion are altered, suggesting an alteration in hypothalamic-pituitary function as well. Hyperprolactinemia that suppresses gonadotropins and zinc deficiency that affects testicular function may contribute to testicular dysfunction in men with CKD.

Hemodialysis and peritoneal dialysis do not improve testosterone or sperm production.^{264,265} Successful renal transplantation usually brings testosterone and sperm production to almost normal levels, although immunosuppression by rapamycin inhibitors (e.g., sirolimus) may impair testis function slightly.^{264,266,267}

Aging. After age 40 years, there is a gradual and progressive decline in total testosterone levels (by approximately 1% per year), such that an increasing proportion of older men have low serum testosterone concentrations in the hypogonadal range.²⁶⁸⁻²⁷⁰ Because SHBG levels increase with age, free and bioavailable testosterone concentrations decline even more rapidly (2% to 3% per year). Daily sperm production, sperm motility, percentage of sperm with normal morphology, Sertoli cell number, and inhibin B levels also decline with aging.¹³⁵ Leydig cell number and testosterone production in response to stimulation by hCG and pulsatile LH are reduced, consistent with primary testicular dysfunction.¹³⁵ In older men, circadian variation in testosterone concentration is present but blunted.⁶⁴ Furthermore, pulsatile LH secretion is more irregular and disorderly and LH pulse amplitude is reduced in older compared with young men. Pulsatile GnRH administration

normalizes pulsatile LH but not testosterone secretion, consistent with an impairment of hypothalamic GnRH secretion occurring in combination with a primary defect in testosterone production by the testis.^{271,272}

Serum LH and FSH levels increase (by about 1% to 2% per year) with aging but do not usually rise above the normal range until very old age (>70 years).^{268-270,273} Therefore, the most common hormonal profile associated with aging observed in middle-aged to older men is low testosterone with normal LH and FSH levels, consistent with "secondary hypogonadism." As men get older, gonadotropins continue to rise. A hormonal pattern of low testosterone and elevated LH and FSH levels, consistent with "primary hypogonadism," is more prevalent in elderly men, particularly after 70 years of age.

As men age, they may develop chronic organ failure or systemic illnesses, take an increasing number of medications, and develop nutritional deficiency or wasting syndromes that are associated with low testosterone concentrations.²⁷⁴ It is likely that these comorbid conditions contribute to low testosterone and clinical hypogonadism associated with aging in men. Conversely, the age-related decline in testosterone levels may contribute to the susceptibility or severity of clinical hypogonadism observed in these conditions.

In community-dwelling middle-aged to older men, the prevalence of low testosterone increased from 12% among men in their 50s to 48% among men older than 80 years of age.²⁶⁹ The prevalence of clinical androgen deficiency (i.e., symptoms and signs consistent with androgen deficiency and low testosterone levels) was 6% to 9% and increased with age, reaching 18% to 23% among men in their 70s.^{175,176} When more stringent criteria for the diagnosis of androgen deficiency associated with aging were used (i.e., three sexual symptoms and a low testosterone level defined as late-onset hypogonadism), the prevalence was 2% and also increased with age, reaching 5% among men in their 70s.¹⁷⁷

In addition to the decline in testosterone levels, aging is associated with alterations in body function that could be related to androgen deficiency.¹³⁵ These include a decline in muscle mass and strength associated with reduced physical function and performance; decreased BMD and increased risk of osteoporosis and fractures; increased body fat; reduction in sexual function and activity, including reduced libido and erectile dysfunction; decline in vitality, energy, mood, and cognitive function; and alterations in sleep quality. Similar changes occur in younger hypogonadal men and improve with testosterone treatment, raising the possibility that the decline in testosterone levels that occurs with aging may contribute to these age-associated changes in body function.

Relatively small, short-term (up to 3 years) studies of testosterone treatment in heterogeneous groups of older men with low or low-normal testosterone levels without regard to the presence of symptoms or signs of androgen deficiency have produced conflicting results. Most have found beneficial effects of testosterone treatment on body composition, with increasing lean or muscle mass and decreasing fat mass, but less consistent effects on muscle strength and performance, BMD, sexual function, vitality, and cognitive function. The only adverse effect found in these studies was excessive erythrocytosis in some men. More recent studies of testosterone treatment in frail older men with low testosterone levels found beneficial effects on muscle strength and physical performance,^{275,276} but there was an increase in cardiovascular events in one small study.²⁷⁵ Larger, long-term, randomized trials are needed to

determine the balance of clinical benefits and risks (particularly as related to prostate cancer and cardiovascular disease) of testosterone treatment in elderly men. Until results from these outcome studies are available, testosterone treatment should be considered only for older men who have clinically significant manifestations of androgen deficiency and unequivocally low serum testosterone levels, and only after a careful discussion of the uncertainty concerning the long-term benefits and risks of treatment.^{110,277}

Other Systemic Disorders. Primary hypogonadism with low testosterone levels or elevated LH levels (or both) occurs in up to 20% of men with *malignancy* such as advanced Hodgkin's disease or testicular cancer before gonadotoxic chemotherapy and radiation therapy.²⁷⁸⁻²⁸⁰ Impairment of sperm production is found more frequently, in about 30% to 50% of men with Hodgkin's disease or testicular cancer before therapy. The mechanism of gonadal dysfunction before treatment is not clear.

Sickle cell disease is an autosomal recessive disorder caused by a point mutation in the β -globulin chain. It results in an abnormal hemoglobin (hemoglobin S) that polymerizes, leading to sickle-shaped, rigid, and fragile red blood cells. The disease is characterized by recurrent episodes of painful, vaso-occlusive events in a variety of organs due to thrombosis, ischemia and infarction, and hemolysis. Sickle cell disease is a common disorder, affecting approximately 1 in 700 African American infants. Sickle cell disease may cause primary hypogonadism characterized by low to low-normal testosterone concentrations, clinical manifestations consistent with androgen deficiency, testicular atrophy and impaired spermatogenesis, and elevated gonadotropin levels, possibly due to repeated testicular vaso-occlusive events and infarction.²⁸¹⁻²⁸³ Hydroxyurea therapy and possibly zinc deficiency may contribute to impaired spermatogenesis. Men with sickle cell disease may experience priapism due to penile vaso-occlusion, and this may be precipitated by restoration of libido with testosterone treatment of hypogonadism.

Within the first few months to 1 year after a *spinal cord injury*, testosterone levels and sperm production are suppressed and gonadotropins are usually normal. However, in some men, LH or FSH levels or both may be elevated in the presence of low to low-normal testosterone, consistent with primary hypogonadism.²⁸⁴ Chronically after a spinal cord injury, serum testosterone remains low and gonadotropins are usually suppressed or normal, consistent with secondary hypogonadism.^{285,286} The latter condition may be caused by hyperprolactinemia associated with medications, nutritional deficiency, obstructive sleep apnea, or debilitation from chronic spinal cord injury. Testis biopsy revealed impaired spermatogenesis in approximately 40% of men with spinal cord injury, but mature sperm that could be used for TESE and ICSI were present in almost 90%.²⁸⁷

Vasculitis (e.g., periarteritis nodosa, Wegener's granulomatosis, Henoch-Schönlein purpura, Behçet's disease) or *infiltrative disease* (e.g., systemic amyloidosis) involving both testes may cause testicular damage and may necessitate orchidectomy, resulting in both androgen deficiency and impaired sperm production.^{288,289}

Isolated Impairment of Sperm Production or Function

Congenital or Developmental Disorders. As described previously, cryptorchidism, myotonic dystrophy, and Down syndrome most commonly manifest with primary

hypogonadism characterized by isolated impairment in sperm production without androgen deficiency and selectively elevated FSH levels. In men with less severely impaired spermatogenesis, serum gonadotropin levels are normal, but it is most appropriate to classify these men as having primary hypogonadism with isolated impairment in sperm production, because gonadotropin treatment has not been demonstrated to improve fertility.

Varicocele. Varicocele is a dilatation of the pampiniform venous plexus surrounding the spermatic cord in the scrotum. It is caused by retrograde blood flow into the internal spermatic vein, which is usually caused by defective or absent valves in spermatic veins or, rarely, by obstruction of normal venous drainage by extrinsic or intrinsic venous compression (e.g., from a tumor). It usually occurs on the left side, and most cases are asymptomatic. A varicocele is present in 10% to 15% of men in the general population and more frequently in infertile men (up to 30% to 40%).^{12,290,291}

The relationship of varicocele to impaired sperm production and infertility is unclear.^{12,290,291} Approximately 50% of men who have a varicocele demonstrate normal semen analyses, and many are fertile. Men with a large varicocele and infertility usually exhibit low sperm counts with reduced motility and increased numbers of sperm with abnormal morphology (e.g., tapered or amorphous sperm heads), but these abnormalities are not specific for varicocele. Testis size and serum levels of testosterone, LH, and FSH are usually normal. Varicocele is painful in 2% to 10% of men with infertility. Testis biopsy in men with a varicocele and abnormal semen parameters reveals a spectrum of histopathologic findings, including hypospermatogenesis, maturation arrest, and Sertoli cell-only histology.

It is unclear whether varicocele ligation improves fertility in men who present with infertility. Controlled trials to investigate the efficacy of varicocele ligation have not demonstrated improved fertility. However, these trials were generally small, heterogeneous, and of poor quality. A small number of controlled trials of infertile men with palpable varicocele and at least one abnormal semen parameter have suggested improvement in the spontaneous pregnancy rate with varicocele ligation. Some organizations have recommended surgical ligation for infertile

men who have a large, palpable varicocele with an abnormal seminal fluid analysis.^{12,290,291}

Y Chromosome Microdeletion. Yq chromosome microdeletions are the most common genetic cause of impaired sperm production and male infertility. They are found in 5% to 10% of men with severe oligozoospermia and in 10% to 15% of men with azoospermia.¹⁶⁴ As mentioned earlier, microdeletions have been identified in three regions of the long arm of the Y chromosome (Fig. 19-28).^{164,165}

Microdeletions in the *AZF_a* region, which contains the *DDX3Y* and *USP9Y* (ubiquitin specific peptidase 9, Y-linked) genes, are usually associated with azoospermia and Sertoli cell-only histology. Microdeletions in the *AZF_b* region, which contains multiple copies of the *RBM_Y* and *PRY* (PTPM13-like, Y-linked) genes, are usually associated with severe oligozoospermia and germ cell arrest at the pachytene primary spermatocyte stage and occasionally with hypospermatogenesis. Microdeletions in the *AZF_c* region, which contains the *DAZ* (deleted in azoospermia) gene and is where the majority of Y chromosome microdeletions reside, are usually associated with germ cell arrest at the spermatid stage or with hypospermatogenesis with some mature spermatids present. *AZF_c* microdeletions are found in approximately 12% of men with nonobstructive azoospermia and 6% of men with severe oligozoospermia. Microdeletions in both the *AZF_b* and the *AZF_c* region are usually associated with azoospermia and Sertoli cell-only histology.

Yq microdeletion analysis should be considered for couples who are contemplating ICSI, because these microdeletions have been shown to be transmitted to male offspring with the ICSI procedure.¹⁶⁴ If ICSI is performed in men with Y chromosome microdeletions, genetic counseling and preimplantation or prenatal testing should be considered.

Sertoli Cell-Only Syndrome (Germ Cell Aplasia). Sertoli cell-only syndrome, or germ cell aplasia, is an uncommon histologic diagnosis in which the seminiferous tubules are completely devoid of germ cells and are lined only with Sertoli cells with little to no fibrosis or hyalinization.²⁹² Men with this disorder present with infertility, normal androgenization, moderately small testes (10 to 20 mL in volume), azoospermia, normal testosterone and LH levels,

Figure 19-28 Schematic diagram of the short (Yp) and long (Yq) arms of the human Y chromosome. Deletions in regions of Yq, specifically in azoospermia factor (AZF) regions, are associated with severe defects in sperm production. Microdeletions in the *AZF_a* region are usually associated with azoospermia and Sertoli cell-only histology. Microdeletions most commonly affect the *AZF_c* region and may be associated with severe oligozoospermia or azoospermia. However, even if oligozoospermia or azoospermia is present, sperm for use in intracytoplasmic sperm injection (ICSI) are recoverable from half of the patients by testicular sperm extraction (TESE) at biopsy. (From McLachlan RI, O'Bryan MK. Clinical Review: state of the art for genetic testing of infertile men. *J Clin Endocrinol Metab.* 2010;95:1013-1024.)

and selectively elevated FSH levels (indicating severe seminiferous tubule dysfunction).²⁹³ Occasionally, LH levels are slightly high and the testosterone response to hCG stimulation is reduced, suggesting mild Leydig cell dysfunction.

The cause of Sertoli cell-only syndrome is not known, but it is thought to result from congenital absence of germ cells due to a failure of gonocyte migration. In some families, however, germ cells were present before puberty but were subsequently lost during or after puberty. As described previously, a Sertoli cell-only histology may be associated with microdeletions in the long arm of the Y chromosome in the AZF regions.²⁹⁴ Severe germ cell damage and loss occurring with Klinefelter's syndrome, mumps orchitis, cryptorchidism, ionizing radiation, or alkylating agents may result in seminiferous tubules lined only with Sertoli cells. However, in these cases of acquired Sertoli cell-only syndrome, there is usually extensive seminiferous tubule sclerosis or hyalinization, and the testes are usually smaller. Infertility is irreversible in congenital Sertoli cell-only syndrome, but it may be reversible with time in some cases of acquired Sertoli cell-only syndrome.

Primary Ciliary Dyskinesia (Immotile Cilia Syndrome). Primary ciliary dyskinesia, or immotile cilia syndrome, is a rare, heterogeneous, autosomal recessive genetic disorder of cilia. It is characterized primarily by recurrent respiratory infections (sinusitis and bronchitis) that lead to the development of bronchiectasis, caused by impaired mucociliary clearance due to dyskinesia of respiratory tract cilia, and to infertility caused by asthenozoospermia (non-motile or poorly motile sperm) due to impaired sperm tail movement.²⁹⁵ In half of the cases, primary ciliary dyskinesia is associated with situs inversus and is known as Kartagener's syndrome. Some men exhibit abnormalities of sperm motility in the absence of respiratory tract involvement.

Patients with primary ciliary dyskinesia and impaired sperm motility demonstrate ultrastructural abnormalities of the axoneme, the microtubule cytoskeleton of the sperm flagellum, especially in the dynein arms (motor protein complexes). Almost all men with primary ciliary dyskinesia have mutations of the genes encoding the dynein axonemal heavy chain 5 (*DNAH5*), dynein intermediate chain 1 (*DNAI1*), or dynein axonemal heavy chain 11 (*DNAH11*). These men present with infertility and an isolated impairment in sperm motility with normal sperm counts and morphology and normal testosterone and gonadotropin levels.

Follicle-Stimulating Hormone Receptor Mutations. Rare inactivating FSH receptor mutations have been described in males.^{58,86} In contrast to females with FSH receptor mutations, who have primary amenorrhea and infertility, men have a more variable presentation. Some demonstrate severe oligozoospermia, whereas others have moderate oligozoospermia or normal sperm concentrations with abnormal sperm morphology and some have normal fertility. Serum testosterone levels are normal, FSH levels are elevated, and LH levels are slightly high to normal. It is possible that normal testosterone production within the testes contributes to the persistence of spermatogenesis and fertility in the absence of FSH action.

Acquired Disorders. Because seminiferous tubule function is more susceptible to damage than Leydig cell function, most men with primary hypogonadism due to chemotherapy agents, ionizing radiation, or orchitis caused by mumps or other infections manifest isolated impairment of sperm production without androgen deficiency.

Alkylating agents (e.g., cyclophosphamide, ifosfamide, procarbazine, busulfan, chlorambucil) used in combination chemotherapy regimens to treat lymphoma and leukemia almost uniformly cause azoospermia that recovers after 5 years in up to two thirds of men.^{254,296,297} High-dose chemotherapy and total body irradiation before bone marrow transplantation commonly causes irreversible germ cell damage associated with azoospermia or severe oligozoospermia and elevated FSH levels. Sperm production is suppressed initially in men with testicular cancer who undergo combination chemotherapy that includes platinum drugs, unilateral orchidectomy, and often radiation therapy.²⁵⁵ However, sperm production recovers in 80% of men by 5 years. Before chemotherapy begins, cryopreservation of sperm for subsequent use in IUI, IVF, or ICSI should be offered to men who desire future fertility.

Approaches aimed at suppressing gonadotropins with GnRH agonists or exogenous testosterone administration have not been effective in preventing germ cell damage by chemotherapy. Methotrexate and sulfasalazine may cause oligozoospermia and low sperm motility and contribute to infertility.²⁹⁸ The processes of human spermatogenesis, and particularly the spermatogonia, are very sensitive to the effects of exposure to ionizing radiation.^{16,252-254} X-radiation doses as low as 15 cGy may suppress sperm production temporarily. The time required to recover spermatogenesis after x-irradiation is dose dependent. Recovery of sperm counts to baseline takes 9 to 18 months after exposure to 100 cGy or less and up to 5 years after 400 to 600 cGy. Although Leydig cell function is more resistant to ionizing radiation, x-irradiation of greater than 800 cGy may cause Leydig cell damage and androgen deficiency. As with chemotherapy, sperm banking before radiation therapy for later use in ART offers hope for subsequent fertility.

Prolonged and repeated **thermal trauma** (e.g., with excessive hot tub use) to the testes may suppress sperm production, usually transiently.^{299,300}

A number of chemical agents used in industry and laboratories have been implicated as direct toxins to the testes. Examples of **environmental toxins** include carbon disulfide, a solvent used in rayon production; dibromochloropropane, an insecticide; lead; deuterium oxide; ethyl glycol; cadmium; fluoroacetamide; nitrofurans; dinitropyroles; diamines; and α -chlorohydrin. Furthermore, it is postulated that environmental or xenobiotic agents such as phthalates act as anti-androgens or estrogens to alter reproductive function; these agents have been termed **endocrine disruptors**.³⁰¹ Such environmental agents have been implicated in causing the increased incidence of testicular dysgenesis syndrome (i.e., hypospadias, cryptorchidism, declining sperm counts, and testicular cancer).³⁰²

Systemic Disorders. An acute febrile illness may cause a temporary suppression of spermatogenesis.³⁰² In men with spinal cord injury resulting in tetraplegia or paraplegia, impaired sperm production may be caused in part by increased scrotal temperature due to loss of lumbar sympathetic innervations.²⁸⁴⁻²⁸⁷ Men with malignancy, in particular Hodgkin's lymphoma or testicular cancer, may have impaired spermatogenesis with azoospermia or oligozoospermia in 30% to 80% of cases before treatment.²⁷⁸⁻²⁸⁰

In the majority of men who present with infertility and an isolated impairment of sperm production, an etiology cannot be identified. Idiopathic oligozoospermia or azoospermia occurs in 60% to 80% of cases (including men with varicocele).¹⁶¹⁻¹⁶³ If isolated impairment of spermatogenesis is severe in men with primary hypogonadism, serum FSH levels may be selectively elevated. As mentioned

earlier, men with less severely impaired spermatogenesis and normal serum gonadotropin levels are still classified as having a disorder of primary hypogonadism, because gonadotropin treatment has not been demonstrated to improve fertility in such cases.

Causes of Secondary Hypogonadism

Androgen Deficiency and Impairment in Sperm Production

Congenital or Developmental Disorders

Constitutional Delay of Growth and Puberty. It is important to consider *constitutional delay of growth and puberty* (CDGP) in the differential diagnosis of secondary hypogonadism because it is a transient cause of secondary hypogonadism and is the most common cause of pubertal delay usually associated with growth delay and short stature in boys.^{136,303,304}

The initial endocrine event that precedes the phenotypic changes of puberty is activation of the CNS mechanisms that regulate GnRH production, which results in pulsatile LH followed by testosterone secretion, initially at night (see Fig. 19-5) and then throughout the day.⁴² Under the influence of increasing testosterone concentrations, secondary sexual characteristics appear at between 9 and 13 years of age.

The first physical sign of pubertal development is an increase of testis size to greater than 4 mL in volume (or >2.5 cm in length) and thinning of the scrotum, which is followed by development of rugal folds and increased pigmentation.^{136,303,304} Subsequently, penile length increases and pubic hair develops over the next 1 to 2 years, followed by long bone growth (with peak height velocity occurring approximately 3 years later) and development of other secondary sexual characteristics, such as laryngeal enlargement and deepening of the voice. In boys, peak bone mass usually is not reached until the third decade. There is considerable variability in the onset and progression of puberty and the degree of virilization, and this is attributable in large part to an individual's genetic and ethnic background.

Delayed puberty is suspected if there is no evidence of sexual maturation and testis size is less than 4 mL at 14 years of age.^{136,303,304} Boys with delayed puberty often experience considerable psychosocial distress due to the lack of sexual and physical development that results in their being considered younger than their peer group and having difficulty competing in athletics. In addition to the lack of sexual development, both boys and their parents are usually also concerned about the boy's failure to undergo a growth spurt and short stature.

CDGP, or transient secondary hypogonadism, is the cause of delayed puberty in approximately 65% of cases.^{136,303,304} Permanent secondary hypogonadism (e.g., due to IHH, pituitary or hypothalamic tumors, infiltrative diseases), which initially may be clinically indistinguishable from CDGP, is the cause of delayed puberty in fewer than 10% of cases. Other causes of delayed sexual development and growth, which are usually clinically apparent on presentation, include functional secondary hypogonadism (e.g., due to chronic systemic illness, hypothyroidism, medications) in about 20% and primary hypogonadism (e.g., due to Klinefelter's syndrome, mumps, chemotherapy, radiation therapy) or androgen resistance in approximately 5% of cases.

CDGP is a physiologic variant of normal puberty that is characterized by a slowing of the growth rate and of the

timing and tempo of pubertal development.^{136,303,304} Because there is an increased prevalence of CDGP in families with GnRH deficiency (IHH), CDGP could represent a mild variant of IHH.³⁰⁵ No genes or genetic polymorphisms have been identified that determine the variations in the timing of normal puberty. However, a family history of delayed puberty or being a "late bloomer" is found in 80% of boys with CDGP.

Clinically, a boy with this condition typically has a height age (i.e., the age that corresponds to the boy's height at the 50th percentile) and a degree of sexual development (usually prepubertal or early pubertal) that are concordant with his bone age, but all of these measures are similarly delayed with respect to chronologic age; in other words, growth, sexual development, and bone age are retarded.^{136,303,304} Height velocity usually proceeds at a prepubertal rate or slightly more slowly, relative to peers of the same chronologic age whose height velocity has accelerated at 12 to 13 years of age.

In the absence of anosmia, hyposmia, or other morphologic abnormalities, CDGP cannot be distinguished clinically or biochemically from permanent IHH (see later discussion). If spontaneous puberty does not develop by 18 years of age in a normosmic patient, the diagnosis is usually IHH rather than CDGP. However, spontaneous reversal of hypogonadism has been reported in some men with normosmic IHH.³⁰⁶

Eventually, boys with CDGP undergo normal growth and sexual development, but several years after their peers.^{136,303,304} Normal height is usually attained, but target midparental height may not be achieved. Also, acquisition of peak bone mass may be compromised in some men. Boys with CDGP may experience severe emotional distress and social exclusion or isolation as a result of immature sexual development and short stature. Therefore, after exclusion of organic causes of delayed puberty, testosterone treatment is usually initiated in boys with CDGP at age 14, or sometimes sooner, to induce sexual maturation and growth that is more consistent with that of their peers. Testosterone is usually started at a low dose and gradually increased over several years; it is stopped intermittently to assess whether spontaneous puberty occurs (see later discussion).

Hereditary Hemochromatosis. Hereditary hemochromatosis is a common autosomal recessive disorder that is characterized by inappropriately high gastrointestinal iron absorption resulting in excessive iron storage in a number of tissues, most prominently liver, pancreas, heart, joints, skin, testes, and pituitary gland.^{307,308} In most cases, hereditary hemochromatosis is caused by mutations in the hemochromatosis gene (*HFE*), most commonly homozygous C282Y/C282Y mutations (70% to 85%) or compound heterozygote C282Y/H63D mutations (5% to 10%), or rarely by other mutations in iron-regulating genes such as transferrin receptor 2 (*TFR2*), hepcidin antimicrobial peptide (*HAMP*), hemojuvelin (*HJV*), and solute carrier family 40 A1 (*SLC40A1*). Homozygous C282Y mutations occur in approximately 1 of every 200 to 400 Caucasians of Northern European descent.

Regardless of the specific mutation causing hereditary hemochromatosis, iron overload results from insufficient hepatic production of hepcidin, a peptide hormone that degrades the iron-exporter protein, ferroportin; this causes unregulated iron absorption in the duodenum and iron overload in tissues.^{307,308} Initially, iron overload causes an increase in transferrin iron saturation, followed by an increase in ferritin concentrations in most men with hemochromatosis. Therefore, the biochemical penetrance is

high. Evaluation for hemochromatosis should be considered if iron saturation is greater than 45% in men. In the absence of inflammation or cancer, a serum ferritin level higher than 1000 µg/L is associated with greater risk of hepatic cirrhosis in patients with hemochromatosis, and a liver biopsy or MRI for hepatic iron content should be considered.

In contrast to biochemical abnormalities consistent with iron overload, the clinical penetrance of hereditary hemochromatosis is quite low (0.5% to 2.0%), and manifestations of iron overload (hepatic cirrhosis or carcinoma, diabetes mellitus, heart failure or arrhythmias, arthralgias or arthritis, bronzing of skin, hypogonadism) are far less common.^{307,308} This may be related to the importance of secondary insults to end organs (e.g., alcoholic liver damage) that contribute to clinical manifestations or to earlier diagnosis with increased awareness and screening. Clinical manifestations, when present, usually appear at between 40 and 60 years of age.

Men with hereditary hemochromatosis almost always manifest secondary hypogonadism resulting in androgen deficiency and impairment in sperm production due to iron overload in the pituitary gland that causes selective gonadotropin deficiency.³⁰⁹ Serum testosterone levels and sperm counts are low, LH and FSH levels are usually low, and gonadotropin response to GnRH stimulation is absent or markedly attenuated. In the presence of hepatic cirrhosis caused by hemochromatosis, SHBG levels may be elevated; as a result, serum testosterone levels may be normal in the presence of low free testosterone levels. Therefore, accurate and reliable measurements of free testosterone are needed to confirm biochemical androgen deficiency in men with hepatic cirrhosis due to hemochromatosis. Iron deposition in the pituitary may be detected by MRI. Iron overload also occurs in the testes and may occasionally cause a modest reduction in testosterone response to gonadotropin stimulation, resulting in combined primary and secondary hypogonadism. However, in most cases, gonadotropin treatment is able to stimulate normal testicular function, including spermatogenesis and fertility.

After diabetes, secondary hypogonadism is the most common endocrinopathy associated with hereditary hemochromatosis.³⁰⁷⁻³⁰⁹ It usually occurs in men with hepatic cirrhosis and ferritin levels higher than 1500 µg/L (i.e., later in the course of iron overload). Because serum SHBG concentrations may be elevated in hepatic cirrhosis, accurate measurements of free rather than total testosterone should be performed to evaluate androgen status in men with hemochromatosis. The prevalence of hypogonadism in iron overload has declined from between 10% and 100% in older reports to approximately 6% more recently, associated with earlier diagnosis and less severe iron overload. Hypogonadism may be reversed with therapeutic phlebotomy, usually early in the course of iron overload.

Idiopathic Hypogonadotropic Hypogonadism. IHH, also referred to as hypogonadotropic eunuchoidism or congenital hypogonadotropic hypogonadism, is an uncommon, clinically heterogeneous group of disorders characterized by isolated gonadotropin deficiency of varying degree with otherwise normal pituitary function.³¹⁰ Males with IHH fail to undergo normal puberty, resulting in incomplete sexual maturation or eunuchoidism, androgen deficiency with very low testosterone (usually in the prepubertal range), low to low-normal LH and FSH levels, and impaired sperm production. Gonadotropin deficiency is caused by a defect in normal GnRH production or action, as evidenced by absent or abnormal patterns of pulsatile

LH secretion (see Fig. 19-7)⁴⁷ and the ability of exogenous pulsatile GnRH treatment to restore normal gonadotropin secretion and testis function. Infants with IHH may have micropenis or cryptorchidism. Rarely, a man with normal virilization develops IHH as an adult.³¹¹

In approximately 60% of cases, IHH is associated with anosmia or hyposmia and is known as Kallmann's syndrome.³¹² Developmental failure of olfactory bulbs (detectable on brain MRI) is responsible for the anosmia or hyposmia. The remaining 40% of men have normosmic IHH. In addition, some men with IHH exhibit other developmental defects, including synkinesia (mirror movements); unilateral renal agenesis; cleft lip/palate or high-arched palate; sensorineural hearing loss; digital skeletal abnormalities such as syndactyly or brachydactyly (fourth metacarpal); dental agenesis; eye movement abnormalities or color blindness (deuteranopia); and agenesis of the corpus callosum.

The prevalence of Kallmann's syndrome is approximately 1 in 8000 to 10,000 men, and there is a marked male predominance (male-to-female ratio, 4:1 to 5:1).³¹² X-linked recessive, autosomal dominant, and autosomal recessive modes of inheritance are observed, but many cases are sporadic. Family members of a man with Kallmann's syndrome may have variable clinical expressions, such as normosmic IHH, isolated anosmia, or CDGP.^{50,313} In approximately 30% to 40% of cases, Kallmann's syndrome is caused by a known mutation of genes that play important roles in the migration of GnRH neurons from the olfactory placode to the hypothalamus and in normal development of the olfactory bulbs during fetal development. These include mutations of *KAL1* (10% to 20%), *FGFR1/KAL2* (10%), *PROK2* (5%), and *PROKR2* (5%).^{50,313}

The *KAL1* gene is located on the X chromosome and encodes an extracellular adhesion glycoprotein known as anosmin 1.^{50,313} Mutation or deletion of *KAL1* results in failure of the normal migration of GnRH neurons from the olfactory placode to the hypothalamus, resulting in severe GnRH deficiency; it is the main cause of X-linked recessive Kallmann's syndrome (type 1). The phenotype of Kallmann's syndrome caused by *KAL1* mutations is more severe and less variable than that of other known genetic defects. Synkinesia is present in 80% and unilateral renal agenesis in 30% of cases. The *FGFR1* gene encodes for a fibroblast growth factor receptor that also plays an important role in the migration of GnRH neurons during development.^{50,313} Mutations in this gene cause a spectrum of phenotypes, from severe autosomal dominant Kallmann's syndrome (type 2) and normosmic IHH to CDGP associated with cleft lip/palate (in 30% of cases), dental agenesis, and skeletal abnormalities such as brachydactyly and syndactyly. *PROK2* and *PROKR2* encode for a peptide and its G protein-coupled receptor that play important roles in normal GnRH neuronal migration and olfactory bulb development.^{50,313} The clinical phenotypes in men with *PROK2* or *PROKR2* mutations are quite variable, ranging from severe Kallmann's syndrome (type 4 or type 3, respectively) to normosmic IHH.

In approximately 30% of cases, normosmic IHH is caused by mutations in genes involved in hypothalamic-pituitary function (particularly during puberty). These include mutations in *GNRHR*, the GnRH receptor (10% to 20%); *KISS1R*, which encodes the receptor for kisspeptin 1/metastin, an important GnRH stimulatory neuropeptide particularly at the time of puberty (2% to 5%); *TAC3*, which encodes neurokinin B, another important GnRH stimulatory neuropeptide, and the gene for its receptor, *TAC3R*; *FGFR1/KAL2* (2% to 5%); *PROK2*; the genes for

leptin (*LEP*) and its receptor (*LEPR*), which are associated with massive obesity; and, rarely, the GnRH gene, *GNRH1*.^{50,313}

Hypogonadotropic hypogonadism is a component of complex genetic syndromes associated with specific dysmorphic features or combined hormonal defects. For example, the *CHARGE syndrome*, characterized by coloboma of the eye or CNS anomalies, heart anomalies, nasal choanal atresia, growth retardation, genital defect (hypogonadism), and ear anomalies (deafness, dysmorphic ears, and hypoplasia of the semicircular canals), may be associated with Kallmann's syndrome or normosmic IHH.^{314,315} In approximately 60% of cases, CHARGE syndrome is caused by a mutation in the chromodomain helicase DNA binding protein 7 (*CHD7*) gene, which encodes for a chromatin remodeling protein. *CHD7* mutations have been found in approximately 3% to 4% of men with Kallmann's syndrome or normosmic IHH, and it is hypothesized that IHH may be a mild variant of the CHARGE syndrome.

X-linked congenital adrenal hypoplasia, characterized by adrenal insufficiency due to adrenal hypoplasia and normosmic IHH, is caused by a mutation in the dose-sensitive sex reversal–adrenal hypoplasia (DSS-AHC) critical region on the X chromosome protein 1 (*DAX1*) gene, now known as *NROB1* (nuclear receptor subfamily 0, group B, member 1), which encodes for an orphan nuclear receptor. Mutations of the SF-1 gene (*NR5A1*), which encodes another orphan nuclear receptor; the prohormone convertase 1 (*PC1*) gene, which encodes an enzyme involved in post-translational processing of pituitary prohormones and neuropeptides; and genes for a number of pituitary transcription factors such as *HESX1* (septo-optic dysplasia or deMorsier syndrome), *LHX3*, *LHX4*, *POU1F1*, and *PROP1* cause deficiencies in multiple anterior pituitary and other hormones in addition to gonadotropin deficiency. Mutations in the latter transcription factors may also be associated with specific dysmorphic features. Unlike men with IHH, those with multiple hormone defects usually fail to normalize gonadotropin and testicular function in response to chronic pulsatile GnRH administration.^{50,313}

In the absence of anosmia, hyposmia, or features of Kallmann's syndrome (e.g., synkinesia), it is not possible to confidently distinguish an individual who has normosmic IHH not associated with a complex genetic syndrome from one who has CDGP.^{136,303,304} In both conditions, there may be a family history of delayed puberty, IHH, or Kallmann's syndrome; a history of cryptorchidism; clinical manifestations of delayed sexual maturation or eunuchoidism; and low serum testosterone and low to low-normal gonadotropin levels. In contrast to boys with IHH, who have normal height for their chronologic age, those with CDGP usually manifest some growth delay and short stature. Boys with IHH may have a history of micropenis and usually demonstrate pubertal delay after 19 years of age, although some individuals undergo spontaneous puberty after 20 years of age or reversal of IHH in adulthood.³⁰⁶ Currently, there is no diagnostic test that completely and reliably distinguishes isolated normosmic IHH from CDGP.

As discussed previously, after organic causes of delayed puberty (e.g., craniopharyngioma) have been excluded, testosterone therapy is usually initiated in boys with delayed puberty at about 14 years of age to induce sexual maturation and growth.^{136,303,304} Testosterone is usually discontinued intermittently to assess whether spontaneous puberty occurs, as determined by an increase in testis size. Boys with IHH usually require continued testosterone treatment to achieve and maintain sexual maturation, whereas those

with CDGP do not require further treatment after spontaneous secretion of gonadotropin and testosterone commences. Sustained reversal occurs after discontinuation of therapy in about 10% of men with Kallmann's syndrome or normosmic IHH who present initially with absent or partial sexual maturation.³⁰⁶ Therefore, it is reasonable to discontinue treatment briefly to assess the reversibility of hypogonadotropic hypogonadism.

If fertility is desired, testosterone therapy is stopped and treatment with gonadotropin or, in some specialized centers, pulsatile GnRH is instituted to stimulate sperm production. Previous treatment with testosterone, which might be expected to suppress endogenous gonadotropin further, does not alter the subsequent response of spermatogenesis to gonadotropin therapy.^{316,317} Gonadotropin or GnRH therapy is much more likely to stimulate spermatogenesis if there is some evidence of sexual maturation and larger testes at baseline and no history of cryptorchidism or another primary testicular disorder.³¹⁸ Even in the absence of clinical evidence of hypothalamic-pituitary-testicular disorder, some men with IHH do not have an adequate gonadotropin or testicular response to chronic pulsatile GnRH therapy, suggesting underlying pituitary or testicular defects.³¹⁹

Men with IHH have varying degrees of gonadotropin deficiency, as evidenced by a persistent but abnormal pattern of pulsatile LH secretion (see Fig. 19-7).⁴⁷ In some men with IHH, FSH secretion predominates relative to LH secretion, resulting in some germ cell maturation and spermatogenesis and a rare variant form of IHH known as *isolated LH deficiency* or the “fertile eunuch syndrome.”³²⁰⁻³²² This syndrome is characterized by prepubertal androgen deficiency or eunuchoidism caused by LH deficiency but pubertal or almost adult-sized testes in which advanced-stage spermatogenesis is present due to relatively preserved FSH secretion. However, spermatogenesis usually is not completely normal in these men, and they are not fertile, as the name of the syndrome might imply. Because there is only relative gonadotropin deficiency and some spermatogenesis is present, treatment with LH-like activity (hCG) stimulates Leydig cell testosterone production and ameliorates androgen deficiency, stimulating spermatogenesis sufficient for induction of fertility. Men with *isolated FSH deficiency* in the absence of an FSH β mutation have been reported, but the degree and nature of the defect in pulsatile gonadotropin secretion has not been well documented.³²³⁻³²⁵

Men with inactivating *LH β mutations* usually demonstrate a lack of pubertal development, impaired spermatogenesis or azoospermia, and infertility.^{59,326,327} Recently, however, a man with an LH β mutation resulting in a partially active LH molecule (as indicated by expression of steroidogenic enzymes in a few mature Leydig cells and low intratesticular testosterone levels) was reported to have complete and quantitatively normal spermatogenesis.⁸⁰ Complete spermatogenesis was achieved in the presence of very low LH and intratesticular testosterone concentrations and high serum FSH levels in this man. Men with inactivating *FSH β mutations* have been found generally to have azoospermia with undetectable FSH, low or low-normal testosterone, and high LH levels.⁸²⁻⁸⁵

Complex Genetic Syndromes. Secondary hypogonadism may be present in a number of complex genetic syndromes, such as Prader-Labhart-Willi, Laurence-Moon-Bardet-Biedl, Alström, Björnstad, Börjeson-Forssman-Lehmann, Bosma, Chudley, Costello, Gordon-Holmes, Johnson-McMillin, Juberg-Marsidi, LEOPARD (multiple lentiginos), Martsof, Moebius-Poland, Roifman, Rud, and

Woodhouse-Sakati syndromes.^{231,244,328-343} Most of these syndromes are diagnosed by pediatricians and pediatric endocrinologists based on the clustering of specific dysmorphic features and congenital anomalies that are characteristic of the syndrome.²³¹ Secondary hypogonadism in these disorders usually causes prepubertal androgen deficiency. Many but not all of these syndromes are associated with CNS abnormalities or intellectual disability. Obesity may contribute to the etiology of hypogonadism and may alert clinicians to the potential presence of a complex genetic syndrome. Some, such as the Prader-Labhart-Willi, Laurence-Moon-Bardet-Biedl, and Alström syndromes, have been reported to be associated with primary as well as secondary hypogonadism.²⁴²⁻²⁴⁴

Acquired Disorders

Hyperprolactinemia. Hyperprolactinemia is a common cause of secondary hypogonadism. These patients have low testosterone concentrations and low to low-normal gonadotropin levels and present with sexual dysfunction (reduced libido and erectile dysfunction), infertility, and gynecomastia.³⁴⁴ Because the male breast usually is not exposed to a relatively high estrogen and progestin milieu such as that associated with induction of ductal hyperplasia and glandular formation, high prolactin levels rarely result in galactorrhea. Hyperprolactinemia causes gonadotropin deficiency primarily by suppressing pulsatile hypothalamic GnRH secretion, as evidenced by reduced spontaneous LH pulse frequency and amplitude and restoration of normal LH pulsatility and testosterone levels with dopamine agonist treatment or pulsatile GnRH administration.³⁴⁵

Common causes of hyperprolactinemia resulting in clinical secondary hypogonadism are a prolactin-secreting adenoma, pituitary stalk disease (e.g., stalk compression from a non-prolactin-secreting adenoma, traumatic stalk section); hypothalamic disease (e.g., hypothalamic tumors, granulomatous disease); and medications.³⁴⁴

In contrast to women, men with prolactin-secreting adenomas usually present with large macroadenomas because of a lack of symptoms, delay in seeking medical care for symptoms such as sexual dysfunction, or possibly a gender-specific difference in the biologic behavior of the tumor.^{346,347} In approximately 10% of cases, there is excessive cosecretion of both prolactin and GH. In men with prolactin-secreting macroadenomas, serum prolactin levels are usually higher than 250 ng/mL, and they can be higher than 1000 ng/mL with tumors larger than 2 cm in diameter. If a patient with a very large pituitary macroadenoma is found to have only modestly elevated prolactin levels, this may be a false-negative result caused by saturation of both the capture and the detection antibodies used in two-site sandwich immunoassays.³⁴⁸ This phenomenon is known as the prozone or "hook" effect and necessitates dilution of serum samples.

Diseases affecting the pituitary stalk and hypothalamic diseases may cause hyperprolactinemia because of disruption of the hypothalamic hypophyseal portal tract and transport of dopamine from the hypothalamus to the pituitary in the former condition or loss of hypothalamic dopamine-containing neurons in the latter. Suprasellar extension of a large, non-prolactin-secreting pituitary macroadenoma that compresses the pituitary stalk usually causes hyperprolactinemia with serum prolactin levels in the 20 to 250 ng/mL range, although higher levels are occasionally seen.³⁴⁴

Medications that cause hyperprolactinemia (prolactin concentration usually <100 ng/mL) interfere with hypothalamic dopamine production or action or affect the

regulation of dopamine secretion by CNS neurotransmitters (e.g., serotonin).^{349,350} The medications that most commonly cause hyperprolactinemia are dopamine D₂ receptor antagonists, such as typical antipsychotic drugs (phenothiazines, thioxanthenes, and butyrophenones), some atypical antipsychotic agents (e.g., risperidone, molindone) and gastrointestinal pro-motility agents (e.g., metoclopramide, domperidone). In contrast, newer atypical antipsychotic medications such as clozapine, olanzapine, quetiapine, ziprasidone, and aripiprazole much less commonly increase prolactin. Other medications that less commonly cause hyperprolactinemia include some tricyclic antidepressants (e.g., clomipramine), monoamine oxidase inhibitors (e.g., pargyline; clorgiline, which is rarely used), and antihypertensive agents (verapamil; α -methyldopa and reserpine, which are rarely used). Selective serotonin and serotonin/norepinephrine reuptake inhibitors in general have minimal to no effect on prolactin levels.

Serum prolactin levels may be elevated in patients with CKD, in proportion to the degree of renal failure, because of both increased secretion and decreased clearance, and this may contribute to the hypogonadism associated with chronic renal failure. The mild hyperprolactinemia associated with primary hypothyroidism does not usually suppress gonadotropin secretion significantly or cause clinical secondary hypogonadism in men. However, if primary hypothyroidism is severe and long-standing, it may cause slight enlargement of the pituitary gland, which may be confused with a pituitary adenoma.

Treatment is aimed initially at the underlying cause of hyperprolactinemia. In men with prolactin-secreting macroadenomas, treatment is initiated with a dopamine agonist medication such as bromocriptine or cabergoline.^{344,346,351} Dopamine agonist therapy usually results in a reduction of serum prolactin, decreased tumor size, and improvement in visual field defects. Treatment with these agents may also improve sexual dysfunction, normalize testosterone levels, and improve semen quality. In men who remain persistently hypogonadal despite adequate dopamine agonist treatment, testosterone therapy may be initiated to treat manifestations of androgen deficiency. Testosterone is aromatized to estradiol, which may act directly on lactotrophs in the pituitary and may increase prolactin levels and tumor growth and cause resistance to dopamine agonist therapy.³⁵² Therefore, careful monitoring is required during testosterone replacement therapy.

In some men who do not respond to dopamine agonist treatment alone, gonadotropin or pulsatile GnRH therapy may be necessary to stimulate spermatogenesis sufficient to induce fertility. Surgery or radiation therapy may be needed for tumors that are resistant to dopamine agonists, and urgent surgery may be needed for pituitary apoplexy or rapidly progressive tumor mass effects such as visual loss. Medications that cause hyperprolactinemia may be stopped or switched to ones that do not elevate prolactin. For antipsychotic and antidepressant medications, such changes should be made in consultation with the patient's psychiatrist.³⁴⁹ If discontinuing or switching drugs is not an option, testosterone treatment may be needed to treat androgen deficiency. Addition of a dopamine agonist while administration of an offending antipsychotic medication is continued should be done with extreme caution, because there is a risk of exacerbating psychosis.

Opiates. Use of opiates or opioid medications, particularly potent, long-acting narcotic analgesics such as methadone (>60 mg daily); controlled-release or intrathecal morphine sulfate or the transdermal fentanyl patch; and drugs of abuse such as heroin (diacetylmorphine) or

time-released oxycodone (OxyContin) profoundly suppress gonadotropin secretion, resulting in severe androgen deficiency.³⁵³⁻³⁵⁵

Prolonged use of opiates causes symptomatic androgen deficiency, resulting in sexual dysfunction and long-term consequences such as loss of BMD and increased risk of osteoporosis; this is a common cause of secondary hypogonadism associated with androgen deficiency and impairment in sperm production. As such, testosterone treatment should be considered in cases of severe secondary hypogonadism due to chronic use of opiates. However, short-term use of opiates or use of short-acting opiates (e.g., postoperatively) may cause only a transient suppression of gonadotropins and testosterone that does not require treatment.

Administration of opiate antagonists such as naloxone or naltrexone results in an increase in LH pulse frequency in normal men, suggesting that endogenous opiate neuronal systems within the hypothalamus exert a negative regulation on pulsatile GnRH secretion.³⁵⁶ Therefore, exogenous administration of opiates most likely causes gonadotropin secretion by suppressing hypothalamic GnRH secretion. The action of exogenous opiates on GnRH secretion is probably mediated by μ -opioid receptors. In this regard, the pure μ -opioid receptor agonist, methadone, more severely suppresses gonadotropins and testosterone than does buprenorphine, which is a partial μ -receptor, δ -receptor, and opioid receptor-like 1 (ORL1)/nociceptin receptor agonist and κ -opioid receptor antagonist.³⁵⁵ Both methadone and buprenorphine are used clinically for detoxification and maintenance treatment of opioid addiction.

In men taking chronic high-dose, long-acting opiates, serum testosterone, LH, and FSH are usually severely suppressed, and sperm production is impaired.³⁵⁷ The most prominent abnormality demonstrated on seminal fluid analysis in men taking methadone is reduced sperm motility (asthenospermia), but abnormalities in sperm morphology (teratospermia) and oligozoospermia are also seen. Functional δ -, κ -, and μ -opioid receptors have been reported to be present on human spermatozoa.³⁵⁸ Therefore, exogenous opiates may have a direct effect by slowing sperm motility, independent of their effects on the hypothalamic-pituitary-testicular axis.

Sex Steroids. Administration of sex steroids, androgens, progestins, or estrogens suppresses gonadotropin secretion by negative feedback mechanisms at the hypothalamus or the pituitary gland or both; chronic administration may cause secondary hypogonadism, resulting in androgen deficiency and impaired sperm production.

Synthetic androgens (androgenic anabolic steroids) and testosterone are being used increasingly by boys and men to increase muscle bulk and strength and enhance athletic performance or physical appearance. For these purposes, these androgens are used in extremely high doses in a variety of combinations and patterns for prolonged periods. The prevalence of anabolic steroid abuse ranges from approximately 1% to 6% in various populations including high school and college students, young recreational athletes, and competitive athletes.^{122,359,360}

During chronic administration of high-dose androgenic anabolic steroids, serum levels of testosterone, LH, and FSH are very low and sperm counts are usually suppressed to severe oligozoospermia or azoospermia.^{122,359,360} Unless testosterone is being administered, serum testosterone concentrations are low, because synthetic anabolic steroids do not cross-react in testosterone assays. Although serum testosterone levels are low, abused anabolic steroids are themselves

androgens, so individuals taking these agents usually do not complain of androgen deficiency symptoms.

After discontinuation of even prolonged anabolic steroid use, recovery of the hypothalamic-pituitary-testicular axis usually occurs within weeks to months. However, for unclear reasons, some men experience a protracted period of symptomatic hypogonadism that may last for several months to several years.^{122,359,360} It usually is not possible to know whether these men had underlying hypogonadism before taking anabolic steroids; therefore, if secondary hypogonadism is severe, an appropriate workup including sellar imaging is usually needed. Prolonged secondary hypogonadism after androgenic anabolic steroid use often causes sexual dysfunction and depressed mood. Severe symptoms may lead to continued use of these agents and anabolic steroid dependence. Treatment with testosterone to relieve symptoms of androgen deficiency or with gonadotropins (hCG) to stimulate sperm production and induce fertility may be needed. Off-label treatment with clomiphene citrate has also been reported to stimulate gonadotropin and testosterone secretion in these men.³⁶¹

Chronic administration of high doses of progestins such as megestrol acetate or depo-medroxyprogesterone acetate or estrogens such as diethylstilbestrol also suppresses gonadotropins and testicular function, resulting in secondary hypogonadism. Megestrol acetate is used to stimulate appetite in wasting conditions such as cancer and HIV disease. At the doses used for this purpose, it causes severe symptomatic androgen deficiency and suppression of sperm production.³⁶² Weight gain induced by megestrol acetate is mostly fat rather than lean mass, in part because of the androgen deficiency that it causes.³⁶³ Most importantly, megestrol acetate may cause symptomatic and potentially life-threatening secondary adrenal insufficiency.³⁶² Both megestrol and depo-medroxyprogesterone acetate have been used to induce medical castration in patients with prostate cancer.³⁶⁴ Medroxyprogesterone acetate has also been used to reduce libido in psychiatric conditions manifested by deviant sexual behavior (paraphilia), and it is used in combination with testosterone (to prevent androgen deficiency) for suppression of spermatogenesis in male contraceptive development trials.^{104,365} Administration of estrogens (e.g., diethylstilbestrol for prostate cancer), exposure to estrogen-containing substances, or excessive estradiol production by estrogen-secreting tumors (e.g., Sertoli cell tumors) suppresses gonadotropin and testosterone production and causes secondary hypogonadism, usually with prominent gynecomastia.³⁶⁶⁻³⁶⁸

Gonadotropin-Releasing Hormone Analogues. GnRH analogues, both agonists and antagonists, severely suppress endogenous gonadotropin and testosterone production (i.e., medical castration); they are used to treat androgen-dependent pathologic states such as locally advanced or metastatic prostate cancer and central precocious puberty.^{180,369} Administration of GnRH agonists (e.g., leuprolide, goserelin) produces an initial stimulation of gonadotropin and testosterone secretion (known as a "flare"), which is followed in 1 to 2 weeks by GnRH receptor down-regulation and marked suppression of gonadotropins and testosterone to castrate levels.¹⁸⁰ The initial surge in testosterone levels has been associated with clinical flares in metastatic prostate cancer, and there have been reports of increased bladder outlet obstruction, bone pain, pathologic fracture, spinal cord compression, and death. However, these complications are very uncommon, and it is not clear that they are directly related to the initial increase in testosterone concentrations. To prevent the potential

complications associated with the testosterone flare, AR antagonists (e.g., bicalutamide) are usually coadministered with a GnRH agonist for men with metastatic prostate cancer.³⁷⁰ In contrast to agonists, GnRH antagonists (e.g., degarelix) cause an immediate suppression of gonadotropin and testosterone secretion without a flare.³⁶⁹

Continuous administration of GnRH agonists in men with locally advanced or metastatic prostate cancer induces castrate or near-castrate testosterone levels and causes symptoms of severe androgen deficiency, including sexual dysfunction with reduced libido and reduced spontaneous erections; diminished energy and motivation; depressed mood and irritability; hot flushes and sleep disturbance; decreased memory and concentration; reduced in muscle mass and strength; increased fat mass and insulin resistance; decreased BMD resulting in osteopenia or osteoporosis; gynecomastia and loss of male hair pattern; and decreased hemoglobin and hematocrit, resulting in significant decline in quality of life.^{179,180} As a result, increasingly, GnRH agonist therapy is administered intermittently in the treatment of advanced prostate cancer. However, in a substantial number of men who stop GnRH agonist therapy, testicular function remains suppressed and testosterone levels persist within the castrate or hypogonadal range for prolonged periods (up to 1 to 3 years).^{371,372} Risk factors for prolonged testicular suppression are longer duration of GnRH agonist therapy, older age (>70 years), and possibly low testosterone levels before treatment.

Large population studies have found that prolonged GnRH agonist therapy increases the risk of diabetes mellitus, coronary heart disease, myocardial infarction, sudden cardiac death, stroke, and fractures. Consequently, the U.S. Food and Drug Administration has recommended that the risk factors for these diseases should be assessed and the benefits and risks of GnRH agonist therapy weighed before it is used and that monitoring for these conditions should be continued during treatment.^{180,369,373,374}

Hypopituitarism. A destructive or infiltrative lesion of the pituitary gland or hypothalamus commonly causes impaired pituitary hormone production (hypopituitarism) and gonadotropin deficiency resulting in androgen deficiency and impairment in sperm production. The prevalence of hypopituitarism has been estimated to be approximately 1 in 2200.^{375,376}

Hypopituitarism is most commonly caused by *pituitary adenomas* and their treatment (hypophysectomy or radiation therapy) or by *hypothalamic or parasellar tumors* such as craniopharyngioma, meningioma, optic glioma or astrocytoma, metastatic carcinoma (from breast, lung, colon, or prostate), pinealoma, germinoma, cordoma, and ependymoma; together, these tumors account for approximately 90% of cases.^{375,376}

Other conditions of the pituitary or hypothalamus (or both) that cause hypopituitarism include cranial radiation therapy (intracranial tumors, acute lymphoblastic leukemia prophylaxis, nasopharyngeal carcinoma, total body irradiation); vascular compromise (traumatic brain injury, infarction or pituitary apoplexy, subarachnoid hemorrhage, ischemic stroke, vascular malformation); granulomatous or infiltrative disease (sarcoidosis, histiocytosis X, Wegener's granulomatosis, hemochromatosis, transfusion-induced iron overload); infection (tuberculosis, fungal infections such as aspergillosis or coccidiomycosis, basilar meningitis, encephalitis, syphilis, Whipple's disease); pituitary stalk disease (traumatic injury such as basilar skull fracture or surgical pituitary stalk section, granulomatous disease, lymphocytic infundibuloneurohypophysitis, infection, tumor); and lymphocytic hypophysitis (in particular,

lymphocytic infundibuloneurohypophysitis, which is more common in men, rather than lymphocytic adenohypophysitis, which is more common in women).^{375,376} These conditions are discussed in detail in Chapter 9.

Destructive or infiltrative lesions of the pituitary gland (e.g., nonfunctioning pituitary adenoma) usually result in a gradual, progressive loss of anterior pituitary function. In these instances, GH and gonadotropin (FSH and LH) deficiency (i.e., secondary hypogonadism) usually occur initially, followed by deficiencies of TSH (secondary hypothyroidism) and, eventually, ACTH (secondary adrenal insufficiency), resulting in *panhypopituitarism*.^{375,376} However, there are many exceptions to this order of loss, depending on the specific location of the pituitary lesion and the nature of the underlying disease process. For example, lymphocytic hypophysitis usually causes ACTH and TSH deficiency without impairment of gonadotropin production, and ACTH deficiency is more common than TSH deficiency after radiation therapy involving the hypothalamic-pituitary axis. Anterior pituitary hormone loss is even less predictable in disease processes involving the hypothalamus, in part because of the more disperse anatomic arrangement in the hypothalamus of nuclei that produce releasing factors for pituitary hormones. Acute destructive processes such as pituitary apoplexy usually cause panhypopituitarism.

Diseases of the hypothalamus or high in the pituitary stalk may be associated with *diabetes insipidus*, which is caused by destruction or retrograde degeneration of neurons producing arginine vasopressin (AVP) in the supra-optic or the paraventricular nuclei, respectively.³⁷⁵⁻³⁷⁷ Processes involving only the pituitary gland do not cause diabetes insipidus.

Hypothalamic and pituitary stalk diseases may cause hyperprolactinemia due to loss of dopamine-containing neurons or interruption of the hypothalamic hypophyseal portal tract and transport of dopamine from the hypothalamus to the pituitary. Pituitary microadenomas or macroadenomas may produce prolactin, and parasellar extension of nonsecretory pituitary macroadenomas or those secreting other hormones (e.g., GH) may cause hyperprolactinemia by interrupting the hypothalamic-hypophyseal portal system.

Prepubertal boys who have hypopituitarism resulting in gonadotropin deficiency present with delayed puberty and eunuchoidism, and men present with adult androgen deficiency and complaints of reduced libido and erectile dysfunction. However, in patients with secondary hypogonadism, clinicians must be alert to the possibility and clinical manifestations of *deficiencies of other pituitary hormones* (ACTH, TSH, GH, and AVP); *excessive pituitary hormone production* by pituitary adenomas and resulting clinical syndromes, such as excessive prolactin production resulting in hyperprolactinemia, ACTH resulting in Cushing's syndrome, GH resulting in acromegaly, gonadotropin and free α - and β -subunits (which usually do not result in a hormone excess syndrome but rarely cause precocious puberty), or, rarely, TSH resulting in hyperthyroidism; and *tumor mass effects* such as headache, visual disturbance, and visual field defects (typically bilateral superior quadrantanopsia or bitemporal hemianopsia, but a unilateral effect and a variety of visual field defects may be present) and, uncommonly, cerebrospinal fluid rhinorrhea, cranial nerve palsies, temporal lobe epilepsy, and personality changes.^{375,376} It is important to have a high index of suspicion for the presence of secondary adrenal insufficiency in patients with hypothalamic or pituitary disease, because it is a life-threatening and treatable condition that manifests with

nonspecific symptoms and signs. In boys with hypopituitarism who present with a clinical picture of CDGP, GH deficiency may occur in conjunction with gonadotropin deficiency and may contribute to short stature and growth delay.

Usually in men with secondary hypogonadism due to hypopituitarism, the serum testosterone level and sperm count are very low, and LH and FSH levels are distinctly low or, less commonly, in the low-normal to slightly low range. The gonadotropin response to acute or chronic GnRH stimulation is not a clinically useful differential diagnostic test because it does not reliably distinguish between pituitary and hypothalamic disease causing gonadotropin deficiency in hypopituitarism. If hypopituitarism is suspected on the basis of the initial clinical and laboratory evaluation, further evaluation should include hypothalamic-pituitary imaging, preferably an MRI with gadolinium contrast enhancement, which can better define the presence and extent of hypothalamic and pituitary disease compared with a computed tomographic scan (although the latter is able to detect pituitary macroadenoma and microcalcifications found frequently in craniopharyngioma); formal visual field examination; and investigation of anterior pituitary hormone deficiency or excess.^{375,376}

Treatment is aimed at the underlying etiology of the hypopituitarism and treatment of pituitary hormone deficiency, including treatment of androgen deficiency secondary to gonadotropin deficiency with testosterone replacement therapy.^{375,376} With transsphenoidal surgical treatment of pituitary adenomas, pituitary function is improved in approximately 50% of cases. Dopamine agonist treatment of prolactin-secreting pituitary adenomas improves pituitary function in 60% to 75% of cases. If fertility is desired, testosterone treatment is stopped and gonadotropin therapy is initiated, initially with hCG. In men with acquired gonadotropin deficiency without coexisting testicular disease, hCG treatment alone may stimulate spermatogenesis to levels sufficient to restore fertility.⁷⁹

Systemic Disorders

Glucocorticoid Excess (Cushing's Syndrome). Excessive levels of either exogenous or endogenous glucocorticoids (the latter due to pituitary Cushing's disease or adrenal adenoma) is a common acquired cause of secondary hypogonadism resulting in symptomatic prepubertal or adult androgen deficiency and impaired sperm production.³⁷⁸⁻³⁸¹ In contrast to those patients with adrenal adenoma, some men with glucocorticoid excess due to adrenal carcinoma secrete excessive amounts of androgens (and mineralocorticoids) and do not demonstrate hypogonadism.

Glucocorticoids act primarily to suppress gonadotropins via inhibition of hypothalamic GnRH secretion, but they may also have direct suppressive effects on testis function and therefore produce combined primary and secondary hypogonadism. However, high-dose immunosuppressive glucocorticoid therapy is most commonly associated with a hormone pattern characterized by low testosterone and low-normal gonadotropin levels, consistent with secondary hypogonadism. Occasionally in men receiving glucocorticoid treatment, gonadotropins are high-normal or slightly elevated, suggesting primary hypogonadism.

Although it occurs most commonly with high-dose glucocorticoid treatment, doses as low as 7.5 mg of prednisone may cause hypogonadism, particularly in older men. Because high doses of glucocorticoids may suppress SHBG concentrations, it is important to confirm the biochemical

diagnosis of hypogonadism using an accurate measurement of free testosterone (i.e., calculated free testosterone or free testosterone by equilibrium dialysis). In preliminary studies of men receiving chronic glucocorticoid therapy, testosterone treatment was found to improve muscle mass, BMD, and quality of life.³⁸²

Chronic Organ Failure. Chronic organ failure, such as in hepatic cirrhosis, CKD, chronic lung disease, or CHF, is a common cause of symptomatic secondary hypogonadism.^{4,5} As discussed previously, chronic systemic illness commonly affects the hypothalamic-pituitary-testicular axis at multiple levels and usually causes combined primary and secondary hypogonadism, but many disorders are associated with a hormone pattern characterized by low serum testosterone and low to low-normal gonadotropin levels, indicative of secondary hypogonadism.

The etiology of clinical and biochemical hypogonadism in these cases is multifactorial and encompasses both the chronic disease itself and its associated conditions of malnutrition, wasting, a pro-inflammatory state (with elevated cytokines such as IL-1 and tumor necrosis factor- α [TNF- α]), medication use (e.g., alcohol, opiates, glucocorticoids), chronic stress, and other comorbid illnesses. These associated factors play a large role in suppressing gonadotropin levels and contribute to the hormonal pattern of secondary hypogonadism associated with chronic organ failure. The degree to which these factors contribute to the clinical and biochemical manifestations of hypogonadism varies considerably among individuals. Furthermore, biochemical confirmation of low testosterone in patients with chronic organ failure or systemic illness may be confounded by alterations in SHBG. Therefore, accurate and reliable measurements of free testosterone are needed to establish biochemical androgen deficiency in the presence of chronic systemic illness.

Hepatic cirrhosis from any etiology (e.g., alcoholic or nonalcoholic liver disease) is commonly associated with a hormone pattern that is consistent with primary hypogonadism (i.e., low free testosterone, high LH, and normal to high-normal FSH levels) in mild to moderate disease (Child-Pugh class A or B) and with secondary hypogonadism (i.e., low free testosterone and low-normal LH and FSH levels) in severe to end-stage liver disease (Child-Pugh class C).^{262,263} SHBG concentrations increase progressively with the severity of cirrhosis, resulting in normal or high serum total testosterone levels despite low free testosterone concentrations and clinical manifestations of androgen deficiency. Sperm production is commonly impaired and sperm motility is reduced in men with hepatic cirrhosis.

In alcoholic cirrhosis, serum estrone and estradiol levels are relatively high due to increased production of adrenal androgens (e.g., androstenedione) induced by alcohol and its metabolite, acetaldehyde; reduced clearance of these by the liver; and subsequent aromatization of androstenedione to estrone and its conversion to estradiol.^{4,5} Relative hyperestrogenism is responsible for a number of the clinical manifestations commonly observed in men with alcoholic compared with nonalcoholic cirrhosis, including gynecomastia, palmar erythema, plethora, spider angiomas, and loss of male body hair (reduced axillary and pubic hair and a female escutcheon). Men with severe alcoholic cirrhosis usually have atrophic testes due to direct toxic effects of alcohol.

In men with severe hepatic cirrhosis, pulsatile GnRH secretion and the pituitary response to GnRH are diminished, contributing to secondary hypogonadal failure.³⁸³ Spironolactone, which is used to treat edema and ascites associated with portal hypertension, is an AR antagonist

and an androgen biosynthesis inhibitor. Its use may contribute to symptoms of androgen deficiency, gynecomastia, and hypogonadism. Protein-calorie malnutrition, complications of cirrhosis such as infection, and continued alcohol abuse contribute to the clinical manifestations and etiology of low testosterone in these chronically ill men. Successful liver transplantation improves but does not normalize gonadal function, probably because of chronic immunosuppressive treatment with glucocorticoids and other agents.²⁶²

As described in a previous section, CKD is commonly associated with a hormone pattern of low serum testosterone and elevated gonadotropin concentrations resulting from reduced renal clearance, consistent with primary hypogonadism.^{4,5,264,265,267} However, the amplitude of pulsatile LH secretion is reduced, suggesting impaired hypothalamic-pituitary function in men with CKD.³⁸⁴ Gonadotropin secretion may also be suppressed by coexisting uremia, hyperprolactinemia, malnutrition, a pro-inflammatory state, comorbid conditions (e.g., diabetes), and obesity, and some men demonstrate a hormone pattern that is more consistent with secondary hypogonadism (i.e., with low testosterone and normal to high-normal gonadotropin levels). Successful renal transplantation usually normalizes levels of testosterone and gonadotropins and sperm production.^{264,265}

Men with *chronic lung disease*, especially COPD, commonly have low serum testosterone levels.^{385,386} The prevalence of biochemical hypogonadism depends on the population studied and varies from 12% in a community-based population to 38% in male veterans, the latter being a population with high comorbidity. In the population of veterans, approximately 75% of men with COPD with low serum testosterone have low or low-normal gonadotropin levels, consistent with secondary hypogonadism, and the remainder have elevated gonadotropins, indicative of primary hypogonadism.³⁸⁶ Coexisting factors that contribute to the clinical symptoms and biochemical diagnosis of hypogonadism in men with severe COPD include muscle wasting, inactivity, and deconditioning; malnutrition and cachexia; chronic stress and inflammation; medications (e.g., glucocorticoids); and hypoxia. Hypoxia suppresses gonadotropin and testosterone secretion independent of glucocorticoid therapy in men with COPD or idiopathic pulmonary fibrosis.³⁸⁵⁻³⁸⁷ Preliminary studies have demonstrated an increase in lean mass with testosterone treatment in men with COPD and low testosterone levels but inconsistent improvements in muscle strength, including respiratory muscle function, and no effects on endurance or quality of life.

CHF is associated with biochemical androgen deficiency in approximately 25% to 30% of cases.³⁸⁸⁻³⁹⁰ Men with CHF who have low serum testosterone usually have normal to low-normal gonadotropin levels, suggesting secondary hypogonadism. However, it is unclear whether men with CHF and low testosterone differ from those with normal testosterone in regard to symptoms and signs or response to testosterone therapy.³⁸⁹ In limited initial clinical trials in men with CHF, testosterone treatment improved exercise tolerance, muscle strength, and oxygen capacity in men with either low or normal testosterone levels, suggesting a pharmacologic effect of testosterone independent of the presence of androgen deficiency.

Chronic Systemic Illness. A number of chronic systemic illnesses, such as diabetes mellitus, malignancy, rheumatic disease, and HIV disease, may also cause secondary hypogonadism characterized by low serum testosterone concentrations and low or low-normal gonadotropin

levels.^{4,5} As in men with chronic organ failure, the etiology of clinical and biochemical hypogonadism is multifactorial due to the chronic illness itself and associated obesity (e.g., with diabetes mellitus) or malnutrition (e.g., with malignancy), wasting, pro-inflammatory state, medication use (e.g., opiates, glucocorticoids), chronic stress, or other comorbid illnesses. These factors suppress gonadotropin levels and contribute variably to the clinical and biochemical androgen deficiency seen in individuals with systemic illness. Because systemic illnesses and associated comorbidities and medications may alter SHBG concentrations, measurements of free testosterone are needed to confirm biochemical androgen deficiency.

Low serum free testosterone and low or low-normal gonadotropin levels, consistent with secondary hypogonadism, occur in 30% to 50% of men with T2DM.^{391,392} Low testosterone levels are associated with nonspecific clinical manifestations that may be caused by androgen deficiency, such as erectile dysfunction. Insulin resistance and moderate obesity are commonly associated with T2DM. In patients with T2DM and moderate obesity, low total testosterone levels may result from reduced SHBG concentrations caused by insulin resistance and action on the liver. Therefore, it is important to confirm biochemical androgen deficiency in these men by using calculated free testosterone values or measurements of free testosterone by equilibrium dialysis.

Secondary hypogonadism and clinical manifestations of androgen deficiency may also be caused by comorbidities and complications associated with diabetes, such as obesity, atherosclerotic vascular disease, the pro-inflammatory state of diabetes, diabetic neuropathy, and CKD. Therefore, testosterone treatment should be considered only in those diabetic men with symptomatic androgen deficiency that has been confirmed by accurate free testosterone measurements. If symptoms do not improve with an adequate trial of testosterone therapy (e.g., 6 months), discontinuation of treatment should be considered, particularly in men who had borderline or slightly low testosterone levels before therapy.

Men with poorly controlled T1DM may have reduced serum testosterone and gonadotropin levels and reduced LH pulse amplitude and frequency, which are not present in those with well controlled disease.³⁹³

Men with *malignancy* commonly have secondary hypogonadism characterized by low serum testosterone concentrations and low or low-normal gonadotropin levels.³⁹⁴⁻³⁹⁶ As mentioned previously, some men with malignancy present with low testosterone and elevated gonadotropin concentrations, consistent with primary hypogonadism. Malnutrition, wasting (cancer cachexia), systemic inflammation, medication use (e.g., opiate pain medications, glucocorticoids), chronic stress, and concomitant comorbid illnesses contribute to clinical and biochemical hypogonadism in men with cancer. Because SHBG may be reduced as a result of these associated conditions, free testosterone measurements are needed to confirm androgen deficiency.

Primary or secondary hypogonadism may be present before systemic chemotherapy or radiation therapy as well as after treatment. A low free testosterone concentration with normal or elevated gonadotropin levels was found in 40% to 60% of men with advanced malignancy (i.e., metastatic cancer) presenting with malnutrition and men with various stages of Hodgkin's disease before chemotherapy.^{279,280} Low levels of free testosterone and bioavailable testosterone were present, respectively, in approximately 78% and 66% of men with a variety of cancers, excluding

those with androgen-dependent cancer (prostate, breast) or testicular cancer, most of whom received chemotherapy or radiation therapy or both.^{394,396} Low testosterone was associated with reduced quality of life and sexual function.³⁹⁵

Men with *rheumatic diseases*, in particular the systemic autoimmune disorder rheumatoid arthritis, may manifest symptoms of sexual dysfunction (reduced libido and erectile dysfunction) and low serum free or bioavailable testosterone and gonadotropin levels in approximately 30% of cases.³⁹⁷ Secondary hypogonadism in rheumatoid arthritis may be due in part to systemic inflammation (with elevated cytokines such as IL-1 and TNF- α), complications such as rheumatoid lung, and treatment with glucocorticoids, but it may also occur early in the course of rheumatoid arthritis in the absence of complications and before glucocorticoid therapy.³⁹⁸ In men with long-standing rheumatoid arthritis, low free testosterone levels do not normalize after marked suppression of inflammation induced by anti-TNF therapy.³⁹⁹ Testosterone treatment may improve symptoms of androgen deficiency, but it does not reduce disease activity.⁴⁰⁰

Men with systemic lupus erythematosus also may demonstrate low free testosterone concentrations in conjunction with normal or low-normal gonadotropin levels, indicative of secondary hypogonadism, or elevated gonadotropins, consistent with primary hypogonadism.⁴⁰¹⁻⁴⁰³ Factors that contribute to gonadotropin suppression and secondary hypogonadism include chronic systemic illness and inflammation, major organ involvement or organ failure (heart, lung, brain, kidney), and glucocorticoid therapy. Factors that contribute to primary testicular dysfunction include systemic and local inflammation or vasculitis, organ failure, and treatment with cytotoxic agents such as cyclophosphamide.

It is also possible that the hypogonadism contributes to the immunologic pathophysiology of rheumatic disorders.^{404,405} Autoimmune diseases, and in particular autoimmune rheumatic diseases (e.g., Sjögren syndrome, systemic lupus erythematosus, rheumatoid arthritis), thyroid disease (Hashimoto's disease, Graves' disease), and autoimmune neurologic diseases (e.g., myasthenia gravis, multiple sclerosis), occur more commonly in women than in men. Sex steroid hormones, primarily estrogens and androgens, modulate immune function by direct actions on immune cell function and may play a role in sex differences in autoimmunity and in the pathophysiology of autoimmune disorders.

Men with *HIV disease* commonly have hypogonadism characterized by symptomatic androgen deficiency and impaired sperm production with low free testosterone levels due to combined primary and secondary hypogonadism.^{406,407} Hypogonadism occurred in up to 50% of men with HIV wasting before the advent of HAART. Although androgen deficiency is less common since the advent of HAART, it occurs in approximately 20% of HIV-infected men. In 75% to 90% of cases, low free testosterone is associated with low or low-normal gonadotropin levels, consistent with secondary hypogonadism.^{408,409} In the remaining 10% to 25% of cases, gonadotropin concentrations are elevated, indicating primary hypogonadism.

As in other chronic systemic illnesses, the etiology of hypogonadism in men with HIV disease is multifactorial.^{4,5} In addition to HIV infection itself, gonadotropin suppression and secondary hypogonadism may be caused by malnutrition, wasting, and cachexia; opportunistic infections resulting in hypothalamic-pituitary function (e.g., CMV, *T. gondii*); systemic inflammation (with elevated levels of cytokines such as IL-1 and TNF- α); medications (e.g.,

opiates, glucocorticoids, megestrol acetate); ongoing substance abuse (e.g., alcohol); and acute and chronic illnesses. Conditions that may play a role in causing primary hypogonadism include opportunistic infections affecting the testes (CMV, *M. avium intracellulare*, *T. gondii*), malignancies involving the testes (Kaposi's sarcoma, lymphoma), systemic inflammation, and medications (chemotherapy for secondary neoplasms, ketoconazole).^{406,407}

Protein-calorie malnutrition may suppress SHBG concentrations, and advancing HIV infection is associated with increased SHBG levels. Therefore, accurate measurements of free testosterone levels should be used to evaluate men with HIV disease for androgen deficiency.^{408,409} Sperm production associated with abnormalities in sperm motility and morphology and testicular atrophy may be present. It is important to recognize that HIV may be present in semen even when it is undetectable in plasma.⁴⁰⁷

In small clinical trials, treatment with testosterone and androgenic anabolic steroid has been demonstrated to improve libido and sexual function; increase muscle mass and strength and BMD; decrease fat mass; improve mood, well-being, and quality of life; and increase hematocrit in HIV-infected men with low serum testosterone levels.¹¹⁰

Men with chronic *spinal cord injury* at any level resulting in tetraplegia or paraplegia may have secondary hypogonadism with low serum testosterone and low or normal gonadotropin levels.^{285,286} In men with lower spinal cord injury causing paraplegia, there may be a transient suppression of testosterone levels within 4 months after the injury that resolves in most cases.⁴¹⁰ Gonadotropin suppression is caused in part by a number of conditions associated with spinal cord injury, such as acute and chronic trauma and stress associated with the injury and attendant complications; obstructive sleep apnea; obesity or nutritional compromise; hyperprolactinemia (usually associated with medications); and medication use (e.g., glucocorticoids, opiates, CNS-active drugs). The benefits and risks of testosterone treatment in patients with spinal cord injury are not clear.

Thalassemia major, or β -thalassemia, is an autosomal recessive disorder characterized by absent or severely deficient synthesis of β -globulin chains of hemoglobin resulting in severe anemia that requires lifelong blood transfusions. It is common in the Mediterranean region, in India, and in Southeast Asia. Chronic blood transfusions in patients with β -thalassemia cause *transfusion-related iron overload* in tissues and produce clinical manifestations similar to those that occur in patients with hereditary hemochromatosis. Transfusion-related iron overload may also occur in patients with sickle cell anemia, refractory aplastic anemia, or myelodysplastic syndrome.

Iron deposition in the testes and pituitary gland usually causes combined primary and secondary hypogonadism.^{411,412} However, males with transfusion-related iron overload usually exhibit a hormonal pattern indicative of secondary hypogonadism, with low serum free testosterone and low to low-normal gonadotropin concentrations in most cases. Hypogonadism due to transfusion-related iron overload may manifest with prepubertal or adult androgen deficiency and impaired sperm production; affected boys usually have short stature and growth delay.⁴¹³ Treatment requires iron chelation therapy with agents such as deferoxamine, deferasirox, or deferiprone. In men with long-standing β -thalassemia, chelation therapy does not reverse hypogonadism.⁴¹⁴

Sickle cell disease may be associated with low serum testosterone and low to low-normal gonadotropin levels, indicative of secondary hypogonadism.⁴¹⁵⁻⁴¹⁷ Gonadotropin

suppression may be caused by transfusion-induced iron overload (although much less commonly than in men with β -thalassemia⁴¹⁸); hypothalamic-pituitary microinfarctions; medications (e.g., opiates for chronic pain); systemic inflammation; nutritional deficiencies; and chronic systemic illness and stress secondary to repeated painful vaso-occlusive events. As discussed earlier, men with sickle cell disease may present with primary hypogonadism due to testicular microinfarctions caused by vaso-occlusive events or iron overload affecting the testes. Priapism, which may occur with vaso-occlusive events, has been reported in patients receiving testosterone therapy.⁴¹⁹

Uncommonly, boys or men with *cystic fibrosis* have low serum testosterone and low to low-normal gonadotropin concentrations, a hormonal pattern consistent with secondary hypogonadism.⁴²⁰ Chronic systemic illness and inflammation, malnutrition, and glucocorticoid use may contribute to gonadotropin suppression.

Nutritional Disorders or Endurance Exercise. Starvation, malnutrition, and eating disorders (anorexia nervosa) suppress gonadotropin and testosterone secretion, resulting in symptomatic secondary hypogonadism with androgen deficiency (usually manifested by reduced libido, sexual activity, and performance) and impaired sperm production; these effects are reversed with restoration of food/calorie intake and weight gain. Fasting for periods of 3 to 5 days suppresses gonadotropin and testosterone secretion and decreases LH pulse amplitude and frequency.⁴²¹⁻⁴²³ These changes are reversed completely by pulsatile GnRH administration or low-dose recombinant methionyl human leptin replacement, suggesting that short-term starvation suppresses leptin production, which in turn suppresses the hypothalamic GnRH pulse generator.^{424,425} Severe protein-calorie malnutrition, often associated with other nutritional deficiencies, may cause severe suppression of testosterone and elevation of gonadotropin levels, indicative of primary hypogonadism.^{422,426}

Chronic *endurance exercise* results in low serum testosterone, low to low-normal gonadotropin concentrations, and impaired sperm production and motility, consistent with secondary hypogonadism.^{427,428} High-intensity endurance training, such as occurs in the military and with overtraining in athletes, is associated with relative calorie deprivation and intense stress and causes more severe suppression of gonadotropin and testosterone levels than is seen with chronic lower-intensity endurance exercise.^{421,429} Suppression of the hypothalamic-pituitary-testicular axis resolves with cessation of training and increased calorie intake. Other than reduced spermatogenesis, the clinical consequences of androgen deficiency induced by endurance exercise are not clear.⁴³⁰ In contrast to chronic endurance exercise, short-term endurance or resistance exercise in some men results in an acute and transient increase in testosterone levels that is modified by the intensity of exercise and prior training and is possibly related to hemoconcentration, reduced metabolic clearance, or increases in serum LH levels.⁴³¹

Mild to moderate obesity results in reduced SHBG and total testosterone levels. Free testosterone is usually normal but may be reduced in association with low or low-normal gonadotropin levels in some men, particularly in those with comorbid conditions such as T2DM or obstructive sleep apnea.⁴³²⁻⁴³⁴ In men with *morbid obesity*, particularly those with a body mass index (BMI) greater than 40 kg/m² or massive obesity (BMI >45 kg/m²), serum free testosterone is low, gonadotropin levels are low or low-normal, and LH pulse amplitude (but not frequency) is reduced, indicative of secondary hypogonadism.⁴³⁵ Morbidly and

massively obese men often complain of reduced libido and sexual dysfunction, but these symptoms are confounded by obesity and comorbidities associated with morbid obesity, such as depression, diabetes, and obstructive sleep apnea. Bariatric surgery and rapid weight loss induced by a very low-calorie diet increase serum testosterone and gonadotropin concentrations.

Morbid obesity may be complicated by *obstructive sleep apnea* syndrome. Men with untreated or inadequately treated obstructive sleep apnea have low gonadotropin and testosterone concentrations independent of obesity and age.^{433,436} Adequate treatment with continuous positive airway pressure (CPAP) may improve symptoms attributed to androgen deficiency and reverse biochemical secondary hypogonadism in some men, particularly those with massive obesity and comorbid conditions that cause hypogonadism independent of sleep apnea. Whereas obstructive sleep apnea may induce androgen deficiency, treatment of hypogonadism with relatively high doses of testosterone (e.g., doses associated with the use of parenteral testosterone esters) may induce or worsen obstructive sleep apnea in men with predisposing conditions such as obesity and in older men.^{433,437,438}

Acute and Critical Illness. Acute and critical illnesses, including medical and surgical illnesses requiring hospital or intensive care unit admission (e.g., myocardial infarction, respiratory illness, sepsis, burns, surgery, polytrauma, stroke, traumatic brain injury, liver disease), suppress gonadotropin and testosterone secretion as a result of combined primary and secondary testicular dysfunction.^{439,440} However, the predominant hormone pattern during acute or critical illness is low serum testosterone with low or low-normal gonadotropin levels, suggesting secondary hypogonadism. Spontaneous LH pulse amplitude is reduced, but pulse frequency is maintained, and pulsatile GnRH administration only partially corrects secondary hypogonadism, underscoring the presence of concomitant pituitary and testicular defects.⁴⁴¹ For unclear reasons, aromatization of testosterone to estradiol and serum levels of estradiol may be elevated, sometimes markedly, in patients with acute or critical illness despite low testosterone levels.⁴⁴² Estradiol levels are associated with mortality in critically ill and injured patients.⁴⁴³

The severity and duration of testosterone suppression are related to the severity of the acute or critical illness, the presence of underlying chronic systemic illnesses, and the medications used (e.g., glucocorticoids, opiates).^{439,440} Recovery of testosterone and gonadotropin levels may take several weeks to months, depending on the severity and duration of the acute illness, duration of subacute recovery and rehabilitation, complications including malnutrition, medications, and underlying chronic systemic illnesses or organ failure. In the presence of underlying chronic disease or organ failure, hypogonadism may persist long after recovery from the acute illness. Evaluation for underlying hypogonadism should not be performed during acute or subacute illness. It should be delayed for several months, until recovery to the individual's baseline or near-baseline clinical condition has occurred.

Aging. As discussed earlier, aging is associated with a gradual and progressive decline in total and free testosterone levels; as a result, an increasing proportion of older men have low serum testosterone concentrations in the hypogonadal range.²⁶⁸⁻²⁷⁰ The prevalence of clinical androgen deficiency is 6% to 9% and increases with age, reaching 18% to 23% among men in their 70s.^{175,176} Serum gonadotropin levels increase with aging but do not usually rise above the normal range until very old age, usually beyond

70 years of age.²⁷⁰ Therefore, the most common hormonal profile observed clinically in middle-aged to older men is low testosterone with normal LH and FSH levels, indicative of secondary hypogonadism. Pulsatile LH secretion is abnormal and is characterized by disorderly LH pulses of reduced amplitude; it is normalized by exogenous pulsatile GnRH administration, suggesting a defect in hypothalamic GnRH secretion.²⁷²

The presence of chronic systemic illness or organ failure, medications, or malnutrition or wasting syndromes may contribute to suppression of gonadotropin and testosterone production. Conversely, the age-related decline in testosterone may contribute to the susceptibility and severity of clinical hypogonadism that occurs in these conditions.²⁷⁴

Relatively small, short-term studies of testosterone treatment in heterogeneous populations of older men have produced conflicting results, with most finding beneficial effects of testosterone treatment on body composition (increasing lean mass and decreasing fat mass) but less consistent effects on muscle strength and performance, BMD, sexual function, vitality, and cognitive function. Larger, long-term, randomized trials are needed to determine the balance of clinical benefits and risks (particularly, prostate cancer and cardiovascular risks) associated with testosterone treatment in elderly men. For now, testosterone treatment should be considered on an individual basis only for older men who have clinically significant symptoms and signs of androgen deficiency and unequivocally low serum testosterone levels and only after a careful discussion of the uncertainty regarding the benefits and risks of treatment.¹¹⁰

Isolated Impairment of Sperm Production or Function

Congenital or Developmental Disorders

Congenital Adrenal Hyperplasia. If untreated or inadequately treated with glucocorticoids, congenital adrenal hyperplasia caused by deficiency of 21-hydroxylase or 11 β -hydroxylase results in excessive secretion of adrenal androgens (androstenedione and DHEA) that are converted to testosterone. Elevated circulating androgen concentrations suppress gonadotropin secretion by negative feedback regulation, which in turn decreases endogenous testosterone secretion and sperm production, resulting in secondary hypogonadism. Excessive androgen production prevents androgen deficiency, so secondary hypogonadism is manifested by isolated impairment of sperm production and function.⁴⁴⁴

Adequate glucocorticoid therapy reduces excessive adrenal androgen production and usually restores gonadotropin secretion and normalizes testis function, including spermatogenesis. However, despite adequate treatment, some men with congenital adrenal hyperplasia continue to manifest impaired sperm production and function, most commonly as a result of long-standing inadequate glucocorticoid treatment and irreversible testicular damage caused by large adrenal rest tumors or excessive glucocorticoid treatment. As discussed previously, excessive glucocorticoid treatment of congenital adrenal insufficiency also suppresses gonadotropin secretion and results in androgen deficiency and impairment in sperm production.

Isolated Follicle-Stimulating Hormone Deficiency and FSHB Mutations. Rare cases of men with isolated FSH deficiency in the absence of *FSHB* gene mutations have been reported; these patients had isolated impairment in sperm production characterized by azoospermia or severe

oligozoospermia, and hypospermatogenesis or maturation arrest was found in the few who underwent testis biopsy.³²³⁻³²⁵ These men had normal virilization, normal levels of testosterone and LH, low to undetectable serum FSH levels with poor or no response to GnRH administration, normal LH, and normal inhibin B and activin A levels when tested. In one man, administration of recombinant human FSH (rhFSH) alone resulted in a robust increase in sperm counts and induced fertility on two occasions.

Men with inactivating mutations of *FSHB* have been found generally to have azoospermia with undetectable FSH, low or low-normal testosterone, and high LH levels.⁸²⁻⁸⁵ In one man, rhFSH administration was demonstrated to increase testosterone levels, suggesting that FSH-stimulated Sertoli cells may enhance LH-induced Leydig cell production of testosterone via a paracrine mechanism.⁴⁴⁵

Acquired Disorders

Androgen Administration or Excess. Exogenous testosterone administration (in normal men or in men with partial hypogonadism)⁴⁴⁶ or stimulation of endogenous testosterone production by hCG administration⁴⁴⁷ or ectopic hCG-secreting tumors (e.g., testis cancer, lung cancer)⁴⁴⁸ suppresses pituitary gonadotropin secretion by negative feedback regulation; this in turn suppresses spermatogenesis by the testes in the presence of normal or high testosterone levels (i.e., secondary hypogonadism with isolated impairment of sperm production).^{449,450} Use of some androgenic anabolic steroids (e.g., nandrolone) may also produce low gonadotropin levels and isolated reduction in spermatogenesis while providing sufficient androgen activity to avoid clinical androgen deficiency.

Discontinuation of androgen or hCG administration results in restoration of normal gonadotropin secretion and recovery of normal sperm production and testosterone production by the testis. Long-term anabolic steroid abuse in athletes has been reported to be associated with testicular atrophy and severe oligozoospermia or azoospermia that persists for several months to years after discontinuation of the performance-enhancing agents. Suppressed sperm production induced by anabolic steroids may respond to treatment with hCG or with clomiphene citrate (off-label use).^{361,451} Administration of testosterone in combination with progestins in normal men has been the main strategy used to suppress sperm production in recent male contraceptive development trials.⁹⁰

Malignancy. Malignancies that occur commonly in men of reproductive age (e.g., testicular cancer, Hodgkin's disease) manifest with impaired sperm production and function before chemotherapy or radiation therapy in 30% to 80% of cases.²⁷⁸⁻²⁸⁰ Among men with cancer who provided semen samples for cryopreservation before treatment, approximately 64% had abnormal semen parameters and 12% had no viable sperm.⁴⁵²

In population studies, testicular cancer is associated with infertility. This association may reflect abnormal testicular development, termed *testicular dysgenesis syndrome*, caused by exposure to environmental gonadotoxins or endocrine disruptors (e.g., estrogens) or by an underlying genetic predisposition.^{278,453} Testicular dysgenesis syndrome is also associated with cryptorchidism and hypospadias, and the former is associated with an increased risk of testicular cancer and abnormal spermatogenesis. Ectopic hCG secretion and possibly increased scrotal temperature associated with cancer within the testis may also contribute to impaired spermatogenesis in men with testicular cancer.⁴⁵³ Hodgkin's disease and other lymphomas and leukemias may be associated with fever, weight loss, and systemic

inflammation.⁴⁵³ These cancers may also involve the testis. All of these factors may play a role in impairing sperm production. Men with these cancers who have systemic disease, symptoms, or inflammation may present with low-normal testosterone, suppressed gonadotropin levels, and abnormal semen analysis, consistent with secondary hypogonadism causing isolated impairment of sperm production or function.

Hyperprolactinemia. As discussed previously, men with severe hyperprolactinemia (e.g., prolactin levels >200 ng/mL) develop secondary hypogonadism causing androgen deficiency and impaired sperm production. Mild hyperprolactinemia may be associated with isolated impairment of sperm production.⁴⁵⁴ In most of these cases, gonadotropin and testosterone levels are normal and spermatogenesis is not improved with dopamine agonist treatment.⁴⁵⁵ Therefore, hyperprolactinemia does not contribute to impairment in sperm production and probably is not clinically significant in most cases. In most instances, abnormal sperm production and function are caused by a primary testicular disorder, such as idiopathic oligozoospermia or azoospermia. Rarely, some men with moderate hyperprolactinemia (e.g., prolactin levels 100 to 200 ng/mL) have low-normal testosterone and gonadotropin levels and isolated impairment of sperm production that responds to dopamine agonist treatment.⁴⁵⁴

Androgen Resistance Syndromes

Congenital Disorders

Congenital androgen resistance and insensitivity syndromes are usually caused by defects in androgen action due to mutations in the AR gene or in the steroid 5 α -reductase type 2 gene, *SRD5A2*.^{116,127,456,457} Males with severe defects in androgen action present at birth either as phenotypic females, as occurs with *complete androgen insensitivity syndrome* (CAIS, previously known as testicular feminization syndrome), or as males with ambiguous genitalia and 46,XY DSDs (previously termed male pseudohermaphroditism).⁴⁵⁷ Individuals with *partial androgen insensitivity syndrome* (PAIS) present with varying degrees of prepubertal or adult androgen deficiency and mildly to severely disordered male sexual development.

Males with CAIS usually present as females with normal breast development, primary amenorrhea, and absence of body hair.⁴⁵⁷ Severe androgen insensitivity results in absence of male facial, axillary, and pubic hair; normal-appearing female external genitalia and distal two thirds of the vagina; and poorly developed or absent male internal genitalia (prostate, epididymides, seminal vesicles, and vasa deferentia) as a result of fetal androgen insensitivity. In adults with CAIS, female breast development is present due to conversion of normal to high concentrations of testosterone (which are secreted by the testes at puberty) to estradiol, which stimulates breast development. Because testes that are intra-abdominal or inguinal in location secrete AMH during fetal development, female internal genitalia (proximal vagina, uterus, and fallopian tubes) are absent.

There is considerable variation in the presentation of individuals with PAIS.⁴⁵⁷ Some of these males present at birth with ambiguous genitalia, whereas others present at puberty or in adulthood with mild genital abnormalities or relatively normal genital development. Clinical manifestations of androgen deficiency and disordered male sexual development range from severe undervirilization to near-normal virilization with infertility. In men with PAIS,

manifestations that are indicative of disordered sexual development, such as micropallus, hypospadias, scrotal abnormalities (e.g., bifid scrotum), cryptorchidism, and gynecomastia, are common. Gynecomastia is present in almost all of these individuals.

As a result of the variability in clinical manifestations, PAIS encompasses a number of disorders previously referred to as Reifstein, Lubs, Rosewater, and Gilbert-Dreyfus syndromes. For example, Reifstein syndrome is characterized by hypospadias, gynecomastia, undervirilization, a small prostate gland, cryptorchidism, and impaired spermatogenesis. However, even in the same family, different members may have different clinical manifestations. Some family members may not have hypospadias, and others may be normally virilized. Given this degree of variability in manifestations, the older eponyms are not clinically useful.⁴⁵⁷

Some men with PAIS have no evidence of disordered male sexual development and present with isolated impairment of sperm (idiopathic oligozoospermia or azoospermia), occasionally in association with gynecomastia, high to high-normal testosterone levels, and elevated LH levels. This disorder is referred to as *minimal AIS*.^{127,456}

In both CAIS and PAIS, serum testosterone levels are high or high-normal and LH concentrations are elevated, but FSH levels are usually normal. Most men with CAIS or PAIS have autosomal recessive mutations of the AR gene on the X chromosome that alter its primary sequence and structure (almost always resulting in CAIS) or its function, resulting in impaired androgen binding to AR, AR binding to DNA, or AR transactivation.^{127,456} In men with androgen insensitivity syndromes, the correlation of AR genotype and clinical phenotype is relatively poor. In some men with PAIS or minimal AIS, no mutations in AR are identifiable and are possibly due to high CAG repeat length in the AR gene, mutations of *SRD5A2*, or mutations of coactivators or corepressors that regulate AR function.

An increase in the number of trinucleotide CAG repeats in the first exon of the AR gene results in expansion of the polyglutamine tract in the NTD of the AR.¹³⁰ The CAG repeat length is inversely correlated with AR function and action. Pathologic increase to more than 40 to 62 CAG repeats (normal range, 11 to 35) causes Kennedy's disease (SBMA), a rare neurodegenerative disease that is thought to be caused by neurotoxicity from intracellular aggregation of the abnormal AR and associated coregulator proteins (see earlier discussion).^{128,129} Men with Kennedy's disease have clinical manifestations of partial androgen resistance, including gynecomastia, sexual dysfunction, oligozoospermia or azoospermia, and infertility, associated with high testosterone and high or normal gonadotropin levels. Higher CAG repeat numbers within the normal range have been reported to be associated with decreased virilization, impaired spermatogenesis and infertility, and gynecomastia in some studies but not in others.¹³⁰

5 α -Reductase deficiency, caused by an autosomal recessive mutation in *SRD5A2*, is a rare cause of PAIS.¹¹⁶ Affected individuals typically present with markedly ambiguous genitalia, usually characterized by a clitoris-like phallus, a severely bifid scrotum, an apparent vaginal opening with perineal and scrotal hypospadias (termed *pseudovaginal perineoscrotal hypospadias*), an atrophic prostate, and testes located in the inguinal canal or scrotum or sometimes intra-abdominally (cryptorchidism). In contrast to men with androgen insensitivity syndromes, wolffian duct differentiation is unaffected, and patients with 5 α -reductase deficiency have normal epididymides, seminal vesicles, ejaculatory ducts, and vasa deferentia. AMH secretion by

the fetal testes causes regression of müllerian duct structures, so no female internal genitalia develop.

Because ambiguous genitalia resemble female more than male external genitalia, individuals with 5 α -reductase deficiency are usually raised as females.¹¹⁶ However, with the marked increase in testosterone production by the testes at puberty, partial virilization occurs (i.e., penile growth, rugation and pigmentation of the scrotum, increased muscle mass and height, deepening of the voice, increase in libido, and spontaneous erections), and some of these individuals take on a male gender role at puberty, depending on complex psychosocial factors and cultural background. Sebaceous gland production is normal in these men. Because normal androgen action in the skin and prostate requires conversion of testosterone to DHT by 5 α -reductase, men with 5 α -reductase deficiency do not develop a male body hair pattern, and the prostate gland remains nonpalpable. Prostate cancer and BPH have not been reported in these men.

Men with 5 α -reductase deficiency have high-normal to high serum testosterone, elevated LH, and normal to elevated FSH levels. Serum DHT levels are low. Spermatogenesis is impaired (oligozoospermia or azoospermia) as a result of cryptorchidism, but normal sperm production has been reported in some men with descended testes.

Individuals with CAIS are usually raised as females and undergo orchidectomy (particularly if cryptorchidism is present) and treatment with estrogen replacement.⁴⁵⁷ In men with PAIS or 5 α -reductase deficiency, virilization has been induced with high-dose testosterone treatment, which increases serum testosterone concentrations to above the normal range and normalizes DHT levels.⁴⁵⁷

Acquired Disorders

AR antagonists (flutamide, bicalutamide or nilutamide) induce androgen resistance and are used to treat androgen-dependent prostate cancer.⁴⁵⁸ Drugs such as spironolactone, cyproterone acetate, marijuana, and H₂ receptor antagonists (specifically cimetidine) have AR antagonist activity.⁴⁵⁹⁻⁴⁶³

Men with *celiac disease* or gluten-sensitive enteropathy may experience manifestations of androgen deficiency, including reduced virilization, sexual dysfunction, impaired sperm production and function, and infertility. They may also demonstrate high to high-normal levels of serum total and free testosterone and high LH levels, indicative of androgen resistance.⁴⁶⁴⁻⁴⁶⁶ Manifestations of androgen deficiency and biochemical androgen resistance may improve with dietary gluten restriction and improvement in small bowel atrophy in some men.⁴⁶⁶ Malnutrition, nutritional deficiencies, chronic systemic illness, and hyperprolactinemia may occur in men with celiac disease and may contribute to their clinical manifestations. Serum DHT concentrations may be low despite high testosterone levels in men with celiac disease, suggesting that partial 5 α -reductase deficiency may also be present and may play a role in androgen resistance. The main source of circulating DHT is from conversion of testosterone to DHT by 5 α -reductase type 1 in skin.⁴⁶⁵ However, 5 α -reductase is also present in the gut, so it is possible that loss of enzyme activity in the small bowel with active celiac sprue contributes to low DHT levels.

Treatment of Androgen Deficiency

Treatment of Reversible Causes

As detailed earlier, it is important before starting testosterone treatment of androgen deficiency to consider whether

a low serum testosterone level might represent transient suppression caused by a critical, acute, or subacute illness or recovery from an acute illness; short-term use of certain medications; transient malnutrition (e.g., associated with illness); or excessive and chronic strenuous endurance exercise. In these clinical situations, serum testosterone measurements and therapy should be delayed until the patient has recovered completely from illness, offending drugs have been discontinued, malnutrition has been corrected, or excessive exercise has been stopped.¹¹⁰

Testosterone Replacement Therapy

Therapeutic Goals and Management. The overall goal of testosterone replacement therapy is to correct or improve the clinical manifestations of androgen deficiency in men with primary or secondary hypogonadism. Because specific manifestations vary with the stage of sexual development, the specific goals of testosterone treatment vary depending on whether the patient is a prepubertal boy or an adult.^{6,110}

In boys with prepubertal androgen deficiency and delayed puberty, the goals of testosterone treatment are the following^{136,303,304}:

- To induce and maintain secondary sexual characteristics, including growth of the penis and scrotum, and a male body hair pattern
- To increase muscle mass and strength
- To stimulate BMD, acquisition of peak bone mass, and long bone growth without compromising adult height by inducing premature closure of epiphyses
- To stimulate libido and spontaneous erections
- To improve energy, mood, and motivation
- To induce laryngeal enlargement and deepening of the voice
- To increase red blood cell production into the normal adult male range

Testosterone treatment also stimulates the growth of accessory sex glands (seminal vesicles and prostate), resulting in seminal fluid production and an increase in ejaculate volume, but it does not stimulate sperm production to a degree sufficient for induction of fertility. The most common cause of delayed puberty is not a pathologic condition but rather CDGP. Testosterone therapy in boys who present with delayed puberty is usually of low dosage to avoid premature epiphyseal closure and compromise of adult height, and it is given intermittently until spontaneous puberty occurs (see later discussion). If spontaneous puberty does not occur, the testosterone dose is increased gradually to adult levels.^{136,303,304}

The goals of testosterone therapy in adults with hypogonadism are the following^{6,110}:

- To improve sexual function and activity by restoring libido and improving erectile function
- To increase muscle mass and strength, potentially improving physical function and performance
- To increase BMD, potentially reducing the risk of fractures
- To improve energy, vitality, mood, and motivation
- To increase hematocrit into the normal adult male range
- To restore male hair growth

Recent-onset gynecomastia that is usually symptomatic may respond to testosterone treatment, but severe or long-standing gynecomastia requires surgical excision. Spermatogenesis requires relatively high intratesticular concentrations of testosterone that cannot be achieved by exogenous androgen administration. Therefore, testosterone replacement therapy does not stimulate sperm production or testis size, nor does it restore fertility. Treatment of

infertility in hypogonadal men is usually possible only in those men with secondary hypogonadism and gonadotropin deficiency; gonadotropin or GnRH therapy is used.⁴⁶⁷

The normal adult range of serum testosterone levels is broad and is usually based on results in healthy young men using blood samples drawn in the morning. In young men with androgen deficiency, testosterone replacement therapy produces beneficial clinical effects as serum testosterone concentrations are increased into this normal range. Serum testosterone levels decline gradually and progressively with age, but the physiologic significance of this age-related decline is unclear. Initial studies in older men with low serum testosterone levels demonstrated some clinical beneficial effects with testosterone treatment that increased testosterone levels into the normal young adult range. Therefore, the goal of testosterone treatment of hypogonadism is to restore serum testosterone concentrations to within the normal adult range, irrespective of age.¹¹⁰

The dose-response effects of testosterone vary in different target organs and for different clinical outcomes.⁴⁶⁸ For example, the action of testosterone on muscle mass demonstrates a continuous dose-response relationship. With testosterone administration, muscle mass increases when testosterone levels are increased from below normal to within the normal range, and it continues to increase as levels are raised from within to above the normal range. In contrast, the actions of testosterone on libido exhibit threshold dose-response characteristics: testosterone administration increases libido when serum testosterone concentrations are increased from low to low-normal levels but does not continue to stimulate libido further as serum testosterone is increased to normal or supraphysiologic levels.

In men with severe, long-standing androgen deficiency, testosterone replacement therapy induces profound alterations in sexuality, behavior, and physical appearance that may be upsetting to patients and their partners and may result in serious adjustment problems. To reduce the likelihood of problems, it is important to inform and counsel hypogonadal men and their partners regarding changes in body characteristics and behavior that are expected during testosterone replacement therapy. In some men with severe, long-standing hypogonadism, initiation of testosterone replacement with a low-dose regimen (e.g., testosterone enanthate or cypionate 100 mg every 2 weeks, testosterone patch 2.5 mg daily, testosterone gel 2.5 g daily) for several months, followed by an increase to full testosterone replacement, may produce a more gradual symptomatic transition from hypogonadism to eugonadism and may result in fewer adjustment difficulties.⁵²³

Because the metabolic clearance rate of testosterone is reduced in older men with hypogonadism, therapeutic testosterone levels may be achieved with lower doses of testosterone.⁴⁶⁹ In some clinical situations, such as severe symptomatic BPH or the presence of a number of comorbid illnesses, full testosterone replacement may be ill advised. In these instances, low-dose testosterone supplementation (e.g., testosterone enanthate or cypionate 50 mg to 100 mg IM every 2 weeks, testosterone patch 2.5 mg daily, testosterone gel 2.5 g daily) may be more prudent than full testosterone replacement therapy. Low doses of testosterone may be sufficient to induce some beneficial effects while minimizing potential adverse stimulatory effects on prostate growth.

The potential effectiveness of low-dose testosterone supplementation is suggested by studies of short-acting testosterone formulations (testosterone undecanoate and cyclodextrin) that produced anabolic effects despite serum

testosterone concentrations that were not sustained within the normal range.^{470,471} An analogy may be made to the use of hydrocortisone for glucocorticoid replacement therapy, in which the duration of biologic action of hydrocortisone on tissues is not reflected by its serum concentrations. Short-term administration of low-dose testosterone enanthate (50 mg/week IM) was found to increase muscle strength and power in some young men in whom hypogonadism was induced by concomitant GnRH agonist treatment.⁴⁷²

Hypogonadism due to gonadotropin deficiency may be caused by hypothalamic-pituitary disease that requires specific management in addition to testosterone replacement. Therefore, careful evaluation to determine the cause of secondary hypogonadism should be performed before testosterone treatment is started. For example, pituitary or hypothalamic tumors may cause mass effects such as visual field defects, or they may be associated with deficiency or excessive secretion of other pituitary hormones. These tumors may require surgery or radiation therapy, additional hormonal replacement, medical therapy, or some combination of these treatments to reduce excessive pituitary hormone secretion. In some cases, treatment of the underlying cause of secondary hypogonadism corrects the androgen deficiency (e.g., stopping a medication that causes hyperprolactinemia or gonadotropin deficiency). In men with gonadotropin deficiency and normal testes who are interested in fathering children, gonadotropin therapy may be used instead of testosterone replacement to stimulate sperm production, restore fertility, and correct androgen deficiency. Similarly, men with secondary hypogonadism due to hypothalamic disease may be treated with pulsatile GnRH to stimulate testosterone and sperm production and restore fertility.

A comprehensive clinical approach is important for optimal management of hypogonadism. It is important to consider etiologies other than androgen deficiency that might contribute to clinical manifestations and to manage them appropriately. In hypogonadal men who complain primarily of sexual dysfunction, an underlying neurovascular disease or use of certain medications is usually the major cause of erectile dysfunction. In these men, testosterone treatment alone is insufficient to completely restore erections and permit satisfactory sexual intercourse. Additional treatment with a type 5 phosphodiesterase inhibitor (sildenafil, vardenafil, or tadalafil), intracavernosal or intraurethral PE₁ (alprostadil [Muse]), or a penile vacuum device may be needed for a satisfactory clinical outcome. In hypogonadal men who present with osteoporosis, it is critical to perform a thorough evaluation for other common causes of bone loss (e.g., vitamin D deficiency, alcohol abuse, smoking, medications, inactivity, primary hyperparathyroidism) and to treat them as well. It is also important to institute measures to prevent falls to reduce the risk of fractures.

Testosterone Formulations. Testosterone formulations that are used to treat male hypogonadism are summarized in Table 19-10.^{6,110} In the United States, these include parenteral testosterone esters that are administered by IM injection, a transdermal testosterone patch and testosterone gels, and a transbuccal testosterone tablet.

Oral 17 α -alkylated testosterone derivatives, such as methyltestosterone and fluoxymesterone, should not be used for testosterone replacement therapy.⁶ It is difficult to achieve full androgen replacement with these oral formulations because they are weak androgens that have low bioavailability. They also have the potential for serious

TABLE 19-10

Treatment of Adult Male Hypogonadism

Formulation	Dosage	Advantages	Disadvantages
TREATMENT OF ANDROGEN DEFICIENCY			
Formulations Available in the United States			
Parenteral Testosterone Esters Testosterone enanthate or cypionate, IM injections	<i>Adults:</i> 150-200 mg IM every 2 wk or 75-100 mg IM every wk. <i>Prepubertal boys:</i> 50-100 mg monthly or 25-50 mg every 2 wk, increasing to 50-100 mg every 2 wk and then to adult replacement dosage over 2-4 yr OR until spontaneous pubertal development occurs	Extensive clinical use Inexpensive with self-injection Some dose flexibility	IM injections, discomfort Symptomatic fluctuation of T levels (supraphysiologic after injection to low-normal or low before next injection) Frequent IM injections to reduce fluctuations of T levels More erythrocytosis than with transdermal T
Transdermal Testosterone Testosterone patch (nonscrotal)	2.5 or 5 mg (one patch) or 7.5 mg or 10 mg (one 2.5-mg plus 5.0-mg patch or two 5-mg patches) applied daily over non-pressure areas	Low- to mid-normal physiologic T levels Mimics normal circadian variation when applied nightly No injections Less erythrocytosis than with parenteral T Rapid withdrawal of T replacement if adverse effects occur	Frequent skin irritation Low-normal T levels: Two patches may be needed Skin adhesion poor with excessive sweating Daily application More expensive than parenteral T
Testosterone gels (1%)	5-10 g of gel (delivering 5-10 mg of T) applied daily over shoulders or trunk Available in foil sachets of 2.5 or 5.0 g, tubes of 5 or 10 g, and metered-dose pumps delivering 1.25 g per pump depression	Low- to high-normal steady-state physiologic T levels No injections Little skin irritation Dose flexibility Rapid withdrawal of T replacement if adverse effects occur	Potential for contact transfer of T to women or children Daily application More expensive than parenteral T, especially with higher doses Moderately high DHT levels One formulation has a musk odor and another is associated with stickiness or skin dryness Slight skin irritation in some men
Transbuccal testosterone	30 mg tablet applied between cheek and gum bid	Mid-normal steady-state physiologic T levels No injections, patch or gel application, or their associated disadvantages Rapid withdrawal of T replacement if adverse effects occur	Twice-daily application Gum irritation or inflammation Altered or bitter taste High learning curve; requires careful instruction or poor acceptability occurs Tablets may be difficult to remove or may fall off prematurely No dose flexibility Moderately high DHT levels More expensive than parenteral T
Testosterone pellets	2-6 pellets (each 8-9 mm containing 75 mg of T) implanted SQ every 3-6 mo	Maintenance of normal T levels for a longer duration	Requires surgical incision Extrusion, bleeding, and infection can occur uncommonly Large number of pellets Not easily removed; fibrosis may occur Lack of ability for rapid withdrawal of T replacement if adverse effects occur Infrequent use
Testosterone Formulations Available Outside the United States			
Oral testosterone undecanoate	40-80 mg PO with meals bid to tid	Oral administration is convenient for many	Twice- or thrice-daily administration Variable T levels and clinical responses Requires administration with meal High DHT levels
Parenteral testosterone undecanoate	1000 mg IM initially and at 6 wk, then 1000 mg IM every 10-14 wk	Less frequent IM injections Maintenance of normal T levels for a longer duration No apparent fluctuations in T levels or symptoms	IM injections, discomfort Large-volume injection (4 mL) Self-injection not possible Rarely, cough immediately after injection Prolonged maintenance of T level after discontinuation for adverse effects
Testosterone-in-adhesive matrix patch	Two patches (delivering 4.8 mg of T per day) applied every 2 days	Low- to mid-normal physiologic T levels Duration 2 days No injections	Some skin irritation Two patches needed

Table continued on following page

TABLE 19-10

Treatment of Adult Male Hypogonadism (Continued)

Formulation	Dosage	Advantages	Disadvantages
Testosterone gel 2%	3-4 g (60-80 mg of T) applied to abdomen or both inner thighs daily	Low-normal to high-normal steady-state physiologic T levels No injections Little skin irritation Dose flexibility Rapid withdrawal of T replacement if adverse effects occur	Potential for contact transfer of T to women or children Daily application
TREATMENT TO INITIATE AND MAINTAIN SPERM PRODUCTION IN MEN WITH HYPOGONADOTROPIC HYPOGONADISM			
Initially to Stimulate Testosterone and Potentially Sperm Production			
Human chorionic gonadotropin (hCG)	500-2000 IU given SQ 2-3 times weekly to maintain serum T levels within the normal range for 6-12 mo	Effective in stimulating endogenous T production In men with acquired and some men with partial congenital hypogonadotropic hypogonadism, sperm production may be stimulated with hCG treatment alone SQ injections easier than IM injections (smaller needle, injection not as deep) Less fluctuation in T levels compared with IM T ester injections No injection, patch, or buccal tablet	Injections 2-3 times weekly Expensive Higher doses needed in men with concomitant primary testicular disease (e.g., cryptorchidism) Breast tenderness or gynecomastia secondary to high estradiol production by testes May require dilution Occasional burning sensation with injection Ineffective in primary hypogonadism
Added to hCG to Stimulate Sperm Production			
FSH Human menopausal gonadotropin (hMG), human FSH (hFSH), or recombinant human FSH (rhFSH)	After 6-12 mo of hCG treatment alone resulting in normal T levels, add FSH 75-300 IU is given SQ three times weekly for an additional 6-12 mo or longer	Effective in stimulating sperm production in men with hypogonadotropic hypogonadism	Injections 3 times weekly Extremely expensive, prohibitive cost for most Breast tenderness or gynecomastia secondary to high estradiol production by testes May require dilution Occasional burning sensation with injection In men with concomitant primary testicular disease (e.g., cryptorchidism), stimulation of spermatogenesis is not likely
To Stimulate Testosterone and Sperm Production			
Gonadotropin-releasing hormone (GnRH)	5-25 ng/kg SC every 2 hr by programmable infusion pump for 6-12 mo	Effective in stimulating both endogenous T and sperm production	GnRH not readily available Requires pump use and management, usually in a specialized center Expensive Infrequently used except at certain sites Rarely, local irritation, infection

DHT, dihydrotestosterone; FSH, follicle-stimulating hormone; IM, intramuscular; SQ, subcutaneous; T, testosterone.

hepatotoxicity.³⁶⁰ 17 α -Alkylated androgens most commonly cause cholestasis that is reversible with discontinuation. More concerning is the potential for these agents to cause peliosis hepatis (blood-filled cysts in the liver) or benign or malignant hepatic tumors. 17 α -Alkylated androgens also lower HDL- and raise LDL-cholesterol, causing a pro-atherogenic lipid profile, and they are relatively expensive. Therefore, these oral androgens carry greater potential risks with few therapeutic benefits compared with other testosterone formulations, and they should not be used to treat male hypogonadism.

Parenteral Testosterone Esters. Relatively long-acting parenteral 17 β -hydroxyl esters of testosterone, *testosterone enanthate* and *testosterone cypionate*, are administered by IM injection. These are effective, safe, and relatively practical and inexpensive preparations that have been used for testosterone replacement in hypogonadal men for decades.

Transdermal testosterone gel formulations provide more physiologic testosterone levels and are now used more commonly than testosterone ester injections. However, testosterone esters are preferred over transdermal formulations by some hypogonadal men because they are the least expensive formulation available, require less frequent administration, and usually produce higher average serum testosterone concentrations. Given proper instruction, most hypogonadal men (or a family member) are able to self-administer IM testosterone ester injections. Otherwise, testosterone injections need to be administered in a clinic setting.

Esterification of testosterone at the 17 β -hydroxyl group increases its hydrophobicity and solubility within an oil vehicle (sesame oil for testosterone enanthate, cottonseed oil for testosterone cypionate). After IM injection, testosterone esters are released slowly from the oil vehicle within

muscle and hydrolyzed rapidly to testosterone, which is released into circulation, resulting in relatively high peak serum testosterone concentrations but an extended duration of release. Testosterone enanthate and testosterone cypionate have similar pharmacokinetic profiles, duration of action, and therapeutic efficacy, so they are considered clinically equivalent.^{473,474}

In adults with hypogonadism, the usual starting dose of testosterone enanthate or cypionate is 150 mg to 200 mg IM every 2 weeks. After IM administration of 200 mg of testosterone enanthate, serum testosterone levels usually rise above the normal range for 1 to 3 days and then decline gradually over 2 weeks to the lower end of the normal range, or sometimes to below-normal levels, before the next injection (Fig. 19-29).^{475,476} The extreme rise and fall of serum testosterone concentrations may cause fluctuations in energy, mood, and libido that are disturbing to

some men. Shortening the dosing interval to every 10 days and reducing the dose to 150 mg (i.e., 150 mg IM every 10 days) may alleviate symptoms associated with nadir testosterone levels occurring before the next injection. Alternatively, some patients prefer changing the dose of testosterone enanthate or cypionate to 75 to 100 mg IM every week to reduce swings in testosterone concentrations and associated symptoms. Administration of testosterone enanthate at doses of 300 mg IM every 3 weeks or 400 mg IM every 4 weeks produces extremely wide fluctuations in serum testosterone concentrations with markedly supraphysiologic levels for several days after an injection and levels below normal 3 weeks after an injection (see Fig. 19-29).^{475,476}

Because CDGP in which puberty eventually occurs spontaneously is clinically indistinguishable from delayed puberty caused by permanent hypogonadotropic hypogonadism (e.g., IHH),^{136,303,304} testosterone treatment usually

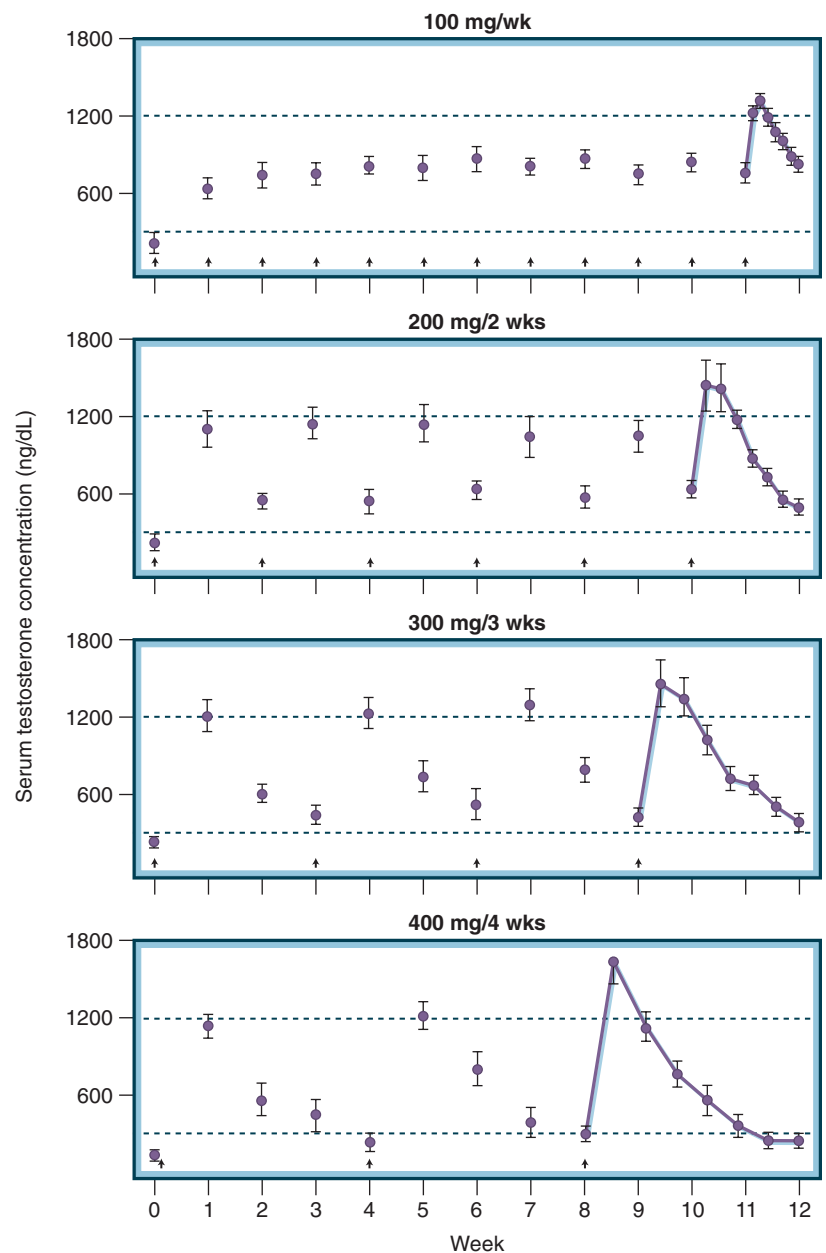

Figure 19-29 Serum total testosterone concentrations in men with primary hypogonadism treated with intramuscular injections of testosterone enanthate for 12 weeks at a dose of 100 mg weekly, 200 mg every 2 weeks, 300 mg every 3 weeks, or 400 mg every 4 weeks. Blood was sampled weekly until the last injection, after which it was sampled more frequently, demonstrating that the optimal dosage to maintain serum testosterone levels within the normal range (dashed lines) is every 200 mg every 2 weeks or 100 mg every week. (From Snyder PJ, Lawrence DA. Treatment of male hypogonadism with testosterone enanthate. *J Clin Endocrinol Metab.* 1980;51:1335-1339.)

is not initiated in boys with prepubertal androgen deficiency until they are about 14 years of age (with a bone age of at least 10.5 years). Testosterone therapy is administered intermittently to allow determination of spontaneous puberty, if it occurs. Occasionally, testosterone therapy is started at a younger age if delayed genital development and growth is causing severe psychological distress in affected boys and their families.

In boys with prepubertal androgen deficiency, treatment is initiated with a very low dose of testosterone enanthate or cypionate (e.g., 50 to 100 mg IM monthly or 25 to 50 mg every 2 weeks) to prevent premature closure of long bone epiphyses that would compromise adult height.^{136,303,304} These low doses of testosterone are sufficient to induce some virilization and long bone growth without interfering with the spontaneous puberty that occurs eventually in boys with CDGP. Testosterone treatment is continued for 3 to 6 months and then stopped for 3 to 6 months to assess whether spontaneous pubertal onset occurs. If there is indication that spontaneous puberty is occurring (e.g., testes size is >8 mL), testosterone therapy is discontinued. If there is no evidence of spontaneous puberty, intermittent testosterone treatment is continued. The dose of testosterone enanthate or cypionate is increased gradually to 50 to 100 mg IM every 2 weeks and then to full adult replacement doses over the next several years to mimic the gradual increase in testosterone concentrations that occurs during puberty.

At present, transdermal testosterone formulations are not approved for use in boys with delayed puberty. However, because they circumvent the need for IM injections, low-dose transdermal testosterone patches and gels would provide very useful alternatives for the treatment of prepubertal androgen deficiency in boys, and they are currently being tested for this indication.

Transdermal Testosterone. Transdermal testosterone formulations available for testosterone replacement therapy for male hypogonadism include an adhesive testosterone patch and two 1% testosterone gels (see Table 19-10). Transdermal delivery of testosterone is used in hypogonadal men who prefer this method or are unable to tolerate or self-administer IM injections of testosterone ester. Testosterone gel is the most frequently used formulation for treatment of male hypogonadism in the United States.

In contrast to testosterone ester injections, which produce transient supraphysiologic testosterone levels, patch and gel formulations produce a more physiologic range of testosterone concentrations; use of the patch results in a normal circadian variation, and the gel formulations produce steady-state serum testosterone levels.

Testosterone stimulates red blood cell production, and testosterone replacement therapy may result in excessive erythrocytosis. In men with hypogonadism, excessive erythrocytosis occurs less commonly with testosterone patch therapy than with testosterone enanthate injections, suggesting that physiologic testosterone levels produced by transdermal testosterone therapy may be associated with fewer androgenic adverse effects.⁴⁷⁷ Compared with testosterone ester injections, transdermal formulations have a short half-life in subcutaneous tissue and in the circulation; consequently, their discontinuation results in a rapid fall in serum testosterone concentrations and a shorter duration of action. Therefore, an advantage of transdermal testosterone is the ability to withdraw androgen replacement relatively rapidly if adverse effects such as excessive erythrocytosis develop or prostate cancer is detected.

Disadvantages of transdermal formulations include the requirement for daily application, greater expense

compared with testosterone ester injections, skin irritation or rash with testosterone patches⁴⁷⁸ (less common with testosterone gels), and the potential with gel formulations for transfer of testosterone to others through skin contact at the application site.

The first transdermal testosterone delivery system for treatment of male hypogonadism was a scrotal testosterone patch.⁴⁷⁹ Treatment required daily application of two relatively large, nonadhesive patches to clean, dry, and preferably shaven scrotal skin and the use of brief-style underwear to hold them in place. These requirements were not acceptable to some hypogonadal men. Also, in some men with long-standing, severe prepubertal androgen deficiency, the scrotum was too small to accommodate even the smaller-sized testosterone patch. Because of poor adherence to scrotal skin, thin adhesive strips were added as an option to this patch. Some men using this testosterone patch experienced skin irritation and itching. The scrotal testosterone patch produced serum DHT levels in the upper-normal range or above the normal range as a result of high 5 α -reductase activity within sexual skin of the scrotum. The nonscrotal testosterone patch and testosterone gels have supplanted the scrotal testosterone patch for testosterone replacement therapy, and it is no longer available in the United States.

A nonscrotal testosterone patch, *Androderm* (Watson, Corona, CA), is available for testosterone replacement therapy in male patients with hypogonadism.⁴⁸⁰ This patch is composed of a central reservoir containing testosterone and permeation enhancers in an alcohol-based gel surrounded by an adhesive patch that is applied to the skin of the back, abdomen, upper arms, or thighs, avoiding areas over a bony prominence. When applied at night, the testosterone patch produces serum testosterone levels that peak in the morning, mimicking the circadian variation of endogenous testosterone concentrations in normal men. *Androderm* patches are available in two sizes, delivering either 2.5 mg (37 cm²) or 5 mg (44 cm²) of testosterone daily. Long-term use of the testosterone patch usually maintains serum testosterone levels within the mid- to low-normal range and improves the clinical manifestations of androgen deficiency. Usually, to achieve consistent mid- to high-normal testosterone concentrations, application of two patches is necessary—either one 2.5-mg patch plus one 5-mg patch or two 5-mg patches.⁴⁸¹

The major limitation of *Androderm* is skin irritation or rash of varying severity; this side effect occurs in at least 30% to 60% of patients.⁴⁷⁸ Mild to moderate erythema and irritation are almost always present, probably because of a skin reaction to the permeation-enhancing agent or adhesive. Uncommonly, severe contact dermatitis or burn-like skin reactions occur. Pretreatment of the skin under the reservoir of the patch with a topical corticosteroid such as triamcinolone acetonide 0.1% cream reduces the incidence and severity of skin irritation produced by testosterone patches.⁴⁸²

Two transdermal formulations containing testosterone in a 1% hydroalcoholic gel, *AndroGel* (Abbott, Abbott Park, Ill.) and *Testim* (Auxilium, Norristown, Penn.), are available for testosterone replacement therapy in hypogonadal men.⁴⁸³ *AndroGel* was the first testosterone gel formulation to be marketed, and it has rapidly become the testosterone formulation most frequently used for treatment of male hypogonadism in the United States.

AndroGel is dispensed into the palm of the hand and applied daily in the morning to clean, dry skin over the shoulders and upper arms or the abdomen and flanks but not on the scrotum.⁶ The alcohol-based gel dries rapidly after application, and testosterone is absorbed into the

subcutaneous space, where it is released steadily over the remainder of the day, producing relatively steady-state testosterone levels. Residual testosterone remains on the surface of the skin of the hands and at the sites of application. Therefore, the hands should be washed with soap and water after application, the sites of gel application should be covered with clothing, and skin contact with these sites by others (especially women and children) should be avoided to prevent transfer of testosterone.⁴⁸⁴ Residual testosterone on the skin at application sites may be washed off (e.g., by showering or bathing), but this should be avoided for the first 5 to 6 hours after application (or 1 to 2 hours if done infrequently) to maximize testosterone absorption.

Long-term use of AndroGel in hypogonadal men maintains steady-state physiologic serum testosterone concentrations and improves the clinical manifestations of androgen deficiency (Fig. 19-30).^{183,485-487} AndroGel is available in foil sachets at two different doses: 2.5 g of gel containing 25 mg of testosterone or 5 g of gel containing 50 mg of testosterone. (Because only about 10% of the medication is absorbed, these sachets deliver, respectively, 2.5 mg or 5.0 mg of testosterone.) The starting dose of AndroGel is 5 g daily. Based on testosterone levels or clinical response approximately 2 weeks after initiation of therapy, the dose may be increased to 7.5 g (i.e., one 2.5 g packet plus one 5.0 g packet) or to 10.0 g (two 5.0 g packets) daily or decreased to 2.5 g daily. A metered-dose pump delivering increments of 1.25 g of AndroGel per pump depression is also available to provide greater flexibility in dose adjustment.

In contrast to testosterone patches, local skin irritation with testosterone gel formulations is relatively uncommon, occurring in fewer than 5% of men, and is probably related mostly to drying of the skin by the alcohol. Some men complain of stickiness of the skin after the alcohol-based gel dries. AndroGel produces serum DHT levels at the upper end or above the normal range as a result of 5 α -reductase activity in the relatively large surface area of skin over

which the gel is applied. A major limitation to the use of AndroGel for testosterone replacement therapy is its expense, particularly if more than one packet is needed daily for adequate testosterone replacement. The cost may be prohibitive for patients who do not have adequate third-party medication coverage.

Testim is the other 1% hydroalcoholic testosterone gel that is available for treatment of male hypogonadism.⁴⁸⁸ It is applied daily in the morning to intact, clean, dry skin over the shoulders and arms but not over the abdomen or on scrotal skin. Like AndroGel, Testim produces steady-state testosterone levels over 24 hours and has the potential for contact transfer of residual testosterone on the skin surface at application sites. Similar precautions are recommended to prevent contact transfer, and washing off of residual testosterone on the skin surface should be avoided for at least 2 hours to maintain normal testosterone levels.

In short-term, placebo-controlled trials, Testim maintained steady-state physiologic serum testosterone levels in hypogonadal men and improved the clinical manifestations of androgen deficiency.⁴⁸⁹ After the initial application of Testim, serum testosterone levels are approximately 30% higher than those achieved after application of AndroGel. However, no direct comparison of steady-state testosterone levels with long-term use of the two testosterone gels is available.⁴⁸⁹

Testim is packaged in two doses, a 5-g tube containing 50 mg of testosterone and a 10-g tube containing 100 mg of testosterone; these deliver approximately 5 mg and 10 mg of testosterone, respectively (i.e., 10% absorption). The starting dose of Testim is 5 g daily. Based on testosterone levels or clinical response approximately 2 weeks after initiation of therapy, the dose may be increased to 10 g daily. In contrast to AndroGel, Testim is not available in a dose of 2.5 g or in a metered-dose dispenser, limiting dose adjustments with this formulation.

Although AndroGel is odorless, Testim has a musk-like scent. Depending on the individual patient and his partners, this odor may be thought of as pleasant or objectionable. Testim contains a skin emollient and is less drying to the skin than AndroGel. However, both testosterone gels are tolerated well with very little skin irritation compared to the testosterone patch. Like AndroGel, Testim produces high-normal to slightly high serum DHT levels and is expensive.

Recently, two new transdermal formulations for the treatment of male hypogonadism were approved in the United States: *Fortesta* (Endo Pharmaceuticals, Chadds Ford, Penn.) is a 2% testosterone gel that is applied to the inner thighs at a dosage of 40-70 mg daily by a metered-dose pump that delivers 10 mg per pump depression. *Axiron* (Eli Lilly, Indianapolis, Ind.) is a 2% testosterone solution that is applied to axillary skin at a dosage of 30-120 mg daily by a metered-dose pump applicator that delivers 30 mg per pump depression.

Transbuccal Testosterone. A transbuccal testosterone tablet, *Striant* (Columbia Laboratories, Livingston, NJ), is available for testosterone replacement therapy in hypogonadal men (see Table 19-10).^{490,491} This formulation is a small mucoadhesive tablet that contains 30 mg of testosterone in an oil-water emulsion carrier vehicle. The tablet contains polycarbophil, which, after application, remains attached to buccal mucosa until epithelial cells turn over (approximately 12 to 15 hours). The tablet is placed in the mouth between the inner cheek and gum, above the incisors, with the monoconvex side toward the gum and the flat side toward the cheek. After placement, the tablet softens and swells with hydration and becomes gelatinous and sticky, causing it to adhere to the gum. Testosterone is released at

Figure 19-30 Serum total testosterone (T) levels after application of T-gel 50 mg (5 g of gel containing 50 mg of T and delivering approximately 5 mg of T) daily, or T-gel 100 mg (10 g of gel containing 100 mg of T and delivering approximately 10 mg of T) daily, or two T patches (delivering a total 5 mg of T) daily in hypogonadal men treated for 90 days. All three treatments achieved T levels within the low-normal, mid-normal, and upper-normal range (dashed lines) over the first 24 hours after application. (From Swerdloff RS, Wang C, Cunningham G, et al. Long-term pharmacokinetics of transdermal testosterone gel in hypogonadal men. *J Clin Endocrinol Metab*. 2000;85:4500-4510.)

a controlled and sustained, constant rate from the tablet through the buccal mucosa into the systemic circulation, circumventing first-pass hepatic metabolism.

Striant tablets are placed on the buccal mucosa twice daily, with one tablet applied in the morning and removed after 12 hours and another applied in the evening on the opposite side.^{490,491} Use of Striant requires careful instruction to orient the tablet with the rounded side against the gum and to hold it firmly in place with a finger over the lip for approximately 30 seconds. If the tablet falls off or is dislodged, a new tablet should be applied and left in place until the next regularly scheduled dose. Swallowing of the tablet is not harmful. The buccal tablet is removed by gently sliding it downward toward the incisor to avoid scratching the gum.

Application of a Striant tablet containing 30 mg of testosterone every 12 hours produces average steady-state testosterone levels in the mid-normal range throughout the day.^{490,491} Although a formal study has not been conducted, unrestricted intake of food and beverage (including alcohol), tooth-brushing, mouth-washing, and gum-chewing did not appear to affect the absorption of testosterone in pharmacokinetic studies. Contact transfer of testosterone in saliva to others has not been reported to occur. Like the transdermal testosterone gels, Striant produces high-normal to high serum DHT concentrations, probably because of 5 α -reductase activity in the buccal mucosa. In general, transbuccal testosterone tablets are tolerated well. Approximately 10% to 15% of men developed gum or mouth irritation or inflammation, and 5% experienced an altered or bitter taste in the mouth.⁴⁹⁰

Like the transdermal testosterone formulations, Striant is relatively expensive compared with testosterone ester injections. Initially, patients are aware and bothered by the tablet between their cheek and gum, resulting in premature discontinuation of the formulation. However, with continued use, the unusual sensation and awareness of the buccal tablet diminishes and it becomes less bothersome. Twice-daily application of Striant is required to sustain physiologic testosterone levels, and this makes compliance challenging. Informing patients that awareness of the buccal tablet diminishes over time and linking application of the transbuccal tablet to a routine daily activity such as morning and evening tooth-brushing may help to improve and maintain compliance.

Testosterone Pellets. Subcutaneous testosterone pellets are used infrequently in the United States but more commonly in Australia and some European countries for testosterone replacement therapy in men with hypogonadism.^{492,493} In the United States, *Testopel Pellets* (Slate Pharmaceuticals, Durham, NC) are available for testosterone replacement (see Table 19-10). These are cylindrically shaped pellets, 3.2 mm diameter by 8 to 9 mm in length, that contain 75 mg of testosterone. Testopel Pellets are used at doses that range from 225 to 450 mg (i.e., three to six 75-mg pellets) and are implanted every 3 to 4 months.⁴⁹²

Pharmacokinetic profiles for testosterone pellets depend on the specific pellet formulation.^{493,494} In European studies using a different formulation, subcutaneous implantation of three to six 200-mg pellets (for a total of 600 to 1200 mg of testosterone) produced the almost zero-order, sustained release of testosterone and maintained steady-state physiologic serum testosterone levels for 4 to 6 months in hypogonadal men.⁴⁹⁴ Testosterone pellets are implanted subcutaneously with the use of a trocar that is introduced through a small skin incision. This minor surgical procedure is repeated two to three times yearly to maintain normal serum testosterone levels.

Although spontaneous extrusion of pellets and local bleeding or infection may occur occasionally, these are uncommon in experienced hands. If adverse effects develop after implantation, a major concern is that removal of the testosterone pellets will be difficult, if not impossible. Therefore, the use of testosterone pellets is inappropriate for testosterone replacement in older patients, who are predisposed to erythrocytosis and prostate disease during treatment, and is not an acceptable formulation for many physicians and patients.

Testosterone Formulations Available Outside the United States

Oral Testosterone Undecanoate. In many countries outside the United States, an oral 17 β -hydroxyl ester of testosterone, testosterone undecanoate (Andriol Testocaps; Organon, Oss, Netherlands), is available to provide testosterone replacement therapy in hypogonadal men.^{495,496} Testosterone undecanoate, which is formulated in a castor oil vehicle, is absorbed directly from the gastrointestinal tract into the lymphatic system and then into the systemic circulation, thereby avoiding first-pass hepatic accumulation and inactivation. Serum testosterone concentrations peak approximately 5 hours after administration of testosterone undecanoate and fall to pretreatment levels within 8 to 12 hours. For testosterone replacement therapy, it is administered at relatively high doses, 40 to 80 mg two to three times daily (total dose, 80 to 240 mg daily). The frequency of administration makes compliance difficult for many men. Absorption of testosterone undecanoate requires concomitant food ingestion, and serum testosterone levels and clinical responses are highly variable. Because of 5 α -reductase activity in the gastrointestinal tract, serum DHT concentrations are often very high.

The use of castor oil and propylene glycol laurate instead of oleic acid, the vehicle used in the original formulation, permits storage at room temperature and extends the shelf-life of Andriol Testocaps for up to 3 years while maintaining pharmacokinetic and pharmacodynamic characteristics similar to those of the original formulation. Testosterone levels fall quickly after discontinuation of testosterone undecanoate. Therefore, it may be particularly useful for testosterone replacement therapy in older men with clinically significant prostate disease and comorbidities, in whom rapid withdrawal of androgen action is desirable if adverse effects develop, and in those for whom only low-dose testosterone supplementation is needed.

Injectable Testosterone Undecanoate. An injectable formulation of testosterone undecanoate in a castor oil vehicle (Nebido; Bayer Schering Pharma AG, Berlin, Germany) has been approved and is used in Europe and other countries for testosterone replacement therapy in hypogonadal men.⁴⁹⁷⁻⁵⁰¹ Testosterone undecanoate in castor oil is administered initially as a slow IM injection in the gluteus muscle at a dose of 1000 mg in 4 mL, followed by another injection of the same dose 6 weeks later and then every 10 to 14 weeks, to produce and maintain serum testosterone levels within the normal range in most hypogonadal men and to correct clinical manifestations of androgen deficiency. Because of the large volume of drug administered and the need for proper injection technique, self-administration is not possible. Coughing may occur in a small number of men immediately after injection of testosterone undecanoate. Although there is no direct evidence for the cause of coughing, it is hypothesized to be related to fat droplet microembolism emanating from the large volume of castor oil vehicle that is injected into the muscle with this formulation.

A different formulation of testosterone undecanoate in castor oil (Aveed, Endo Pharmaceuticals, Chadds Ford, PA) is awaiting approval in the United States. This formulation will be administered in a dose of 750 mg in 3 mL initially, followed by another, similar injection 4 weeks later and then every 10 weeks.⁴⁸⁵

Transdermal Testosterone Formulations. A *testosterone-in-adhesive matrix patch* (Testopatch, Pierre Fabre, Castres, France) is available in a number of countries in Europe for testosterone replacement therapy in patients with male hypogonadism.^{502,503} This patch is composed of an adhesive matrix that contains testosterone (0.5 mg per cm²) and excipients that comes in three sizes—30, 45, and 60 cm². Two 60-cm² patches (delivering approximately 4.8 mg of testosterone daily) are applied to the skin of the arms, trunk, or thighs every 2 days to maintain serum testosterone levels in the normal range in hypogonadal men. Skin irritation has been reported to occur in about 20% of patients using this patch.

A *testosterone gel 2%* formulation (Tostran or Tostrex, ProStrakan, Galashiels, UK) is available in some countries in Europe for testosterone replacement therapy.⁵⁰⁴ One gram of gel contains 20 mg of testosterone in butylhydroxytoluene and propylene glycol, and it comes in a metered-dose canister that delivers 0.5 g of gel (10 mg of testosterone). The dose of testosterone gel is 3 to 4 g (60 to 80 mg of testosterone) applied to the skin of the abdomen or both inner thighs daily. Precautions must be taken to avoid contact transfer of testosterone to women and children.

Selective Androgen Receptor Modulators. There is considerable interest in the development of selective androgen receptor modulators (SARMs), nonsteroidal molecules that interact with AR and have differential effects on various androgen target organs.^{505,506} The goal is to develop an orally active, nonsteroidal SARM that will maintain the beneficial anabolic and androgenic actions of testosterone on muscle, bone, sexual function, and mood but have reduced potential for adverse effects (e.g., on the prostate gland). These novel drugs are being developed primarily for use in muscle-wasting conditions such as age-related sarcopenia and cancer cachexia but not at present for treatment of male hypogonadism. The mechanisms by which SARMs act in a tissue-specific manner are unclear. It is possible that SARMs have less stimulatory effect on the prostate because they are not actively metabolized by 5 α -reductase, or they may act by unique interactions with tissue-specific AR coactivator and corepressor molecules.

Nonsteroidal SARMs have been developed that have anabolic actions in muscle and bone but reduced stimulatory effects on the prostate gland in animals.^{505,506} SARMs do not have intrinsic ER activity, and if they suppress endogenous gonadotropin, testosterone, and estradiol secretion, they will produce a state of relative estrogen deficiency. Therefore, studies evaluating the clinical benefits and risks of an SARM must consider potential adverse effects on target actions that are regulated by estradiol in men, such as effects on BMD, lipids (HDL-cholesterol), cardiovascular function, and brain function. The importance of estrogens on bone, for example, was underscored by a recent long-term study of the potent, nonaromatizable androgen, DHT gel, administered to older men. Compared with placebo, DHT gel stimulated lean body mass and reduced fat mass but suppressed BMD.⁹⁹

Monitoring Clinical Response and Testosterone Levels. The clinical responses to testosterone replacement and serum testosterone levels are used to monitor the

adequacy testosterone therapy in androgen-deficient men (Table 19-11).¹¹⁰ Symptoms and signs of androgen deficiency should be assessed before the initiation of testosterone treatment, 3 to 6 months after starting testosterone, and then yearly. By 3 to 6 months, most hypogonadal men experience improvements in libido, sexual function and activity, energy, vitality, motivation, and mood.⁵⁰⁷ Increases in body hair growth, muscle mass and strength, and BMD occur over the subsequent months to years of testosterone therapy.

Serum testosterone concentrations are monitored to determine the adequacy of therapy and to avoid overreplacement or underreplacement. This is particularly important in men treated with transdermal testosterone patches and gels, because the bioavailability of these formulations is highly variable among individuals. The goal of testosterone replacement therapy is to achieve serum testosterone levels in the mid-normal range.¹¹⁰

For testosterone ester injections, testosterone concentrations should be measured at 3 to 6 months of treatment, midway between two injections (e.g., 1 week after an injection if the injections are given every 2 weeks). Serum testosterone levels measured at the nadir of the injection interval (i.e., just before the next injection) may help to document an inadequate dosing interval. For the testosterone patch, testosterone levels should be measured after approximately 3 to 4 weeks of daily use, 8 to 10 hours after application of a patch on the previous evening. For testosterone gels, testosterone levels should be measured after about 2 weeks of daily use, at any time after application of the gel. For buccal testosterone, serum testosterone should be measured 4 to 6 weeks after initiation of therapy, at any time after application of the buccal tablet, preferably in the morning.

Risks and Adverse Effects

Contraindications and Precautions. Testosterone treatment is contraindicated in men with metastatic prostate cancer or breast cancer.¹¹⁰ The primary concern is that testosterone administration could stimulate the growth of these androgen-dependent malignancies. Testosterone therapy is particularly risky in men with metastatic prostate cancer, in whom rapid growth of metastatic tumors may worsen bone pain or cause spinal cord compression. In fact, the mainstay of treatment for metastatic prostate cancer is androgen-deprivation therapy to reduce endogenous testosterone production and action; this is achieved by GnRH agonist and AR antagonist treatment or by surgical orchidectomy.⁵⁰⁸ The effect of testosterone replacement in hypogonadal men with localized prostate cancer is not known. However, in the absence of evidence, testosterone treatment in men with clinical evidence of prostate cancer should be avoided.

The safety of testosterone therapy in hypogonadal men who have been surgically cured of organ-confined, low-grade prostate cancer and have had clinically undetectable disease and an undetectable PSA level for several years also is not clear. Because these men would not have been treated with androgen-deprivation therapy, testosterone replacement to restore eugonadal levels of testosterone seems reasonable. In these patients, a careful discussion of the potential benefits and risks of testosterone replacement should be undertaken, and therapy should be initiated only after informed consent and with careful monitoring by DRE and measurement of PSA levels.

Before testosterone replacement therapy is started in middle-aged and older men (>40 years) with androgen deficiency, a PSA measurement and a careful DRE to look

TABLE 19-11

Monitoring During Testosterone Treatment

Parameter	Timing	Further Management
MEASURES OF EFFICACY		
Symptoms and signs of androgen deficiency	At baseline, after 3-6 mo, and then yearly For men at high risk for fracture, BMD before treatment; for men with osteoporosis or minimum-trauma fracture, BMD after 1-2 yr	Continue testosterone treatment in men with clinical improvement and no adverse effects Consider discontinuing testosterone treatment in men if no clinical improvement Institute appropriate treatment for men with osteoporosis, including calcium and vitamin D
Serum testosterone	<i>Testosterone ester injection:</i> after 3-6 mo, measured midway between injections or at end of dosing interval (if androgen deficiency symptoms are present at that time) <i>Testosterone patch:</i> after 3-4 wk, at 8-10 hr after application <i>Testosterone gel:</i> after 2 wk, at any time after application <i>Buccal testosterone:</i> after 4-6 wk, at any time after application (preferably in the morning) <i>Testosterone pellets:</i> at end of dosing interval <i>Oral testosterone undecanoate:</i> after 1 wk, at 3-5 hr after oral dose <i>Testosterone undecanoate injection:</i> at end of dosing interval	Adjust dose or dosing interval to achieve serum testosterone levels in mid-normal range
ADVERSE EFFECTS		
Hematocrit	At baseline, after 3-6 mo, and then yearly	If hematocrit >54%, stop or reduce dosage of testosterone until hematocrit declines to normal and reinstitute testosterone at lower dosage Investigate for hypoxic condition such as obstructive sleep apnea, chronic lung disease
PSA level, DRE, and IPSS in men > 40 yr	At baseline, after 3-6 mo, and then according to accepted guidelines	Urologic evaluation if any of the following: PSA increase >1.4 ng/mL within any 12-mo period PSA velocity >0.4 ng/mL per year after 6 mo of testosterone treatment (only if 2 yr of PSA values are available) Palpable abnormality (nodule or induration) on DRE IPSS score >19
Obstructive sleep apnea (snoring, witnessed apnea, daytime somnolence, unexplained erythrocytosis, worsening hypertension or edema)	At baseline, after 3-6 mo, and then yearly	Evaluation for obstructive sleep apnea or adjustment of CPAP settings Evaluation of other causes of hypoxia
Formulation-specific adverse effects	At baseline, after 3-6 mo, and then yearly	
Testosterone ester injections	Discomfort, bleeding, or hematoma with IM injections Fluctuations in energy, mood, libido Allergy to oil vehicle (rare)	Reinstruct on self-injection site technique Consider shortening injection interval if nadir testosterone level low
Testosterone patch	Skin irritation Adhesion to skin	Coadministration of corticosteroid cream may reduce skin irritation
Testosterone gel	Contact transfer to others Skin dryness	Reinstruct on washing hands and covering application area after gel dries or showering 4-6 hr after application, avoiding prolonged skin-to-skin contact of application site with women and children
Buccal testosterone tablets	Gum irritation or inflammation Poor adhesion to gums Altered or bitter taste	Reinstruct on proper application and reassure to complete an adequate trial with correct technique
Subcutaneous testosterone pellets	Pellet extrusion Implantation-site infection, bleeding, fibrosis	Reimplant pellets Treat infection with appropriate drainage and antibiotics

BMD, bone mineral density; CPAP, continuous positive airway pressure; DRE, digital rectal examination; IM, intramuscular; IPSS, International Prostate Symptom Score; PSA, prostate-specific antigen.

for a suspicious prostate nodule or induration should be performed.¹¹⁰ Hypogonadal men with an abnormal DRE or a consistently elevated PSA value (e.g., >4 ng/mL in Caucasian men, >3 ng/mL in African American men and men at high risk for prostate cancer) should have a urologic evaluation that may include a transrectal ultrasound study and biopsy of the prostate before starting testosterone. Older men, African American men, men with an abnormal DRE, and men with a history of a first-degree relative with prostate cancer have an increased risk of prostate cancer; men with a previous negative prostate biopsy and men who are taking a 5 α -reductase inhibitor have a reduced risk. A prostate cancer risk calculator, based on data from placebo-treated men in the Prostate Cancer Prevention Trial, is available to assess the risk of clinical (biopsy-detectable) and high-grade (Gleason score ≥ 7) prostate cancer according to ethnicity, age, PSA level, family history of prostate cancer, normal or abnormal DRE, results of prior prostate biopsy, and use of a 5 α -reductase inhibitor. This calculator is available at <http://deb.uthscsa.edu/URORiskCalc/Pages/uroriskcalc.jsp> (accessed January 2010).^{509,510} Although it has not been validated for men with androgen deficiency, this prostate cancer risk calculator may be helpful in assessing the risk of clinical or high-grade prostate cancer that may be present in a hypogonadal man before testosterone replacement is instituted.

Although breast cancer in men is rare, some disorders that cause androgen deficiency, such as Klinefelter's syndrome, are associated with an increased risk of breast cancer.²⁰¹ Therefore, a careful breast examination for suspicious masses should be performed in hypogonadal men before starting testosterone treatment. The conversion of testosterone to estradiol may stimulate growth of ER-positive breast cancer.

Relative contraindications to testosterone replacement therapy include the following¹¹⁰:

- Untreated obstructive sleep apnea, because higher-dose testosterone treatment may rarely worsen sleep-disordered breathing and its complications
- Baseline hematocrit in the high-normal range (e.g., hematocrit >50 at or near sea level), because further stimulation of erythropoiesis induced by testosterone therapy may result in erythrocytosis and, potentially, hyperviscosity and vascular complications, particularly in elderly men with underlying vascular disease
- Severe edematous conditions (e.g., uncontrolled or poorly controlled congestive heart failure), because the fluid retention associated with testosterone therapy may worsen preexisting edema
- Severe LUTS due to BPH, such as in men with IPSS greater than 19

Potential Adverse Effects and Monitoring. Monitoring for potential adverse effects of testosterone therapy is summarized in Table 19-11.

Hematocrit. Testosterone replacement stimulates erythropoiesis in hypogonadal men, increasing the hemoglobin concentration and hematocrit from the female range into the normal adult male range.⁵¹¹ Occasionally, testosterone treatment causes excessive erythrocytosis (e.g., hematocrit >54%) that may require temporary discontinuation of therapy or lowering of the testosterone dose until the hematocrit declines to normal, reinitiation of testosterone at a lower dose, or sometimes therapeutic phlebotomy.⁵¹² Excessive erythrocytosis occurs more commonly in older men and in those treated with parenteral testosterone esters rather than transdermal testosterone patches, probably related to the supraphysiologic testosterone levels that are present for a few days after administration and the higher average testosterone concentrations produced by IM testosterone.⁴⁷⁷ A

greater erythropoietic response to testosterone is associated with greater suppression of hepcidin, a liver-derived peptide that is the main regulator of iron bioavailability.⁵¹³

Adverse effects of erythrocytosis induced by testosterone are poorly documented. However, there is concern that an excessive increase in red cell volume and blood viscosity could cause vascular complications such as thrombosis, especially older men with underlying atherosclerotic cardiovascular disease, resulting in stroke or myocardial infarction. Therefore, hematocrit should be measured before testosterone therapy is initiated, 3 to 6 months after starting treatment, and then yearly.¹¹⁰ If erythrocytosis develops during testosterone replacement therapy, testosterone should be stopped and an evaluation should be performed to determine whether an underlying predisposing condition, such as hypoxia due to obstructive sleep apnea syndrome or chronic lung disease, is stimulating or contributing to erythrocytosis. Subsequently, testosterone may be restarted at a lower dosage.

Prostate. Prostate size is reduced in men with androgen deficiency, and testosterone replacement therapy increases prostate volume to that of age-matched eugonadal men.⁵¹⁴ Testosterone therapy does not cause excessive prostate enlargement, and there is no evidence that it worsens LUTS, reduces urinary flow rate, causes urinary retention, or increases the need for invasive intervention for BPH (e.g., TURP). However, long-term, controlled studies have not been performed to evaluate these outcomes in middle-aged to older hypogonadal men, who are most at risk for development of clinically significant, symptomatic BPH. Therefore, in hypogonadal men older than 40 years of age, LUTS should be monitored with the use of the IPSS or the AUA Symptom Index before testosterone treatment, at 3 to 6 months after starting treatment, and then in accordance with accepted guidelines.¹¹⁰ Concomitant therapy for LUTS (e.g., α -adrenergic receptor antagonists, 5 α -reductase inhibitors, surgical bladder outlet procedures) should be considered in hypogonadal men with bothersome severe LUTS that affects quality of life.

There is no evidence that testosterone treatment causes prostate cancer. In middle-aged to older men with androgen deficiency, there is concern that long-term testosterone therapy might stimulate previously unrecognized or clinically undetectable localized or metastatic prostate cancer or accelerate the growth of preexisting subclinical disease into clinically apparent prostate cancer. There is evidence that testosterone treatment stimulates the growth of metastatic prostate cancer, but its effect on progression of subclinical prostate cancer is not known. Small, short-term, controlled studies (up to 3 years in duration) have not found an increased incidence of prostate cancer in older men treated with testosterone.⁵¹² Larger, longer-term, prospective, randomized, controlled trials are needed to determine whether testosterone therapy stimulates the growth and progression of subclinical prostate cancer into clinically evident and significant high-grade disease.

Along with reduced prostate size, serum PSA concentrations in androgen-deficient men are decreased, and testosterone replacement increases PSA to levels observed in age-matched eugonadal men.⁵¹⁴ Because testosterone replacement is a potentially disease-modifying intervention that may alter the natural history of prostate cancer, initial monitoring of PSA is prudent and should be performed to detect marked rises in PSA that might indicate stimulation of previously unrecognized prostate cancer growth.¹¹⁰ PSA monitoring is distinct from PSA screening for prostate cancer, which is more controversial and has been demonstrated recently to have no effect or only

modest effect on mortality in the general population of men.⁵¹⁵⁻⁵¹⁷

Therefore, in men older than 40 years of age, both PSA measurement and DRE should be performed before testosterone therapy is initiated, 3 to 6 months after starting treatment, and then in accordance with accepted guidelines. More intensive PSA monitoring should not be performed, because abnormal levels that would trigger a prostate biopsy are more likely to occur in older hypogonadal men on testosterone therapy, resulting in an increased likelihood of detecting localized prostate cancer, for which the management is unclear.⁵¹⁸ The diagnosis of subclinical or localized low-grade prostate cancer may not affect overall mortality, but the potential medical, surgical, psychological, and socioeconomic consequences and morbidity of this diagnosis may be considerable.

Hypogonadal men receiving testosterone therapy who demonstrate a verified increase in PSA greater than 1.4 ng/mL in any 12-month period during therapy; a PSA velocity of greater than 0.4 ng/mL per year using the value at 3 to 6 months as baseline (and only if 2 or more years of PSA values are available); an abnormal finding on DRE (nodule or induration); or an AUA Symptom Index or IPSS greater than 19 should undergo urologic evaluation.¹¹⁰ Elevated PSA levels should be confirmed with a repeat measurement. If prostatitis or urinary tract infection that can markedly elevate PSA concentrations is suspected, PSA measurements should be repeated after appropriate antibiotic treatment.

Sleep Apnea. Testosterone treatment has been reported to induce or worsen obstructive sleep apnea, but the prevalence of clinically significant obstructive sleep apnea during testosterone replacement therapy is probably very low and may be dose related.^{433,437,438} Short-term, high-dose testosterone treatment in older hypogonadal men significantly worsened obstructive sleep apnea, increased the duration of hypoxemia, and shortened total sleep time as assessed by polysomnography. In contrast, older men treated with a scrotal testosterone patch for 3 years did not demonstrate a significant worsening of sleep apnea as assessed by a portable device.⁵¹⁹ As discussed earlier, sleep apnea may conversely cause gonadotropin and testosterone suppression and secondary hypogonadism, probably because of the stress of oxygen desaturation and sleep disturbance.

Sleep apnea is associated with significant morbidity and mortality. Therefore, hypogonadal men, and especially those at increased risk (e.g., obese men), should be monitored for symptoms of obstructive sleep apnea syndrome (e.g., loud snoring, apnea witnessed by a bed partner, daytime somnolence, unexplained erythrocytosis, worsening or recent onset of hypertension or edema) before starting testosterone therapy, after 3 to 6 months, and then yearly.¹¹⁰ If symptoms suggest sleep apnea, a formal sleep study (polysomnography) should be performed. If obstructive sleep apnea is confirmed, appropriate treatment (e.g., CPAP) should be instituted before testosterone treatment is started or continued.

Reduced Sperm Production and Fertility. In men who have androgen deficiency and persistence of some sperm production with either partial primary or secondary hypogonadism, testosterone treatment suppresses gonadotropin production by negative feedback regulation, which in turn suppresses spermatogenesis and may further impair fertility.⁴⁴⁶ Suppression of sperm production is most important in men with secondary hypogonadism and normal testes who wish to father children. In these men, testosterone therapy should be discontinued and gonadotropin therapy should be started, initially with hCG alone and then, if necessary, with combined hCG and FSH treatment to

stimulate spermatogenesis.⁷⁹ In the absence of coexisting testicular disease (e.g., cryptorchidism), prior testosterone therapy does not impair the subsequent induction of sperm production with gonadotropins.^{316,317}

Acne and Oily Skin. Boys with prepubertal androgen deficiency who are receiving testosterone therapy to induce puberty and men with severe hypogonadism who are treated with full replacement doses of testosterone may develop acne and increased oiliness of the skin.^{136,303} These conditions usually respond to local skin measures (e.g., benzoyl peroxide, retinoic acid) and antibiotics, reduction in testosterone dose, or both.

Gynecomastia. Occasionally, breast tenderness or gynecomastia develops or worsens during testosterone replacement therapy, particularly in boys who are receiving testosterone for induction of puberty, men with severe androgen deficiency who are treated with full replacement or high-dose testosterone, and hypogonadal men with predisposing conditions such as hepatic cirrhosis. Gynecomastia is commonly found in boys and men with androgen deficiency before the initiation of testosterone therapy. A careful breast examination should be performed before and again during testosterone replacement therapy to detect the presence or worsening of gynecomastia and the rare occurrence of breast cancer.

Lipids. In hypogonadal men, testosterone replacement results in no change or only a slight decrease in HDL-cholesterol and no change in total cholesterol or LDL-cholesterol levels.^{512,520} The reduction in HDL-cholesterol is greater in men with more severe androgen deficiency and in those treated with supraphysiologic testosterone doses or with nonaromatizable, oral 17 α -alkylated androgens.³⁶⁰

The clinical significance of HDL-cholesterol suppression induced by testosterone in terms of cardiovascular risk is not known. Understanding of the effects of testosterone therapy on major cardiovascular outcomes (e.g., myocardial infarction, stroke, cardiovascular mortality) will require larger, longer-term, randomized, controlled studies. Cardiovascular risk and lipid measurements should be evaluated as recommended by available practice guidelines; at present, more intensive monitoring in hypogonadal men receiving therapy is not justified.

Other Potential Adverse Effects. Frontal balding or androgenic alopecia may develop or worsen in genetically predisposed hypogonadal men during testosterone replacement therapy. Mild to moderate *weight gain* usually occurs during testosterone treatment, because of the anabolic actions of testosterone on muscle mass and associated fluid retention. Testosterone therapy usually does not cause clinically significant edema, except occasionally in hypogonadal men with underlying edematous states such as congestive heart failure or hepatic cirrhosis.

Stimulation of excessive libido and erections by testosterone is rare and usually occurs in boys or young men with severe, long-standing androgen deficiency who are treated with full replacement or high-dose testosterone therapy. These symptoms usually resolve spontaneously or with a reduction in testosterone dose. Contrary to popular opinion, testosterone treatment does not cause pathologic aggressiveness, anger, or rage.^{521,522} Instead, testosterone replacement therapy increases social aggressiveness, motivation, and initiative and reduces irritability and anger.

Profound behavioral and physical changes induced by testosterone treatment in men with severe, long-standing androgen deficiency may be upsetting to both patients and their partners. Therefore, changes that are expected to occur with testosterone replacement should be discussed

with patients and their partners before and during treatment. Oral 17α -alkylated androgens may cause cholestasis or potentially serious hepatotoxicity.³⁶⁰ However, liver toxicity does not occur with testosterone replacement therapy, and routine monitoring of liver enzymes is not necessary in hypogonadal men.

Formulation-Specific Adverse Effects. *Testosterone ester injections* may cause local discomfort, bleeding, or hematoma at the site of IM injections.¹¹⁰ Instruction on proper injection technique minimizes the likelihood of these adverse effects. Fluctuations in energy, mood, and libido associated with the peak and nadir swings of testosterone levels after testosterone ester injections may be disturbing to some hypogonadal men and may require reduction of the dose injected and shortening of the injection interval or switching to transdermal testosterone. Rarely, an allergy may occur to the sesame oil (enanthate) or cottonseed oil (cypionate) vehicle used.

Testosterone patches frequently cause local skin erythema, irritation, itching, and contact dermatitis and occasionally lead to more severe reactions.¹¹⁰ Use of a topical corticosteroid cream under the reservoir of the patch may reduce skin irritation and reactions, but often men prefer to switch to another testosterone formulation. Testosterone patches may adhere poorly to skin, particularly with excessive perspiration.

In contrast to testosterone patches, *testosterone gels* cause little to no skin irritation. However, residual testosterone remains on the skin surface at the application sites, and there is a potential for transfer of testosterone to women and children who have prolonged intimate contact with these sites.¹¹⁰ Precautions to avoid contact transfer of testosterone include washing the hands immediately after application of testosterone gel, covering the application site with clothing, washing off residual testosterone on skin by showering or bathing (4 to 6 hours after application), and avoiding prolonged skin-to-skin contact of the application site with women or children.

Buccal testosterone tablets may cause gum irritation or inflammation or an altered or bitter taste sensation, and they may adhere poorly to gums if not they are not properly applied.¹¹⁰

Subcutaneous testosterone pellets may uncommonly extrude spontaneously; rarely, there may be bleeding or infection at the site of implantation.¹¹⁰

Gonadotropin Therapy

Secondary hypogonadism manifests as prepubertal or adult androgen deficiency and impairment of sperm production due to gonadotropin deficiency. The primary goal of gonadotropin therapy in men with secondary hypogonadism is to initiate and maintain spermatogenesis in order to establish and restore fertility.⁵²³ Because gonadotropin therapy is more complex (requiring multiple injections weekly) and more expensive than testosterone replacement therapy, symptomatic androgen deficiency is usually treated with the latter. In patients with partial gonadotropin deficiency, testosterone treatment may suppress remaining gonadotropin secretion by negative feedback regulation. When fertility is desired and stimulation of sperm production is needed in a man with secondary hypogonadism, testosterone is discontinued and gonadotropin therapy is initiated. Previous testosterone treatment does not compromise subsequent stimulation of spermatogenesis by gonadotropins.^{316,317}

The gonadotropin preparations most commonly used to treat secondary hypogonadism are purified urinary gonadotropins. Human recombinant gonadotropin

preparations are now available and have much higher purity than urinary preparations, but they are more expensive. Because urinary gonadotropins are highly effective in treating gonadotropin deficiency, they remain the most commonly used preparations for treatment of secondary hypogonadism.

hCG is used to provide LH-like activity because its half-life is longer than that of LH. In contrast to LH, which would require pulsatile administration approximately every 2 hours, hCG is administered two to three times per week. Purified urinary preparations of hCG (derived from urine of pregnant women) that contain LH-like activity are used almost exclusively in gonadotropin therapy. FSH activity is usually provided by purified urinary *human menopausal gonadotropin (hMG)*, which is derived from urine of menopausal women and contains both FSH and LH; by highly purified urinary *human FSH*; or, rarely, by *recombinant human FSH (rhFSH)*. FSH preparations are administered three times daily. hCG and FSH preparations may be administered either intramuscularly or subcutaneously.^{524,525} Both are equally effective, but the latter is better tolerated and more easily self-administered.

In patients with prepubertal gonadotropin deficiency, initiation of sperm production requires treatment with both hCG and FSH (Fig. 19-31).⁷⁹ Gonadotropin therapy is initiated with administration of hCG alone at a dose of 500 to 2000 IU subcutaneously (SQ) two to three times weekly to stimulate sufficient endogenous testosterone production to increase and maintain circulating testosterone levels in the normal range and to correct manifestations of androgen deficiency.⁶ The dose of hCG is increased until serum testosterone concentrations are within eugonadal range. Despite the more frequent injections, some men with secondary hypogonadism prefer hCG over testosterone treatment because costs are comparable (if purified urinary preparations are used), SQ injections using smaller needles are better tolerated, and testes size and spermatogenesis may increase slightly, particularly in patients with partial prepubertal gonadotropin deficiency.

Men with gonadotropin deficiency who also have primary testicular disease (e.g., cryptorchidism) or severe prepubertal isolated hypogonadotropic hypogonadism may require larger doses of hCG (e.g., up to 3000 to 5000 IU two to three times weekly, or occasionally much more). Men with secondary hypogonadism who have coexisting severe testicular damage may be completely unresponsive to hCG treatment (see Fig. 19-31). Because hCG stimulates Leydig cell aromatase activity within the testes, serum estradiol concentrations may increase disproportionately relative to testosterone levels, resulting in breast tenderness or gynecomastia more frequently than with testosterone replacement therapy. Some men may complain of burning at the site of SQ injections of hCG.

hCG stimulates Leydig cell testosterone production, resulting in relatively high intratesticular testosterone concentrations that cause Sertoli cells to mature and sperm production to be initiated to varying degrees. In a small proportion of patients with partial prepubertal deficiency and in almost all men with acquired postpubertal gonadotropin deficiency, treatment with hCG alone may stimulate sperm production (see Fig. 19-31).⁷⁹ Evidence for partial gonadotropin deficiency includes testes size larger than 4 mL, physical examination evidence of partial androgenization, low-normal gonadotropin concentrations, and low-normal levels of inhibin B.⁵²⁶⁻⁵³⁰ Most patients with severe prepubertal gonadotropin deficiency require FSH treatment in addition to hCG to stimulate complete spermatogenesis and induce fertility.⁵³⁰⁻⁵³³

Figure 19-31 Total sperm count response to gonadotropin therapy with human chorionic gonadotropin (hCG) alone or in combination with human menopausal gonadotropin (hMG) in males with hypogonadotropic hypogonadism of postpubertal onset (left), prepubertal onset without cryptorchidism (middle), or prepubertal onset with cryptorchidism (right). Sperm production was induced by hCG alone in all men with postpubertal hypogonadotropic hypogonadism and in some with prepubertal onset who did not have cryptorchidism. Both hCG and hMG treatment was required to increase sperm production above the lower limit of normal (dashed line) in patients with prepubertal hypogonadotropic hypogonadism who did not have cryptorchidism. With one exception, men with prepubertal hypogonadotropic hypogonadism who also had cryptorchidism failed to respond to hCG alone or to combined hCG and hMG therapy. (From Finkel DM, Phillips JL, Snyder PJ. Stimulation of spermatogenesis by gonadotropins in men with hypogonadotropic hypogonadism. *N Engl J Med*. 1985;313:651-655.)

If no sperm is present in the ejaculate after 6 to 12 months of treatment with hCG and serum testosterone concentrations in the eugonadal range, hMG or FSH at a dose of 75 IU three times weekly (increasing to 300 IU SQ three times weekly) is added, in combination with the same dose of hCG, for an additional 6 to 12 months or longer, until spermatogenesis is induced.

The induction of sperm production by gonadotropin therapy may take 12 to 24 months. Factors that limit the duration of gonadotropin treatment are impatience by patients or their partners and the expense of gonadotropins, in particular hMG or FSH preparations, which are very costly. Some couples may opt for alternative means to have children (e.g., adoption). In patients with prepubertal gonadotropin deficiency, sperm output is often low, possibly because of inadequate gonadotropin stimulation of Sertoli cell number and maturation during development.⁵³⁴ Despite quantitatively low sperm production during gonadotropin therapy, fertility may be possible, sometimes at very low sperm counts (e.g., <1 million/mL).⁵²⁶ Some patients who have very low sperm counts and remain infertile on gonadotropin treatment may elect to use ejaculated sperm for ICSI.

Once spermatogenesis has been initiated with combined hCG and FSH treatment in patients with prepubertal gonadotropin deficiency, sperm production may be maintained with hCG treatment alone.⁴⁶⁷ In men with acquired postpubertal gonadotropin deficiency, reinitiation of spermatogenesis can usually be accomplished with hCG therapy alone.⁷⁹

In men with secondary hypogonadism due to hypothalamic GnRH deficiency (e.g., IHH, Kallmann's syndrome), pulsatile GnRH therapy may be used to stimulate production of endogenous gonadotropins (both LH and FSH) and testosterone and to initiate and maintain sperm production sufficient for fertility.³¹⁹ GnRH is administered SQ with the use of a portable infusion pump that delivers small

doses (pulses) of GnRH every few hours (e.g., GnRH 5 to 25 ng/kg SQ every 2 hours, increasing to higher doses if needed); this treatment mimics a near-normal physiologic stimulus to the pituitary gland. In men with IHH, pulsatile GnRH treatment is successful in stimulating gonadotropin, testosterone, and sperm production in approximately 75% of cases; in the other 25% of cases, men fail to respond due to concomitant pituitary or testicular defects.³¹⁹ The effectiveness of pulsatile GnRH replacement in stimulating sperm production is comparable to that of gonadotropin therapy. Practically, however, the use of pulsatile GnRH therapy is limited to specialized centers because GnRH is not readily available, the infusion pump requires additional expertise and management, and therapy is expensive.

Sexual Dysfunction in Men and Women

SHALENDER BHASIN • ROSEMARY BASSON

Endocrine disease and its treatment can frequently disturb sexual function in men and women.¹ In addition, many patients believe, often incorrectly, that their sexual dysfunction must be due to “hormonal imbalance” and seek management from endocrinologists.² Patients consider their sexual lives to be important, and, recognizing the importance of sexual function as a determinant of quality of life, the World Health Organization has declared sexual health a fundamental right of men and women.

Michael Kinsey’s pioneering epidemiologic investigations provided the first evidence of the considerable variability in sexual practices of American men and women.³ Excellent epidemiologic surveys using modern sampling techniques, such as the Massachusetts Male Aging Study (MMAS) led by John McKinlay⁴ and the National Health and Social Life Survey (NHSLs) led by Laumann and Rosen,^{5,6} revealed high prevalence rates of sexual dysfunction among community-dwelling, middle-aged and older men. Ongoing and distressing sexual dysfunction affects 10% of people, and prevalence rates are even higher among older men.^{7,8} Temporary or nondistressing dysfunction is frequently reported by up to 40% of the population.

William Masters and Virginia E. Johnson⁹ found that both men and women display predictable physiologic responses after sexual stimulation. Their landmark descriptions of the human sexual response cycle provided the basis for rational classification of human sexual disorders. Sigmund Freud ascribed sexual problems in adult men and women to earlier difficulties in maturation of childhood sexuality and development of parent-child relationships. Recent advances in understanding of the physiologic and biochemical mechanisms of penile erection and the development of mechanism-specific therapies for erectile dysfunction (ED) have largely supplanted Freud’s psychoanalytic theories.

The 1980s and 1990s witnessed remarkable progress in understanding of the physicochemical mechanisms that lead to penile tumescence and rigidity. It was recognized that penile erections are the result of cavernosal smooth muscle relaxation and increased penile blood flow.¹⁰⁻¹² The appreciation of nitric oxide (NO) as a key vasodilator in the vascular smooth muscle was a pivotal discovery that was later recognized by the awarding of the Nobel Prize in Physiology or Medicine to Robert F. Furchgott, Louis J.

Ignarro, and Ferid Murad. The recognition that NO caused cavernosal smooth muscle relaxation by simulating guanylyl cyclase provided the foundation for the development of highly effective oral therapies for the treatment of ED.

Historically, the classification and nomenclature for sexual disorders were based on the *Diagnostic and Statistical Manual* (DSM), which is primarily a psychiatric nomenclature, reflecting the belief that sexual disorders in men and women are psychogenic in their origin.¹³ In the 1990s, several expert groups updated the clinical definitions of sexual disorders in men.^{14,15} The growing recognition that ED is commonly a manifestation of systemic disease and the availability of easy-to-use therapeutic options, including oral and intraurethral drugs, have duly placed sexual disorders in men within the purview of the endocrinologist and the primary care provider. In middle-aged and older men, but less so in women, sexual dysfunction is often related to comorbid medical conditions.¹⁶⁻²⁰ Sexual dysfunction can be a manifestation of serious underlying medical disease, such as a pituitary neoplasm, diabetes, or coronary artery disease.²⁰ ED may signal asymptomatic coronary artery disease.¹⁹ In women, sexual dysfunction is more strongly linked to mental health.¹⁶⁻¹⁸

The clinical definitions of sexual dysfunction, especially in women, remain shrouded in debate. In women, there is poor correlation between a clinician's diagnosis of sexual dysfunction and a woman's perception of the problem.²¹ For instance, in one study,²¹ some 20% of middle-aged women were given a diagnosis of sexual dysfunction even though they reported no problem, whereas a similar number did not receive a diagnosis of sexual dysfunction but reported problematic sex. The definitions of sexual dysfunction are being revised by both the American Psychiatric Association's DSM5 committee and the International Classification of Diseases (ICD) committee and will be published in 2013. It is hoped that patients' and clinicians' perceptions of dysfunction will become more aligned.

This chapter describes the current conceptualization of sexual response in men and women, the underlying pathophysiologic mechanisms, the sexual sequelae of various endocrine disorders, and clinical assessment of sexual dysfunction and its management. Management strategies for sexual dysfunction stemming from hormonal and nonhormonal factors are outlined.

HUMAN SEXUAL RESPONSE CYCLE

Masters and Johnson⁹ found that both men and women display predictable physiologic responses after sexual stimulation that can be categorized in four phases: the excitement phase, the plateau phase, the orgasmic phase, and the resolution phase (Fig. 20-1A). The traditional model of human sexual response stemming from the research of Masters, Johnson and Kaplan was that of a linear progression—from desire, to arousal, to a plateau of high arousal, followed by orgasm/ejaculation, and finally a phase of resolution. However, recent studies have revealed greater variability and flexibility and a more circular nature of human sexual response than was appreciated before (see Fig. 20-1B). In both men and women, the relationship between desire and arousal is variable and complex; women are often unable to separate the two.^{22,23} The motivations and incentives for sex are multiple and varied. A wish to increase emotional intimacy between the partners is important for both men and women.²³⁻²⁷ Sexual “desire,” as in

lust or drive, is only one of many reasons people engage in sex.²⁵ The new models reflect this complexity, including the multiple reasons to initiate or agree to sex, a variable order and overlap of the phases of desire and arousal, and the potential for gradually increasing arousal to allow more intense stimulation to be effective and desired (see Fig. 20-1B).²²

Bancroft and Graham proposed dual control theories for sexual motivation in men and women.²⁸⁻³¹ Their dual control model envisions a balance between sexual activation and sexual inhibition in an individual's brain, with this balance determining whether sexual stimulation leads to arousal.^{29,30} A questionnaire was used to characterize the specific factors associated with an individual's sexual excitation and sexual inhibition (due to the threat of performance failure, the threat of performance consequences, or both).³⁰ In women, factor analysis identified five factors related to excitation and three related to inhibition. The excitation factors included sexual arousability, partner characteristics, sexual power dynamics, smell, and setting. The inhibition factors were relationship importance (reflecting the need for sex to occur within a specific type of relationship), concerns about sexual function (the tendency of worries and distractions about sexual function to impair arousal), and arousal contingency (the potential for arousal to be inhibited by some contextual/situational factor).^{30,31} This model explains certain basic neurophysiologic aspects of individual variability and is open to further refinement and validation.

Physiology of Desire and Arousal

Functional Brain Imaging of Sexual Arousal

Brain imaging studies indicate that many brain regions are involved in sexual response.^{32,33} In healthy individuals, erotic images activate limbic and paralimbic regions that are thought to be important for sexual motivation and parietal areas (among others) that modulate the emotional and motor response.^{32,33} Specific inhibitory regions deactivate these sexual responses.^{32,33} Many additional brain areas also are activated, including those associated with visual processing, attention, motor and somatosensory function, emotion, and reward.

Men generally show greater responsiveness to visual sexually arousing stimuli than women do.^{34,35} When men and women viewed couples interacting in nonsexual ways, men showed significantly greater activation in the amygdala than the women did, yet the women rated their arousal higher.^{34,35} It is possible that amygdala activation is not related to sexual arousal per se. These researchers suggest that the amygdala may mediate the more important role of visual stimuli in male sexual behavior.^{34,35} Men showed greater activation of the amygdala in response to those stimuli that generated higher subjective arousal. In contrast, women showed significantly greater amygdala activation in response to less arousing stimuli. When viewing sexually explicit couple images, the men showed greater activation in some brain areas, including the hypothalamus, than the women did. Moreover, in women, viewing the sexually explicit images did not lead to greater activation in these regions than viewing the neutral couple scenes. In other studies, during the sexual arousal phase of genital stimulation, women displayed more activation in

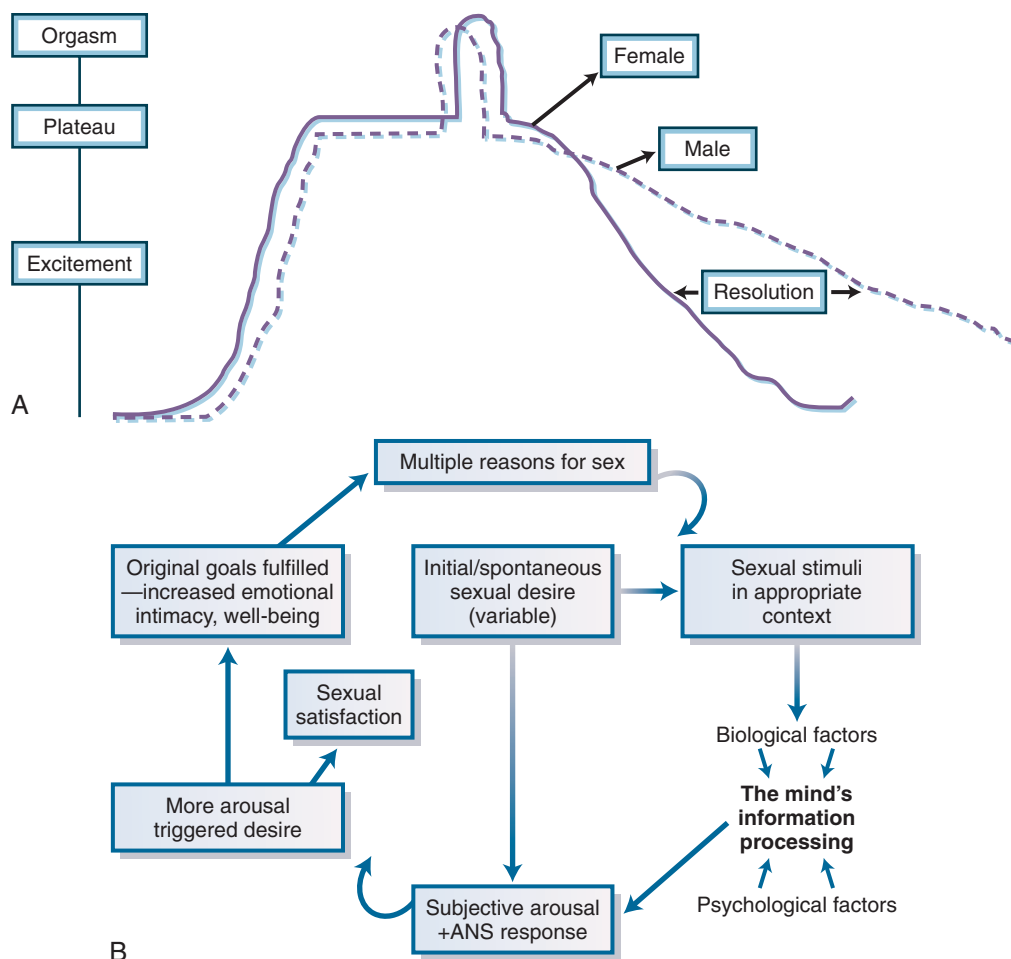

Figure 20-1 **A**, The four phases of the human sexual response cycle as postulated by Masters and Johnson.⁹ Because the resolution phase is prolonged considerably in men, men can experience refractoriness to further stimulation for varying lengths of time before they can achieve another orgasm. As discussed in the text, understanding of the human sex response cycle has evolved substantially since the publication of this work. **B**, The circular human response cycle of overlapping phases. It is increasingly recognized that the human sexual response involves much more complexity, circularity, and flexibility than is reflected in Masters and Johnson's original model. "Desire" may or may not be present initially; it can be triggered during the experience. Arousal and desire overlap. Multiple psychological and biological factors influence the information processing of sexual stimuli. Underlying this processing may be the individual's unique tendency for excitation versus inhibition. ANS, autonomic nervous system.

the left frontoparietal areas, whereas men showed more activation in the right claustrum and ventral occipitotemporal cortex.^{34,35}

The complexity of these systems was reflected in a study of surgically menopausal women who were sexually active but were receiving no hormonal therapy.³⁶ When these women viewed erotica during functional magnetic resonance imaging (MRI), they failed to display the brain activation observed in premenopausal women or in themselves when they were treated with testosterone and estrogen; yet, they reported sexual arousal from the erotic videos, both without and with hormonal supplementation.³⁶

Neurotransmitters and Hormones Involved in Sexual Desire and Subjective Arousal

A variety of hormones and peptides are involved in the sexual response.³⁵⁻⁴¹ The interplay among androgens and neurotransmitters is complex: androgens influence neurotransmitter release, and neurotransmitters may modulate androgen receptor signaling.^{35,38,41} The role of testosterone in desire and arousal is better documented in men than in women. In animal models, steroid hormones modulate

sexual arousal by directing synthesis of the enzymes and the receptors for a number of neurotransmitters, including dopamine, noradrenalin, melanocortin, and oxytocin.³⁵⁻⁴¹ Systems that act within the hypothalamus and limbic regions of the brain are involved in the process of arousal, attention, and sexual behavior. It is thought that dopamine transmission in the medial preoptic area and the nucleus accumbens focuses the person's attention on sexual stimuli (the incentives or motivations for sexual activity).³⁵⁻⁴¹ It is postulated that the behavioral pattern stimulated by those systems and the subjective feelings that accompany them constitute the phenomenon commonly referred to as *sexual desire* or *arousal* when genital sensations triggered by these systems are subjectively felt. The main part of this neural pathway includes the medial preoptic area and its outputs to the ventral tegmental area. The latter contains dopamine cell bodies that project to various limbic and cortical regions, including the prefrontal cortex, the nucleus accumbens, the anterior cingulate cortex, and the amygdala.

Brain pathways for sexual inhibition include opioid, endocannabinoid, and serotonin neural transmissions

feeding back to various levels of the excitatory pathways.³⁸⁻⁴² It is thought that the behavioral pattern stimulated by the inhibitory pathways includes both sexual reward and satiety refractoriness.³⁸⁻⁴²

Exogenous opiates are sexually inhibiting independent of their inhibitory effect on luteinizing hormone (LH), LH-releasing hormone, and testosterone. Endogenous opioids modulate the feedback effects of sex steroids on the hypothalamus and pituitary. β -Endorphin is synthesized in the anterior pituitary, the hypothalamus, and the nucleus of the solitary tract in the brain stem. The sexual inhibiting effects occur mainly through opioid action in the medial preoptic area and in the amygdala.⁴³ Low doses of opiates can have facilitatory effects, possibly through actions in the ventral tegmental area to activate the mesolimbic dopamine system. Exogenous opiates can induce an intense feeling of pleasure which has been likened to orgasm followed by a state of relaxation and calm.⁴⁴

Melanocortins are derived from pro-opiomelanocortin and modulate sexual response through a specific receptor subtype, the melanocortin-4 receptor. Administration of melanocortin receptor agonists has been associated with an increase in spontaneous erection in healthy men and in men with ED and with increased desire, but not genital responses, in women.^{45,46}

Oxytocin levels increase close to orgasm. This hormone is known to be involved in pair bonding in some animal species,⁴⁷ but its relevance in humans is not known.

The physiologic role of prolactin in the human sexual response remains unclear. Because a generalized reduction of dopamine activity in the hypothalamus results in increased prolactin secretion, it has been difficult to distinguish between the effects of raised prolactin itself and the possible effects of the reduced dopamine transmission.⁴⁸ High levels of prolactin are associated with impaired sexual function in men and women.^{49,50}

The effects of the biologic factors are intertwined with those of the environmental and social factors. For instance, dopamine and progesterone, acting on their cognate receptors in the hypothalamus, can increase sexual behavior in oophorectomized, estrogenized female rats, and the presence of a male animal alongside the cage can cause an identical stimulation of the sexual behavior without the administration of either progesterone or dopamine.⁵¹ In rodents, birds, and fish, complex neural networks enable the animal to assess the context of potential sexual activity and relate it to past experience and to expectation of reward.⁵²

Genital Sexual Congestion and Arousal

Men and women differ substantially with respect to the correlation between genital congestion and subjective sexual arousal (excitement). Whereas subjective arousal is typically concordant with genital congestion in men, there

is a poor correlation between subjective arousal and measures of genital congestion in women.^{53,54} Also, in contrast to men's assessment of their erections, women's assessment of their degree of genital congestion is less accurate. It is thought that genital congestion in women is a prompt, automatic reflex that occurs within seconds of an erotic stimulus; it may not be deemed at all sexually arousing by the woman, or it may even be deemed emotionally negative.⁵⁵ Viewing primates engaging in sexual activity subjectively arouses neither young men nor young women. However, young women display marked genital congestion, as measured by vaginal photoplethysmography (VPP), whereas no genital response is recorded in the men.^{53,54} Similarly, heterosexual women viewing lesbian women engaged in sexual activity report minimal subjective arousal but show a prompt vasocongestive response; in contrast, heterosexual men viewing male same-sex activity show little genital or subjective response.⁵⁴

Physiologic Mechanisms of Penile Erection

Penile Anatomy and Blood Flow

The erectile tissue of the penis consists of two dorsally positioned corpora cavernosa and a ventrally placed corpus spongiosum.^{10-12,56} The erectile tissue of both the corpora cavernosa and the corpus spongiosum is composed of numerous cavernous spaces separated by trabeculae.^{10-12,56} These trabeculae are composed mainly of smooth muscle cells that are arranged in a syncytium. Endothelial cells cover the surfaces of the trabeculae.

The penile arterial blood supply is derived from pudendal arteries, which are branches of the internal iliac arteries (Fig. 20-2). The pudendal artery divides into cavernosal, dorsal penile, and bulbourethral arteries. The cavernosal arteries and their branches, the helicine arteries, provide blood flow to the corpora cavernosa.^{10,11} Dilatation of the helicine arteries increases blood flow and pressure in the cavernosal sinuses.^{10-12,56}

Penile Innervation

The neural input to the penis consists of sympathetic (T11 through L2), parasympathetic (S2 through S4), and somatic nerves (Table 20-1).⁵⁷ Sympathetic and parasympathetic fibers converge in the inferior hypogastric plexus, where the autonomic input to the penis is integrated and communicated to the penis through the cavernosal nerves. In humans, the inferior hypogastric ganglionic plexus is located retroperitoneally, near the rectum.^{12,57}

Several brain regions, including the amygdala, the medial preoptic area, the paraventricular nucleus of the hypothalamus, and the periaqueductal gray matter, act coordinately to affect penile erections.⁵⁷ The medial preoptic area of the hypothalamus serves as the integration site

TABLE 20-1

Innervation of the Penis

Type of Fiber	Location of Neurons in Spinal Cord	Nerves Carrying the Fibers	General Function
Sympathetic	T10-L2	Prevertebral outflow through the hypogastric and cavernous nerves; paravertebral outflow through the parasympathetic ganglia and pudendal or pelvic and cavernous nerves	Generally antierecile; sympathetic innervation plays an important role in regulating seminal emission
Parasympathetic	S2-S4	Cavernosal and pelvic nerves	Proerecile
Somatic	S2-S4	Pudendal nerve	Penile sensation, contraction of the striated muscles during ejaculation

Figure 20-2 Anatomy and mechanism of penile erection. The corpora cavernosa are made up of trabecular spaces that are surrounded by cavernosal smooth muscle. Helicine arteries provide the arterial supply to the cavernosal spaces. The dorsal nerve provides the sensory innervation to the penis. During erection, relaxation of the trabecular smooth muscle and increased blood flow result in engorgement of the sinusoidal spaces in the corpora cavernosa. The expansion of the sinusoids compresses the venous return against the tunica albuginea, resulting in entrapment of blood. This imparts rigidity to the tumescent penis. (Adapted from Lue TF. Erectile dysfunction. *N Engl J Med*. 2000;342:1802-1813.)

for the central nervous system control of erections; it receives sensory input from the amygdala and sends impulses to the paraventricular nuclei of the hypothalamus and the periaqueductal gray matter. Neurons in paraventricular nuclei project onto the thoracolumbar and sacral nuclei associated with erections.

The parasympathetic input to the penis is proerectile, and sympathetic input is mainly inhibitory.⁵⁷ The stimuli from the perineum and lower urinary tract are carried to the penis through the sacral reflex arc.⁵⁷

Hemodynamic Changes during Penile Erection

Penile erection results from a series of biochemical and hemodynamic events that are associated with activation of central nervous system sites involved in regulation of erections, relaxation of cavernosal smooth muscle, increased blood flow into cavernosal sinuses, and venous occlusion resulting in penile engorgement and rigidity.^{10,56} Normal penile erection requires coordinated involvement of intact central and peripheral nervous systems, corpora cavernosa and spongiosa, and normal arterial blood supply and venous drainage.^{10,56}

As cavernosal smooth muscle relaxes and the blood flow to the penis increases, the increased pooling of blood in

the cavernosal spaces results in penile engorgement (see Fig 20-2).^{10,56} The expanding corpora cavernosa compress the venules against the rigid tunica albuginea, restricting the venous outflow from the cavernosal spaces.^{10,56} This facilitates entrapment of blood in the cavernosal sinuses, imparting rigidity to the erect penis.

Biochemical Regulation of Cavernosal Smooth Muscle Tone

The tone of the corporal smooth muscle cells determines the erectile state of the penis.^{10-12,56} When the cavernosal smooth muscle cells are relaxed, the penis is engorged with blood and erect. When the cavernosal smooth muscle cells are contracted, there is predominance of sympathetic neural activity, and the penis is flaccid.⁵⁶

The smooth muscle tone in the corpora cavernosa is maintained by the release of stored intracellular calcium (Ca^{2+}) into the cytoplasm and influx of calcium through membrane channels.⁵⁸⁻⁶¹ The transmembrane influx of calcium in the cavernosal smooth muscle cells is mediated mostly by L-type voltage-dependent calcium channels, although T-type calcium channels are also expressed in cavernosal smooth muscle cells.⁵⁸⁻⁶¹ An increase in

Figure 20-3 Regulation of cavernosal smooth muscle contractility by prostaglandin E₁ (PGE₁). Relaxation of the cavernosal smooth muscle is regulated by intracellular 3',5'-cyclic adenosine monophosphate (cAMP) and cyclic guanosine monophosphate (cGMP). These intracellular second messengers, by activating specific protein kinases, cause sequestration of intracellular calcium (Ca²⁺) and closure of Ca²⁺ channels and opening of potassium K⁺ channels. This results in a net decrease in intracellular Ca²⁺, leading to smooth muscle relaxation. PGE₁, by binding to PGE₁ receptors, increases the intracellular concentrations of cAMP, which activates protein kinase A (PKA). PKA promotes the sequestration of intracellular Ca²⁺, inhibits Ca²⁺ influx, and stimulates K⁺ channels. The net result is a decrease in intracytoplasmic Ca²⁺ and smooth muscle relaxation. PGE₁ stimulates cAMP generation. (Adapted from Bhasin S, Benson GS. Male sexual function. In: De Kretser D, ed. *Knobil and Neill's Physiology of Reproduction*, 3rd ed. Boston, MA: Academic Press; 1173-1194; and Lue TF. Erectile dysfunction. *N Engl J Med*. 2000;342:1802-1813.)

intracellular calcium activates myosin light-chain kinase, resulting in phosphorylation of myosin light chain, actin-myosin interactions, and smooth muscle contraction.⁶¹

The transmembrane and intracellular calcium flux in the cavernosal smooth muscle cells is regulated by a number of cellular processes that involve potassium (K⁺) flux through potassium channels, connexin43-derived gap junctions, and a number of cholinergic, adrenergic, and noradrenergic noncholinergic mediators (Figs. 20-3 through 20-6).⁵⁸⁻⁶⁵ The nonadrenergic noncholinergic mediators include vasoactive intestinal peptide (VIP), calcitonin gene-related peptide (CGRP), and NO.⁶⁶

Adrenergic pathways, acting through norepinephrine and α₁-adrenergic receptors, activate phospholipase C, which generates diacyl glycerol and inositol triphosphate.⁶¹ Diacyl glycerol activates protein kinase C, which inhibits potassium channels and activates transmembrane calcium influx by activating L-type calcium channels (see Fig. 20-4).¹⁹ Inositol triphosphate increases intracellular calcium by promoting the release of calcium from intracellular calcium stores.^{20,21} The net increase in intracellular calcium promotes actin-myosin interactions, resulting in smooth muscle contraction and a flaccid penis.

Prostaglandin E₁ (PGE₁), binding to its cognate receptor, results in generation of cyclic adenosine monophosphate (cAMP), which activates protein kinase A. Activated protein kinase A stimulates potassium channels resulting in K⁺ efflux from the cell (see Fig. 20-3). The protein kinase A-mediated processes also result in a net decrease in intracellular calcium, favoring smooth muscle cell relaxation.

Figure 20-4 Regulation of cavernosal smooth muscle contractility by norepinephrine (NE). NE, which mediates adrenergic signals, binds to adrenergic receptors and stimulates diacyl glycerol (DAG) and inositol 1,4,5-triphosphate (IP₃). DAG stimulates protein kinase C (PKC), which, along with IP₃, causes an increase in intracytoplasmic calcium (Ca²⁺) and inhibition of potassium (K⁺) channels. Increased intracellular Ca²⁺ causes cavernosal smooth muscle contraction and loss of penile erection. (Adapted from Bhasin S, Benson GS. Male sexual function. In: De Kretser D, ed. *Knobil and Neill's Physiology of Reproduction*, 3rd ed. Boston, MA: Academic Press; 1173-1194; and Lue TF. Erectile dysfunction. *N Engl J Med*. 2000;342:1802-1813.)

Figure 20-5 The interconnection of cavernosal smooth muscle cells in the penis. Connexin43-derived gap junctions connect adjacent corporal smooth muscle cells and allow flow of ions among interconnected smooth muscle cells. Therefore, alterations in action potential and potassium-channel activity in any myocyte affect the adjacent myocytes. Ca²⁺, calcium ions; K⁺, potassium ions. (Adapted from Melman A, Christ GJ. Integrative erectile biology: the effects of age and disease on gap junctions and ion channels and their potential value to the treatment of erectile dysfunction. *Urol Clin North Am*. 2001;28:217-230.)

Figure 20-6 Regulation of cavernosal smooth muscle relaxation by nitric oxide (NO). Cyclic guanosine monophosphate (cGMP) regulates cavernosal smooth muscle relaxation by promoting sequestration of cytoplasmic calcium. NO is released from noradrenergic cholinergic nerve endings and possibly from the endothelium. NO activates guanylyl cyclase, which generates cGMP from guanosine triphosphate (GTP), which in turn activates cGMP-dependent kinases, resulting in sequestration of intracellular calcium and smooth muscle relaxation. cGMP is degraded by cyclic nucleotide phosphodiesterases. Sildenafil, vardenafil, and tadalafil are selective inhibitors of phosphodiesterase isoform 5 (PDE5), which is present in cavernosal smooth muscles. (Adapted from Bhasin S, Benson GS. Male sexual function. In: De Kretser D, ed. *Knobil and Neill's Physiology of Reproduction*, 3rd ed. Boston, MA: Academic Press; 1173-1194; and Lue TF. Erectile dysfunction. *N Engl J Med*. 2000;342:1802-1813.)

Potassium Channels. At least three types of potassium channels— K_{ATP} , K_v , and the calcium-sensitive K^+ channels, referred to as BK_{Ca} or maxi-K channels—are expressed in the cavernosal smooth muscle cells.⁵⁸ Of these, the BK_{Ca} channels are the most important, because they account for 90% of K^+ efflux from the cavernosal smooth muscle cells. BK_{Ca} channel openers have been shown to relax cavernosal smooth muscle cells in vitro.⁶⁴ Strategies that increase BK_{Ca} channel expression in vivo improve erectile capacity in diabetic and older rodents⁶⁵ and are being explored as therapies for ED. A phase I human gene therapy trial has shown the feasibility of this approach.⁶⁷

Connexin43 Gap Junctions. The smooth muscle cells in the corpora cavernosa are connected by connexin43 gap junctions that allow the ions and some signaling molecules such as inositol triphosphate to diffuse freely across smooth muscle cells.^{58,68} The ionic changes induced by a stimulus in one smooth muscle cell are communicated rapidly across other smooth muscle cells, resulting in coordinated regulation of the entire corpora cavernosum.^{58,68} Therefore, the corpora cavernosa can be viewed functionally as a syncytium of interconnected smooth muscle cells (see Fig. 20-5).^{58,68}

Nitric Oxide. NO, derived from the nerve terminals innervating the corpora cavernosa, the endothelial lining of

penile arteries, and the cavernosal sinuses, is an important biochemical regulator of cavernosal smooth muscle relaxation. NO also induces arterial dilatation.⁶⁹ The actions of NO on the cavernosal smooth muscle and the arterial blood flow are mediated through the activation of guanylyl cyclase, the production of cyclic guanosine monophosphate (cGMP), and activation of cGMP-dependent protein kinase (also called protein kinase G, or PKG) (see Fig. 20-6). cGMP causes smooth muscle relaxation by lowering intracellular calcium. There is some evidence that NO inhibits Rho kinase-induced cavernosal smooth muscle sensitivity to calcium.⁷⁰

Cyclic Nucleotide Phosphodiesterases. Cyclic nucleotide phosphodiesterases (PDEs) hydrolyze cAMP and cGMP, thereby reducing their concentrations within the cavernosal smooth muscle. Of the 13 or more isoforms of PDEs that have been identified, isoforms 2, 3, 4, and 5 are expressed in the penis.⁷¹⁻⁷⁸ Only phosphodiesterase 5 (PDE5) is specific to the NO/cGMP pathway in the corpora cavernosa.⁷¹⁻⁷⁷ Hydrolysis of cGMP by this enzyme results in reversal of the smooth muscle relaxation and reversal of penile erection. Sildenafil, vardenafil, and tadalafil are potent and selective inhibitors of the activity of PDE5; they prevent breakdown of cGMP and thereby enhance penile erection.^{73,76,77,79}

Regulation of Sensitivity to Intracellular Calcium by Rho A/Rho Kinase Signaling. Considerable attention has focused on the role of Rho kinase in modulating the sensitivity of cavernosal smooth muscle to intracellular calcium.⁶⁰ A growing body of evidence suggests that sensitization to intracellular calcium is regulated by the balance between phosphorylation of the regulatory light chain of myosin II by a myosin light-chain kinase and its dephosphorylation by a myosin light-chain phosphatase (Fig. 20-7).^{60,80-85} Phosphorylation of the regulatory light chain of myosin II is necessary for activation of myosin II adenosine triphosphatases (ATPases) by actin, and its dephosphorylation prevents activation of myosin II

Figure 20-7 The role of Rho A/Rho kinase in regulation of cavernosal smooth muscle sensitivity to intracellular calcium (Ca^{2+}). Sensitivity to calcium and smooth muscle contractility is regulated by the Rho A/Rho kinase system. The balance between phosphorylation (P) of myosin regulatory light-chain (Myosin II RLC₂₀) kinase and its dephosphorylation by a myosin light-chain phosphatase is a major determinant of the smooth muscle sensitization to Ca^{2+} . By inhibiting the activity of MLC phosphatase, Rho kinase, the downstream effector of Rho A, can regulate smooth muscle responsiveness to calcium. Ca.CaM, calcium calmodulin. (Adapted from Somlyo AP, Somlyo AV. Ca^{2+} sensitivity of smooth muscle and nonmuscle myosin II: modulated by G proteins, kinases, and myosin phosphatase. *Physiol Rev*. 2003; 83:1325-1358.)

ATPases.^{60,80-85} The ratio of kinase to phosphatase activities is an important determinant of the contractile sensitivity of the cavernosal smooth muscle cell to intracellular calcium.⁶⁰

Rho A is a guanosine triphosphatase (GTPase) of approximately 20 kd that modulates Rho kinase activity, myosin light-chain phosphorylation, and calcium sensitivity in smooth muscle cells.⁶⁰ The Rho A-GDP complex is associated with a GDP dissociation inhibitor (RhoGDI) in its inactive state.³¹ A number of intracellular signals can promote an exchange of GDP for GTP on Rho A through the mediation of guanine nucleotide exchange factors.⁶⁰ The Rho A-GTP interacts with its downstream effector, Rho kinase,^{80,81} increasing the sensitivity of vascular smooth muscle to intracellular calcium by inhibiting the myosin light-chain phosphatases. Although the Rho A/Rho kinase expression is not significantly different between young and older rats, the activity of Rho kinase is higher in the older rats⁸⁴; the age-related increase in Rho kinase activity has been proposed as one possible mechanism to explain the age-related decrease in erectile capacity.^{84,85} Inhibition of Rho kinase activity in experimental animals increases cavernosal smooth muscle relaxation and improves intracavernosal pressures and penile erections.⁸⁵ Therefore, inhibitors of Rho A/Rho kinase signaling promise to provide attractive targets for the development of therapies for ED.⁸⁵

Mechanisms of Ejaculation

The ejaculatory mechanisms consist of three processes: emission, ejection, and orgasm.⁸⁶⁻⁸⁹ Although orgasm and seminal fluid ejection often occur contemporaneously, these two processes are regulated by separate mechanisms. *Emission*, the deposition of seminal fluid into the posterior urethra, is dependent on the integrity of the vasa deferentia, seminal vesicles, prostate gland, and bladder neck.^{88,89} *Ejaculation* refers to the ejection of seminal fluid containing sperm and the secretions of seminal vesicles, prostate, and bulbourethral glands from the posterior urethra out through the urethral meatus; it is regulated primarily by central nervous system activation of the sympathetic nervous system.⁸⁸ This emission is ejaculated out of the urethra by contractions of the bulbospongiosus and levator ani muscles, closure of the bladder sphincter due to sympathetic activation, and synchronized opening of the external urinary sphincter.⁸⁸ The sensation associated with the rhythmic contractions of these pelvic floor muscles is referred to as the *orgasm*.

The stria terminalis, the posteromedial amygdala, the subparafascicular thalamus, the medial preoptic area of the hypothalamus, the periaqueductal gray matter in the mid-brain region, and the paragigantocellular nucleus in the pons integrate seminal fluid emission and ejection during copulatory behavior.^{89,90} The paragigantocellular nucleus, through serotonergic pathways, inhibits the lumbosacral motor nuclei that are involved in ejaculation^{89,90}; input from the medial preoptic area to the paragigantocellular nucleus causes loss of this inhibition, resulting in ejaculation.^{90,91} An ejaculation generator in the spinal cord integrates the central and peripheral, sympathetic and parasympathetic signals to control ejaculation.⁸⁹⁻⁹¹ The parasympathetic fibers from the spinal ejaculation generator feed into the sacral parasympathetic nucleus and are carried from there through the pelvic nerve and the major parasympathetic ganglion into the seminal tract.⁹¹ Sympathetic fibers are carried from the spinal ejaculation generator into the dorsal gray commissure and intermediolateral cell column and then through the lumbar sympathetic

chain, pelvic nerve, superior hypogastric plexus, and major pelvic ganglion into the seminal tract.⁹⁰

Neural pathways that use serotonin and dopamine as neurotransmitters play an important role in regulating ejaculation.⁹⁰ Administration of selective serotonin reuptake inhibitors (SSRIs) is being explored for the treatment of premature ejaculation.^{92,93} At least 14 different serotonin receptor subtypes have been identified in different brain regions; the 5-HT_{1A} somatodendritic receptors in the mesencephalic and medullary raphe nuclei reduce ejaculatory latency.^{89,90} A better understanding of the neurochemical mechanisms that regulate ejaculation may provide mechanism-specific targets for treatment of ejaculatory disorders.

ROLE OF TESTOSTERONE IN REGULATING SEXUAL FUNCTION IN MEN

Testosterone regulates many domains of sexual function in men. Although androgen-deficient men can achieve penile erections in response to visual erotic stimuli, their overall sexual activity is decreased.⁹⁴ Spontaneous but not stimulus-bound erections are testosterone responsive (Table 20-2).⁹⁴ Testosterone promotes sexual thoughts and desire⁹⁴⁻¹⁰¹ and increases sexual arousal and attentiveness to erotic auditory and other stimuli.^{95,96} Nocturnal erections, temporally related to peaks of nighttime testosterone secretion, are of lower amplitude and duration in androgen-deficient men, and testosterone therapy increases the frequency, fullness, and duration of nocturnal penile tumescence.^{101,102} Maximum rigidity may require a threshold level of androgen activity.¹⁰³⁻¹⁰⁷ Testosterone regulates nitric oxide synthase (NOS) in the cavernosal smooth muscle,^{104,105} exerts trophic effects on cavernosal smooth muscle¹⁰⁶ and the ischiocavernosus and bulbospongiosus muscles, and is necessary for the veno-occlusive response.^{103,104} Androgen-deficient men show delayed orgasm and low ejaculatory volume.

TABLE 20-2

Domains of Sexual Function Regulated by Testosterone: Effects of Testosterone Therapy in Androgen-Deficient Men*

Domains That Are Improved by Testosterone Therapy

Sexual desire
Spontaneous sexual thoughts
Attentiveness to erotic auditory stimuli
Frequency of nighttime and daytime erections
Duration, magnitude, and frequency of nocturnal penile erections
Overall sexual activity score
Volume of ejaculate

Domains That Are Not Improved or for Which There Is Insufficient or Inconclusive Evidence

Erectile response to visual erotic stimulus
Erectile function in men who have normal testosterone levels
Therapeutic response to selective phosphodiesterase inhibitors
Orgasms

*Testosterone administration in androgen-deficient men improves overall sexual activity scores through its effects on specific domains of sexuality. Reproduced with permission from Bhasin S, Enzlin P, Coviello A, et al. Sexual dysfunction in men and women with endocrine disorders. *Lancet*. 2007;369:597-611.

Testosterone therapy in androgen-deficient men improves overall sexual activity, sexual desire, spontaneous sexual thoughts, and attentiveness to erotic auditory stimuli; frequency of nighttime and daytime erections; duration, magnitude, and frequency of nocturnal penile erections; overall sexual activity scores; and the volume of ejaculate.^{94,98,101,103,105,110} However, testosterone does not improve erectile response to visual erotic stimuli,⁹⁴ or erectile function in men with ED who have normal testosterone levels, or orgasms.¹⁰⁷⁻¹¹⁰

Brain imaging studies suggest that processing of sexual stimuli may be altered in androgen-deficient men, with decreased activation in those brain areas that typically are activated in eugonadal men and in androgen-deficient men after testosterone replacement in response to erotic stimuli.⁹⁸

Acting on dopaminergic receptors in the medial preoptic area of the hypothalamus, testosterone elicits reward-seeking behavior in male mammals.⁹⁹ This may be the basis for testosterone's motivational effects on mammalian sexual behavior.⁹⁹ The roles of cytochrome P450 (CYP19) aromatase and steroid 5 α -reductase systems in mediating androgen effects on sexual function remain unclear.¹⁰⁰ Studies suggest that 5 α -reduction of testosterone is not necessary for mediation of testosterone's effects on desire, but investigations of men with mutations of the CYP19 aromatase gene suggest that aromatization to estradiol may be important in mediating testosterone's effects on sexual desire.^{111,112}

There is some, albeit inconclusive, evidence to support the proposal that testosterone improves therapeutic response to selective PDE inhibitors.¹¹³⁻¹¹⁵ Androgen deficiency and ED are two independently distributed disorders that coexist in 6% to 10% of middle-aged and older men.¹¹⁶ Testosterone trials after failure of sildenafil therapy have been inconclusive.¹¹³

PHYSIOLOGY OF PHYSICAL SEXUAL AROUSAL IN WOMEN

A number of physical changes accompany subjective excitement or arousal in women, including genital swelling; increased vaginal lubrication; breast engorgement and nipple erection; increased skin sensitivity to sexual stimulation; changes in heart rate, blood pressure, muscle tone, breathing, and temperature; and mottling of the skin, a sexual flush of vasodilatation over the chest and face.⁹ These changes result from the reflex action of the autonomic nervous system. Within seconds there is increased blood flow to the vagina: vasodilatation of the arterioles in the submucosal plexus increases transudation of interstitial fluid from the capillaries across the epithelium and into the vaginal lumen. Simultaneously, there is relaxation of smooth muscle cells around the clitoral sinusoids. MRI studies have confirmed the presence of extensive clitoral tissue far beyond the visible portion of the clitoris.¹¹⁷ The clitoris comprises the head, the shaft, the rami that extend along the pubic arch, and the periurethral tissue in front of the anterior vaginal wall, as well as the bulbar tissue that surrounds the anterior distal vagina and is contiguous with the periurethral tissue. The vagina lengthens and dilates during arousal, elevating the uterus. The labia become swollen and darker red, and the lower third of the vagina swells. As the clitoris becomes more swollen, it elevates to lie nearer the symphysis pubis.

When increases in genital congestion in response to visual erotic stimuli were recorded using VPP, the

correlation between genital congestion and subjective arousal was found to be highly variable.^{53,118} This was true in sexually healthy women and in women reporting a lack of desire or arousal or sexual pain. Women reporting chronic lack of arousal showed prompt increases in vaginal congestion, comparable to those in control women, but reported no subjective sexual excitement in response to the erotic stimulation. Functional MRI studies showed that, unlike in men, activation of the areas organizing genital vasocongestion in women does not correlate with a woman's subjective excitement.³⁴

The neurobiology of the genital vasocongestive response in women is incompletely understood but involves release of NO from the parasympathetic nerves, along with release of VIP.¹¹⁹ Acetylcholine, which blocks noradrenergic vasoconstricting mechanisms and promotes NO release from the endothelium, is also released. There is communication between the NO-containing cavernous nerve to the clitoris and the distal portion of the somatic dorsal nerve of the clitoris from the pudendal nerve. Pelvic sympathetic nerves release primarily vasoconstrictive noradrenalin, adrenalin, and adenosine triphosphate (ATP), but some release acetylcholine, NO, and VIP. The provoked anxiety in the laboratory situation can increase the vasocongestive response of the genitalia to erotic stimulation in sexually healthy women.¹²⁰ The melanocortin-4 receptors and oxytocin also may be involved in clitoral and vaginal efferent pathways.

There is some evidence for a "cervical motor reflex," such that touch to the cervix reduces pressure in the upper portion of the vagina but increases pressure in the middle and lower portions.¹²¹ Reduced uterine tone can occur in response to mechanical or electrical stimulation of the clitoris. Possibly, this reflex contributes to an increase in size and elevation of the uterus with sexual arousal.¹²¹

The clitoris is the most sexually sensitive area of the body. Immunohistologic studies have identified neurotransmitters thought to be associated with sensation (substance P and CGRP) that are concentrated immediately under the epithelium of the glans clitoris. The physiology of nongenital physical changes and their correlation with subjective excitement remain poorly understood.

PHYSIOLOGY OF ORGASM

Orgasm is a brain event, triggered typically by genital stimulation but also by sleep, stimulation of other parts of the body (including breast and nipple), fantasy, certain medications, and, in women with spinal cord injury, vibrostimulation of the cervix.

Orgasm is a subjective experience in both men and women, and it has been difficult to determine an objective marker. In healthy men, there is the associated ejaculation, and in both genders, there are involuntary (reflexive) muscular contractions of the striated perineal muscles. One objective and quantitative measure has been established that shows strong correspondence with the subjective experience of orgasm.^{122,123} The researchers performed spectral analysis of rectal pressure data while volunteers imitated orgasm, tried to achieve orgasm and failed, or experienced orgasm. The most significant and important difference in spectral power between orgasm in both control tasks was found in the alpha band.¹²² Outbursts of alpha fluctuations in rectal pressure occurred only during orgasm.¹²²

Positron emission tomography studies during orgasm have shown largely similar brain activations and deactivations in both men and women: activations mainly in the

anterior lobe of the cerebellar vermis and deep cerebellar nuclei and deactivations in the left ventromedial and orbitofrontal cortex.³⁴ The only major difference between the genders during orgasm itself was the activation in the periaqueductal gray matter in men.³⁴ The lateral orbitofrontal cortex is thought to be involved in urge suppression and behavioral release, whereas the medial parts encode hedonic experiences, becoming activated with increasing satiation and subjective pleasantness and deactivated with feelings of satiety. It is thought that the orgasm-related deactivation of the middle orbitofrontal cortex reflects satiety and not the hedonic experience of orgasm. The medial orbitofrontal cortex is part of the neuronal network that includes the amygdala, whose deactivation during orgasm is associated with a more carefree state of mind.³³

The role of oxytocin in orgasm is unclear. Oxytocin levels increase at the time of orgasm.¹²⁴ Possibly, the increase in oxytocin modulates the experience of orgasm stemming from the action of the smooth muscles in the genitalia.¹²⁴ The periorgasmic release of oxytocin may contribute to the postorgasmic refractory period in men.¹²⁵

DEFINITIONS OF SEXUAL DYSFUNCTION IN MEN

Both the DSM and the ICD definitions of sexual disorder are under revision, with new editions to be published in 2013. Changes are expected, especially in women, given the blurring of the phases of sexual response and the common comorbidity of dysfunction in various phases.¹²⁶⁻¹³¹

Hypoactive Sexual Desire in Men

Hypoactive sexual desire disorder is persistent or recurrent deficiency (or absence) of sexual fantasies and desire for sexual activity that causes marked distress or interpersonal difficulty and that is not better explained by another disorder, direct physiologic effects of a substance (i.e., medication), or general medical condition.¹³²⁻¹³⁴ A diagnosis of hypoactive sexual desire disorder is appropriate only if the person reports “distress or interpersonal difficulty” due to low sexual desire.¹³²⁻¹³⁴ Low sexual desire is not necessarily pathologic; it may be an appropriate adaptation to relationship and health-related issues.¹³²⁻¹³⁴

Hypoactive sexual desire disorder in men, when it is generalized—that is, when self-stimulation (masturbation) is also absent—is a multifactorial disorder that can result from androgen deficiency, use of medications (e.g., SSRIs, antiandrogens, gonadotropin-releasing hormone [GnRH] analogs, antihypertensives, cancer chemotherapeutic agents, anticonvulsants), systemic illness, depression and other psychological problems, other causes of sexual dysfunction, or relationship and differentiation problems. Androgen deficiency is an important, treatable cause of hypoactive sexual desire disorder and should be excluded by measuring serum total testosterone levels.

True incidence and prevalence rates of hypoactive sexual desire disorder in the general population are unknown. In studies of referred patient populations, the prevalence rate has been estimated at 5% in men and 22% in women.^{7,8,134} Prevalence rates increase with age.^{134,135} Whether these figures include situational hypoactive sexual desire disorder (i.e., desire for partnered sex is absent but self-stimulation continues) is unclear. Hypoactive sexual desire disorder often coexists with other sexual disorders, such as

ED, and may develop as a consequence of other preexisting sexual disorders.¹³⁴⁻¹³⁶

Appropriate evaluation and treatment of hypoactive sexual desire disorder is important, because evaluation may lead to the detection of treatable androgen deficiency. Also, hypoactive sexual desire in one partner can strain the relationship between sexual partners^{136,137} and lead to ED. Low sexual desire may impede or reduce the effectiveness of treatments for other sexual dysfunctions.

Erectile Dysfunction

Erectile dysfunction, previously referred to as impotence, is the inability to attain or to maintain an erection sufficient for satisfactory sexual intercourse.^{11,14-15} *Sexual dysfunction* is a more general term that also includes libidinal, orgasmic, and ejaculatory dysfunction, in addition to the inability to attain or maintain penile erection. The MMAS⁴ and NHSLS^{6,7} investigations revealed a surprisingly high prevalence of ED in men (see later discussion). ED significantly affects quality of life of both the affected individual and his partner. In one study, ED had a negative impact on the sexual life of female partners, specifically on their sexual satisfaction and sexual drive.¹³⁷

Prevalence and Incidence Rates

The best data on the prevalence of ED in men have emerged from two cross-sectional studies that used population-based sampling techniques, the MMAS^{4,138}; and the NHSLS.^{6,7} The MMAS was a cross-sectional and longitudinal, community-based epidemiologic survey in which 1709 men, 40 to 70 years of age, residing in the greater Boston area, were surveyed between 1987 and 1989.^{4,138} Of these, 847 men were resurveyed between 1995 and 1997.¹³⁸ This study revealed that 52% of men between the ages of 40 and 70 were affected by ED of some degree; 17.2% of surveyed men reported minimal ED, 25.2% moderate ED, and 9.6% complete ED.^{4,138} The NHSLS was a national probability survey of English-speaking Americans, 18 to 59 years of age, living in the United States.^{6,7} This survey also revealed a high prevalence of ED in men, and the prevalence increased with increasing age.^{6,7}

These two landmark studies and data from several other studies are in agreement that ED is a common problem worldwide.^{4,6,7,135,138-143} ED has been estimated to affect 20 to 30 million men in the United States alone and 150 to 200 million men worldwide. The prevalence of ED increases with age; it affects fewer than 10% of men before 45 years of age but is present in 75% of men older than 80 years of age.⁴ Men with other medical problems, such as hypertension, diabetes, cardiovascular disease, or end-stage renal disease, have a significantly higher prevalence of ED than healthy men.⁴

There is a paucity of longitudinal data on the incidence rates of ED in men. In the MMAS, the crude incidence rate among white men in the Boston area was 25.9 cases per 1000 man-years overall¹³⁸: 12.4 cases per 1000 in the group aged 40 to 49 years, 29.8 per 1000 among 50- to 59-year-olds, and 46.4 per 1000 in the 60- to 69-year-old group.¹³⁸ In another study, incidence rates were derived from a survey of men seen at a preventive medicine clinic.⁸ This study found the incidence rates of ED to be less than 3 cases per 1000 man-years among men younger than 45 years of age and 52 cases per 1000 man-years among men aged 65 years or older. These studies suggest a worldwide incidence of ED of 152 million in 1995 and an annual incidence of 600,000 to 700,000 in the United States.¹⁴²

Risk Factors for Erectile Dysfunction

The risk factors for ED include age, diabetes mellitus, hypertension, smoking, medication use, depression, dyslipidemia, and cardiovascular disease.^{4,140,141} Advancing age is an important risk factor for ED in men^{4,140,141}; less than 10% of men younger than 40 years and more than 50% of those older than 70 have ED. In both the MMAS and the NHLS, the prevalence of ED increased with each decade of life.^{4,6}

Among the chronic diseases associated with ED, diabetes mellitus is the most important risk factor. In the MMAS, the age-adjusted risk of complete ED was three times higher in men with a history of treated diabetes mellitus than in those without a history of diabetes mellitus.^{4,138} Fifty percent of men with diabetes mellitus will experience ED sometime during the course of their illness. In the MMAS, treated heart disease, treated hypertension, and hyperlipidemia were associated with significantly increased risk of ED. Among men with treated heart disease and hypertension, the probability of ED was more than two times greater for smokers than for nonsmokers. Smoking also increases the risk of ED in men taking medications for cardiovascular diseases. Cardiovascular disorders, including hypertension, stroke, coronary artery disease, and peripheral vascular disease, are all associated with increased risk of ED. Physical activity is associated with reduced risk of ED.¹⁴⁰

Several reviews have emphasized the relationship between prescription medications and the occurrence of ED. In the MMAS, use of antihypertensives, cardiac medications, or oral hypoglycemic drugs was associated with an increased risk of ED.⁴ Thiazide diuretics and psychotropic medications used in the treatment of depression may be the drugs most commonly associated with ED, simply because of the high prevalence of their use. However, a variety of drugs, including almost all antihypertensives, digoxin, histamine-2 receptor antagonists, anticholinergics, cytotoxic agents, and androgen antagonists, have been implicated in the pathophysiology of ED.

Erectile Dysfunction as a Marker of Cardiovascular Disease

Cardiovascular disease and ED share common risk factors, including diabetes mellitus, obesity, hypertension, smoking, and dyslipidemia.¹⁴⁴⁻¹⁵² ED precedes the symptoms of coronary artery disease by 2 to 3 years and cardiovascular events such as myocardial infarction or stroke by 3 to 5 years.¹⁴⁴⁻¹⁴⁶ ED in men is associated with increased risk of death, particularly mortality due to cardiovascular disease.¹⁴⁷ The presence of ED is a good predictor of subsequent coronary artery disease, especially in younger men, independent of traditional coronary risk factors; however, it does not enhance the predictive ability of models that include traditional risk factors, likely reflecting the common pathophysiologic mechanisms of ED and coronary artery disease.¹⁴⁷ Men reporting ED are 1.3 to 1.6 times more likely to experience a cardiovascular event within 10 years than men without ED.¹⁴⁵⁻¹⁴⁸

Lower Urinary Tract Symptoms and Erectile Dysfunction

Surveys have revealed an association between lower urinary tract symptoms (LUTS) and ED,¹⁵³⁻¹⁵⁹ even after adjusting for age and other risk factors. The Cologne Male Study and the Multinational Study of the Aging Male revealed that the presence and severity of LUTS is an predictor of ED irrespective of age.¹⁵⁴ LUTS and age are stronger predictors of ED than all other risk factors, including diabetes,

dyslipidemia, and hypertension. Because LUTS and ED are two common conditions in middle-aged and older men, it is possible that this association reflects the coexistence of two highly prevalent conditions. However, there is growing evidence that the two conditions may be mechanistically linked, because the biochemical mechanisms that regulate bladder detrusor and cavernosal smooth muscle function share many similarities.^{159,160}

Potassium channels, especially the calcium-sensitive BK_{Ca} channels, Rho A/Rho kinase signaling, L-type calcium channels, and gap junctions are important mediators of both detrusor and cavernosal smooth muscle contractility and relaxation. Increased myocyte contractility that characterizes both bladder detrusor dysfunction and ED may be mechanistically related to increased Rho kinase activity, impairments of potassium channel function,¹⁵⁹⁻¹⁶¹ α -adrenergic receptor imbalance, and endothelial dysfunction. Additional proposed hypotheses include increased sympathetic activity and autonomic dysfunction and alterations in NO generation or PKG activity in the detrusor and cavernosal smooth muscles.¹⁵⁹⁻¹⁶¹ Some therapies for LUTS, such as some types of surgery and 5 α -reductase inhibitors, may worsen sexual dysfunction. PDE5 inhibitors are being investigated for the treatment of LUTS.¹⁶¹⁻¹⁶⁴

Ejaculatory Disorders

Ejaculatory disorders include premature ejaculation, delayed ejaculation, retrograde ejaculation, anejaculation/anorgasmia, and painful ejaculation.^{86,89} Recent surveys have highlighted the high prevalence and clinical importance of ejaculatory disorders.^{89,165,166} Although the availability of oral PDE5 inhibitors has increased awareness of ED, ejaculatory disorders are at least as prevalent and may be even more prevalent than ED.^{165,166} *Premature ejaculation*, defined as ejaculation associated with lack of or poor ejaculatory control that causes distress in one or both partners, is the most prevalent sexual disorder in men 18 to 59 years of age.^{86,89,165} *Delayed ejaculation* refers to inability to ejaculate in a reasonable period that interferes with sexual or emotional satisfaction and is associated with distress.

Retrograde ejaculation is the failure of the semen to be ejected out through the urethral meatus; instead, the semen is propelled backward into the urinary bladder. Retrograde ejaculation can be the result of autonomic neuropathy associated with diabetes mellitus; sympathectomy; therapy with adrenergic antagonists, some types of antihypertensives, antipsychotics, or antidepressants; bladder neck incompetence; or urethral obstruction. Retrograde ejaculation due to diabetes-associated autonomic neuropathy is the second most prevalent ejaculatory disorder. After transurethral resection of the prostate, the bladder neck closure mechanism may be damaged. Patients remain continent because of a second, more distal, continence mechanism that is present in the region of the membranous urethra; however, many patients who have undergone transurethral resection of the prostate experience retrograde ejaculation. Ejaculatory disorders can lead to infertility among men.

DEFINITIONS OF SEXUAL DISORDERS IN WOMEN

The Third International Consensus on Sexual Dysfunctions in Men and Women in 2009 endorsed the interim revisions to the current DSM (Fourth Edition, Text Revised)

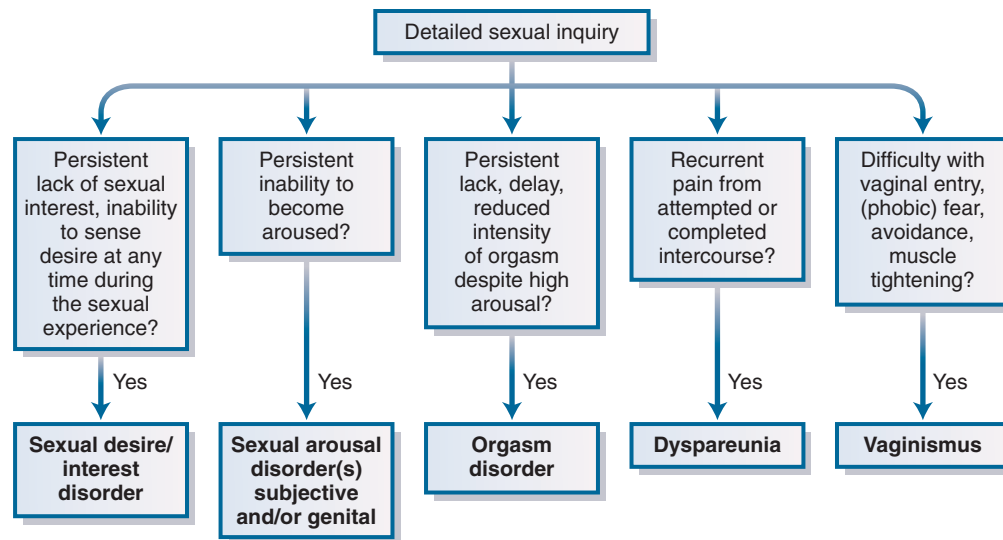

Figure 20-8 Currently recommended definitions for women's sexual dysfunction. Comorbidity is usual, especially sexual desire/interest disorder with one of the sexual arousal disorders. (From Basson R, Leiblum S, Brotto L, et al. Definitions of women's sexual dysfunctions reconsidered: advocating expansion and revision. *J Psychosom Obstet Gynaecol.* 2003;24:221-229.)

definitions of women's sexual dysfunction proposed in 2003.¹⁶⁷ Definitive changes (DSM5) are expected in 2013. The currently recommended definitions for women's sexual dysfunction are shown in Figure 20-8.

Sexual Desire/Interest Disorder

In sexual desire/interest disorder, feelings of sexual interest or desire are absent or diminished, sexual thoughts or fantasies are absent, and there is a lack of responsive desire. Motivations (here defined as reasons or incentives) for attempting to become sexually aroused are scarce or absent. The lack of interest is considered to be beyond the normative lessening with lifecycle and relationship duration.¹⁶⁷

Apparently innate or "spontaneous" desire, present before sexual stimulation begins, is often present for women especially early in a relationship and sometimes is associated with the menstrual cycle. However, absence of sexual desire does not equate to dysfunction: typically, initial or spontaneous desire lessens with relationship duration.¹⁶⁸

Prevalence is unclear given the lack of consistency of definition of hypoactive sexual desire in the different studies. Studies reporting low desire and distress have had reported prevalence rates of about 10%, not increasing with age.

Risk factors include negative feelings for the partner and mood disorders. Depression, either currently or in the past, and, in the absence of any diagnosed depression, more depressive and anxious thoughts and low self-esteem are found significantly more commonly than in control women.¹⁶⁹

Arousal Disorders

Most women complaining of lack of arousal show physiologically healthy vasocongestive responses in the genitalia to erotic sexual stimulation, as measured by VPP, but do not experience subjective arousal; it is their lack of subjective arousal that is the key to their distress, rather than failure of genital congestion.⁵³ The subtypes of sexual

arousal disorder include subjective sexual arousal disorder, genital sexual arousal disorder, and persistent genital arousal disorder.

Subjective Arousal Disorder

In subjective arousal disorder, feelings of sexual arousal (sexual excitement and sexual pleasure) from any type of sexual stimulation are absent or markedly diminished. Vaginal lubrication or other signs of physical response still occur.¹⁶⁷ (See Fig. 20-10.)

Genital Sexual Arousal Disorder

In patients with complaints of impaired genital sexual arousal, the self-report may include minimal vulvar swelling or vaginal lubrication with any type of sexual stimulation and reduced sexual sensations from caressing of the genitalia. Subjective sexual excitement still occurs from nongenital sexual stimuli.¹⁶⁷

A woman diagnosed with the genital subtype of arousal disorder indicates that she can still be subjectively aroused by, for instance, viewing an erotic film, pleasuring her partner, being kissed, or receiving breast stimulation. She complains of the marked loss of intensity of any genital response including orgasm. Awareness of throbbing, swelling, and lubrication is absent or markedly diminished.

It is the woman's self-report of absent or impaired genital congestion and lubrication that is the basis of the definition. There may or may not be demonstrable physical pathophysiology if such testing were available. Moreover, loss of sexual quality of sensations despite apparently adequate engorgement can occur and is little understood.

Interim publications referring to DSM5 revisions to definitions advocate that desire and arousal disorders be merged.^{126,127} Increasing evidence that desire ahead of and at the outset of sexual engagement, although welcomed probably by both partners, is not mandatory for a woman's sexual enjoyment and satisfaction.^{136,127} It is the inability to trigger desire and arousal during sexual engagement (as well as an absence of desire initially) that constitutes disorder. Therefore, merging of sexual and desire difficulties into one disorder appears logical.

Persistent Genital Arousal Disorder

In persistent genital arousal disorder, there is spontaneous, intrusive, and unwanted genital arousal (e.g., tingling, throbbing, pulsating) in the absence of sexual interest and desire. Any awareness of subjective arousal is typically, but not invariably, unpleasant. The arousal is unrelieved by one or more orgasms, and the feelings of arousal persist for hours or days.¹⁶⁷

The disorder is poorly understood but is becoming a more frequently recognized syndrome. The definition is recommended to facilitate investigation of prevalence and etiology.

Women's Orgasmic Disorder

In women with orgasm disorder, despite self-reports of high sexual arousal or excitement, there is either lack of orgasm, markedly diminished intensity of orgasmic sensations, or marked delay of orgasm from any kind of stimulation.¹⁶⁷

The prevalence is unclear, because many studies include women with low arousal who do not reach orgasm. Risk factors include anxiety about the partner's presence, fear of being vulnerable, fear of not being in control, and fear of intimacy. These factors often stem from childhood (non-sexual) experiences.

Dyspareunia

In dyspareunia, there is persistent or recurrent pain with attempted or complete vaginal entry or penile vaginal intercourse.¹⁶⁷ It is recommended that the experience of women who cannot tolerate full penile entry and the movements of intercourse because of pain be included in the definition of dyspareunia. Clearly, the outcome depends on the woman's pain tolerance and her partner's hesitancy or insistence.

Reported prevalence rates vary between 20% and 35%. The most common form of dyspareunia, provoked vestibulodynia (PVD), affects some 16% of (mostly young) women.¹⁷⁰ Risk factors for PVD include some personality traits—perfectionism, reward dependency, fear of negative evaluation—as well as harm avoidance, hypervigilance for pain, higher levels of trait anxiety, and shyness.¹⁷⁰ For a small subset, vaginal candidiasis appears to precipitate and maintain the condition.

Vaginismus

A woman with vaginismus has persistent or recurrent difficulties in allowing vaginal entry of a penis, a finger, and/or any object, despite her expressed will to do so. There is often (phobic) avoidance, involuntary pelvic muscle contraction, and anticipation or fear of pain or the experience of pain. Structural and other physical abnormalities must be ruled out or addressed.¹⁶⁷

Prevalence rates are unclear. Risk factors include depression, anxiety, social phobia, somatization, and hostility. Some studies identify increased catastrophic thinking in women with vaginismus compared with women without dyspareunia or women with other forms of pain (e.g., PVD); moreover, women with vaginismus show higher disgust propensity.¹⁷⁰ Despite the theories, there is no scientific evidence that vaginismus is secondary to religious orthodoxy, negative sexual upbringing, or concerns about sexual orientation. There is typically extreme fear of vaginal entry, fear that harm will come from something the size of

a penis entering the vagina, and fear of damage by vaginal delivery.

SEXUAL DYSFUNCTION IN THE CONTEXT OF ENDOCRINE DISEASE

This section focuses on sexual sequelae of endocrine disease and its treatment, but in any given person, nonendocrine factors may be more important. These include psychological, relational, contextual, cultural, and nonendocrine medical influences, especially depression, hypertension, neurologic disease, and LUTS.²¹ For patients with chronic disease, the disease itself, its treatment, its psychological effects, and interpersonal, personal, and contextual issues affect sexual response.^{21,171}

In healthy women, factors such as attitudes toward sex, feelings for the partner, past sexual experiences, duration of the relationship, and mental and emotional health have been shown to modulate desire and arousability more strongly than biologic factors.^{16,171-174} Contrary to gender stereotypes, recent analysis of the 1035 sexually active adults who participated in the NHSLS in 1992 showed that men's physical sexual pleasure was more closely linked to relational factors than was the case for women.²⁶ Similarly, in a recent international study of midlife and older couples, men rated the importance of sex for closeness and intimacy to their partner more highly than did their female partners.²⁷ Qualitative research also suggests that men as well as women note that positive self-esteem and feeling attractive enhance desire and arousal.^{24,30} Sexual context is also important for both men and women.^{24,30,174}

Endocrine Disorders and Sexual Dysfunction in Men

Androgen Deficiency Syndromes

Androgen deficiency can occur because of primary testicular dysfunction or as a result of disorders affecting the hypothalamus or the pituitary.¹⁰⁷ Common causes of primary testicular dysfunction include Klinefelter's syndrome, uncorrected cryptorchidism, human immunodeficiency virus (HIV) disease, orchitis, trauma, torsion, and irradiation and cancer chemotherapy.¹⁰⁷ Before arriving at a diagnosis of idiopathic hypogonadotropic hypogonadism, systemic illness, excessive exercise, recreational drugs (especially marijuana, cocaine, and alcohol), central hypogonadism from pituitary or suprasellar tumors, hemochromatosis, hyperprolactinemia, and infiltrative disorders should be considered.¹⁰⁷ The testosterone levels required to maintain sexual function are close to the lower limit of the normal male range.^{109,175-177} Therefore, some men with pituitary tumors may remain asymptomatic until their tumor has grown substantially and testosterone levels have declined to a level below this threshold.

Diabetes and Sexual Dysfunction in Men

Men with diabetes mellitus are at increased risk for ED, retrograde ejaculation, and low testosterone levels. Peyronie's disease is an important comorbid condition in older diabetic men with ED.¹⁷⁸⁻¹⁸⁶ Men with diabetes have significantly lower scores for sexual desire, activity, arousal, and satisfaction,^{179,180} in part due to the medical and psychological factors associated with diabetes, such as the variations in glycemic control, reduced energy, altered self-image, and interpersonal difficulties regarding dietary compliance, glucose monitoring, and medications. Diabetes also is

associated with increased risk of low testosterone levels.^{177,187-190} In population studies, sex hormone-binding globulin (SHBG) and total testosterone are more strongly associated with diabetes risk than free testosterone levels; these data suggest that the observed association of testosterone with diabetes risk may be related to factors such as insulin sensitivity and inflammation that regulate SHBG.¹⁹¹

The prevalence of ED in men with diabetes increases with age and has been as high as 75% in some studies. ED in men with type 2 diabetes, even without other risk factors for coronary artery disease, may signal silent cardiac ischemia.¹⁹² Among men with diabetes, those with ED are more likely to be older smokers with longer duration of diabetes, poor metabolic control, untreated hypertension, and presence of neuropathy, microalbuminuria, macroalbuminuria, retinopathy, cardiovascular disease, diuretic treatment, low testosterone levels, and psychological vulnerability.¹⁸³⁻¹⁸⁶ Increased physical activity and consumption of small amounts of alcohol have been found to be protective. The risk of ED generally increases with chronic elevation of glycosylated hemoglobin (HbA_{1c}).¹⁸³

Endothelial and smooth muscle dysfunction, autonomic neuropathy, and psychological and interpersonal issues contribute to sexual dysfunction in men with diabetes.¹⁹³⁻¹⁹⁵ Endothelial dysfunction is evident in penile blood vessels and in nongenital vascular beds.¹⁹⁴ Endothelial NOS (eNOS) is reduced, possibly due to overexpression of arginase or lack of reduced nicotinamide adenine dinucleotide phosphate (NADPH), an essential cofactor for NOS.¹⁹³⁻²⁰⁰ Additionally, accumulation of oxygen free radicals, including those from advanced glycosylation end products, quench NO and attenuate the action of potassium channels.¹⁹⁶ The low NADPH is also associated with increased diacylglycerol and protein kinase C and, consequently, increased smooth muscle contractility.^{193,195} Increased activation of the RhoA/Rho kinase pathway may increase the sensitivity of cavernosal smooth muscle to calcium.¹⁹⁷ Autonomic neuropathy affecting the pelvic nerves may lead to ED as well as ejaculatory dysfunction.¹⁹⁸

Retrograde ejaculation and partial ejaculatory incompetence affect up to one third of men with diabetes.²⁰¹ Autonomic nerve damage in diabetes may be associated with dysfunction of the internal sphincter so that all or a part of the seminal fluid is propelled into the bladder.¹⁹⁸ *Partial ejaculatory incompetence* refers to the condition in which ejaculatory emission remains intact but the expulsion phase is inhibited; consequently, the semen trickles out of the penis and the experience of orgasm is altered in quality. Both ejaculatory problems may be a cause of infertility.

Sexual Dysfunction Associated with Therapies for Benign Prostatic Hypertrophy

Benign prostatic hypertrophy is frequently associated with LUTS and sexual dysfunction.^{154-157,202} Although treatment with some α_1 -adrenergic receptor blockers can improve erectile function, others (e.g., tamsulosin) are associated with ejaculatory dysfunction.²⁰³ Treatment of men with LUTS with 5 α -reductase inhibitors has been associated with increased risk of ejaculatory disorder, ED, and decreased libido.^{204,205}

Hyperprolactinemia and Sexual Dysfunction

Hyperprolactinemic men often present with decreased libido or ED; 75% of men with macroprolactinomas and 50% of men with microprolactinomas report reduced desire or ED, and almost all have subnormal nocturnal

penile erections.²⁰⁶⁻²⁰⁹ Hyperprolactinemia affects 1% to 5% of men presenting with ED²⁰⁶⁻²⁰⁷; a fraction of these men have prolactin-secreting pituitary adenomas.

Prolactin lowers testosterone levels through its inhibitory effects on GnRH secretion and on the pituitary response to GnRH. Most, but not all, men with sexual dysfunction and hyperprolactinemia have low testosterone levels.^{208,209} Whether and how hyperprolactinemia directly affects erectile function through target organ effects is not well understood. Erectile function usually improves in hyperprolactinemic men after treatment with dopamine agonists.²¹⁰

Sexual Dysfunction in Patients with Thyroid Disease

Hypothyroidism has been associated with increased risk of hypoactive sexual desire and ED.²¹¹⁻²¹⁵ The exact prevalence of sexual dysfunction in men with hypothyroidism is unknown. Free testosterone levels are lower in hypothyroid men than in controls and become normal after thyroxine replacement.²¹¹⁻²¹⁵ Serum LH and follicle-stimulating hormone (FSH) levels are typically not elevated in men with primary hypothyroidism.²¹¹ Hyperprolactinemia is noted in a small fraction of hypothyroid men.²¹¹

Free testosterone levels are typically normal in men with hyperthyroidism, but SHBG and estradiol levels are elevated, resulting in a high ratio of estradiol to testosterone and gynecomastia in some hyperthyroid men.²¹¹⁻²¹³ Hyperthyroidism has been observed in a small fraction of men with ED.⁷⁹

Sexual Dysfunction in Men with Metabolic Syndrome

Men with metabolic syndrome have a higher prevalence of ED than men without the metabolic syndrome.²¹⁶⁻²¹⁹ The risk of ED is correlated with the number of identified components of metabolic syndrome.²¹⁶⁻²¹⁹

Endocrine Disorders and Sexual Dysfunction in Women

Diabetes in Women

That women with diabetes mellitus are more likely than age-matched controls to report sexual dissatisfaction is confirmed in most studies.²²⁰⁻²²⁵ In contrast to men with diabetes and ED, in whom glycemic control and disease duration correlate with the incidence of ED, usually no such correlation has been observed in women with diabetes and sexual dysfunction. A review of sexual dysfunction in women with diabetes mellitus confirmed a consistent link with comorbid depression.²²⁶

Past studies often failed to differentiate between type 1 and type 2 diabetes, and many did not separate premenopausal and postmenopausal women with diabetes mellitus. The rates of decreased desire are generally similar in women with and without diabetes, but decreased arousal and reduced lubrication are more common in women with diabetes. However, in one study, younger women with diabetes had low desire but otherwise normal sexual responses, whereas all phases of sexual response, including sexual desire, were blunted in women older than 50 years of age, compared with controls.²²⁵ A recent large study of women enrolled in the long-term Epidemiology of Diabetes, Interventions, and Complications (EDIC) study, albeit without a comparison group of control subjects, confirmed

dysfunction in 35% of those women who were sexually active. Low desire was present in more than one half of the women; problems with orgasm, arousal, and lubrication in 40% to 50%; and pain in 21%.²²⁷ In multivariate analysis, only depression and marital status predicted sexual dysfunction. Data on dyspareunia and orgasmic difficulties are conflicting.

In women, hyperandrogenism is associated with increased risk of diabetes due to increased insulin resistance and pancreatic beta cell dysfunction.²²⁸⁻²³¹ Lower SHBG levels are associated with type 2 diabetes in both genders.^{187,191} In women with polycystic ovary syndrome, the length of the polyglutamine tract in exon 1 of the androgen receptor gene has been reported to modulate the association between increased testosterone and insulin resistance.²³² Estrogen therapy has been shown to decrease androgen levels and improve glucose control.^{233,234} The protective effects of estrogen on pancreatic insulin secretion, insulin sensitivity, and genital tissue health in women need further investigation.

Diabetes has been associated with reduced clitoral blood flow and cavernosal smooth muscle content and decreased sensation in the clitoris, labia, and vagina as well as extragenital sites.^{235,236} The peripheral vascular dysfunction and neuropathy in diabetes also potentially impair sexual response.

Metabolic Syndrome in Women

Metabolic syndrome has been shown to have a negative effect on women's sexuality, independent of associated diabetes and obesity.²³⁷⁻²³⁹ This negative effect seems to be more prevalent in premenopausal rather than postmenopausal women.²³⁷⁻²³⁹

Polycystic Ovary Syndrome

Limited research has shown that women with polycystic ovary syndrome may be less sexually satisfied and may find themselves less attractive than controls.²⁴⁰⁻²⁴² The presumption is that these findings are related to obesity and androgen-related symptoms.^{240,241} There is minimal information on treatment of androgen excess with antiandrogens: one small case study reported that desire increased in 6 women and decreased in 13 women treated with an antiandrogen.²⁴³ Another study showed that the insulin sensitizer, metformin, improved psychosexual function in women with polycystic ovary syndrome.²⁴⁴

Congenital Adrenal Hyperplasia

Nonclassic forms of congenital adrenal hyperplasia may manifest with signs of hyperandrogenism in childhood or adulthood, depending on the severity of the 21-hydroxylase enzyme deficiency.²⁴⁵ The presenting features of 21-hydroxylase enzyme deficiency may include menstrual disorders such as amenorrhea, anovulation, hirsutism, or oligomenorrhea with infertility.^{245,246} Limited research suggests that sexual functioning of women with nonclassic 21-hydroxylase deficiency is not different from that of controls. However, women with classic congenital adrenal hyperplasia may show gender-atypical behavior²⁴⁷; in one study, male-typical role-playing in childhood correlated with reduced satisfaction with the female gender role and reduced heterosexual interest in adulthood.²⁴⁸ Disturbed body image, repeated genital examinations, and genital surgery may also affect sexual function in women with congenital adrenal hyperplasia.²⁴⁷ Clearly, caring for these women requires careful individualized treatment with appropriate therapy for signs and symptoms of androgen excess as well as psychosexual counseling.

Hyperprolactinemia in Women

Hyperprolactinemia is associated with increased risk of sexual dysfunction.²⁴⁹⁻²⁵¹ Women with hyperprolactinemia report lower overall satisfaction with sexual function and lower scores for sexual desire, arousal, lubrication, and orgasm domains than women with normal prolactin levels.²⁵⁰ Prolactin inhibits GnRH pulses, attenuates gonadotropin response to GnRH, and is associated with reduced ovarian secretion of estrogen and androgen. Therefore, sexual dysfunction in women with hyperprolactinemia may be related to changes in sex hormones. Although menstrual disturbance or infertility is more commonly the presenting symptom of hyperprolactinemia, lower scores for sexual function and desire have also been found in women with hyperprolactinemia who have regular menses.²⁴⁹⁻²⁵¹ Normal menstruation, younger age, and small tumor size are more likely to be associated with normal sexual function than the actual level of prolactin or testosterone.²⁴⁹⁻²⁵¹ Sexual outcomes of treatment of hyperprolactinemic women with dopamine agonists have not been well studied.

Pituitary Disease in Women

There is limited research on sexual function in women who have deficiencies of various pituitary hormones. Most women with pituitary disease report menstrual irregularity or problems with sexual function, including decreased sexual desire and problems with lubrication or orgasm.²⁵¹ In one randomized trial of 51 women, testosterone therapy in women who were receiving estrogen therapy was associated with some benefit in sexual function and mood, compared with placebo, and a higher frequency of androgenic side effects than placebo.²⁵² The effects of dehydroepiandrosterone (DHEA) on sexual function and mood in women with hypopituitarism are poorly understood.²⁵³

Adrenal Insufficiency

In addition to the deficiency of cortisol and aldosterone, women with adrenal insufficiency also have low levels of testosterone and DHEA.²⁵³⁻²⁵⁷ Adrenal insufficiency in women has been associated with low sexual desire, general lack of well-being, and poor quality of life. However, clinical trials of DHEA replacement in women with adrenal insufficiency have reported inconsistent results, possibly due, in part, to their small size.²⁵³⁻²⁵⁷ An earlier small trial in women with primary or secondary adrenal insufficiency reported greater improvements in sexual interest and satisfaction and in mood for women receiving DHEA, compared with placebo²⁵³; however, two other studies did not find significant improvements in sexual function.^{254,255}

Natural Menopause

A majority of women who discontinue postmenopausal estrogen supplementation develop signs of vulval vaginal atrophy, which is a risk factor for sexual dysfunction.²⁵⁸ Among sexually active women, those with sexual dysfunction are 3.8 times more likely to have atrophy than those with normal sexual function.²⁵⁸ However, epidemiologic studies have not shown an increase in the prevalence of dyspareunia with age.²⁵⁹⁻²⁶¹ Clearly, not all postmenopausal women develop sexual symptoms of estrogen deficiency. It is likely that multiple factors contribute to sexual symptoms, including variations in the intracrine production of estrogen from adrenal precursors, in the number and sensitivity of estrogen receptors, and in the degree of sexual arousal or excitement at the time of vulval stimulation and vaginal entry.²⁶²⁻²⁶⁴

Most studies report a decrease in sexual desire with advancing age²⁶⁵ that is not easily explained by estrogen deficiency alone. Adaptive changes occur in the brain in response to the reductions in circulating levels of sex hormones associated with age and menopause.^{266,267} Sex hormones may be produced locally within the brain: in women, steroidogenic enzymes and sex receptors in the brain are upregulated in response to decreased circulating levels of sex hormones.^{266,267} Investigation of the question of biologic adaptation to reduced amounts of sex hormones is in its infancy.

Surgical Menopause

Surgical menopause is a state of both androgen and estrogen deficiency and has often been viewed as a risk factor for sexual dysfunction in women. However, studies have shown that most women undergoing bilateral salpingo-oophorectomy (BSO) for benign clinical indications do not develop sexual dysfunction.²⁶⁸⁻²⁷⁰ Three prospective studies found that women choosing BSO plus hysterectomy for benign indications did not develop sexual dysfunction over the next 1 to 3 years.²⁶⁸⁻²⁷⁰

A large national survey of 2207 American women confirmed an increased prevalence of distress about low sexual desire in women with a relatively recent BSO. However, both older and younger women with a relatively recent BSO reported low sexual desire per se as often as age-matched subjects with intact ovaries. Moreover, despite their continued hormonal deficit, women older than 45 years who underwent oophorectomy before menopause had fewer complaints of low desire than women of similar age with intact ovaries.²⁶⁵

Aging-Associated Decline in Sex Hormone Precursors in Women

From the middle 30s to the early 60s, a woman's adrenal production of precursor hormones—DHEA, androstenedione, and DHEA sulfate (DHEAS)—declines by 70%.^{262,263,271,273} However, the trajectories of decline in these precursor steroids vary among women.^{261-263,271,274} The relationship of the age-related decline in these circulating precursors to sexual function remains poorly understood. On the population level, variation in circulating levels of sex steroids and their precursors²⁷¹⁻²⁷⁴ is related to variation in the activities of steroidogenic enzymes such as 3 β -hydroxysteroid dehydrogenase (3 β -HSD), 17 β -HSD, 17,20-lyase, and aromatase and to variation in the plasma clearance of these hormones and precursors.²⁶²⁻²⁶⁴ Total androgen production is measured by means of androgen metabolites, most notably androsterone glucuronide (ADT-G).²⁶³ A recent study of 250 women carefully evaluated for sexual dysfunction found that ADT-G levels in the 124 control women were comparable to those in the 121 women with sexual dysfunction.²⁷⁵

Selective Estrogen Receptor Modulators

Selective estrogen receptor modulators (SERMs) are a class of ligands that bind estrogen receptor subtypes and induce a unique profile of tissue-specific gene expression. Accordingly, each SERM may also be associated with a unique set of clinical responses. Currently available SERMs do not ameliorate the genital sexual symptoms of estrogen lack. Sexual symptoms and hot flashes are more frequent in women receiving raloxifene than in those receiving tamoxifen.²⁷⁶ Ospemifene is a novel SERM under trial for the treatment of vaginal atrophy in postmenopausal women.²⁷⁷

Oral Contraceptives

Combined oral contraceptives containing ethinyl estradiol increase SHBG and thus decrease available free testosterone. The decrease in sexual desire and subjective arousability in some women receiving oral contraceptives has been attributed to the decrease in free testosterone levels.^{278,279} However, oral contraceptives exert multiple psychological and biologic actions, some of which may positively affect sexuality (e.g., by reducing anxiety about unwanted pregnancy and diminishing dysmenorrhea).^{278,279}

Androgen Insensitivity Syndrome

Research on sexual function in 46,XY women with androgen insensitivity syndrome due to mutations in the androgen receptor is very limited. Women with complete androgen insensitivity syndrome have a female phenotype with full breast development but variable shallow vaginal development.²⁸⁰ These women are often confronted with complex psychosocial issues related to the mismatch between their genetic sex and their gender role, the timing of diagnosis and timing of disclosure to the woman, and infertility. However, limited information from retrospective case series suggests that, despite androgen insensitivity, these women have normal sexual desire and function.²⁸⁰

ASSESSMENT OF SEXUAL DYSFUNCTION

Assessment of sexual function is an important part of the general assessment of patients with endocrine diseases. Open-ended, nonjudgmental questions such as, "Many men with diabetes notice changes in their erections or ejaculation—are you having any difficulties?" can facilitate further discussion of sexual problems. When sexual problems are identified, sensitive and respectful inquiry into their nature and the current and past sexual context is necessary. Evaluating both partners together as well as individually can often uncover problems that may not be apparent in individual interviews (see Table 20-4).

Evaluation of Men with Sexual Dysfunction

There are four important considerations in the evaluation of men with hypoactive sexual desire disorders. First, an important initial step in the evaluation is an interview of the couple to determine which dysfunctions are present, such as ED, problematic sexual desire, and difficulties with ejaculation or orgasm. Second, the clinician should ascertain whether the couple has a relationship problem. It should be established whether self-stimulation continues despite lack of desire for partnered sex. With the availability of Internet sites, sex alone, possibly on a frequent basis, may allow sexual expression in spite of relationship difficulties. Third, a general health evaluation is necessary to exclude systemic illness, depression, and medication use. Fourth, testosterone levels should be measured to exclude androgen deficiency, which is an important treatable cause of hypoactive sexual desire disorder.

The diagnostic workup of men with ED should start with an evaluation of general health (Tables 20-3 and 20-4). The presence of diabetes mellitus, coronary artery disease, peripheral vascular disease, hypertension, stroke, spinal cord or back injury, multiple sclerosis, depression, or dementia should be verified. Information about use of

TABLE 20-3

Diagnostic Evaluation of Erectile Dysfunction**History****Ascertain Psychosexual History**

The nature of sexual dysfunction: whether the primary problem is decreased desire, ED, premature or delayed ejaculation, or difficulty in achieving orgasms
 The strength of the marital relationship and marital discord
 Depression
 Stress
 Sexual performance anxiety
 Knowledge and beliefs about sexuality

Ascertain Risk Factors

The presence of diabetes mellitus, hypertension, CAD, end-stage renal disease, or peripheral vascular disease
 History of spinal cord injury, stroke, or Alzheimer's disease
 Prostate or pelvic surgery
 Pelvic injury
 Medications such as antihypertensives, antidepressants, antipsychotics, antiandrogens, and inhibitors of androgen production
 The use of recreational drugs such as alcohol, cocaine, opiates, and tobacco

Ascertain Factors That Might Affect Choice of Therapy or the Patient's Response to Therapy

Coexisting CAD and its symptoms and severity
 Exercise tolerance
 The use of nitrates or nitrate donors
 The use of α -adrenergic blockers
 The use of vasodilators for hypertension or congestive heart failure
 The use of foods (e.g., cranberry juice) or drugs (e.g., erythromycin, protease inhibitors, ketoconazole, itraconazole) that might affect the metabolism of PDE5 inhibitors

Physical Examination

Ascertain signs of androgen deficiency, such as loss of secondary sex characteristics, eunuchoidal proportions, small testicular volume, or breast enlargement
 Evaluate genital and perineal sensation to evaluate neurologic deficit due to spinal cord lesion, previous stroke, or peripheral neuropathy
 Measure blood pressure and postural change in blood pressure
 Evaluate femoral and pedal pulses and evidence of lower-extremity ischemia
 Conduct a penile examination to exclude Peyronie's disease and other penile deformities

Basic Laboratory Evaluation* for All Men with Erectile Dysfunction

Fasting blood glucose level
 Serum testosterone level

*Basic tests that should be performed in all men with ED.

CAD, coronary artery disease; ED, erectile dysfunction; PDE5, phosphodiesterase isoform 5.

recreational drugs such as alcohol, marijuana, cocaine, or tobacco; prescription medications, particularly antihypertensives, antiandrogens, antidepressants, and antipsychotic drugs; and nonprescription, over-the-counter supplements is important, because almost a quarter of all cases of ED can be attributed to medications. A detailed sexual history, including the nature of relationships, partner expectations, situational erectile failure, performance anxiety, and marital discord or dissatisfaction, needs to be elicited. It is important to distinguish between inability to achieve erection, changes in sexual desire, and failure to achieve orgasm and ejaculation, because the etiologic factors vary with the type of sexual disorder.

A directed physical examination should focus on secondary sex characteristics, the presence or absence of breast enlargement, testicular volume, evaluation of femoral and pedal pulses; neurologic examination to determine the presence of motor weakness, perineal sensation, anal sphincter tone, and bulbocavernosus reflex; and examination of the penis to evaluate any unusual curvature, palpable plaques, or superficial lesions.^{276,277}

The laboratory tests in the evaluation of a man with ED usually include the measurements of hemoglobin, blood glucose, blood urea nitrogen, creatinine, plasma lipids, and testosterone levels.

The initial diagnostic work in most men presenting with ED consists of general health evaluation, evaluation of cardiovascular risk, and the measurements of hemoglobin, blood glucose, BUN and creatinine, plasma lipids, and measurement of serum testosterone levels. Further evaluation using more invasive diagnostic testing is limited to those men who do not respond to an empiric trial of oral PDE5 inhibitors; these patients should be referred to a specialist for detailed evaluation of sexual function.²⁷⁸⁻²⁸¹

The diagnosis of androgen deficiency should be made only in men with consistent symptoms and signs and unequivocally low early-morning serum testosterone levels that are below the lower limit of the normal range for healthy young men (e.g., testosterone <300 ng/dL in some laboratories) on at least two occasions.¹⁰⁷ Initial evaluation is directed at excluding systemic illness, eating disorders, excessive exercise, and the use of medicines and recreational drugs that can suppress testosterone levels. Measurement of the morning total testosterone level by a reliable assay remains the best initial test. Measurements of free or bioavailable testosterone levels may be useful in men with suspected SHBG abnormalities due to aging, obesity, chronic illness, thyroid disease, or liver disease.

In men found to be androgen-deficient, measurement of LH levels helps distinguish between testicular (LH elevated) and hypothalamic-pituitary (LH low or inappropriately normal) defects. Men with hypogonadotropic hypogonadism may require measurement of serum prolactin, serum transferring, evaluation of other pituitary hormones, and pituitary MRI. The diagnostic yield of pituitary imaging to exclude pituitary tumors can be improved by selecting men with testosterone levels lower than 150 ng/dL, panhypopituitarism, persistent hyperprolactinemia, or symptoms of tumor mass.^{282,283}

There is considerable debate about the usefulness and cost-effectiveness of hormonal evaluation and the extent to which androgen deficiency should be investigated in men presenting with ED. Between 8% and 10% of men with ED have low testosterone levels; the prevalence of androgen deficiency increases with advancing age.²⁸⁴⁻²⁸⁷ The prevalence of low testosterone levels is not significantly different among men who present with ED and men in an age-matched population.¹¹⁶ These data are consistent with the proposal that ED and androgen deficiency are two common but independently distributed disorders.¹¹⁶ However, it is important to exclude androgen deficiency in this patient population. Androgen deficiency is a correctable cause of sexual dysfunction, and in some men, ED and low testosterone levels respond to testosterone replacement. Androgen deficiency can have additional deleterious effects on the individual's health; for instance, it may contribute to osteoporosis and loss of muscle mass and function.

In large studies,^{116,282,283} only a small fraction of men with ED and low testosterone levels have been found to

TABLE 20-4

Assessment of Sexual Dysfunction

Assessment Questions	Comments
Questions Asked of Both Partners	
1. Sexual problems and reason for presenting at this time	Ask patients to describe sexual problems in their own words; clarify further with direct questions, giving options rather than leading questions, support and encouragement, acknowledgement of embarrassment, and reassurance that sexual problems are common
2. Duration, consistency, and priority if more than one problem is present Context of sexual problems	Are problems present in all situations? Which problem is most troubling? Emotional intimacy between partners, activity or behavior just before sexual activity, privacy, sexual communication, time of day and fatigue level, birth control (adequacy, type), risk of STDs, usefulness of sexual stimulation, sexual knowledge.
3. Rest of each partner's sexual response, other than the given problem area	Both currently and before the onset of the sexual problems
4. Reaction of each partner	How each has reacted emotionally, sexually, and behaviorally.
5. Previous help	Compliance with recommendations and effectiveness
Questions Asked of Each Partner When Seen Alone*	
1. Partner's own assessment of the situation	Sometimes it is easier to disclose symptom severity (e.g., total lack of desire) in the partner's absence
2. Sexual response with self-stimulation	Also inquire about sexual thoughts and fantasies
3. Past sexual experiences	Positive and negative aspects
4. Developmental history	Relationships to others in the home while growing up; losses, traumas, to whom (if anyone) was the patient close; was he or she shown physical affection, love, respect?
5. Past or current sexual, emotional, and physical abuse	Explain that abuse questions are routine and do not necessarily imply causation of the problems; it is helpful to ask whether the patient ever felt hurt or threatened in the relationship and, if so, whether he or she wishes to give more information
6. Physical health, especially conditions leading to debility and fatigue, difficulty with mobility (e.g., in caressing a partner; performing self-stimulation), and difficulties with self-image (e.g., from obesity, hypogonadism)	Specifically, ask about medications with known sexual side effects, including SSRIs, β -blockers, antiandrogens, GnRH agonists, oral contraceptives
7. Evaluation of mood	A significant correlation of sexual function and mood (including anxiety and depression) warrants routine screening for mood disorder using either a questionnaire, e.g., Beck Inventory or semi-structured series of questions.

*Items 3 through 5 of the single-patient interview may sometimes be omitted (e.g., for a recent problem after decades of healthy sexual function).

SSRIs, selective serotonin reuptake inhibitors; GnRH, gonadotropin-releasing hormone; STDs, sexually transmitted diseases.

have space-occupying lesions of the hypothalamic-pituitary region. In one large survey, all of the hypothalamic-pituitary lesions were found in men with serum testosterone levels lower than 150 ng/dL.^{282,283} Therefore, the cost-effectiveness of the diagnostic workup to rule out an underlying lesion of the hypothalamic-pituitary region can be increased by limiting the workup to men with serum testosterone levels lower than 150 ng/dL.¹⁰⁷

If the history, physical examination, and laboratory tests do not identify medical problems needing further workup, then a cost-effective approach is to prescribe a trial of an oral PDE5 inhibitor, provided there are no contraindications (e.g., nitrate use).

Tests that evaluate the integrity of penile vasculature and blood flow^{288,289} are not needed in most patients with ED; they are reserved for patients in whom the results of these tests would alter the management or prognosis. These tests should be performed only by those with considerable experience with their use. The penile brachial blood pressure index is a simple and specific, but not a sensitive, index of vascular insufficiency.²⁸⁸ It is rarely used today in the evaluation of ED.

Intracavernosal injection of a vasoactive agent such as PGE₁ can be useful as a diagnostic as well as a potential therapeutic modality. This procedure can reveal whether there will be a response to this therapeutic modality, and it facilitates patient education about the procedure and its

potential side effects. Failure to respond to intracavernosal injection can raise the suspicion of vascular insufficiency or a venous leak that might need further evaluation and treatment.

Most men with ED do not need duplex color sonography, cavernosography, or pelvic angiography.^{11,277,289} Angiography could be useful in a young man with arterial insufficiency associated with pelvic trauma. Suspicion of congenital or traumatic venous leak in a young man presenting with ED would justify a cavernosography. In each instance, confirmation of the vascular lesion might lead to consideration of surgery. Duplex ultrasonography can provide a noninvasive evaluation of vascular function.²⁸⁹

Nocturnal penile tumescence testing is not needed for most patients being evaluated for ED; it is recommended only when there is high clinical suspicion of psychogenic ED or situational problems or to document poor penile rigidity preoperatively, or for medicolegal reasons. Although recording of nocturnal penile tumescence in a sleep laboratory on successive nights can help differentiate organic from psychogenic impotence, this test is expensive and labor intensive. For most cases, a careful history of nighttime or early-morning erections provides a reasonable correlation with nocturnal penile tumescence and RigiScan studies.²⁹⁰

The introduction of portable RigiScan devices in 1985 provided clinicians with a reliable means of continuously

monitoring penile tumescence and rigidity at home.²⁹⁰ It is a multicomponent device that the patient wears at bedtime for two or three nights. It has two wire gauge loops that are placed around the base and tip of the penis and record changes in penile circumference and rigidity. Data are stored and downloaded by means of a software program that allows for interpretation.

Evaluation of Women with Sexual Dysfunction

Physical examination, including pelvic and genital examination, is part of routine care (Table 20-5; see Table 20-4) and can be reassuring to the patient by confirming normal anatomy and tissue health. Unless dyspareunia is involved, it is not often that physical examination identifies the cause of sexual dysfunction. For some women with a history of coercive or abusive sexual experiences, such an examination can cause extreme anxiety. The reason for the

examination and an explanation of what will and will not be done should be provided before the examination begins. In women with vaginismus, the vaginal examination should be delayed until psychological therapy renders it possible without undue discomfort to the patient.

Laboratory testing plays a small role in women’s sexual evaluation. Estrogen activity is best evaluated by history and examination. The commercially available estradiol radioimmunoassays lack the sensitivity and precision required to measure the low concentrations present in the older woman; also, these assays do not measure estrone, the major estrogen in postmenopausal women. Serum levels of testosterone do not correlate with sexual function, and the available radioimmunoassays currently do not have the required sensitivity or accuracy at the low levels found in women. Liquid chromatography/mass spectrometry can provide accurate measurements of testosterone levels in women and is now available from several commercial laboratories. However, the levels of testosterone so measured were similar in women with and without sexual dysfunction in a recent study of 250 carefully evaluated women.²⁷⁵

The circulating testosterone levels may not reflect intracrine production or metabolism of androgens. Measurement of testosterone metabolites has been proposed as a marker of intracrine plus gonadal production of testosterone, but the circulating levels of these metabolites have been shown to be similar in women with and without sexual dysfunction.²⁷⁵ Prolactin or thyrotropin should be measured if there are other symptoms that suggest abnormality.¹

TABLE 20-5
Physical Examination for the Woman with Sexual Dysfunction: What to Look For
General Examination
Signs of systemic disease leading to low energy, low desire, low arousability, such as anemia, bradycardia, and slow relaxing reflexes of hypothyroidism
Signs of connective tissue disease, such as scleroderma or Sjögren’s syndrome, that are associated with vaginal dryness
Disabilities that might preclude movements involved in caressing a partner, self-stimulation, or intercourse
Disfigurements or presence of stomas or catheters that may decrease sexual self-confidence leading to low desire, low arousability
External Genitalia
Sparsity of pubic hair suggesting low adrenal androgens
Vulval skin disorders, including lichen sclerosis, that may cause soreness with sexual stimulation
Cracks or fissures in the interlabial folds suggestive of chronic candidiasis
Labial abnormalities that may cause embarrassment or sexual hesitancy
Introitus
Vulval disease involving introitus, such as pallor, friability, loss of elasticity and moisture of vulval atrophy, lichen sclerosis, recurrent splitting of the posterior fourchette manifested as just visible white lines perpendicular to the fourchette edge
Abnormalities of the hymen, adhesions of the labia minora, swellings in the area of the major vestibular glands, allodynia (pain sensation from touch stimulus) of the crease between the outer hymenal edge and the inner edge of the labia minora—typical of provoked vestibulodynia
Presence of cystocele, rectocele, prolapse interfering with the woman’s sexual self-image
Inability to tighten and relax perivaginal muscles often associated with hypertonicity of pelvic muscles and midvaginal dyspareunia; abnormal vaginal discharge associated with burning dyspareunia
Internal Examination
Pelvic muscle tone, presence of tenderness, “trigger points” on palpation of deep levator ani due to underlying hypertonicity
Full Bimanual Examination
Presence of nodules or tenderness in the cul-de-sac or vaginal fornix and along uterosacral ligaments, retroverted fixed uterus as causes of deep dyspareunia
Tenderness on palpation of posterior bladder wall from anterior vaginal wall suggestive of bladder pathology

MANAGEMENT OF SEXUAL DYSFUNCTION IN MEN

Treatment of Hypoactive Sexual Desire in Men

It is important to distinguish between a generalized condition, in which there is no desire for any sexual activity, and a situational disorder, in which the man still self-stimulates but has little desire to be sexually active with a partner. The latter situation reflects difficulties with intimacy rather than a sexual disorder. It is necessary to focus on the couple when the patient has an ongoing sexual relationship. Treating the sexual dysfunction in the male partner improves the female partner’s sexual function and satisfaction. Comorbid depression should be treated and relationship difficulties addressed. The efficacy of cognitive and behavioral therapies has not been evaluated systematically in men with hypoactive sexual desire disorder.

Testosterone therapy should be considered in men with hypoactive sexual desire who have androgen deficiency, even though there are no randomized trials of testosterone in men with hypoactive sexual desire disorder. Much of the information about the effects of testosterone on sexual desire has emerged from open-label trials of testosterone in hypogonadal men, which recruited participants based on low testosterone levels.²⁹¹⁻²⁹⁴ Testosterone therapy in these trials was associated with significant improvements in overall sexual activity, sexual desire, attention to erotic cues, and duration and frequency of nocturnal penile erections.^{94,97,101,102,109,110,291,294} Meta-analyses of randomized testosterone trials, mostly in middle-aged and older men, reported greater improvements in nocturnal erections, sexual thoughts and motivation, number of successful attempts at intercourse, scores of erectile function, and

TABLE 20-6

A Step-Wise Approach to Treatment of Erectile Dysfunction

1. All patients and their sexual partners can benefit from and should receive psychosexual counseling.
2. First-line therapies: oral selective phosphodiesterase inhibitors (sildenafil, vardenafil, or tadalafil)
3. Second-line therapies: external vacuum devices, intraurethral alprostadil, intracavernosal injection of alprostadil
4. Third-line therapies: penile prosthesis, vascular surgery

overall sexual satisfaction in men receiving testosterone compared with placebo.^{107,110,295}

Treatment of Erectile Dysfunction

The current practice employs a step-wise approach that first applies minimally invasive therapies that are easy to use and have fewer adverse effects and progresses to more invasive therapies that may require injections or surgical intervention after the first-line choices have been exhausted (Table 20-6 and Fig. 20-9). The physician should discuss the risks, benefits, and alternatives of all therapies with the couple. The selection of the therapeutic modality should be based on the underlying etiology, patient preference, the nature and strength of the patient's relationship with his sexual partner, and the absence or presence of underlying cardiovascular disease and other comorbid conditions.^{11,276,277} All patients with ED can benefit from psychosexual counseling.^{11,276,277}

In the execution of good medical practice, treatment of all associated medical disorders should be optimized. In men with diabetes mellitus, efforts to optimize glycemic control should be instituted, although improving glycemic control may not improve sexual function. In men with hypertension, control of blood pressure should be optimized; if possible, the therapeutic regimen may be modified to remove antihypertensive drugs that impair sexual function. This strategy is not always feasible, because almost all antihypertensive agents have been associated with sexual dysfunction; the frequency of this adverse event is less with angiotensin converting enzyme inhibitors and angiotensin receptor blockers than with other agents.

First-Line Therapies

Psychosexual Counseling. As Rosen emphasized, the major goals of psychosexual therapy are to reduce performance anxiety, develop the patient's sexual skills and knowledge, modify negative sexual attitudes, and improve communication between partners.²⁹⁶ Counseling can be of benefit in patients with psychogenic or organic causes of sexual dysfunction (Table 20-7).²⁹⁶

Masters and Johnson postulated that an individual's focus on sexual performance rather than erotic stimulation is a major factor in the pathophysiology of psychogenic ED^{296,297}; they referred to this behavior as "spectatoring." Many experts recommend a "sensate focus" treatment approach in which the couple avoids intercourse and engages in nongenital, nondemanding, pleasure-seeking exercises to reduce performance anxiety.²⁹⁶

Involving the partner in the counseling process helps dispel misperceptions about the problem, decreases stress,

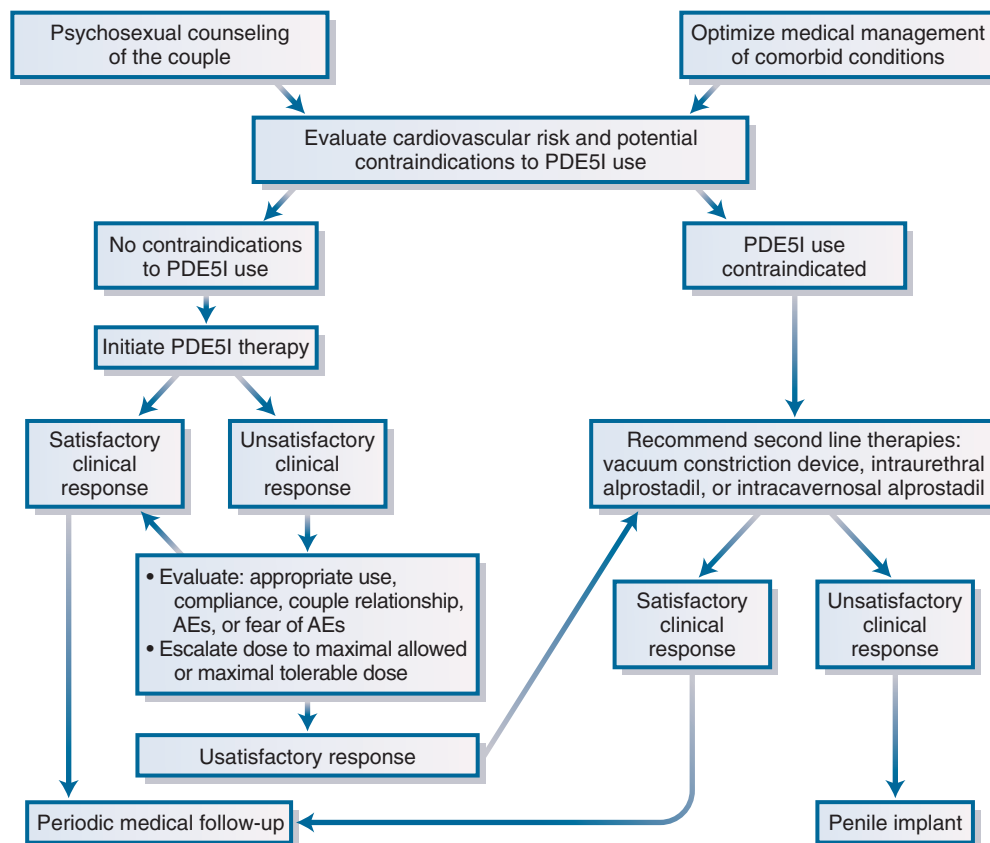

Figure 20-9 An algorithmic approach to the treatment of erectile dysfunction in men. AE, adverse effects; PDE5I, phosphodiesterase 5 inhibitor.

TABLE 20-7

Goals of Psychosexual Therapy in Men with Sexual Dysfunction

- Reduce performance anxiety; train the couple to avoid “spectatoring” and to be “sensate focused”
- Identify relationship problems and improve partner communication and intimacy
- Modify sexual attitudes and beliefs
- Improve couple’s sexual skills

Adapted from Rosen RC. Psychogenic erectile dysfunction: classification and management. *Urol Clin North Am.* 2001;28:269-278.)

enhances intimacy and the ability to talk about sex, and increases the chances of successful outcome.²⁹⁶ Counseling sessions are also helpful in uncovering conflicts in relationships, psychiatric problems, alcohol and drug abuse, and significant misperceptions about sex. Because many men and women harbor misinformation and unrealistic expectations about sexual performance and age-related changes in sexual function, cognitive restructuring techniques are helpful in correcting sexual myths and beliefs.²⁹⁶ There is a paucity of outcome data on the effectiveness of this psychobehavioral therapy, but meta-analyses have reported benefit from group psychotherapy administered in conjunction with PDE5 inhibitors.^{298,299}

Selective Phosphodiesterase 5 Inhibitors. Selective PDE5 inhibitors are safe and effective and have become widely accepted as first-line therapy for patients with ED, except in men for whom these drugs are contraindicated.^{10,11,276,277,300-302} Selective PDE5 inhibitors are

contraindicated for men using nitrates on a regular basis, those with heart disease in whom sexual activity is not recommended, and those with nonarteritic anterior ischemic optic neuropathy.^{11,276,277,300-301}

Mechanisms of Action of Phosphodiesterase Inhibitors. Three classes of enzymes—adenylyl cyclase, guanylyl cyclase, and PDEs—play an important role in regulating the intracavernosal concentrations of cAMP and cGMP. PDEs hydrolyze cAMP and cGMP, thereby reducing their concentrations within the cavernosal smooth muscle.^{72,303-308}

Although PDE isoforms 2, 3, 4, and 5 are expressed in the penis, only PDE5 is specific to the NO/cGMP pathway in the corpora cavernosa.⁷² PDE inhibitors, sildenafil, vardenafil, and tadalafil are relatively selective inhibitors of PDE5.^{72,303-307} These drugs block the hydrolysis of cGMP induced by NO, resulting in cavernosal smooth muscle relaxation. The action of these drugs requires an intact NO response as well as constitutive synthesis of cGMP by the smooth muscle cells of the corpora cavernosa. By selectively inhibiting cGMP catabolism in the cavernosal smooth muscle cells, PDE5 inhibitors restore the natural erectile response to sexual stimulation, but do not produce an erection in the absence of sexual stimulation.

Clinical Pharmacology of Oral PDE5 Inhibitors. Although the three currently available PDE inhibitors have some structural similarities, they differ in their selectivity and pharmacokinetics (Tables 20-8 and 20-9; Fig. 20-10). The common adverse effects of the available PDE5 inhibitors—headache, visual problems, flush, and myalgias—are related to nonselective inhibition of PDE6 and PDE11 in other organ systems.^{301,303} The selectivity of a PDE5 inhibitor is the ratio of its inhibitory potency for PDE isoforms other than PDE5 relative to its inhibitory potency

TABLE 20-8

Clinical Pharmacology of Selective PDE5 Inhibitors*

	Sildenafil	Vardenafil	Tadalafil
Commercial name	Viagra	Levitra	Cialis
T _{max} (hr)	0.5-2.0	0.7-0.9	2
T _{1/2} (hr)	3-4	4-5	16.9 (young) 21.6 (old)
Onset of erection (min)	30-60	15-45	20-30
Muscle selectivity (ratio of PDE6 IC ₅₀ to PDE5 IC ₅₀)	11 (least selective)	25	187 (most selective)
Retinal selectivity (ratio of PDE11 IC ₅₀ to PDE5 IC ₅₀)	780	1160 (most selective)	5 (least selective)
Effect of food and alcohol	C _{max} decreased	Minimal change	No change
Protein binding (%)	96	94	94
Bioavailability (%)	41	Not available	15

*Comparative pharmacokinetic data on the three oral selective PDE5 inhibitors. Selectivity refers to the ratio of the IC₅₀ for a PDE isoform other than PDE5 to the IC₅₀ for PDE5. A higher number implies greater selectivity. Sildenafil is more selective than tadalafil for PDE5 relative to PDE11, but it is less selective than tadalafil for PDE6 relative to PDE5.

C_{max}, maximum plasma concentration; IC₅₀, 50% inhibitory concentration; PDE, phosphodiesterase; T_{1/2}, half-life; T_{max}, time to peak concentration. Adapted from references 301, 303, 307.

*These adverse effects are related to nonselective inhibition of phosphodiesterase isoforms in other tissues.

Adapted from Brock GB, McMahon CG, Chen KK, et al. Efficacy and safety of tadalafil for the treatment of erectile dysfunction: results of integrated analyses. *J Urol* 2002;168:1332-1336; Morales A, Gingell C, Collins M, et al. Clinical safety of oral sildenafil citrate (Viagra) in the treatment of erectile dysfunction. *Int J Impot Res* 1998;10:69-73; and Wespes E, Rammal A, Garbar C. Sildenafil no-responders: hemodynamic and morphometric studies. *Eur Urol* 2005;48:136-139.

for the PDE5 isoform. For PDE6, tadalafil is the most selective and sildenafil is the least selective agent; for PDE11, vardenafil is the most selective and tadalafil is the least selective.^{301,303} The retinal side effects of sildenafil are related to inhibition of PDE6 in the retina; the muscle aches experienced by a small fraction of men using tadalafil are related to inhibition of PDE11 in the skeletal muscle.^{301,303}

Pharmacokinetics of PDE5 Inhibitors. After oral administration of sildenafil, peak plasma concentrations are achieved within 30 to 120 minutes, after which plasma concentrations decline with a half-life of 4 hours (see Table 20-8).^{307,309} Vardenafil achieves peak concentrations within 0.7 to 0.9 hours and has a half-life of 4 to 5 hours. The peak concentrations of tadalafil are achieved at 2 hours,

and its half-life of 16.9 hours in young men, significantly longer than that of sildenafil or vardenafil. The half-life of tadalafil is even longer in older men (21.6 hours). Because of the relatively short half-lives of vardenafil and sildenafil, these drugs should be taken 1 to 4 hours before the planned intercourse; in contrast, tadalafil can be (but does not have to be) taken on demand.^{308,309}

Food, particularly a high-fat meal, and large amounts of alcohol can delay and decrease the absorption of sildenafil.^{310,311} However, early pharmacokinetic studies have not reported changes in maximum serum concentrations or absorption rates of vardenafil or tadalafil due to food or moderate alcohol ingestion.³¹⁰

Efficacy. All three orally active, selective PDE5 inhibitors have been shown to be effective and safe in randomized clinical trials of men with ED.^{302,312-318} In men treated with these agents, the rates of successful intercourse vary from 50% to 65%, and rates of improved erections vary from 70% to 75%.³¹²⁻³¹⁸ The selective PDE5 inhibitors are effective in men of all ethnic groups and ages³¹²⁻³¹⁸ and in patients who have ED due to a multitude of causes, although response rates vary in different patient subgroups.^{302,312-318}

Introduced to the U.S. market in March 1998, sildenafil citrate (Viagra; Pfizer, New York, NY) was the first effective oral agent for the treatment of ED.⁷⁹ The efficacy of sildenafil has been demonstrated in men with organic, psychogenic or mixed ED in multiple randomized, controlled trials^{79,319} and confirmed by meta-analyses of randomized trials.³¹²⁻³¹⁷ In these trials, patients receiving sildenafil experienced greater increments in number of successful attempts per month, penile rigidity, frequency of vaginal penetration, and maintenance of erection, compared with those receiving placebo.³¹²⁻³¹⁷ Increasing doses of sildenafil were associated with higher mean scores for frequency of penetration and maintenance of erections after sexual penetration. The mean scores for orgasms, intercourse satisfaction, and overall satisfaction were also significantly higher with sildenafil than with placebo.³¹²⁻³¹⁷ Sildenafil also is an effective treatment for ED in men with diabetes mellitus.³¹² A meta-analysis of randomized clinical trials of sildenafil confirmed its efficacy in improving erectile function in men with diabetes mellitus.³²⁰

In the vardenafil efficacy trials, 5-, 10-, and 20-mg doses of vardenafil were all superior to placebo in improving erectile function domain scores, and the improvements in erectile function scores were dose related. Vardenafil improved rates of vaginal penetration, penile rigidity, intercourse success, and satisfaction with sexual experience in men with ED from diverse causes.³²¹⁻³²⁵

Similarly, in randomized clinical trials, doses of 2.5, 5, 10, and 20 mg of tadalafil were each superior to placebo in improving erectile function scores.³²⁶⁻³³⁰ The beneficial effects of tadalafil were dose related.³²⁶⁻³³⁰

PDE5 inhibitors are effective in men with ED from a variety of causes, including spinal cord injury and radical prostatectomy.²¹⁹ In general, baseline sexual function correlates positively with response to PDE5 inhibitors, and patients with diabetes mellitus or previous prostate surgery respond less well than patients with psychogenic or vasculogenic ED.²¹⁹ Because there is no baseline characteristic that predicts the likelihood of failure to respond to sildenafil therapy, a therapeutic trial of PDE5 inhibitors should be tried in all patients unless it is contraindicated.³¹⁹

Adverse Effects Associated with PDE5 Inhibitors. In clinical trials, the adverse effects that have been reported with greater frequency in men treated with PDE5 inhibitors than in those treated with placebo include headaches,

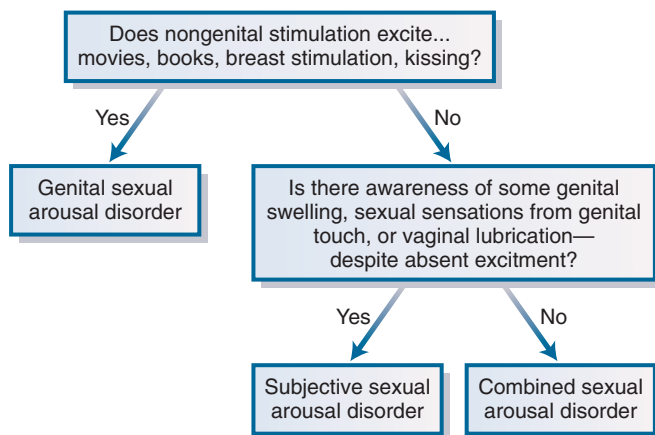

Figure 20-10 Diagnosis of sexual arousal disorders. Subjective arousal disorder is characterized by absence of or markedly diminished feelings of sexual excitement or sexual pleasure from any type of sexual stimulation. Vaginal lubrication and/or other evidence of physical response is present. Genital sexual arousal disorder is characterized by lack of minimal vulvar swelling, vaginal lubrication, and reduced genital sexual sensation in spite of subjective feeling of sexual excitement.

flushing, rhinitis, dyspepsia, muscle aches, and visual disturbances³³¹⁻³³³ (see Table 20-9). The occurrence of headache, flushing, and rhinitis—a direct consequence of non-selective PDE5 inhibition in other organ systems—is related to the administered dose. These drugs do not affect semen characteristics.^{334,335} No cases of priapism were noted in the pivotal clinical trials.

Several cases of nonarteritic anterior ischemic optic neuropathy have been reported after ingestion of oral PDE5 inhibitor.^{336,337} This condition is characterized by the sudden onset of monocular visual loss due to acute ischemia of the anterior portion of the optic nerve in the absence of demonstrable arteritis. This may progress to partial or complete infarction of the optic nerve head, resulting in permanent visual loss or visual field cuts.^{336,337} Although a cause-and-effect relationship with PDE5 inhibitor use has not been established, patients with a history of sudden visual loss should not be treated with PDE5 inhibitors without ophthalmologic evaluation.

Recently, the U.S. Food and Drug Administration (FDA) noted several reports of sudden hearing loss with and without vestibular symptoms (e.g., tinnitus, vertigo, dizziness) in temporal relationship to the administration of sildenafil, vardenafil, or tadalafil in postmarketing surveillance. Hearing loss was also reported in a few patients in clinical trials of these drugs.^{338,339} Hearing loss has been observed in patients using sildenafil for the treatment of pulmonary arterial hypertension. Although a causal relationship has not been established, the temporal relationship between use of a PDE5 inhibitor and onset of sudden hearing loss prompted the FDA to recommend changes in product labeling for the drug class.

Cardiovascular and Hemodynamic Effects of Phosphodiesterase Inhibitors. In postmarketing surveillance of adverse events associated with sildenafil use, several instances of myocardial infarction and sudden death were reported among men using sildenafil in temporal relation to the ingestion of the drug³⁴⁰; many of these deaths occurred in individuals who also were taking nitrates. Men presenting with ED also have a high prevalence of cardiovascular risk factors, and it is unclear whether these events were causally related to the ingestion of sildenafil, the underlying heart disease, or both.³⁴⁰

In controlled studies,³⁴¹⁻³⁴⁴ oral administration of 100 mg of sildenafil to men with severe coronary artery disease produced only a small decrease in systemic blood pressure and no significant changes in cardiac output, heart rate, coronary blood flow, or coronary artery diameter. In a separate pooled analysis of five randomized, placebo-controlled trials of vardenafil,³⁴³ the overall frequency of cardiovascular events was similar in men treated with vardenafil versus placebo-treated men. However, vardenafil treatment was associated with a mild reduction in blood pressure (decrease of 4.6 mm Hg in systolic blood pressure) and a small increase in heart rate (2 beats/minute).³⁴³ This led the American Heart Association and other experts to conclude that preexistent coronary artery disease by itself does not constitute a contraindication for the use of PDE5 inhibitors (Table 20-10).³⁴⁵⁻³⁴⁹

Drug-Drug Interactions. Sildenafil is metabolized mostly by CYP2C9 and the CYP3A4 pathways. Cimetidine and erythromycin, inhibitors of CYP3A4, increase the plasma concentrations of sildenafil. HIV protease inhibitors may also alter the activity of the CYP3A4 pathway and affect the clearance of sildenafil.³⁵⁰ Conversely, sildenafil is an inhibitor of the CYP2C9 metabolic pathway, and its administration could potentially affect the metabolism of drugs metabolized by this system, such as warfarin and

TABLE 20-10

ACC/AHA Guidelines for Use of Selective Phosphodiesterase Inhibitors

1. Do not administer selective PDE5 inhibitors to men taking long-acting or short-acting nitrate drugs on a regular basis.
2. If the patient has stable CAD, is not taking long-acting nitrates, and uses short-acting nitrates only infrequently, the use of selective PDE5 inhibitor should be guided by careful consideration of risks.
3. Do not administer selective PDE5 inhibitors within 24 hours of the ingestion of any form of nitrate.
4. Advise men about the risks of the potential interaction between selective PDE5 inhibitors and nitrates, nitrate donors, and α -adrenergic blockers. Concurrent use of such agents could result in hypotension that may be serious or even fatal.
5. In men with preexisting CAD, assess the risk of inducing cardiac ischemia during sexual activity before prescribing selective PDE5 inhibitors. This assessment may include a stress test.
6. In men who are taking vasodilators and diuretics for the treatment of hypertension or congestive heart failure, consider the potential risk of inducing hypotension due to interaction between PDE5 inhibitors and vasodilators, especially in patients with low blood volume.
7. In HIV-infected men, consider potential drug-drug interactions between selective PDE5 inhibitors and antiretroviral drugs and antimicrobial agents.

ACC/AHA, American College of Cardiology/American Heart Association; CAD, coronary artery disease; HIV, human immunodeficiency virus; PDE5, phosphodiesterase isoform 5.

Adapted with modifications from Cheitlin MD, Hutter AM Jr, Brindis RG, et al. Use of sildenafil (Viagra) in patients with cardiovascular disease: Technology and Practice Executive Committee [published erratum appears in *Circulation*. 1999; 7;100:2389] [see comments]. *Circulation*. 1999; 99:168-177; Lue TF, Giuliano F, Montorsi F, et al. Summary of recommendations on sexual dysfunctions in men. *J Sex Med* 2004;1:6-23.

tolbutamide. Combined administration of sildenafil and ritonavir results in significantly higher plasma levels of sildenafil than when sildenafil is given alone.³⁵⁰ There are similar interactions with other drugs, including saquinavir and itraconazole. Therefore, doses of PDE5 inhibitors should be reduced appropriately in men who are taking protease inhibitors or erythromycin.

Grapefruit juice can alter oral drug pharmacokinetics by different mechanisms. Grapefruit juice given in normal amounts (e.g., 200 to 300 mL) or as whole fresh fruit segments can irreversibly inactivate intestinal CYP3A4, thereby reducing presystemic metabolism and increasing oral bioavailability of PDE5 inhibitors.³⁵¹ Although the magnitude of this problem in clinical practice is unknown, it seems prudent to warn men who are contemplating the use of PDE5 inhibitors not to ingest more than a small amount of grapefruit juice.

The most serious interactions of PDE5 inhibitors are with the nitrates. The vasodilator effects of nitrates are augmented by PDE5 inhibitors; this also applies to inhaled forms of nitrates, such as amyl nitrate or nitrites that are sold under the street name “poppers.” Concomitant administration of the two drugs could cause a potentially fatal decrease in blood pressure.³⁴²⁻³⁴⁹

PDE inhibitors should be used carefully in men taking α -adrenergic blockers. In men with congestive heart failure and in those receiving vasodilator drugs or complex regimens of antihypertensive drugs, blood pressure should be monitored after initial administration of PDE5 inhibitors.³⁴²⁻³⁴⁹ Several trials have demonstrated the safety of administering PDE5 inhibitors in combination with α -adrenergic blockers in men with ED and LUTS.³⁵²⁻³⁵⁴

Therapeutic Regimens. Excellent therapeutic guidelines have been published by expert panels from several societies.^{300,302} To minimize the risk of hypotension and adverse cardiovascular events in association with the use of PDE5 inhibitors, the American Heart Association/American College of Cardiology has published a list of recommendations (see Table 20-10), which should be followed rigorously.³⁴⁵

In most men with ED, sildenafil is started at an initial dose of 25 or 50 mg. If this dose does not produce any adverse effects, the dose can be titrated up to 100 mg.^{300,302,355} Further dose adjustment should be guided by the therapeutic response and the occurrence of adverse effects. Typically, unit doses higher than 100 mg are not recommended. Vardenafil should be started at an initial dose of 10 mg; the dose should then be increased to 20 mg or decreased to 5 mg, depending on the clinical response and the occurrence of adverse effects. Unit doses higher than 20 mg are not recommended. Tadalafil is started at an initial unit dose of 10 mg, with further dose adjustment based on effectiveness and side effects. Tadalafil need not be taken more frequently than once every 48 hours.

In men taking protease inhibitors (particularly ritonavir or indinavir), erythromycin, ketoconazole, itraconazole, or large amounts of grapefruit, the doses of PDE5 inhibitors should be reduced, and doses greater than 25 mg of sildenafil, 5 mg of vardenafil, or 10 mg of tadalafil are not recommended.

Sildenafil and vardenafil are taken at least 1 hour before sexual intercourse and not more than once in any 24-hour period; because of its longer half-life, tadalafil need not be taken immediately before intercourse.

Based on the results of the randomized clinical trials,³⁵⁶⁻³⁵⁸ the FDA has approved 2.5 mg or 5 mg tadalafil once daily for the treatment of ED. In the pivotal trials, men using 2.5 mg or 5 mg tadalafil once daily experienced greater improvements in erectile function compared with those taking a placebo.^{356,357} Subsequent open-label extension studies indicated that 5 mg tadalafil taken once daily for up to 2 years was effective in maintaining improvements in erectile function.^{356,357} Therefore, tadalafil may be taken at 2.5 mg or increased to 5 mg, as tolerated. The adverse events associated with once-daily administration of tadalafil included headaches, indigestion, back pain, muscle aches, nasal congestion, and flushing and were similar to those observed with on-demand tadalafil ingestion.³⁵⁶⁻³⁵⁸ Once-daily tadalafil had no significant effect on semen or reproductive hormone levels.³⁵⁸

Guidelines for the Use of PDE5 Inhibitors in Men with Coronary Artery Disease. Before PDE5 inhibitors are prescribed, cardiovascular risk factors should be assessed. If the patient has hypertension or symptomatic coronary artery disease, the treatment of those clinical disorders should be addressed first.³⁴⁵ The use of nitrates must be ascertained, because PDE5 inhibitors are contraindicated in individuals taking any form of nitrates regularly. PDE5 inhibitors should not be used within 24 hours of the use of nitrates or nitrate donors.^{12,345}

Sexual activity can induce coronary ischemia in men with preexisting coronary artery disease³⁴⁶; therefore, men contemplating use of ED therapies should undergo assessment of their exercise tolerance. One practical way to assess exercise tolerance is to have the patient climb one or two flights of stairs. If this can be done safely without angina or excessive shortness of breath, the patient can likely engage in sexual intercourse with a stable partner without inducing similar symptoms. Exercise testing before prescribing PDE5 inhibitors may be indicated in some men

with significant heart disease to assess the risk of inducing cardiac ischemia during sexual activity.^{345,346} Selective PDE inhibitors have been shown not to impair the ability of patients with stable coronary artery disease to engage in exercise at levels equivalent to that attained during sexual intercourse.³⁴²⁻³⁴⁷ Furthermore, each of the three PDE5 inhibitors has been shown not to have significant adverse effect on hemodynamics and cardiac events in carefully selected men with ED who did not have any contraindication for the use of PDE5 inhibitors.³⁴²⁻³⁴⁷ None of the PDE5 inhibitors adversely affects total exercise time or time to ischemia during exercise testing in men with stable angina.

Treatment in Patients Who Do Not Respond to PDE5 Inhibitors. Although oral PDE5 inhibitor therapy has revolutionized the management of ED, not all men respond to this treatment. The cumulative probability of intercourse success with sildenafil citrate increases with the number of attempts, reaching a maximum after eight attempts.³⁵⁵ Based largely on these data,³⁵⁵ the failure to respond to PDE inhibitor therapy has been defined as failure to achieve a satisfactory response even after eight attempts of either the highest approved dose (e.g., 100 mg sildenafil) or the highest tolerable dose of PDE inhibitor, whichever is lower. Many factors can contribute to apparent treatment failure, including failure to take the medication as recommended, suboptimal dose, dose-limiting adverse effects, psychological issues, partner and relationship issues, incorrect diagnosis, and patient-specific pathophysiologic factors.³⁵⁹⁻³⁶¹ In clinical trials of PDE5 inhibitors, treatment failures were reported predominantly in men who had diabetes mellitus, non-nerve-sparing radical prostatectomy, or high disease severity.^{355,359-361} In an evaluation of cavernosal smooth muscle biopsies in sildenafil-nonresponders, Wespes and colleagues³⁶¹ found severe vascular lesions and cavernosal smooth muscle atrophy and fibrosis to be the underlying pathology.

Patients may not take their medication appropriately due to inadequate instructions, failure to understand the instructions, adverse effects, or fear of adverse effects.^{355,359,360} Oral PDE5 inhibitors are taken optimally 1 to 2 hours before planned intercourse. The medication is unlikely to be effective if it is taken immediately before intercourse; high-fat meals and large amounts of alcohol may further affect the maximal serum concentrations of sildenafil citrate. Men who have been misdiagnosed as having ED and whose primary sexual disorder is unresponsive to PDE5 inhibitors may be incorrectly deemed treatment failures. For instance, men with hypoactive sexual desire disorder, Peyronie's disease, orgasmic disorder, or ejaculatory disorder would not be expected to respond to PDE5 inhibitors. The anxiety associated with resumption of sexual activity and unresolved relationship and partner issues can attenuate response to treatment. The sexual partner may not be willing or able to engage in sexual activity because of relationship issues, sexual disorder, or real or perceived health issues.

Patients who report lack of satisfactory response to initial administration of PDE5 inhibitors should be asked about the time of drug administration, the dose taken, and adverse effects experienced. Psychological and partner issues should be evaluated. The dose of PDE5 inhibitor should be increased gradually as tolerated. If the patient does not respond to maximal tolerable doses of PDE5 inhibitors, PDE5 inhibitors can be combined with vacuum devices or intraurethral therapy. Second-line therapies such as intracavernosal injections should be pursued. Men who are unresponsive to oral PDE5 inhibitors and

second-line therapies may find penile implant an acceptable alternative.³⁵⁵

Cost-Effectiveness of PDE5 Inhibitor Use for Erectile Dysfunction. A number of studies have evaluated the economic cost of treating ED in men with managed care health plans.³⁶²⁻³⁶⁶ One simulation estimated the cost of sildenafil citrate therapy to be approximately \$11,000 per quality-adjusted life year that it produces.³⁶⁴ This amount compares favorably with many other accepted treatments for medical disorders, which can cost \$50,000 to \$100,000 per quality-adjusted life year. Other analyses have concluded that PDE5 inhibitors and vacuum constriction devices are the most cost-effective of all the available therapeutic options.³⁶²⁻³⁶⁶

Several analyses have shown that the financial burden imposed by patients with ED on managed care plans is surprisingly small.³⁶⁵⁻³⁶⁶ In one such cost-utility analysis, the monthly cost of providing ED-related treatment services in a health plan with 100,000 members amounted to less than \$0.10 per member.³⁶⁶ Therefore, the failure of many insurance companies to cover the cost of PDE5 inhibitor therapy is not informed by cost-utility analyses.

Second-Line Therapies

Vacuum Devices for Inducing Erection. The available vacuum devices consist of a plastic cylinder, a vacuum pump, and an elastic constriction band.³⁶⁷⁻³⁶⁹ The plastic cylinder fits over the penis and is connected to a vacuum pump. The negative pressure created by the vacuum within the cylinder draws blood into the penis, producing an erection. An elastic band slipped around the base of the penis traps the blood in the penis, maintaining erection as long as the rubber band is retained. The constriction band should not be left in place for more than 30 minutes. Also, only vacuum devices with a pressure-limiting mechanism should be recommended, to avoid injury from high vacuum.

Limited data on the efficacy of vacuum devices in open-label trials indicate that these devices are safe, relatively inexpensive, and moderately effective.³⁶⁷⁻³⁶⁹ They can impair ejaculation, resulting in entrapment of semen. Some couples dislike the lack of spontaneity engendered by the use of these devices, and partner cooperation is important for their successful use.³⁶⁹

Intraurethral Therapies. An intraurethral system for delivery of alprostadil, called MUSE (Medicated Urethral System for Erection; Vivus, Menlo Park, CA), was released in 1997. Alprostadil is a stable, synthetic form of PGE₁ that results in generation of cAMP and activation of protein kinase A. Activated protein kinase A stimulates potassium channels, resulting in K⁺ efflux from the cell. In addition, protein kinase A-mediated processes result in a net decrease in intracellular calcium, favoring smooth muscle cell relaxation.

Alprostadil, when applied into the urethra, is absorbed through the urethral mucosa into the corpus cavernosum. In comparison to intracavernosal injection of PGE₁, intraurethral PGE₁ is easier to administer and has a lower frequency of adverse effects, particularly penile fibrosis.

Alprostadil is available in 125-, 250-, 500-, and 1000-µg strengths. Typically, the initial alprostadil dose of 250 µg is applied in the clinician's office to observe changes in blood pressure or urethral bleeding secondary to misapplication of the device into the urethra.

Initial randomized, placebo-controlled studies reported success rates of 40% to 60%, with success defined as at least one successful sexual intercourse during a 3-month study

period.³⁷⁰⁻³⁷² In clinical practice, only about one third of men using intraurethral alprostadil have a response.³⁷³

Common side effects of intraurethral alprostadil are penile pain and urethral burning in up to 30% of patients³⁷⁰⁻³⁷²; its use also may cause dizziness, hypotension, and syncope in a small fraction of users. Intraurethral alprostadil can cause mild burning or itching in the vagina of the sexual partner. Intraurethral alprostadil should not be used by men whose partners are pregnant or planning to get pregnant.

Intracavernosal Injection of Vasoactive Agents. The use of intracavernosal injections of vasoactive agents has been a cornerstone of the medical management of ED since the early 1980s. Patients can be taught to inject a vasoactive agent into their corpora cavernosa using a 27- or 30-gauge needle before planned intercourse. Erections occur typically 15 minutes after intracorporal injection and last 45 to 90 minutes. Although intracavernosal injection therapy is highly effective,³⁷⁴⁻³⁸¹ it is associated with significantly higher complication rates than oral therapy. It should be used only by practitioners who are experienced in the use of this therapy and who can provide emergency medical support to their patients in the event of a serious adverse event, such as priapism (Table 20-11).

Although several different agents—PGE₁, papaverine, and phenolamine—have been used alone or in combination,³⁸¹⁻³⁸² only intracavernosal PGE₁ has been approved for clinical use. The long-term data on the efficacy and safety of intracavernosal therapy are sparse.

Several formulations of alprostadil (PGE₁) are commercially available (Caverject or Prostin VR, Pharmacia & Upjohn, Kalamazoo, MI; Edex, Schwarz Pharma, Milwaukee, WI). PGE₁ binds to PGE₁ receptors on the cavernosal smooth muscle cells, stimulates adenylyl cyclase, increases the concentrations of cAMP, and is a powerful smooth muscle relaxant. The usual dose is 5 to 20 µg; the response to therapy is dose related and should be titrated.³⁷⁴

In one placebo-controlled efficacy trial, intracavernosal alprostadil injection resulted in satisfactory sexual

TABLE 20-11

Guidelines for Intracavernosal Therapy

1. Do not prescribe intracavernosal therapy to men who have psychiatric disorders, hypercoagulable states, or sickle cell disease; who are receiving anticoagulant therapy; or who are unable to comprehend the risks or take appropriate action should complications occur.
2. Designate a physician or a urologist to be available to handle emergencies related to complications of intracavernosal injections, such as prolonged erection and priapism.
3. Instruct the patient in the injection technique, the risks of intracavernosal therapy, and the steps to be taken in the event of prolonged erection or priapism.
4. Administer the first injection in the office, and observe the blood pressure and heart rate response. This provides an excellent opportunity for educating the patient, observing adverse effects, and determining whether the patient will respond to intracavernosal therapy.
5. Start with a low dose of alprostadil and titrate the dose based on the erectile response and the duration of erection. Adjust the dose of alprostadil to achieve an erection that is sufficient for sexual intercourse but does not last more than 30 min.
6. If the erection does not abate in 30 min, the patient should be instructed to take a tablet of pseudoephedrine or terbutaline (Brethine) or an intracavernosal injection of phenylephrine. If this is not effective, the patient should call the designated physician or urologist and go to the emergency room.

performance after more than 90% of administrations, and approximately 85% of men and their partners reported satisfactory sexual activity.³⁷⁴ Intracavernosal alprostadil is more effective than intraurethral alprostadil.³⁷⁸

The common adverse effects of intracavernosal therapy include penile pain, occurrence of hematoma, formation of corporal nodules, penile fibrosis, and the possibility of prolonged erections.³⁷⁴⁻³⁸¹ Despite the effectiveness of this approach in producing rigid erections, many patients do not relish injecting a needle into their penis; therefore, it is not surprising that long-term dropout rates are high.

Papaverine, derived originally from the poppy seed, is a nonspecific PDE inhibitor that increases both intracellular cAMP and cGMP. It has a greater propensity to induce priapism and fibrosis with long-term use, and efficacy and long-term safety data from randomized, placebo-controlled trials are lacking. Therefore, there is insufficient information to evaluate its efficacy and safety.

Phentolamine is a competitive α_1 - and α_2 -adrenergic antagonist that contributes to smooth muscle relaxation. As a single agent, it is minimally efficacious, but it has been used to potentiate the effects of papaverine, VIP, and PGE₁.³⁸¹ Randomized clinical trial data on its efficacy and safety are insufficient to evaluate its efficacy and safety.

A serious concern with the use of intracavernosal injection therapy is priapism. In patients who develop a prolonged or painful erection with PGE₁, either terbutaline (Brethine, 5 mg) or pseudoephedrine (60 mg) administered orally may be of benefit. If priapism persists for longer than 4 hours, patient should be instructed to seek medical care in which aspiration, alone or with the injection of an α -adrenergic agent, is used to induce detumescence. If this fails, surgical therapy may be indicated to reverse a prolonged erection; otherwise, anoxic damage to the cavernosal smooth muscle cells and fibrosis can occur.

Third-Line Therapies

Penile Prosthesis. The penile prosthesis is invasive and costly, but it can be an effective method for restoring erectile function in patients who have advanced organic disease that is unresponsive to other medical therapies, who have significant structural disorders of the penis (e.g., Peyronie's disease), or who have suffered corporal loss from cancer or traumatic injury.³⁸³

Penile implants are paired supports that are placed in each of the two erectile bodies. There are two basic types of penile implants: hydraulic (fluid filled), referred to as inflatable prostheses, and malleable (semirigid rods), which are bendable but always remain firm in the penis.³⁸⁴⁻³⁸⁶ Penile prostheses come in a variety of lengths and girths. Implantation surgery usually takes less than 1 hour and in most cases can be done as an outpatient procedure using general or regional anesthesia.

Infection and mechanical malfunction are the most common problems with penile prostheses. With recent improvements in materials and design, the chance of mechanical malfunction has decreased to 5% to 10% within the first 10 years.³⁸⁴⁻³⁸⁶ Infection occurs in 1% to 3% of cases, but infection rates can be higher in revision surgery, especially in men with diabetes mellitus.

The total cost of penile prosthesis implantation varies from \$3,000 to \$20,000, depending on the type of device used and the community in which the procedure is performed. There are no randomized efficacy trials, but retrospective analyses have reported that more than 80% of patients and 70% of partners are pleased with their prosthesis and the togetherness that it brings to their relationship.³⁸⁴⁻³⁸⁶

Testosterone Replacement in Androgen-Deficient Men Presenting with Erectile Dysfunction. Testosterone treatment does not improve sexual function in men with ED who have normal testosterone levels.^{107,108,110,295} It is not known whether testosterone replacement improves sexual function in men with ED and borderline serum testosterone levels. Many, but not all, of the men with ED and low testosterone levels experience improvements in their libido and overall sexual activity with androgen replacement therapy.^{107,108} The response to testosterone therapy even in this group of men is variable because of the coexistence of other disorders such as diabetes mellitus, hypertension, cardiovascular disease, and psychogenic factors. Meta-analyses of testosterone trials have concluded that testosterone administration is associated with greater improvements in sexual function than those associated with placebo administration in men with ED and low testosterone levels.^{107,108,110,295}

ED in middle-aged and older men is a multifactorial disorder, often associated with other comorbid conditions such as diabetes mellitus, hypertension, medications, peripheral vascular disease, psychogenic factors, and end-stage renal disease. Therefore, it is not surprising that testosterone treatment alone may not improve sexual function in all men with androgen deficiency. Testosterone induces NOS activity,¹⁰⁵ has trophic effects on cavernosal smooth muscle and ischiocavernosus and bulbospongiosus muscles,¹⁰⁶ increases penile blood flow,¹¹⁴ and has been shown to be essential for achieving venous occlusion in animal models.³⁸⁷ Therefore, it is possible that testosterone might improve response to PDE5 inhibitors, although this hypothesis has not been rigorously tested.¹¹³⁻¹¹⁵

Therapies with Unproven Efficacy or Limited Efficacy Data. There is insufficient efficacy data to support the use of trazodone³⁸⁸ or yohimbine³⁸⁹ in men with ED. The literature on the effectiveness of herbal therapies is difficult to interpret because of lack of consistency in product formulations and potencies, contamination of herbal products with PDE5 inhibitors, poor trial design, and paucity of randomized clinical trial data.³⁹⁰⁻³⁹² One randomized trial of Korean red ginseng reported this product to be effective in the treatment of ED;³⁹⁰ however, these data need further confirmation. Therefore, the use of this or other herbal therapies is not recommended.³⁹⁰

Apomorphine also functions as a dopamine agonist and acts centrally to initiate erection; its main adverse effect is nausea.

Gene Therapy and Erectile Dysfunction. The goal of gene therapy for ED is to introduce novel genetic material into the cavernosal smooth muscle cells to restore normal cellular function and produce a therapeutic effect.³⁹³⁻³⁹⁵ Gene therapy has been proposed as a treatment option for diseases that have a vascular origin, such as arteriosclerosis, congestive heart failure, and pulmonary hypertension.³⁹³⁻³⁹⁵ ED may be particularly amenable to gene therapy because of the easily accessible external location of the penis,³⁹³⁻³⁹⁵ which permits direct injection into the corpora cavernosa. A tourniquet placed around the base of the penis limits entry of the injected material into the systemic circulation. This represents a distinct advantage of gene therapy for penile diseases over gene therapy for other systemic diseases, because introduction of the genetic material into the systemic circulation can potentially induce adverse systemic effects due to insertion of the material into an incorrect organ or vascular bed. Moreover, in the penis, only a small number of cells need to be transfected, because the

TABLE 20-12

Physiologic Targets for Gene Therapy

Gene Target	Vector and Mechanism
Nitric oxide isoforms	Increase eNOS, nNOS, and iNOS activity in the cavernosal smooth muscle ^{405-407,409-410,413,419}
Protein inhibitor of NOS (PIN)	Antisense and short hairpin RNA (shRNA) constructs targeting PIN ⁴⁶¹
Maxi-K ⁺ channel	Transfer of maxi-K ⁺ channels using a plasmid vector that carries the hSlo gene encoding the α -subunit of the maxi-K ⁺ channel; first human trial demonstrated the safety and feasibility of gene therapy in humans ^{66,68,408,416-417}
PKG-1 α	Replication-deficient recombinant adenoviruses carrying the PKG-1 α ⁴⁶²
VEGF	Transfer of VEGF cDNA into rat corpora cavernosa to promote neovascularization ^{412,414,463-464}
Angiopoietin I	Adenovirus-mediated transfer of human Angiopoietin I ⁴⁶⁵⁻⁴⁶⁶
BDNF	Transfer of brain derived neurotrophic factor using adeno-associated virus ^{414,467}
Neurotrophin 3 gene	Transfer of neurotrophin 3 gene using HSV vector ⁴⁶⁸
Neurturin	Neurturin (NTN), a member of the glial cell line-derived neurotrophic factor (GDNF) family ⁴⁶⁹
VIP	Transfection of corpora cavernosa of streptozotocin-treated diabetic rats using pcDNA3 carrying VIP cDNA ⁴⁷⁰
CGRP	Adenoviral transfer of CGRP in aged rats ⁴¹⁵
Superoxide dismutase	Adenoviral-mediated gene transfer of extracellular superoxide dismutase injected into the corpora cavernosa ⁴⁷¹
IGF I	Adenoviral-mediated gene transfer of IGF I ⁴⁷²

BDNF, brain-derived neurotrophic factor; cDNA, complementary DNA; CGRP, calcitonin gene-related peptide; HSV, human syncytial virus; IGF I, insulin-like growth factor I; NOS, nitric oxide synthase (epithelial [e], inducible [i], or neuronal [n] isoforms); PIN, protein inhibitor of NOS; PKG, protein kinase G; VEGF, vascular endothelial growth factor; VIP, vasoactive intestinal protein.

interconnection of smooth muscle cells in the corpus cavernosum via gap junctions allows second-messenger molecules and ions to be transferred to other interconnected smooth muscle cells.³⁹³⁻³⁹⁵ The low turnover rate of the vascular smooth muscle cells of the penis allows the desired gene to be expressed for long periods.

The current strategies of gene therapy for ED treatment have focused on the molecules that regulate corporal smooth muscle relaxation or neovascularization (Table 20-12).³⁹³⁻³⁹⁵ A number of candidate genes have been explored, including the penile-inducible NOS, eNOS, VIP, CGRP, maxi-K⁺ channel, vascular endothelial growth factor (VEGF), brain neurotrophic factor, angiopoietin-1, neurturin (a member of the glial cell line-derived neurotrophic factor family), superoxide dismutase, insulin-like growth factor 1, PKG-1 α , and Rho A/Rho kinase (see Table 20-12).³⁹³⁻⁴⁰³ A number of vectors have been used to transfer exogenous genes, including adenoviruses, adeno-associated viruses, retroviruses, sinbisviruses, replication-deficient retroviruses, liposomes, naked DNA, and gold nanoparticles.³⁹³⁻³⁹⁵

Garban and coworkers³⁹⁶ first demonstrated that gene therapy can be performed in the penis by utilizing naked complementary (cDNA) encoding of the penile-inducible NOS gene and that this treatment leads to physiologic benefit in the aging rat. Christ and colleagues³⁹⁷ injected human Slo cDNA, which encodes the human smooth muscle maxi-K⁺ channel, into the rat corpora cavernosa and demonstrated increased gap junction formation and enhanced erectile responses to nerve stimulation in the aged rat. Adenoviral constructs encoding the eNOS and CGRP genes were shown to reverse age-related ED in rats.^{398,399} In these studies, both eNOS and CGRP expression were sustained for at least 1 month in the corpora cavernosa of the rat penis. Five days after transfection with the AdCMVeNOS or AdRSVeNOS virus, aged rats had significant increases in erectile function, as determined by cavernosal nerve stimulation and pharmacologic injection with the endothelium-dependent vasodilator acetylcholine and PDE5 inhibitors.^{398,399} In one study, intracavernous injection of adeno-associated virus construct carrying the brain-derived neurotrophic factor gene improved erectile

function after cavernosal nerve injury.⁴⁰³ This neurotrophic factor purportedly restored neuronal NOS in the major pelvic ganglion, thereby enhancing the recovery of erectile function after bilateral cavernous nerve injury.⁴⁰³ In other studies, intracavernosal VEGF injection and adeno-associated virus-mediated VEGF gene therapy were each shown to reverse venogenic ED in rats.⁴⁰¹ These preclinical studies and others using additional targets for gene therapy such as CGRP, superoxide dismutase, and Rho A/Rho kinase provided evidence that in vivo gene transfer can be accomplished technically. The translation of these preclinical data into human trials has been slow.

Ion Channel Innovations, Inc. has completed a phase I trial of the slow K⁺ channel in men with ED.^{404,405} In this trial, hMaxi-K, a “naked” DNA plasmid carrying the human cDNA encoding the gene for the α -subunit of the human smooth muscle maxi-K channel, was injected directly into the penis of 11 men with ED. Patients who received the highest dose of hMaxi-K experienced significant improvements in erectile function that were sustained for the 24-week duration of the trial. This trial demonstrated the feasibility and safety of injecting naked DNA into the human penis.^{67,404,405} A trial of hMaxi-K in patients with overactive bladder is ongoing. Phase I gene therapy trials using VEGF and hepatocyte growth factor have been conducted in patients with peripheral vascular disease and chronic limb ischemia and to prevent the development of stent restenosis; these trials have reported low frequency of serious adverse effects.⁴⁰⁶⁻⁴¹² However, phase 2 studies have not confirmed efficacy.⁴⁰⁶⁻⁴¹² Therefore, the therapeutic promise of gene therapy has yet to be realized. Successful gene therapy may require introduction of multiple gene products using vectors with higher efficiency for transfection of a larger number of target cells and more prolonged action than can be realized with the current generation of vectors.

The Potential of Stem Cell Therapy. Human mesenchymal stem cells (hMSCs) are bone marrow-derived cells that are endowed with the potential of differentiating into skeletal and smooth muscle cells as well as adipocytes, osteocytes, and chondrocytes. hMSCs are attractive gene delivery

vehicles because they can replicate in vitro as well as in vivo, thus potentially providing a large pool of cells.^{393,394} Autologous hMSCs are not immunogenic. When transplanted into an appropriate tissue environment, they have the potential of differentiating into the desired cell type.

Initial studies demonstrated that rat mesenchymal stem cells, when expanded and transfected ex vivo and implanted into the corpora cavernosa, are capable of expressing the gene product of interest.⁴¹³⁻⁴¹⁵ In another study, autologous adipose-derived stem cells injected into the penis improved erectile function and altered the microarchitecture of the corpus cavernosum.⁴¹⁴ It is not known whether transplanted hMSCs can differentiate into functional cavernosal smooth muscle cells and restore erectile capacity in men with ED. Also, the long-term outcomes, including the tumorigenic potential of these transplanted progenitor cells, are unknown.

Management of Retrograde Ejaculation

Case reports have shown benefit from methoxamine, imipramine, midodrine, and ephedrine in men with retrograde ejaculation, although randomized clinical trial data are lacking.⁴¹⁶⁻⁴¹⁸ Induction of fertility in men with retrograde ejaculation may require retrieval of sperm from the urinary bladder after sexual stimulation or electrostimulation of the prostatic nerve plexus per rectum plus assisted reproductive techniques such as intrauterine insemination or in vitro fertilization, with or without intracytoplasmic sperm injection using the retrieved sperm.⁴¹⁹

MANAGEMENT OF SEXUAL DYSFUNCTION IN WOMEN

Testosterone Therapy in Women

Women with sexual desire disorder and those experiencing difficulty in becoming subjectively aroused may benefit from testosterone therapy. However, these women have not been recruited to randomized, controlled trials of testosterone therapy. The clinical trials have focused on women who have lack of desire at the outset of sexual interaction but who have a variable ability to trigger arousal, pleasure, and desire during the experience. In some of these trials, sexual experiences at baseline were satisfactory it was noted that 50% of women's. The women recruited had, on average, two to three sexually satisfying events per month.

Four randomized, controlled trials of testosterone therapy of 6 months' duration were conducted in surgically postmenopausal women and one in naturally postmenopausal women using transdermal testosterone along with systemic estrogen.⁴²⁰⁻⁴²⁴ Modest benefit was shown from treatment with 300 µg but not from 450 µg of testosterone daily.⁴²⁰⁻⁴²⁴ In women assigned to the testosterone arm of the study, sexually satisfying events increased to approximately five per month, compared with four events per month in women assigned to the placebo arm.⁴²⁰⁻⁴²⁴ Serum testosterone and dihydrotestosterone concentrations exceeded the target high-normal serum concentrations of these hormones in a significant number of women receiving testosterone.⁴²⁵ A 52-week study with a high discontinuation rate reported similar benefit in naturally menopausal estrogen-deficient women but not in women with surgical menopause.⁴²⁶ A small study of naturally menopausal women, 73% of whom were not receiving estrogen, had a similar outcome.⁴²⁷ A previous small study

had demonstrated minimal or no benefit from transdermal testosterone in estrogen-deficient women with a past history of cancer.⁴²⁸ Minimal benefit was shown in a study of 261 premenopausal women recruited on the basis of loss of their former sexual satisfaction.⁴²⁹

Clinical trials have been conducted largely in women who were able to have satisfactory sexual experiences 50% of the time, leading to the criticism that these women probably did not have a biologic cause or consistent sexual dysfunction and may not have needed pharmacologic therapy.⁴³⁰⁻⁴³² The studies of postmenopausal women showed improvements in desire and response domains using validated sexual questionnaires; however, increasing the degree of pleasure and arousal currently experienced by study subjects does not necessarily imply that improvements would be observed in women with total absence of pleasure and arousal.⁴³⁰ Long-term safety data are lacking, but published safety data from trials of up to 2 years' duration are reassuring.⁴³³ There are theoretical reasons to consider exogenous testosterone as either a risk factor or a protective factor for breast cancer: high endogenous testosterone may be associated with an increased risk.⁴³² A high endogenous testosterone-to-estrogen ratio can increase the risk of metabolic syndrome and cardiovascular disease.⁴³⁴ In most randomized trials, testosterone therapy has been administered in the background of estrogen therapy. However, the current advice, especially in North America, is to limit the duration of estrogen therapy. For these reasons and others, the Endocrine Society currently recommends against testosterone supplementation for women.⁴³⁵

A recent study evaluated the efficacy of a pharmacologic dose of testosterone (0.5 mg sublingually) to correct attention deficit for erotic cues in women with low desire.⁴³⁶ The testosterone was combined with sildenafil, a PDE inhibitor, to facilitate genital arousal and congestion. In those women who at baseline showed high levels of subconscious attention bias for erotic cues (as measured by a masked version of the emotional Stroop task), this drug combination had no effect, and, in fact, testosterone alone reduced attention to erotic cues. However, the women with lower arousability or sensitivity to erotic cues at baseline showed increased physiologic genital arousal and congestion and increased awareness of the genital sensation and of sexual desire when they subsequently viewed an erotic video. The safety of intermittent use of markedly supraphysiologic testosterone therapy is unknown.

Local DHEA Therapy in Women

A recent phase 3, randomized trial of local vaginal DHEA therapy in postmenopausal women with vulval vaginal atrophy reported benefit of such therapy in improving vaginal symptoms of dryness and dyspareunia and all domains of sexual function.⁴³⁷ Moreover, all steroids remained in the postmenopausal range. Specifically, ADT-G remained constant. This delivery of precursor hormones to the target tissue may allow strictly local estrogen and androgen actions and may be a preferable choice for women in whom any systemic estrogen therapy is undesirable, such as those receiving aromatase inhibitors for breast cancer who develop severe vulval vaginal atrophy.

Estrogen Therapy in Women

Local vaginal therapy is recommended for dyspareunia associated with vulval vaginal atrophy. Low doses of estrogen can be supplied by a Silastic vaginal ring, vaginal cream, or a mucoadhesive vaginal tablet with similar

benefit and low systemic absorption. Progesterone is usually considered unnecessary for endometrial protection, but some doubt remains as to the safety of long-term unopposed vaginal estrogen therapy. A pilot study showed benefit for vaginal atrophy and no endometrial hyperplasia from administration of vaginal suppositories containing 1 mg estriol and 30 mg Prometrium on alternate days.⁴³⁸

When systemic estrogen is needed, it is sometimes necessary to give additional local estrogen. However, for other women, ultra-low-dose (0.014 mg/day) systemic transdermal estradiol may be sufficient.⁴³⁹ If systemic supplementation improves insomnia and dyspareunia, the motivation to be sexual would logically be expected to increase, but this has not been vigorously studied. No significant differences were found between estrogen and placebo groups in reported sexual satisfaction in the Women's Health Initiative Trial.⁴⁴⁰ However, sexual dysfunction was not a primary focus of that trial; women with marked menopausal symptoms were excluded; and the instruments used to assess sexual function were substandard.

Management of Low Desire and Arousal in Women

Behavioral, Cognitive, Sexual, and Psychoeducational Therapies and Mindfulness

Psychological therapies continue to be the mainstay of therapy for women with low desire and arousal disorders.⁴⁴¹⁻⁴⁴³ Cognitive-behavioral therapy (CBT) rests on the premise that thoughts, feelings, and behaviors are tightly linked and that by changing one of these, the other two are influenced. Psychological treatment aims to identify and challenge maladaptive thoughts, reduce problematic behaviors, and improve affect. CBT can identify distractions that impede sexual arousal and address emotions that interfere with arousal (e.g., fear of losing control, fear of being vulnerable). Outcome studies are few but suggest improvements in some 75% of women after 12 sessions.⁴⁴¹⁻⁴⁴³

Mindfulness has been added to traditional CBT administered in small-group format to women with desire and arousal disorder in uncontrolled trials.⁴⁴⁴ Mindfulness is an Eastern practice stemming from Buddhist meditation that focuses on the present moment and nonjudgmental awareness. The mindfulness-based CBT administered in group format resulted in significant improvements in sexual desire and arousal and in mood.⁴⁴²

Sex therapy techniques originate from the work of Masters and Johnson, and the most commonly used technique is sensate focus, a method of reducing performance anxiety and spectating (i.e., monitoring of oneself during sexual activity). The couple take turns touching and caressing one another, initially excluding breast and genital areas. The partners attempt to relax and attune to the sensation and, importantly, focus on themselves when it is "their turn." Verbal and nonverbal feedback from the partner receiving the touch to the other partner is encouraged. With successive stages in therapy, more genital and breast contact is permitted, but intercourse is still precluded. The final stage includes the option of intercourse. Efficacy rates with this approach reach approximately 65%.⁴⁴⁵

Psychoeducation includes giving information while simultaneously soliciting the woman's input to share thoughts and feelings that emerge in session, which are then addressed and processed. It also includes teaching cognitive techniques. It can help dispel widespread myths about sexuality in women (e.g., that the absence of desire

preceding sexual activity denotes sexual dysfunction).⁴⁴⁵⁻⁴⁴⁷ Bibliotherapy with self-help reading material or videos can be helpful. For some women, information on anatomy and physiology is necessary. Psychoeducation alone has been found to be effective for improving sexual function and distress among women with arousal concerns secondary to gynecologic cancer.⁴⁴⁷

Pharmacologic Interventions

There is no FDA-approved medication for treatment of sexual dysfunction in women, with the exception of estrogen therapy for dyspareunia related to vulval vaginal atrophy. Table 20-13 shows medications that have been used off-label; efficacy data are sparse.^{170,444,448-458} No studies have included psychological intervention in conjunction with pharmacologic therapy. In contrast, in clinical practice, CBT and sexual therapy are typically used to augment any investigational drug therapy.

Management of Women's Orgasmic Disorder

Although in clinical practice CBT methods and mindfulness training have been used in women with orgasmic disorder, outcome research is sparse. In their 1997 review, Heiman and Meston noted that only directed masturbation treatment for lifelong orgasmic disorder fulfilled the criteria of "well-established," and directed masturbation for acquired disorder fell within the "probably efficacious group."⁴⁵⁵ These therapies have not been evaluated in randomized trials. No effective pharmacologic treatment has yet been shown to be effective for orgasmic disorder. In one trial with highly selective inclusion criteria, sildenafil was reported to improve orgasm dysfunction associated with SSRI use.⁴⁵⁶

Management of Dyspareunia and Vaginismus

Of the two most common causes of chronic dyspareunia, PVD and vulval vaginal atrophy, evidence-based therapy exists only for the latter. A number of medical, psychological, and surgical approaches for the management of PVD were reviewed in a National Institutes of Health consensus report in 2006.⁴⁵⁷ More recently, PVD and a number of other pelvic pain syndromes in women and men (including interstitial cystitis, nonbacterial prostatitis, and chronic pelvic pain syndrome) were attributed to stress-induced chronic pelvic muscle hypertonicity.^{458a}

As with other chronic pain syndromes, PVD has features suggesting both central and peripheral sensitization within the nervous system—that is, there are physical changes within the nervous system that perpetuate the pain cycles, and these can be targeted both by medications (chronic pain drugs) and by mind skills including CBT and mindfulness. The cause of the sensitization within the nervous system has not been established with certainty, but internal stress appears to be a likely cause. Women with PVD report higher levels of perfectionism, reward dependency, fear of negative evaluation, harm avoidance, hypervigilance for pain, trait anxiety, and shyness. Clinical practice often combines both psychological and medical therapies. Such combined intervention awaits scientific study. Nonpharmacologic approaches that have shown benefit include CBT and pelvic floor physical therapy with or without electromyography (EMG) feedback¹⁷⁰ and vestibulectomy.⁴⁵⁷

Only a small number of randomized trials have been conducted in women with PVD. These trials evaluated the

TABLE 20-13

Investigational Pharmacotherapy for Women's Sexual Dysfunctions

Sexual Dysfunction	Mechanisms of Dysfunction	Drug Type	Off-Label and Investigational Drugs	Comments
Sexual interest/desire disorder	Loss of brain's arousability to sexual stimuli	Drugs with specific serotonin receptor subtype or agonist/antagonist profile Melanocortin agonists	Flibanserin: 5-HT _{1A} agonist and 5-HT _{2A} antagonist, weak partial D ₄ agonist	RCTs (discontinued in 2010)
Subjective arousal disorder			Bremelanotide: synthetic peptide, α -MSH analog agonist at MC1R, MC3R, MC4R	Small RCT showed benefit for women's arousal disorder with in-home use of nasal drug 45 min before sex. ⁴⁶ Sponsor has discontinued trials.
Combined arousal disorder			Dopamine agonists Bupropion	One small 4-mo study in nondepressed premenopausal women showed increased arousability and sexual response, no increase in initial desire. ⁴⁴⁸
Genital arousal disorder: Estrogen deplete	Loss of genital vasocongestion in response to sexual stimulation	To provide local substrate for estrogen and testosterone intracrine synthesis	Local vaginal DHEA	Phase 3 RCT showed increased maturation of vaginal epithelium, lower pH, and sexual benefit in all domains of response from local vaginal DHEA for 12 wk. ⁴³⁷
		Selective tissue estrogenic activity regulator with androgenic and progestogenic properties	Tibolone	RCT of dysfunctional women showed tibolone marginally superior to 50 μ g/140 μ g combined transdermal estradiol/norethisterone. ⁴⁴⁹ Major problem is distinguishing the subgroup of women with genital arousal disorder who have reduced genital vasocongestion. Small RCTs in diabetes ¹¹⁵ and MS ⁴⁵³ showed only modest benefit from sildenafil.
Genital arousal disorder despite Estrogen replete		To enhance the action of NO-PDEIs	Sildenafil, tadalafil, vardenafil	
Serotonergic antidepressant-associated orgasmic disorder	Former orgasmic response absent or extremely delayed	PDEIs	Sildenafil	8-wk RCT with very strict entry criteria showed benefit from 50-100 mg ⁴⁵⁶ sildenafil.

D4, dopamine 4 receptor; DHEA, dehydroepiandrosterone; 5-HT, serotonin; ISSWSH, International Society for the Study of Women's Sexual Health; MC1R, melanocortin-1 receptor; MS, multiple sclerosis; MSH, melanocyte-stimulating hormone; NO, nitric oxide; PDEIs, phosphodiesterase inhibitors; RCTs, randomized controlled trials.

efficacy of fluconazole, cromolyn, and botulinum toxin, but none was found to be more effective than placebo.^{170,458} Anecdotally, lidocaine, capsaicin, ketoconazole, tricyclic antidepressants, duloxetine, venlafaxine, and anticonvulsants have been reported to be of benefit.¹⁷⁰

Negative prognostic factors for successful vestibulectomy include lifelong PVD, comorbid muscle tightening, a large amount of the introital margin involved with the allodynia, involvement of the Skene's duct openings, unwillingness to have sex therapy if offered, and comorbid depression and anxiety. Negative prognostic factors for all treatment modalities include disgust and contamination sensitivity, erotophobia (the tendency to respond with negative effects to sexual cues), and coexistence of depression and anxiety.¹⁷⁰

Management of Vaginismus

A Cochrane review found very limited evidence on the effectiveness of therapies for vaginismus from controlled

trials.⁴⁵⁹ However, clinical experience shows that, if women are motivated to improve, treatment outcomes are frequently positive. In clinical practice, the treatment of vaginismus is directed at the muscle tightening and the symptom of (feared) pain. Therapy involves progressive desensitization and progressive vaginal accommodation using a variety of relaxation techniques and vaginal inserts.^{170,459,460} The term "dilators" is preferably avoided, because women fear that their therapy is going to (painfully) "stretch" the vagina. Psychotherapies including mindfulness and CBT are often used to reduce anxiety.

In a recent randomized, controlled trial, women with lifelong vaginismus were randomly assigned to CBT, bibliotherapy, or a waitlist control group.⁴⁶⁰ After treatment, 14% of the women in the CBT group were able to experience painless vaginal penetration, compared with none in the control group. By 12 months of follow-up, 21% of women in the CBT group and 15% of those in the bibliotherapy group were reporting satisfying intercourse. Successful outcome was mediated by changes in fear of

intercourse and in avoidance behaviors. Based on these results, investigators conducted a smaller treatment study to determine whether directed exposure aimed at decreasing fear of penetration and avoidance behavior would be effective for women with lifelong vaginismus. For 10 women, therapy included a maximum of three 2-hour sessions during a 1-week period, in which the participant performed vaginal penetration exercises on herself in the presence of a female therapist. Nine of the 10 women were able to experience intercourse after two exposure sessions, and these benefits were maintained at 1 year during follow-up. Further studies are needed to confirm the results of this approach, which some might find intrusive.

CONCLUSION

Routine screening for sexual dysfunctions and their careful assessment will usually identify nonhormonal etiologies as well as any sequelae of endocrine disease. The detailed assessment often allows patients to understand and address the psychosexual factors, or the endocrinologist can make the appropriate referral. Benefit from hormonal adjustment will then be more apparent, and the same applies to pharmacologic therapy. Although current medications can greatly benefit reduced penile vasocongestion caused by genital neurovascular compromise, and others can delay rapid ejaculation, there is no comparable secure pharmacologic approach to the more complex dysfunctions of reduced desire, subjective arousal, and orgasm delay. Moreover, the optimal management of the chronic pain associated with PVD remains unclear.

CHAPTER 21

Endocrine Changes in Pregnancy

GLENN D. BRAUNSTEIN

PLACENTAL DEVELOPMENT

Normal placentation requires a coordinated series of events, beginning with fertilization. The fertilization rate after unprotected regular intercourse during a single menstrual cycle is 25% to 30%. However, in approximately one third of conceptions, there is either failure of implantation or clinical or subclinical spontaneous abortion.¹

For the first 5 days, preimplantation development takes place within the fallopian tube. During this period, the zygote undergoes cleavage division, and at least through the eight-cell stage, the blastomeres remain totipotent. In the 16-cell stage, differentiation of the innermost cells into the *inner cell mass* and the surrounding cells into the *trophectoderm* occurs. The inner cell mass develops into the fetus, and the trophectoderm gives rise to the placenta and membranes. On approximately day 5 or 6 after fertilization, the blastocyst enters the uterus, but implantation does not occur for another 1 to 2 days. Implantation occurs after the zona pellucida disappears from around the embryo.²

Implantation is a complex process that involves apposition of the microvilli on the trophectoderm cells with the pinocytes (i.e., fused microvilli) on the endometrial cells, followed by removal of fluid between the cells through

pinocytosis by the endometrial cells, a process stimulated by progesterone.³ Progesterone synthesis by the corpus luteum is stimulated and sustained during this time and for the first 6 to 7 weeks of pregnancy by secretion of human chorionic gonadotropin (hCG) by the trophoblast cells. The hCG is first detected in the maternal serum 6 to 9 days after conception.⁴ Attachment of the embryo is enhanced through the expression of a variety of adhesion molecules, including mucins, integrins, and trophinin, a trophoblast-specific cell membrane adhesion protein; cytokines; growth factors; and a variety of transcription factors encoded by homeobox genes.^{3,5,6}

After the trophoblast attaches to the endometrium during the window of implantation 6 to 10 days after ovulation, the embryo invades the endometrium through a complex process involving matrix metalloproteinases and differentiation of the trophectoderm into *cytotrophoblasts* or *syncytiotrophoblasts*. The syncytiotrophoblasts are multinucleated cells formed by the fusion of cytotrophoblasts. The cytotrophoblasts form a column of cells that invade the endometrium, form anchoring villi, and enter the maternal vasculature, eventually replacing the endothelial layer of the endometrial and myometrial spiral arterioles with a layer of cytotrophoblasts (i.e., vascular trophoblasts).⁵ This process converts the high-resistance, low-capacity uterine vessels into low-resistance, high-volume vessels, which are

essential for growth of the placenta and fetus.⁷ At the site of implantation, the endometrial cells undergo decidualization, enlarging and increasing their metabolic activity with enhanced production of tissue inhibitors or metalloproteinase, extracellular matrix proteins, cytokines, and growth factors that modulate the extent of trophoblast invasion and influence trophoblast function.^{3,4,8}

The trophoblast cells secrete several angiogenic proteins, including vascular endothelial growth factor, platelet-derived growth factor (PDGF), and basic fibroblast growth factor (bFGF), which stimulate blood vessel development within the villi.⁵ The syncytiotrophoblasts form an outer layer of cells in the chorionic villi between the cytotrophoblast cells and the maternal blood space on the exterior surface. Only three tissues separate the fetal blood from maternal blood: the endothelium of the fetal vessels in the villi, connective tissue, and the trophoblasts; this form of placentation is referred to as *hemochorial*. Therefore, in addition to hCG secretion, which is responsible for maintaining early pregnancy; progesterone secretion, which is required for continuation of pregnancy after the luteal-placental shift; and the synthesis and secretion of other hormones and growth factors (Table 21-1), the syncytiotrophoblasts provide the major site for transportation of oxygen and nutrients to and removal of waste from the fetus.

Substances are transferred across the placenta through transcellular pathways that include carrier-mediated transport (e.g., immunoglobulin G through the Fcγ receptor) and simple extracellular diffusion. The degree of transplacental passage of a hormone from the mother to the fetus through diffusion depends on the rate of placental blood flow, the maternal concentration of hormone that is free or readily dissociable from binding proteins, and the molecular mass, lipid solubility, charge, and degree of placental metabolic degradation of the hormone. Maternal-to-fetal transfer occurs for hormones smaller than 700 d, but the placenta is not permeable to hormones larger than 1200 d.⁹

The trophoblast anchors the placenta and fetus to the uterus and helps protect the fetus, which contains paternal antigens, from rejection by the maternal immune system. This immunologic protection may be mediated by high concentrations of progesterone at the trophoblast-maternal interface and the expression by the trophoblasts of a histocompatibility complex antigen, human leukocyte antigen G (HLA-G), which exhibits reduced polymorphism compared with other major HLA antigens.¹⁰ The mass of the trophoblast increases logarithmically during the first trimester, followed by a more gradual increase throughout the remainder of pregnancy. Trophoblastic mass closely correlates with maternal serum concentrations of human placental lactogen (hPL) and pregnancy-specific β₁-glycoprotein throughout pregnancy and with hCG during the first trimester but not during the subsequent trimesters.¹¹

MATERNAL ADAPTATIONS TO PREGNANCY

Myriad physiologic changes take place beginning shortly after implantation. During early pregnancy, these effects are hormonally mediated. In the second and third trimesters, the uteroplacental vascular system and mechanical factors associated with the enlarging gravid uterus combine with the hormonal milieu to alter the function of every system.

TABLE 21-1

Hormones, Peptides, and Growth Factors Produced by the Placenta

Hypothalamic Analogues and Neuropeptides

Anandamide (endocannabinoid)
Corticotropin-releasing hormone
Dopamine
Met-enkephalin
Ghrelin
Gonadotropin-releasing hormone
Growth hormone-releasing hormone
Melatonin
Neuropeptide Y
Oxytocin
Somatostatin
Substance P
Thyrotropin-releasing hormone
Urocortin
Vasoactive intestinal peptide

Pituitary Analogues

α-Melanocyte-stimulating hormone
β-Endorphin
Chorionic corticotropin
Chorionic gonadotropin
Placental lactogen
Placental variant growth hormone

Steroid Hormones

Estrogens
Progesterone

Growth Factors and Other Hormones

Activins
Adrenomedullin
Angiotensinogen
Basic fibroblast growth factor
Calcitonin
Colony-stimulating factor
Endothelin I
Epidermal growth factor
Erythropoietin
Follistatin
Hepatocyte growth factor
Inhibins
Insulin-like growth factor type I
Insulin-like growth factor type 2
Interleukins
Leptin
Leukemia inhibitory factor
Metastin
Nerve growth factor
Oncomodulin
Osteopontin
Parathyroid hormone-related protein
Platelet-derived growth factor
Pro-early placental insulin-like peptide
Renin
Transforming growth factor-α and -β
Tumor necrosis factor-α
Vascular endothelial growth factor

Other

Corticotropin-releasing hormone-binding protein
Insulin-like growth factor-binding protein
Nitric oxide
Prostate-specific antigen

General Adaptations

Weight gain averages 12.5 kg, of which the fetus accounts for about 3.4 kg, the placenta for 0.65 kg, amniotic fluid for 0.8 kg, uterus for 1 kg, breasts for 0.4 kg, blood for 1.5 kg, extravascular fluid for 1.5 kg, and maternal fat stores for approximately 3.3 kg.¹² The volume of the uterine cavity increases from about 10 mL to an average of 5 L at term, and blood flow through the uteroplacental circulation reaches 450 to 650 mL/minute.¹²

To maintain appropriate perfusion of the mother and the fetal-placental unit, blood volume increases throughout pregnancy and is 40% to 45% higher at term than in the nonpregnant state. The plasma volume increases by about 45% to 50% as a result of aldosterone-stimulated sodium and water retention. The red cell mass increases approximately 20% because of increased production resulting from a twofold to threefold increase in erythropoietin secretion. The net effect is a decrease in the hematocrit by about 15% at term.¹²

The renal blood flow and glomerular filtration rate (GFR) increase rapidly and peak during the second trimester, and a 50% increase in creatinine clearance results in a reduction in the serum creatinine level. Atrial natriuretic peptide (ANP) levels increase during pregnancy and may in part be responsible for increased renal blood flow, GFR, 24-hour urine volume, and natriuresis.¹³ An alteration in the osmotic thresholds for the release of vasopressin and activation of the hypothalamic thirst centers, possibly caused by an extragonadal effect of hCG, lead to an approximately 4% reduction in serum osmolality (approximately 10 mOsm/kg).¹⁴

Several hemodynamic changes are induced by the low-resistance, high-capacity uteroplacental vessels, which in many respects act like an arteriovenous malformation; the increased blood volume; and the large quantities of estrogens, progesterone, prostaglandins, and angiotensin present during pregnancy. Changes include an increase in the heart rate by 10 to 15 beats/minute, a 30% to 50% increase in cardiac output resulting from increased stroke volume in early pregnancy and heart rate during the third trimester, a reduction in diastolic blood pressure of 10 to 15 mm Hg with little or no change in systolic pressure, and an approximately 20% reduction in peripheral vascular resistance.¹²

The pulmonary vascular resistance is reduced by about one third. Pregnancy also is associated with increases in pulmonary tidal volume by about 30%, which results in a respiratory alkalosis that is compensated by increased bicarbonate excretion by the kidneys; in minute ventilatory volume by 30% to 40%; and in minute oxygen uptake. There are no changes in respiratory rate, maximum breathing capacity, or forced or timed vital capacity. However, there is an approximately 40% reduction in the expiratory reserve because of the elevation of the diaphragm by the enlarged uterus.¹²

Gastrointestinal tract function is altered during pregnancy. Gastric emptying time is unchanged until labor, when it becomes prolonged. Reduced lower esophageal sphincter tone and displacement of the abdominal contents by the pregnant uterus result in a marked increase in gastroesophageal reflux disease. Motility of the intestine is also reduced, contributing to the constipation that is common during pregnancy. Decreased motility of the gallbladder leads to an increased gallbladder volume and reduced emptying of bile after meals, producing a more lithogenic bile and increasing cholelithiasis during pregnancy.¹²

Maternal Endocrine Alterations

Pituitary Gland

The anterior pituitary gland enlarges by an average of 36% during pregnancy, primarily because of a 10-fold increase in lactotroph size and number. This enlargement increases the height and convexity of the pituitary that is observed on magnetic resonance imaging. Numbers of somatotrophs and gonadotrophs are reduced, and there are no changes in corticotrophs or thyrotrophs.¹⁵ The size of the posterior pituitary gland diminishes during pregnancy.¹⁶

The marked increase in estrogen levels during pregnancy enhances prolactin synthesis and secretion, and maternal prolactin serum levels increase in parallel with the enlargement of the lactotrophs. At term, the mean serum prolactin concentration is 207 ng/mL (range, 35 to 600 ng/mL), in contrast to a mean of 10 ng/mL in nonpregnant, premenopausal women. Prolactin also is present in the amniotic fluid and appears to be primarily of decidual origin because the decidua actively synthesizes prolactin. Amniotic fluid prolactin levels are 10 to 100 times higher than in the maternal circulation in early pregnancy, and maternal bromocriptine ingestion does not reduce the amniotic fluid prolactin levels but does reduce the maternal and fetal serum concentrations.¹⁷ Prolactin levels return to the baseline of nonpregnancy approximately 7 days after delivery in the absence of breast-feeding. With breast-feeding, the basal prolactin levels remain elevated for several months but gradually decrease; however, with suckling, there is a brisk rise in prolactin levels within 30 minutes.¹⁵

Growth hormone (GH) levels in maternal serum remain unchanged throughout pregnancy, although the source of immunoreactive GH during gestation does change. Relaxin, secreted by the corpus luteum of pregnancy, and estrogens stimulate GH secretion during early pregnancy.¹⁸ Pituitary GH is known as GH1 or hGH-N; its messenger ribonucleic acid (mRNA) and GH1 secretion decrease after the 25th week of pregnancy, and beginning in the fourth month of gestation, the placental syncytiotrophoblast secretes a variant of GH (called GH2 or hGH-V) in a nonpulsatile pattern.^{19,20} In concert with the different sources of GH during the first and second halves of pregnancy, the GH response to provocative stimuli differs in each half. Insulin hypoglycemia or arginine infusion results in an enhanced GH response during the first half of gestation, and during the second half, the response is decreased compared with the response in nonpregnant women.¹⁵

Maternal serum concentrations of insulin-like growth factor type 1 (IGF1) are elevated during the second half of pregnancy, probably through the combined effect of the placental GH variant and hPL, which is evolutionarily related to GH and prolactin. hPL has somatotrophic biologic activity, and its serum concentration increases throughout pregnancy, paralleling that of IGF1.¹⁹⁻²² It is likely that the suppression of GH1 synthesis and secretion is caused by the high IGF1 concentrations, which in late pregnancy are five times higher than those in nonpregnant women.²⁰

Although the placenta synthesizes and secretes biologically active gonadotropin-releasing hormone (GnRH), pituitary gonadotropin production decreases throughout pregnancy, as indicated by a marked reduction in gonadotropin immunoreactivity in the gonadotrophs beginning at 10 weeks' gestation and by a reduction in serum levels of luteinizing hormone (LH) and follicle-stimulating hormone (FSH).¹⁵ Suppression is probably mediated through the elevated blood levels of ovarian and placental

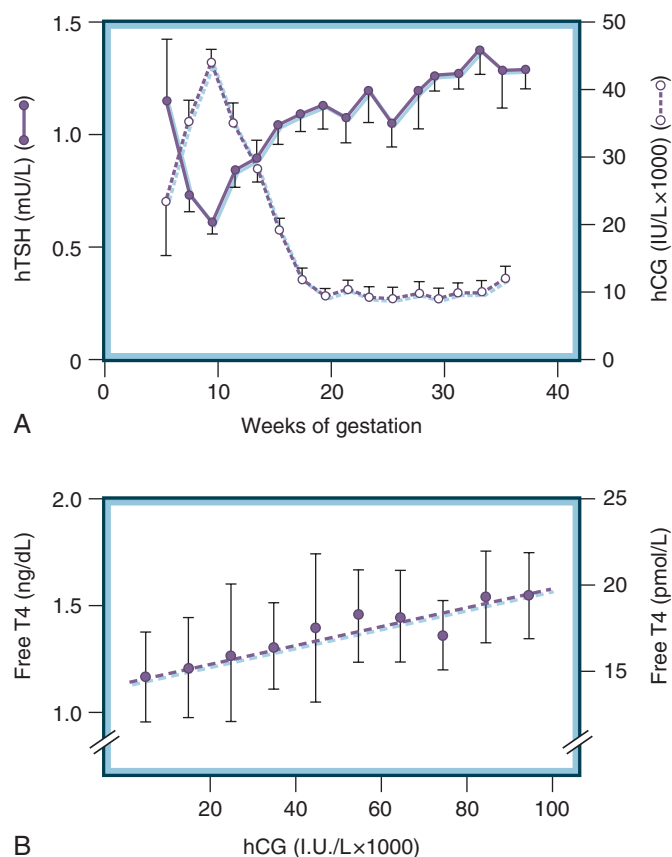

Figure 21-1 **A**, Concentrations of serum thyrotropin (hTSH, filled circles) and human chorionic gonadotropin (hCG, open circles) throughout pregnancy. Between 8 and 14 weeks of gestation, there is a significant negative correlation between the individual hTSH and hCG levels ($P < .001$). Each point represents the mean (\pm standard error). **B**, Linear regression of maternal serum free thyroxine (T_4) and hCG concentrations during the first half of gestation ($P < .001$). (From Glinier D, de Nayer P, Bourdoux P, et al. Regulation of maternal thyroid during pregnancy. *J Clin Endocrinol Metab*. 1990;71:276.)

sex steroid hormones and by placental production of inhibin. Suppression is incomplete because administration of exogenous GnRH leads to release of gonadotropins, although the response is blunted compared with that of nonpregnant women and does not return to normal until a month after birth.¹⁵

The mean concentrations of human thyroid-stimulating hormone (thyrotropin or hTSH) during the first trimester are significantly lower than in the second and third trimesters or in the nonpregnant state.²³ Much of this early decrease may be accounted for by the intrinsic thyrotropic activity of hCG. The maximal biologic thyrotropic activity in maternal serum corresponds to the peak concentration of hCG at 10 to 12 weeks after the last menstrual period, when there is a reciprocal relationship between the rising hCG levels and falling hTSH concentrations (Fig. 21-1).^{23,24} The only time during pregnancy when the free thyroxine concentration in the maternal serum is elevated corresponds to the time of peak hCG and lowest hTSH, suggesting that the depressed hTSH is the result of feedback suppression by thyroxine. Despite the lower mean hTSH during early pregnancy, the hTSH response to exogenous thyrotropin-releasing hormone (TRH) is normal.¹⁵

Maternal adrenocorticotrophic hormone (ACTH, or corticotropin) levels rise during pregnancy, increasing fourfold

over concentrations in the nonpregnant state between 7 and 10 weeks' gestation. There is a further gradual rise to weeks 33 to 37, when a mean fivefold increase over pre-pregnancy values is found, followed by a 50% drop just before parturition and a marked 15-fold increase during the stress of delivery.²⁵ The ACTH concentration returns to the prepregnancy level within 24 hours of delivery. The pituitary gland and placenta are sources of circulating ACTH during pregnancy, and exogenous corticotropin-releasing hormone (CRH) stimulates the release of ACTH from both tissues in a dose-dependent manner.²⁵ Biologically active CRH is synthesized and secreted by the placenta and, to a lesser extent, by the decidual and fetal membranes, but unlike the inhibitory effect on pituitary CRH, glucocorticoids stimulate the expression of placental CRH.²⁵

There appears to be a disconnect between CRH and ACTH during pregnancy. Although biologically active CRH would be expected to stimulate ACTH production, the qualitative patterns of CRH production, which shows an exponential rise during the sixth month of gestation, and ACTH secretion, which demonstrates a more gradual rise during pregnancy, are quite different. The lack of a significant correlation between maternal plasma CRH and ACTH during pregnancy suggests that factors such as the elevated levels of free cortisol in the maternal serum may modulate the response to CRH. The circadian rhythm and the ability to respond to stress are maintained throughout pregnancy; however, the ACTH response to exogenous CRH during the third trimester is blunted, whereas the responsiveness to vasopressin is maintained, suggesting that the elevation of CRH in the maternal serum downregulates the responsiveness to CRH.²⁵

Arginine vasopressin (AVP) concentrations in the maternal serum are similar to those in nonpregnant women.²⁶ During pregnancy, however, there is increased synthesis of AVP, which is offset by the increased metabolic clearance of the hormone through destruction by a trophoblast-derived cysteine aminopeptidase (i.e., vasopressinase), whose levels rise throughout pregnancy in parallel with the increase in trophoblastic mass.^{26,27} The osmolar set point for thirst is reduced, and the release of AVP is related to the 10 mOsm/kg average decrease in plasma osmolality during pregnancy, possibly reflecting an extragonadotropic effect of hCG.¹⁴ Taking into account the reduced set point, the AVP response to dehydration and water loading is normal.

Oxytocin levels progressively increase in the maternal blood and parallel the increase in maternal serum levels of estradiol and progesterone.²⁸ The levels increase further with cervical dilation and vaginal distention during labor and delivery, stimulating contraction of the uterine smooth muscles and enhancing fetal ejection.²⁸ Uterine oxytocin receptors also increase throughout pregnancy, resulting in a 100-fold increase in oxytocin binding at term in the myometrium.²⁹

Thyroid Gland

The thyroid gland enlarges by an average of 18% during pregnancy.²³ Enlargement is associated with an increase in the size of the follicles with increased amounts of colloid and enhanced blood volume. This enlargement may be a response to the thyrotropic effect of hCG and asialo-hCG, which may account for some of the increase in serum thyroglobulin concentrations observed during pregnancy. Enhanced iodine I 131 uptake by the maternal thyroid gland reflects the combined effects of hCG stimulation and reduction of the blood levels of iodide by increased renal iodide clearance.²³

Rising estrogen concentrations during pregnancy induce increased hepatic synthesis of thyroxine-binding globulin (TBG) and enhanced sialylation of TBG, which decreases its metabolic clearance rate.²⁴ The results are a twofold increase in TBG and increased total thyroxine (T_4) and triiodothyronine (T_3) levels in maternal serum throughout pregnancy,²³ whereas for most of the gestation, the free T_4 and free T_3 concentrations remain normal. There are no significant changes in the levels of thyroxine-binding pre-albumin, but albumin levels are decreased because of the increase in vascular volume.

Parathyroid Glands

During pregnancy, approximately 30 g of calcium is transferred from the maternal compartment to the fetus, with most of the transfer occurring during the last trimester. Maternal total serum calcium levels decrease during pregnancy, with a nadir at 28 to 32 weeks related to the decrease in albumin levels that accompanies the increase in vascular volume. However, the albumin-adjusted total calcium and the ionized calcium concentrations rise slightly above the level in the nonpregnant state.³⁰ The urinary calcium excretion rate increases in parallel with the increased GFR, and intestinal calcium absorption undergoes a twofold increase.³⁰

Although some studies have suggested that parathyroid hormone (PTH) levels increase during pregnancy, measurements of intact PTH levels by two-site immunometric assays indicate that they are within the normal, nonpregnancy range throughout pregnancy.³⁰ In contrast, the circulating concentrations of PTH-related protein (PTHrP) increase throughout pregnancy.³⁰ Many normal tissues produce this protein, and the source of the elevated levels during pregnancy is unclear, although the two most likely sites are the mammary tissue and the placenta. PTHrP is probably involved in placental calcium transport. Serum calcitonin levels increase during pregnancy, which may reflect the combined contribution of the thyroid C cells, the breast, and the placenta.³⁰

The serum levels of 25-hydroxyvitamin D are unchanged during pregnancy, but the estrogen-induced rise in vitamin D-binding globulin results in a twofold increase in 1,25-dihydroxyvitamin D concentrations in maternal serum.³⁰ The biologically active free fraction of 1,25-dihydroxyvitamin D₃ (calcitriol) also increases, which may reflect both increased maternal renal 1 α -hydroxylase activity, stimulated in part by pregnancy-induced increased calcitonin secretion, and the synthesis and secretion of calcitriol by the placenta.³⁰ This increase in the active metabolite of vitamin D may be responsible in part for the enhanced intestinal calcium absorption.

Pancreas

Hyperplasia and hypertrophy of the beta cells in the islets of Langerhans are probably the result of stimulation by estrogen and progesterone.³¹ During early pregnancy, the glucose requirements of the fetus lead to enhanced transport of glucose across the placenta by facilitated diffusion, and maternal fasting hypoglycemia may occur. Although basal insulin levels may be normal, there is hypersecretion of insulin in response to a meal. Because studies have shown no change or an increase in insulin clearance during pregnancy, this increase represents an increase in synthesis and secretion.³² The results are enhanced glycogen storage and decreased hepatic glucose production.

As pregnancy progresses, the levels of hPL rise, as do the levels of glucocorticoids, progesterone, free fatty acids, and tumor necrosis factor- α , leading to the insulin resistance

found during the last half of pregnancy.³² In late pregnancy, glucose ingestion produces higher and more sustained levels of glucose and insulin and a greater degree of glucagon suppression than in the nonpregnant state.

Adrenal Glands

As a result of the hyperestrogenemia of pregnancy, hepatic production of cortisol-binding globulin is increased. Amplified production results in a doubling of the maternal serum levels of cortisol-binding globulin, which decreases metabolic clearance of cortisol and produces a threefold rise in total plasma cortisol by week 26, when the levels reach a plateau until they rise at the onset of labor.^{25,33} The rate of cortisol production is increased, and the plasma free cortisol concentrations are also increased. Cortisol production is enhanced by an increase in the maternal plasma ACTH concentration and hyperresponsiveness of the adrenal cortex to ACTH stimulation during pregnancy.²⁵ Cortisol secretion follows that of ACTH, and the diurnal rhythm is maintained during pregnancy.³³ Despite the elevated free cortisol levels, pregnant women do not develop the stigma of glucocorticoid excess, possibly because of the antiglucocorticoid activities of the elevated concentrations of progesterone.

Plasma renin substrate levels are increased as a consequence of the effects of estrogen on the liver. Renin levels are also increased, and increased renin activity produces higher levels of angiotensin II, which lead to an 8- to 10-fold increase in aldosterone production and serum aldosterone levels.²⁵ The aldosterone levels peak in midpregnancy and are maintained until delivery.

Despite their baseline elevations, the various components of the renin-angiotensin-aldosterone system demonstrate normal responses to positional changes, sodium restriction, and sodium loading. Elevated aldosterone levels do not result in increased serum sodium concentrations, decreased serum potassium levels, or increased blood pressure; this may reflect the high concentrations of progesterone, which can displace aldosterone from its renal receptors. Another mineralocorticoid, 11-deoxycorticosterone, shows a 6- to 10-fold increase in concentration at term.²⁵ Elevated levels of this hormone are caused by estrogen-induced extraglandular 21-hydroxylation of progesterone produced by the placenta.³⁴

Levels of androstenedione and testosterone, whether they are of adrenal or ovarian origin, are elevated because of the estrogen-induced increase in hepatic synthesis of sex hormone-binding globulin. However, the free androgen levels remain normal or low. Adrenal production rates of dehydroepiandrosterone (DHEA) and dehydroepiandrosterone sulfate (DHEAS) are increased twofold, but the maternal serum concentration of DHEAS is reduced to one third to one half of the nonpregnancy levels because of enhanced 16-hydroxylation and placental use of 16-hydroxydehydroepiandrosterone sulfate in estrogen formation.³⁴

Adrenal medullary function remains normal throughout pregnancy. The 24-hour urine catecholamine and plasma epinephrine and norepinephrine levels are similar to concentrations in the nonpregnant state.^{35,36}

PLACENTAL HORMONE PRODUCTION

Steroid Hormones

Placental steroidogenesis takes place in the syncytiotrophoblast, and synthesis and secretion of estrogens and

progesterone increase throughout pregnancy in concert with the increase in the trophoblast mass (Fig. 21-2).¹¹ The placenta does not express steroidogenic factor 1 (SF1), a transcription factor that is an important regulator of genes involved in adrenal and gonadal steroid hormone synthesis.³⁷ The trophoblast has reduced levels of, or lacks, several enzymes that are important for the de novo production of estrogens and progesterone and therefore depends on precursors of maternal and fetal origin. This dependence underlies the concept of the *maternal-fetal-placental unit*.³⁸ These interactions are outlined in Figure 21-3.^{39,40}

Progesterone

Although the trophoblast can synthesize cholesterol from acetate, the amount of an essential enzyme needed for cholesterol synthesis, hydroxymethylglutaryl-coenzyme A reductase, in placental microsomes is low because of the inhibitory effects of the high intracellular concentrations of cholesterol that result from progesterone inhibition of cholesterol esterification.⁴¹ Steroid synthesis by the placenta depends on the delivery of low-density lipoprotein (LDL) and very-low-density lipoprotein (VLDL) from the maternal circulation. The syncytiotrophoblast contains receptors for LDL, VLDL, and high-density lipoprotein (HDL). Receptor-mediated uptake of LDL cholesterol is stimulated by estrogens, as is the activity of the cholesterol side-chain cleavage/desmolase enzyme (CYP11A1), which converts cholesterol to pregnenolone.^{38,42} The placenta lacks the steroidogenic acute regulatory (STAR) protein, which mediates the transport of cholesterol from the outer to inner mitochondrial membrane, the site where CYP11A1 acts, so another mitochondrial transport mechanism must be present in the placenta. Altered placental steroid production is not seen in pregnancies with STAR mutations that result in congenital lipid hyperplasia affecting the adrenals and gonads.⁴³

Figure 21-2 Mean plasma concentrations of estrone (E_1), estradiol (E_2), estranol (E_3), and progesterone (P) during pregnancy. (Data from Tulchinsky D, Hobel CJ, Yeager E, et al. Plasma estrone, estradiol, estranol, progesterone, and 17-hydroxyprogesterone in human pregnancy: I. Normal pregnancy. *Am J Obstet Gynecol.* 1972;112:1095; and Levitz M, Young BK. Estrogens and pregnancy. *Vitam Horm.* 1977;35:109.)

Progesterone is synthesized in the trophoblast from pregnenolone by a placental isoform of 3 β -hydroxysteroid dehydrogenase 1 (3 β -HSD1).⁴² Approximately 90% of the progesterone synthesized is secreted into the maternal compartment, and at term, the mean maternal serum concentration is about 150 ng/mL. The fetal adrenals lack 3 β -HSD activity and therefore are not essential for progesterone production.⁴² Progesterone production continues after fetal death.⁴⁴

Progesterone appears to have multiple functions during pregnancy, the most important of which is preparation of the uterus for implantation and maintenance of the pregnancy.³⁸ The corpus luteum is the primary source of progesterone during the first 6 to 8 weeks of pregnancy, after which ovarian progesterone production declines and placental synthesis and secretion become the major source of the hormone (i.e., luteal-placental shift).⁴⁴

Luteectomy, or removal of the ovary containing the corpus luteum, within the first 35 days after conception leads to abortion, but the pregnancy usually continues if these procedures are performed 46 or more days after conception. This indicates that placental progesterone production is sufficient to maintain the pregnancy even before the luteal-placental shift.⁴⁴ Administration of the progesterone receptor antagonist mifepristone during the first 49 days after conception results in abortion, demonstrating that progesterone is essential for the maintenance of early pregnancy.⁴⁵

Progesterone is an important substrate for fetal adrenal glucocorticoid and mineralocorticoid synthesis and for maintenance of myometrial quiescence, possibly through inhibition of prostaglandin formation.^{38,42} A possible role for the high concentrations of progesterone at the trophoblast-decidua junction is suppression of cell-mediated rejection of the fetus, which expresses paternal antigens, by maternal T lymphocytes.³⁸

Estrogens

Because the trophoblast lacks 17 α -hydroxylase and 17,20-lyase (CYP17) activities, it cannot directly convert progesterone to estrogen. Pregnenolone produced in the placenta enters the fetal compartment, where it is taken up by the fetal zone of the adrenal cortex, which also synthesizes pregnenolone from fetal LDL cholesterol. Pregnenolone is conjugated with sulfate by fetal steroid sulfotransferase in the fetal liver and adrenals to form pregnenolone sulfate; this is converted in the fetal adrenals to 17 α -hydroxypregnenolone sulfate and then to DHEAS by 17 α -hydroxylase and 17,20-lyase (CYP17) activities.⁴⁶

DHEAS enters the fetal circulation and undergoes hydroxylation in the fetal liver to form 16 α -hydroxy-DHEAS, which is converted to 16 α -DHEA in the placenta through the action of placental sulfatase. Further metabolism in the trophoblast by 3 β -HSD1, 17 β -hydroxysteroid dehydrogenase (17 β -HSD), and aromatase (CYP19) leads to the generation of estriol, which is quantitatively the major estrogen in the maternal circulation during pregnancy. The maternal liver actively conjugates estriol with glucosiduronate and sulfate, which are excreted into the urine. Because approximately 90% of the estriol in maternal serum and urine is derived from fetal precursors, these estriol levels serve as an index of fetal well-being.⁴⁶

DHEAS from the fetus and mother is taken up by the placenta and converted to estradiol by the actions of sulfatase, 3 β -HSD1, 17 β -HSD, and aromatase or converted to estrone by sulfatase, 3 β -HSD1, and aromatase. An estrogen unique to pregnancy, estetrol, is generated by 15 α -hydroxylation of 16 α -DHEAS in the fetal adrenal and

enzymatically converted by placental sulfatase, 3 β -HSD1, 17 β -HSD, and aromatase.⁴⁷ During pregnancy, estrogens have several actions³⁸:

- They enhance receptor-mediated uptake of LDL cholesterol, which is important for normal placental steroid production.
- They increase uteroplacental blood flow.
- They increase endometrial prostaglandin synthesis.
- They increase uterine sensitivity to progesterone in late pregnancy.
- They prepare the breasts for lactation.

However, estrogen action does not appear to be essential in maintaining pregnancy, because a fetus with deletion of the gene encoding placental sulfatase cannot remove the sulfate moiety from 16 α -hydroxy-DHEAS and therefore has maternal estrogen levels approaching only about 10% of normal.⁴⁸ Similarly, pregnancies complicated by fetal aromatase deficiency may continue to term, suggesting that the high concentrations of estrogens found in normal pregnancy are not necessary.⁴⁹

Protein Hormones

Human Chorionic Gonadotropin

Chemistry. The glycoprotein hCG is composed of two dissimilar subunits, α and β , which are noncovalently linked through hydrophobic bonding. This molecule shares structural homology with the other glycoprotein hormones: hLH, hFSH, and hTSH. These hormones have α -subunits that contain the same sequence of 92 amino acids and differ only in their carbohydrate composition; the β -subunits differ in amino acid and carbohydrate structures and are responsible for the biologic and immunologic specificity of the heterodimeric (intact) hormones. The 22,200-d β -subunit of hCG is composed of 145 amino acids. Approximately 80% of the first 115 amino acids are homologous to those in the β -subunit of hLH. The hCG molecule has an additional 24 amino acids on its carboxy-terminal end that enhance its biologic activity.

Both subunits of hCG contain two oligosaccharide chains attached to asparagine residues through *N*-glycosidic linkages, and the β -subunit contains an additional four *O*-serine-linked oligosaccharide units in the C-terminal peptide. The carbohydrate composition of hCG contains microheterogeneity that affects hormone clearance and biologic activity. The tertiary structure of hCG is determined by the carbohydrate composition and multiple disulfide bonds within each subunit. The α -subunit contains five disulfide bonds, and the β -subunit has six. In each of the subunits, three of the disulfide bonds form a cystine knot, similar to that found in PDGF- β and transforming growth factor- β (TGF- β).⁵⁰⁻⁵²

Biosynthesis. The single α -subunit gene, located on chromosome 6, is actively expressed in the cytotrophoblast and syncytiotrophoblast. In contrast, the β -subunit is encoded by a cluster of six genes located on chromosome 19 in proximity to the hLH- β gene (*LHB*). Three of the hCG- β genes are actively transcribed during pregnancy, primarily in the syncytiotrophoblast, which has the ability to synthesize and secrete free subunits and intact hCG. After synthesis of the protein core, each subunit is glycosylated, undergoes further post-translational modification through trimming of the carbohydrate, and then combines to form intact hCG.⁵⁰⁻⁵²

Secretion of hCG differs from that of many of the other placental proteins, whose secretory patterns parallel that

Figure 21-4 Mean (\pm standard error) levels of maternal serum human chorionic gonadotropin (hCG) throughout normal pregnancy. (From Braunstein GD, Rasor J, Danzer H, et al. Serum human chorionic gonadotropin levels throughout normal pregnancy. *Am J Obstet Gynecol.* 1976;126:678.)

of the trophoblastic mass. HCG is first detected in maternal serum 6 to 9 days after conception.⁴ The levels rise in a logarithmic fashion, peaking 8 to 10 weeks after the last menstrual period, followed by a decline to a nadir at 18 weeks, with subsequent levels remaining constant until delivery (Fig. 21-4).⁵³ A hyperglycosylated form of hCG produced by the cytotrophoblasts is the major form of hCG during the first 2 to 3 weeks after implantation; afterward, the normally glycosylated form produced by the syncytiotrophoblast predominates throughout the rest of pregnancy.^{51,52} The placenta also secretes free subunits. During the first 13 weeks of pregnancy, relatively more β -subunit is synthesized than α -subunit, and throughout the remainder of pregnancy, the opposite occurs.⁵³ A hyperglycosylated form of the α -subunit (called "big α ") is unable to combine with the free β -subunit and is secreted into the maternal serum.

The physiologic factors that regulate hCG secretion in vivo are unknown. Much of the data concerning factors that stimulate or inhibit hCG synthesis and secretion have been derived from in vitro studies and are difficult to extrapolate to the in vivo situation. There is strong circumstantial evidence that GnRH, synthesized in the cytotrophoblast and the syncytiotrophoblast, may be an important factor in hCG secretion. This peptide is identical to hypothalamic GnRH and stimulates placental hCG production in vitro and in vivo, whereas GnRH antagonists decrease basal hCG secretion.^{50,54,55}

Immunohistochemical staining for GnRH in placental tissue is highest at 8 weeks' gestation and lower afterward,⁵⁶ roughly paralleling the pattern of hCG production, as do the circulating levels of GnRH measured in maternal serum.⁵⁷ The placenta contains GnRH receptors.⁵⁸ Placental GnRH release is stimulated by cyclic adenosine monophosphate (cAMP), prostaglandin E_2 , prostaglandin F_2 , epinephrine, epidermal growth factor, insulin, and vasoactive intestinal peptide (VIP), factors that also increase hCG secretion in vitro.^{50,54,59}

Two other peptides synthesized by the cytotrophoblast, activin and inhibin, modulate GnRH and hCG secretion; activin increases both, and inhibin inhibits the action of GnRH on the syncytiotrophoblast.⁵⁴ Increases in hCG production have been found after trophoblast exposure to FGF, calcium, glucocorticoids, phorbol esters, and leptin.^{54,60} Decreased production occurs with TGF- β , follistatin, and

progesterone.⁵⁴ The decidua may influence hCG production through paracrine mechanisms.⁸ Decidual interleukin-1 stimulates hCG secretion in cultured trophoblasts,⁶¹ whereas decidual prolactin and an 8- to 10-kd decidual protein inhibit hCG production.⁶²

HCG may regulate its own production to some extent. The hCG receptors are present on the surface of trophoblastic cells, and the addition of hCG to placental cells in culture stimulates cAMP production and promotes proliferation and differentiation of the cytotrophoblasts into syncytiotrophoblasts.⁵⁰ Both hCG mRNA and hCG production are stimulated by analogues of cAMP or agents that activate adenylate cyclase, probably through a protein kinase.^{50,60} The net effect of an increase in syncytiotrophoblast mass and cAMP levels is enhancement of hCG secretion.

The placenta is not the only site of hCG synthesis. Immunoreactive hCG has been found by immunocytochemistry or by immunoassay of extracts of a wide variety of normal tissues, including spermatozoa, testes, endometrium, kidney, liver, colon, gastric tissue, lung, spleen, heart, fibroblast, brain, and pituitary gland,⁶³ and the hormone is synthesized in some fetal tissues.⁵⁰ The pituitary appears to be the major source of hCG or an hCG-like material present in nonpregnant individuals. Immunoreactive and bioactive hCG has been partially purified from pituitary glands; the material is secreted in vitro by fetal pituitary cells and has been shown by immunocytochemistry to be present in gonadotroph-type cells that do not contain hLH or human FSH.^{63,64}

Immunoreactive hCG has been measured in sera from normal, nonpregnant individuals, with the highest concentrations found in postmenopausal women.^{51,65} In postmenopausal women, this material is secreted in a pulsatile fashion in parallel with hLH pulses, and during the normal menstrual cycle, the immunoreactive hCG shows a mid-cycle peak concomitant with the hLH peak.⁶⁵ In men and postmenopausal women, GnRH stimulates secretion of the hormone, whereas its secretion is inhibited by oral contraceptives in women and by a GnRH agonist in agonadal men.^{51,65}

Gestational and nongestational trophoblastic tumors secrete hCG and its free subunits. The syncytiotrophoblastic cells of nongestational trophoblastic neoplasms secrete hCG, as do the trophoblastic giant cells of seminomas.⁶⁶ In many instances, the tumors produce incomplete forms of hCG or its subunits, and differences in carbohydrate content from the hCG variants in pregnancy have been especially apparent. A wide variety of nontrophoblastic tumors also secrete hCG, although the predominant moiety appears to be the free β -subunit of hCG.^{51,66}

Metabolism. After it is secreted, hCG exhibits biexponential clearance from the circulation, with a fast half-life ($T_{1/2}$) of 6 hours and a slow $T_{1/2}$ of approximately 36 hours. In contrast, the free β -subunit has a fast $T_{1/2}$ of 41 minutes and a slow $T_{1/2}$ of 4 hours, and the free α -subunit has a 13-minute fast $T_{1/2}$ and a 76-minute slow $T_{1/2}$.⁶⁷ Approximately 22% of the intact hormone appears in the urine unchanged; the rest undergoes metabolic degradation (Fig. 21-5). One of the early steps is proteolytic cleavage ("nicking") of the β -subunit at Val44-Leu45 and Gly47-Val48. Human leukocyte elastase, present in macrophages and leukocytes, appears to be responsible for some of the nicking of the β -subunit.⁶⁷

Nicked hCG is unstable and dissociates into free α -subunit and nicked free β -subunit. The latter is further metabolized, primarily in the kidney, to produce the β -core

Also contains $\alpha:N\beta$, $N\beta$, CTP fragment, α fragments

Figure 21-5 Proposed pathways for metabolism of human chorionic gonadotropin (hCG). $\alpha:\beta$, intact hCG; $\alpha:N\beta$, hCG with nicked β -subunit; Big α : hyperglycosylated form of the α -subunit; HLE, human leukocyte elastase; $N\beta$, free nicked β -subunit; CTP fragment, carboxy-terminal fragment; mRNA, messenger RNA. fragment, which is composed of the β -subunit amino acids 6 to 40 disulfide-bridged to amino acids 55 to 92, trimmed of a portion of carbohydrate. The β -core fragment has a molecular mass of 10,479 d.⁶⁷ This fragment is the major form of immunoreactive hCG in the urine in pregnancy. In normal pregnancy, the urine also contains variable quantities of the big α , free α -subunit, free β -subunit, nicked hCG, nicked free β -subunit, C-terminal fragments of the β -subunit, and fragments of the α -subunit.⁶⁷

Physiologic Functions. The physiologic functions of hCG occur after interaction of the hormone with the hLH-hCG receptor. The receptor gene (*LHCGR*) is located on chromosome 2 and encodes a G protein-coupled receptor with seven hydrophobic transmembrane domains and a large extracellular amino-terminus that binds to hCG and hLH. The receptor is part of superfamily of receptors, including those for hFSH, hTSH, AVP, VIP, PTH, and receptors for a variety of biogenic amines and neurotransmitters.⁵⁰ The hCG-receptor interaction results in increased cAMP production and, in some tissues, increased activation of the phosphatidylinositol pathway.⁴⁴

Because of the close structural homology of the hLH-hCG receptor with the other glycoprotein hormone receptors, hCG may interact with the hTSH and hFSH receptors and may therefore have weak intrinsic hTSH and hFSH biologic activity. The hTSH-like activity of hCG clinically manifests during normal pregnancy by the reciprocal decrease in maternal hTSH at the time of the hCG peak between 8 and 12 weeks after the last menstrual period. It is especially important in patients with hydatidiform moles and other forms of trophoblastic disease, in which hCG levels may

exceed 100,000 IU/L and result in clinical thyrotoxicosis (see Fig. 21-1).^{23,24}

One of the major functions of hCG during pregnancy is the “rescue” of the corpus luteum during the conception cycle.⁴⁴ During a menstrual cycle without conception, progesterone concentrations in the serum increase for the first 6 to 7 days of the luteal phase, followed by a 3- to 4-day plateau and then a decrease that results in shedding of the endometrial lining. After conception and implantation, the corpus luteum continues to secrete progesterone and 17-hydroxyprogesterone for another 4 to 6 weeks. The maternal serum progesterone and 17-hydroxyprogesterone concentrations then decrease, indicating a marked diminution in corpus luteum function.⁶⁸ The fall in 17-hydroxyprogesterone concentrations continues, but the drop in progesterone levels is only transient. This marks the transition from dependence on ovarian progesterone production to placental progesterone secretion (i.e., luteal-placental shift). Luteectomy during the first 50 days after the last menstrual period is associated with a decline in progesterone levels and expulsion of the products of conception. After a therapeutic abortion, progesterone levels drop rapidly.

The fetal-placental unit is responsible for the signal to maintain the corpus luteum. Several data support the idea that hCG is that physiologic signal,⁴⁴ including

- The presence of hLH-hCG receptors on the corpus luteum
- The early production of hCG by the implanting trophoblast
- The dose-dependent increases in cAMP, progesterone, and estradiol from luteal cells cultured in vitro after exposure to hCG
- The parallel rise of progesterone and hCG in early pregnancy
- The enhanced progesterone secretion and prolongation of the menstrual cycle in nonpregnant women given exogenous hCG during their luteal phase

The inability of hCG to prolong the life of the corpus luteum of pregnancy beyond the sixth to eighth week of pregnancy results from homologous desensitization of the adenylate cyclase system and the inhibitory effects of the high estrogen levels on progesterone synthesis through inhibition of 3β -hydroxysteroid dehydrogenase and Δ^5 -isomerase in the corpus luteum.

Another physiologic role for hCG is in the differentiation of fetal male genitalia through stimulation of the hLH-hCG receptors on the fetal testicular Leydig cells during the period when differentiation of wolffian duct structures and development of the external genitalia occur. The maximum testosterone production per unit weight of the testes coincides with the maximum binding of ¹²⁵I-labeled hCG to the fetal testicular receptors at 10 to 12 weeks of development, and fetal Leydig cells produce cAMP and testosterone in vitro after exposure to hCG. The hCG concentrations in fetal serum parallel the fetal testicular testosterone levels at a time when the amount of fetal pituitary hLH is not sufficient to stimulate the testosterone production.⁶⁹

During normal pregnancy, hCG has several other possible actions. In vitro, hCG stimulates the differentiation of cytotrophoblast to syncytiotrophoblast and therefore may play an important paracrine role in regulating syncytiotrophoblast mass and production of trophoblast hormones.^{62,70} Additional data supporting this autoregulatory effect of hCG include the in vitro stimulation of placental synthesis of cAMP, activation of glycogen phosphorylase, and incorporation of radiolabeled galactose and leucine

into placental proteins on exposure to hCG.⁶⁹ hCG stimulates the secretion of vascular endothelial growth factor (VEGF) from the cytotrophoblast, which may be important for placental angiogenesis.⁵⁰ Vasodilation of myometrial blood vessels mediated by hCG binding to vascular hCG receptors may enhance uterine blood flow in early pregnancy.⁵⁰ The fetal zone of the adrenal releases DHEAS in response to hCG exposure in vitro; hCG may have adrenocorticotrophic activities in concert with fetal pituitary ACTH and placental ACTH.⁶⁹

It has been suggested that hCG plays a role in the immunosuppression that occurs during pregnancy. Many early studies on this topic were hampered by the use of impure preparations of hCG or the presence of preservatives such as phenol that can alter the end points of the test systems used to define immunosuppression. The immunosuppressive effects may be caused by gonadal steroid secretion in response to the hCG in the in vivo models used in some of the studies.⁷¹ Relaxin secretion from the corpus luteum is stimulated by hCG in vivo and in vitro.⁵⁰

The decreased osmotic threshold for thirst and AVP release during pregnancy is clearly related to hCG.²⁶ It may be a direct effect of hCG or an indirect effect through stimulation of gonadal steroids or interaction with hLH-hCG receptors in vascular smooth muscle.

Gestational Trophoblastic Disease. Gestational trophoblastic disease (GTD) includes complete and partial hydatidiform moles, choriocarcinoma, and placental-site trophoblastic tumor.⁷² Complete molar pregnancy is the most common variety, occurring in 1 to 2 of 1000 pregnancies. Patients classically present in the second trimester with vaginal bleeding, a uterus that is larger than expected for the duration of pregnancy, anemia, and excessive vomiting, although with the increased use of ultrasound examination early in pregnancy, the diagnosis is often made in the first trimester before the classic signs and symptoms develop.⁷³ Pathologically, trophoblast hyperplasia, marked edema of the chorionic villi, and absence of fetal tissues are observed. In contrast, partial moles demonstrate focal trophoblast hyperplasia and villous swelling, and they often have fetal tissues with congenital malformations. Approximately 20% of patients with complete moles develop persistent trophoblastic disease, whereas only 2% to 4% of patients develop persistent disease after partial molar pregnancy. Persistent trophoblastic disease also can occur after a normal term pregnancy and in pregnancies that end in spontaneous or induced abortion.

Choriocarcinoma is the most aggressive malignant form of persistent trophoblastic disease and may involve complications from local uterine disease, such as bleeding and rupture of the uterus, or from the effects of metastases, especially those involving the liver, lungs, and brain. The least common form of GTD is placental-site trophoblastic tumor, which is derived from the intermediate trophoblast and is often associated with vaginal bleeding and amenorrhea.⁷²

All of these neoplasms secrete hCG and free β -subunit, and they often secrete additional forms of these molecules. With the exception of placental-site trophoblastic tumor, which secretes relatively low amounts of hCG, the serum and urine concentrations of hCG roughly parallel the tumor burden and provide prognostic information. The hCG measurements in concert with clinical and radiologic findings, especially vaginal ultrasonographic findings, are useful for making the diagnosis of GTD. Rarely, false-positive, low-level hCG results may be found in some women who have heterophilic antibodies and other

interfering substances in their sera. This may lead to a misdiagnosis of GTD. Because these substances are not excreted in the urine, a urine pregnancy test result will be negative in the presence of such "phantom hCG."^{72,73}

Hydatidiform moles are initially treated with uterine dilation and evacuation with or without adjunctive single-agent chemotherapy with methotrexate or actinomycin D. Approximately 90% of patients with low-risk, persistent trophoblastic disease are cured by single-agent chemotherapy; 75% of patients with high-risk, metastatic disease are cured by multiagent chemotherapy, including etoposide, methotrexate, actinomycin D, cyclophosphamide, and vincristine. Serial hCG measurements are invaluable for monitoring because they accurately reflect the effect of therapy on the tumor.^{51,72,73}

Human Placental Lactogen

Also called chorionic somatomammotropin, hPL is a single-chain, nonglycosylated polypeptide composed of 191 amino acid residues and two disulfide bridges, with a molecular mass of 21,600 d.^{19,74} It is closely related chemically and biologically to both GH (85% amino acid homology) and prolactin (13% amino acid homology). The GH-hPL gene cluster is located on the long arm of chromosome 17 and consists of five genes—one coding for the pituitary GH1, one for the placental GH2, and three for placental hPL: chorionic somatomammotropin hormone 1 or hPL-A (*CSH1*), chorionic somatomammotropin hormone 2 or hPL-B (*CSH2*), and chorionic somatomammotropin hormone-like 1 or hPL-L (*CSHL1*), of which only *CSH1* and *CSH2* are transcribed).^{20,74}

HPL is synthesized and secreted by the syncytiotrophoblast and is detected in maternal serum between 20 and 40 days of gestation.¹⁹ The maternal serum levels rise rapidly and peak at 34 weeks, followed by a plateau (Fig. 21-6).⁷⁵ The serum concentrations and placental hPL mRNA concentrations are closely correlated with placental weight and syncytiotrophoblastic mass.⁷⁴⁻⁷⁶ The maternal serum concentrations at term average between 6 and 7 $\mu\text{g/mL}$; at that time, on the basis of the 9- to 15-minute $T_{1/2}$ of disappearance from the circulation, the placental production rate of hPL is in excess of 1 g/day. The fetal serum levels are $\frac{1}{50}$ to $\frac{1}{100}$ of the maternal levels.⁷⁴

The physiologic in vivo regulation of hPL synthesis and secretion, other than the constitutive production related to placental mass, is unknown. Several studies have examined the possible role of nutrients in hPL secretion in pregnant women. Neither acute hyperglycemia nor hypoglycemia appeared to alter the hPL concentrations, although prolonged glucose infusions decreased and prolonged fasting increased the concentrations.^{19,54,74,77} Arginine infusions, dexamethasone administration, and changes in plasma free fatty acid levels did not affect the maternal hPL concentrations.^{78,79} Glucose, estrogens, glucocorticoids, prostaglandins, epinephrine, oxytocin, TRH, GnRH, and L-dopa have been examined in in vitro systems and found to be without consistent effects.⁸⁰⁻⁸³

Angiotensin II, IGF1, phospholipase A_2 , arachidonic acid, and epidermal growth factor stimulated hPL release in vitro.^{54,84} Epidermal growth factor probably enhances production through promotion of cytotrophoblast-to-syncytiotrophoblast differentiation.⁸⁴ Apolipoprotein AI also stimulated hPL synthesis and release through cAMP-dependent and arachidonic acid-dependent pathways.^{19,85,86} Because changes in the maternal plasma apolipoprotein AI concentrations parallel those of hPL during pregnancy, it is likely that this apoprotein, alone and as part of circulating HDL, is important in the secretion of hPL.⁸⁶

Figure 21-6 Placental weight (Pl. wt.), maternal serum concentrations of human placental lactogen (hPL), and the ratio of hPL to Pl. wt. during pregnancy. (From Selenkow HA, Saxena BN, Dana CL. Measurement and pathophysiologic significance of human placental lactogen. In: Pecile A, Finzi C, eds. *The Feto-Placental Unit*. Amsterdam: Excerpta Medica, 1969:340.)

Several biologic activities of hPL are qualitatively similar to those of GH and prolactin, and hPL can bind to both GH and prolactin receptors.⁸⁷ In various bioassay systems, hPL had weak somatotrophic and lactogenic effects.^{87,88} It appears to be a major regulator of IGF1 production, and during pregnancy, hPL concentrations correlate with those of IGF1.^{19,88} hPL also affects the metabolism of maternal nutrients. It stimulates pancreatic islet insulin secretion directly and after carbohydrate administration,^{87,88} and it is a diabetogenic factor during pregnancy through its promotion of insulin resistance. It enhances lipolysis, leading to a rise in free fatty acid levels, which may in part be responsible for insulin resistance.⁸⁷

The various biologic activities of hPL suggest that the role of hPL during pregnancy is to provide the fetus with a constant supply of glucose and amino acids.⁸⁷ The hPL-stimulated lipolysis allows the mother to use free fatty acids for energy during fasting, allowing glucose, amino acids, and ketone bodies to cross the placenta for use by the fetus. In addition, hPL promotes amino acid uptake by muscle and stimulates protein production, IGF1 production, and glycogen synthesis in the fetus.^{88,89}

Despite the proposed importance of hPL in maternal and fetal metabolic homeostasis during pregnancy, its absence does not appear to impair pregnancy. Deficient or absent hPL production related to gene defects has been described in several women who experienced normal pregnancies and delivered normal infants.⁹⁰

Placental Growth Hormone

GH2 is synthesized and secreted by the syncytiotrophoblast.^{19,20} Alternate splicing of the *GH2* gene results in two nonglycosylated isoforms with molecular masses of 22 and 26 kD.^{20,74} The 22-kD variant may be glycosylated and circulate as a 26-kD protein.⁷⁹ GH2 is detected in the maternal plasma from 10 weeks' gestation and peaks during the third trimester (Fig. 21-7).

GH2 has somatotrophic activity and stimulates IGF1 production, and the increased IGF1 concentrations may be responsible for the suppression of maternal pituitary hGH secretion (see Fig. 21-7).^{20,91} GH2 also may modulate trophoblast invasion.⁹² Unlike GH1, GH2 is not secreted in a pulsatile fashion, nor is it released from the trophoblast by growth hormone-releasing hormone (GHRH); however, it is inhibited by glucose. At term, 85% of the GH biologic activity in maternal serum may be attributed to GH2, 12%

to hPL, and only 3% to GH1.⁹³ Within 48 hours after delivery, GH1 secretion by the pituitary returns to normal.

Human Chorionic Corticotropin

The syncytiotrophoblast synthesizes an ACTH-like peptide, human chorionic corticotropin (hCC), and several

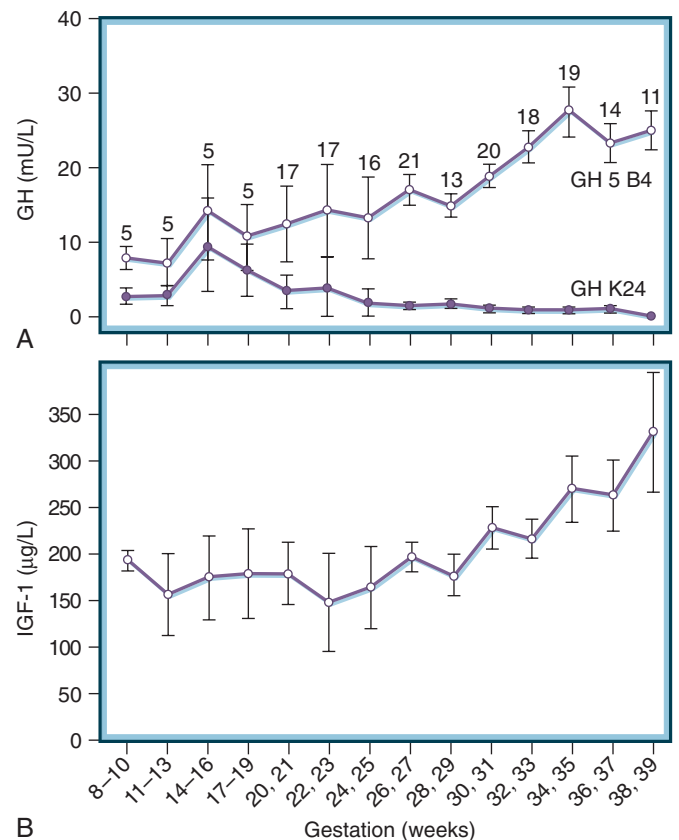

Figure 21-7 Mean (\pm standard error) of plasma human growth hormone (GH) (**A**) and insulin-like growth factor type I (IGF1) (**B**) levels throughout pregnancy. The number of individual assays of growth hormone (GH) and IGF1 at each gestational stage is indicated in **A** at the top of vertical bars. GH 5 B4 indicates placental GH (GH2); GH K24 indicates pituitary GH (GH1). (From Mirlesse V, Franken F, Alsat E, et al. Placental growth hormone levels in normal pregnancy and in pregnancies with intrauterine growth retardation. *Pediatr Res*. 1993;34:39.)

pro-opiomelanocortin-derived peptides, including β -lipotropin, β -endorphin, and α -melanocyte-stimulating hormone.²⁵ The maternal serum concentrations of ACTH increase as pregnancy progresses, and the elevation of free cortisol levels during pregnancy may be related in part to placental hCC and pituitary ACTH production.²⁵

The hCC secretion is stimulated by CRH, which is probably the most important factor regulating the local production of the peptide through paracrine or autocrine mechanisms, or both, because it is also produced by the cytotrophoblast and the syncytiotrophoblast. Unlike the situation with the pituitary, glucocorticoids and oxytocin stimulate hCC release from placental cultures.²⁵ The resistance of maternal plasma ACTH concentrations to suppression after glucocorticoid administration may reflect the placental hCC contribution to the total pool of circulating immunoreactive ACTH.²⁵

Hypothalamic Peptides

Gonadotropin-Releasing Hormone. The cytotrophoblast and the syncytiotrophoblast synthesize and secrete GnRH, which has the same chemical structure and biologic activity as hypothalamic GnRH.^{54,56} Although the GnRH mRNA levels in the placenta are similar throughout gestation, the highest concentrations of the peptide in the placenta and serum are found during the first trimester and correlate with the mass of the cytotrophoblast and peak hCG concentrations.^{56,94}

In vitro, GnRH production by placental explants or purified trophoblasts is stimulated by prostaglandins, epinephrine, activin, insulin, epidermal growth factor, VIP, estradiol, and estriol, and secretion is reduced by inhibin, progesterone, and κ -opiate and μ -opiate agonists.^{95,96} The syncytiotrophoblast contains low-affinity GnRH receptors, whose concentrations parallel the hCG secretory pattern.⁵⁸

Because GnRH stimulates hCG secretion by placental explants and purified trophoblast cells in vitro, with the response of early to midtrimester placentas being greater than that of term trophoblast, it is reasonable to conclude that GnRH is an important autocrine or paracrine regulator of hCG secretion.⁹⁵ The hCG-stimulatory effect of GnRH can be blocked by administration of a GnRH antagonist.⁵⁵ Because GnRH stimulates metalloproteinases in cytotrophoblasts, the peptide may be important during implantation.⁹⁷

Corticotropin-Releasing Hormone. The cytotrophoblast and the syncytiotrophoblast synthesize and secrete a 41-amino-acid peptide that is identical to hypothalamic CRH.^{25,98} CRH mRNA is first detected in the trophoblast at 7 weeks' gestation. The levels remain low during the first 30 weeks of pregnancy but rise 20-fold during the final 5 weeks, a pattern that parallels the rise of CRH content in the placenta and concentrations in maternal plasma.⁹⁸ In maternal plasma, CRH circulates bound to a 37-kD protein that is synthesized by the placenta, liver, and brain and that reduces the biologic activity of the CRH.^{25,98}

In vitro, placental CRF production is stimulated by prostaglandins (E_2 and $F_{2\alpha}$), norepinephrine, acetylcholine, oxytocin, neuropeptide Y, AVP, angiotensin II, and interleukin-1. Glucocorticoids increase CRH mRNA and peptide, whereas in the hypothalamus, suppression is found. CRH secretion is reduced by progesterone and nitric oxide donors. The placenta contains CRH binding sites, and the addition of CRH to cultured placental cells results in a dose-dependent increase in hCC, β -endorphin, and α -melanocyte-stimulating hormone secretion.^{25,54,98} It is likely that CRH has an autocrine or paracrine effect in the placenta.

Whether CRH has a physiologic effect on the maternal pituitary secretion of ACTH is unclear; the circulating CRH may be biologically inactive because of the binding protein. However, just before parturition, the binding protein concentration decreases by approximately 50%, and the CRH levels rise.^{25,98} At this time, CRH stimulates the synthesis and release of prostaglandins from the decidua, amnion, and chorion, which enhances cervical ripening.⁹⁹ The myometrium contains CRH receptors, and CRH may increase myometrial contractility.⁹⁸ In this way, CRH may have a role in initiating and promoting parturition. CRH may also stimulate the fetal pituitary production of ACTH, which may lead to increased fetal adrenal DHEA production and ultimately to estriol synthesis by the fetal-placental unit.⁹⁸ In addition to CRH, the syncytiotrophoblast and fetal membranes secrete urocortin-1, which in vitro stimulates placental ACTH, prostaglandin E_2 , and activin secretion through the CRH receptor.¹⁰⁰

Other Peptides. A peptide with properties of TRH that is not identical to hypothalamic TRH has been identified in the placenta.^{101,102} It can stimulate the release of hTSH in vitro and in vivo.^{103,104} It has unknown physiologic significance because there is no convincing evidence that a chorionic thyrotropin exists, and hCG appears to be the major trophoblastic thyrotropin-like substance.

Immunoreactive somatostatin has been identified in the cytotrophoblast in first-trimester placentas.^{105,106} The levels decrease as pregnancy advances.¹⁰⁵ This pattern has led to the speculation that somatostatin inhibits hPL production and that the loss of inhibition allows the placenta to secrete increasing quantities of hPL.¹⁰⁵ The finding of somatostatin receptors in the placenta adds some indirect support to this hypothesis.¹⁰⁶ However, somatostatin does not inhibit hPL (or GH2) production by placental cells exposed to the peptide in vitro.¹⁰⁶

A substance with GHRH-like activity has been found in the placenta.¹⁰⁷ However, because exposure of placental cells to hypothalamic GHRH does not result in stimulation of hPL or GH2 secretion, it is unlikely that human placental GHRH is physiologically important. Ghrelin also is produced by the placenta, with the highest maternal serum levels found during midgestation, which corresponds to the highest ghrelin mRNA levels.¹⁰⁸

Several other neuropeptides have been found in the placenta, usually through immunohistochemical techniques. They include methionine enkephalin,^{54,109} leucine enkephalin,¹¹⁰ dynorphin,^{109,110} neuropeptide Y,^{54,111} and oxytocin.^{54,112} The physiologic functions of these placental peptides are unknown. It has been suggested that dynorphin may have a role in the paracrine regulation of hPL release through its binding to placental κ -opiate receptors.^{109,110} Neuropeptide Y and oxytocin stimulate the secretion of CRH from placental cells in culture.⁵⁹

Growth Factors

Several growth factors, growth factor-binding proteins, and growth factor receptors have been identified in the placenta. They include IGF1, IGF2, relaxin, epidermal growth factor, PDGF, nerve growth factor, FGF, TGF- β , inhibin, activin, and folliculostatin.^{54,59} As reviewed earlier, a number of these factors have been implicated in the autocrine or paracrine regulation of placental hormone synthesis and release and in placental angiogenesis, and they may have important actions in fetal development. In addition to the placenta, the human endometrium is a rich source of growth factors, cytokines, and vasoactive neuropeptides that are important for uteroplacental function.⁸

CHAPTER 22

Endocrinology of Fetal Development

MEHUL T. DATTANI • PETER C. HINDMARSH • DELBERT A. FISHER

The unfolding of our understanding of mammalian pregnancy and fetal development represents one of the dramatic chapters of scientific progress during the past half-century. Successful pregnancy involves complex genetic, cellular, and hormonal interactions facilitating implantation, placentation, embryonic and fetal development, parturition, and fetal adaptation to extrauterine life. An array of signaling molecules, transcription factors, and epigenetic events program embryogenesis and fetal development in concert with autocrine, paracrine, and endocrine networks of hormones and growth factors that provide the cellular communication coordinating maternal-placental-fetal interactions and fetal maturation. Unique features of the placental-fetal endocrine environment include a growing spectrum of placental hormones and growth factors and a variety of fetal endocrine adaptations to the intrauterine environment (Table 22-1).¹ The fetal adrenal cortex, the para-aortic chromaffin system including the paired organs of Zuckerkindl, and the intermediate lobe of the pituitary are prominent among these. Vasotocin, the parent neurohypophyseal hormone in

submammalian species, is expressed transiently during fetal life, and calcitonin, a largely vestigial hormone in adult mammals, plays a significant role in fetal calcium and bone metabolism.

In addition, the active adrenal glucocorticoid, cortisol, and the thyroid hormones are largely inactive during much of fetal life because of the production of inactive analogues. Hormones and growth factors that play prominent roles in the fetus include catecholamines, parathyroid hormone-related protein (PTHrP), anti-müllerian hormone (AMH), insulin-like growth factor 2 (IGF2), transforming growth factor- β (TGF- β), and the neuroregulins. In the perinatal period, cortisol serves to modulate the functional adaptations that are required for extrauterine survival. In addition, hormonal programming during the fetal-perinatal period conditions the adult functional characteristics of selected endocrine systems. This chapter reviews the current status of our understanding of the maternal-placental-fetal endocrine and growth factor milieu, maturation of the fetal endocrine systems, and adaptations of the fetal endocrine systems to extrauterine life.

PLACENTAL HORMONE TRANSFER

The fetal endocrine milieu is largely independent of maternal hormones because the placenta is impermeable to most peptide hormones. Hormones larger than 0.7 to 1.2 kd have little or no access to the fetal compartment.² The exception is immunoglobulin G, which is actively transported from mother to fetus during the latter half of gestation.³ Steroid and thyroid hormones and catecholamines do cross the placenta, but several of these are metabolized en route, including cortisol, estradiol, thyroxine, triiodothyronine, and catecholamines.⁴⁻⁸

In particular, the placental cells contain an active 11 β -hydroxysteroid dehydrogenase (11 β -HSD) that catalyzes the conversion of most of the maternal cortisol to inactive cortisone.^{5,6} This is important considering the steep gradient between the maternal cortisol concentration and that of the fetus—almost a 10-fold difference. This enzymatic inactivation can be bypassed with dexamethasone, leading to fetal exposure to glucocorticoid, which, in rodent models, has adverse effects on blood pressure, blood glucose, and memory.^{9,10} This altered metabolism is used by physicians to promote glucocorticoid maturation of the fetal lung in cases of preterm delivery and in the management of fetuses affected by a virilizing form of congenital adrenal hyperplasia. Single doses appear to be safe for mother and child,¹¹ but the safety of more chronic exposure is not established.

Figure 22-1 Placental neutralization of biologic activity of hormones during maternal-fetal transfer. The neutralizing enzymes, 17 β -hydroxysteroid dehydrogenase (17 β -HSD) and 11 β -HSD, are shown. See text for details. CAT, catecholamines; COMT, catechol O-methyltransferase; MAO, monoamine oxidase; MDI3, type 3 iodothyronine monodeiodinase; MET, metanephries; rT₃, 3,3',5' (reverse) triiodothyronine; T₂, diiodothyronine; T₃, 3,5,3' triiodothyronine; T₄, thyroxine.

Placental 17 β -HSD is considered to prevent passage of excessive estrogens to the fetus by catalyzing inactivation of estradiol to estrone.⁷ Placental tissue also contains an iodothyronine inner ring monodeiodinase, which deiodinates most of the thyroxine (T₄) to inactive reverse triiodothyronine (rT₃) and converts active 3,5,3'-triiodothyronine (T₃) to inactive diiodothyronine.^{8,12} Nonetheless, there is some transplacental passage of T₄ to the fetus in early pregnancy, and this may be of importance, because observational studies have suggested altered intellectual function, albeit mild, in infants born to mothers with mild untreated hypothyroidism.^{13,14}

Catecholamine-degrading enzymes in placental tissue include monoamine oxidase and catechol O-methyltransferase, 3,9 and both metanephrine and dihydroxymandelic acid metabolites of catecholamines are present in placental homogenates (Fig. 22-1).¹⁵

ECTOPIC FETAL HORMONE PRODUCTION

Kidney, liver, and testes from 16- to 20-week-old human fetuses produce immunoreactive and bioactive human chorionic gonadotropin (hCG) in vitro.^{16,17} Kidney tissue produces almost half as much hCG per milligram of protein as placenta; liver activity is lower. Adrenocorticotrophic hormone (ACTH)-like immunoreactivity is present in relatively high concentrations in neonatal rat pancreas and kidney.¹⁸ This material is presumably derived from a pro-opiomelanocortin (POMC) parent molecule. Hypothalamic neuropeptides are present in a variety of adult tissues, particularly in the pancreas and gut.¹⁹⁻²³ In the fetus, hypothalamic neuropeptides are also present in the gut and tissues derived from it. High concentrations of

thyrotropin-releasing hormone (TRH) and somatostatin immunoreactivity have been reported in neonatal rat pancreas and gastrointestinal tract tissues, whereas hypothalamic concentrations of these immunoreactive substances are low.^{24,25} These neuropeptides have immunoreactive and chromatographic properties similar to those of the synthetic hypothalamic peptides.

Encephalectomy does not alter the circulating TRH levels in the neonatal rat, whereas significant reductions are produced by pancreatectomy. In the sheep fetus, thyroid hormones modulate pancreatic and gut TRH concentrations, pointing to thyroid hormone control of extra-hypothalamic *TRH* gene transcription or translation in the fetus.²⁶ TRH and somatostatin also are present in the human neonatal pancreas and in blood of the human newborn, with both hormones derived mostly from extra-hypothalamic sources.²⁷⁻³⁰ The presence of TRH at high concentrations in fetal ovine blood and the modulation of fetal pancreatic, placental, and blood TRH levels by thyroid hormones suggest a role for extrahypothalamic TRH in the control of fetal pituitary thyrotropin secretion before the near-term maturation of hypothalamic TRH.²⁶ The role of extraneural somatostatin in the fetus is undefined.

FETAL ENDOCRINE SYSTEMS

Anterior Pituitary and Target Organs

The anterior and intermediate lobes of the pituitary gland are derived from oral ectoderm, whereas the posterior pituitary is derived from neural ectoderm.^{31,32} The human fetal forebrain is identifiable by 3 weeks of gestation, the diencephalon and telencephalon by 5 weeks. Rathke's pouch, the buccal precursor of the anterior pituitary gland, separates from the primitive pharyngeal stomodeum by 5 weeks of gestation.^{31,33,34} The neural components of the transducer system (hypothalamus, pituitary stalk, and posterior pituitary) are largely developed by 7 weeks of gestation, and the bony floor of the sella turcica is also present by that time, separating the adenohypophysis from the primitive gut. Capillaries develop within the proliferating anterior pituitary mesenchymal tissue around Rathke's pouch and the diencephalon by 8 weeks of gestation, and intact hypothalamic-pituitary portal vessels are present by 12 to 17 weeks. Maturation of the pituitary portal vascular system continues, and the system becomes functionally intact during the period of histologic differentiation of the hypothalamus and development of the portal vascular extension into hypothalamic tissue; this maturation process extends to 30 to 35 weeks of gestation.

The hypothalamic cell condensations, which represent the hypothalamic nuclei, and the interconnecting fiber tracts are demonstrable histologically by 15 to 18 weeks of gestation.^{26,33} Hypothalamic cells and diencephalic fiber tracts for the hypothalamic neuropeptides somatostatin, corticotropin-releasing hormone (CRH), growth hormone-releasing hormone (GHRH), and gonadotropin-releasing hormone (GnRH) are also visible by that time. Concentrations of dopamine, TRH, GnRH, and somatostatin are significant in hypothalamic tissue by 10 to 14 weeks of gestation. Specialized anterior pituitary cell types, including lactotropes, somatotropes, corticotropes, thyrotropes, and gonadotropes, can be recognized in the anterior pituitary between 7 and 16 weeks of gestation. Anterior pituitary hormones—including growth hormone (GH), prolactin (PRL), thyroid-stimulating hormone (TSH), luteinizing hormone (LH), follicle-stimulating hormone (FSH), and ACTH—are detectable by radioimmunoassay

between 10 and 17 weeks of gestation. Therefore, the anatomy and biosynthetic mechanisms that make up the hypothalamic-pituitary neuroendocrine transducer appear to be functional by 12 to 17 weeks of gestation in humans.

Development of the pituitary gland has been extensively studied in the mouse. Although little is known about pituitary development in humans, it would appear to mirror that seen in the rodent, because pituitary development is similar in all vertebrates. The development of the anterior pituitary occurs in four distinct stages of differentiation leading to the formation of a complicated secretory organ containing five different cell types secreting six different hormones:

Stage 1. Formation of the pituitary placode from oral ectoderm. Cell types of the pituitary gland are derived from the most anterior midline portion of the embryo in a region contiguous with the anterior neural ridge. The anterior neural ridge is displaced ventrally to form the oral epithelium, which gives rise to the roof of the oral cavity. Onset of pituitary organogenesis coincides with a thickening (pituitary placode) in the roof of the oral ectoderm at embryonic day (E) 8.5 in the mouse, corresponding to 4 to 6 weeks' gestation in humans.

Stage 2. Formation of rudimentary Rathke's pouch. Invagination of the oral ectoderm forms a rudimentary pouch, and evagination of the ventral diencephalon forms the posterior pituitary. The pituitary placode makes contact with the floor of the ventral diencephalon. Apposition between the rudimentary Rathke's pouch and neural ectoderm of the diencephalon is critical to normal development and is maintained throughout early pituitary organogenesis.

Stage 3. Formation of definitive Rathke's pouch. The rudimentary Rathke's pouch deepens and folds on itself until it closes, forming a definitive pouch. The infundibulum or pituitary stalk is formed by evagination of the posterior part of the presumptive diencephalon.

Stage 4. Formation of the adult pituitary gland. The definitive pouch is completely detached from the oral cavity. Spatial and temporal differentiation of various cell types within the pituitary gland results in the development of individual hormone-secreting cells in a sequential order.

Complex genetic interactions dictate normal pituitary development. A cascade of signaling molecules and transcription factors plays a crucial role in organ commitment, cell proliferation, cell patterning, and terminal differentiation, and the final product is a culmination of this coordinated process (Fig. 22-2). Initially, cells within the primordium of the pituitary gland are competent to differentiate into all cell types. After expression of the earliest markers of pituitary gland development, such as homeobox gene expressed in embryonic stem cells (*Hesx1*), further signaling pathways are established from within the gland and ventral diencephalon that direct these cells toward terminal differentiation into mature hormone-secreting cell types. Signaling molecules and transcription factors are expressed sequentially at critical periods of pituitary development, and expression of many of these factors is attenuated subsequently (Fig. 22-3). Genes that are expressed early are implicated in organ commitment but are also implicated in repression and activation of downstream target genes that have specific roles in directing the cells toward a particular fate.

Spontaneous or artificially induced mutations in the mouse have led to significant insights into human pituitary disease, and identification of mutations associated

Figure 22-2 Schematic representation of the developmental cascade of genes implicated in human pituitary development with particular reference to pituitary cell differentiation.

with human pituitary disease have, in turn, been invaluable in defining the genetic cascade responsible for the development of this embryologic tissue. Mutations involved specifically in human hypothalamopituitary disease are listed in Table 22-2 and are briefly discussed here.

Extrinsic molecules within the ventral diencephalon and surrounding structures, such as bone morphogenetic proteins 2 and 4 (*Bmp2*, *Bmp4*), fibroblast growth factor 8 (*Fgf8*), sonic hedgehog (*Shh*), wingless (*Wnt4*), thyroid

transcription factor 1 (*Ttf1*; also called *Nkx2-1*), and molecules involved in Notch signaling play critical roles in early organogenesis.^{31,34,35} Recent studies in the mouse have shown that a close interaction between oral ectoderm and neural ectoderm is critical for initial development of the pituitary gland. Rathke's pouch develops in a two-step process that requires at least two sequential inductive signals from the diencephalon. First, induction and formation of the rudimentary pouch is dependent upon *Bmp4*, and second, *Fgf8* activates two key regulatory genes, LIM

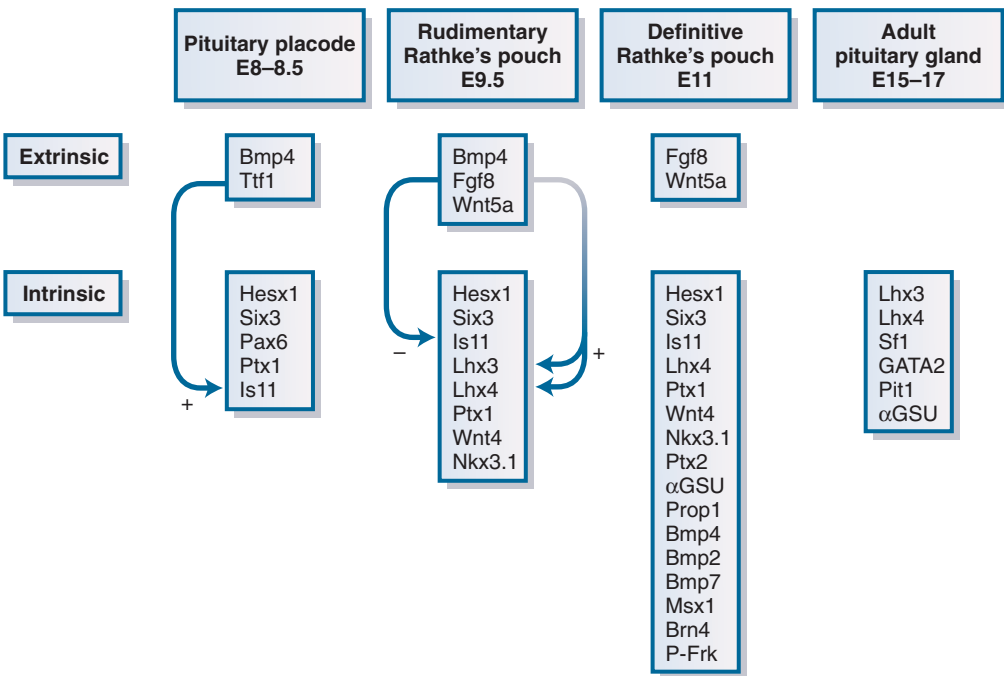

Figure 22-3 Transcription factors and signaling molecules involved in anterior pituitary development.

TABLE 22-2

Comparison of Murine and Human Phenotypes in Pituitary Development

Gene	Protein	Murine Loss-of-Function Phenotype	Human Phenotype	Inheritance (Murine and Human)
<i>HESX1</i>	HESX1	Anophthalmia or microphthalmia, agenesis of corpus callosum, absence of septum pellucidum, pituitary dysgenesis or aplasia	Variable: SOD, CPHD, IGHD with EPP Anterior pituitary hypoplastic or absent Posterior pituitary ectopic or eutopic Frequency of mutations: <1%	Dominant or recessive in humans, recessive in mouse
<i>OTX2</i>	OTX2	Lack of forebrain and midbrain, olfactory placode, optic placodes	Anophthalmia, APH, ectopic posterior pituitary, absent infundibulum Frequency of mutations: 2-3% of anophthalmia/microphthalmia cases	Heterozygous: haploinsufficiency/dominant negative
<i>SOX2</i>	SOX2	Homozygous null mutants: embryonic lethal Heterozygous mice and further dose reduction: poor growth, reduced fertility, CNS abnormalities, anophthalmia; pituitary hypoplasia with reduction in all cell types	Hypogonadotropic hypogonadism; APH, abnormal hippocampi, bilateral anophthalmia/microphthalmia, abnormal corpus callosum, learning difficulties, esophageal atresia, sensorineural hearing loss, hypothalamic hamartoma Frequency of mutations: 8/235	De novo haploinsufficiency in humans, heterozygous mutation associated with haploinsufficiency in mouse
<i>SOX3</i>	SOX3	Poor growth, weakness, craniofacial abnormalities, ACC, hypothalamic and infundibular abnormalities	IGHD and mental retardation, hypopituitarism; APH, infundibular hypoplasia, EPP, midline abnormalities Frequency of mutations: 6% (duplications), 1.5% (mutations)	X-linked recessive in both mice and humans
<i>GLI2</i>	GLI2	N/A	Holoprosencephaly, hypopituitarism, craniofacial abnormalities, polydactyly, single nares, single central incisor; partial ACC Frequency of mutations: 1.5%	Haploinsufficiency in humans
<i>LHX3</i>	LHX3	Hypoplasia of Rathke's pouch	GH, TSH, gonadotropin deficiency with pituitary hypoplasia ACTH insufficiency variable Short, rigid cervical spine Variable sensorineural hearing loss. Frequency of mutations: 1.3%	Recessive in both
<i>LHX4</i>	LHX4	Mild hypoplasia of anterior pituitary	GH, TSH, cortisol deficiency, persistent craniopharyngeal canal and abnormal cerebellar tonsils; APH, ectopic/eutopic posterior pituitary, absent infundibulum Frequency of mutations: 1.2%	Recessive in mouse, dominant in humans
<i>PROPI</i>	PROPI	Hypoplasia of anterior pituitary with reduced somatotropes, lactotropes, thyrotropes, corticotropes, and gonadotropes	GH, TSH, PRL, and gonadotropin deficiency Evolving ACTH deficiency Enlarged pituitary with later involution Frequency of mutations: 1.1% sporadic cases, 29.5% familial cases	Recessive in both
<i>POU1F1</i>	POU1F1 (PIT1)	Anterior pituitary hypoplasia with reduced somatotropes, lactotropes, and thyrotropes	Variable anterior pituitary hypoplasia with GH, TSH, and PRL deficiencies Frequency of mutations: 3.8% sporadic cases, 18% familial cases	Recessive in mouse, dominant/recessive in humans

ACC, agenesis of corpus callosum; ACTH, adrenocorticotrophic hormone; APH, anterior pituitary hypoplasia; CNS, central nervous system; CPHD, combined pituitary hormone deficiencies; EPP, ectopic posterior pituitary; GH, growth hormone; IGHD, isolated growth hormone deficiency; N/A, not applicable; PRL, prolactin; SOD, septo-optic dysplasia; TSH, thyroid-stimulating hormone.

homeobox 3 (*Lhx3*) and LIM homeobox 4 (*Lhx4*), that are essential for subsequent development of the rudimentary pouch into a definitive pouch.

Bmp4 and *Fgf8* are present only in the diencephalon and not in Rathke's pouch. Murine mutations within the *Tf1/Nkx2-1* (also called thyroid-specific enhancer binding protein), which is expressed only in the presumptive ventral diencephalon, can cause severe defects in the development of the diencephalon and the anterior pituitary gland. Conditional deletion of *Rbp-J*, which encodes the major mediator of the Notch pathway, leads to conversion of the late (pituitary-specific transcription factor 1 [*Pit1*]) lineage into the early (corticotroph) lineage. Notch signaling is required for maintaining expression of *Prop1* (prophet

of *Pit1*), which is required for generation of the *Pit1* lineage. Attenuation of Notch signaling is necessary for terminal differentiation in *Pit1* cells and for maturation and proliferation of the GH-producing somatotroph.³⁵ There have been no reported mutations of these early morphogenetic signals in humans.

Mutations of the sonic hedgehog (SHH) signaling pathway (SHH, *TGIF*, *ZIC2*, *PTCH1*, *GLI2*) and the transcription factor *SIX3* have been identified in patients with holoprosencephaly, with and without hypothalamo-pituitary defects.³⁶⁻³⁸ Mutations in *HESX1* have been identified in patients with septo-optic dysplasia (SOD; a combination of pituitary, eye, and midline forebrain defects), combined pituitary hormone deficiencies (CPHD),

and isolated growth hormone deficiency (IGHD).^{31,39} Mutations in *SOX2* and *OTX2* have recently been described in association with severe eye defects, hypogonadotropic hypogonadism, and variable hypopituitarism.⁴⁰⁻⁴⁴ Mutations and genomic duplications in *SOX3* have been identified in patients with hypopituitarism with and without learning defects.⁴⁵

Mutations in the gene encoding the LIM homeodomain transcription factor *LHX3* have been identified in patients with hypopituitarism, neck abnormalities, and sensorineural deafness, whereas mutations in *LHX4* have been identified in patients with hypopituitarism and cerebellar abnormalities.⁴⁶⁻⁴⁸ Mutations in genes expressed later in pituitary development, such as *PROP1* and *POU1F1* (previously known as *PIT1*), are associated with more specific pituitary phenotypes (variable GH, TSH, ACTH, PRL, and gonadotropin deficiencies and often a large anterior pituitary that later involutes with *PROP1* mutations; GH, TSH, and PRL deficiencies with *POU1F1* mutations), in keeping with a role for these genes in cellular proliferation and differentiation and hormone secretion.^{31,49-51} Mutations in the T-box transcription factor *TBX19/TPIT* have been described in patients with early-onset isolated ACTH deficiency.⁵² No genetic etiology has been identified in most cases of congenital hypopituitarism to date, suggesting a role for other, unidentified genes or environmental factors.

Growth Hormone and Prolactin

The human fetal pituitary gland can synthesize and secrete GH by 8 to 10 weeks of gestation.^{2,33} Pituitary GH content increases from about 1 nmol (20 ng) at 10 weeks to 45 nmol (1000 ng) at 16 weeks of gestation. Fetal plasma GH concentrations in cord blood samples are in the range of 1 to 4 nmol/L during the first trimester and increase to a mean peak of approximately 6 nmol/L at midgestation. Plasma GH concentrations fall progressively during the second half of gestation, to a mean value of 1.5 nmol/L at term.³³ Pituitary GH messenger RNA (mRNA) and GH content generally parallel the increase in plasma GH concentration between 16 and 24 weeks of gestation.⁵³ This pattern of ontogenesis of plasma GH reflects a progressive maturation of hypothalamic-pituitary and forebrain function. The responses of plasma GH to somatostatin and GHRH and to insulin and arginine are mature at term in human infants.^{33,54}

The high plasma GH concentrations at midgestation after development of the pituitary portal vascular system may reflect unrestrained secretion.³³ Studies of 9- to 16-week-old human fetal pituitary cells in culture showed a predominant response to GHRH and a limited effect of somatostatin, suggesting that the inhibitory action of somatostatin develops later in gestation.⁵⁵ This interpretation was substantiated by in vivo studies in the sheep fetus, which showed a failure of somatostatin to inhibit GHRH-stimulated GH release early in the third trimester and maturation of the inhibitory effect of somatostatin near term.³³ The predominant GHRH enhancement and limited somatostatin inhibition of GH secretion at midgestation presumably relate to a limited capacity for inhibition of GH release by somatomedin feedback. In addition, there may be unrestrained GH secretion at the pituitary cell level, or immaturity of limbic and forebrain inhibitory circuitry that modulates hypothalamic function, or both.³³ Whatever the mechanisms, control of GH secretion matures progressively during the last half of gestation and the early weeks of postnatal life, so that mature responses to sleep, glucose, and L-dopa are present by 3 months of age.

Figure 22-4 Patterns of change of fetal plasma human placental lactogen (hPL), growth hormone (GH), prolactin (PRL), insulin-like growth factor I (IGF1), and insulin-like growth factor 2 (IGF2) during gestation and in the neonatal period. The shaded area indicates the range of fetal plasma hPL concentrations. (Data from references 323-325.)

The ontogenesis of fetal plasma PRL differs significantly from that of GH; concentrations are low until 25 to 30 weeks of gestation and increase to a mean peak value of approximately 11 nmol/L at term (Fig. 22-4).³³ Pituitary PRL content increases progressively from 12 to 15 weeks, and in vitro fetal pituitary cells from midgestation fetuses show limited autonomous PRL secretion, although PRL release increases in response to TRH and decreases in response to dopamine. Brain and hypothalamic control of PRL matures late in gestation and during the first months of extrauterine life.^{33,54} Estrogen stimulates PRL synthesis and release by pituitary cells, and the marked increase in fetal plasma PRL concentration in the last trimester parallels the increase in fetal plasma estrogen levels, although lagging by several weeks.^{33,54} Anencephalic fetuses have plasma PRL concentrations in the normal or low-normal range. These data support a role for estrogen in stimulating fetal PRL release. The fetal sheep exhibits a similar pattern of fetal plasma PRL levels, indicating that maturation and integration of brain and hypothalamic mechanisms modulating PRL release develop late in gestation and in the postnatal period, accounting for the delayed postnatal fall in plasma PRL level in the neonate of this species.³³

There is a general tendency toward hypersecretion of fetal pituitary hormones during the last half of gestation, and pituitary hormones found at high levels in cord blood from aborted human fetuses and premature human infants include GH, TSH, ACTH, β -endorphin, β -lipotropin, LH, and FSH.^{33,54} Development of hypothalamic-pituitary control is complex, involving maturational events in the

cortex and midbrain, the hypothalamus and hypothalamic-pituitary portal vascular system, peripheral endocrine systems, and the placenta itself, including hormone, growth factor, and neuropeptide production. The fetal pituitary hyperfunction appears to be related more to relatively delayed maturation of the central nervous system (CNS) and hypothalamic control with unrestrained secretion of stimulating hypothalamic hormones than to the action of placental neuropeptides.³³

Postnatally, GH acts through receptors in liver and other tissues to stimulate production of IGF1 and, to a lesser degree, IGF2. Prenatally, GH receptor mRNA levels and receptor binding are low in fetal liver, although receptor mRNA is present in other fetal tissues.³³ The growth of anencephalic fetuses is almost normal, suggesting that factors other than GH stimulate fetal IGF production. Nutritional factors are known to play a role.^{56,57}

PRL receptors are present in most fetal tissues during the first trimester of gestation, and it is likely that lactogenic hormones have a significant role in organ and tissue development early in gestation.^{56,58} The coordinated increase in fetal adipose tissue and the adipose tissue PRL receptors PRLR1 and PRLR2 suggests that PRL may play a role in growth and maturation of fetal adipose tissue later in gestation.⁵⁹ PRL may also play a role in fetal skeletal maturation.⁵⁹ Ovine placental lactogen stimulates glycogen synthesis in fetal ovine liver, and HPL stimulates amino acid transport, DNA synthesis, and IGF1 production in human fetal fibroblasts and muscle cells. GH and PRL have little activity in these tissues (see “Fetal Growth”).⁵⁸

Adrenal System

Embriology

The primordia of the adrenal glands can be recognized just cephalad of the bilaterally developing mesonephros by 3 to 4 weeks of gestation.^{60,61} The adrenal cortex is derived from a thickening of the intermediate mesoderm at 4 to 5 weeks of gestation in humans, in contrast to the adrenal medulla, which derives from the ectoderm. This region, known as the *gonadal ridge*, contains adrenogonadal progenitor cells that give rise to the steroidogenic cells of the adrenal gland and the gonad. The gonadal cells migrate caudally. Cells destined to become adrenal tissue migrate retroperitoneally to the upper pole of the mesonephros. They are then infiltrated at 7 to 8 weeks of gestation by sympathetic cells derived from the neural crest that will form the adrenal medulla. Encapsulation of the adrenal gland occurs after 8 weeks of gestation and results in the formation of a distinct organ just above the developing kidney.

The fetal adrenal is composed of three functional zones: an outer definitive zone capable of producing both glucocorticoids and mineralocorticoids, a transitional zone with enzymes for cortisol production, and a much larger inner fetal zone capable of producing significant amounts of C19 androgens such as dehydroepiandrosterone (DHEA) and dehydroepiandrosterone sulphate (DHEAS), which are then converted to estrogens by the placenta. The large eosinophilic cells of the fetal zone are well differentiated by 9 to 12 weeks of gestation and are capable of active steroidogenesis. The fetal adrenal glands grow rapidly and progressively in mass and form 0.4% of body weight at term; the combined glandular weight is approximately 8 g at term, when the fetal zone makes up about 80% of the mass of the gland with a relative size 10- to 20-fold that of the adult adrenal.^{16,60,61} The fetal zone is identified only in higher primates. The adrenal gland undergoes rapid

Figure 22-5 Hemi-cross-section of a 5-week human embryo showing the locations of the adrenal primordia (suprarenal cortices) and gonadal ridges. The homeobox genes programming adrenal and gonadal embryogenesis are indicated. Steroidogenic factor 1 (SF1) is involved in testicular and ovarian development. SRY is the single critical regulator of testicular embryogenesis. Inactivation of the *DAX1* gene leads to adrenal hypoplasia. The steroidogenic acute regulatory protein (StAR) is the rate-limiting factor for adrenal steroidogenesis. See text for details.

involution postnatally, largely due to regression of the fetal zone, which is absent by 6 months of age in most cases.

Genetic Regulation of Adrenal Development

Fetal adrenal cortical development is under the control of several genes and growth factors. Much of our understanding of adrenal development derives from studies of transgenic mice and of patients with various forms of adrenal hypoplasia. The earliest stages of adrenal development may be regulated by a number of transcription factors (e.g., SALL1, FOXD2, PBX1, WT1, SF1 [NR5A1], DAX1 [NROB1]), coregulators (e.g., CITED2), signaling molecules (e.g., Hedgehog/GLI3, WNT3/WNT4/WNT11, midkine), matrix proteins (e.g., SPARC), and regulators of telomerase activity (e.g., ACD). Of these molecules, the genes encoding the orphan nuclear receptors SF1 (steroidogenic factor 1) and DAX1 (dosage-sensitive sex reversal, adrenal hypoplasia congenita, X-chromosome factor)⁶²⁻⁶⁴ appear to be critical for early development (Fig. 22-5). These genes show coordinated expression in adrenal cortex, testis, ovary, hypothalamus, and pituitary tissues.

SF1 gene knockout mice manifest adrenal and gonadal agenesis, gonadotropin deficiency, and absence of the hypothalamic ventromedial nucleus.⁶³ Inactivating *DAX1* gene mutations are associated with adrenal hypoplasia and gonadotropin deficiency.⁶³ Several other transcription factors including *WT1*, *LIM1*, and *PBX1* are involved earlier in the complex genetic cascade programming adrenal gland organogenesis from the celomic epithelium and urogenital ridge.^{63,64} The steroidogenic acute regulatory protein (StAR) is a rate-limiting factor in adrenal steroidogenesis. StAR knockout mice manifest glucocorticoid and mineralocorticoid deficiency and female genitalia in XY animals.⁶⁵ In humans, inactivating *StAR* mutations cause adrenal hypoplasia and adrenal hormone insufficiency, and 46XY males with normal male genitalia have been described in association with *StAR* mutations.^{65,66}

Later adrenal gland development and growth is mediated by a variety of growth factors. Proliferation of the fetal and definitive zones is stimulated by basic fibroblast growth factor (bFGF) and epidermal growth factor (EGF), and the fetal adrenal expresses high levels of IGF2 mRNA and protein, which are responsive to ACTH.¹⁶ Moreover, IGF2 augments ACTH-stimulated expression of steroidogenic enzymes and stimulates steroid hormone production in fetal adrenal cortical cells, suggesting a role in adrenal regulation during fetal and postnatal life.¹⁶ The pattern of enzyme maturation in the fetal adrenal suggests that cortisol production by the definitive zone does not occur *de novo* from cholesterol until 30 weeks of gestation, but some production using progesterone as the precursor probably occurs earlier.¹⁶

Adrenal Steroidogenetics

The fetal adrenal expresses the same five steroidogenic apoenzymes as the adult gland. One microsomal enzyme has 17-hydroxylase/17-20-lyase (CYP17A1 or P450c17) activities, and another has 21-hydroxylase (CYP21A2 or P450c21) activity. Two mitochondrial cytochrome P450 enzymes provide cholesterol side-chain cleavage (CYP11A1 or P450scc) and C11/C18 hydroxylation of the parent steroid structure (CYP11B1/CYP11B2 or P450c11/aldosterone synthase). A fifth enzyme, expressed by the smooth endoplasmic reticulum, exhibits both 3 β -HSD and Δ^4 , Δ^5 -isomerase activities.^{60,61} Quantitative differences in the relative activities of these enzymes are found between cells derived from the fetal versus the definitive zones, and these differences are largely due to regulated steroidogenic gene transcription.⁶⁰

The fetal zone has relatively high steroid sulfotransferase activity, and because of the low 3 β -HSD and high sulfotransferase activities, the major steroid products of the fetal adrenal are DHEA, DHEAS, pregnenolone sulfate, several Δ^5 3 β -hydroxysteroids, and limited amounts of Δ^5 3-ketosteroids, including cortisol and aldosterone.^{60,61} The definitive zone contributes only a small fraction of total fetal adrenal steroid output. Glucocorticoids are synthesized in the first trimester due to transient expression of type 2 3 β -hydroxysteroid dehydrogenase (HSD3B2), which is maximal between 8 and 9 months of gestation.⁶⁷ The hypothalamic-pituitary-adrenal axis is sensitive to glucocorticoid-mediated feedback at this time; 46XX fetuses with steroidogenic defects (e.g., in CYP21 or CYP11) lack cortisol and have an elevated ACTH drive that results in excess production of fetal androgens at a time when the genital and scrotal folds are sensitive to androgen exposure, resulting in virilization of female genitalia.⁶⁷

Cholesterol, the major substrate for fetal adrenal steroidogenesis, is derived from circulating low-density lipoprotein (LDL) and from *de novo* adrenal synthesis. LDL-cholesterol, largely of fetal liver and testicular origin, contributes 70% of the total. The fetal zone contains more LDL binding sites and manifests a greater rate of *de novo* cholesterol synthesis than does the definitive zone, in keeping with its greater steroidogenic activity. Both ACTH and angiotensin II receptors (AT₁ and AT₂) are present on fetal adrenal cells early in gestation. ACTH stimulates steroid production by activating StAR and increasing delivery of substrate cholesterol to P450scc; angiotensin II inhibits 3 β -HSD activity and promotes DHEA production in the fetal zone.⁶⁰ Both fetal adrenal cortisol and placental estradiol regulate hepatic synthesis of cholesterol in the fetus.

The major stimulus to fetal adrenal function is fetal pituitary ACTH.^{16,60,68} Although placental hCG may support early adrenal growth, the involution of the adrenal gland

that occurs after 15 weeks in the anencephalic fetus suggests a crucial role for pituitary-derived factors. CRH protein has been demonstrated in fetal baboon pituitary, adrenal, liver, kidney, and lung tissues during the last third of gestation. The levels are highest in the pituitary (300 to 500 pg/mg protein); levels in adrenal and lung average 20 to 30 pg/mg protein, and those in liver and kidney tissues average 5 to 10 pg/mg protein.⁶⁹ CRH gene knockout in mice leads to neonatal death due to pulmonary hypoplasia, suggesting that CRH-stimulated glucocorticoid production is essential for adrenergic chromaffin and normal lung development.⁷⁰ Circulating CRH levels are elevated in the fetus, largely from extrahypothalamic and placental sources.^{16,69,71} Maternal levels of CRH are elevated during the last trimester of gestation and reach values of 0.5 to 1 nmol/L at term; normal values in nonpregnant women are lower than 0.01 nmol/L.⁷² This placental CRH is bioactive, and levels correlate with maternal cortisol concentrations, suggesting that this circulating placental CRH plays a role in stimulating maternal corticotropin release. Fetal plasma CRH levels at term are approximately 0.03 nmol/L; relative to the presumably high level in pituitary portal blood, plasma CRH probably has little role in modulating fetal corticotropin release. Midgestation fetal plasma corticotropin concentrations average about 55 pmol/L (250 pg/mL), levels that maximally stimulate fetal adrenal steroidogenesis, and concentrations are higher throughout gestation than in postnatal life, although they fall near term (Fig. 22-6).^{16,60} Arginine vasopressin (AVP) and catecholamines also are significant stimuli for fetal ACTH secretion.⁷³

The paradox of human fetal adrenal function is that steroidogenesis is programmed largely to production of inactive products.⁶⁰ The gland is maximally stimulated to

Figure 22-6 Patterns of change of fetal plasma adrenocorticotropic hormone (ACTH), cortisol, cortisone, and dehydroepiandrosterone sulfate (DHEAS) during gestation and in the neonatal period. The trend of average values is shown for each hormone in nanomoles per liter. Notice the broken scale for DHEAS. (Data from references 60, 326-328.)

maintain fetal cortisol levels and ACTH feedback homeostasis but is programmed by the steroidogenic enzyme expression pattern (e.g., relative 3 β -HSD deficiency) to produce inactive DHEA and pregnenolone and their sulfate conjugates. Much of the DHEA is converted to 16-hydroxy-DHEAS by the fetal adrenal and fetal liver. As already discussed, this programming is designed to provide DHEA substrate for placental estrone and estradiol production: 16-hydroxy-DHEA undergoes metabolism to estriol in the placenta. Fetal DHEAS production and maternal estriol concentrations increase progressively to term; DHEAS production approximates to 200 mg/day near term.¹⁶ In the anencephalic fetus, placental estrogen production is reduced to about 10% of normal.^{16,60} In pregnant baboons with placental estrogen production suppressed by administration of an aromatase inhibitor, the volume of the fetal zone of the fetal adrenal increased markedly.⁷⁴ This effect was reversed by administration of inhibitor plus estrogen, suggesting that estrogen selectively suppresses fetal zone growth and development during the second half of primate pregnancy. It is proposed that this represents a feedback system to regulate secretion of fetal adrenal DHEA, thereby maintaining normal fetal-placental function and development.⁷⁴ Near term, the fetal cortisol production rate in blood, per unit body weight, is similar to that in the adult.⁶⁰ About two thirds of fetal cortisol is derived from the fetal adrenal glands, and one third is derived from placental transfer.⁶⁰ The metabolic clearance of cortisol in the fetus is rapid; 80% is oxidized in fetal tissues or placenta to cortisone or further metabolites.⁶⁰

The corticotropin feedback control system matures progressively during the second half of gestation and the early neonatal period. Dexamethasone can suppress the human fetal pituitary-adrenal axis at term but not at 18 to 20 weeks of gestation.⁶⁰ In the fetal sheep, hypothalamic and pituitary glucocorticoid receptors are present at midgestation, and corticotropin suppressibility can be demonstrated by the midpoint of the third trimester of gestation.⁷⁵ The number of glucocorticoid receptors in the sheep fetal hypothalamus increases at term, at the time of increasing glucocorticoid levels, suggesting that some process in the fetus allows the normal autoregulation of glucocorticoid receptors to be overridden at term.⁷⁶

Adrenal hormone receptors, including glucocorticoid receptors (GRs) and mineralocorticoid receptors (MRs), are members of the nuclear receptor superfamily of steroid hormone, thyroid hormone, vitamin D, and retinoid receptors.⁷⁷ GRs are present in most body tissues by the second trimester and play an important role in fetal development. Mice lacking GR function manifest enlarged and disorganized adrenal cortices, adrenal medullary atrophy, lung hypoplasia, and defective gluconeogenesis.^{72,77} They appear normal at birth but are not viable.

GRs are present at birth and are probably present at midgestation in most tissues, including placenta, lung, brain, liver, and gut.^{60,76,78} Fetal cortisol is converted to cortisone through 11HSDB2 in fetal tissues, and levels of circulating cortisone in the fetus at midgestation are fourfold to fivefold higher than cortisol concentrations (see Fig. 22-6). Cortisone is a relatively inactive glucocorticoid, and this metabolism protects the anabolic milieu of the fetus, because cortisol can retard both placental and fetal growth.⁷⁹ As term approaches, selected fetal tissues including liver and lung express 11HSDB1, a reductase that promotes local conversion of cortisone to cortisol.⁶⁰ Cortisol serves as an important stimulus to prepare the fetus for extrauterine survival. An increase in fetal cortisol concentration occurs during the last 10 weeks of gestation and is

the result of increased cortisol secretion and decreased conversion to cortisone.⁶⁰ This increase in fetal cortisol production has an important role in the maturation of several fetal systems or functions that are critical to extrauterine survival (see "Transition to Extrauterine Life").^{60,80}

The human fetal adrenal gland is capable of aldosterone secretion near term with the development of the zona glomerulosa, and fetal plasma aldosterone concentrations in infants who are born by cesarean section are threefold to fourfold higher than maternal levels.^{60,81} Vaginal delivery and maternal salt restriction increase concentrations in both mother and infant. The increased aldosterone levels in the fetus are a result of increased fetal adrenal secretion and persist during the first year of extrauterine life.⁸¹ However, there is a poor correlation between plasma renin activity (PRA) and aldosterone concentrations in cord blood.⁸² Aldosterone secretion is low in the midgestation human fetal adrenal and is unresponsive to the secretagogues that are known to modulate aldosterone production in the adult. In sheep, fetal aldosterone becomes responsive to PRA and angiotensin II in the neonatal period.⁸³ In this species, in which late fetal aldosterone levels are also high compared with adult levels, furosemide stimulates PRA but not aldosterone during the third trimester; the aldosterone response to furosemide (and PRA) is delayed until the neonatal period.^{83,84} This situation also appears to be the case in the human fetus and neonate.

MRs are present in fetal tissues from 12 to 16 weeks of gestation.⁸⁵ MR immunoreactivity is detectable in fetal kidney, skin, hair follicles, trachea and bronchioles, esophagus, stomach, small intestine, colon, and pancreatic exocrine ducts. The role of MRs in these fetal tissues remains unclear. MR knockout mice appear normal at birth but demonstrate defects in mineralocorticoid and renin-angiotensin system functions in the postnatal period.⁸⁶

Angiotensin II levels in the sheep fetus are similar to maternal values, and blockade of fetal production with angiotensin-converting enzyme inhibitors decreases the fetal glomerular filtration rate.⁸⁴ Both subtypes of angiotensin receptors, AT₁ and AT₂, are detectable in various tissues early in fetal development.⁸⁷ AT₁ receptor mRNA expression in the fetal sheep kidney is low early in gestation, increases in the latter third of pregnancy, and decreases postnatally. AT₂ mRNA levels are high at midgestation and decrease during the third trimester.⁸⁷ These changes are believed to reflect growth factor-mediated changes in cells that contain AT in various tissues. Hormonal factors modulate fetal renal AT gene expression in sheep: angiotensin II suppresses both AT₁ and AT₂, and cortisol increases AT₁ gene expression in kidney and lungs.^{87,88}

The role of the fetal renin-angiotensin system is not clear; rather than modulating renal sodium excretion through aldosterone, it may maintain renal excretion of salt and water into amniotic fluid to prevent oligohydramnios.⁸⁴ This renal effect is presumably mediated by modulation of arterial pressure. The mechanism for the high aldosterone concentrations in the fetal and neonatal periods remains unclear. Atrial natriuretic peptide (ANP), a cardiac hormone, is known to inhibit aldosterone secretion. Because plasma atrial natriuretic factor concentrations (ANP, BNP, and CNP) are high in the fetus, the increased PRA and aldosterone levels are not caused by relative atrial natriuretic factor deficiency.⁸⁹

Aldosterone affects renal sodium excretion in the fetal sheep and in premature infants.^{60,83} Manifestations of mineralocorticoid deficiency in the newborn term infant can occur as a result of aldosterone deficiency or competition for binding to renal MRs by other steroids such as

17-hydroxyprogesterone.⁶⁰ Relatively reduced glomerular filtration in the newborn limits sodium loss initially, but by 1 week of age, aldosterone deficiency produces the characteristic manifestations of hyponatremia, hyperkalemia, and volume depletion.

Defects of Adrenal Steroidogenesis

Adrenal insufficiency may occur secondary to ACTH deficiency, or it may be primary, resulting from adrenal failure. The mature ACTH peptide is cleaved from the larger precursor molecule, POMC, together with other small peptides such as β -endorphin and α - and β -melanocyte-stimulating hormone (MSH). Defects in ACTH synthesis, processing, or release can lead to secondary adrenal hypoplasia resulting in neonatal hypoglycemia, prolonged jaundice, or collapse. Given that mineralocorticoid secretion is largely independent of ACTH secretion, it is preserved, and salt loss is therefore unusual. Nevertheless, mineralocorticoid deficiency can be an issue in some patients with ACTH insensitivity. Low serum concentrations of ACTH, absence of hyperpigmentation, and the presence of associated features such as pale skin, red hair, diarrhea, and obesity (*POMC/PC1* mutations) are important diagnostic clues.

The presence of multiple pituitary hormone deficiencies (e.g., GH, ACTH, TSH, gonadotropins, vasopressin, and PRL) may point to a diagnosis of multiple pituitary hormone deficiency (MPHD), often in association with structural abnormalities of the pituitary gland, eye abnormalities, and forebrain abnormalities (SOD). Signs such as those of congenital hypothyroidism, hypoglycemia, congenital hypogonadotropic hypogonadism (micropenis, undescended testes), and severe postnatal growth failure may be suggestive of the diagnosis. A number of single-gene defects have now been associated with this disorder (e.g., mutations in *HESX1*, *SOX3*, *LHX3*, *LHX4*, *PROP1*).³¹ Occasionally, ACTH insufficiency may not be present at the time of diagnosis but may develop progressively with time.

Recessive mutations in the T-box factor *TPIT* (*TBX19*) have been identified in patients with severe, early-onset isolated ACTH deficiency with profound hypoglycemia, prolonged jaundice, and sudden neonatal death.⁵² *TPIT* is required for the specification, maturation, and maintenance of both precorticotrope and premelanotrope populations and for the suppression of gonadotrope fate. It is also required to activate the expression of POMC in conjunction with the transcription factor *PTX1*. Murine transgenesis resulted in ACTH and glucocorticoid deficiencies, adrenal hypoplasia, and pigmentation defects in mice deleted for *TPIT*.⁵²

ACTH resistance can occur in a number of well-defined entities, such as defects in the ACTH receptor (melanocortin 2 receptor [*MC2R*], familial glucocorticoid deficiency [FGD] type 1), in *MC2R* accessory protein (*MRAP*, FGD type 2), or as part of the triple-A syndrome (alacrimia, achalasia, addisonism; also known as Allgrove syndrome, caused by defects in *ALADIN/AAAS*). These disorders are characterized by isolated glucocorticoid deficiency, hyperpigmentation, and markedly elevated concentrations of ACTH.^{90,91} Nevertheless, approximately 15% of individuals with triple-A syndrome have evidence of mineralocorticoid insufficiency, those with the most severe loss of function manifesting hyponatremia on presentation.

Primary adrenal failure may be caused by congenital adrenal hypoplasia (or adrenal hypoplasia congenita [AHC]).⁹² This results in severe salt-losing primary adrenal failure in early infancy or childhood, although milder, delayed onset forms of the condition exist. The most common form of the condition is X-linked. Patients have mutations in the nuclear receptor *DAX1* (*NROB1*), and, in

addition to adrenal failure, the males also suffer from hypogonadotropic hypogonadism. Rarely, patients present with isolated mineralocorticoid deficiency with normal cortisol levels; however, glucocorticoid deficiency usually develops later. The exact role of *DAX1* in adrenal development remains unknown, although data suggest that it probably acts as a repressor of *SF1* transcription. It may also act to regulate adrenal progenitor cell development and maturation, because loss of function is associated with aberrant cellular differentiation.⁹³

Heterozygous and homozygous mutations in *SF1* have been associated with adrenal failure in 46XY phenotypic females, as well as in at least one 46XX girl, although the latter phenotype is rare.⁹² Recently, mutations in *SF1* have been associated with gonadal dysgenesis in 46XY individuals, in the absence of adrenal involvement.⁹⁴ Additionally, *SF1* mutations have recently also been associated with primary ovarian failure.⁹⁵

Various forms of congenital adrenal hyperplasia may be associated with variable adrenal failure (e.g., mutations in *CYP11A1*, *StAR*, *HSD3B2L*, *CYP17*, *CYP21*, *CYP11B1*) with varying degrees of genital ambiguity. The enzyme *P450c11* (aldosterone synthase), which is found in the zona glomerulosa, has 11 β -hydroxylase, 18-hydroxylase, and 18-methyl-oxidase activities and catalyses all the reactions needed to convert 11-deoxycorticosterone (DOC) to aldosterone. Mutations in the gene encoding the enzyme are associated with isolated mineralocorticoid deficiency. Functional mineralocorticoid deficiency with severe salt loss resulting in hyponatremia and hyperkalemia may also arise as a result of mutations in the mineralocorticoid receptor or in the gene encoding the epithelial sodium channel, *ENaC*.

Thyroid System

Embryology

The thyroid gland is a derivative of the primitive buccopharyngeal cavity and develops from contributions of two anlagen: a midline thickening of the pharyngeal floor (median anlage) that acts as the precursor of the *T₄*-producing follicular cells and paired caudal extensions of the fourth pharyngobranchial pouches (lateral anlagen) that give rise to the parafollicular calcitonin-secreting cells (C cells).^{96,97} These structures are discernible by 16 to 17 days of gestation, and by 24 days the median anlage develops a thin, flask-like diverticulum extending from the floor of the buccal cavity, at a point that is later known as the foramen cecum on the developing tongue, to the fourth branchial arch. At 24 to 32 days, this median anlage has already become a bilobed structure, and by 50 days of gestation, the median and lateral anlagen have fused and the buccal stalk has ruptured.

During this period, the thyroid gland, which initially consists of a round cluster of cells, migrates caudally from the pharyngeal floor, through the anterior midline of the neck, to its definitive location in the anterior neck; during this time, the cells multiply. Data suggest that localization of growing thyroid tissue along the anteroposterior axis is linked to the development of the ventral aorta in the zebrafish; in other words, vessels provide guidance cues in zebrafish thyroid morphogenesis.⁹⁸ In mouse thyroid development, the midline primordium bifurcates and two lobes relocate cranially along the bilateral pair of carotid arteries. In sonic hedgehog-deficient mice, thyroid tissue always develops along the ectopically and asymmetrically positioned carotid arteries, suggesting that in mice, as in

zebrafish, codeveloping arteries define the presence of the thyroid.⁹⁸

Additionally, Fagman and colleagues⁹⁹ implicated *Tbx1* in the development of the thyroid gland, although it cannot be detected in the thyroid primordium at any embryonic stage. In *Tbx1*^{-/-} mice, the downward translocation of *Titf1/Nkx2.1*-expressing thyroid progenitor cells is much delayed. In late mutant embryos, the thyroid fails to form symmetric lobes but persists as a single mass that is approximately one quarter of the normal size. The hypoplastic gland mostly attains a unilateral position resembling thyroid hemiagenesis. The data suggest that failure of the thyroid primordium to reestablish contact with the aortic sac is a major factor in the prevention of normal growth of the midline anlage along the third pharyngeal arch arteries. This interaction may be facilitated by *Tbx1*-expressing mesenchyme filling the gap between the pharyngeal endoderm and the detached thyroid primordium.⁹⁹ Conditional ablation of *Fgf8* in *Tbx1*-expressing cells caused an early thyroid phenotype similar to that of *Tbx1* mutant mice. In addition, expression of an *Fgf8* complementary DNA in the *Tbx1* domain rescued the early size defect of the thyroid primordium in *Tbx1* mutants. These data suggest that a *Tbx1*-*Fgf8* pathway in the pharyngeal mesoderm is a key regulator of mammalian thyroid development.⁹⁹

At 51 days, the gland exhibits its definitive external form, with an isthmus connecting the two lateral lobes, and it reaches its final position below the thyroid cartilage by the 7th week of embryonic life. At the same time, connection of the median anlage with the ultimobranchial body, developed from the endoderm of the fourth pharyngeal pouch, occurs, resulting in incorporation of the C cells into the thyroid. During its descent, the developing thyroid gland retains an attachment to the pharynx by a narrow epithelial stalk known as the thyroglossal duct.¹⁰⁰ By 37 days, this structure that connects the median thyroid anlage with the point of origin of its migration on the floor of the pharynx has usually disappeared,¹⁰¹ and normally the only remnant of the thyroglossal duct is the foramen cecum itself. An ectopic thyroid and persistent thyroglossal duct or cyst may occur as a consequence of abnormalities of thyroid descent.

Usually, the terminal differentiation of thyroid follicular cells—as evidenced by expression of the genes encoding the TSH receptor (*TSHR*), the sodium-iodide symporter (*NIS*), thyroglobulin (*Tg*), and thyroperoxidase (*TPO*) and the formation of follicles—occurs in the normal embryo only after migration is complete.¹⁰² Gene expression studies performed on thyroid tissues derived from human embryos and fetuses showed that *TTF1*, *FOXE1*, *PAX8*, *TSHR*, and *DUOX2* were stably expressed from the 7th to the 33rd gestational weeks.^{103–106} Genes encoding *Tg*, *TPO*, and *pendrin* were expressed as early as 7 weeks' gestational age. *NIS* expression appeared last and showed the highest fit by the broken line regression model of all genes. Immunohistochemical studies detected *TTF1*, *TSHR*, and *Tg* in unpolarized thyrocytes before follicle formation. *T₄* and *NIS* labeling were found in developing follicles from the 11th gestational week onward. These studies suggest a key role for *NIS* in the onset of human thyroid function.¹⁰³

By 70 days of gestation, colloid is visible histologically and thyroglobulin synthesis and iodide accumulation can be demonstrated within the gland. During the final follicular phase of development, colloid spaces increase in size, and there is progressive cell growth and accumulation of thyroid hormones. Terminal differentiation of the human thyroid is characterized by the onset of follicle formation and thyroid hormone synthesis at 11 weeks' gestation. At

Figure 22-7 Illustration of the homeobox genes that program development of the thyroid and parathyroid glands. *HEX* is involved early in the integrated cascade that programs thyroid gland embryogenesis. *HOXB3* and *HOXA3* may be responsible for activation of thyroid transcription factors *TTF1* and *TTF2*, respectively, during early embryogenesis. *PAX8* is essential in the cascade. These factors are also involved in thyroid follicular cell function, promoting thyroglobulin (*TG*), thyroid peroxidase (*TPO*), and thyroid-stimulating hormone receptor (*TSHR*) gene transcription. *HOX15* gene knockout in mice causes parathyroid gland aplasia. See text for details.

12 weeks of gestation, the fetal thyroid gland weighs about 80 mg, and at term it weighs 1 to 1.5 g. The parathyroid glands develop between 5 and 12 weeks of gestation from the third and fourth pharyngeal pouches.

At least five developmental genes are involved in thyroid and parathyroid gland embryogenesis. These include the genes for thyroid transcription factors *HEX* (*Hex* in the mouse), *TTF1* (*Titf1/Nkx2.1*), *FOXE1* (*Titf2/Foxe1*), *NKX2-5*, and *PAX8* (Fig. 22-7).^{97,104–107} *Hex* gene knockout in mice is associated with thyroid agenesis or severe hypoplasia. *Ttf2* knockout results in thyroid dysgenesis and cleft palate. *Ttf1* knockout leads to pulmonary hypoplasia and thyroid agenesis. Inactivating *Pax8* mutations lead to thyroid hypoplasia and renal anomalies. *Ttf1* knockout is also associated with parafollicular C-cell aplasia. The *HOX* genes appear to be important in the expression of *Ttf1* and *Pax8*. *HOX15* gene disruption in mice results in parathyroid gland aplasia.¹⁰⁸ *TTF1/NKX2.1* and *PAX8* also play a role in the survival of thyroid cell precursors and regulation of thyroid-specific gene expression, whereas *FOXE1/TTF2* is critical for cellular migration.

TTF1, *TTF2*, *PAX8*, *NKX2-5*, and *TSHR* gene mutations account for fewer than 10% of patients with familial thyroid dysgenesis and congenital hypothyroidism; no mutations have been identified in *HEX* as yet.¹⁰⁶ Most cases of congenital hypothyroidism occur sporadically, and the pathogenesis in these cases remains unclear. It is known that signaling molecules such as those in the FGF pathway and the SHH pathway are also implicated in murine thyroid development.¹⁰⁸ In late organogenesis, the *SHH* gene appears to have an important role in the symmetric bilobation of the thyroid; it also suppresses the ectopic expression of thyroid follicular cells. It is not inconceivable that mutations in these genes may be identified in patients with congenital hypothyroidism.⁹⁸

In the rat, at fetal day 15, despite early evidence of *Tg*, *TPO*, and *TSHR* gene expression, the thyroid gland is difficult to distinguish from the surrounding structures, and

iodine organification, thyroid hormoneogenesis, and evidence of a follicular structure are absent. These data suggest that TTF1/NKX2-1 and PAX8 are necessary but not sufficient for the expression of the fully differentiated thyroid phenotype. Expression of the *TSHR* gene is significantly upregulated on fetal day 17, and this is accompanied by significant growth and rapid development in terms of structure and function. The expression of *Tg* and *TPO* is increased and thyroid follicles are seen with thyroid hormoneogenesis, suggesting that the *TSHR* has an important role to play in these events. Murine mutation of the *TSHR* gene is associated with the *hyt/hyt* phenotype in mice, which exhibits severe hypothyroidism and a hypoplastic but normally located thyroid gland with a poorly developed follicular structure. In humans, a similar phenotype is observed in babies of mothers with potent *TSHR*-blocking antibodies and in babies with severe loss-of-function mutations in *TSHR*.

Embryogenesis is largely complete by 10 to 12 weeks' gestation, equivalent to fetal day 15 to 17 in the rat, and thyroid follicle precursors are first seen at this stage. *Tg* is also detected in follicular spaces, and evidence of iodine uptake and organification is obtained at this stage. Pituitary and plasma thyrotropin (TSH) concentrations begin to increase during the second trimester in the human fetus, at about the time that pituitary portal vascular continuity develops (Fig. 22-8).^{103,109} Plasma thyrotropin levels increase progressively during the last half of gestation. Plasma concentrations of T_4 -binding globulin and total T_4 increase progressively, from low levels at 16 to 18 weeks of gestation to maximal levels at 35 to 40 weeks. Free T_4 levels also increase as a consequence of the increase in T_4 production. The increases in plasma TSH and T_4 levels during the third trimester reflect a progressive maturation of hypothalamic pituitary control and of thyroid gland responsiveness to TSH. Pituitary TSH secretion is responsive to

hypothyroxinemia and to TRH early in the third trimester.¹⁰⁶ Hypothyroxinemia results in an elevated fetal serum TSH concentration, whereas hyperthyroidism due to maternal Graves' disease is associated with a suppressed fetal TSH concentration. Premature infants born at 26 to 28 weeks of gestation respond to exogenous TRH with an increase in plasma TSH concentration comparable to that in adults.¹¹⁰ However, their TSH response to extraterine exposure is reduced, indicating hypothalamic immaturity.

Thyroid Hormonogenesis

Hypothalamic-pituitary-thyroid control matures during an interval corresponding to the late third trimester and early neonatal period of human development.^{109,111} The period of parallel increases in fetal TSH and free T_4 levels during the latter half of gestation is followed by the sequential TSH and free T_4 surges in the early neonatal period and a final slow equilibration of the TSH/free T_4 ratio to adult values during infancy and childhood.¹¹¹⁻¹¹³ This maturation includes coordinated maturation of hypothalamic TRH secretion, pituitary TRH sensitivity, thyrotropin negative-feedback control, and thyroid follicular cell responsiveness to TSH. Fetal serum TRH levels are higher than in maternal blood, and this is the consequence of extrahypothalamic (placenta and pancreas) TRH production and decreased TRH degradation in fetal serum. Functionally, the fetus progresses from a state of both primary (thyroidal) and tertiary (hypothalamic) hypothyroidism at midgestation, through a state of mild tertiary hypothyroidism during the final weeks in utero, to a fully mature hypothalamic-pituitary-thyroid axis by 2 months after birth. The neonatal free T_4 increments also are reduced (compared with term infants) in premature infants born at 31 to 34 weeks, attenuated at 28 to 30 weeks, and absent in 23- to 27-week infants.¹¹³

The adult thyroid follicular cell can modify iodine transport or uptake with changes in dietary iodine intake, independent of variations in serum thyrotropin levels.^{114,115} Before 36 to 40 weeks of gestation, the thyroid gland lacks this autoregulatory mechanism and is susceptible to iodine-induced inhibition of thyroid hormone synthesis.^{110,115} The fetal thyroid follicular cell, when exposed to high circulating levels of iodide, is unable to reduce iodide trapping and prevent the high intracellular iodide concentrations that produce the blockade of hormone synthesis referred to as the *Wolff-Chaikoff effect*. Failure of the immature thyroid to exhibit autoregulation is probably due to failure of downregulation of thyroid cell membrane NIS units, which may be related to the absence or reduced iodination of an 8- to 10-kD protein in the thyroid follicular cell.^{114,115} In addition to maturation of autoregulation, thyroidal responsiveness to thyrotropin increases during the last trimester.⁹⁷

The metabolism of thyroid hormones occurs through a progressive series of monodeiodinations.^{109,116} Three deiodinase enzymes act to remove an iodine atom from the outer (phenolic) ring or the inner (tyrosyl) ring of the tetraiodothyronine (T_4) molecule, thus, respectively, activating or inactivating the hormone. The deiodinases are encoded by separate genes and share sequence homology. Most of the circulating, biologically active T_3 in adults is derived by outer-ring monodeiodination of T_4 in liver and other nonthyroidal tissues; biologically inactive rT_3 derives from inner-ring deiodination of T_4 in peripheral tissues. The type I enzyme (D1), an outer-ring monodeiodinase, is a high-Michaelis-constant (K_m) enzyme inhibited by propylthiouracil and stimulated by thyroid hormone. It

Figure 22-8 Patterns of change of fetal plasma thyroid-stimulating hormone (TSH), thyroxine (T_4), triiodothyronine (T_3), reverse T_3 (rT_3), and iodothyronine sulfates (T_4S , rT_3S , and T_3S) during gestation and in the neonatal period. The patterns for T_4S and rT_3S are based on limited 30-week data. (Data from references 109, 329, 330.)

Modified from St. Germain DL, Hernandez A, Schneider MJ, et al. Insights into the role of deiodinases from studies of genetically modified animals. *Thyroid*. 2005;15:905-916.

deiodinates T_4 to T_3 and rT_3 to T_2 . D1 also has inner-ring deiodinase activity, converting T_3 to T_2 . Activity of D1 is low throughout gestation. The type 2 outer-ring monodeiodinase (D2) is a low- K_m enzyme that is insensitive to propylthiouracil and inhibited by thyroid hormone. It deiodinates T_4 to T_3 and rT_3 to T_2 , and it is highly expressed in brain and pituitary. Type 3 monodeiodinase (D3) inactivates T_4 and T_3 via inner-ring deiodination of T_4 to rT_3 and of T_3 to T_2 ; it is highly expressed in fetal tissues and placenta. D1 is largely responsible for production of T_3 that escapes from the cells, especially liver and kidney, into the circulation, whereas D2 is responsible for production of local tissue T_3 . Inactive rT_3 also diffuses out of most tissues to appear in plasma.

The distribution of the deiodinases has been characterized in rodent and human tissues (Table 22-3).¹¹⁶ D2 is detectable by midgestation and plays an important role in supplying T_3 to developing brain tissue, regulating thermogenesis in brown adipose tissue in the neonatal period, and regulating pituitary TSH secretion. D3 activity is present in placenta, liver, and perhaps fetal skin, accounting for the higher levels of rT_3 in the fetus and limiting the metabolic effects of thyroid hormones during much of fetal life. There is little conversion of T_4 to circulating T_3 via D1 deiodination until midgestation in the human fetus; plasma T_3 levels are low (<0.2 nmol/L or <15 ng/dL) until 30 weeks of gestation, after which the mean value increases to 0.7 nmol/L (50 ng/dL) at term (Fig. 22-7).¹¹⁷ On the other hand, fetal brain T_3 concentrations are 60% to 80% of those in the adult by fetal age 20 to 26 weeks due to D2 activity. In the presence of fetal hypothyroidism, D2 increases while D3 decreases in an effort to maintain near-normal brain T_3 concentrations. Sulfation is active in fetal tissues, and the predominant thyroid hormone metabolites in the fetus are iodothyronine sulfates.^{109,118,119}

High levels of phenolsulfotransferases (SULT) have been characterized in fetal liver, lung, and brain by midgestation. SULT activities decrease rapidly in the neonatal period.¹¹⁹ In the last third of gestation in fetal sheep, the mean plasma production rates for T_4 and metabolites (in micrograms per kilogram of body weight per day) are as follows: T_4 , 40; T_4 sulfate (T_4S), 10; rT_3 , 5; rT_3S , 12; T_3 , 2;

and T_3S , 2. All metabolites are biologically inactive except T_3 and perhaps T_3S , so that 90% of the T_4 metabolites in the fetus are biologically inactive.¹¹⁸ The sulfated metabolites accumulate in fetal serum as a result of the low D1 activity in fetal tissues and because the sulfated iodothyronines are not substrates for D3.^{114,118} The production rate of T_3 increases progressively between 30 weeks of gestation and term because of maturation of D1 activity in the liver and other tissues and because of decreasing D3 activity in placenta.^{97,120} In the fetal sheep, hepatic D1 activity increases progressively during the last trimester.¹²¹

It has long been assumed that thyroid hormones passively diffuse into cells. However, several classes of cell membrane iodothyronine transporters have been described, questioning this hypothesis.¹²²⁻¹²⁴ These transporters belong to different families of organic anion, amino acid, and monocarboxylate solute carriers, including the organic anion transporting polypeptide (OATP) family and the solute carrier family 21 (SLC21).¹²²⁻¹²⁴ The significance of these transporters is not yet clear, but mutation of the human monocarboxylate transporter 8 (MCT8), a member of the SLC21 family shown to be a specific thyroid hormone transporter present in developing brain, leads to a syndrome of combined thyroid dysfunction and psychomotor retardation.^{123,124} *Mct8* expression in neonatal mice has been localized to neurons in the olfactory bulb, cerebral cortex, hippocampus, and amygdala. Presumably, all thyroid hormone-sensitive cell populations express iodothyronine membrane transporters. A cell surface T_4 receptor has been characterized as an $\alpha_v\beta_3$ integrin that serves as the initiation site for T_4 -induced activation of the mitogen-activated protein kinase (MAPK) pathway for angiogenesis and perhaps actin polymerization and neuronal migration.¹²⁵ The ontogenesis and significance of these cell surface receptors and membrane transporters in fetal development remain to be further defined.

Thyroid Hormone Action

Classic thyroid hormone actions are mediated via functional thyroid hormone nuclear receptors, members of the steroid/retinoid/vitamin D family of nuclear transcription factors. Two genes code for the receptors: *THRA* on chromosome 17 encodes $TR\alpha$, and *THRB* on chromosome 3 encodes $TR\beta$.¹²⁶ These genes code for four classic receptor isoforms ($TR\alpha 1$, $TR\alpha 2$, $TR\beta 1$, and $TR\beta 2$), three of which bind thyroid hormones (T_3/T_4 affinity, 10:1) and bind to DNA to effect gene transcription. The $TR\alpha 2$ isoform does not bind thyroid hormone but binds to DNA and can inhibit binding of other TRs. The TRs exist as monomers, homodimers, and heterodimers with other nuclear receptor family members such as retinoid X (RXR). Other TR transcripts, including $TR\Delta\alpha 1$ and $TR\Delta\alpha 2$, have been characterized. These do not bind DNA or T_3 but can inhibit TR and retinoid receptor activities.¹²⁷

The TRs are expressed developmentally and differentially in various fetal and adult tissues. $TR\alpha$ proteins are present in most tissues. $TR\beta 1$ is expressed in liver, kidney, and lung and in developing brain, cochlea, and pituitary. $TR\beta 2$ expression is restricted largely to the pituitary gland, retina, and cochlea.^{97,126} The receptors function redundantly, as indicated by knockout studies in mice, but predominant effects of one or another TR have been characterized (Table 22-4). Knockout of both the $TR\alpha$ and $TR\beta$ genes in mice is not lethal but results in elevated TSH levels, deafness, bradycardia, and decreased postnatal growth with delayed bone maturation.^{97,126,127} Lethality occurs because of improper intestinal development associated with persistent $TR\Delta\alpha$ isoforms in $TR\alpha$ or combined

TABLE 22-4

Predominant Thyroid Hormone Receptor Subtype Functions in Developing Mice

Brain	Thermogenesis
TR α 1, TR β 1	TR α 1, TR β 1, TR β 2
Pituitary TSH secretion	Inner ear
	TR α 1, TR β 2
	TR β 2, TR α 1
Pituitary GH secretion	Retina
	TR β 2
	TR α 1
Bone maturation	Intestine
TR α 1	TR α 1
Liver	Heart
TR β 1	TR α 1

Philadelphia, PA: Lippincott Williams and Wilkins, 2005:135-150; and Flamant F, Samarut J. Thyroid hormone receptors: lessons from knockout and knockin mutant mice. *Trends Endocrinol Metab*. 2005;14:85-90.

TR α and TR β knockout mice.¹²⁷ In the fetal rat brain, TR α 1 mRNA and receptor binding are detectable by 12 to 14 days of gestation (term is 21 days), increasing to maximal levels at birth. The TR β 1 isoform is detected at birth and increases approximately 40-fold in the early postnatal period.^{97,128} In human fetal brain, TR α 1 and TR β 1 isoforms and receptor binding are present by 8 to 10 weeks of gestation; TR α 1 transcripts and receptor occupancy increase 8- to 10-fold by 16 to 18 weeks.^{97,129,130} Liver, heart, and lung receptor binding can be identified by 13 to 18 weeks.^{97,130,131}

Ontogeny of Thyroid Hormone Secretion

The role of maternal thyroid hormone during fetal development remains controversial. The high placental concentration of D3 inactivates most of the thyroid hormone presented from the maternal circulation. The iodide released in this manner is used for fetal thyroid hormone synthesis. Despite the limited maternal-fetal placental transfer of T₄ and the predominant production of inactive thyroid hormone metabolites in the human fetus, significant levels of free T₄ are present in fetal fluids, from placental transfer early in gestation and from fetal thyroid production during later gestation.^{97,128} Early in gestation, placental transfer is the only source of T₄ in fetal fluids and is essential for normal fetal neurodevelopment. T₄ is detectable in human celomic fluid at levels of 0.5 to 2 nmol/L between 6 and 11 weeks of gestation, before the onset of fetal thyroid function.¹³² Low concentrations of T₄ are detectable in the fetal brain at about 10 weeks of gestation. Significant placental transfer continues to term, when serum T₄ levels in the athyroid fetus range from 30 to 70 nmol/L (2.3 to 5.4 μ g/dL).¹³³ Isotopic equilibrium studies with pregnant rats at term suggest that 15% to 20% of the T₄ in fetal tissues is of maternal origin.¹³⁴ As indicated, thyroid hormones cross the placenta early in gestation, supplying the low levels of free T₄ that are essential for brain development between 12 and 20 weeks, before the onset of fetal thyroid hormone production.¹²⁸ Most thyroid hormone in the fetal compartment is inactivated to sulfated and deiodinated analogues until the perinatal period.^{109,118,119} This neutralization of active circulating thyroid hormone maintains the low T₃ metabolic state, facilitating fetal growth and programmed tissue maturation.

Thyroid hormone-programmed development of selective fetal tissues requires the interaction of local tissue D1,

D2, thyroid receptors, receptor coactivators, and thyroid-responsive genes. In most responsive tissues, the timing of maturation events is controlled by the state of the thyroid receptors acting as a molecular switch.^{127,135} In the absence of T₃, the unliganded receptor (aporeceptor) recruits corepressors, repressing gene transcription. Non-T₃-binding receptors also can repress transcription by inhibiting receptor DNA binding. Local tissue maturation events are initiated by the coincident availability of T₃, liganded T₃ receptor, T₃-mediated receptor exchange of co-repressor with coactivators for creation of an active holoreceptor, and activation of responsive gene transcription.

These programming events have been investigated in studies of transgenic mice, including brain, liver, heart, intestine, and bone tissues, thermogenesis, and spleen erythropoiesis.¹³⁵⁻¹⁴¹ The timing of these events in the mouse range from early midbrain neuronal development at gestational day 15; through perinatal activation of hepatic enzymes, cardiac ion channels, and spleen erythropoiesis; to postnatal brain, intestinal, and bone maturation and thermogenesis. Parturition occurs at a gestational age equivalent to human midgestation. In hypothyroid mice, repressive effects of aporeceptors have been shown to delay tissue maturation in brain, bone, intestine, spleen, and heart.¹³⁸ The increase in circulating T₃ levels associated with parturition in mice and humans normally triggers development of tissue functions essential to postnatal metabolism and homeostasis (e.g., hepatic, intestinal, and cardiac functions and brown fat thermogenesis). Thyroid hormone-stimulated maturation of vision and hearing appear to be triggered by the local expression of D2, mediating local T₃ production, postnatally in the mouse and probably toward the end of the second midtrimester in the human fetus.¹¹⁶

In humans, T₃-mediated maturation of fetal tissues, including liver, heart, brown adipose tissue, and bone, allows them to become thyroid hormone-responsive during late gestation and in the perinatal period. Paracrine actions of thyroid hormone are critical for normal fetal development—for example, in the cochlea, where D2 is expressed in connective tissue immediately adjacent to the sensory epithelium and spiral ganglion, where thyroid hormone receptors are located. This implies that D2-containing cells in the connective tissue take up T₄ from the circulation, convert it to T₃, and then release D3 to adjacent responsive cells. Similarly, in the brain, D2 is expressed predominantly in glial cells, whereas TRs are expressed in adjacent neurons and oligodendrocytes. In other areas of the brain, such as the pituitary gland, hippocampus, and caudate nucleus, there is coexpression of D2 and TRs. On the other hand, D3 is coexpressed with TRs in neurons, thereby protecting sensitive tissues from the effects of excess thyroid hormone.

The actions of thyroid hormones and their developmental regulation in the brain are complex. Functionally, thyroid hormones are critical for the establishment of neural circuits during a critical window of brain development. They provide inductive cues for the differentiation and maturation of a number of processes such as neurogenesis and neural cell migration (occurring between 5 and 24 weeks of gestation), neuronal differentiation, dendritic and axonal growth, synaptogenesis, gliogenesis (late fetal period to 6 months postpartum), myelination (second trimester to 24 months postpartum), and neurotransmitter enzyme synthesis. TRs are found in highest concentration in developing neurons and in multiple areas of the fetal brain, including the cerebrum, the cerebellum, and the auditory and visual cortex. The hormones bind to receptors and stimulate a number of genes such as myelin,

neurotrophins and their receptors, cytoskeletal components, transcription factors, extracellular matrix proteins and adhesion molecules, intracellular signaling molecules, and mitochondrial and cerebellar genes.

Thyroid hormone is also important for normal bone growth. T_3 regulates endochondral ossification and controls chondrocyte differentiation in the growth plate both in vivo and in vitro. TRs are expressed on osteoblasts and growth plate chondrocytes, and T_3 target genes have been identified in bone. T_3 stimulates skull suture closure in vivo.

In the perinatal period, thyroid hormone stimulates the transcription of thermogenin (also known as uncoupling protein 1 [UCP1]), a protein that uncouples nucleotide phosphorylation and the storage of energy as adenosine triphosphate ATP, actions that are important for nonshivering thermogenesis by brown adipose tissue.

Congenital Hypothyroidism

Classic signs of congenital hypothyroidism (jaundice, lethargy, feeding difficulties, macroglossia, myxedema, hypothermia, growth retardation, and progressive developmental delay and IQ deterioration) accrue during the early weeks and months of extrauterine life as maternal T_4 becomes unavailable and the non-CNS tissues become responsive to thyroid hormone.^{97,109} Rarely, hypothyroidism is associated with respiratory distress in the neonatal period. Maternal hypothyroxinemia has been associated with attention deficit-hyperactivity disorder and with 5 to 10 points of IQ deficit in the offspring of such pregnancies.^{14,97,128} The period of brain dependency for thyroid hormone extends postnatally to 2 to 3 years of age, but the early weeks and months of life are most critical. Untreated thyroid agenesis is associated with a loss of 5 to 7 IQ points monthly during the first months of postnatal life, and over 6 to 8 months this can amount to a 30- to 40-point IQ deficit.¹²⁸ Most countries, therefore, have a rigorous screening program to ensure early diagnosis and treatment.

In congenital hypothyroidism, there is an increased net flux of maternal thyroid hormone to the fetus, resulting in cord T_4 concentrations that are 25% to 50% of normal. There is increasing evidence of maternal-fetal T_4 transfer in the first half of pregnancy, when fetal thyroid hormone levels are low.¹⁴² The transplacental passage of thyroid hormone, in conjunction with adjustments in brain deiodinase activity, has a critical role in minimizing the adverse effects of fetal hypothyroidism and helps explain the normal or near-normal outcome of hypothyroid fetuses (provided that prompt and adequate treatment of hypothyroidism ensues postnatally) as well as the relatively normal clinical appearance of the majority of babies with congenital hypothyroidism at birth. On the other hand, in the presence of both maternal and fetal hypothyroidism—such as that observed in the presence of potent TSH receptor-blocking antibodies, maternal and fetal POU1F1 deficiency, and severe iodine deficiency—there is severe neurocognitive impairment despite early and adequate commencement of thyroid replacement. Importantly, the presence of maternal hypothyroxinemia or inadequately controlled hypothyroidism is also associated with significant neurocognitive deficit in the offspring that is not reversible by early postnatal therapy.^{13,14}

Pituitary-Gonadal Axis

The mammalian gonad originates from the intermediate mesoderm from which the bipotential genital ridge differentiates. The gonad is derived from two tissue anlagen:

the primordial germ cells of the yolk sac wall and the somatic, stromal cells that migrate from the primitive mesonephros.^{143,144} By 4 to 5 weeks of gestation, the germ cells have begun their migration from the yolk sac, and the gonadal ridge has appeared as a derivative of the mesonephros. The germ cells are incorporated into the developing gonadal ridge during the 6th week, when the primitive gonad is composed of a surface epithelium, primitive gonadal cords continuous with the epithelium, and a dense cellular mass referred to as the *gonadal blastema*, which includes the steroidogenic cell precursors.¹⁴³

Until the appearance of testicular cords made up of Sertoli cells at 6 weeks, the fetal testis and ovary are indistinguishable. Embryogenesis of the gonads is programmed by genes encoding the male sexual determinant SRY as well as SF1, SOX9, and DAX1.^{145,146} SRY is a critical regulator of male gonadal differentiation. Three other genes—WT1, SOX9, and SF1—are expressed in the bipotential gonadal ridge during its differentiation from the intermediate mesoderm and are critical for normal male sexual differentiation. WT1, the Wilms' tumor suppressor gene located at 11p13, is expressed in both the primitive kidney and the genital ridge. Its expression is related to the transition from mesenchyme to epithelium. WT1 is a transcription factor that contains four zinc fingers and binds to an ERG1 consensus binding sequence. SRY is activated by certain WT1 isoforms in vitro.

SF1 is required for testicular and ovarian development and mediates müllerian-inhibiting hormone (AMH) gene expression and gonadotropin production. SF1 and DAX1 are orphan receptors of the steroid/thyroid hormone family of nuclear receptors and appear to interact as heterodimers coordinately involved in the regulation of target genes in the adrenal glands and in hypothalamic gonadotrope cells and the ventromedial hypothalamic nucleus.^{145,146} SF1 also regulates the expression of the cytochrome P450 enzymes. Recent data suggest that SRY binds to multiple elements within a SOX9 gonad-specific enhancer in mice and that it does so along with SF1. SF1 and SRY cooperatively upregulate SOX9; then, together with SF1, SOX9 also binds to the enhancer to help maintain its own expression after that of SRY has declined.¹⁴⁷

A current view of the pathways for genes programming gonadal differentiation is shown in Figure 22-9. The full menu of downstream gene targets remains to be defined, but the net result is the highly organized pattern of gonadal development and phenotypic sexual differentiation. Fetal pituitary gonadotropins are not required for gonadal development or sexual differentiation; LH or FSH receptor knockout mice are born phenotypically normal.¹⁴⁸

Human mutations in several of the genes programming gonadal differentiation have been described.¹⁴⁴ Loss-of-function mutations of SRY or SOX9 produce XY sex reversal, whereas gain-of-function mutations or duplications produce XX sex reversal. Mutations in SOX9 are associated with campomelic dysplasia and 46XY sex reversal. SF1 mutations have been associated with 46XY sex reversal with gonadal dysgenesis, with or without adrenal failure. More recently, the phenotypic spectrum of SF1 mutations has widened to encompass gonadal dysgenesis, premature ovarian failure, and the vanishing testis syndrome.^{94,95,149} Mutations may be heterozygous or recessive, the latter likely to be associated with a more severe loss of function. WT1 mutations produce several syndromes associated with abnormal testicular embryogenesis (WAGR syndrome [Wilms' tumor, aniridia, genitourinary anomalies, and mental retardation], Denys-Drash syndrome, and Frasier syndrome) and renal abnormalities such as Wilms' tumor or glomerulosclerosis. WNT4 gain-of-function mutations

Figure 22-9 Summary of the molecular and cellular events of gonadal differentiation. AMH, antimüllerian hormone or müllerian inhibiting substance; DHH, desert hedgehog. See text for details. (Molecular cascades developed from Harley VR, Clarkson MJ, Argentaro A. The molecular action and regulation of the testis-determining factors, SRY (sex determining region of the Y chromosome) and SOX9 (SRY-related high-mobility group [HMG] Box 9). *Endocr Rev.* 2003;24:466-487; and Park SY, Jameson JL. Minireview: transcriptional regulation of gonadal development and differentiation. *Endocrinology.* 2005;146:1035-1042.)

result in XX sex reversal, whereas *Dax1* duplication is associated with XY sex reversal.¹⁴⁴

In the presence of SRY, male gonadal differentiation begins at 7 weeks of gestation with organization of the gonadal blastema into interstitium and germ cell-containing testicular cords. The primitive cords lose their connections with the epithelium, primitive Sertoli cells and spermatogonia become visible within the cords, and the epithelium differentiates to form the tunica albuginea.¹⁵⁰ Leydig cells derived from the undifferentiated interstitium are visible by the end of the 8th week of gestation and are capable of androgen synthesis at that time. By 14 weeks of gestation, these cells make up as much as 50% of the cell mass, but as the tubules develop, they account for a smaller percentage of the tissue. The fetal testes grow from approximately 20 mg at 14 weeks of gestation to 800 mg at birth; at 5 to 6 months they descend into the inguinal canal in association with the epididymis and the ductus deferens.¹⁵⁰ The gonad, adrenal, and kidney all initially develop in close proximity, and as the testes descend, they may carry rests of adrenocortical cells with them. These adrenal rests may become hyperplastic with resulting testicular enlargement if subjected to prolonged ACTH stimulation (e.g., in patients with poorly controlled congenital adrenal hyperplasia). In the mouse, testicular descent is regulated by *Ins13*, which is a member of the

insulin-like family and is secreted by Leydig cells.¹⁵¹ Targeted disruption of the *Ins13* gene is associated with maldevelopment of the gubernaculum and bilateral cryptorchidism.¹⁵¹ *Ins13* is also secreted by theca cells of the postnatal ovary, and females homozygous for *Ins13* mutations are subfertile with deregulation of the estrous cycle.

In human females, differentiation of ovaries begins during the 7th week of gestation, in the absence of SRY. The gonadal blastema differentiates into interstitium and medullary cords containing the primitive germ cells, referred to as oögonia. The cords degenerate, and cortical layers of surface epithelium, containing individual small oögonia, appear. By 11 to 12 weeks of gestation, clusters of dividing oögonia are surrounded by cord cells within the cortex; the medulla at this time consists largely of connective tissue.¹⁵² At 12 weeks of gestation, primitive granulosa cells begin to replicate and many of the large oögonia in the deepest layers of the cortex enter their first meiotic division. Primordial follicles are first observed at about 18 weeks of gestation, and the number increases rapidly thereafter.¹⁵³ However, the number of oocytes progressively declines, from a peak of 3 to 6 million at 5 months' gestation to approximately 2 million at term.^{16,153} Germ cell proliferation and apoptosis are ongoing simultaneously. Proliferating oocytes cluster, but the clusters break down with the development of follicles because only those oocytes enfolded by developing granulosa cells (as primordial follicles) survive.^{16,153} By 5 months of gestation and during the 7th month, stroma-derived thecal cells develop around the primordial follicles as they mature to primary follicles. This process continues after birth, again progressing toward the superficial layers. Each fetal ovary weighs about 15 mg at 14 weeks of gestation and 300 to 350 mg at birth.¹⁵² The number of surviving primary follicles at birth correlates with the duration of subsequent postpubertal ovulation. Interstitial cells with characteristics of steroid-producing cells are present after 12 weeks, and during the third trimester theca cells with steroidogenic capacity surround the developing follicles.¹⁶ Significant aromatase activity also is present, but few if any steroids are produced by the ovary during development.^{16,152}

The specific genetic mechanisms dictating ovarian development are largely unknown, but recently, mutations in *RSPO1* have been reported in association with 46XX sex reversal.^{155,156} *RSPO1* belongs to the R-spondin family of proteins that is implicated in Wnt/ β -catenin signaling, and the gene encoding the protein may be ovary-determining.

In the male, the development of Leydig cells leads to an increase in fetal testosterone production between gestational weeks 10 and 20 (Fig. 22-10).¹⁵⁰ In vitro studies in the rat have shown that hCG binding to fetal testis cells does not downregulate LH receptors. If this is true in vivo in the human, continuous exposure of the Leydig cell to hCG would not desensitize the fetal testis and would allow the maintenance of augmented testosterone production during development. Fetal LH may contribute to fetal Leydig cell function, but quantitatively hCG is the predominant gonadotropin. Testosterone itself, acting through the androgen receptor, stimulates differentiation of the primitive mesonephric ducts into bilateral ductus deferens, epididymides, seminal vesicles, and ejaculatory ducts. Androgen receptors appear in the mesenchyme of urogenital structures at 8 weeks of gestation, followed by appearance of the receptors in the epithelium during development at 9 to 12 weeks.¹⁵⁴ There was no difference in receptor expression in male and female fetuses. Dihydrotestosterone stimulates male differentiation of the urogenital sinus

Figure 22-10 Patterns of change of plasma concentrations of human chorionic gonadotropin (hCG), luteinizing hormone (LH), testosterone (T), and estradiol (E_2) in a male fetus during gestation and in the neonatal period. (Data from references 277, 331–334.)

and external genitalia, including differentiation of the prostate, growth of the genital tubercle to form a phallus, and fusion of the urogenital folds to form the penile urethra. Dihydrotestosterone is formed from testosterone by the 5α -reductase enzyme within the urogenital sinus and urogenital tubercle, and it acts through the same androgen receptor that mediates the action of testosterone in the wolffian ducts. Mutations in the gene encoding the enzyme 5α -reductase are associated with variable disorders of sex development with 46XY phenotypes.

The fetal testis also produces AMH, which causes dedifferentiation of the müllerian duct system in the male fetus.^{157,158} AMH is a glycoprotein with a monomer molecular size of approximately 72 kD and multimer sizes ranging from 145 to 235 kD. It is produced by testicular Sertoli cells and reaches the müllerian ducts largely by diffusion; duct regression *in vitro* requires a 24- to 36-hour exposure to AMH. AMH is synthesized early in gestation, with production peaking at the time of müllerian duct regression; biosynthesis continues throughout gestation and decreases after birth. AMH gene expression is activated by the *SRY* and *SF1* genes.¹⁵⁷ AMH also has autocrine and paracrine effects on testicular steroidogenic function during fetal life.¹⁵⁸ Male phenotypic differentiation is mediated by testicular testosterone and AMH and occurs between 8 and 14 weeks of gestation. In the female fetus, the müllerian duct system differentiates in the absence of AMH, the mesonephric ducts fail to develop in the absence of testosterone, and the undifferentiated urogenital sinus and external genitalia mature into female structures. Mutation of the AMH gene results in a persistent müllerian duct syndrome in the XY fetus.¹⁵⁷

Estrogen effects are mediated by cognate receptors, members of the large family of steroid and thyroid hormone, vitamin D, and retinoid receptors.^{159,160} Two receptors, $ER\alpha$ and $ER\beta$, have been identified, with 96% and 58% homology in the DNA-binding and ligand-binding domains, respectively. $ER\alpha$ is encoded by *ESR1* on chromosome 6 and $ER\beta$ by *ESR2* on chromosome 14. Expression profiles of

mRNAs of both receptors have been characterized in the 16- to 23-week human fetus. One or both receptor mRNAs are present in most tissues. The $ER\beta$ message is predominant, particularly in testis, ovary, spleen, thymus, adrenal, brain, kidney, and skin. The $ER\alpha$ message is prominent in the uterus, with relatively low levels in most other tissues.^{159,160} The significance of ERs in fetal development is unclear. Knockout of the *ER α* gene in mice does not impair fetal development of any tissue, but adult females are infertile, with hypoplastic uteri and polycystic ovaries, and adult males manifest decreased fertility.¹⁶⁰ $ER\beta$ knockout mice develop normally, and female adults are fertile with normal sexual behavior; adult males reproduce normally but have prostate and bladder hyperplasia.¹⁵⁹ It is known that estrogens regulate DHEA production in the baboon and human fetal adrenal.¹⁵⁹ Knockout of both *ER α* and *ER β* genes also has little impact on fetal development, but after birth the uterus, fallopian tubes, vagina, and cervix in females are hypoplastic and unresponsive to estrogen.¹⁶⁰

Both androgens and estrogens are involved in the structural development of the rat brain.¹⁶¹ Gonadal hormones also control gonadotropin production in the brain that results in cyclic ovarian function and normal function of the testes.^{162,163} Testosterone administration to neonatal female rats produces permanent inhibition of cyclic hypothalamic control through local aromatization to estradiol and ER binding. In primates and humans, estrogens seem to be more effective in this regard. However, there is no evidence for permanent programming in the primate, and there appear to be no major tissue biochemical differences between the sexes *in utero* to account for sexual dimorphic behavioral or gonadotropic programming.¹⁶³ Therefore, the mechanisms for these effects are not yet clear in the primate and human fetus.

Intermediate Lobe of the Pituitary

The intermediate lobe of the pituitary gland is prominent in both the human and the sheep fetus. Intermediate lobe cells begin to disappear near term and are virtually absent in the adult human pituitary, although the intermediate lobe in the adult of some lower species is anatomically and functionally distinct.¹⁶⁴ The major secretory products of the intermediate lobe are α -MSH and β -endorphin, both derived from cleavage of the POMC molecule.¹⁶⁵ Cleavage of POMC in the anterior lobe results predominantly in corticotropin and β -lipotropin formation. In rhesus monkeys and humans, the fetal pituitary contains high concentrations of compounds resembling α -MSH and corticotropin-like intermediate lobe peptide (CLIP).¹⁶⁶ In the human fetus, α -MSH levels decrease with increasing fetal age.¹⁶⁷ The circulating levels of β -endorphin and β -lipotropin are high in the fetal lamb, and the ratio of β -endorphin to β -lipotropin increases during hypoxic stimulation of the anterior pituitary.¹⁶⁷ Because hypoxia provokes corticotropin release and β -lipotropin production from the anterior pituitary, these data have been interpreted to suggest that basal β -endorphin levels in the fetus originate in the intermediate lobe. α -MSH and CLIP may play a role in fetal adrenal activation, and α -MSH may play a role in fetal growth.^{168,169} However, these effects are probably minor. The processing of pituitary POMC in the human fetus by the end of the second trimester is similar to that in the adult, but the role of these intermediate lobe peptides in the fetus remains obscure.¹⁷⁰

Posterior Pituitary

The fetal neurohypophysis is well developed by 10 to 12 weeks of gestation and contains both AVP (also called

antidiuretic hormone) and oxytocin (OT).^{171,172} In addition, arginine vasotocin (AVT), the parent neurohypophyseal hormone in submammalian vertebrates, is present in the fetal pituitary and pineal glands and in adult pineal glands from several mammalian species, including humans.¹⁷³ AVT is present in the pituitary during fetal life and disappears in the neonatal period. In adult mammals, instillation of AVT into cerebrospinal fluid inhibits gonadotropin and corticotropin release, stimulates PRL release by the anterior pituitary, and induces sleep; however, the physiologic importance of these effects remains unclear. The role of AVT in the fetal pineal gland is unknown.

In the fetal sheep, the baseline fetal plasma AVP concentrations are similar to maternal levels after midgestation. During the last trimester of gestation, fetal hypothalamic and pituitary responsiveness to both volume and osmolar stimuli for AVP secretion are well developed, and AVP exerts antidiuretic effects on the fetal kidney.^{171,172} Baseline plasma levels of AVT in fetal sheep during the last trimester approximate values for AVP and OT.¹⁷³ Presumably this AVT is derived from the posterior pituitary, but the stimuli for AVT secretion in the fetus are not defined. The neurohypophyseal peptides are synthesized as large precursor molecules (neurophysins) and processed to bioactive amidated peptides.¹⁷⁴ Enzymatic processing involves progressive cleavage of carboxyl terminal-extended peptides, sequentially producing (for OT) OT-glycine-lysine-arginine (OTGKR), OTGK, OTG, and OT. Similar progressive processing yields AVPG and AVP from the AVP neurophysin. Enzymatic processing of neurophysins matures progressively in the fetus so that early in gestation fetal plasma contains relatively large concentrations of the extended peptides. For OT, the ratio of OT-extended peptides to OT in fetal sheep serum is approximately 35:1 early in gestation and 3:1 late in gestation.¹⁷⁴

In the fetus, AVP appears to function as a stress-responsive hormone. Perhaps the major potential stress for the fetus is hypoxia, and the response of AVP to hypoxia is increased compared with the maternal response and with fetal AVP responses to osmolar stimuli.^{172,175-177} Plasma AVP concentrations in human cord blood are elevated in association with intrauterine bradycardia and meconium passage.¹⁷⁶ The vasopressor action of AVP may be important in the maintenance of fetal circulatory homeostasis during hemorrhage and hypoxia; AVP has a limited effect on fetoplacental blood flow.^{171,177} Fetal hypoxia is also a major stimulus for catecholamine release. There is little information on interactions between AVP and catecholamines during fetal hypoxia, but both fetal hypoxia and AVP stimulate anterior pituitary function.¹⁷⁷ A role for AVP as a corticotropin-releasing hormone is established in the adult, and the ovine fetal pituitary responds separately and synergistically to AVP and CRH early in the third trimester.¹⁷⁸ The role of AVP in controlling fetal corticotropin release seems to decrease with gestational age. It is not known whether AVT functions as a corticotropin-releasing hormone in the fetus.

OT receptors have been demonstrated in human fetal membranes at term, and AVP receptors have been found in renal medullary membranes of newborn sheep.¹⁷⁹⁻¹⁸¹ Both AVP and AVT evoke antidiuretic actions in the sheep fetus during the last third of gestation, and both hormones act to conserve water for the fetus by inhibiting fluid loss into amniotic fluid through the lungs and kidneys.^{171,172} Aquaporin-1, -2, and -3 water channel receptors are present in the human fetal and newborn kidney, and the ability of the newborn infant to regulate free water clearance in response to volume and osmolar stimuli has been

demonstrated.^{182,183} Whether AVT exerts its effects through AVP receptors or separate fetal AVT receptors is not clear. Maximal concentrating capacity by the fetal kidney is limited to about 600 mmol/L. This limitation is not related to inadequate AVP stimulation but rather to inherent immaturity of the renal tubules.

Lack of AVP is associated with diabetes insipidus and with a failure to retain water in the body leading to polyuria and polydipsia. Although most cases of diabetes insipidus are from acquired causes such as pituitary germinoma, craniopharyngioma, or Langerhans' cell histiocytosis, the condition may rarely be due to mutations in the AVP-neurophysin gene. Mutations in *WFS1* are associated with autosomal recessive Wolfram syndrome that includes diabetes insipidus, diabetes mellitus, optic atrophy, and sensorineural hearing loss.¹⁸⁴

Fetal Autonomic Nervous System

The primordia of the sympathetic trunk ganglia are visible in the human fetus by 6 to 7 weeks of gestation. The preaortic sympathetic primordia at that time are composed of primitive sympathetic neurons and chromaffin cells, which condense into chains of cell masses along the abdominal aorta. By 10 to 12 weeks of gestation, the paired adrenal masses are well developed. In addition, numerous extramedullary paraganglia (derived from preaortic condensations of sympathetic neurons and chromaffin cells) are scattered throughout the abdominal and pelvic sympathetic plexuses.¹⁸⁵ Each of these extramedullary paraganglia may reach a maximal diameter of 2 to 3 mm by 28 to 30 weeks of gestation. The largest of the paraganglia, the organs of Zuckerkandl near the origin of the inferior mesenteric arteries, enlarge to 10 to 15 mm in length at term. After birth, the paraganglia gradually atrophy and disappear by 2 to 3 years of age. With increasing gestational age, there is progressive growth of the adrenal medullae, increasing catecholamine content of the adrenal medullae, and progressive maturation of medullary functional capacity. Histologically, the adrenal medullae are somewhat immature at birth, but by 1 year they resemble the adult glands.

Both chromaffin and sympathetic nerve cells are derived from common neuroectodermal stem cells. In mice, the sympathoadrenal progenitor cells first aggregate at the dorsal aorta, where they migrate in a dorsolateral direction to form sympathetic ganglia or ventrally to colonize the adrenal glands.¹⁸⁶ In the adrenal glands, they differentiate into neuroendocrine cells, expressing tyrosine hydroxylase and dopamine β -hydroxylase in response to a series of transcription factors including PHOX2B, MASH1, PHOX2A, and dHAND.¹⁸⁶ The *PHOX2B* gene is pivotal in development of most relays of the autonomic nervous system; mutation of this gene has been associated with the congenital hypoventilation syndrome, with Hirschsprung's disease, and with a predisposition to neuroblastoma.¹⁸⁷ Sympathetic nervous system development is nerve growth factor (NGF) dependent, and injections of NGF antiserum into neonatal rats led to degeneration of immature chromaffin cells, sympathetic cells, and pheochromoblasts.¹⁸⁸ Whether NGF and other growth factors are involved in the transient life span and function of the paraganglia in the human fetus and neonate is not clear. The role of placental NGF in maturation of the fetal autonomic nervous system is also unclear.

Catecholamines are present in the para-aortic chromaffin tissue by 10 to 15 weeks of gestation, and concentrations increase until term. The predominant catecholamine is norepinephrine (NE), presumably because of low activity

of phenylethanolamine *N*-methyltransferase (PNMT) in para-aortic chromaffin tissue. This enzyme, which catalyzes the methylation of NE to epinephrine, appears to be activated by the high levels of cortisol that diffuse into the adrenal medulla from the adrenal cortex; in contrast, cortisol levels in extramedullary chromaffin tissue are low.^{185,189,190} In fetal mammals, the chromaffin cells of the adrenal medulla can respond directly to asphyxia, long before splanchnic innervation develops, by secreting NE; the noninnervated para-aortic tissue responds similarly. In the fetal sheep, a similar developmental transition occurs between days 120 and 135 of the 150-day gestation.^{185,189,190} The CNS responds to stimuli that evoke sympathetic nervous system responses before the adrenomedullary splanchnic innervation, but the adrenal medulla is relatively unresponsive to such stimuli. The transition is heralded by an adrenomedullary response to hypoglycemia mediated by the CNS.¹⁸⁹ This response is present in developing sheep, monkeys, and human fetuses during the third trimester of gestation.¹⁹¹⁻¹⁹³ Central and adrenal enkephalins are also involved in fetal autonomic nervous system function, and pretreatment with naloxone potentiates and methadone inhibits the catecholamine response to hypoxia.^{185,190}

Basal plasma epinephrine, NE, and dopamine levels during the last third of gestation in sheep decrease as term approaches.^{193,194} The metabolic clearance rate of epinephrine increases with gestational age, whereas the production rate remains unchanged, indicating that the decrease in basal catecholamine levels that occurs with fetal age is due to maturation of clearance mechanisms.¹⁹⁴ The fetal sheep responds to maternal exercise or hypoxia with increased catecholamine levels.¹⁹⁵ The human neonate responds to parturition with an increase in plasma epinephrine and NE concentrations, and these responses are augmented by hypoxia and acidosis.¹⁹⁵⁻¹⁹⁷ In the newborn infant, catecholamine secretion also increases after cold exposure and hypoglycemia.^{189,192}

Catecholamines are critical for fetal cardiovascular function and fetal survival. Gene knockout studies in mice, targeting either tyrosine hydroxylase or dopamine β -hydroxylase, produced fetal catecholamine deficiency and midgestation fetal death in 90% of the mutant embryos.^{196,197} In addition, fetal catecholamines are the major stress hormones in the fetus.¹⁸⁹⁻¹⁹² The fetal adrenal and the para-aortic chromaffin masses discharge large amounts of catecholamines directly into the circulation in response to fetal hypoxia.¹⁸⁹ Moreover, the defense against fetal hypoxia involves catecholamine actions mediated through cardiac α -receptors that are unique to immature animals. α -Adrenergic receptors predominate in immature cardiac tissue and gradually decline in number as β -adrenergic receptors increase with maturation. Chromaffin tissue in the fetus is also innervated by opiate receptors and contains relatively large amounts of opiate peptides that appear to be cosecreted with the catecholamines.¹⁸⁹ The extent to which these peptides or pituitary endorphins are involved in modulating fetal catecholamine secretion remains unclear.

Parathyroid Hormone/Calcitonin System

Parathyroid gland development from the third and fourth pharyngeal pouches proceeds in synchrony with thyroid embryogenesis.^{96,97} The third pouches encounter the migrating thyroid anlage, and the parathyroid anlagen are carried caudally with the thyroid gland, finally coming to rest at the lower poles of the thyroid lobes as the inferior

parathyroid glands. The fourth pouches encounter the thyroid anlage later and come to rest at the upper poles of the thyroid lobes as the superior parathyroid glands. The individual parathyroid glands increase in diameter from less than 0.1 mm at 14 weeks of gestation to 1 to 2 mm at birth. The fifth pouches contribute paired ultimobranchial bodies that are incorporated into the developing thyroid gland as the parafollicular or C cells that secrete calcitonin. Both endocrine systems are functional during the second and third trimesters (see Fig. 22-8). Disruption of the *HOX15* gene in mice results in parathyroid gland aplasia, indicating that this gene functions as part of the gene cascade programming normal thyroid-parathyroid gland development. Additional genes involved in parathyroid gland embryogenesis include *SOX3*, *GCM2*, *GATA3*, *CRKL*, and *TBX1*.¹⁹⁸⁻²⁰⁰ *CRKL* and *TBX1* mutations have been associated with the DiGeorge syndrome and *GATA3* mutation with a DiGeorge-like syndrome; *GCM2* mutation leads to isolated hypoparathyroidism.¹⁹⁸ *SOX3* mutations are generally associated with variable hypopituitarism, but studies have implicated the gene in parathyroid development.²⁰⁰

Studies in fetal sheep and monkeys and measurements in human preterm and term infants indicate that high concentrations of fetal calcium (averaging 2.75 to 3 mmol/L in the last trimester) are maintained by active placental transport from maternal blood.^{201,202} The transport of calcium occurs across the syncytiotrophoblast, which contains a calcium-binding protein that buffers intracellular calcium ions as they are transported across the syncytial cell to the basement membrane. An ATP-dependent calcium pump transports the calcium across the cell membrane to the fetal circulation.²⁰² The placental calcium pump is stimulated by a midmolecule portion of PTHrP secreted by the fetal parathyroid gland and by the placenta, where it may exert a paracrine effect.²⁰²⁻²⁰⁴ The placenta is impermeable to parathyroid hormone (PTH), PTHrP, and calcitonin, but 25-hydroxyvitamin D and 1,25-dihydroxyvitamin D (calcitriol) are transported across the placenta, and free vitamin D levels in fetal blood are similar to or higher than maternal values.^{201,202}

Thyroparathyroidectomy in the fetal sheep causes a rapid decrease in fetal plasma calcium concentration and a loss of the placental calcium gradient.²⁰¹ In mice, knockout of the gene for PTHrP abolished the maternal-fetal calcium gradient and reduced placental transport of calcium.^{202,205} Placental calcium transport in these models was restored by the midmolecule fragment of PTHrP (amino acids 67 to 86) but not by PTH or the PTHrP(1-34) fragment, both of which activate the PTH/PTHrP receptor.^{204,205} Therefore, a second, as yet unidentified PTHrP receptor recognizing the PTHrP(38-94) ligand appears to be involved in placental calcium pump activation.²⁰²

Other factors are also involved in maintenance of fetal serum calcium levels, because knockout of the mouse gene for PTH-PTHrP also results in hypocalcemia in the presence of normal or increased placental calcium transport.^{201,203} PTH and PTHrP, through the PTH/PTHrP receptor, presumably modulate fetal skeletal calcium flux, calcium excretion through the fetal kidney, and perhaps reabsorption of calcium from amniotic fluid. PTHrP has a major role in fetal bone development and metabolism as well as fetal calcium homeostasis. PTHrP knockout mice display increased ossification of the basal portion of the skull, long bones, vertebral bodies, and pelvic bones and mineralization of the normally cartilaginous portions of the ribs and sternum; as a result of the cartilaginous mineralization, the animals die of asphyxiation in the early neonatal period.^{202,204,205}

Figure 22-11 Proposed actions of parathyroid hormone (PTH), PTH-related protein (PTHrP), and calcitonin (CT) in the fetus. PTHrP and perhaps PTH from the parathyroid glands and PTHrP from the placenta act on the placenta to promote calcium (Ca) and phosphate (PO_4) transport from the maternal to the fetal circulation to maintain the relative fetal hypercalcemia and the high rate of fetal bone formation during the last half of gestation. PTHrP also acts on the kidney to promote 1-hydroxylation of 25-hydroxycholecalciferol to 1,25(OH) $_2$ D (1,25-dihydroxyvitamin D, calcitriol), which augments placental calcium transport and promotes fetal bone growth. High fetal CT levels tend to promote bone accretion. See text for details.

Fetal nephrectomy also reduces fetal calcium concentrations, and the hypocalcemia can be prevented by administration of 1,25(OH) $_2$ D (calcitriol).²⁰¹ Moreover, infusion into the sheep fetus of antibody to 1,25(OH) $_2$ D reduced the placental calcium gradient.²⁰¹ Therefore, fetal PTHrP and PTH appear to stimulate fetal renal 1,25(OH) $_2$ D production, which acts to enhance maternal-fetal transport of calcium by the placenta. The fetal kidney can synthesize 1,25(OH) $_2$ D via 1-hydroxylation of 25-hydroxycholecalciferol, and the placenta contains both 1,25(OH) $_2$ D receptors and a vitamin D-dependent calcium-binding protein. In the sheep fetus, the endogenous production rate of 1,25(OH) $_2$ D during the last third of gestation was six times greater than that in the mother.²⁰⁶ The metabolic clearance of 1,25(OH) $_2$ D was also higher in the fetus than in the mother.

The fetal parathyroid-placental axis promotes maternal-fetal transfer of bone mineral and accretion of fetal bone mineral. The high blood levels of calcitonin in the fetus, probably resulting from the chronic stimulation by fetal hypercalcemia, are thought to contribute to the fetal bone mineral accretion.^{199,201} A prominent effect of calcitonin is to inhibit bone resorption, and the high fetal serum calcium concentrations coupled with high circulating calcitonin promote bone mineral anabolism.¹⁹⁹ Placental calcitonin production may contribute to the calcitonin in fetal plasma, but the persistence of high plasma levels in neonatal plasma argues for predominant fetal production. Also, 1,25(OH) $_2$ D or 24,25(OH) $_2$ D may play a role in fetal cartilage growth and bone mineral accretion.²⁰⁶ These concepts are summarized in Figure 22-11.

Endocrine Pancreas: Insulin and Glucagon

Embryogenesis of the pancreas is mediated in the mouse by a series of homeobox genes and transcription factors that program pancreatic budding from the gut tube, development of branching ducts and undifferentiated epithelium, differentiation of exocrine and endocrine cell lineages that originate from endodermal tissue, and organization of the endocrine cells into islets of Langerhans. The process begins at day 8 of the 21-day gestation and extends 2 to 3 weeks after birth (Fig. 22-12).²⁰⁷ Studies in mice have shown that knockout of the *Pdx1*, *HlxB9*, *Isl1*, or *Hes1* genes results in pancreatic agenesis or dysgenesis. In humans, mutations in *PDX1* are associated with neonatal diabetes mellitus due to pancreatic agenesis. In mice, *NGN3* or *Beta2* knockout leads to complete absence of endocrine cells, whereas knockout of the lower pathway genes shown in Figure 22-13 impairs specific islet cell differentiation.²⁰⁷ Members of the EGF family of growth factors, laminin, and perhaps other growth factors including the IGFs contribute to pancreatic growth and differentiation.^{208,209}

The human fetal pancreas is identifiable by 4 weeks of gestation, and alpha and beta cells can be recognized by 8 to 9 weeks. Insulin, glucagon, somatostatin, and pancreatic polypeptide are measurable by 8 to 10 weeks of gestation.²¹⁰ Alpha cells are more numerous than beta cells in the early fetal pancreas and reach a relative peak at mid-gestation; beta cells continue to increase throughout the second half of gestation, so that, by term, the ratio of alpha to beta cells is approximately 1:1. The insulin content of

Figure 22-12 Expression of transcription factors during pancreatic embryogenesis. Knockout of *PDX1*, *HLXB9*, or *Isl1* is associated with early arrest of pancreatic development. *HLXB9* knockout leads to failure of the pancreatic dorsal bud to develop with decreased beta cell number in the remnant pancreas. *HES1* or neurogenin 3 (*NGN3*) disruption leads to aplasia or hypoplasia of the islets of Langerhans. Disruption of the downstream transcription factors impairs formation of the beta cells or alpha cells. *SOX9* and *HNF3B* (not shown) are required for early foregut formation and pancreas specification. (From Habener JF, Kemp DM, Thomas MJ. Mini review: transcriptional regulation in pancreatic development. *Endocrinology*. 2005;146:1025-1034.)

the pancreas increases from less than 3.6 pmol/g (0.5 U/g) at 7 to 10 weeks to 30 pmol/g (4 U/g) at 16 to 25 weeks of gestation and 93 pmol/g (13 U/g) near term; the concentration in the adult pancreas is approximately 14 pmol/g (2 U/g).²¹¹ Endocrine cells are dispersed throughout the exocrine tissues by 20 weeks, and the islets of Langerhans are clearly differentiated by 31 weeks.

Although the fetal beta cell is functional by 14 to 24 weeks of gestation, secretion of insulin into the bloodstream by the fetal pancreas is low. Insulin release from the fetal rat pancreas *in vitro* in response to glucose or pyruvate is minimal but can be stimulated by leucine, arginine, tolbutamide, or potassium chloride, indicating that parts of the secretory mechanism are functional in the fetus.²¹¹⁻²¹³ Insulin secretion in adult islets is mediated by two or more mechanisms, including stimulation of the adenylate cyclase system with production of cyclic adenosine monophosphate (cAMP) and inhibition of potassium efflux, which leads to depolarization of the cell membrane and opening of voltage-dependent calcium channels. The former mechanism, although suppressed in the fetal islets,

can be augmented by theophylline, but calcium channel activation does not occur in fetal islets in response to initiators of insulin release that cause depolarization of adult islet cells.²¹³ Infusion of glucose or arginine to pregnant women before hysterotomy fails to provoke fetal insulin secretion at midgestation or near term, and plasma insulin concentrations in the late human fetus are relatively unresponsive to high glucose concentrations before the onset of labor.²¹¹

Similar observations have been made in the monkey: neither glucose nor arginine stimulated fetal insulin release near term, but glucagon evoked prompt insulin secretion.²¹¹ Late in gestation in the ovine fetus, epinephrine inhibits insulin release through a receptor pathway.²¹¹ In the anencephalic human fetus, the endocrine pancreas develops normally if maternal carbohydrate metabolism is not impaired; however, beta cell hypertrophy and hyperplasia do not occur in the anencephalic fetus nor in decapitated fetal rabbits exposed to chronic hyperglycemia. This lack of beta cell response to hyperglycemia may be the result of deficiency of GH or IGF1 or both, because GH

Figure 22-13 Actions of cortisol and catecholamines during fetal adaptation to the extrauterine environment. The prenatal cortisol surge acts to promote functional maturation of several organ systems. The neonatal catecholamine surge triggers or potentiates a number of the extrauterine cardiopulmonary and metabolic functional adaptations that are critical to extrauterine survival. See text for details. BAT, brown adipose tissue; E, epinephrine; NE, norepinephrine; T₃, triiodothyronine; T₄, thyroxine.

stimulates insulin gene expression and may play a permissive role in beta cell hyperplasia and hypertrophy.²⁰⁹

Pancreatic glucagon concentrations are relatively high in fetal plasma and increase progressively with fetal age.^{211,212} The fetal pancreatic glucagon content at midgestation is approximately 6 µg/g, compared with an adult level of 2 µg/g. As is true for insulin, the capacity for glucagon secretion is blunted in the fetus. Hyperglycemia does not suppress fetal plasma glucagon concentrations in rats, monkeys, or sheep, and acute hypoglycemia does not evoke glucagon secretion in the rat fetus. Amino acids, which are important secretagogues for insulin and glucagon in the adult, probably have little role in modulating insulin and glucagon secretion in the preterm fetus. However, infusion of alanine into women at term increases both maternal and cord blood glucagon concentrations, indicating a fetal glucagon response to amino acids in the term fetus. Catecholamines also evoke glucagon release in the near-term ovine fetus.²¹¹

Therefore, the fetal pancreatic islet cells, although histologically mature and capable of hormone synthesis and hyperplasia, are relatively immature functionally at birth with regard to their capacity to secrete insulin and glucagon. The rapid maturation of responsiveness to glucose in the neonatal period in both premature and mature infants suggests that this blunted state may be a secondary result of the relatively stable fetal serum glucose concentrations maintained by placental transfer of maternal glucose rather than a primary, temporally fixed maturation process. Alternatively, the lack of any enteric signal to the pancreas from feeding via release of incretins may also account for this stability. The blunted capacity for insulin and glucagon secretion has been related to a deficient capacity of the fetal pancreatic islet cells to generate cAMP or to rapid destruction of cAMP by phosphodiesterase, or both.²¹¹

In rodents, a period of a rapid increase in beta cell mass at the time of birth and shortly thereafter has been observed, and this rapid change is attenuated by a period of apoptosis before adult mass is achieved. Beta cell mass is more difficult to determine from a developmental standpoint in humans. At birth in the human, there are some 200 to 300 × 10⁶ beta cells, which is approximately one third of the population present in adulthood. However, most of the actual mass change takes place in the newborn period and is associated with changes in beta cell size rather than number.²¹⁴ Thereafter, there is rapid further expansion in terms of cell numbers, but the waxing and waning of the beta cell mass, particularly with pregnancy, is poorly understood. How much beta cell mass is a determinant of duration to type 2 diabetes mellitus is unclear.

Insulin and glucagon are normally not necessary for substrate metabolism in the fetus.²¹² Glucose is obtained by placental transfer through facilitated diffusion. The fetal respiratory quotient is approximately 1, which suggests that glucose is the primary energy substrate for the fetus. Other substrates, such as amino acids and lactate, may also be utilized in the human as in the sheep fetus. However, at least early in gestation, hepatic metabolism and substrate utilization appear to be independent of insulin and to be modulated in an autoregulatory fashion by glucose.²¹¹ In addition, the constant supply of glucose normally precludes the necessity for endogenous gluconeogenesis, and gluconeogenic enzyme activities are low in the fetal liver.

Glycogen storage in the fetus is modulated by fetal glucocorticoids and probably by placental lactogen (hPL). Fetal insulin plays a role near term, when insulin also has the capacity to increase fetal glucose uptake and lipogenesis.^{211,212} Insulin receptors are present on most fetal cells

in higher numbers than on adult cells; moreover, hyperinsulinemia fails to downregulate fetal insulin receptors.²¹¹ Fetal hepatic glucagon receptors, in contrast, are reduced in number, and fetal liver is relatively resistant to the glycemic effect of glucagon. These conditions tend to potentiate the fetal anabolic milieu during the period of rapid growth in the last trimester of gestation.

Poorly controlled maternal diabetes mellitus is associated with fetal macrosomia, an increased risk of spontaneous abortion, and fetal malformation. Maternal hyperglycemia also leads to hyperinsulinism and beta cell hyperplasia in the infant. Infants of diabetic mothers are prone to polycythemia, renal vein thrombosis, hypocalcemia, respiratory distress syndrome, jaundice, persistent fetal circulation, cardiomyopathy, congenital heart disease, and malformations of other organs.

NEUTRALIZATION OF HORMONE ACTIONS IN THE FETUS

After the period of embryogenesis, the fetal milieu is programmed to optimize body growth and organ development through an array of generalized and specialized growth factors (see “Fetal Growth”). These function in a stable metabolic environment with substrate supply maintained by the placenta. The endocrine and metabolic systems characterizing the extrauterine environment are programmed to maintain metabolic stability in a changing external environment with intermittent substrate provision. Hormonal systems in the fetus are programmed to maintain anabolism with minimal hormonal perturbation. Therefore, production of catabolic and thermogenic hormones is limited, and the effects of the hormones altering metabolic substrate supply and distribution pathways are muted (Table 22-5).

TABLE 22-5

Neutralization of Hormone Actions in the Fetus*

PRODUCTION OF INACTIVE METABOLITES	
Active Hormone	Inactive Metabolites
Cortisol	Cortisone
Thyroxine (T ₄)	rT ₃ , T ₄ S, rT ₃ S
Triiodothyronine (T ₃)	T ₃ S, T ₂
DELAYED EXPRESSION OR NEUTRALIZATION OF RECEPTORS	
Active Hormone	Receptor
Growth hormone (GH)	GHR
Thyroid hormone	TRα, TRβ
Catecholamines	β-AR
Estrogens	ER
Glucagon	GR
LIMITED HORMONE SECRETION	
Active Hormone	Secretory Cell
Insulin	Islet cell beta
Glucagon	Islet cell alpha

*See text for details.

AR, adrenergic receptor; T₂, diiodothyronine; rT₃, reverse T₃; T₄S, T₄ sulfate.

Limitation of Hormone Secretion

The human fetal pancreas is functional during the second trimester, but secretion of insulin in response to glucose or pyruvate is minimal until the neonatal period.^{211,212} Glucagon secretion is also blunted, although fetal blood glucagon levels are relatively high. Fetal islet hyperplasia and increased insulin secretion occur in response to chronic hyperglycemia (e.g., in the infant of a diabetic mother), and insulin release can be stimulated by acute fetal infusions of leucine, arginine, or tolbutamide.^{211,213} Moreover, responsiveness of both insulin and glucagon secretion to glucose develops rapidly in the neonatal period.²¹¹ It is not clear whether the limited fetal islet cell responsiveness results from the relatively stable fetal serum glucose levels or from a temporally fixed maturation process (see earlier discussion).

Production of Inactive Metabolites

Throughout the second half of gestation, cortisol is metabolized in fetal tissues to inactive cortisone through the activity of HSD11B2. The placenta is permeable to steroid hormones, including cortisol. During midgestation, placental HSD11B2 activity is low, and some cortisol is transferred to the fetus. Placental HSD11B2 activity increases during the second half of pregnancy under the control of placental estrogens, and enzyme activity near term is high.^{16,215} Maternal-fetal cortisol transfer decreases progressively. In addition, although many adult tissues can convert cortisone to cortisol, conversion is limited during most of fetal life. Consequently, most of the cortisol that crosses the placenta or is produced by the fetus is inactivated to cortisone by the placenta or by fetal tissues.

Levels of cortisone in fetal plasma exceed those of cortisol by threefold to fourfold until after 30 weeks of gestation (see Fig. 22-6). Teleologically, this would help preserve the anabolic and growth-promoting milieu of the fetus and minimize premature maturational and parturitional effects of cortisol. After 30 weeks, the ratio of cortisol to cortisone in fetal tissues and plasma increases as a result of increased fetal secretion and decreased conversion of cortisol to cortisone within the placenta and fetal tissues.²¹⁵ Cortisol has an important maturational action on several fetal tissues near term (see later discussion).

Fetal thyroid hormone metabolism is characterized by conversion of active thyroid hormones to inactive rT_3 and inactive sulfated iodothyronines and by limited receptor and postreceptor responsiveness to thyroid hormone in selected tissues.^{109,118} The placenta contains an iodothyronine inner-ring monodeiodinase that catalyzes conversion of maternal T_4 to rT_3 . The fetal sheep liver and kidney, in contrast to the adult liver and kidney, manifest low levels of D1 outer-ring monodeiodinase activity, so conversion of T_4 to active T_3 is limited and large amounts of inactive iodothyronine sulfoconjugates accumulate.^{109,120} As a consequence, plasma T_3 levels in the fetus remain low until the last few weeks of gestation (see Fig. 22-8). Selected fetal tissues (brain, brown adipose tissue) have active D2 outer-ring monodeiodinase activities that contribute to local tissue T_3 concentrations; local T_3 is important in development, particularly in the hypothyroid fetus.^{109,216} Near term and in the neonatal period in the human fetus, the dramatic increase in plasma T_3 levels, and presumably in T_3 production, heralds the onset of thyroid hormone actions on growth and development and on metabolism (see Fig. 22-8).

Neutralization of Receptor Response

Selected ovine fetal tissues seem relatively unresponsive to thyroid hormones. Fetal ovine liver and kidney thermogenesis—as evidenced by oxygen consumption, sodium-potassium pump (Na^+,K^+ -ATPase) activity, and mitochondrial α -glycerophosphate activity—is unresponsive to exogenous T_3 during the third trimester, and thyroid hormone responsiveness in a number of tissues (cardiac, hepatic, renal, and skin) develops only during the perinatal period.²¹⁷ β -Adrenergic receptor binding in heart and lung of the ovine fetus is unresponsive to T_3 late in the third trimester but increases in response to T_3 in the neonatal period.^{97,217} In rodent species, in which development at birth is comparable to human fetal development at midgestation, pituitary GH concentrations become responsive to thyroid hormone only during the first weeks of extrauterine life.²¹⁸ Mouse submandibular gland EGF and NGF levels become responsive to thyroid hormone during the second week of life, as do urine and kidney EGF concentrations and hepatic EGF receptor levels.^{219,220} Mouse skin EGF levels and EGF receptors are responsive during the first neonatal week.^{221,222} Therefore, despite the presence of nuclear T_3 receptors in significant concentrations in developing rat and sheep fetuses, many thyroid hormone actions in these species are delayed.²²³ The mechanism of this delayed thyroid hormone responsiveness is not clear; developmental programming of iodothyronine monodeiodinase expression and gene expression programming via unliganded TRs or TR-interacting corepressors probably all play a role.

The effect of the high circulating concentrations of GH in the fetus is also limited. Fetal somatic growth is only partially GH dependent; indeed, the GH-deficient fetus has little or no growth retardation.^{58,224} The paucity of fetal GH effects is due to delayed maturation of GH receptors or postreceptor mechanisms. In animals such as sheep, hepatic GH receptor binding appears only during the neonatal period.⁵⁸ Receptor deficiency may also be a factor in the limited PRL bioactivity in the fetus near term.⁵⁸

There is less information on fetal hormone responsiveness in other systems. β -Adrenergic receptor binding in heart and lung of the sheep fetus is relatively low near term and increases in the neonatal period in response to thyroid hormones.²¹⁷ Premature lambs have an augmented plasma catecholamine surge at birth but have a relatively mild increase in plasma free fatty acid levels, which suggests reduced catecholamine responsiveness.²²⁵ The high concentrations of progesterone and estrogens in fetal blood also seem to have limited effects in the fetus. Progesterone receptors are present in low concentration in fetal guinea pig kidney, lung, and uterus at midgestation and increase progressively until term.²²⁶ ERs appear in neonatal rat uterus, oviduct, cervix, and vagina during the first 10 days of extrauterine life, and both $ER\alpha$ and $ER\beta$ mRNAs are present in human fetal tissues during the second trimester.^{159,227} The human neonate often manifests mild breast enlargement at birth, and vaginal estrogenization may be evident in female infants at birth. Estrogen effects otherwise appear to be limited (see Table 22-5).

FETAL GROWTH

Insulin-Like Growth Factors

The IGFs are involved in regulation of uterine and placental growth during pregnancy. In early embryonic and fetal

development, IGF1, EGF, and estrogens are mitogens for endometrial stromal cells, and the endometrial contents of IGF1 and IGF1 mRNA are high at implantation and during early embryogenesis in the sow.²²⁸ Uterine IGF1 and IGF1 mRNA levels decrease progressively with advancing gestation.²²⁸ Placental tissue also contains IGF1 and IGF2 mRNAs, significant concentrations of the respective proteins, and IGF1 receptors.¹⁶ Autocrine and paracrine roles for the IGFs in uterine and placental tissues are postulated. IGF1 and insulin are produced by embryonic tissues during the prepancreatic stage of mouse development, and both factors stimulate growth of embryonic mouse cells.²²⁹

IGF2 is genomically imprinted and paternally expressed in the fetus and placenta. The mature IGF2 protein is generated from the biologically inactive pro-IGF2 peptide by the action of proprotein convertase 4. Recent studies have shown a role of IGF2 in determining placental nutrient supply and, hence, fetal growth.²³⁰ In mutant mice lacking the imprinted placental-specific IGF2 transcript, growth of the placenta is altered from early gestation, but fetal growth is normal until late gestation, suggesting functional adaptation of the placenta to meet the fetal demands. It is believed that this adaptation may be mediated by the altered expression of placental transporters GLUT3 and Slc38a4.²³¹

Studies of transgenic mice with null mutations of the genes encoding *IGF1*, *IGF2*, or the IGF1 receptor have defined the role of the somatomedins; the birth weight of the embryos lacking IGF1 or IGF2 was only 60% that of control mice. When both genes were inactive, birth weight was reduced another 30%, and mice lacking the IGF1 receptor had birth weights averaging 45% of control values.⁵⁶ IGF2-deficient mice also manifested intrauterine growth retardation in association with a small placenta. They had near-normal postnatal growth but delayed bone development.⁵⁶ IGF2-receptor knockout fetal mice are 30% overweight, suggesting a negative growth-modulating effect of this receptor.

The normal growth in fetuses with both IGF1 and IGF2 receptor knockout is caused by IGF1 signaling via the insulin receptor; combined IGF1, IGF2, and insulin receptor knockout results in severe intrauterine growth retardation and fetal death. Knockout of individual IGF binding proteins has little effect on fetal or placental growth.⁵⁶ In humans, mutations in *IGF1* or *IGFIR* are associated with intrauterine growth retardation,^{232,233} suggesting that IGF1 signaling contributes significantly to fetal growth.

Hypomethylation of the 11p15 imprinted region has been associated with the phenotype of Silver-Russell syndrome.²³⁴ This results in the relaxation of imprinting and biallelic expression of *H19* and downregulation of *IGF2*. Additionally, abnormal processing of IGF2 by proprotein convertase 4 in the placenta has been implicated in the etiology of fetal growth restriction.²³⁵ Pregnant women carrying fetuses with intrauterine growth retardation (IUGR, low birth weight for gestational age) had higher levels of pro-IGF2 compared with controls. More recently, Murphy and colleagues reported severe intrauterine growth retardation and atypical diabetes mellitus secondary to insulin resistance in association with disruption of regulation of the *IGF2* gene.²³⁶ On the other hand, overexpression of IGF2 as a result of loss of imprinting associated with uniparental paternal disomy, *CDKN1C* gene loss of function, alteration in the KvLQT1 differentially methylated region (DMR), or microdeletions in the human H19 DMR is associated with overgrowth in the form of Beckwith-Wiedemann syndrome.²³⁷

IGF-binding proteins (IGFBPs) are present as early as 5 weeks of gestation; prenatally as postnatally, the IGFs circulate in association with binding proteins.⁵⁶ High concentrations of circulating IGFBP1 are associated with fetal growth restriction in the mouse, as is overexpression of fetal IGFBP1 in the human.^{238,239} Therefore, during fetal and postnatal life, plasma concentrations of IGFs are relatively high compared with tissue concentrations. In the fetus, IGF2 levels are five to six times higher than those of IGF1, in contrast to these concentrations in children and adults, and concentrations of both increase progressively throughout gestation.²⁴⁰ Fetal concentrations of both peptides at term are 30% to 50% of the adult concentrations.

In most studies, cord blood IGF1 concentrations correlate with birth size.⁵⁶ Despite the fetal growth-enhancing effects of IGF2, blood concentrations are only weakly related to size at birth, largely because of the inhibiting effect of soluble IGF2 receptor (IGF2R)²⁴¹ but also because IGF2 appears to exert most of its growth effects in the earlier part of gestation. Soluble IGF2R is derived through proteolytic cleavage of the transmembrane region of the receptor in many tissues. IGF receptors have been identified as early as 5 weeks of gestation and are widespread in fetal tissues.⁵⁶ IGF1 stimulates glycogenesis in cultured fetal rat hepatocytes and induces formation of myotubes in cultured myoblasts. IGF2 is active in cultured muscle and neonatal rat astroglial cells. Insulin receptors are increased in fetal cells and are resistant to downregulation; no similar data are available for the IGF1 receptor.

As discussed earlier, the control of IGF production differs in fetal and postnatal life. GH receptors are relatively deficient, and receptors for hPL predominate in fetal tissues.^{58,59} GH does play a minor role in the fetus, as reflected in the low IGF concentrations and slight reduction in birth weight and length in infants with GH resistance (Laron dwarfism) and growth hormone deficiency.²²⁴ hPL stimulates IGF1 production and augments amino acid transport and DNA synthesis in human fetal fibroblasts and muscle cells.⁵⁸ IGF1 and IGF2 levels are reduced in fetuses of protein-starved pregnant rats, and the low IGF2 levels are reversed by hPL.²⁴² Thyroidectomy of the third-trimester sheep fetus impairs skeletal muscle growth in association with a decrease in muscle GH receptor mRNA and IGF1 mRNA without an effect on IGF2 levels.²⁴³ This period is equivalent to the postnatal period in the human, and there is no evidence that thyroid hormones modulate GH receptor or IGF1 levels in the human fetus. Glucocorticoids can inhibit fetal growth, presumably by inhibiting IGF gene transcription.²⁴³

Nutrition is the major factor modulating IGF production in the fetus. IGF concentrations fall in suckling rats deprived of milk, and IGF1 and IGF2 concentrations are reduced in fetuses of protein-starved pregnant rats and placentally restricted sheep.^{56,57} These data support the view that the IGFs are important in embryonic and fetal growth and that in the fetus they are regulated, at least in part, by hPL and by nutritional substrate derived transplacentally. The high concentrations of IGF2 in fetal rat serum, the high levels of IGF2 mRNA in fetal tissues, and the presence of a truncated form of IGF1 in human fetal brain tissue suggest unique developmental actions of these peptides.

Insulin

Insulin has been proposed to act as a fetal growth factor. Infants born to women with diabetes mellitus may have

hyperinsulinemia associated with increased birth weight.²⁴⁴ Most of this increased weight is accounted for by body fat; there is little increase in body length, but some organomegaly may occur. Infants with hyperinsulinemia caused by congenital hyperinsulinism or the Beckwith-Wiedemann syndrome may also have increased somatic growth in utero. Conversely, the human fetus with pancreatic agenesis is small and has decreased muscle bulk and little or no adipose tissue.²⁴⁴

Mice with insulin or insulin receptor gene mutations have a 10% decrease in birth weight and early neonatal death with hyperglycemia and ketonemia.⁵⁶ Insulin receptor mutations in humans lead to severe intrauterine growth retardation and limited postnatal weight gain.⁵⁶ In contrast to mice, the human fetus during the latter half of gestation has a significant increase in adipose mass, and adipose tissue is highly sensitive to insulin. In clinical conditions associated with fetal hyperinsulinemia, the human neonate is born large for gestation age, primarily due to increased lipogenesis mediated by insulin or IGF1 receptors.

Epidermal Growth Factor/Transforming Growth Factor System

The EGF/TGF- α system has been characterized in considerable detail.^{245,246} EGF is a 6-kd peptide product of a large, 1207-amino-acid precursor molecule and acts through a 170-kd membrane receptor glycoprotein. This receptor, like the IGF receptor, has intrinsic tyrosine kinase activity, and tyrosine kinase-mediated autophosphorylation is a critical event in EGF signal transduction. TGF- α , which has 35% amino acid homology with murine EGF and 44% homology with human EGF, also acts through the EGF receptor system.^{245,246} Several additional family members have been characterized, including amphiregulin, heparin-binding EGF, betacellulin, and neuregulins.²⁴⁶ Three additional receptors are referred to as ErbB2, ErbB3, and ErbB4 in animals; the human receptors are called human EGF receptor 2 (HER2), HER3, and HER4.²⁴⁶

EGF, pre-pro-EGF mRNA, and EGF receptors are present in most tissues in the postnatal rodent, but mRNA levels are highest in salivary glands and kidneys. EGF and pre-pro-EGF mRNA levels are absent or low in the fetal mouse and remain low in mouse tissues during the early neonatal period.²⁴⁷ Nonetheless, the EGF receptor knockout mouse exhibits epithelial immaturity and multiorgan failure with early death.²⁴⁷ Tissue concentrations of both EGF and EGF mRNA increase in the mouse during the first 2 months of postnatal life; indeed, concentrations of EGF in the salivary glands increase several thousand-fold between 3 weeks and 3 months of age. Mouse urinary levels increase 200-fold and kidney concentrations increase 10-fold between 1 week and 2 months of age. EGF concentrations in mouse ocular tissues increase 100-fold during the first week of life.²⁴⁵ Liver EGF concentrations increase more slowly, as do serum levels, and there is a high degree of correlation between serum and liver EGF levels in the developing mouse.²⁴⁵ Therefore, the production of EGF in the rodent is accelerated during the early neonatal period, and it is during this time that most hormone-stimulated growth and development occur.

Fetal mouse and human tissues have high concentrations of TGF- α .^{246,248,249} Immunoreactive TGF- α concentrations in mice are measurable at relatively high levels in lung, brain, liver, and kidney tissues in the fetal/neonatal rat, and the ontogenic pattern of TGF- α is tissue specific; most late fetal tissues studied contained TGF- α , and levels persisted or increased in most tissues through the period

of growth and development.²⁴⁸ In rodents and sheep, EGF provokes precocious eyelid opening and tooth eruption in neonatal animals; stimulates lung maturation; promotes palatal development in organ culture; stimulates gastrointestinal maturation; evokes secretion of pituitary hormones including GH, PRL, and corticotropin; and stimulates secretion of chorionic gonadotropin and placental lactogen by the placenta.^{245,247} Both EGF and TGF- α compete for binding to the EGF receptor, and both factors accelerate eye opening and tooth eruption in the neonatal rodent, presumably through interaction with the same EGF receptor.²⁴⁵

Considerable evidence suggests a role for the EGF family of growth factors in mammalian CNS development.²⁵⁹ EGF, TGF- α , neuregulins, and the EGF receptors are widely distributed in the nervous system.^{245,250-253} EGF promotes proliferation of astroglial cells, acts as an astroglial differentiation factor, and enhances survival and outgrowth of selected neuronal cells.^{250,251} Transgenic mice with a deficiency of neuregulin, ErbB2, ErbB3, or ErbB4 die in utero with cardiac anomalies and developmental anomalies of the hindbrain, midbrain, and ventral forebrain (see Table 22-5).^{252,253}

EGF also plays an important role in rodent pregnancy. Maternal salivary gland and plasma EGF concentrations in the mouse increase fourfold to fivefold during pregnancy.²⁵⁴ Removal of the salivary glands prevents the increase in plasma EGF; moreover, salivary gland removal reduces the number of mice completing term pregnancy (by 50%), decreases the percentage of live pups, and decreases the crown-rump length of fetuses delivered.²⁵⁴ Administration of EGF antiserum to pregnant mice without salivary glands further increases the abortion rate, whereas administration of EGF improves pregnancy outcome.²⁵⁴ Because maternal EGF is too large a molecule to traverse the placental barrier, an effect on maternal metabolism or on the placenta is likely.²⁵⁴ The placenta is richly endowed with EGF receptors, and placental tissue binds and degrades EGF to constituent amino acids.²⁴⁵ TGF- α is also produced by the maternal decidua in rodents and stimulates proliferation of decidual tissue and decidual PRL production.

Nerve Growth Factor

NGF is a 13-kd protein that is present at high concentrations in mouse salivary gland and at low concentrations in many adult tissues.²⁴⁶ It is also produced by human placental tissue. It is the original member of an expanding family of neurotropic growth factors that now includes brain-derived neurotropic factor, neurotrophin 3, and two less well-characterized factors; these ligands act via two receptors, NGF and NGF2 (or Trk).^{246,255} NGF binds to high-affinity plasma membrane receptors and is internalized and transported to subcellular organelles, including the nucleus, in neurons of the peripheral nervous system. It promotes neurite outgrowth and enhances tyrosine hydroxylase and dopamine β -hydroxylase activities in developing sympathetic neurons. NGF acts on undifferentiated sympathetic cell precursors to evoke both hyperplastic and hypertrophic effects and plays a permissive role in stimulating the development of immature autonomic neurons along either a sympathetic or a cholinergic pathway.^{246,256}

The injection of NGF in neonatal mice causes a marked increase in the volume of the superior cervical ganglia and increases the nerve supply of body organs. Likewise, injection of NGF antiserum during early neonatal life results in a decrease in the size of the superior cervical ganglia,

reduction in tyrosine hydroxylase activity, and permanent sympathectomy.²⁵⁶ Maternal NGF autoantibodies in rats and rabbits impair autonomic nervous system development in utero.²⁵⁷ This impairment affects sympathetic and dorsal root ganglia and autonomic innervation of peripheral organs. NGF is produced by neonatal mouse astroglial cells in tissue culture, is present in developing mouse brain tissue, and, together with brain-derived neurotrophic factor and neurotrophin 3, plays an important role in brain development.^{254,255,258} Thyroid hormones and testosterone modulate postnatal NGF levels in the submandibular gland of the mouse. Thyroid hormones increase NGF, neurotrophin 3, and brain-derived neurotrophic factor mRNA levels in adult rat brain.^{245,259}

Other Factors

Additional growth factors are involved in fetal growth and development, including hematopoietic growth factors, platelet-derived growth factors (PDGFs), fibroblast growth factors (FGFs), vascular endothelial growth factor (VEGF), and members of the TGF- β family.^{56,246} Hematopoietic growth factors are also active in the fetus during development; erythropoietin in fetal sheep is produced by the liver rather than the kidney, and erythropoietin gene expression in fetal sheep is regulated by glucocorticoids.²⁶⁰ A switch to kidney production occurs after parturition.²⁶¹ Postnatally, thyroid hormones, testosterone, and hypoxia modulate erythropoietin production. PDGF represents a family of homodimers and heterodimers of PDGFA and PDGFB chains derived from two gene loci.²⁶² Two PDGF receptors have been characterized, PDGF α and PDGF β . The genes for PDGF and its receptors are expressed in many tissues. *PDGFA* gene inactivation in mice leads to defects in lung, skin, intestine, testes, and brain resulting in early postnatal death.²⁶² *PDGFB* gene inactivation leads to microvessel disruption and leakage with hemorrhage, edema, and intrauterine death.

The FGF family of heparin-binding growth factors now includes 17 members with diverse effects on development, angiogenesis, wound healing, and other biologic systems.^{263,264} These effects are mediated by ligand-activated tyrosine protein kinase receptors (FGFRs) transcribed from four related genes. Several receptor isoforms are products of alternative RNA splicing.^{56,246} Targeted disruptions of *FGF* and *FGFR* genes in mice have defined critical roles in development.^{246,263} FGF3-deficient mice show tail and inner ear defects. Knockout of the *FGF4* gene is lethal, leading to early death. Knockout of the *FGFR1* gene also leads to early fetal death. *FGF10* knockout mice die at birth because of pulmonary agenesis. Deficiency of FGF4, FGF8, FGF9, FGF10, or FGF17 is associated with limb deformities. FGF8 deficiency leads to abnormal left-right axis patterning. In mice, *FGFR3* knockout results in chondrocyte hypertrophy and increased bone length.²⁴⁶ In humans, a variety of gain-of-function *FGFR* mutations are associated with chondrodysplasias and craniosynostosis syndromes.²⁴⁶ FGF, like EGF, stimulates the production of hCG from a choriocarcinoma cell line.²⁶⁴ These observations and the fact that the placenta contains FGF, NGF, TGF- α , TGF- β , IGF1, and IGF2 suggest that the placenta plays an important role in modulating fetal growth.

TRANSITION TO EXTRAUTERINE LIFE

The transition to extrauterine life involves abrupt delivery from the protected intrauterine environment and succor

by the placenta into the relatively hostile extrauterine environment. The neonate must initiate air breathing and defend against hypothermia, hypoglycemia, and hypocalcemia as the placental supply of energy and nutritional substrate is removed. Both the adrenal cortex and the autonomic nervous system, including the para-aortic chromaffin system, are essential for extrauterine adaptation. Longer-term transition requires adaptation to an environment of intermittent nutrient supply and transient substrate deficiency and requires maturation of the secretory control mechanisms for the PTH-calcitonin system and the endocrine pancreas.

Cortisol Surge

In most mammals, a cortisol surge occurs near term and is mediated by increased cortisol production by the fetal adrenal and a decreased rate of conversion of cortisol to cortisone. Pepe and Albrecht have proposed that the preterm fetal cortisol surge is due to the progressive stimulation by estrogens of placental HSD11B2 activity and the subsequent increase in placental conversion of cortisol to cortisone.²¹⁵ The resulting decrease in maternal-to-fetal cortisol transfer results in stimulation of fetal CRH and corticotropin secretion through the negative-feedback control loop. The concomitant estrogen-stimulated increase in HSD11B2 activity in fetal tissues potentiates the relative fetal cortisol deficiency and the CRH-corticotropin response.²¹⁵ Placental CRH may also potentiate fetal adrenal activation. Recent data suggest an increase in HSD11B1 expression and activity in placenta and intrauterine fetal membranes during late gestation, with a consequent increase in local cortisol production in preparation for parturition.²⁶⁵

The cortisol surge augments surfactant synthesis in lung tissue; increases lung liquid reabsorption; increases adrenomedullary PNMT activity, which in turn increases methylation of NE to epinephrine; increases hepatic iodothyronine outer-ring monodeiodinase activity and hence conversion of T_4 to T_3 ; decreases sensitivity of the ductus arteriosus to prostaglandins, facilitating ductus closure; induces maturation of several enzymes and transport processes of the small intestine; and stimulates maturation of hepatic enzymes (see Fig. 22-13).^{80,266} In some cases, these events involve increased synthesis of specific proteins or enzymes. In other instances, such as the action on the ductus arteriosus, the mechanism remains obscure.

Secondary effects of cortisol also promote extrauterine adaptations. The increased T_3 levels stimulate β -adrenergic receptor binding, potentiate surfactant synthesis in lung tissue, and increase the sensitivity of brown adipose tissue to NE. The significance of prenatal cortisol is demonstrated by the effects of gene-targeted CRH or glucocorticoid receptor deficiency in mice; the progeny of homozygous CRH-deficient or glucocorticoid receptor-deficient animals die in the first 12 hours with lung dysplasia and surfactant deficiency.^{267,268}

Catecholamine Surge

Parturition also evokes a dramatic catecholamine surge in the newborn, resulting in extraordinarily high levels of NE, epinephrine, and dopamine in cord blood.¹⁸⁵ As discussed earlier, plasma NE concentrations exceed epinephrine concentrations because of peripheral and adrenomedullary and para-aortic catecholamine release. Cord blood NE levels of 15 nmol/L (2500 pg/mL) and epinephrine concentrations of 2 nmol/L (370 pg/mL) are common after

spontaneous delivery of term infants.¹⁸⁵ Concentrations of 25 nmol/L (4200 pg/mL) of NE and 35 nmol/L (640 pg/mL) of epinephrine are common in cord blood of premature infants. These changes evoke critical cardiovascular adaptations, including increased blood pressure and increased cardiac inotropic effects; increased glucagon secretion; decreased insulin secretion; increased thermogenesis in brown adipose tissue and increased plasma free fatty acid levels; and pulmonary adaptation, including mobilization of pulmonary fluid and increased surfactant release.^{185,189,265}

Thermogenesis in Neonatal Brown Adipose Tissue

Brown adipose tissue is the major site of thermogenesis in the newborn and is especially prominent in the mammalian fetus. The largest accumulations of brown adipose tissue envelop the kidneys and adrenal glands, and smaller amounts surround the blood vessels of the mediastinum and neck.²⁶⁹ The mass of brown adipose tissue peaks at the time of birth and gradually decreases during the early weeks of life. Surgical removal of this tissue leads to neonatal hypothermia. NE, through β -adrenergic receptors, stimulates thermogenesis by brown adipose tissue, and optimal responsiveness of this tissue to NE is dependent on thyroid hormone.^{269,270} Brown adipose tissue is rich in mitochondria containing a unique 32-kd protein (thermogenin) that uncouples oxidation and phosphorylation of adenosine diphosphate, reduces ATP production, and consequently enhances thermogenesis.^{269,271} Thermogenin is T_3 dependent, and brown adipose tissue contains a 5'-monoiodothyronine deiodinase that deiodinates T_4 locally to T_3 .^{269,271} Full maturation of catecholamine-stimulated cellular respiration in brown adipose tissue occurs before delivery in the ovine fetus and requires thyroid hormone.^{269,272} Fetal thyroidectomy in this species leads to marked hypothermia, with low plasma free fatty acid levels and increased plasma epinephrine concentrations.²⁷² In vitro, basal brown adipose tissue thermogenesis and NE-stimulated and dibutyryl cAMP-stimulated thermogenesis are decreased by fetal thyroidectomy.

The rapid onset of thermogenesis in brown adipose tissue is essential for survival in newborn infants. Catecholamine release is the stimulus for brown adipose tissue thermogenesis in the early neonatal period, and responsiveness to catecholamines is markedly increased by cutting of the umbilical cord.²⁷⁰ Fetal hypoxia and placental inhibitors, including prostaglandin E_2 and adenosine, appear to inhibit brown adipose tissue thermogenesis in utero.²⁷⁰ Cord cutting, neonatal cooling, catecholamine stimulation, and augmented conversion of T_4 to T_3 in brown adipose tissue in the neonatal period are the essential features that mediate and condition newborn thermogenesis.

Calcium Homeostasis

The neonate must adjust rapidly from a high-calcium environment regulated by PTHrP and calcitonin to a low-calcium environment that requires regulation by PTH and vitamin D. With removal of the placenta in term infants, plasma total calcium concentration falls, reaching a nadir of approximately 2.3 mmol/L (9 mg/dL),²⁰² and the ionized calcium concentration reaches a low level of about 1.2 mmol/L (4.8 mg/dL) by 24 hours of life.²⁷³ Plasma PTH levels are relatively low in the neonatal period and are minimally responsive to hypocalcemia during the first 2 to 3 days of life. Calcitonin concentrations are high in cord

blood (approximately 2000 ng/L), increase further during the early neonatal period, and remain high for several days after birth.^{202,274} The relatively obtunded PTH response and the high calcitonin levels lead to a 2- to 3-day period of transient neonatal hypocalcemia.^{274,275} Inhibition of calcitonin secretion and stimulation of PTH secretion gradually result in increased serum calcium levels in the neonate. The disappearance of PTHrP in the neonatal lamb is approximately coincident with the time of restoration of calcium levels to the adult range.²⁰² The mechanism of transition from PTHrP to PTH secretion by the neonatal parathyroid glands is not clear.

Calcium homeostasis is also affected in the human newborn by the low level of glomerular filtration that persists for several days.^{274,275} In addition, renal responsiveness to PTH is reduced in the first few days of life. These factors limit phosphate excretion and predispose the neonate to hyperphosphatemia, particularly if the diet includes high-phosphate milk such as unmodified cow's milk. Premature infants, compared with term infants, tend to have lower PTH and higher calcitonin levels and more immature kidney function; in these infants, neonatal hypocalcemia may be more marked and prolonged, and the incidence of symptomatic hypocalcemia is higher. Birth asphyxia also predisposes the neonate to hypocalcemia.²⁷⁵ Infants born to mothers with hypercalcemia related to hyperparathyroidism have a high incidence of symptomatic hypocalcemia. These infants have a more marked suppression of parathyroid function and a longer period of transient hypoparathyroidism in the neonatal period. PTH secretion and calcium homeostasis usually return to normal in 1 to 2 weeks in full-term infants and within 2 to 3 weeks in the small premature infant.

Glucose Homeostasis

The abrupt withdrawal of the placental glucose supply leads to a prompt fall in plasma glucose in the term neonate.^{211,212} The low glucose and high catecholamine levels stimulate glucagon secretion, and the plasma glucagon level peaks within 2 hours after birth.^{211,212} Plasma insulin levels are low at birth and tend to fall further with hypoglycemia. The early glucagon response is short-lived; however, concentrations remain at about 100 ng/L for the first 12 to 24 hours, and the glucagon/insulin ratio is high enough to stabilize glucose levels in the range of 2.8 to 4 mmol/L (50 to 70 mg/dL) during this period. The early glucagon and catecholamine surges deplete hepatic glycogen stores, so the return of plasma glucose concentrations to normal after 12 to 18 hours requires maturation of hepatic gluconeogenesis under the stimulus of a high plasma glucagon/insulin ratio.²¹² Glucagon secretion gradually increases during the early hours after birth, especially with protein feeding, which stimulates gut glucagon release and pancreatic glucagon secretion.^{211,212} Premature infants have more severe and more prolonged hypoglycemia because of reduced glycogen stores and impaired hepatic gluconeogenesis. Infants born to diabetic mothers have more severe neonatal hypoglycemia because of relative hyperinsulinism. In the healthy term infant, glucose homeostasis is achieved within 5 to 7 days of life; in premature infants, 1 to 2 weeks may be required.

Other Hormonal Adaptations

Delivery of the placenta results in decreases in fetal blood concentrations of estrogens, progesterone, hCG, and hPL. The fall in estrogen concentrations presumably removes

the major stimulus to fetal pituitary PRL release, and PRL concentrations decrease within several weeks. The relatively delayed fall may be due to lactotrope hyperplasia in the fetal pituitary or to delayed maturation of hypothalamic dopamine secretion. The gradual fall of GH concentrations during the early weeks of life is due to delayed maturation of hypothalamic-pituitary feedback control of GH release.³³ In the neonatal primate, there are concomitant decreases in plasma GH concentrations and GH responsiveness to exogenous GHRH.²⁷⁶ The mechanisms remain unclear; changes in secretion or in pituitary sensitivity to GHRH or somatostatin, or both, may be involved. IGF1 and IGF2 levels fall to infantile values within a few days, presumably because of the removal of placental hPL and placental IGF production (see Fig. 22-4).

In male infants (see Fig. 22-10), after a transient fall in testosterone concentrations as the hCG stimulus abates, pituitary LH secretion rebounds modestly, and there is a secondary surge of plasma testosterone that persists at significant levels for several weeks.^{33,277} This surge is mediated by hypothalamic GnRH; blockade of neonatal activation of the pituitary-testicular axis with a GnRH agonist in neonatal monkeys ablates the neonatal increments in LH and testosterone.²⁷⁸ Such a blockade also results in subnormal increments in plasma LH and testosterone levels and subnormal testicular enlargement at puberty in these animals, suggesting that neonatal GnRH release with pituitary-testicular activation may be critical for normal sexual maturation of male primates.²⁷⁸ In females, a transient, secondary surge in FSH may transiently elevate estrogen concentrations.

Delivery results in a reversal of the high fetal cortisone/cortisol ratio, and plasma cortisol concentrations are higher in the neonate despite relatively lower plasma corticotropin concentrations (see Fig. 22-6). Presumably, this increase is due to decreased inhibition of adrenal 3 β -HSD by estrogen and perhaps to removal of a placental CRH action on fetal pituitary corticotropin release. Plasma DHEAS and DHEA levels fall as the fetal adrenal atrophies.

The increase in serum thyrotropin levels during the early minutes after birth is due to cooling of the neonate in the extrauterine environment.^{97,109} In term infants, the thyrotropin surge peaks at 30 minutes at a concentration of about 70 mU/L (see Fig. 22-8). This peak evokes increased secretion of T₄ and T₃ by the thyroid gland. In addition, increased conversion of T₄ to T₃ by liver and other tissues maintains the T₃ concentration in the extrauterine range of 1.6 to 3.4 nmol/L (105 to 220 ng/dL). The re-equilibration of thyrotropin levels to the normal extrauterine range is probably a result of the readjustment of prevailing serum T₃ concentrations and maturation of feedback control of thyrotropin by thyroid hormones during the early weeks of life.^{97,111} Production of rT₃ by fetal and neonatal tissues abates by 3 to 4 weeks of age, at which time serum rT₃ reaches adult levels.

PROGRAMMING OF DEVELOPING ENDOCRINE SYSTEMS

During the past several decades, the concept of the plasticity of fetal endocrine systems has evolved from experiments in several mammalian species indicating that hormonal programming occurs during a critical fetal or perinatal period of development. There is a growing list of examples. In the female rodent, transient neonatal androgen administration masculinizes the pattern of hypothalamic control of GnRH secretion and pituitary gonadotropin

secretion, masculinizes adult behavior and adult sexual activity, permanently alters the pattern of GH secretion, increases longitudinal bone growth and body weight, and masculinizes the pattern of hepatic steroid metabolism.^{279,280} Prenatal androgens program the timing of neuroendocrine puberty in sheep: the higher the dose of prenatal testosterone, the earlier the initiation of the pubertal LH rise.²⁸¹ Estrogen administration to pregnant rats during the last third of gestation produces cryptorchid male offspring and may permanently suppress spermatogenesis in adult males.²⁸² Transient levothyroxine administration to neonatal rodents leads to growth retardation, delayed puberty, decreased adult pituitary weight, decreased pituitary TRH concentrations, low serum thyrotropin levels, and decreased thyrotropin responsiveness to propylthiouracil challenge.^{283,284} Administration of insulin or alloxan to neonatal rats produces permanent alteration of glucose tolerance.²⁸⁵ A single dose of vasopressin to the neonatal rat permanently enhances the adult response to vasopressin.²⁸⁶ Fetal exposure to high maternal glucocorticoid levels in the rat inhibits fetal growth and leads to subsequent hypertension in the offspring.²⁸⁷ Moreover, it has been observed that the permanent programming can be transmitted to later generations, leading to the concept of epigenetic effects.^{285,288}

The concept of fetal programming was extended with the observation of ecologic associations between fetal and early-life health indicators (e.g., birth size, infant mortality) and adult diseases. The concept, advanced in the 1980s, that adult diseases have fetal and perinatal genesis has been referred to as the *Barker hypothesis*.²⁸⁹ There is now extensive documentation of the association of IUGR with an increased risk of later hypertension, insulin resistance, diabetes, and cardiovascular and coronary heart disease.²⁹⁰⁻²⁹⁷ The programming involves epigenetic, neuroendocrine, hormonal receptor, and metabolic alterations involving the placenta and fetus.²⁹⁸⁻³⁰⁶

Epigenetic effects include genetic imprinting. Imprinted genes are a class of genes in placental mammals and marsupials whose expression depends on the parental origin.²⁹⁸⁻³⁰⁴ Imprinting is controlled epigenetically (by such factors as nutrition) via DNA methylation and chromatin modifications. In mice, imprinted genes in the placenta regulate the supply of nutrients; in the fetus, they control nutrient metabolism.²⁹⁸ In mice, approximately 60 imprinted genes have been identified, and for most the imprinting status is conserved in humans; many of these genes are involved in the control of fetal growth.³⁰⁴ Paternally expressed imprinted genes tend to enhance and maternally expressed genes tend to suppress fetal growth. Knockout of paternally expressed genes for IGF2, PEG1, PEG2, and insulin result in IUGR, whereas knockout of the maternal genes *H19*, *IGF2R*, or overexpression of *IGF2* results in fetal overgrowth.²⁹⁸ Other genetic alterations including modification of tandem repeats in the insulin gene have been described.²⁹⁹

Hormones in the fetus are derived from the placenta, from the mother, from fetal endocrine glands, and from circulating precursors in fetal or placental tissues. These extensive networks linking maternal-placental-fetal endocrine interactions, and the apparent plasticity of developing endocrine and metabolic systems, facilitate endocrine system programming. As discussed earlier, the programming may be relatively system limited.²⁷⁹⁻²⁸⁷ Other examples include the observation many years ago that diethylstilbestrol administration to pregnant women increased the prevalence of vaginal adenocarcinoma in female offspring during the second and third decades of

life.²⁹⁵ More recently, it was shown that prenatal or neonatal diethylstilbestrol exposure in hamsters and mice perturbs normal uterine development by affecting the genetic pathways programming uterine differentiation and results in hyperplastic and neoplastic uterine lesions with increased levels of cJun, cFos, Myc, Bax, and Bcl-x.^{307,308} Excessive androgen exposure during fetal life has been associated with later polycystic ovary syndrome.²⁹⁵ Hormonal programming also is demonstrable in cell lines and in unicellular organisms, in which a single exposure to a hormone can produce persistent alteration of the hormonal response characteristics or of prohormone processing.^{309,310} Undernutrition during pregnancy in the rat results in the development of obesity, hyperinsulinemia, and hyperleptinemia during adult life; this phenotype is potentiated when the offspring are fed a high-fat diet.³¹¹ Neonatal leptin treatment normalized the programmed phenotype, indicating that metabolic programming may be reversible during the period of developmental plasticity.³¹¹

The effects of maternal undernutrition and fetal IUGR extend to several systems, and it is hypothesized that excessive maternal-fetal glucocorticoids play a significant programming role. Glucocorticoids have wide-ranging effects in the fetus, altering receptors, enzymes, ion channels, and transporters in a variety of cells and tissues in the late-gestation fetus, and can induce programming of other endocrine systems. Throughout gestation, they modify *GLUT* gene expression in placenta and fetus, influence IGF and glucocorticoid receptor gene expression in various tissues, affect expression of several transcription factors, and affect a wide variety of enzymes in placenta, liver, kidney, intestine, and lung.³⁰¹ Maternal undernutrition, stress, and placental dysfunction are associated with increased maternal and fetal glucocorticoid levels, which contribute importantly to IUGR and programmed alterations in adult endocrine systems and metabolism.^{293,301,302}

MATERNAL AND FETAL MEDICINE

The foregoing review summarizes current understanding of the intrauterine endocrine milieu and highlights progress in this challenging frontier of medicine. This progress has set the stage for fetal endocrine disease diagnosis, therapy for fetal endocrine and metabolic disorders, management of disorders of fetal growth, and diagnosis and management of perinatal or neonatal endocrine dysfunction. In addition, understanding of developmental endocrinology is increasingly relevant to management strategies for premature infants and infants and children with fetal growth retardation and for understanding of the pathogenesis of adult endocrine and metabolic diseases.

We are now entering an era of direct access to and management of the intrauterine environment with provision of medical and surgical fetal therapy, entailing both potential advantages and risks.³¹² With expansion of the application and scope of amniotic fluid fetal cell sampling, maternal plasma DNA analysis, and the advent of fetal visualization and intrauterine fetal blood sampling, direct access for fetal diagnosis is now possible.³¹³⁻³¹⁶ Intrauterine diagnosis and treatment of fetal adrenal and thyroid disorders have become the standard of care.^{317,318} Intravenous nutritional supplementation of fetal sheep can prevent some forms of growth retardation, and chronic fetal therapy through indwelling pumps is feasible in animal fetuses.³¹⁹ These approaches, coupled with increasing availability of synthetic hormones and growth factor agonists and antagonists, facilitate direct fetal endocrine therapy. In

addition, intrauterine stem cell transplantation has been successful in the correction of congenital hematologic disease. The fetus in early gestation is a favorable recipient of cellular therapy, and fetal cell transplantation may be applicable to therapy for selected endocrine and metabolic disease.^{320,321} Finally, there is a growing experience with fetal and neonatal gene therapy in animals.³²²

CHAPTER

23

Disorders of Sex Development

JOHN C. ACHERMANN • IEUAN A. HUGHES

Under most circumstances, the distinction between male and female is considered to be absolute, and sex assignment at birth is instantaneous. The sex assignment based on the birth phenotype is simultaneously accompanied by gender assignment and sex of rearing as male or female. When genital anomalies preclude initial sex assignment, the consensus is that assigning male or female sex remains the preferred option in most societies. Nevertheless, reaching a final decision may be delayed by the nature and complexity of the investigations and assessments required. Ambiguity of the external genitalia sufficient to prevent immediate sex assignment at birth is rare, but it is estimated that abnormalities of the external genitalia that need formal investigation occur in 1 of every 4000 births.¹

Investigation and management of disorders of sex development in infants and young people require an understanding of the embryology of the urogenital system, the genes that control organ development, and the mechanism of normal hormone production and action. Previous editions of this textbook have held that tenet and emphasized the scientific advances that allow the many causes of abnormal genital development to be better characterized.² Many of the advances in identifying key genes involved in normal sex determination and sex differentiation have resulted from detailed clinicopathologic assessment of prismatic cases. However, causation remains unexplained for

many forms of gonadal dysgenesis and for the male who has normal testis determination, androgen production, and action but abnormal external genital development. Application of techniques such as array comparative genome hybridization and high-throughput sequencing is providing information about the disorders that remain unexplained.

Clarity in terminology is essential to understand disorders of sex development and their management. The importance of this element of management was a key component of a statement known as the Chicago Consensus, published by a group of experts working in this field.³ It was resolved that the term *intersex* should be abandoned in view of pejorative elements and be replaced by the generic term *disorders of sex development* (DSDs). Linked to this change was the recommendation to abandon nomenclature such as *male pseudohermaphroditism*, *female pseudohermaphroditism*, and *true hermaphroditism*. Already there is evidence that centers providing a service for DSDs are embracing these new developments, and the terminology is appearing in scientific literature.⁴ The alternative nomenclature is shown in Table 23-1; its use for classification of the causes of DSDs is discussed later.

There has been a major change in how DSDs are managed, with families and the affected individual at an appropriate age being fully engaged in the decision-making

TABLE 23-1

Proposed Revised Nomenclature

Previous Terms	Proposed Terms
Intersex	Disorders of sex development (DSDs)
Male pseudohermaphrodite	46,XY DSD
Undervirilization of an XY male	
Undermasculinization of an XY male	
Female pseudohermaphrodite	46,XX DSD
Overvirilization of an XX female	
Masculinization of an XX female	
True hermaphrodite	Ovotesticular DSD
XX male or XX sex reversal	46,XX testicular DSD
XY sex reversal	46,XY complete gonadal dysgenesis

Reproduced with permission from Hughes IA, Houk C, Ahmed SF, et al. Consensus statement on management of intersex disorders. *Arch Dis Child*. 2006;91:554-562.

process that involves disclosure commensurate with changing cognitive and psychological development. The need to understand the embryology and genetic and hormonal control of typical sex development underpins the investigation and management of a DSD.

DEVELOPMENT OF REPRODUCTIVE SYSTEMS

Development of reproductive systems begins at 4 to 5 weeks' gestation in humans and may be considered complete with the development of secondary sexual characteristics and fertility (i.e., production of viable gametes) after puberty. Sex development is a dynamic process that requires the appropriate and timely interaction of a multitude of genes, proteins, signaling molecules, paracrine factors, and endocrine stimuli.⁵⁻⁹ Marked differences in the basic mechanisms of sex determination, differentiation, and

reproductive strategy have evolved in different species, with variability in sex chromosome complement, gonad development, and gametogenesis throughout the animal kingdom.^{10,11} In this chapter, we focus on the basic mechanisms of reproductive development in humans. We also include important insights obtained from studies of normal and transgenic mice and discuss the relevance of these findings to individuals with DSDs.

The three basic processes of normal development are sex determination and sex differentiation, development of the hypothalamic-gonadotroph axis in the fetus, and function of the hypothalamic-pituitary-gonadal (HPG) axis in infancy and childhood. A more detailed explanation of pituitary development is provided in Chapter 22 and of normal and disordered puberty in Chapter 25.

Sex Determination and Sex Differentiation

Sex determination is the process whereby the bipotential gonad develops into a testis or an ovary. *Sex differentiation* requires the developing gonad to function appropriately to produce peptide hormones and steroids.

In the male, the process of sex differentiation involves regression of Müllerian structures (uterus, fallopian tubes, and the upper one third of the vagina), stabilization of Wolffian structures (seminal vesicles, vasa deferentia, and epididymides), and androgenization of the external genitalia (penis and scrotum), and descent of the testes from their origin in the urogenital ridge to their final position in the scrotum (Fig. 23-1).

In the female, the ovary usually is steroidogenically quiescent until the time of puberty, when estrogen synthesis stimulates breast and uterine development and follicular development results in regular menstrual cycles. Defects in ovarian development usually first manifest in adolescence. Ovarian development and differentiation has been viewed in the past as a default process that occurs in the absence of the chromosomal, genetic, and endocrine signals deemed actively necessary to "make a male." Although male sex differentiation is undoubtedly a more active developmental process—as defined in the classic experiments of Alfred Jost¹²—studies of gene expression

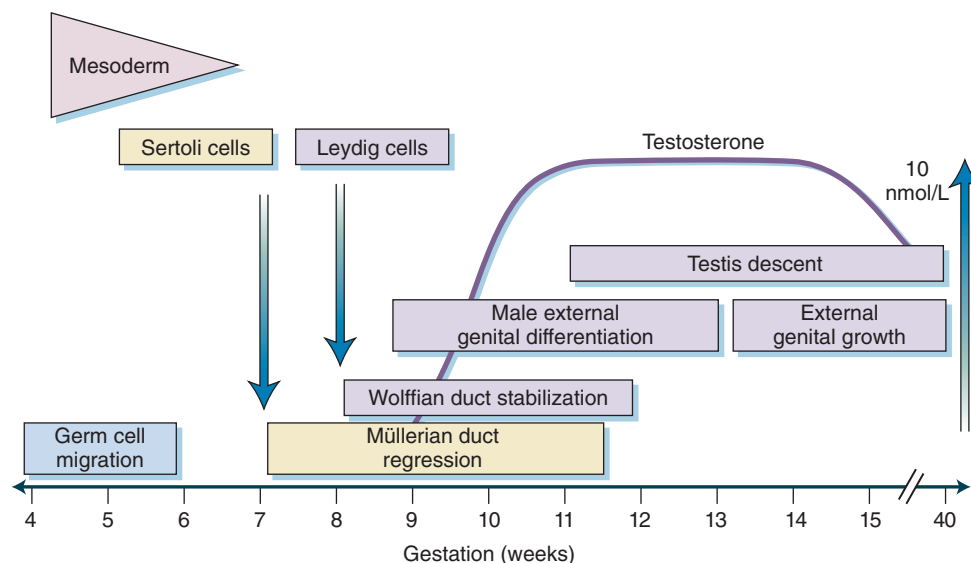

Figure 23-1 Events temporally related to sex differentiation in the male fetus. Mesoderm refers to the tissue source for Sertoli and Leydig cell formation. The continuous line depicts the rise in fetal serum testosterone, with a peak concentration of about 10 nmol/L (300 ng/dL).

Figure 23-2 Division of sex development into three major components provides a useful framework for diagnosis and classification. Chromosomal sex refers to the karyotype (46,XX, 46,XY, or variants). Gonadal sex refers to the presence of a testis or ovary after the process of sex determination. Phenotypic (anatomic) sex refers to the appearance of the external genitalia and internal structures after the process of sex differentiation.

show that a specific complement of genes are implicated in ovarian development and integrity, some of which (e.g., *RSPO1*) may actively antagonize testis differentiation.¹³⁻¹⁵ Even the concept of a fixed and quiescent population of ovarian germ cells at birth has been challenged by some.¹⁶ Ovarian development probably involves many active processes rather than being simply a default mechanism.

Classically, sex determination and sex differentiation can be divided into three major components: chromosomal sex (i.e., presence of a Y or X chromosome), gonadal sex (i.e., presence of a testis or ovary), and phenotypic or anatomic sex (i.e., presence of male or female external and internal genitalia) (Fig. 23-2). None of these processes absolutely defines a person's "sex," and psychosexual development ("brain sex") may be an unpredictable outcome of several biologic factors, as well as environmental and social influences. The presence or absence of a Y chromosome or well-formed testes should not be the focus of how a physician views an individual with a DSD after a diagnosis or management plan has been established. Consideration of sex development in terms of chromosomal sex, gonadal sex, and phenotypic (or anatomic) sex can be a useful way of understanding the processes involved in reproductive development, and it can be a helpful construct for the investigation and diagnosis of patients with these conditions, especially because the (somatic) karyotype is usually readily available as one of the first and potentially guiding investigations. The chromosomal-gonadal-phenotypic model is described in this chapter.

Chromosomal Sex

Chromosomal sex describes the complement of sex chromosomes present in an individual (e.g., 46,XY; 46,XX). In humans, the usual complement of 46 chromosomes consists of 22 pairs of autosomes (identified numerically from 1 to 22 based on decreasing size) and a pair of sex chromosomes (XX or XY) (Fig. 23-3). Other species have different numbers of chromosomes, or they may have sexually dimorphic autosomes.^{10,11}

In humans, chromosomal sex usually is determined at the time of fertilization, when two haploid gametes (ova and sperm, with 23 chromosomes each) fuse to generate a diploid zygote (46 chromosomes). Gametes are ultimately derived from germ cells, which initially replicate their chromosome complement and then undergo a series of two meiotic divisions, meiosis I (reduction division) and

meiosis II, to produce haploid ova or sperm. Normal ova have a single X chromosome. Normal sperm contain a single Y chromosome or a single X chromosome, resulting, respectively, in a 46,XY or 46,XX zygote after fertilization.

Nondisjunction is the failure of either of a pair of sister chromatids to separate during anaphase (Fig. 23-4).^{17,18} *Meiotic nondisjunction* during gametogenesis can result in ova or sperm with gain or loss of sex chromosomal material. Fertilization by such gametes can give rise to a zygote with an imbalance in sex chromosome number, called *sex chromosome aneuploidy*. For example, a zygote with a single X chromosome (i.e., 45,X) defines Turner syndrome, and the presence of an extra X causes Klinefelter syndrome (47,XXY) or triple-X syndrome (47,XXX).¹⁸ Zygotes with no X chromosomal material (45,Y) are nonviable.

Mitotic nondisjunction can occur in the zygote, resulting in an imbalance in sex chromosome number in a proportion or subset of cells, and this is called *sex chromosome mosaicism* (e.g., 45,X/46,XY). In such cases, the two (or more) cell lines originate from a single zygote. This situation differs from *chimerism*, which is the existence of two or more cell lines with different genetic origins in one individual. Chimerism can occur through double fertilization (dispermy) of a binucleate ovum, fusion of two complete zygotes or morulae before implantation, or fertilization by separate sperm of an ovum and its polar body.

Chimerism is difficult to detect if the separate cell lines have the same sex chromosomes. However, if the different cell lines are of different sexes, a 46,XX/46,XY karyotype occurs. This form of true *sex chromosome chimerism* is rare in humans, but it is seen more frequently in cattle in a condition called *freemartinism*, which results from admixture of hematopoietic and primordial germ cells (PGCs) between biovular twins of opposite sex through anastomotic placental channels. A 46,XX/46,XY karyotype also can result from mosaicism. The consequences of some of these events in humans are discussed later (see "Sex Chromosome Disorders of Sex Development").

The Y Chromosome. Although the Y chromosome was initially thought to be "inert," detection of a 46,XY karyotype in males and a 47,XXY karyotype in men with Klinefelter syndrome provided evidence that the Y chromosome carries a gene (or genes) responsible for male sex determination. In fact, a single Y chromosome usually is sufficient to drive testis development, even in the presence of multiple copies of chromosome X.

The human Y chromosome is approximately 60 megabases (Mb) long and represents only 2% of the human genome DNA (Fig. 23-5).^{19,20} The Y chromosome consists of the highly variable and largely genetically inactive heterochromatic region on the long arm, the remnants of a conserved male-specific region, and autosomal-derived regions that are estimated to have been added approximately 80 to 130 million years ago. It is thought that Y-chromosomal genes encode only 60 proteins and that the male-specific regions are undergoing rapid evolution, with marked differences even between humans and chimpanzees.²¹ Although some of these genes have putative roles in growth, cognition, and tooth development, several genes in the male-specific region are involved in reproductive development and function. For example, a cluster of genes at Yq11.22 (e.g., the *AZF* region) is essential for spermatogenesis, and genes within the gonadoblastoma locus (e.g., *TSPY*) increase the risk of malignancy when present in dysgenetic gonads. Deletions of other genetic loci, such as a 1.6-Mb deletion of the Y chromosome that

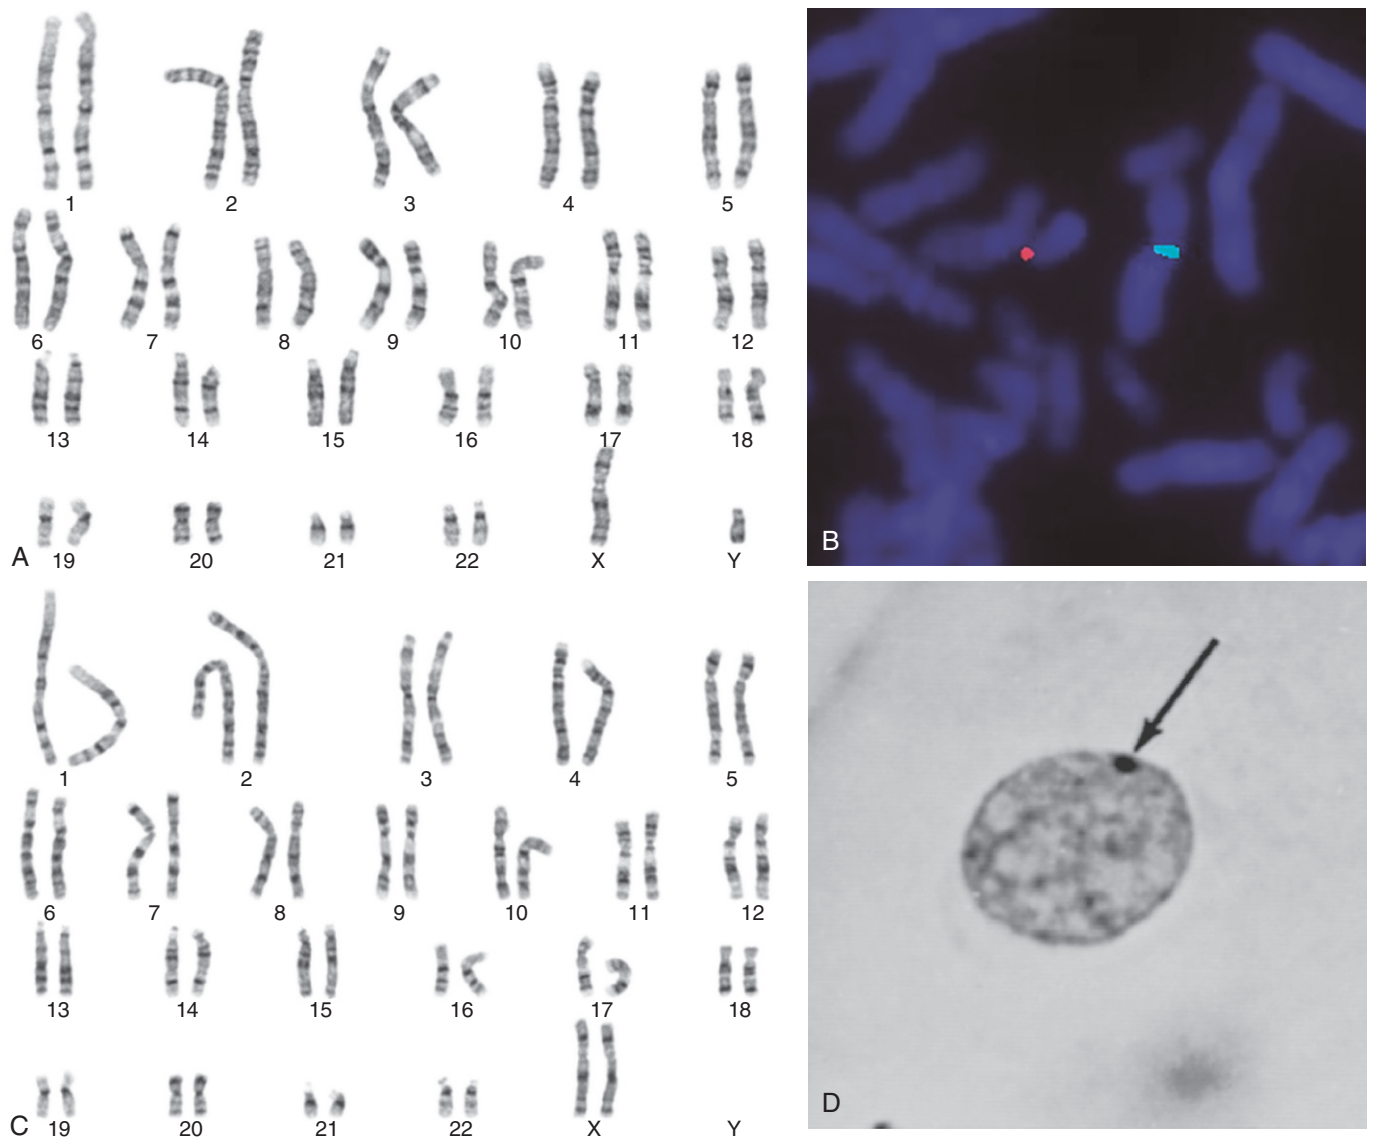

Figure 23-3 Cytogenetic and fluorescence in situ hybridization (FISH) studies. **A**, Male (46,XY) G-banded karyotype. **B**, FISH analysis of a male (46,XY) using fluorescent probes directed against SRY (spectrum red) and against the X centromere (spectrum green). **C**, Female (46,XX) G-banded karyotype. **D**, Photomicrograph shows the X chromatin body (Barr body, arrow) in the nucleus of buccal mucosa cells from a 46,XX female (thionine stain; original magnification, $\times 2000$). removes part of the AZFc region, known as the *gr/gr* deletion, result in susceptibility to germ cell tumors.²²⁻²⁴

The euchromatic (conserved) portion of the Y chromosome consists of a Y-specific segment and regions at the distal ends of the short and long arms, called the *pseudo-autosomal regions* (PARs) (see Fig. 23-5).¹⁹ These PARs are homologous to the distal ends of the short and long arms of the X chromosome and are the only regions involved in pairing and recombination during meiosis. This process is essential for proper distribution of recombined sex chromosomal material to daughter cells. PAR1 (distal short arm, Yp and Xp) contains at least 10 genes, including the homeobox gene *SHOX* (formerly called *PHOG*). *SHOX* haploinsufficiency contributes to the short stature associated with Turner syndrome, Xp- or Yp-deletions, and Léri-Weill syndrome (i.e., dyschondrosteosis). These regions are not subject to dosage compensation (i.e., gene inactivation).

PAR2 (distal long arm) contains genes that mostly encode growth factors and signaling molecules.

The quest for a testis-determining factor on the Y chromosome began more than 50 years ago. The discovery by Eichwald and Silmsler in 1955 of a male cell membrane-specific antigen that causes rejection of skin grafts by female mice led to pursuit of the H-Y antigen as a candidate testis-determining factor.²⁵ In 1987, Mardon and Page proposed that the sex-determining function of the Y chromosome is located within a 140-kb segment of the short arm, within the Y-specific euchromatic portion.²⁶ A zinc finger transcription factor, ZFY, was the initial candidate in this region. However, in 1989, Palmer and colleagues described several 46,XX males who harbored Y-to-X translocations of Y chromosomal material that was distal (telomeric) to the ZFY locus; this discovery finally refuted the role of ZFY as the putative testis-determining gene and focused attention

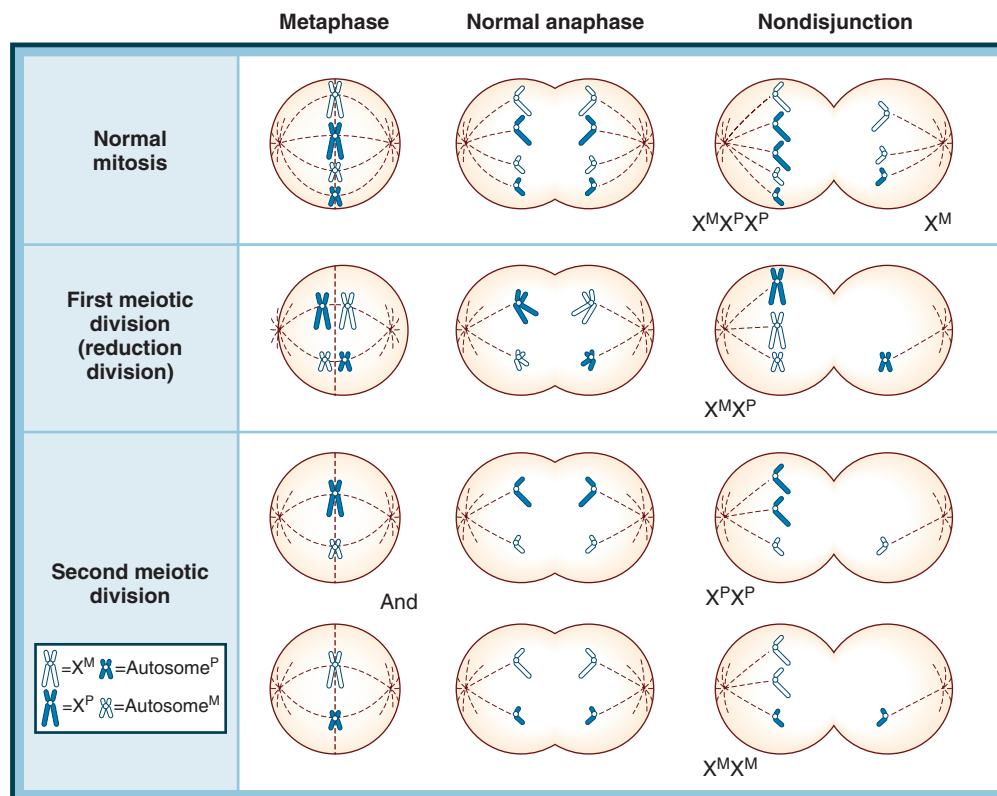

Figure 23-4 A female somatic cell is represented to show the types of cell division. At the metaphase plate are two X chromosomes and two homologous autosomes of group 21 to 22. Division occurs through the centromere, giving rise to two daughter cells of identical chromosomal composition. Replication of each arm into two chromatids takes place while the chromosomes are extended and before the next metaphase. The first meiotic division involves pairing of homologous chromosomes. The centromere does not divide in this cell division. Chance determines whether the maternal (X^M) or paternal (X^P) member of each pair goes to a specific daughter cell. During the complex prophase of first meiotic division (not shown), multiple chiasmata are formed between the chromosomes of each pair, facilitating exchanges of chromosomal segments (crossover) between them. During the second meiotic division, the centromere again divides, giving rise to daughter cells identical to the parent cell. This division more nearly resembles mitosis than the first meiotic division. Nondisjunction can take place in mitosis or in the first or second meiotic division.

on a 35-kb region of the Y chromosome close to the pseudoautosomal boundary.²⁷ This region contained a putative transcription factor subsequently called *sex-determining region Y* (*SRY*) that was expressed in appropriate tissues (see Fig. 23-5).

A series of elegant studies in mice and humans established *SRY* as the likely primary Y-chromosomal testis-determining gene.²⁸⁻³⁰ The first definitive proof came with the generation of transgenic XX mice specifically expressing the *SRY* locus (14 kb); some of these mice had a male phenotype, developed testes (without spermatogenesis), and showed male sexual mating behavior (Fig. 23-6).³¹ This work was supported by reports of deletions and loss-of-function mutations in *SRY* in humans with 46,XY complete gonadal dysgenesis (Swyer syndrome) (see later discussion).^{29,32,33}

The X Chromosome. The X chromosome is a relatively large and gene-rich chromosome compared with the Y chromosome, and it consists of about 160 Mb of genomic DNA (see Fig. 23-5).^{19,34,35} This DNA contains 5% of the haploid genome and more than 1000 expressed genes, of which about 800 encode proteins. Genes on the X chromosome play an important role in sex development in males and females at the level of the gonad and gametogenesis and also in hypothalamic-pituitary (gonadotroph) function (e.g., androgen receptor [AR], KAL1, DAX1 [NR0B1], MAMLD1, SOX3). More than 100 X-chromosome genes are expressed in the testis.³⁴ However, most X-linked genes are

unrelated to sex development and have a diverse range of cellular functions.

The X chromosome contains PARs at the distal end of each arm, similar to the Y chromosome (see Fig. 23-5).¹⁹ These regions and several genes in their boundaries do not undergo X inactivation; they function in an autosomal fashion with their homologs on the Y-chromosome PARs. A large number of genes on the X chromosome are located outside the PARs and do not have homologs on the Y chromosome. Because many of these genes are involved in a wide range of cellular processes unrelated to sex development or sex-specific function, a process must exist to maintain the balance in expressed copy number (i.e., gene dosage) of these genes in both males with a single X chromosome and females with two X chromosomes.

The first insight into a mechanism that could explain correction of this potential imbalance came after identification in 1949 of the X chromatin body (i.e., Barr body) in a proportion of cells in females (see Fig. 23-3). Subsequent studies showed that this X chromatin is derived from only one of the two X chromosomes in interphase nuclei of these somatic cells.³⁶ Grumbach and colleagues showed that the X chromosome giving rise to X chromatin completes DNA synthesis later than any other chromosome.³⁶ These findings led to the concept that only one X chromosome is genetically active during interphase, whereas the other X chromosome is heterochromatinized and relatively inactive. This change in activation state occurs in early gestation in humans (12 to 18 days, late blastocyte stage)

Figure 23-5 Schematic diagrams of the X chromosome (left) and Y chromosome (right) show key regions and genes involved in sex development and reproduction. AR, androgen receptor; ARX, aristaless-related homeobox, X-linked; ATRX, α -thalassemia, X-linked mental retardation; AZF, azoospermia factor; BMP15, bone morphogenetic protein 15; DAX1, dosage-sensitive sex reversal congenital adrenal hypoplasia critical region on the X chromosome type 1; DAZ, deleted in azoospermia; DIAPH2, human homolog of the *Drosophila* diaphanous gene; FMR, fragile X, mental retardation; KAL1, Kallmann syndrome type 1; MAMLD1, mastermind-like domain containing 1 (CXorf6); p, short arm; PAR, pseudoautosomal region; POF1B, actin-binding protein, 34 kd; q, long arm; SOX3, SRY-related HMG box 3; SRY, sex-determining region Y; TSPY, testes-specific protein Y.

and is a multistep process leading to stable and epigenetic silencing of genes on all X chromosomes in excess of one (Lyon hypothesis).³⁷ However, female germ cells beyond the stage of oogonia are exempt from X inactivation, in keeping with the need for a second X chromosome for germ cell and ovarian development.

X inactivation involves a number of important steps, including chromosome counting, random selection of which X chromosome to inactivate (maternal or paternal), and silencing—the initiation, establishment, and maintenance of X inactivation. These complex molecular and cellular silencing processes involve DNA methylation, histone acetylation, and maintenance of inactivation by a noncoding RNA gene *XIST*, located in the X-inactivating center (Xq13), and its antisense transcript TSIX.^{38,39} After inactivation has occurred, the inactive state of that particular X chromosome is transmitted to all descendants of that cell, so that normal females effectively function as genetic mosaics insofar as X-linked traits are concerned. If the initial population of cells is small, skewed X inactivation can occur as a chance event despite random inactivation. In these situations, heterozygous female carriers of an X-linked disorder may manifest symptoms of the condition. Profiles of X inactivation exhibit extensive variability.⁴⁰ Some studies have proposed that certain genes on the X chromosome in males and the active chromosome in females undergo a further process of upregulation so that the ratio of sex chromosome to autosome expression is maintained.^{38,39,41} A subset of genes on the X chromosome may be imprinted.

It was hoped that studying families with ovarian failure or women with Turner syndrome who have chromosomal variations such as partial loss of X material would lead to identification of the loci for key genes involved in ovarian development and function.⁴²⁻⁴⁴ Although several X-chromosomal loci and genes for premature ovarian failure (POF) or primary ovarian insufficiency (POI) have been identified, including those for POF1 (*FMR1* per mutations on Xq26-q28), POF2A (*DIAPH2* on Xq22), POF2B (*POF1B* [an actin-binding protein] on Xq21), and POF4 (*BMP15* on Xp11.2), the gene for POF3 (*FOXL2*) is on 3q23, that for POF5 (*NOBOX*) is on 7q35, that for POF6 (*FIGLA*) is on 2p12, and that for steroidogenic factor 1 or SF1 (*NR5A1*) is on 9q33.⁴⁵⁻⁵¹ Certain variants of Turner syndrome are more likely to involve ovarian dysfunction (e.g., isochromosome for Xq), but it is likely that the accelerated oocyte atresia in Turner syndrome also reflects impaired meiosis and subsequent germ cell apoptosis caused by sex chromosome imbalance, rather than only the loss of certain genetic loci containing ovarian development genes.⁴²

Gonadal Sex

Gonadal sex refers to the development of the gonadal tissue as testis or ovary. The principal embryologic and morphologic changes involved in gonad development are shown in Figure 23-7 and have been described in excellent reviews by Brennan and Capel⁵ and by Wilhelm and colleagues.⁷

The Bipotential Gonad. The primitive gonad arises from a condensation of the medioventral region of the urogenital ridge at approximately 4 to 5 weeks after conception in humans (see Fig. 23-7). The primitive gonad separates from the adrenal primordium at about 5 weeks but remains bipotential (“indifferent”) until about 42 days’ post-conception. Testes and ovaries are morphologically indistinguishable from each other until approximately the 6th week of post-conception (13-mm stage).

Several important genes are expressed in the developing urogenital ridge in mice that facilitate formation of the bipotential gonad; they include *Emx2*, *Lim1*, *Lhx9*, *M33/CBX2*, *Pod1*, *Gata4/Fog2*, *Map3k4*, *Wt1*, and *Nr5a1/Sf1* (Fig. 23-8). Deletion of these genes causes gonadal dysgenesis in mice, but only some of them have been associated with human DSDs.

Emx2 is a mouse homolog of the *Drosophila* empty spiracles (*Ems*) homeobox gene involved in head morphogenesis. It is expressed early in the development of the urogenital system; *Emx2* null mice have absent kidneys, ureters, gonads, and genital tracts and have developmental abnormalities of the brain.⁵² Although heterozygous mutations in *EMX2* have been found in patients with schizencephaly (without gonadal dysgenesis), mutations causing a gonadal phenotype in humans have not been reported.⁵³

The homeobox gene *Lhx1* (also called *Lim1*) is expressed in the intermediate mesoderm and nephrogenic cords. Targeted deletion of this gene in mice results in a failure to develop kidneys, gonads, and anterior brain structures.⁵⁴ Human *LHX1* mutations have not been described, although the expected phenotype would be quite severe. The related homeobox gene *Lhx9* is also expressed in the brain, limb buds, and urogenital ridge, but deletion of this gene in mice leads to gonadal dysgenesis alone.⁵⁵ No human *LHX9* mutations have been identified, despite a study of 41 patients with 46,XY gonadal dysgenesis.⁵⁶

Other genes implicated in early gonad development in mice are *M33/CBX2*, *Pod1*, *Gata4/Fog2*, and *Map3k4*.⁵⁷⁻⁵⁹ *M33* is the mouse homolog of the *Drosophila* polycomb

Figure 23-6 **A**, The $XXSRY^{+}$ mouse (right) has testis development and a male phenotype, providing convincing evidence that *SRY* is a testis-determining gene. A normal XY male littermate is shown for comparison (left). **B**, Model of the structure of the *SRY* high-mobility group (HMG) box bound to DNA. The HMG domain contains three α -helices (red), which adopt an L-shaped conformation. Binding of this region of *SRY* to the minor groove of DNA (green) causes it to bend and unwind. (**A**, Courtesy of Professor Robin Lovell-Badge, National Institute of Medical Research, London, UK; **B**, From Harley VR, Clarkson MJ, Argentaro A. The molecular action and regulation of the testis-determining factors, *SRY* [sex-determining region on the Y chromosome] and *SOX9* [*SRY*-related high-mobility group {HMG} box 9]. *Endocr Rev.* 2003;24:466-487, with permission of The Endocrine Society, copyright 2003.)

Figure 23-7 Schematic representation of the principal morphologic and functional events during early gonad or testis development in humans. DHT, dihydrotestosterone. (Modified from Achermann JC, Jameson JL. Testis determination. *Top Endocrinol.* 2003;22:10-14, with permission of Chapterhouse Codex.)

Figure 23-8 The flow chart provides an overview of the major events involved in sex determination and sex differentiation. Mutations or deletions in the genes reported to cause disorders of sex development in humans are shown in upper case. The genes and factors shown in lower-case letters have been proposed to play an important role in sex development, largely based on results from studies of mice.

gene, which may play a role in chromatin modification and gene silencing. Deletion of this gene in mice causes impaired 46,XY sex development through effects early in the sex development pathway, and disruption of the human homolog, *CBX2*, has been reported in a 46,XY child with a female phenotype and ovaries.^{57,58} *Pod1* encodes a basic helix-loop-helix transcription factor that appears to be essential for gonad development in both sexes in mice.⁵⁹ *Gata4* (and its cofactor, *Fog2*) encodes a transcriptional regulator involved in early gonadal and cardiac development. Mice with deletions of these genes have cardiac defects and variable gonadal phenotypes.^{60,61} Haploinsufficiency and point mutations in *GATA4* have been identified in patients with cardiac defects, and resulting human mutations associated with gonadal dysgenesis has been reported.^{61a}

Signaling pathways may play a role in early gonad development. For example, deletions of multiple components of the insulin signaling pathway (i.e., insulin receptor, insulin-related receptor, and insulin-like growth factor 1 receptor) disrupt the early stages of testis development and downstream *SRY* expression in mice, whereas alterations in *Map3k4* (formerly called *Mekk4*) affect mitogen-activated protein kinase kinase signaling, resulting in impaired gonadal growth, altered mesonephric cell migration, and reduced *SRY* and *SOX9* expression.^{62,63} This work adds to the body of literature showing the importance of signaling factors in endocrine development. Other factors implicated in gonadal development in mice include the transcription regulators *Cited2* and *Pbx1*.^{64,65}

The role of transcription factors such as the product of the Wilms' tumor 1 gene (*WT1*) and SF1 in early gonad development has become better understood as murine models are characterized, and alterations in these genes have been found in patients with impaired gonad development (see "46,XY Disorders of Sex Development" and Fig. 23-8).

The *WT1* gene (11p13) encodes a four-zinc finger transcription factor expressed in the developing genital ridge, kidney, gonads, and mesothelium.^{66,67} Homozygous deletion of the gene encoding *Wt1* in mice prevents gonad and kidney development.⁶⁸ The *WT1* protein is subject to complex post-translational modification and splicing processes, and it is thought that at least 24 *WT1* isoforms exist.⁶⁹ The two most common variants are an isoform with alternative splicing of exon 5 and insertion of an additional 17 amino acids in the middle of the protein and an isoform that uses an alternative splice donor site for exon 9, resulting in the addition of three amino acids (lysine, threonine, and serine; called +KTS) between zinc finger 3 and 4. It is thought that +KTS and -KTS isoforms have different cellular functions and differential effects on gonad and renal development.⁷⁰ The ratio of +KTS to -KTS isoforms may be important in testis development, with the +KTS isoform having a cell-autonomous role in regulating *SRY* expression and influencing cellular proliferation and Sertoli cell differentiation.⁷¹ *WT1* also regulates expression of *Sf1* and *SOX9* in mice and may oppose β -catenin pathways. Although significant insight into the roles of different *WT1* isoforms is being obtained from transgenic mice, the overall role of *WT1* in cellular biology is complex and incompletely understood.

In humans, *WT1* transcripts can be detected in the indifferent gonadal ridge when it first forms at 32 days after ovulation.⁷² Deletions or mutations of *WT1* cause well-defined syndromes in humans. Haploinsufficiency of *WT1* due to deletion of the chromosomal locus containing *WT1* and *PAX6* (11p13) causes WAGR syndrome (Wilms' tumor,

aniridia, genitourinary abnormalities, and mental retardation).⁷³ Dominant negative point mutations in *WT1* cause Denys-Drash syndrome (gonadal dysgenesis, genital ambiguity, nephropathy, and predisposition to Wilms' tumor),⁷⁴ whereas mutations in the exon 9 splice site of *WT1*, causing an altered ratio of +KTS to -KTS isoforms of *WT1*, result in Frasier syndrome (gonadal dysgenesis, late-onset nephropathy, and predisposition to gonadoblastoma) (see "46,XY Disorders of Sex Development" and Fig. 23-20).^{75,76} Although these isoforms may play different roles in regulating various stages of renal and gonad development, it is likely that significant phenotypic overlap in the latter two conditions exists.⁷⁷

Another key transcription factor expressed in the urogenital ridge is steroidogenic factor 1 (SF1, *NR5A1*).⁷⁸ SF1 is a member of the nuclear receptor superfamily that regulates the transcription of at least 30 genes known to be involved in gonadal development, adrenal development, steroidogenesis, and reproduction. In mice, complete deletion of the gene encoding SF1 results in apoptosis of the developing gonad and adrenal gland during early embryonic development.⁷⁹ Other features of these homozygous-deleted animals include persistent Müllerian structures and impaired androgenization in XY animals, hypogonadotropic hypogonadism, abnormalities of the ventromedial hypothalamus, altered stress responses, and late-onset obesity in adult animals rescued by adrenal transplantation.⁸⁰ Heterozygous animals have reduced gonadal size and impaired adrenal stress responses.⁸¹

SF1 is expressed during the early stages of urogenital ridge formation in humans (32 days after ovulation), where it is involved in maintaining gonadal integrity and permitting testicular differentiation.⁷² Consistent with the mouse phenotype, heterozygous or homozygous loss-of-function mutations have been described in two patients with primary adrenal failure, severe 46,XY gonadal dysgenesis, and persistent Müllerian structures (see later discussion).^{82,83} Haploinsufficiency of SF1 is emerging as a relatively frequent cause of 46,XY DSD.^{78,84} Data for mice suggest that *Sf1* plays a critical role in testis development and facilitates *SRY* regulation of *SOX9* expression.⁸⁵ Although SF1 was originally thought to play a less significant role in the ovary compared with the testis, studies in mice and humans show that SF1 is also an important regulator of ovarian integrity and function.^{51,86,87}

In addition to the single-gene defects outlined previously, several chromosomal duplications or deletions have been associated with impaired gonad development in patients. Dosage-sensitive overexpression or underexpression of key factors in these regions may interfere with normal sex development. For example, duplication of a region of the X chromosome (Xp21, dosage-sensitive sex reversal) containing the gene encoding *DAX1* (*NROB1*) has been reported in several 46,XY patients with impaired testicular development or ovotestes.⁸⁸ These reports suggest that the orphan nuclear receptor *DAX1* may act to antagonize testis development as an anti-testis gene. This concept was supported by studies in mice (*Mus poshiavinus*) in which overexpression of *DAX1* caused impaired male development in the presence of a weakened *SRY* locus.⁸⁹ However, targeted deletion of *Dax1* in a similar mouse strain also caused impaired testis development or ovotestis. Patients with X-linked adrenal hypoplasia congenita due to mutations in *DAX1* have abnormal testis architecture and infertility, suggesting that critical doses of these factors have important roles; underactivity or overactivity could have deleterious effects at different stages of gonadal development.⁹⁰

Impaired gonadal development has been described in a 46,XY individual with duplication of 1p35 that resulted in overexpression of the signaling molecules WNT4 and RSPO1, further supporting the concept that genes in certain loci have a role in opposing testis development.⁹¹

In addition to these regions of genomic duplication, many chromosomal rearrangements and deletions have been described in individuals with reproductive disorders. The most frequent ones associated with abnormalities of testis development (i.e., 9p24, 10q25-qter, Xq13, or 16p13.3-pter) are considered in later sections of this chapter.

Primordial Germ Cell Migration. PGCs are the embryonic precursors of gametes (spermatocytes or ova). Surprisingly, in all species, PGCs arise some distance from the developing gonad and undergo a process of migration during the early stages of embryogenesis.^{92,93} In humans, PGCs arise from pluripotent epiblast cells and are initially located in the 24-day embryo in a region of the dorsal endoderm of the yolk sac, close to the allantoic evagination (see Fig. 23-7). After mitotic division, PGCs migrate into the primitive gonad (between 4 and 5 weeks' gestation) under the influence of signaling molecules, receptors, and extracellular matrix proteins such as KIT, the KIT ligand KITLG (formerly called Steel), β_1 -integrin, E-cadherin, interferon-induced transmembrane protein 1 (IFITM1), and IFITM3.⁹⁴ Hindgut expansion may also regulate or facilitate this process. Gonadal colonization is mediated by CXCL12 (previously called SDF1) and its receptor CXCR4 and influenced by CXCR7.

In the first few months of gestation, PGCs undergo multiple cycles of mitotic division. In the testis, a self-renewing population of germ cells exists. These undifferentiated PGCs are maintained by factors such as POU5F1 (also called OCT4), but they commit to differentiation in response to the expression of specific signaling molecules and transcription factors. After several cycles of mitotic division, these cells enter mitotic arrest.⁹⁵ Subsequent testicular development can occur in the absence of this germ cell population.⁹⁶ Meiosis occurs only during the progress of spermatogenesis during puberty (see Chapter 19).

In the developing ovary, primordial ova (oogonia) undergo mitotic expansion in the first few months of gestation (5 to 24 weeks), followed by meiotic division (8 to 36 weeks) and a process of meiotic arrest (oocytes).^{94,95} Although it was originally thought that entry into meiosis occurred autonomously, data suggest that retinoic acid signaling from the mesonephros stimulates this process.^{97,98} Male germ cells may be protected from this signal by their location within the testis cord and by Sertoli cell expression of the cytochrome P450 isoenzyme 26B1 (CYP26B1), which breaks down retinoic acid. Meiotic arrest occurs in the first prophase, when the chromatids of homologous pairs have begun to separate but are fixed by chiasmata (diplotene stage), and it is maintained by G protein-coupled protein 3 (GPR3).⁹⁹ The presence of these PGCs and subsequent meiotic oocytes is critical for differentiation of prefollicular cells into follicular cells and for the maintenance of ovarian development (see Chapter 17).

More than 6 million oogonia and prophase oocytes exist in the developing ovary at about 16 weeks' gestation, and formation of oogonia from PGCs ceases by the 7th month. At that stage, some oocytes remain in undifferentiated nests, whereas others associate with somatic pregranulosa cells to form primitive or primordial follicles. However, approximately 80% of oogonia fail to form follicles and undergo apoptosis, so that only 1 million germ cells are

present in the ovary at the time of birth. These "resting" primordial follicles can remain in that stage of development throughout the woman's reproductive life, and meiosis progresses only in response to ovulation of the graafian follicle (approximately 400 times in a woman's reproductive lifetime). It was once widely held that the population of germ cells present at birth represented a fixed pool that was gradually reduced with time through apoptosis and ovulation; however, this view has been challenged by reports of a potential self-renewing population of germline stem cells in the mouse ovary that are active into adult life.¹⁶ Whether such mechanisms exist in primates remains a subject of debate.^{94,100}

Testis Determination. Testis determination is an active process that begins at about 6 weeks' post-conception in humans and consists of several distinct genetic and morphologic events.^{5,7} One of the first and most significant events in testis determination is a transient wave of SRY expression through the undifferentiated gonad. Data from several species indicate that SRY expression must reach a certain threshold within a definite time window for testis development to occur.^{7,101,102} Initially, this occurs centrally, followed by expression in cells located at the cranial and caudal poles.

In humans, SRY is a single-exon gene (Yp11.3) that encodes a 204-amino-acid, high-mobility group (HMG)-box transcription factor.^{28,101} Mutations and deletions in SRY tend to cluster within the region encoding the HMG box and have been reported in approximately 10% to 15% of patients with sporadic or familial 46,XY gonadal dysgenesis (see "46,XY Disorders of Sex Development" and Fig. 23-21).^{29,32,101} As described earlier, translocation or transgenic expression of SRY is sufficient to induce testis development in XX patients and mice (see "The Y Chromosome" and Fig. 23-6).³¹

In humans, SRY is first detected in the XY gonad at approximately 42 days' post-conception, just before differentiation of the bipotential gonad into a testis.¹⁰³ Expression levels peak from approximately day 44, when testicular cords are first visible, but unlike in the mouse, SRY expression does not switch off completely in humans. Instead, low-level SRY expression is confined to Sertoli cells (day 52), where it persists into adulthood.

The HMG box of human SRY is a 79-amino-acid structure that has moderate homology with SRY in other species (approximately 70%) and with the HMG box of related SOX (SRY-like HMG box) proteins (60%) (see "46,XY Disorders of Sex Development" and Fig. 23-21).¹⁰¹ The HMG box consists of three α -helices, which are able to adopt an L-shaped or boomerang-shaped configuration (see Fig. 23-6). The HMG box binds to variations on specific response elements (ACAAT/A) in the minor groove of DNA and induces a 40- to 85-degree structural bend in its target, depending on the sequence. The precise function of protein-directed DNA bending is not known, although this interaction results in minor groove expansion, DNA unwinding, and altered base stacking.^{101,104-106} These effects likely alter DNA architecture in chromatin and may permit the interaction of other protein complexes with the DNA, resulting in activation or repression.

Other important domains in SRY are two nuclear localization signals that can interact with calmodulin and importin- β to regulate cellular localization¹⁰⁷; several serine residues in the amino-terminus of SRY that can undergo phosphorylation and influence DNA binding¹⁰⁸; and a carboxyl-terminal, 7-amino-acid motif that interacts with PDZ domains of SRY-interacting protein 1 (SIP1).¹⁰⁹ This

interacting protein is thought to be important for SRY function in humans, because it can replace the function of the long C-terminal, glutamate-rich repeat domain (285 amino acids) of SRY found in mice. Human SRY lacks a classic transactivation domain; most human mutations in SRY interfere with DNA binding or nuclear localization.^{101,105,110,111}

SRY expression is thought to switch the fate of the progenitor cells to that of pre-Sertoli cells; elegant studies of chimeric XX-XY gonads have shown that most Sertoli cells are XY derived.¹¹² These SRY-positive cells can signal to other cell lineages to induce male-specific differentiation.^{5,113-116} The onset of SRY expression is followed by marked cellular proliferation and the migration of mesonephric cells into developing testis (Fig. 23-9).^{5,117-119} These mesonephric cells are thought to differentiate into Leydig, endothelial, and peritubular myoid cells, depending on their interactions with somatic cells in the gonad. However, although SRY was shown convincingly to be the primary testis-determining gene more than 15 years ago, relatively little is known about the regulation of SRY expression.

Figure 23-9 Model of SOX9 regulation required for maintenance of gonadal phenotype in mammals. During initial phases of sex determination, SRY upregulates SOX9 expression. SOX9 expression in male gonads is activated and maintained by subsequent positive autoregulatory loops involving SOX9 itself, together with FGF9 and prostaglandin D₂ signaling. In contrast, β-catenin stabilization by WNT4 and RSPO1 signaling suppresses SOX9 expression in female gonads. After birth, β-catenin activity declines. In adult female gonads, FOXL2 and estrogen receptors (ESR1 and 2) are required to actively repress SOX9 expression to ensure ovarian somatic cell fate. The transcriptional repression of SOX9 by FOXL2 and estrogen receptors is necessary throughout the lifetime of the female to prevent transdifferentiation of the somatic compartment of the ovary into a testis. PTGDS, prostaglandin D synthase. (From Uhlénhult NH, Jakob S, Anlag K, et al. Somatic sex reprogramming of adult ovaries to testes by FOXL2 ablation. *Cell*. 2009;139:1130-1142, with permission of Cell Press, copyright 2009.)

Some studies have shown that SF1, WT1, and SP1 can all regulate SRY promoter activity in vitro, and signaling pathways may be important, but the exact mechanisms that activate SRY in vivo remain poorly understood.¹²⁰ The downstream targets of SRY are also unknown, although SOX9 is an obvious candidate. Recent evidence has demonstrated that SRY and SF1 can synergistically regulate SOX9 expression through a testis-specific enhancer region (TESCO).^{85,113} It is unclear whether other direct SRY target genes exist or whether SRY also acts as a negative regulator of factors involved in testis repression, such as R-spondin 1 or β-catenin.¹²¹

SOX9 is an SRY-related HMG box factor comprising 3 exons (509 amino acids) that shows upregulation and nuclear localization in the developing male gonad shortly after the initial wave of SRY expression.^{101,122-125} In humans, SOX9 becomes strongly localized to the developing sex cords at 44 to 52 days after ovulation and is expressed in Sertoli cells thereafter.¹⁰³ SOX9 is also expressed in the developing cartilage under the regulation of parathyroid hormone-related protein (PTHrP)/Indian hedgehog signaling pathways. Heterozygous mutations or deletions in SOX9 cause campomelic dysplasia, a form of severe skeletal dysplasia associated with variable gonadal dysgenesis in approximately 75% of patients.^{101,106,122,123} Mutations have been found in the HMG box of SOX9, in the C-terminal transactivation domain, and in a region that interacts with heat shock proteins (e.g., HSP70) (see “46,XY Disorders of Sex Development” and Fig. 23-21).^{101,126}

Although SOX9 is a key target of SRY, an important body of evidence has emerged to show that SOX9 can be a testis-determining factor in its own right. In addition to the gonadal dysgenesis caused by loss-of-function mutations in SOX9, overexpression of SOX9 due to mosaic duplication of the locus containing SOX9 (17q24.3-q25.1) has been reported in a 46,XX individual with ambiguous genitalia.¹²⁷ Transgenic expression of SOX9 in mice results in testis development in XX animals, and the XX *odsex* (*Ods*) mouse develops as a male due to disruption of a regulatory element 1 Mb upstream of SOX9 that causes testis-specific overexpression of SOX9 during development.¹²⁸⁻¹³⁰ Similar disruption of an upstream *cis*-regulatory region resulting in SOX9 overexpression has been proposed as a cause of 46,XX testicular DSD.¹³¹ The regulatory region of the SOX9 promoter is very large. Breakpoints have been reported up to 350 kb from the start of the SOX9 gene in patients with campomelic dysplasia and gonadal dysgenesis. In mice, SOX9 may mediate its effects through direct interactions with other target genes (e.g., *FGF9*, *PTGDS*, *AMH*) and through the mutual degradation of β-catenin, thereby promoting testis development pathways rather than those opposing testis development (see Fig. 23-9).¹¹³ Autoregulatory loops may also be important in maintaining SOX9 expression.

Around the time of SRY and SOX9 expression (and nuclear localization), the developing testis undergoes a series of distinct cellular and morphologic changes (Fig. 23-10). Understanding of these processes has resulted largely from studies in mice.⁵ As outlined earlier, the first stage of testis development in mice involves a proliferation of Sf1-positive somatic cells that results in an increase in Sertoli cell precursors and Sertoli cell differentiation. This process is influenced by growth factors such as Fgf9 and the receptor Fgfr2.¹³² These primitive Sertoli cells coalesce with peritubular myoid cells to form primary sex cords, which then condense to form primitive seminiferous cords (at about 7 weeks' post-conception in humans). Sex cord development is supported by a striking reorganization of the gonadal vasculature in the developing testis, but not

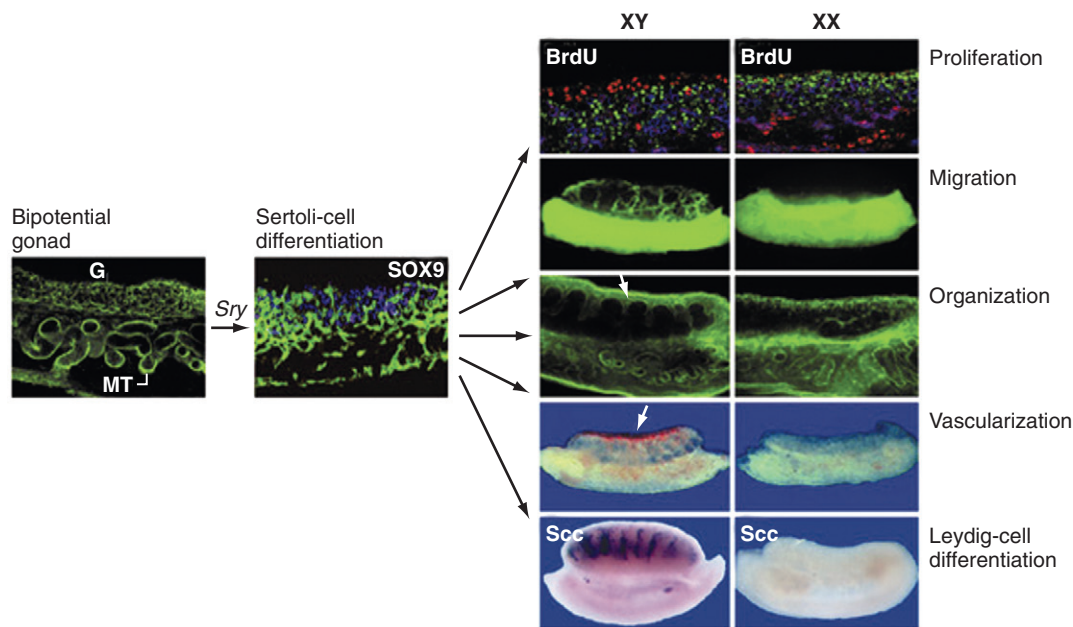

Figure 23-10 Key morphologic changes in the developing testis in mice. No morphologic differences between the XY and XX gonad are seen during the bipotential gonad stage at 10.5 to 11.5 days postcoitum (dpc) (far left). In XY gonads, SRY expression is followed by expression and nuclear localization of SOX9 (blue) in pre-Sertoli cells (middle), resulting in Sertoli cell differentiation by 11.5 dpc (vasculature and germ cells are labeled with platelet–endothelial cell adhesion molecule [PECAM] and appear green). Between 11.5 and 12.5 dpc, distinct changes occur in the XY gonad (near right column), which are not seen in the XX gonad (far right). These changes include proliferation of coelomic epithelial cells (measured by BrdU incorporation; red, arrow); migration of cells from the mesonephros (shown by recombinant culture of a wild-type gonad and a mesonephros in which the cells express green fluorescent protein); structural organization of testis cords (detected by laminin deposition, green); male-specific vascularization (by light microscopy with blood cells indicated by an arrow); and Leydig cell differentiation (detected by mRNA in situ hybridization for the steroidogenic enzyme P450scc). MT, basal lamina of mesonephric tubules; G, gonad. (From Brennan J, Capel B. One tissue, two fates: molecular genetic events that underlie testis versus ovary development. *Nat Rev Genet.* 2004;5:509–521, with permission of Macmillan Publishers Ltd.)

in the ovary (see Fig. 23-10).^{5,133} These changes include the development of a discrete coelomic vessel, restriction of endothelial cells to the interstitial space between the sex cords, and increased branching of blood vessels. The development of these vascular systems is influenced by growth factor signaling systems, such as *Pdgfra/Ptgds*, and can be repressed by the *Wnt4/β-catenin/follistatin* systems.^{134–136} These changes in vascular architecture play an important role in determining cellular patterning and organization in the developing testis, in supporting paracrine interactions, and in the export of androgens from the developing Leydig cells to the perineal and systemic circulation.

Although the expression of SRY plays a crucial role as a testis-determining factor, it is becoming clear that many other factors are necessary for early testis development (see Fig. 23-8). Some of these factors may be expressed exclusively within the developing testis, whereas others may play a facilitative role in supporting gonad development and are also expressed in other developing tissues (e.g., brain).

Desert hedgehog (DHH) is a member of the hedgehog signaling pathway that is expressed in mouse embryonic Sertoli cells and interstitium, and it plays a key role in the differentiation of peritubular myoid cells through its action on the Patched receptor.¹³⁷ The peritubular myoid cells are flat, smooth muscle–like cells that ensheath the testis cords and are necessary for cord development and structural integrity. Deletion of the *Dhh* gene in the mouse leads to impaired differentiation of peritubular myoid cells and Leydig cells and to impaired androgenization in males.^{138,139} In humans, *DHH* mutations have been reported in patients with impaired testicular development, with or without minifascicular neuropathy.¹⁴⁰

DMRT1 (double sex, Mab3–related transcription factor 1; 9p24.3) encodes a 373-amino-acid protein that is homologous to the sex-development *double sex* gene of *Drosophila* and the *Mab3* gene of *Caenorhabditis elegans*. *DMRT1* shows a male-specific pattern expression in the developing genital ridge and is expressed in the developing Sertoli cells by 7 weeks' post-conception.^{141,142} Deletion of *Dmrt1* in the mouse results in normal androgenization but regression of testes later in embryonic development.¹⁴³ No specific point mutations in *DMRT1* have been described in humans, but impaired gonadal development and 46,XY DSDs are well-established features of the 9p deletion syndrome. Disruption of *DMRT* is the most likely explanation for this condition.¹⁴⁴

ARX (aristaless-related homeobox, X-linked gene) encodes a transcription factor that regulates neuronal migration, brain development, and Leydig cell development. Deletion of *Arx* in the mouse causes abnormal neuronal development and a block in Leydig cell differentiation.¹⁴⁵ Mutations in *ARX* in humans cause a condition known as X-linked lissencephaly and ambiguous genitalia (XLAG).¹⁴⁵ *MAMLD1* (mastermind-like domain-containing 1; previously called *CXORF6*) is a regulator of fetal Leydig cell function. Defects in *MAMLD1* have been reported in infants with severe hypospadias.¹⁴⁶ Signaling through *Pdgfr* and the *Pdgfra* also has been shown to be important in fetal and adult Leydig cell differentiation after deletion of these genes in mice.¹⁴⁷

Other genes proposed to play a role in early testis development have been identified from chromosome deletions or differential expression studies. For example, *Tescalcin* encodes a calcium-binding protein that is expressed in the early mouse fetal testes.¹⁴⁸ *ATRX* (Xq13.3; also known as

XH2 or *XNP*) is a transcription factor deleted in the α -thalassemia mental retardation syndrome.^{149,150} The syndrome includes a range of genital phenotypes from partial gonadal dysgenesis to micropenis. The locus containing *SOX8* is deleted in the ATR-16 (α -thalassemia mental retardation) syndrome affecting the tip of chromosome 16p,¹⁵¹ and terminal deletions of chromosome 10 (10q25-qter) are frequently associated with urogenital abnormalities and sometimes with complete gonadal dysgenesis.¹⁵² More than 50 syndromic conditions or human chromosomal rearrangements have been associated with a range of urogenital phenotypes.¹⁵³ Furthermore, gene expression profiling in the embryonic mouse gonad is revealing a host of expressed and differentially expressed genes involved in testicular and ovarian development. Higher-resolution analysis of chromosomal changes using techniques such as array comparative genome hybridization is allowing the identification of much smaller chromosomal deletions, duplications, and rearrangements that may affect genes related to sex development.¹⁵⁴

Ovary Development. For many years, ovary development was thought to be a constitutive (default) process, because an external female phenotype occurs in the absence of gonadal tissue and Müllerian structures persist in the absence of anti-Müllerian hormone (AMH; also known as Müllerian-inhibiting substance [MIS]). Although the presence of PGCs was known to be necessary to maintain ovarian integrity, evidence now shows that ovarian development is an active process that requires expression of a set of specific genes and factors necessary to actively prevent testis development.

Several genes, including *Dazl*, *Bmp8b*, *Smad5*, *Gja4* (previously known as *Cx37*), *Foxl2*, and the POF family of genes listed previously, have been implicated in ovarian and follicular development in mice.^{9,45-51} Studies comparing gene expression profiles in the testes and ovaries of mice at critical stages of fetal development (e10.5 to e13.5) have shown that a specific subset of ovarian genes (e.g., follistatin, cyclin kinase inhibitors) are turned on soon after the onset of testis determination.^{13,14} It is unclear whether any ovary-determining genes exist or whether these factors play a role in maintaining ovarian development in the absence of testis-determining gene expression. However, it seems likely that certain active processes are involved, because many of the genes and proteins (e.g., WNT4, RSP01/ β -catenin, FOXL2, estrogen receptors), as well as meiotic germ cells, may antagonize testis development or prevent development of a male-type cell lineage.^{15,155-160} Data in mice suggest that these processes may be ongoing, even in the postnatal ovary (see Fig. 23-9).¹⁶⁰

Phenotypic or Anatomic Sex

The developing gonad produces several steroid and peptide hormones that mediate sexual differentiation and result in the phenotypic sex seen at birth. Alfred Jost first showed the importance of fetal testicular androgens in this process in 1947.¹² In his classic experiments, Jost demonstrated that surgical removal of the gonads during embryonic development of the rabbit resulted in development of female reproductive characteristics, regardless of chromosomal sex of the embryo.

Male Sexual Differentiation

Sertoli Cells and Müllerian Regression. Sertoli cells play a key role in supporting germ cell survival, and they produce two important peptide hormones: AMH and inhibin B. AMH, a glycoprotein homodimer, is a member

of the transforming growth factor- β (TGF- β) superfamily and is first secreted in humans from about 7 weeks' post-conception under the regulation of key transcription factors such as *SOX9*, *SF1*, *WT1*, and *GATA4* (see Figs. 23-1 and 23-7).^{161,162} AMH causes regression of Müllerian structures (e.g., fallopian tubes, uterus, upper two thirds of the vagina) by its paracrine action on the AMH type 2 receptor (AMHR2). This receptor forms a serine/threonine kinase heterodimeric receptor complex with ALK2 (ACVR1) to induce apoptosis through secondary paracrine signals, such as matrix metalloproteinase 2 (MMP2).¹⁶²

Müllerian structures appear to be maximally sensitive to AMH between 9 and 12 weeks' gestation, a time when the developing testis is producing peak concentrations of AMH but before the onset of significant AMH production by the developing ovary. Consequently, boys with mutations in the *AMH* or *AMHR2* genes can present with persistent Müllerian duct syndrome (PMDS) and undescended testes but otherwise normal external genitalia. In contrast, severe forms of 46,XY gonadal dysgenesis can result in persistent Müllerian structures due to impaired Sertoli cell development and AMH release. In some cases, a hemiuterus is present if testicular development is more severely affected on that same side, but it is likely that androgenization of the external genitalia also is impaired. Defects confined to Leydig cell steroidogenesis in 46,XY DSD are not associated with persistent Müllerian structures, because Sertoli cell production of AMH is unaffected. In normal boys, a small Müllerian remnant sometimes persists as a testicular appendage. Inhibin B suppresses pituitary follicle-stimulating hormone (FSH) activity, but its local role during testis development is less clear. AMH and inhibin B may have important functions throughout life at multiple levels of the HPG axis.¹⁶³

Fetal Leydig Cells and Steroidogenesis. Fetal Leydig cells develop within the interstitium of the developing testis and secrete androgens by 8 to 9 weeks' post-conception (see Fig. 23-1).¹⁶⁴ Luteinizing hormone/human chorionic gonadotropin (LH/hCG) receptors are present on the Leydig cells only from 10 to 12 weeks' post-conception, suggesting that the initial secretion of testosterone is independent of hCG and fetal LH. A massive expansion in fetal Leydig cells occurs between 14 and 18 weeks' gestation, resulting in marked increase in testosterone secretion at about 16 weeks.^{165,166} Fetal Leydig cell steroidogenesis is stimulated by placental hCG during the first two trimesters of pregnancy, but the developing hypothalamic-gonadotroph system produces significant amounts of LH from about 20 weeks' gestation.¹⁶⁷

The pathways of testicular steroidogenesis are shown in Figure 23-11. The role of individual enzymes is discussed in relation to individual steroidogenic defects later in this chapter and in several excellent reviews.^{8,168} Cholesterol is taken up into Leydig cells by low-density lipoprotein or high-density lipoprotein receptors or is generated de novo by cholesterol synthesis pathways or from cholesterol ester. Stimulation of the LH/hCG receptor by the appropriate glycoprotein hormone increases the ability of steroidogenic acute regulatory protein (StAR) to facilitate movement of cholesterol from the outer to the inner mitochondrial membrane. The first and rate-limiting step in steroid hormone synthesis involves three distinct reactions: 20 α -hydroxylation, 22-hydroxylation, and cleavage of the cholesterol side chain to generate pregnenolone and isocaproic acid. These steps are catalyzed by a single enzyme, P450_{scc} (CYP11A1).

Pregnenolone is converted to progesterone by the microsomal enzyme 3 β -hydroxysteroid dehydrogenase

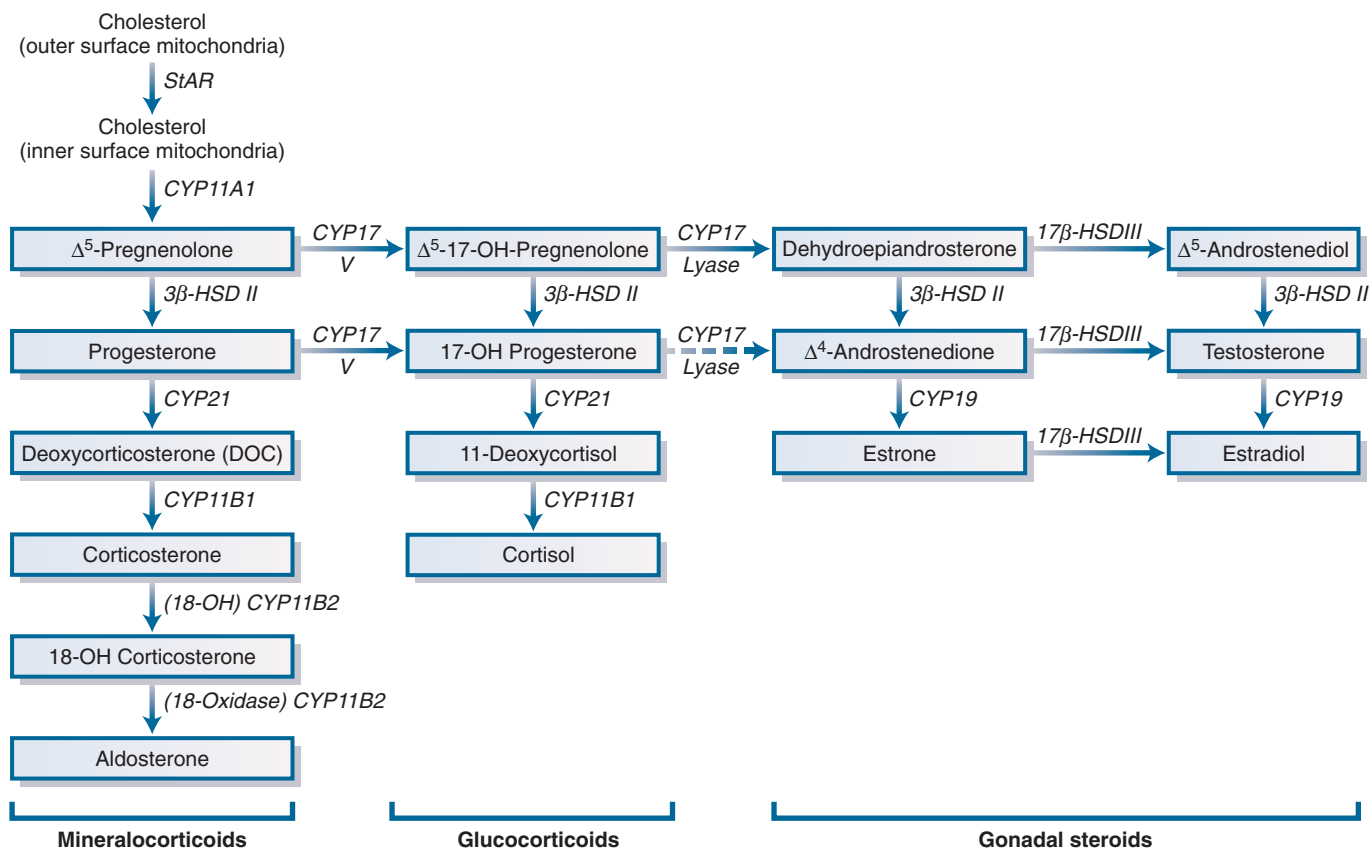

Figure 23-11 Schematic diagram shows the steroid biosynthetic pathways leading to androgen production in the testis. In humans, the main pathway to androgen production is through conversion of 17-hydroxypregnenolone to dehydroepiandrosterone (DHEA) rather than through conversion of 17-hydroxyprogesterone to androstenedione. Subsequent testosterone biosynthesis can occur through conversion of DHEA to androstenedione (by 3 β -hydroxysteroid dehydrogenase type 2 [3 β -HSD II]), followed by the actions of 17 α -hydroxysteroid dehydrogenase type 3 (17 β -HSD III) to generate testosterone, or through the intermediate metabolite androstenediol. During male sex development, testosterone undergoes local conversion to dihydrotestosterone (DHT) by 5 α -reductase type 2 (not shown). The high-affinity action of dihydrotestosterone on the androgen receptor results in androgenization of the external genitalia. The pathways responsible for mineralocorticoid and glucocorticoid synthesis are present in the adrenal gland. Additional or alternative pathways to dihydrotestosterone production may exist in the fetal testis.

type 2 (HSD3B2), or it can undergo 17 α -hydroxylation by P450c17 (CYP17) to yield 17-hydroxypregnenolone. CYP17 also has 17,20-lyase activity, which can cleave the C17,20 carbon bond of 17-hydroxypregnenolone to generate dehydroepiandrosterone (DHEA). This 17,20-lyase activity is favored by the presence of Δ^5 -substrates, redox partners such as P450 oxidoreductase (POR) and cytochrome *b₅*, and serine phosphorylation. These reactions are facilitated by the relative abundance of these factors in Leydig cells in humans, and the main pathway to androgen production is through conversion of 17-hydroxypregnenolone to DHEA rather than through conversion of 17-hydroxyprogesterone (17-OHP) to androstenedione.¹⁶⁹ Subsequent testosterone production can occur through conversion of DHEA to androstenedione (by HSD3B2), followed by the actions of HSD17B3 to generate testosterone, or by the intermediate metabolite androstenediol (see Fig. 23-11). During male sex development, testosterone undergoes local conversion to dihydrotestosterone (DHT) by 5 α -reductase type 2. DHT's high-affinity action on the androgen receptor results in androgenization of the external genitalia. Studies based on the phenotype of patients with POR deficiency and the fetal Tammur wallaby have proposed that an alternative pathway to DHT production may exist in the human fetal testis (see "P450 Oxidoreductase Deficiency").^{170,171}

Local production of testosterone is thought to be necessary for stabilization of Wolffian structures such as the epididymides, vasa deferentia, and seminal vesicles, whereas the potent metabolite DHT induces androgenization of the external genitalia and urogenital sinus (Fig. 23-12). In the male, the urogenital sinus develops into the prostate and prostatic urethra, the genital tubercle develops into the glans penis, the urogenital (urethral) folds fuse to form the shaft of the penis, and the urogenital (labio-scrotal) swellings form the scrotum (Figs. 23-13 and 23-14). The distinction between a clitoris and a penis at this stage is based primarily on size and whether the labia minora fuse to form a corpus spongiosum. The effects of androgenization on the genital tubercle between 8 and 10 weeks' post-conception were shown by Goto and colleagues (see Fig. 23-14).¹⁷²

Testosterone and DHT mediate their effects through the androgen receptor (AR; Xq11-q12), which is a transcription factor (see "46,XY Disorders of Sex Development"). Surprisingly little is known about AR targets in the developing Wolffian structures (testosterone responsive) and in the key target tissues (DHT responsive). However, various degrees of impaired androgen action are seen in a range of syndromic conditions and may reflect defects in genes that mediate target-tissue responsiveness and genital tubercle growth (e.g., *HOXA10*, *HOXA13*).⁷ Studies in mice have

Figure 23-12 Embryonic differentiation of female and male genital ducts from Wolffian and Müllerian primordial tissue before descent of the testes into the scrotum. In females, Müllerian structures persist to form the fallopian tubes, uterus, and upper portion of the vagina. The lower portion of the vagina and urethra are derived from the urogenital sinus. In males, Wolffian structures develop into the epididymides, vasa deferentia, and seminal vesicles, whereas the prostate and prostatic urethra are derived from the urogenital sinus. In some cases, a small Müllerian remnant can persist in males as a testicular appendage.

revealed a number of factors that are necessary for development of the Wolffian ducts (e.g., *Gdf7*, *Bmps4*, *Bmps7*, *Bmps8a*, *Bmps8b*, *Hoxa10*, *Hoxa11*) and for growth of the genital tubercle (e.g., *Fgfs*, *Shh*, *Wnts*, *Hoxa13*, *Hoxd13*, *Bmp/noggin*, ephrin signaling).⁷

Testis Descent. Testicular descent is a two-stage process that starts at about 8 weeks' gestation and is usually complete by the middle of the third trimester.¹⁷³ The initial *transabdominal* stage of testicular descent (8 to 15 weeks) involves contraction and thickening of the gubernacular ligament and degeneration of the craniosuspensory ligament. This stage is mediated by the testis itself after secretion of factors such as insulin-like 3 (*INSL3*, a relaxin-like factor) and its G protein-coupled receptor, *GREAT* (also called *LGR8* or *RXFP2*).¹⁷⁴ Other testicular factors are likely to be involved in testicular descent, because most dysgenetic testes are intra-abdominal. The subsequent *transinguinal* (or inguinoscrotal) phase of testicular descent (25 to 35 weeks) is primarily driven by androgens. The genitofemoral nerve and its neurotransmitter, calcitonin gene-related peptide (CGRP), have also been implicated in this process.

Subsequent Testicular Development. During the second and third trimesters, the testes show several distinct morphologic changes, including a reduction in fetal Leydig cell mass and elongation and coiling of seminiferous cords. There is no further significant development of germ cells during this time, and seminiferous cords do not canalize until later in childhood. Nevertheless, certain developmental insults can affect the testis at this stage. For example, vanishing (absent) testis syndrome is most likely a late fetal

event, because boys with this condition have adequate androgenization and no Müllerian structures.

Female Sexual Differentiation. The processes of female sexual differentiation are less obvious than in the male and do not involve significant changes in the external genitalia. Müllerian structures persist to form the fallopian tubes, uterus, and upper portion of the vagina (see Fig. 23-12). Normal uterine development in mice occurs in the absence of the ovary, but it is not a passive process, because a host of factors are required for uterine development (e.g., *Pax2*, *Lim1*, *Emx2*, *Wnt4/Lp*, *Hoxa13*) and differentiation (e.g., *Wnt7a*, *Hoxa10*, *Hoxa11*, *Hoxa13*, progesterone and estrogen receptors).¹⁷⁵ The lack of local testosterone production leads to degeneration of Wolffian structures. The urogenital sinus develops into the urethra and lower portion of the vagina, the genital tubercle develops into the clitoris, the urogenital (urethral) folds form the labia minora, and the urogenital (labioscrotal) swellings form the labia majora (see Figs. 23-12 and 23-13).

In contrast to the testis, the developing ovary does not express FSH and LH/hCG receptors until after 16 weeks' gestation. At about 20 weeks' gestation, plasma concentrations of FSH reach a peak and the first primary follicles are formed.¹⁶⁷ By 25 weeks' gestation, the ovary has developed definitive morphologic characteristics. Folliculogenesis can proceed, and a few Graafian follicles have developed by the third trimester. However, the amount of estrogen secreted by the developing ovary is likely to be insignificant compared with placental estrogen synthesis, and the ovary is thought to remain generally quiescent until activation at the time of puberty. Abnormalities in several factors (e.g., connexin 37, *GDF9*, FSH receptors, estrogen receptor- α , progesterone receptor) can interfere with this early folliculogenesis.

Several conditions can affect female sexual development in utero. Exposure of the fetus to androgens results in androgenization of the external genitalia.¹⁷² A uterus is present, but the local testosterone concentration typically is not sufficient to stabilize Wolffian structures because the androgens are usually adrenal in origin. Most frequently, androgenization of the 46,XX fetus results from disorders of adrenal steroidogenesis (e.g., 21-hydroxylase [*CYP21*] deficiency, 11 β -hydroxylase deficiency, *POR* deficiency) or from mild androgenic effects after conversion of excess DHEA in *HSD3B2* deficiency (discussed later). Rare causes of androgenization include aromatase deficiency, glucocorticoid resistance, ovotesticular DSD, and maternal virilizing tumors (e.g., luteoma of pregnancy). Exposure to certain chemical agents in pregnancy has been proposed as a cause of fetal androgenization. For other developmental abnormalities of the female genital tract (e.g., Mayer-Rokitansky-Küster-Hauser syndrome) see "46,XX Disorders of Sex Development."

Psychosexual Development

Psychosexual development is traditionally viewed as having several distinct components (Table 23-2). *Gender identity* refers to a person's self-representation or identification as male or female (with the caveat that some individuals may not identify exclusively with either). *Gender role* (sex-typical behaviors) describes the expression or portrayal of psychological characteristics that are sexually dimorphic within the general population, such as toy preferences and physical aggression. *Sexual orientation* refers to choice of sexual partner and erotic interest (e.g., heterosexual, bisexual, homosexual) and includes behavior, fantasies, and attractions.

Figure 23-13 Differentiation of male and female external genitalia. (Adapted from Spaulding MH. The development of the external genitalia in the human embryo. *Contrib Embryol Carnegie Inst.* 1921;13:69-88.)

Figure 23-14 Differentiation of male external genitalia in humans between 8 and 10 weeks postconception (wpc). **A**, Undifferentiated human external genitalia at 8 wpc. **B**, Differentiation of scrotal folds and fusion of the urethral folds (asterisks indicate patent regions on either side) at 10 wpc. gs, genital swelling; gt, genital tubercle; sf, scrotal folds; uf, urethral folds. Scale bars: 500 μ m. (From Goto M, Piper Hanley K, Marcos J, et al. In humans, early cortisol biosynthesis provides a mechanism to safeguard female sexual development. *J Clin Invest.* 2006;116:872-874, with permission of the American Society for Clinical Investigation, copyright 2006.)

TABLE 23-2

Terminology for Gender-Related Behavior

Gender identity	Identification of sex as male or female
Gender role	Expression of sexually dimorphic behavior
	Aggression
	Parenting rehearsal
	Peer and group interactions
	Labeling (e.g., "tomboy")
	Grooming behavior
Sexual orientation	Choice of sexual partner

The past 50 years have seen a number of opposing theories about the origins of psychosexual development and debate about the relative contributions of chromosomes, hormones, brain structure, and societal and family influences on the various components. Much of this work has focused on the study of rodents and nonhuman primate species. For example, Young and colleagues first showed in 1959 that exposure of guinea pigs to testosterone during pregnancy resulted in altered mating behavior of female offspring.¹⁷⁶ These effects may be most pronounced during a critical window of exposure and, in rodents, may depend in part on aromatization of the androgens to estrogens, receptor availability, and social environment.^{177,178} More recently, interest has focused on the role of genes and chromosomes in sex behavior. For example, studies of differential gene expression patterns in the developing mouse brain have shown upregulation of different X and Y chromosomal genes in early embryonic life, even before the onset of significant androgen secretion by the developing testis in males.¹⁷⁹ Studies of mice in which SRY was deleted (XYSRY⁻) or transgenically expressed (XXSRY) showed certain neuroanatomic differences between XY and XX mice independent of gonad development and endocrine status.¹⁸⁰ These findings suggest that factors related to chromosome complement have at least the potential to affect psychosexual development independent of sex hormone action, and a model integrating classic organizational and activational effects with sex chromosome effects may be more appropriate.¹⁸¹

Understanding the complex issues related to human psychosexual development is much more challenging, especially because gender identity is a component of psychosexual development that cannot readily be assessed in nonhuman species. For many years, it was thought that gender identity would be concordant with assigned sex, provided that the child was raised unambiguously and appropriate surgical "correction" and hormone therapies were instituted concordant with the gender chosen. This theory assumed psychosexual neutrality at birth, but it has been challenged by a refocusing on the potential importance of prenatal (e.g., endocrine) and innate (e.g., chromosomal) influences on psychosexual development. Direct data to assess such effects in humans are limited, but studies in women with complete androgen insensitivity syndrome (CAIS) argue against a strong behavioral role for Y chromosome genes alone in human psychosexual development, because the karyotype is 46,XY but psychosexual development is female.¹⁸² However, the gender characteristics of individuals with a Y chromosome and a degree of androgen exposure or responsiveness (e.g., partial androgen insensitivity syndrome [PAIS], 5 α -reductase deficiency) can vary, and long-term gender identity can be difficult to predict.¹⁸³

Prenatal exposure to androgens can also influence certain aspects of psychosexual development in 46,XX

individuals.^{184,185} Girls with congenital adrenal hyperplasia (CAH) who harbor more severe mutations and have more marked genital androgenization are more likely to play more with boys' toys, with long-term effects evident into adulthood.¹⁸⁶ Prenatal androgen exposure can also be associated with other psychological characteristics, such as sexual orientation.^{186,187} However, the association between high prenatal androgen exposure and gender identity is less marked, except perhaps in some cases of testicular DSD.¹⁸⁸ Although gender dissatisfaction (i.e., unhappiness with assigned sex) is more common in individuals with DSD, more than 90% of 46,XX individuals with CAH who are assigned female gender in infancy later identify as female.¹⁸⁹ The causes of gender dissatisfaction are poorly understood and are hard to predict from karyotype, prenatal androgen exposure, degree of genital virilization, or assigned gender.¹⁹⁰⁻¹⁹² Because gender identity, sex-typical behavior, and sexual orientation are separate components of psychosexual development, it is important to appreciate that homosexual orientation (relative to sex of rearing) or strong cross-sex interest in an individual with DSD is not necessarily an indication of incorrect gender assignment.³

Challenges in assessing gender identity in young children make it difficult to know when this is established, although it is thought to be between 18 and 36 months and possibly younger.¹⁹³ Many of the sexually dimorphic differences in brain structures reported at puberty or in adulthood are not seen in early childhood and are therefore not useful for guiding gender assignment.^{194,195} Potential plasticity in psychosexual development may exist, as is evident from studies of some patients with conditions such as 5 α -reductase deficiency who may change their gender role in adolescence. A better understanding of the processes of human psychosexual development and of the influences of different forms of DSD is needed to help make early gender assignment decisions and to guide psychological support in the future.

Development of the Hypothalamic-Gonadotroph Axis in the Fetus

Fetal hypothalamic-gonadotroph development occurs from 6 weeks' post-conception, in parallel with the processes of sex determination and sexual differentiation in humans. Pituitary gonadotropin release probably does not influence the gonad until about 20 weeks of gestation.¹⁶⁷ Detailed descriptions of the development of the neuroendocrine system and congenital disorders of the hypothalamic-pituitary axis are provided in other Chapters. However, development of the hypothalamic-gonadotroph axis has some unique features, and abnormalities in this process can cause congenital forms of hypogonadotropic hypogonadism (HH).

Development and Migration of Gonadotropin-Releasing Hormone-Synthesizing Neurons

Embryonic development of the hypothalamic gonadotropin-releasing hormone (GnRH) neurosecretory system is intimately related to development of the extracranial and intracranial olfactory apparatus, and in all species studied, the GnRH-synthesizing neurons originate extracranially before migrating to their final position in the fetal hypothalamus (Fig. 23-15).¹⁹⁶

In humans, GnRH-synthesizing neurons first appear in the embryonic medial olfactory placode at about 6 weeks' post-conception and begin to migrate along axons of the terminal vomeronasal nerve complex on a neural cell

Figure 23-15 Development of the hypothalamic-gonadotroph axis in humans. **A**, Migration of gonadotropin-releasing hormone (GnRH) neurons from the olfactory placode to the fetal hypothalamus is facilitated by proteins such as anosmin 1 (now called KALI), fibroblast growth factor 8 (FGF8), FGF receptor 1 (FGFR1), NELF, prokineticin 2 (PROK2), its receptor PROKR2, and CHD7. Defects in these factors have been reported in association with Kallmann syndrome (i.e., hypogonadotropic hypogonadism and anosmia), although in some cases, sense of smell can be normal. **B**, Differentiation of the anterior pituitary gland. The gradient of factors such as GATA2/SF1 and TPIT (TBX19) may provide a switch for gonadotroph differentiation. Variations in several transcription factors (e.g., HESX1, GLI2, LHX3, OTX2, SOX3, PROP1) are associated with multiple pituitary hormone deficiency in humans. Mutations affecting isolated gonadotroph factors have not been described, except as part of complex phenotypes associated with mutations in SF1, DAX1, and SOX2. Defects in GnRH, the GnRH receptor, and GPR54 have also been reported in individuals with congenital hypogonadotropic hypogonadism.

adhesion molecule (NCAM)-rich scaffold. At about 6.5 weeks', these migrating neurons pass through the primitive cribriform plate and penetrate the forebrain medial and caudal to the developing olfactory bulbs. GnRH neurons then migrate posteriorly in the submeningeal space by the interhemispheric fissure before proceeding laterally to reach their final position in the fetal mediobasal hypothalamus starting at about 14 weeks' gestation.¹⁹⁶ Fetal GnRH neuron migration is complete by approximately 19 weeks' gestation, by which stage pulsatile GnRH release is established.

Several cell adhesion molecules and signaling factors have been implicated in this migratory process, including anosmin 1/KALI, FGFR1, NELF, and AXL/GAS6, and GnRH neurons express different transcription factors at different stages of maturation. Other neuroendocrine cells co-migrate with GnRH-synthesizing neurons. Some of these cells synthesize neurotransmitters and hormones such as neuropeptide Y, leptin, corticotropin-releasing factor (CRF), and glutamate; these factors may interact with GnRH neurons along the migratory path or in their final position in the hypothalamus. The association of GnRH neuronal migration with development of the olfactory system explains the association of some forms of HH with anosmia (i.e., lack of a sense of smell) in Kallmann syndrome. This condition can result from mutations in several X-linked and autosomal genes, which often represent ligand-and-receptor pairs (e.g., *KAL1*, *FGF8/FGFR1*, *PROK2/PROKR2*, *NELF*, *CHD7*). However, clinical features can vary within families (e.g., normosmic HH rather than anosmia), and inheritance patterns may be influenced by changes in more than one of these genes (i.e., digenic pattern). These features are discussed in more detail in other chapters.^{197,198}

Gonadotropin-Releasing Hormone Synthesis and Action

GnRH-synthesizing neurons are located throughout the hypothalamus, with a concentration in the arcuate nucleus.

GnRH is synthesized as a precursor polypeptide; this precursor undergoes cleavage and enzymatic processing to form a mature, 10-amino-acid hormone that is stored in secretory granules. GnRH is released from neuronal projections at the medial eminence into the portal blood system in a pulsatile manner to stimulate GnRH receptors on the anterior pituitary gonadotrophs. GnRH pulsatility is thought to be established in the second trimester and may be modulated at various stages of development by a G protein-coupled receptor (KISS1R, formerly called GPR54) and its ligand kisspeptin, as well as a host of other neuroendocrine factors and regulators (e.g., neurokinin B). Congenital HH has been reported in patients with defects in GnRH or the GnRH receptor, loss of function of KISS1R, and defects in the neurokinin B system (TAC3/TACR3).¹⁹⁷⁻¹⁹⁸ In humans, HH can result from abnormalities in GnRH processing (e.g., prohormone convertase 1 [PCSK1]) and leptin/leptin receptor signaling.

Pituitary Gonadotroph Development and Function

During development, cells destined to form the anterior pituitary arise within the oral ectoderm and Rathke's pouch, and they undergo a process of differentiation into corticotrophs, thyrotrophs, mammotrophs, and gonadotrophs (see Fig. 23-15). The mechanisms underlying these processes are discussed in Chapter 22. Developmental events that affect differentiation of early progenitor cells can cause congenital gonadotropin insufficiency as part of a multiple pituitary hormone deficiency. For example, mutations or variations in transcription factors such as HESX1, GLI2, OTX2, LHX3, SOX3, and PROP1 have been associated with HH, although in some conditions the onset of HH is often delayed until adolescence (e.g., with PROP1 variants).¹⁹⁹

Differentiation of the gonadotropin cell line from other pituitary lineages may be controlled by gradient-dependent switches such as GATA2 and TBX19 (previously called TPIT). A limited number of factors that appear to affect gonadotroph function have been identified, including SF1

(NRSA1), DAX1 (NROβ1), and SOX2. Individuals with changes in SF1 may have partial deficits in gonadotropin synthesis, but the phenotype is more complex because it also involves gonadal dysgenesis. Mutations in DAX1 cause X-linked adrenal hypoplasia congenita. HH is an established part of this condition, but only about 10% of affected boys have evidence of congenital gonadotropin insufficiency, and the HPG axis is usually intact in early postnatal life.²⁰⁰ SOX2 mutations can cause congenital HH with developmental delay and microphthalmia.²⁰¹

Gonadotropins

Fetal pituitary gonadotropin synthesis and release begins at about 14 weeks' gestation and peaks at 20 to 22 weeks.¹⁶⁷ Synthesis of these hormones is regulated by hypothalamic GnRH, downstream signaling mechanisms such as pituitary adenylate cyclase-activating peptide (PACAP, now called ADCYAP1), and transcription factors such as SF1, DAX1, PITX1, early growth response 1 (EGR1), and the stress protein p8. The α-subunits of these hormones undergo post-translational modification and heterodimerize with a common α-subunit to form the mature glycoprotein hormones FSH and LH.

Gonadotropin hormones are influenced by inhibin, activin, and follistatin. Inhibin is a heterodimeric hormone comprising an α-subunit bound to one of two distinct β-subunits, β_A or β_B. Inhibin A and inhibin B are produced by the gonads (predominantly ovarian granulosa cells and testicular Sertoli cells, respectively) and placenta, and they suppress FSH. Activins stimulate FSH and consist of homodimers or heterodimers of inhibin β-subunits (i.e., activin A, activin B, or activin AB). Follistatin binds activin to attenuate its action and reduce FSH release. These hormones are likely to function at a local (paracrine) level in the pituitary, to have a systemic influence on gonadotropin release, and to signal through TGF-β/SMAD pathways.

Mutations in genes encoding the gonadotropin hormones LH and FSH have been described in a small number of patients with abnormalities of puberty or spermatogenesis, but severe congenital abnormalities associated with these conditions have not been described. Males with inactivating mutations of the LHβ subunit had descended testes and small penises but no evidence of hypospadias. These findings support the role of placental hCG signaling through the LH/hCG receptor as the primary mediator of fetal Leydig cell androgen production.

The Hypothalamic-Pituitary-Gonadal Axis in Infancy and Childhood

At birth, the infant is removed from the influence of maternal and placental hormones and undergoes a series of distinct endocrine changes.

Postnatal Endocrine Changes in Boys

In boys, low concentrations of testosterone can be detected by standard assays at birth, but these levels fall during the first few days of life. Thereafter, a reactivation of the HPG axis occurs, beginning at about 6 weeks of age, which results in peaks of testosterone nearing midpubertal levels between 2 and 3 months after birth (Fig. 23-16).^{202,203} This peak of testosterone is associated with an acceleration in penile growth.²⁰³ The HPG axis then becomes relatively quiescent by 4 to 6 months of age, until the onset of puberty in late childhood.

Inhibin B concentrations are high at birth and fall during the first 2 years of life before rising with the onset of puberty between 11 and 15 years of age (see Fig.

Figure 23-16 Typical postnatal changes are shown for testosterone, anti-Müllerian hormone (AMH/MIS), and inhibin B in normal males from birth to adulthood. Pubertal stages (I through IV) are indicated. Conversions: testosterone, ng/dL \times 0.0347 for nmol/L; AMH/MIS, ng/mL \times 7.14 for pmol/L; ranges may vary with the assay.

23-16).^{204,205} In contrast, AMH concentrations remain high from birth through childhood and decline to low concentrations with the onset of puberty (see Fig. 23-16).^{161,206} AMH and inhibin B can be useful markers of active testicular tissue in boys with cryptorchidism, anorchia, and 46,XY DSD. INSL3 assays may provide a useful additional marker of testicular integrity in the future.

Postnatal Endocrine Changes in Girls

The early postnatal endocrine events in girls are less well understood. Placental estrogen exposure can result in breast development before birth, and a small episode of menstrual bleeding can occur several days after birth from withdrawal of estrogen and progesterone. It is likely that girls also have a discrete activation of the HPG axis in infancy. However, detectable concentrations of estradiol (5 to 20 pg/mL [20 to 80 pmol/L]) and inhibin B (50 to 200 pg/mL) can be measured in the first few months of life, and surprisingly high concentrations of FSH with marked interindividual variability can be found during infancy and early childhood (median, 3.8 IU/L; range, 1.2 to 18.8 IU/L [2.5% to 97.5%] at 3 months of age in healthy, term girls).²⁰⁷ Inhibin A has been proposed as a test of ovarian tissue in

the newborn period in children with possible ovotesticular DSD, but this hormone is below the limits of detection in many normal, term newborn girls, and FSH stimulation may be needed to detect it.

DISORDERS OF SEX DEVELOPMENT

DSDs can have a wide range of presenting phenotypes depending on the underlying condition and its severity. Individuals with these conditions can present to many different health care professions, including neonatologists, geneticists, urologists, gynecologists, and internists. When an infant is born with ambiguous genitalia, the need for further investigation is usually clear. However, 46,XY individuals with complete 17 α -hydroxylase/17,20-lyase deficiency may first present in early adolescence with hypertension and delayed puberty, or a young woman with CAIS (46,XY) may first present to a gynecologist with amenorrhea.

Significant progress in understanding of the molecular basis of gonad development has occurred during the past 20 years. Although several single-gene disorders causing gonadal dysgenesis in humans have been described and many more candidate genes are emerging from studies in mice, the percentage of patients with disorders of gonad development who can be diagnosed at the molecular level remains disappointingly low (15% to 20%). Defining the

exact bases of different DSDs can have important implications for gender assignment, predicting response to treatment (e.g., androgen supplementation), assessing associated features (e.g., adrenal dysfunction) or the risk of tumorigenesis, and determining likely fertility options and long-term counseling for the individual and family. However, long-term outcome studies are often inadequate, and an evidence-based approach to management is not possible in many cases.

Nomenclature and Classification of Disorders of Sex Development

The proposal to change terminology by replacing *intersex* with the DSD acronym has led to a new classification for DSDs.^{3,4} DSD has been defined as “congenital conditions in which development of chromosomal, gonadal, or anatomic sex is atypical.”³ This definition is wide ranging enough to cover conditions such as cloacal extrophy but sufficiently specific not to embrace, for example, disorders of puberty. The most common cause of ambiguous genitalia of the newborn, CAH, is classified as 46,XX DSD, and the next most common cause, PAIS, is classified as 46,XY DSD. Table 23-3 shows how such a classification system can be applied to DSDs. The list is not exhaustive but provides a framework for the following discussion of the more common causes of DSD, which classifies them as sex chromosome variations (sex chromosome DSD), disorders of

TABLE 23-3

Example of a DSD Classification

Sex Chromosome DSD	46,XY DSD	46,XX DSD
A: 47,XXY (Klinefelter syndrome and variants) B: 45,X (Turner syndrome and variants) C: 45,X/46,XY (mixed gonadal dysgenesis) D: 46,XX/46,XY (chimerism)	A: Disorders of gonadal (testis) development 1. Complete or partial gonadal dysgenesis (e.g., SRY, SOX9, SF1, WT1, DHH) 2. Ovotesticular DSD 3. Testis regression B: Disorders in androgen synthesis or action 1. Disorders of androgen synthesis Luteinizing hormone (LH) receptor mutations Smith-Lemli-Opitz syndrome StAR protein mutations Cholesterol side-chain cleavage (CYP11A1) 3 β -Hydroxysteroid dehydrogenase 2 (HSD3B2) 17 α -Hydroxylase/17,20-lyase (CYP17) P450 oxidoreductase (POR) Cytochrome b ₅ (CYP5A) 17 β -Hydroxysteroid dehydrogenase (HSD17B3) 5 α -Reductase 2 (SRD5A2) 2. Disorders of androgen action Androgen insensitivity syndrome Drugs and environmental modulators C: Other 1. Syndromic associations of male genital development (e.g., cloacal anomalies, Robinow, Aarskog, hand-foot-genital, popliteal pterygium) 2. Persistent Müllerian duct syndrome 3. Vanishing testis syndrome 4. Isolated hypospadias (MAMLD1) 5. Congenital hypogonadotropic hypogonadism 6. Cryptorchidism (INSL3, GREAT) 7. Environmental influences	A: Disorders of gonadal (ovary) development 1. Gonadal dysgenesis 2. Ovotesticular DSD 3. Testicular DSD (e.g., SRY+, dup SOX9, RSPO1, WNT4) B: Andro of gen excess 1. Fetal 3 β -Hydroxysteroid dehydrogenase 2 (HSD3B2) 21-Hydroxylase (CYP21A2) P450 oxidoreductase (POR) 11 β -Hydroxylase (CYP11B1) Glucocorticoid receptor mutations 2. Fetoplacental Aromatase (CYP19) deficiency Oxidoreductase (POR) deficiency 3. Maternal Maternal virilizing tumors (e.g., luteomas) Androgenic drugs C: Other 1. Syndromic associations (e.g., cloacal anomalies) 2. Müllerian agenesis/hypoplasia (e.g., MURCS) 3. Uterine abnormalities (e.g., MODY5) 4. Vaginal atresias (e.g., McKusick-Kaufman) 5. Labial adhesions

CYP, cytochrome P450 isoenzyme; DSDs, disorders of sex development; MODY5, maturity-onset diabetes of the young type 5; MURCS, Müllerian, renal, and cervical spine syndrome; StAR, steroidogenic acute regulatory (protein).

testis development and androgenization (46,XY DSD), and disorders of ovary development and androgen excess (46,XX DSD) (see Fig. 23-2).

Sex Chromosome Disorders of Sex Development

Differences in the number of sex chromosomes (i.e., sex chromosome aneuploidy) can be considered *sex chromosome DSDs*. These conditions include Klinefelter syndrome (47,XXY and its variants), Turner syndrome (45,X and its variants), mixed gonadal dysgenesis (45,X/46,XY mosaicism and its variants), and true sex chromosome chimerism (46,XY/46,XX) (Table 23-4). A 45,Y cell line is nonviable.

Mixed gonadal dysgenesis and sex chromosome chimerism can manifest with ambiguous genitalia at birth, but such a presentation is unlikely in Klinefelter syndrome unless multiple X chromosomes are present or in Turner syndrome unless there is a Y fragment. In many cases of classic sex chromosome aneuploidy, the diagnosis is made in adolescence or adult life as a result of associated features, impaired pubertal development, or infertility. More detailed descriptions of the long-term management of some of these conditions are provided in the relevant chapters (e.g., Turner syndrome and Klinefelter syndrome in Chapter 25).

Klinefelter Syndrome and Its Variants

Klinefelter syndrome is the most common forms of sex chromosome aneuploidy, with a reported incidence of 1 in 500 to 1 in 1000 live births.^{208,209} This incidence may be increasing.²¹⁰ The classic form of Klinefelter syndrome is associated with a 47,XXY karyotype and is caused by meiotic nondisjunction of the sex chromosomes during gametogenesis (Fig. 23-17; see Fig. 23-4).^{209,210} This abnormality occurs during spermatogenesis in approximately 40% of patients and during oogenesis in approximately 60%. Mosaic forms of Klinefelter syndrome (46,XY/47,XXY) represent mitotic nondisjunction within the developing zygote and are thought to occur in approximately 10% of individuals with this condition (see Fig. 23-4). Other

chromosomal variants associated with Klinefelter syndrome (e.g., 48,XXXXY) have been reported.

The clinical features of Klinefelter syndrome and its variants are summarized in Table 23-4.^{208,209} In the most severe situations, a young man may be diagnosed because of small testes, gynecomastia, poor androgenization at puberty, eunuchoid proportions, or infertility. Diagnosis before puberty is the exception. Other features, such as learning difficulties, language delay, and altered motor development, may occur.^{211,212} However, it is likely that the clinical detection of Klinefelter syndrome based on postnatal karyotyping is biased toward detection of those individuals with a more severe phenotype. As few as 25% of men with Klinefelter syndrome may be diagnosed throughout their life span.²⁰⁹

The development of testes and a male phenotype in individuals with Klinefelter syndrome provides important evidence for the key role of the Y chromosome in testis determination and subsequent prenatal androgen production. However, micropenis and hypospadias may be presenting features in some cases (personal observation), and some studies report elevated early postnatal gonadotropin concentrations.²¹³

A more predictable elevation in gonadotropin concentrations (e.g., FSH, LH) occurs in the preadolescent and periadolescent periods in patients with Klinefelter syndrome, after activation of the HPG axis.^{214,215} By adolescence, plasma concentrations of FSH are increased in 90% of patients with Klinefelter syndrome, and plasma concentrations of LH are increased in 80%. Other serum markers of testicular function (e.g., prepubertal AMH, peripubertal inhibin B, midpubertal INSL3) are often below the normal ranges.^{216,217} Although some androgenization usually occurs during puberty in classic Klinefelter syndrome, plasma testosterone is decreased in 50% to 75% of cases.²¹⁴ Testes usually remain small and firm; the median length and volume are 2.5 cm (4 mL), but most are smaller than 3.5 cm (12 mL). They typically appear inappropriately small for the degree of androgenization. The serum estradiol concentration is often elevated, which contributes to the gynecomastia observed during the adolescent period.

Testicular biopsy is not warranted clinically, because the diagnosis can usually be made on karyotyping from

TABLE 23-4

Clinical Features of Sex Chromosome DSDs

Condition	Karyotype	Gonad	Internal Genitalia	Features
Klinefelter syndrome	47,XXY and variants	Hyalinized testes	No uterus	Small testis, azoospermia, hypoandrogenemia; tall stature and increased leg length; increased incidence of learning difficulties, obesity, breast tumors, varicose veins, impaired glucose tolerance
Turner syndrome	45,X and variants	Streak gonad or immature ovary	Uterus	<i>Childhood:</i> Lymphedema, shield chest, web neck, low hairline; cardiac defects and coarctation of the aorta; renal and urinary abnormalities; short stature, cubitus valgus, hypoplastic nails, scoliosis; otitis media and hearing loss; ptosis and amblyopia; nevi; autoimmune thyroid disease; visuospatial learning difficulties <i>Adulthood:</i> Pubertal failure, primary amenorrhea; hypertension; aortic root dilatation and dissection; sensorineural hearing loss; increased risk of CVD, IBD, colon cancer; thyroid disease, glucose intolerance and diabetes mellitus, osteoporosis (note that some of these may be related to estrogen deficiency)
Mixed gonadal dysgenesis	45,X/46,XY and variants	Testis or dysgenetic gonad	Variable	Increased risk of gonadal tumors; short stature; some features of Turner syndrome may be present
Ovotesticular DSD	46,XX/46,XY chimerism	Testis, ovary, or ovotestis	Variable	Possible increased risk of gonadal tumors

CVD, cardiovascular disease; DSDs, disorders of sex development; IBD, inflammatory bowel disease.

Figure 23-17 G-banded karyotypes of Klinefelter syndrome (47,XXY) (**A**) and Turner syndrome (45,X) (**B**). **C**, Structural changes of the X chromosome seen in variants of Turner syndrome (from left to right: normal X; ring chromosome [r(X)(p22.3q22)]; short-arm deletion [del(X)(p21)]; long-arm deletion [del(X)(q21.31)]; isochromosome [i(X)(q10)]). peripheral blood cells. However, studies in which testicular histology has been obtained report germ cell depletion, progressive hyalinization of seminiferous tubules, and Leydig cell hyperplasia after chronic LH stimulation. A significant proportion of men with Klinefelter syndrome receive testosterone supplementation to fully induce puberty and to support sexual characteristics, libido, and bone mineralization into adult life. Management of Klinefelter syndrome in adolescence and adulthood is discussed in Chapters 23 and 25. Although some cases of spontaneous fertility have been reported for mosaic forms of Klinefelter syndrome (46,XY/47,XXY), the prospects for fertility in classic Klinefelter syndrome have been thought to be poor. However, testicular sperm extraction (TESE) combined with intracytoplasmic sperm injection (ICSI) has reportedly led to successful pregnancy for approximately 50% of men with classic Klinefelter syndrome (47,XXY) in specialist centers.^{218,219} The potential risk of transmission of the sex chromosome aneuploidy must be considered, although it seems to be low. Benefits of this approach may decrease with age, suggesting that progressive deterioration in testicular function is a feature of Klinefelter syndrome.

Turner Syndrome and Its Variants

Turner syndrome is the second most frequent form of sex chromosome aneuploidy, with an incidence of approximately 1 case in 2500.⁴² The classic form of Turner syndrome is associated with a 45,X karyotype, which occurs in approximately one half of individuals with this

condition (see Fig. 23-17). Mosaic forms of Turner syndrome (45,X/46,XX) account for approximately one fourth of the patients, and the remainder have structural abnormalities of the X chromosome, such as long arm or short arm deletions, isochromosomes, or ring chromosomes (see Fig. 23-17).^{42,220}

A 45,X chromosome constitution may be the consequence of nondisjunction or chromosome loss during gametogenesis in either parent that results in a sperm or ovum that lacks a sex chromosome (see Fig. 23-4). Although errors in mitosis in normal zygotes often lead to mosaicism, a purely 45,X constitution may arise at the first cleavage division from anaphase lag with loss of a sex chromosome or, less often, from mitotic nondisjunction with failure of the complementary 47,XXX or 47,XYY cell line to survive.¹⁷ An estimated 2% of all zygotes have a 45,X karyotype, and approximately 7% of spontaneous abortions have a 45,X karyotype, making this the most frequent chromosomal anomaly in humans.

The clinical features of Turner syndrome are highly variable and depend on the age of the child and time of diagnosis. For example, a prenatal diagnosis of Turner syndrome may be made incidentally after amniocentesis or chorionic villous sampling for another reason, such as advanced maternal age, or after the detection of increased nuchal translucency on fetal ultrasound scanning.^{220,221} In early infancy, the diagnosis should be considered in females with lymphedema, nuchal folds, low hair line, or left-sided cardiac defects. Unexplained growth failure or somatic features (e.g., abnormal nails, shield chest, abnormal carrying

angle, recurrent ear infections) may point to the diagnosis during childhood, and Turner syndrome should be considered in all girls with pubertal delay or pubertal failure. The clinical features of Turner syndrome are summarized in Table 23-4, and the diagnosis and management of this condition are discussed in Chapter 25. Timely and appropriate introduction of estrogens is necessary in adolescence to ensure adequate breast and uterine development, thereby optimizing the opportunity to carry a pregnancy by ovum donation in the future.^{221,222} Women with Turner syndrome benefit from dedicated transition in adolescence and long-term follow-up with a focus on issues such as cardiovascular, bone, and reproductive health and hearing.^{42,221-223}

Girls with classic Turner syndrome show ovarian dysgenesis, which highlights the importance of having two copies of the X chromosome for ovarian development and integrity. Studies of Turner syndrome embryos have shown normal germ cell migration and normal ovarian development until the third month of gestation.²²⁴ Then, accelerated germ cell apoptosis and subsequent oocyte atresia occur, resulting in progressive degeneration of the ovary in the prenatal or postnatal period. With these gonadal changes, LH and FSH tend to rise in late childhood, after activation of the hypothalamic pulse generator. Nevertheless, sufficient estrogen synthesis for puberty to commence in adolescence occurs in approximately 25% of girls with Turner syndrome (10% of those with 45,X; 30% to 40% of those with 45,X/46,XX mosaicism), and menstruation occurs in about 2% of cases.^{42,225} Gonadectomy is not usually required except when a Y fragment containing the *TSPY* locus is present; in such patients, the risk of gonadoblastoma is increased.^{23,226} It is unclear whether any follicular tissue can be usefully cryopreserved for girls in whom spontaneous puberty has occurred, although oocyte cryopreservation has been used successfully in several women with Turner mosaicism.²²⁷⁻²²⁹

45,X/46,XY Mosaicism and Variants

A mosaic 45,X/46,XY karyotype, sometimes referred to as *mixed gonadal dysgenesis*, probably arises through anaphase lag during mitosis in the zygote, although Y chromosomal abnormalities are sometimes seen, and interchromosomal rearrangements with loss of structural abnormal Y material may be a common mechanism for variants of this condition. Although the classic form of this condition is associated with 45,X/46,XY mosaicism, 45,X/47,XYY or 45,X/46,XY/47,XYY mosaic karyotypes have also been reported.

The clinical phenotype associated with a 45,X/46,XY mosaicism is highly variable, and the true prevalence of this condition is unknown (see Table 23-4). Historically, individuals with the most severe forms of 45,X/46,XY mosaicism have been referred for further assessment, and most series of patients reported in the literature have probably reflected this bias.^{230,231}

Reported genital phenotypes associated with 45,X/46,XY mosaicism range from female external genitalia or mild clitoromegaly through all stages of ambiguous genitalia to hypospadias or a normal penis.^{230,231} Gonadal phenotypes range from streak gonads through dysgenetic testes to testes with normal histologic architecture. In rare cases, ovarian-like stroma and sparse primordial follicles may be present. The gonads may be positioned anywhere along the pathway of testicular descent, with streak gonads more likely to be intra-abdominal and well-formed testes more likely to be in the inguinoscrotal region. Müllerian structures may be present in the most severe cases because of impaired AMH production by Sertoli cells. Marked

differences in gonadal development and histology can be seen between the right and the left sides or even within a single gonad (hence, the term *mixed gonadal dysgenesis*).² The presence of a hemiuterus and fallopian tube on the side of the most severely affected gonad in some cases provides important evidence for the paracrine actions of AMH on developing Müllerian structures.

Somatic features associated with a 45,X/46,XY karyotype are highly variable and do not always correlate well with the gonadal phenotype.²³¹ At the most severe end of the spectrum, clinical features reminiscent of Turner syndrome may be seen, such as short stature, nuchal folds, low-set hairline, and cardiac and renal abnormalities. Detailed evaluation and long-term follow-up of these patients may be warranted, as for Turner syndrome (see Chapter 25). In other cases, a reduction in predicted height may be the only somatic manifestation. It is unclear whether detailed, ongoing monitoring for features associated with Turner syndrome (e.g., thyroid function, hearing, cardiac anomalies) is required for this group of individuals, but a low threshold should be maintained if there are any concerns.

Gender assignment can be difficult in individuals with 45,X/46,XY, and several factors should be considered, including genital appearance and urogenital anatomy, risk of gonadal malignancy, fertility and reproductive options, potential need for hormone replacement, and probable gender identity, sex role behavior, and psychosexual functioning.

Most infants with female or minimally androgenized genitalia are raised as female, and the presence of a uterus or hemiuterus allows the potential for pregnancy by ovum donation in the future. Intra-abdominal streak and dysgenetic gonads are thought to pose a significant risk of malignancy and should be removed.^{3,23,232,233} Estrogen replacement is required to induce breast and uterine development in adolescence, and the addition of progestins allows menstruation when a uterus is present. Growth-promoting agents have been used on an individual basis when short stature or Turner syndrome-like features are present, but no proper trials have been performed to assess this group of patients. Similarly, no long-term outcome data on gender identity or psychosexual functioning are available.

Infants with hypospadias and reasonable phallic development are usually raised as male. Testosterone can be given to promote phallic growth in infancy, and hypospadias repair is usually undertaken as a two-stage procedure. Attempts should be made to perform orchidopexy as a one- or two-stage procedure, because there may be a significant risk of malignancy in these gonads, and careful monitoring is necessary.²³ Gonads that cannot be placed within the scrotum are usually removed.^{3,233} Gonads that can be secured within the scrotum need careful monitoring and biopsy in early adolescence to assess for carcinoma in situ.^{23,233} Puberty should be carefully monitored to ensure adequate endogenous testosterone production, and in some cases, testosterone supplementation is needed. Loss of height potential is generally unpredictable but needs careful monitoring.

Assignment of gender and management of a 45,X/46,XY child with *highly ambiguous genitalia* can be a difficult situation for parents and physicians, and long-term outcome data for this group are not available. Limited data suggest that approximately 60% of infants with this phenotype are raised female, but they are infertile, have no uterus, require gonadectomy, and are likely to undergo urogenital surgery.² In contrast, those raised as male require multiple

hypospadias operations, may have poor corporal tissue, are infertile if dysgenetic gonads are present that need to be removed, and may have a significantly reduced height potential. These situations highlight the need for a multidisciplinary approach to initial assessment and management and for long-term monitoring and support. Long-term outcome data from larger studies may provide better guidance on the management of this group of individuals in the future.

In addition to the most severe cases described earlier, a 45,X/46,XY mosaic karyotype can be associated with a male phenotype and apparently normal testis development. Initial cases of normal males with a 45,X/46,XY karyotype were described after screening of family members as potential bone marrow transplant donors,² but later studies of amniocentesis showed that 90% of fetuses diagnosed as 45,X/46,XY by amniocentesis and confirmed as having this karyotype have normal male genitalia and apparently normal testes postnatally.^{234,235} Moreover, there seems to be limited correlation between the degree of mosaicism on peripheral blood sampling and gonadal or somatic phenotype. Follow-up data on this cohort are limited, HPG function has not been reported in detail, and fertility outcome and tumor risk are not known. Although a 45,X/46,XY karyotype is an uncommon finding in men presenting with testicular tumors or in the infertility clinic, more detailed long-term studies of the 45,X/46,XY male cohort are required to know whether extensive follow-up is necessary. It may seem prudent to monitor gonadal function in this cohort and to assess for evidence of testicular carcinoma in situ in adolescence, but evidence for the best approach is lacking.

Ovotesticular Disorders of Sex Development: 46,XX/46,XY Chimerism and Variants

The diagnosis of ovotesticular DSD (true hermaphroditism) requires the presence of ovarian tissue (containing follicles) and testicular tissue in the same or the opposite gonad (Fig. 23-18; see Table 23-4). Gonadal stroma arranged in whorls, similar to those found in the ovary but lacking oocytes, is not considered sufficient evidence to designate the rudimentary gonad as an ovary.²

Figure 23-18 Ovotestis, showing immature seminiferous tubules lined with Sertoli cells and germ cells (upper left) and ovarian tissue with follicles (lower right) (Hematoxylin-eosin stain; original magnification, $\times 400$). Relative Frequency (%) of Different Karyotypes in Ovotesticular DSD (True Hermaphroditism)

Location	46,XX/46,XY	46,XX	46,XY
North America	21	72	7
Europe	41	52	7
Africa	—	97	—

Adapted from Krob G, Braun A, Kuhnle U. True hermaphroditism: geographical distribution, clinical findings, chromosomes and gonadal histology. *Eur J Pediatr*. 1994;153:2-10.

Ovotesticular DSD is an uncommon condition that has been reported in approximately 500 individuals worldwide. Although 46,XX/46,XY chimerism (sometimes caused by double fertilization or ovum fusion; see “[Chromosomal Sex](#)”) does occur in a proportion of these patients, especially in North America and Europe, most individuals with 46,XX/46,XY chimerism do not have this condition (Table 23-5).²³⁶ Rather, most patients with ovotesticular DSD, especially those in South and Western Africa, have a 46,XX karyotype.²³⁶⁻²³⁸ The molecular basis of this disorder is not known, but familial cases have been reported, and autosomal recessive and sex-limited autosomal dominant transmission have been proposed. *RSPO1* mutations have been found occasionally, but *SRY* translocations are rare.^{239,240} Ovotesticular DSD associated with a 46,XY karyotype is not prevalent and may represent cryptic gonadal mosaicism for a Y chromosome deletion or early sex-determining gene mutation. Ovotesticular DSD likely has several causes.

Patients with ovotesticular DSD may be subclassified according to the type and location of the gonads.² *Lateral* cases (20%) have a testis on one side and an ovary on the other. *Bilateral* cases (30%) have testicular and ovarian tissue present bilaterally, usually as ovotestes. *Unilateral* cases (50%) have an ovotestis present on one side and an ovary or testis on the other. The ovary (or ovotestis) is more frequently found on the left side of the body, whereas the testis (or ovotestis) is found more often on the right. An ovary is likely to be in its normal anatomic position, whereas a testis or ovotestis can be anywhere along the pathway of testicular descent and is often found in the right inguinal region.

Differentiation of the genital tract and development of secondary sex characteristics vary in ovotesticular DSD.²⁴¹ Most patients who present early have ambiguous genitalia or significant hypospadias. Cryptorchidism is common, but at least one gonad is palpable, usually in the labioscrotal fold or inguinal region, more often on the right, and often associated with an inguinal hernia. The differentiation of the genital ducts usually follows that of the gonad, and a hemiuterus or rudimentary uterus is often present on the side of the ovary or ovotestis.

Breast development at the time of puberty is common in ovotesticular DSD. Menses occurs in a significant proportion of cases, and ovulation and pregnancy have been reported in a number of patients with a 46,XX karyotype, especially when an ovary is present. However, progressive androgenization can occur in girls with significant testicular tissue, which can result in voice changes and clitoral enlargement during adolescence if left untreated. Individuals raised as male often present with hypospadias and undescended testes, although bilateral scrotal ovotestes have been reported. These individuals can experience significant estrogenization at the time of puberty and may have cyclic hematuria if a uterus is present. Spermatogenesis is rare, and interstitial fibrosis of the testis is common.

Although ovotesticular DSD is rare, the diagnosis should be considered in all patients with ambiguous genitalia, especially if there is more pronounced scrotalization or detection of a gonad on the right. A 46,XX/46,XY karyotype strongly supports the diagnosis, but the detection of a 46,XX or 46,XY karyotype does not exclude the diagnosis. Pelvic imaging with ultrasound or magnetic resonance imaging (MRI) is useful for visualizing internal genitalia. The presence of testicular tissue may be detected by measurement of basal testosterone, AMH, and inhibin B in the first months of life, and by measuring basal AMH and testosterone inverse of hCG stimulation thereafter. Ovarian tissue is more difficult to detect in early childhood, although estradiol, inhibin A, and follicular response to repeated injection of recombinant human FSH can provide useful information.²⁴² Examination under anesthesia and laparoscopy may provide the most detailed information about internal structures and allow a biopsy to confirm the diagnosis of ovotesticular DSD when other forms of DSD have been excluded.

The management of ovotesticular DSD depends on the age at diagnosis, genital development, internal structures, and reproductive capacity. Male or female assignment may be appropriate for the young infant in whom a strong gender identity has not been established. Individuals with a 46,XX karyotype and a uterus are likely to have functional ovarian tissue, and female assignment is likely to be appropriate. Potentially functional testicular tissue should be removed and monitored postoperatively by measuring serum AMH levels and by demonstrating a lack of testosterone response to hCG stimulation. The risk of malignant transformation in ovarian tissue of 46,XX patients is not known.

A male gender assignment may be more appropriate if there is reasonable phallic development and müllerian structures are absent or very poorly formed. Ovarian tissue is usually removed to prevent estrogenization at puberty, and remnant müllerian structures can be removed by an experienced surgeon. The prevalence of gonadoblastoma or germinoma arising in the testicular tissue of patients with 46,XX ovotesticular DSD has been estimated at 3% to 4%. Because the ovotesticular tissue is usually dysgenetic, removal of this testicular tissue has been advocated.²³ However, management of a histologically normal, scrotally positioned testis is more difficult, and careful monitoring and biopsy for carcinoma in situ in adolescence may be an appropriate strategy.

Gender identity is an important consideration in patients with ovotesticular DSD who first present in late childhood or adolescence due to androgenization in girls or estrogenization in boys. In most cases, gender identity is consistent with sex of rearing. After appropriate counseling, the discordant gonad and dysgenetic tissue should be removed to prevent further androgenization in girls and estrogenization in boys. Sex hormone supplementation may be required for complete pubertal development.

46,XY Disorders of Sex Development

The 46,XY DSDs can be categorized as disorders of testis development, disorders of androgen synthesis, disorders of androgen action, and other conditions affecting sex development (Table 23-6; see also Fig. 23-8).

Disorders of Testis Development

Disorders of testis development can have a spectrum of phenotypes and presentations. In the most extreme cases, *complete testicular dysgenesis* is associated with a complete

lack of androgenization of the external genitalia and persistent müllerian structures due to insufficient AMH production—a condition sometimes called Swyer syndrome. In contrast, *partial gonadal dysgenesis* may be associated with clitoromegaly or ambiguous genitalia. A uterus and vagina may or may not be present. A subset of less severe forms of male reproductive development, such as isolated hypospadias, testicular regression, micropenis, or male infertility, may represent milder variants of the more severe phenotypes.

Several single-gene disorders have been described in patients with various degrees of testicular dysgenesis. Table 23-6 summarizes these factors, and their role in development has already been discussed (see “*Testis Determination*”). Candidate genes for these disorders have been discovered based largely on mouse phenotypes and on cases of gonadal dysgenesis occurring as part of a more complex syndrome. In such cases, the presence of any associated features can help to direct genetic analysis appropriately. A genetic diagnosis is reached only in 20% to 30% of cases of 46,XY testicular dysgenesis at present.

Single-Gene Disorders

Steroidogenic Factor 1: NR5A1. SF1 (encoded by *NR5A1*) is a member of the nuclear receptor superfamily that regulates the transcription of at least 30 genes involved in gonadal development, adrenal development, steroidogenesis, and reproduction.^{78,243} Complete deletion of the gene encoding SF1 in mice results in apoptosis of the developing gonad and adrenal gland during early embryonic development.⁷⁹ XY animals are phenotypically female and have persistent müllerian structures. Abnormalities of the ventromedial hypothalamus and variable HH are also described.

Based on the phenotypic findings in the mouse, SF1 mutations were first reported in two 46,XY individuals with female external genitalia, persistent müllerian structures, and primary adrenal failure.^{82,83} These changes resulted in impaired DNA binding. The first mutation was a de novo heterozygous Gly35Glu change in the P-box primary DNA-binding region of SF1, and the second was a recessively inherited homozygous Arg92Gln mutation in the A-box secondary DNA-binding region (Fig. 23-19).

An increasing number of heterozygous nonsense, frameshift, and missense mutations in *NR5A1* have been associated with 46,XY DSD (see Fig. 23-19).^{78,84,244} These changes result in haploinsufficiency of SF1 and a spectrum of phenotypes, most commonly mild gonadal dysgenesis and significantly impaired androgenization but with normal adrenal function.^{78,84,245} These variations usually arise de novo but may be inherited from the mother in a sex-limited dominant fashion (i.e., the mother carries the mutation but is unaffected).⁸⁴ In other cases, there is a family history of ovarian insufficiency.⁵¹ Loss of SF1 function also is reported in some boys with severe hypospadias and undescended testes, bilateral anorchia, and a small penis, and in men with infertility.²⁴⁶⁻²⁴⁷ Therefore, variable loss of SF1 activity is associated primarily with testicular dysfunction or variable ovarian dysfunction in humans. Adrenal function may need to be monitored over time.

Chromobox Homolog 2: CBX2. Chromobox homolog 2 (*CBX2*) is a human homolog of the polycomb protein M33. Deletion of its gene causes XY sex reversal in mice. Loss-of-function mutations in *CBX2* were described in a 46,XY girl with a uterus and ovaries who was diagnosed by prenatal karyotyping.²⁴⁸

Wilms' Tumor 1 Gene: WT1. WT1 (11p13) is a four-zinc finger transcription factor expressed in the developing genital ridge, kidney, gonads, and mesothelium.⁶⁶⁻⁶⁷

TABLE 23-6

Overview of Important Genes Involved in DSDs

Gene	Protein	OMIM	Locus	Inheritance	Gonad	Müllerian Structures	External Genitalia	Associated Features/Variants
A. Causes of 46,XY DSD								
<i>Disorders of Gonadal (Testicular) Development: Single-Gene Disorders</i>								
WT1	TF	607102	11p13	AD	Dysgenetic testis	±	Female or ambiguous	Wilms' tumor; renal abnormalities, gonadal tumors (WAGR, Denys-Drash, and Frasier syndromes)
CBX2	Polycomb protein	602770	17q25	AR	Ovary (one case)	+	Female	More severe phenotypes include primary adrenal failure; milder phenotypes have isolated partial gonadal dysgenesis or impaired androgenization or both
NR5A1 (SF1)	Nuclear receptor TF	184757	9q33	AD/AR	Dysgenetic testis (variable)	±	Female, ambiguous, or hypospadias	
SRY	TF	480000	Yp11.3	Y	Dysgenetic testis or ovotestis	±	Female or ambiguous	
SOX9	TF	608160	17q24-q25	AD	Dysgenetic testis or ovotestis	±	Female or ambiguous	Camptomelic dysplasia (17q24 rearrangements have a milder phenotype than point mutations)
DHH	Signaling molecule	605423	12q13.1	AR	Dysgenetic testis, testis	–	Female	The severe phenotype of one patient included minifascicular neuropathy; other patients have isolated gonadal dysgenesis
ARX	TF	300382	Xp22.13	X	Dysgenetic testis (Leydig)	–	Ambiguous	X-linked lissencephaly, epilepsy, temperature instability
TSPYL1	? Chromatin remodeling	604714	6q22-23	AR	Dysgenetic testis	–	Female or ambiguous	Sudden infant death
MAMLD1 (CXORF6)	Unknown	300120	Xq28	X	Normal (Leydig cell dysfunction)	–	Hypospadias	
<i>Disorders of Gonadal (Testicular) Development: Chromosomal Changes Involving Key Candidate Genes*</i>								
DMRT1	TF	602424	9p24.3	Monosomic deletion	Dysgenetic testis	±	Female or ambiguous	Mental retardation
ATRX	Helicase (? chromatin remodeling)	300032	Xq13.3	X	Dysgenetic testis	–	Female, ambiguous, or male	α-Thalassemia, mental retardation
NR0B1 (DAX1)	Nuclear receptor TF	300018	Xp21.3	dupXp21	Dysgenetic testis or ovary	±	Female or ambiguous	
WNT4	Signaling molecule	603490	1p35	dup1p35	Dysgenetic testis	+	Ambiguous	Mental retardation
<i>Disorders in Hormone Synthesis or Action</i>								
DHCR7	Enzyme	602858	11q12-q13	AR	Testis	–	Variable	Smith-Lemli-Opitz syndrome: coarse facies, second-third toe syndactyly, failure to thrive, developmental delay, cardiac and visceral abnormalities
LHCR	G-protein receptor	152790	2p21	AR	Testis	–	Female, ambiguous, or micropenis	Leydig cell hypoplasia
STAR	Mitochondrial associated protein	600617	8p11.2	AR	Testis	–	Female, ambiguous, or micropenis	Lipoid CAH (primary adrenal failure), pubertal failure
CYP11A1	Enzyme	118485	15q23-q24	AR	Testis	–	Female or ambiguous	CAH (primary adrenal failure), pubertal failure
HSD3B2	Enzyme	201810	1p13.1	AR	Testis	–	Ambiguous	CAH, primary adrenal failure, ↑ Δ ⁵ :Δ ⁴ ratio
CYP17A1	Enzyme	202110	10q24.3	AR	Testis	–	Female, ambiguous, or micropenis	CAH, hypertension due to DOC (except in isolated 17,20-lyase deficiency)

POR (P450 oxidoreductase)	CYP enzyme electron donor	124015	7q11.2	AR	Testis	–	Male or ambiguous	Mixed features of 21-hydroxylase deficiency, 17 α -hydroxylase/17,20-lyase deficiency, and aromatase deficiency; sometimes associated with Antley-Bixler craniostenosis
CYP5A	Cofactor	613218	18q23	AR	Testis	–	Ambiguous or hypospadiac	Methemoglobinemia
HSD17B3	Enzyme	605573	9q22	AR	Testis	–	Female or ambiguous	Partial androgenization at puberty, \uparrow ratio of androstenedione to testosterone
SRD5A2	Enzyme	607306	2p23	AR	Testis	–	Ambiguous or micropenis	Partial androgenization at puberty, \uparrow ratio of testosterone to DHT
Androgen receptor	Nuclear receptor TF	313700	Xq11-q12	X	Testis	–	Female, ambiguous, micropenis, or normal male	Phenotypic spectrum from complete AIS (female external genitalia) to partial AIS (ambiguous) to normal male genitalia/infertility
AMH	Signaling molecule	600957	19p13.3-p13.2	AR	Testis	+	Normal male	Persistent müllerian duct syndrome (PMDS)
AMH receptor	Serine/threonine kinase transmembrane receptor	600956	12q13	AR	Testis	+	Normal male	Male external genitalia, bilateral cryptorchidism
B. Causes of 46,XX DSD								
Disorders of Gonadal (Ovarian) Development								
SRY	TF	480000	Yp11.3	Translocation	Testis or ovotestis	–	Male or ambiguous	
SOX9	TF	608160	17q24	dup17q24	Not determined	–	Male or ambiguous	
RSPO1	Thrombospondin (Wnt signaling)	609595	1p34.3	AR	Testis or ovotestis	–	Male	Palmar-plantar hyperkeratosis, squamous cell carcinoma
WNT4	Wnt signaling	611812	1p35	AR	Testis or ovotestis	–	Male or ambiguous	SERKAL syndrome
Androgen Excess								
HSD3B2	Enzyme	201810	1p13	AR	Ovary	+	Clitoromegaly (mild)	CAH, primary adrenal failure, partial androgenization due to \uparrow conversion of DHEA
CYP17A2	Enzyme	201910	6p21-p23	AR	Ovary	+	Ambiguous; rarely Prader-V	CAH, phenotypic spectrum from severe salt-losing forms associated with adrenal failure to simple virilizing forms with compensated adrenal function, \uparrow 17-OHP
CYP11B1	Enzyme	202010	8q21-q22	AR	Ovary	+	Ambiguous; rarely Prader-V	CAH, hypertension due to \uparrow 11-deoxycorticosterone
POR (P450 oxidoreductase)	CYP enzyme electron donor	124015	7q11.2	AR	Ovary	+	Normal or ambiguous	Mixed features of 21-hydroxylase deficiency, 17 α -hydroxylase/17,20-lyase deficiency and aromatase deficiency, associated with Antley-Bixler craniostenosis
CYP19	Enzyme	107910	15q21	AR	Ovary	+	Ambiguous	Maternal androgenization during pregnancy, absent breast development at puberty except in partial cases
Glucocorticoid receptor [†]	Nuclear receptor TF	138040	5q31	AR	Ovary	+	Normal or ambiguous	\uparrow ACTH, 17-OHP cortisol, mineralocorticoids, and androgens; failure of dexamethasone suppression

*Chromosomal rearrangements likely to include key genes are included.

[†]Note: patient heterozygous for a mutation in CYP21.

–, absent; +, present; ACTH, adrenocorticotropin; AD, autosomal dominant (often de novo mutation); AIS, androgen insensitivity syndrome; AR, autosomal recessive; CAH, congenital adrenal hyperplasia; CYP, cytochrome P450 enzyme; DHEA, dehydroepiandrosterone; DHT, dihydrotestosterone; DOC, 11-deoxycorticosterone; DSDs, disorders of sex development; 17-OHP, 17-hydroxyprogesterone; LHCG, the luteinizing hormone (LH) or human chorionic gonadotropin (hCG) receptor; OMIM, *Online Mendelian Inheritance in Man*; SERKAL, sex-reversal, kidney, adrenal and lung dysgenesis; TF, transcription factor; WAGR, Wilms' tumor; aniridia, genitourinary anomalies, and mental retardation.

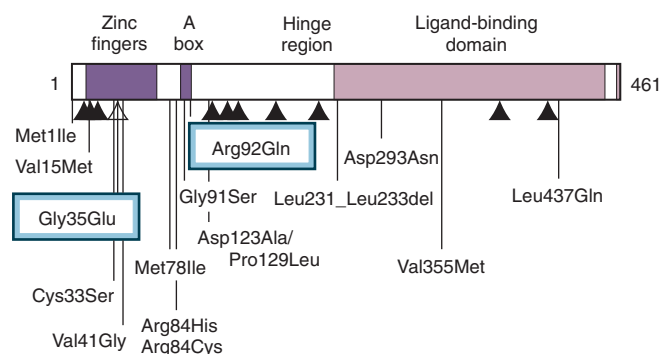

Figure 23-19 Schematic diagram of steroidogenic factor I (SF1) shows key domains and mutations associated with a gonadal phenotype. The Gly35Glu (heterozygous) and Arg92Gln (homozygous) changes (boxes) affect DNA-binding regions of the protein (P box and A box, respectively) and are associated with marked underandrogenization, dysgenetic gonads, Müllerian structures, and primary adrenal failure. Heterozygous frameshift and nonsense mutations (triangles), as well as missense mutations, have been described in 46,XY individuals with milder phenotypes of disorders of sex development and in women with primary ovarian insufficiency. (From Lin L, Philibert P, Ferraz-de-Souza B, et al. Heterozygous missense mutations in steroidogenic factor-I [SF1/Ad4BP NR5A1] are associated with 46,XY disorders of sex development with normal adrenal function. *J Clin Endocrinol Metab*. 2007;92:991-999, with permission of The Endocrine Society, copyright 2007.)

Homozygous deletion of *WT1* in mice prevents development of the gonads and kidneys.⁶⁸ The *WT1* protein has several different isoforms that have complex roles in sex development, as outlined previously and shown in Figure 23-20. The important role of *WT1* in human testis development has been confirmed through the description of various *WT1* mutations in patients with WAGR syndrome, Denys-Drash syndrome, and Frasier syndrome.

WAGR syndrome is caused by deletion of a region of chromosome 11p13.²⁴⁹ The resultant phenotype is likely to be the consequence of haploinsufficiency of *WT1*, together with loss of developmental genes such as *PAX6*, which is involved in eye development.⁷³ Renal abnormalities include renal agenesis and horseshoe kidney. Genitourinary abnormalities are usually relatively mild and include hypospadias, cryptorchidism, and ureteral atresia.

Denys-Drash syndrome is characterized by gonadal dysgenesis, severe congenital or early-onset nephropathy (i.e., diffuse mesangial sclerosis), and predisposition to Wilms' tumor.⁷⁴ Most 46,XY patients with Denys-Drash syndrome present with genital ambiguity in the newborn period, although normal male or female phenotypes have been described. The presence or absence of Müllerian structures

depends on the degree of Sertoli cell dysfunction. Denys-Drash syndrome usually results from heterozygous de novo point mutations in *WT1* that have a dominant negative effect on the function of the wild-type protein. These point mutations usually affect the DNA-binding region (zinc fingers) of *WT1*. The risk of early-onset end-stage renal failure is high, and Wilms' tumor usually develops in the first decade of life. Gonadoblastoma occurs in fewer than 10% of cases.

Frasier syndrome usually results from heterozygous mutations in the donor splice site of exon 9 of *WT1*.^{75,76} These changes are predicted to result in an imbalance in the ratio of +KTS to -KTS isoforms of *WT1*. Frasier syndrome is characterized by streak gonads, a 46,XY female phenotype with Müllerian structures, and later-onset nephropathy (i.e., focal segmental glomerulosclerosis) that usually causes renal failure in the second decade of life. There is a high risk of gonadal tumors such as gonadoblastoma in patients with Frasier syndrome.²³ In practice, Denys-Drash syndrome and Frasier syndrome may represent a continuum of phenotypes rather than distinct conditions.⁷⁷ Milder variants of these conditions may also occur; for example, a man with hypospadias was found to have late-onset nephropathy due to a *WT1* mutation.²⁵⁰ Taken together, these cases highlight the importance of considering this diagnosis in 46,XY DSD and of performing urinalysis for proteinuria in cases of 46,XY DSD.

Management of patients with *WT1* mutations includes monitoring and treatment of renal function and assessment for Wilms' tumor, as well as gonadectomy in individuals with Frasier syndrome and in patients with Denys-Drash syndrome who have a Y chromosome.²³ Meacham syndrome (i.e., DSD, cardiac defects, and diaphragmatic hernia) also may result from changes in *WT1*.²⁵¹

Sex-Determining Region of the Y Chromosome: SRY. The sequence of events leading to the identification of *SRY* as the primary testis-determining gene and the actions of *SRY* in testis development were described earlier. *SRY* is a 204-amino-acid, HMG box transcription factor that is encoded by a single exon on the Y chromosome (Yp11.3) (see Fig. 23-5).^{28,29,101} The discovery of inactivating mutations in *SRY* in patients with 46,XY gonadal dysgenesis confirmed the key role played by this factor in testis determination in humans.^{29,32,33,101}

Approximately 15% of individuals with the complete form of 46,XY gonadal dysgenesis have inactivating mutations in *SRY*.¹⁰¹ Most of the mutations occur in the HMG box DNA-binding domain of the *SRY* protein (Fig. 23-21), a region that is involved in binding and bending of DNA.^{101,104} Rare mutations in the 5' and 3' flanking regions

Figure 23-20 Schematic diagram shows the structure of *WT1* and the changes associated with exon 5 and exon 9 (addition of lysine, threonine, and serine) in +KTS isoforms. Many point mutations associated with Denys-Drash syndrome are located within zinc fingers 2 and 3 (especially Arg394). Mutations affecting the exon 9 splice site are associated with Frasier syndrome. (Modified from Koziell A, Grundy R. Frasier and Denys-Drash syndromes: different disorders or part of a spectrum? *Arch Dis Child*. 1999;81:365-369, with permission of the BMJ Publishing Group, copyright 1999.)

Figure 23-21 Structure of human SRY and SOX9 proteins and a selection of reported mutations. **A**, Diagram of SRY. The high-mobility group (HMG) box is an 80-amino-acid, DNA-binding domain with nuclear localization signals (NLSs) at either end, one of which binds calmodulin (CaM) and the other importin- β (imp- β). The last seven amino acids of SRY can bind to either of the PDZ domains found in SRY-interacting protein 1 (SIPI). The solid circles indicate missense mutations reported in the SRY protein that affect testicular development and cluster within the HMG box. Nonsense and frameshift mutations in SRY are indicated by solid triangles. **B**, Diagram of SOX9. SOX9 has an HMG box with two NLSs, similar to SRY. However, SOX9 is encoded by three exons, binds to heat shock protein 70 (HSP70), and has a trans-activation domain at the carboxyl-terminal end, unlike SRY. Selected mutations causing 46,XY DSD and camptomelic dysplasia are indicated by the solid circles (missense) and solid triangles (nonsense and frameshift). Mutations that cause only camptomelia or a bony phenotype in 46,XY males or affect 46,XX females are indicated by open triangles.

lead, respectively, to complete and partial gonadal dysgenesis.²⁵²⁻²⁵⁵ The HMG box contains two nuclear localization signals that bind calmodulin and importin B.¹⁰¹ Mutations in these nuclear localization signal domains in the HMG box of SRY result in failure to transport the SRY protein into the nucleus and consequent XY gonadal dysgenesis.¹⁰⁷

SRY Box 9: SOX9. Heterozygous mutations of the autosomal SOX9 gene (17q24-q25) cause camptomelic dysplasia.^{101,122,123} Features of this condition include bowed long bones, hypoplastic scapula, a deformed pelvis, 11 pairs of ribs, a small thoracic cage, cleft palate, macrocephaly, micrognathia, hypertelorism, and a variety of cardiac and renal defects. Death from respiratory distress often occurs in the neonatal period, but long-term survival has been reported.

SOX9 is emerging as an important testis-determining gene in its own right, and it may be one of the key regulators of testis determination downstream of SRY (see “Testis Determination”).⁸⁵ Consistent with this hypothesis, three fourths of affected 46,XY patients have dysgenetic gonads, but a complete spectrum of genital phenotypes can be seen, from completely male to completely female appearance.¹⁰¹ Histologic examination of the gonads from 46,XY patients with ambiguous or female external genitalia shows various degrees of testicular dysgenesis extending to streak gonads with primordial follicles or even ovaries.²⁵⁶ Müllerian structures may or may not be present, depending on the degree of gonadal dysgenesis. Affected 46,XX females have normal external genitalia and apparently normal ovaries.

The locus for camptomelic dysplasia with 46,XY DSD was mapped to 17q24.3-q25.1 after studies of three patients with balanced, de novo reciprocal translocations and the proposal of SOX9 as a candidate gene based on expression studies in the mouse.^{124,125} Subsequently, missense, nonsense, frameshift, and splice junction mutations have been detected in SOX9 in patients with camptomelic dysplasia with or without gonadal dysgenesis.¹⁰¹ These mutations are usually heterozygous de novo changes. In one kindred, multiple siblings were affected due to germline mosaicism for a SOX9 mutation in a parent.²⁵⁶ The gonadal phenotype in this kindred varied in the two affected 46,XY siblings: one of them had dysgenetic gonads, and the other was reported to have normal ovaries.

The SOX9 gene has three exons and two introns; it encodes a 509-residue protein that contains an HMG box with 71% homology to that of the SRY protein and a C-terminal, trans-activation domain (see Fig. 23-21). Unlike SRY, in which most mutations are located within the HMG box, SOX9 mutations are located throughout the protein, with little relation between functional domains and phenotype. Chromosomal translocations that disrupt regulatory elements upstream of the SOX9 promoter can be associated with a less severe phenotype or camptomelic dysplasia without gonadal abnormalities. Heterozygous changes that allow residual DNA binding and transactivation may also be associated with the acamptomelic variant and variable or absent DSD.

Desert Hedgehog: DHH. The hedgehog signaling pathways play an important role in many aspects of neuronal, skeletal, and endocrine development. A homozygous

mutation in the desert hedgehog gene (*DHH*) was reported in a patient with partial gonadal dysgenesis and minifascicular neuropathy.¹⁴⁰ Subsequently, a number of *DHH* changes were reported in patients with complete 46,XY gonadal dysgenesis but no apparent neurologic features.²⁵⁷

Aristaless-Related Homeobox, X-Linked Gene: ARX. ARX is a transcription factor that plays a central role in neuronal migration, and the *Arx* knockout mouse has a profound myelination defect. ARX was considered a candidate gene for the X-linked lissencephaly ambiguous genitalia (XLAG) syndrome, and mutations in *ARX* have been described in several patients with this condition.¹⁴⁵ This unusual form of lissencephaly is associated with severe epilepsy and thermal instability. The genital abnormality most likely represents a defect in Leydig cell function. Additional ARX mutations have been described in patients with neurologic defects (e.g., infantile spasms) without significant DSDs.

Testis-Specific Protein, Y-Linked-Like 1 Gene: TSPYL1. An association between 46,XY gonadal dysgenesis and sudden infant death syndrome was characterized in a large Amish kindred and named sudden infant death, dysgenetic testes (SIDDT).²⁵⁸ An autosomal recessive gene responsible for this condition, *TSPYL1*, encodes a protein of unknown function that may be involved in chromatin remodeling. Additional variants of *TSPYL1* and 46,XY DSD have recently been described.²⁵⁹

Mastermind-Like Domain-Containing 1: MAMLD1. *MAMLD1* (formerly called *CXORF6*) is a gene on the X chromosome that encodes a protein expressed in the developing testes. Hemizygous mutations in *MAMLD1* were originally described in cases of isolated severe hypospadias, although a range of severities has been described.^{146,260} *MAMLD1* disruption results in a defect in fetal Leydig cell development and function.²⁶¹

Chromosomal Rearrangements Associated with Gonadal Dysgenesis. Abnormalities of genital development are associated with a number of chromosomal deletions, duplications, and rearrangements.¹⁵³ The most frequently seen changes are deletions of 9p24-pter, 10q25-qter, and Xq13 and duplications of Xp21.

Deletions of 9p24-pter likely disrupt *DMRT1*, a gene with sex-specific homologs in *Drosophila* (*double sex* gene) and *Caenorhabditis elegans* (*Mab3*) that is expressed in early gonad development (see “Normal Sex Development”).^{141,143} No specific point mutations in *DMRT1* have been described in humans, but impaired gonadal development and 46,XY DSD are well-established features of the 9p-deletion syndrome, suggesting that haploinsufficiency of the *DMRT* locus may be a cause of testicular dysgenesis in humans.^{142,144}

Terminal deletions of chromosome 10 (10q25-qter) are frequently associated with urogenital abnormalities and sometimes with complete gonadal dysgenesis.¹⁵² The gene in this locus has not been identified.

Deletions of Xq13.3 and of the tip of chromosome 16p cause α -thalassaemia mental retardation (ATR) syndromes that may have gonadal dysgenesis as part of the phenotype.^{150,151} The Xq13.3 locus contains the transcription factor gene *ATRX* (also known as *XH2* or *XNP*), and the *SOX8* gene is located on 16p.^{150,151}

Duplications of the Xp21.3 region that contains the *DAX1* gene can cause abnormal testis development in some cases.⁸⁸ The role of *DAX1* and the *WNT4* pathway (duplication 1p35) in opposing testis development was discussed previously (see “Development of Reproductive Systems”).^{89,91}

Syndromic Causes of 46,XY Disorders of Sex Development. In addition to the specific syndromes outlined earlier, various degrees of testicular dysgenesis and impaired genital development (e.g., hypospadias, cryptorchism, scrotal transposition) are seen in many discrete syndromes.¹⁵³ In some situations, a genetic basis has been identified, but in many cases the cause is unknown.

46,XY DSD is often associated with intrauterine growth restriction (IUGR). Monozygotic twins can show disparate genital development, with the growth-restricted twin having ambiguous genitalia and the larger twin appearing as a normal male. The mechanism of this association is unclear. However, more common genetic causes of 46,XY DSD (e.g., mutations of *SRY*, *SF1*, androgen receptor, and steroidogenic enzymes) are rarely found in this group of IUGR patients. In these conditions, the birth weight usually is normal for gestational age (personal observation).

Disorders of Androgen Synthesis

Defects anywhere along the pathway of androgen synthesis and target organ action can result in impaired androgenization and 46,XY DSD (i.e., male pseudohermaphroditism) (see Table 23-6 and Fig. 23-11).

Cholesterol Synthesis Defects: Smith-Lemli-Opitz Syndrome. Smith-Lemli-Opitz syndrome has a broad phenotypic spectrum but typically includes microcephaly, mental retardation, cardiac defects, ptosis, upturned nose, micrognathia, cleft palate, polydactyly, syndactyly of toes (especially the second and third toes), severe hypospadias, micropenis, and growth failure.²⁶² The abnormalities of the external genitalia in approximately 65% of 46,XY patients vary from micropenis and hypospadias to complete failure of androgenization, resulting in a female phenotype.

Smith-Lemli-Opitz syndrome is caused by a deficiency of 7-dehydrocholesterol reductase (3 β -hydroxysterol Δ^7 -reductase [DHCR7]), the phylogenetically conserved sterol-sensing domain-containing enzyme required for the last step in the biosynthetic pathway from acetate to cholesterol. Cholesterol is necessary as a substrate for steroid synthesis, and intermediates of cholesterol synthesis may have important interactions with hedgehog signaling pathways.

The syndrome is diagnosed by finding elevated plasma levels of 7-dehydrocholesterol (7-DHC) and low levels of cholesterol. The *DHCR7* gene maps to 11q12-q13, and more than 70 mutations have been described.²⁶² Measurement of serum 7-DHC should be considered in all underandrogenized males with relevant phenotypic features, however mild. Testis development is apparently normal, and normal, elevated, or low concentrations of plasma testosterone have been described in affected male infants with intact HPG function. Compromised adrenal function can occur in rare cases.

Luteinizing Hormone Receptor Mutations. Mutations in the LH/hCG receptor cause impaired responsiveness to hCG and LH, resulting in Leydig cell agenesis or hypoplasia.²⁶³ Phenotypically, the external genitalia vary from a female appearance to a male with a micropenis (Table 23-7). Müllerian derivatives are absent in all patients, and rudimentary Wolffian derivatives may be present, even in some patients with severely underandrogenized external genitalia. This finding may reflect some early hCG-independent mechanisms of testosterone synthesis between 8 and 10 weeks' gestation.² Small, undescended testes are usually found in the inguinal region in the most severe forms of this Leydig cell hypoplasia. Patients with milder

TABLE 23-7

Clinical Features of Leydig Cell Hypoplasia in 46,XY Individuals

Karyotype	46,XY
Inheritance	Autosomal recessive; mutations in <i>LHCGR</i> gene
Genitalia	Female, hypospadias, or micropenis
Wolffian duct derivatives	Hypoplastic
Müllerian duct derivatives	Absent
Gonads	Testes
Habitus	Underandrogenization with variable failure of sex hormone production at puberty
Hormone profile	Low T and DHT; elevated LH (and FSH); exaggerated LH response to LHRH stimulation; poor T and DHT response to hCG stimulation

DHT, dihydrotestosterone; FSH, follicle-stimulating hormone; hCG, human chorionic gonadotropin; LH, luteinizing hormone; *LHCGR*, the LH or hCG receptor; LHRH, luteinizing hormone-releasing hormone; T, testosterone.

phenotypes may have appropriately descended testes of relatively normal size because the Leydig cell population contributes only about 10% to testicular volume. On histologic examination, the testes lack distinct Leydig cells in prepubertal patients. Postpubertal patients have absent or

decreased numbers of Leydig cells without Reinke's crystalloids, normal-appearing Sertoli cells, and discrete seminiferous tubules with spermatogenic arrest. This observation highlights the important role of intratesticular androgen in the final stages of sperm maturation.

The typical biochemical profile of patients with Leydig cell hypoplasia includes elevated basal and luteinizing hormone-releasing hormone (LHRH)-stimulated LH (and FSH) levels in early infancy or at puberty. In childhood, when the GnRH pulse generator is quiescent, basal LH levels may sometimes be detected above the normal range. Plasma levels of 17-OHP, androstenedione, and testosterone are low, with little or no response to prolonged hCG stimulation. Plasma LH falls after testosterone administration. Less marked biochemical changes can occur with milder forms of this condition.

More than 30 different homozygous or compound heterozygous mutations have been reported in the LH/hCG receptor gene (*LHCGR*) in individuals with various forms of this condition (Fig. 23-22).^{264,265} The original reports of Kremer and colleagues²⁶⁴ and Latronico and associates²⁶⁵ described homozygous Ala593Pro and Arg554Stop mutations, respectively, in 46,XY phenotypic females with Leydig cell hypoplasia, hypergonadotropic hypogonadism, and no testosterone response to hCG stimulation. An affected 46,XX sister showed normal sexual maturation at puberty but had an elevated LH level and amenorrhea,

Figure 23-22 Diagram of the seven transmembrane domain of the luteinizing hormone/human chorionic gonadotropin (LH/hCG) receptor with selected inactivating mutations shown by squares. Most of these changes are associated with marked underandrogenization. However, the changes at residues 616 and 625 in the seventh transmembrane domain are associated with a milder phenotype of micropenis.

demonstrating that the LH receptor is not necessary for estrogen synthesis but is necessary for normal ovulation in females. These mutations impair hCG stimulation of intracellular cyclic adenosine monophosphate (cAMP) in vitro studies through disturbances in hCG binding, intracellular signaling, or receptor stability and trafficking, depending on the nature of the change. Defects in a novel cryptic exon of the LH receptor (exon 6A) have also been described as a cause of 46,XY DSD.²⁶⁶ Partial loss-of-function mutations in the LH/hCG receptor causing milder phenotypes such as micropenis have tended to localize within the seventh transmembrane domain (Ser616Tyr, Ile625Lys) (see Fig. 23-22).^{265,267} Individuals with complete Leydig cell hypoplasia are usually raised as females and require estrogens at puberty. Gonadectomy is usually performed. If a male gender assignment is chosen, testosterone supplements may be given in early infancy and to support puberty. The risk of gonadal malignancy is unknown.²³

Steroidogenic Acute Regulatory Protein Defects. Steroidogenic acute regulatory protein (StAR) is a 30-kd mitochondrial protein that is present in the adrenal gland and gonads. It plays a key role in facilitating the rapid movement of cholesterol from the outer to the inner mitochondrial membrane.^{268,269} This process is necessary to allow de novo steroid biosynthesis in response to an increase in adrenocorticotrophic hormone (ACTH) or angiotensin II in the adrenal gland or an LH pulse in the gonad. The exact mechanism by which StAR facilitates this movement is unclear, but it is likely that the protein remains on the mitochondrial surface in a molten globule structure.²⁶⁹ Although a limited amount of cholesterol transfer is StAR independent (14%), this protein certainly plays a central role in the acute regulation of adrenal and gonadal steroidogenesis.

Consistent with these actions, patients with recessively inherited defects in StAR develop a severe form of primary adrenal failure called *lipoid congenital adrenal hyperplasia* (lipoid CAH).²⁷⁰ Patients with this condition tend to present with severe glucocorticoid deficiency (e.g., hypoglycemia, hyperpigmentation) early in life and progressive mineralocorticoid insufficiency resulting in hyponatremia, hyperkalemia, dehydration, acidosis, and collapse (Table 23-8). Little or no C18, C19, and C21 steroids are detectable in

plasma or urine, even after corticotropin or hCG stimulation. Females (46,XX) with lipoid CAH have normal genitalia and a uterus. In 46,XY individuals, mutations in *STAR* typically cause a marked deficiency in testosterone synthesis by fetal Leydig cells so that completely female genitalia are seen. Testes may be abdominal, inguinal, or labial. A blind vaginal pouch is present, and Müllerian structures have regressed. A karyotype should be performed in all apparent girls presenting with early-onset adrenal failure.

The typical finding in lipoid CAH is lipid accumulation within steroidogenic cells. In the steroid-deficient state, the tropic drive by ACTH, angiotensin II, and LH causes increased cholesterol uptake and synthesis by steroidogenic cells. Coupled with the inability of StAR to facilitate cholesterol movement into mitochondria, this leads to marked accumulation of cholesterol in cells and results in the appearance of enlarged, lipid-laden adrenal glands seen on MRI or computed tomography (CT). Eventually, cholesterol accumulation causes engorgement and results in disruption of the structural and functional integrity of the cell—the two-hit hypothesis (Fig. 23-23).²⁷¹ The StAR-knockout mouse has a comparable phenotype to patients with lipoid CAH, consistent with the two-hit hypothesis model.²⁷² StAR is not necessary for placental progesterone production, unlike P450scc (CYP11A1).

The two-hit hypothesis also explains why 46,XX girls with lipoid CAH show evidence of estrogenization and breast development at puberty but have progressive hypergonadotropic hypogonadism.^{271,273} Follicular cells are relatively quiescent in utero and before puberty and are therefore undamaged. At the beginning of each cycle, they are recruited, and a small amount of estradiol can be produced as a result of StAR-independent mechanisms. This can occur until the follicular cells are engorged and rendered nonfunctional. Puberty can occur, but any cycles are anovulatory because progesterone synthesis in the latter half of the cycle is disturbed. Without treatment, polycystic ovaries and progressive ovarian failure usually ensue.

Although more than 20 different StAR mutations have been described in patients from around the world, lipoid CAH is especially prevalent in Japan and Korea, where it is the second most common steroidogenic disorder after CYP21 deficiency (Fig. 23-24).^{271,274} Most Japanese patients and virtually all Korean patients harbor the Gln258Stop mutation, which is estimated to be carried by 1 in 300 Japanese people.²⁷⁴ Other geographic clusters include the Leu260Pro mutation in patients of Swiss ancestry, Arg182His in Eastern Saudi Arabia, and Arg182Leu in Palestinians. Most of these mutations show complete loss of function. However, a nonclassic form of lipoid CAH has been described that is caused by point mutations in StAR, and retains approximately 20% function.²⁷⁵ These patients presented with progressive glucocorticoid deficiency between 2 and 4 years of age; affected males had normal androgenization of the external genitalia. StAR mutations may also be associated with hypospadias and adrenal failure.²⁷⁶

Treatment of classic lipoid CAH includes glucocorticoid and mineralocorticoid replacement and salt supplementation in early life. Gonadectomy is usually performed in individuals with a 46,XY karyotype. Estrogen treatment is given to induce puberty and is administered to 46,XX females when gonadal failure occurs.

P450 Side-Chain Cleavage Enzyme Deficiency. P450scc (CYP11A1) is the mitochondrial enzyme that converts cholesterol to pregnenolone by three distinct enzymatic

TABLE 23-8

Clinical Features of Lipoid CAH in 46,XY Individuals

Karyotype	46,XY
Inheritance	Autosomal recessive; mutations in <i>STAR</i> gene
Genitalia	Female; sometimes ambiguous, hypospadiac, or male
Wolffian duct derivatives	Hypoplastic or normal
Müllerian duct derivatives	Absent
Gonads	Testes
Habitus	Severe adrenal insufficiency in infancy with salt loss; failure of pubertal development; rare "nonclassic" cases associated with isolated glucocorticoid deficiency
Hormone profile	Usually deficiency of glucocorticoids, mineralocorticoids, and sex steroids except in rare "nonclassic" cases

CAH, congenital adrenal hyperplasia; STAR, steroidogenic acute regulatory protein.

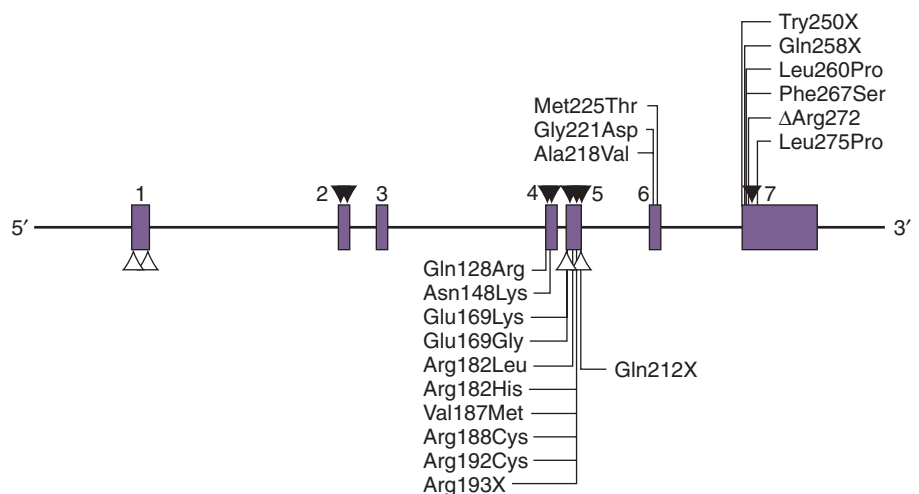

Figure 23-23 Model of the steroid-synthesizing cell (adrenal/gonadal) showing conversion of cholesterol to steroids. **A**, Cholesterol from low-density lipoprotein, from cholesterol esters stored in lipid droplets, and from endogenous synthesis in the endoplasmic reticulum is transported from the outer mitochondrial membrane to the inner membrane. This transport is facilitated by the steroidogenic acute regulatory protein (StAR) and by other, StAR-independent mechanisms. In the mitochondria, steroid synthesis begins with the conversion of cholesterol to Δ^5 -pregnenolone by the enzyme CYP11A1 (P450scc). **B**, In patients with lipid congenital adrenal hyperplasia, a mutation in the gene encoding StAR results in little or no activity of the mutant StAR, greatly reducing cholesterol transport into the mitochondria. Low levels of steroidogenesis by mechanisms independent of StAR can occur; however, increased secretion of corticotropin (or luteinizing hormone or follicle-stimulating hormone) results in cholesterol accumulation in the cells as lipid droplets. **C**, Continued stimulation and resultant accumulation of cholesterol causes engorgement of these cells, with mechanical and chemical perturbation of cell function. This results in primary adrenal insufficiency and impaired androgen biosynthesis by fetal Leydig cells. Females with lipid congenital adrenal hyperplasia feminize at puberty and menstruate but have progressive hypergonadotropic hypogonadism. This may occur because the follicular cells are relatively quiescent in utero and before puberty and therefore are undamaged. At the beginning of each cycle, follicles are recruited, and a small amount of estradiol can be produced as a result of StAR-independent mechanisms. This can occur until the follicular cells are engorged and rendered nonfunctional. ATP, adenosine triphosphate; cAMP, cyclic adenosine monophosphate. (From Bose HS, Sujjwara T, Strauss JF III, et al. The pathophysiology and genetics of congenital lipid adrenal hyperplasia. *N Engl J Med*. 1996;335:1870-1878, with permission of the Massachusetts Medical Society, copyright 1996.)

reactions: 20 α -hydroxylation, 22-hydroxylation, and cleavage of the cholesterol side chain. P450scc is therefore responsible for the first and rate-limiting step in steroid synthesis, which is necessary for pregnenolone production by the placenta and for mineralocorticoid, glucocorticoid, and androgen production by the adrenal glands and gonads.

Although a natural model of lipid CAH due to P450scc deficiency exists in the rabbit, it was thought that severe loss of P450scc activity in humans would be incompatible with survival. Placental progesterone production is necessary to support pregnancy (i.e., luteoplacental shift) after the second trimester in higher primates but not in rodents.

Figure 23-24 Diagram of selected mutations identified in the STAR gene associated with lipid congenital adrenal hyperplasia. Numbered solid boxes depict the exons. The three-letter abbreviations for amino acids are used to indicate the position of missense mutations; X indicates a nonsense (stop) mutation; insertions and deletions resulting in frameshift mutations (solid triangles) and splice site mutations (open triangles) are shown. Although STAR mutations are common in Japan, Korea, and regions of the Middle East, an increasing number of sporadic changes in the steroidogenic acute regulatory (StAR) protein are being detected in other countries. Two missense mutations at residues 187 and 188 have been associated with a nonclassic late-onset phenotype of glucocorticoid insufficiency.

However, complete disruption of P450 activity due to a frameshift mutation in *CYP11A1* has been reported in a 46,XY infant with a female phenotype and severe early-onset, salt-losing adrenal failure.²⁷⁷ A small number of other mutations in P450scc have also been described, usually in 46,XY phenotypic females with severe salt-losing adrenal failure (Table 23-9).²⁷⁸ Partial loss of function defects in P450scc have been described in boys with hypospadias who developed adrenal failure in late childhood.²⁷⁹ This condition is now well established as a cause of combined adrenal and gonadal failure.

3 β -Hydroxysteroid Dehydrogenase/ Δ^4 , Δ^5 -Isomerase Type 2 Deficiency. 3 β -HSD deficiency is a rare cause of CAH and is one of the steroidogenic deficiencies that affects both adrenal and gonadal steroid production. The autosomal recessive disorder is a consequence of mutations in *HSD3B2*, the gene encoding the 3 β -HSD/ Δ^4 , Δ^5 -isomerase type 2 isozyme, which is expressed mainly in the adrenals and gonads. This enzyme catalyses a crucial step in the biosynthesis of all steroid hormones, the conversion of Δ^5 - to Δ^4 -steroids (see Fig. 23-11). The other 3 β -HSD isoenzyme in humans, *HSD3B1*, is expressed in the placenta and in peripheral tissues such as the skin (mainly sebaceous glands), breast, and prostate; it is not associated with CAH. Type 1 and 2 isoenzymes are 93.5% homologous in protein structure, and their genes are located on chromosome 1p13.1.²⁸⁰ Human pregnancy is maintained by high levels of progesterone produced by placental HSD3B1 activity, and a homozygous type 1 gene defect would not be compatible with survival of an affected fetus.

Classic HSD3B2 deficiency is subdivided into salt-losing and non-salt-losing forms. Males with HSD3B2 deficiency have clinical features as summarized in Table 23-10. The external genitalia are usually ambiguous, with a small penis, severe hypospadias, partial labioscrotal fusion, a urogenital sinus, and a blind vaginal pouch.

Newborns with severe HSD3B2 deficiency develop adrenal insufficiency soon after birth. The 46,XY males with partial deficiency of HSD3B2 are not salt losers because they have mutant enzymes that retain 2% to 10% of HSD3B2 enzymatic activity, as assessed by transient expression of the mutant in intact cells.²⁸¹ Gynecomastia can occur at puberty in affected males and females. This is presumably the result of HSD3B1-mediated peripheral conversion of Δ^5 -C19-steroids to Δ^4 -C19-steroids and

TABLE 23-10

Clinical Features of HSD3B2 Deficiency in 46,XY Individuals

Karyotype	46,XY
Inheritance	Autosomal recessive; mutations in <i>HSD3B2</i> gene
Genitalia	Ambiguous; hypospadiac male
Wolffian duct derivatives	Normal
Müllerian duct derivatives	Absent
Gonads	Testes
Habitus	Severe adrenal insufficiency in infancy; poor virilization at puberty with gynecomastia Mild form: no mineralocorticoid deficiency, premature adrenarche \rightarrow mild virilization
Hormone profile	Increased concentrations of Δ^5 C ₂₁ - and C ₁₉ -steroids (e.g., 17-hydroxypregnenolone/cortisol ratio response to corticotropin, 17-hydroxypregnenolone, DHEA suppressible by dexamethasone)

DHEA, dehydroepiandrosterone; HSD3B2, 3 β -hydroxysteroid dehydrogenase type 2.

aromatization to estrogens.²⁸² Normal puberty and fertility have been reported in males with a null mutation in the *HSD3B2* gene.^{283,284}

The straightforward biochemical profile of classic HSD3B2 deficiency is based on an elevated ratio of Δ^5 - to Δ^4 -steroids, determined in plasma or urine. The most specific analyte to confirm the diagnosis is 17-hydroxypregnenolone, which is present at levels greater than 100 nmol/L basally or after ACTH stimulation.²⁸¹ However, this steroid is measured only in specialist laboratories. The concentrations of Δ^4 -steroids such as 17-OHP and androstenedione may also be elevated in HSD3B2 deficiency because of peripheral HSD3B1 activity. In a neonatal screening program, an elevated 17-OHP level in a salt-losing person with HSD3B2 deficiency may invoke a diagnosis of CYP21 deficiency.²⁸⁵

HSD3B2 is a four-exon gene that encodes 371 amino acids. About 36 mutations have been reported, and many affected individuals are compound heterozygotes (Fig. 23-25). The concordance between genotype and phenotype is close, so that the presence or absence of salt losing in HSD3B2 deficiency is quite predictable. Examples of mutants that retain no enzyme activity and cause severe salt losing include Gly15Asp, Leu108Trp, Glu142Lys, Pro186Leu, Leu205Pro, Pro222Gln, Tyr253Asn, and Thr259Arg. In contrast, mutations such as Ala10Val and Ala245Pro retain considerable enzyme activity and have been found in males with perineoscrotal hypospadias and no salt loss. A late-onset form of HSD3B2 deficiency usually manifests as premature pubarche and idiopathic hirsutism in females. Clearer biochemical markers consistent with mutation-proven HSD3B2 deficiency have been derived for this late-onset group.^{286,287} These markers include ACTH-stimulated 17-hydroxypregnenolone and 17-hydroxypregnenolone-to-cortisol ratios that are 54 and 38 standard deviations above the control means, respectively. However, biochemical phenotyping is not possible for carrier detection in families with known *HSD3B2* mutations.²⁸⁸ Targeting analysis of this gene in patients with idiopathic hypospadias yields, at best, only subtle changes in a few cases.²⁸⁹

17 α -Hydroxylase/17,20-Lyase Deficiency. P450c17 (CYP17) is a microsomal enzyme with 17 α -hydroxylase and

TABLE 23-9

Clinical Features of CYP11A1 Deficiency in 46,XY Individuals

Karyotype	46,XY
Inheritance	Autosomal recessive; mutations in <i>CYP11A1</i> gene
Genitalia	Female; rarely ambiguous or hypospadiac male
Wolffian duct derivatives	Hypoplastic or normal
Müllerian duct derivatives	Absent
Gonads	Testes (or absent)
Habitus	Severe adrenal insufficiency in infancy with salt loss ranging to milder adrenal insufficiency with onset in childhood; prematurity associated in one case
Hormone profile	Usually deficiency of glucocorticoids, mineralocorticoids, and sex steroids

CYP11A1, cytochrome P450 side-chain cleavage enzyme.

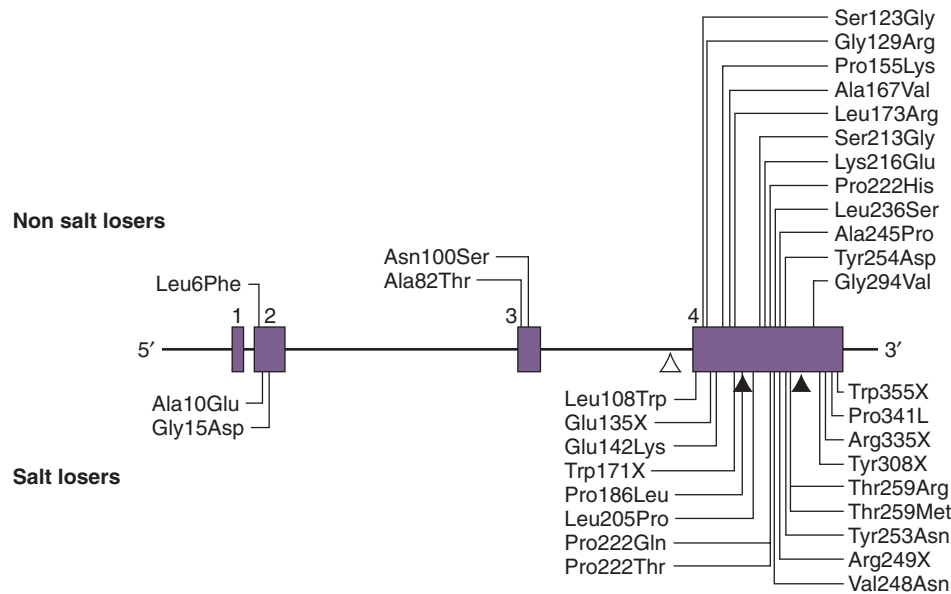

Figure 23-25 Diagram of the 3 β -hydroxysteroid dehydrogenase type 2 gene (*HSD3B2*) shows the mutations that result in deficiency of the enzyme. The numbered solid boxes depict the exons. Mutations are subdivided according to their association with salt-losing and non-salt-losing states. The three-letter abbreviations for amino acids are used to indicate the position of missense mutations; X indicates a nonsense (stop) mutation; insertions and deletions resulting in frameshift mutations (solid triangles) and splice site mutations (open triangles) are shown.

17,20-lyase activity that is expressed in the adrenals and gonads but not in the placenta or in ovarian granulosa cells.²⁹⁰⁻²⁹² The 17 α -hydroxylase action of P450c17 catalyzes the conversion of pregnenolone (Δ^5) to 17-hydroxypregnenolone and the conversion of progesterone (Δ^4) to 17-OHP (see Fig. 23-11). The 17,20-lyase action of P450c17 can convert 17-hydroxypregnenolone (Δ^5) to DHEA and 17-OHP (Δ^4) to androstenedione (see Fig. 23-11). P450c17 is bound to the smooth endoplasmic reticulum, where it accepts electrons from a specific flavoprotein, reduced nicotinamide adenine dinucleotide phosphate (NADPH)-P450. The 17,20-lyase activity of P450c17 is favored by the presence of Δ^5 substrates, redox partners such as POR and cytochrome *b₅*, and serine phosphorylation. Unlike in rodents, the Δ^5 -17,20-lyase activity of human P450c17 is 50 times more efficient than its Δ^4 -17,20-lyase activity; therefore very little androstenedione is formed directly from 17-OHP, and the principal pathway to androgen production is through DHEA.¹⁶⁹ P450c17 also has 16 α -hydroxylase activity.

Defects in P450c17 action can result in two different forms of CAH. Most often, combined 17 α -hydroxylase/17,20-lyase deficiency is seen, but rare cases of isolated 17,20-lyase deficiency have been reported (Tables 23-11 and 23-12).²⁹²

Combined 17 α -hydroxylase/17,20-lyase deficiency is an uncommon form of CAH, although an increasing number of cases are being reported from many different countries.²⁹³ A prevalence of approximately 1 case per 50,000 individuals is reported. The classic phenotype of complete combined 17 α -hydroxylase/17,20-lyase deficiency is that of a phenotypic female (46,XX, or underandrogenized 46,XY) who presents with an absence of secondary sexual characteristics (i.e., hypergonadotropic hypogonadism) at puberty and is found to have low-renin hypertension and hypokalemic alkalosis (see Table 23-11).

The classic phenotype and underlying biochemistry can be explained by the enzyme deficiency (see Fig. 23-11).²⁶² A defect in 17 α -hydroxylation in the adrenal cortex and

gonads results in impaired synthesis of 17-OHP and 17-hydroxypregnenolone and therefore of cortisol, androgens, and estrogens. Decreased cortisol synthesis causes increased corticotropin secretion, which results in excessive secretion of 17-deoxysteroids by the adrenal cortex, including the mineralocorticoids 11-deoxycorticosterone (DOC), corticosterone, and 18-hydroxycorticosterone. Excess DOC secretion leads to hypertension, hypokalemic alkalosis, and suppression of the renin-angiotensin system. Diminished aldosterone synthesis and secretion are sometimes reported. Corticosterone is a weak glucocorticoid; the high plasma concentrations in this disorder prevent the signs and symptoms of cortisol deficiency (e.g., hypoglycemia) and modulate the secretion of corticotropin.

Affected 46,XX females have normal female internal and external genital tracts, but the ovaries cannot secrete

TABLE 23-11

Clinical Features of Combined CYP17 Deficiency in 46,XY Individuals

Karyotype	46,XY
Inheritance	Autosomal recessive; mutations in <i>CYP17</i> gene
Genitalia	Female, ambiguous, or hypospadiac male
Wolffian duct derivatives	Absent or hypoplastic
Müllerian duct derivatives	Absent
Gonads	Testes
Habitus	Absent or poor virilization at puberty, gynecomastia, hypertension
Hormone profile	Decreased T; increased LH and FSH; increased plasma deoxycorticosterone, corticosterone, and progesterone; decreased plasma renin activity Low renin hypertension with hypokalemic alkalosis

CYP17, 17 α -hydroxylase/17,20-lyase; FSH, follicle-stimulating hormone; LH, luteinizing hormone; T, testosterone.

TABLE 23-12

Clinical Features of Isolated 17,20-Lyase Deficiency in 46,XY Individuals

Karyotype	46,XY
Inheritance	Autosomal recessive; mutations in <i>CYP17</i> gene, usually affecting key redox domains
Genitalia	Female, ambiguous, or hypospadiac male
Wolffian duct derivatives	Absent or hypoplastic
Müllerian duct derivatives	Absent
Gonads	Testes
Habitus	Absent or poor virilization at puberty; gynecomastia
Hormone profile	Decreased plasma T, DHEA, androstenedione, and estradiol; abnormal increase in plasma 17-hydroxyprogesterone and 17-hydroxypregnenolone; increased LH and FSH; increased ratio of C ₂₁ -deoxysteroids to C ₁₉ -steroids (DHEA, androstenedione) after hCG stimulation

CYP17, 17 α -hydroxylase/17,20-lyase; DHEA, dehydroepiandrosterone; FSH, follicle-stimulating hormone; hCG, human chorionic gonadotropin; LH, luteinizing hormone; T, testosterone.

estrogens at puberty, resulting in absent breast development and hypogonadism with elevated plasma FSH and LH levels. The lack of adrenal and ovarian androgens can result in little or no growth of pubic and axillary hair. In affected 46,XX individuals, the ovaries have a high proportion of atretic follicles, and some ovaries contain an increased number of enlarged follicular cysts.

Affected 46,XY individuals with complete combined 17 α -hydroxylase/17,20-lyase deficiency who are diagnosed in adolescence usually have female external genitalia and a blind vaginal pouch (see Table 23-11). Testes may be intra-abdominal, in the inguinal canal, or in the labioscrotal folds. Inguinal hernias are common, Müllerian

structures are absent, and Wolffian derivatives are hypoplastic. Bone age is frequently delayed, and prolonged linear growth can lead to tall stature. Pubic and axillary hair is absent or sparse, and hypergonadotropic hypogonadism is associated with a failure to develop secondary sexual characteristics at puberty. Excessive secretion of DOC and corticosterone usually leads to low-renin hypertension and hypokalemic alkalosis, as in 46,XX girls with this condition.

Complete 17 α -hydroxylase/17,20-lyase deficiency is associated with a variety of mutations in the *CYP17* gene that cause complete loss of function in assays of enzyme activity. These changes include a range of missense, frameshift, and nonsense mutations (Fig. 23-26). A common mutation is the 4-base-pair duplication in exon 8, which is shared by Mennonites and individuals in the Friesland region of the Netherlands and is attributed to a founder effect originating in Friesland. Other geographic clusters include an in-frame deletion of residues 487 to 489 in Southeast Asia and the Arg362Cys and Trp406Arg missense mutations found among Brazilians of Portuguese and Spanish ancestry, respectively.^{292,294} However, many different changes occur in other populations and are located throughout the enzyme.²⁹⁵

Partial forms of combined 17 α -hydroxylase/17,20-lyase deficiency have been described. This condition most frequently manifests in a 46,XY infant with ambiguous genitalia or severe hypospadias for whom the steroid profile is consistent with the diagnosis of P450c17 deficiency. Hypertension may or may not be present in partial forms of combined 17 α -hydroxylase/17,20-lyase deficiency, and aldosterone secretion may be normal or even elevated. Corticosterone levels, which are usually 50- to 100-fold higher than normal, provide adequate glucocorticoid effects and prevent symptoms of cortisol deficiency. The development of male secondary sexual characteristics at puberty may be incomplete, and gynecomastia is often seen. This rare condition has been associated with a

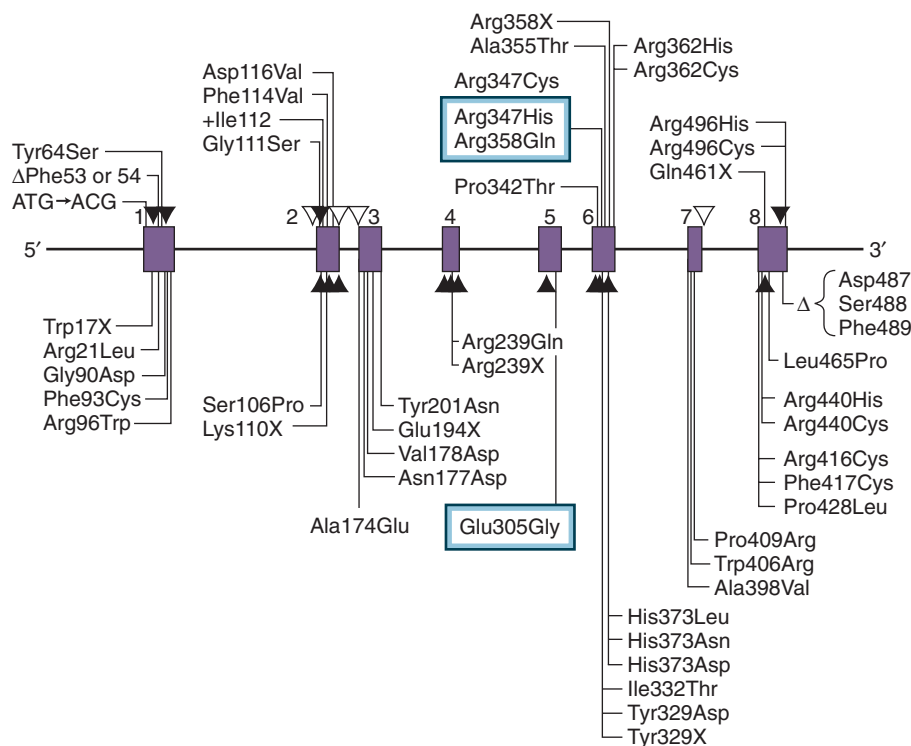

Figure 23-26 Diagram of selected mutations in the *CYP17* gene causing 17 α -hydroxylase/17,20-lyase deficiency. The numbered solid boxes depict the exons. The three-letter abbreviations for amino acids are used to indicate the position of missense mutations; X indicates a nonsense (stop) mutation; insertions and deletions resulting in frameshift and splice site mutations are shown by solid triangles and open triangles, respectively. All of these mutations cause 17 α -hydroxylase deficiency. Several missense mutations, such as those at codons 305, 347, and 358 (boxes), have been associated with "isolated" 17,20-lyase deficiency.

phenylalanine deletion at codon 53 or 54²⁹⁶, in a patient compound heterozygous for a null mutation in P450c17, a Pro342Thr mutation, and 20% of normal 17 α -hydroxylase activity²⁹⁷; and in a small number of additional cases in which some residual enzyme function was retained. Analysis of these patients suggests that 5% of normal activity in a 46,XX female is sufficient to allow estrogen production with normal secondary sexual characteristics and irregular menses, whereas more than 25% of normal activity appears to be necessary to achieve normal androgenization of the external genitalia of affected 46,XY males.

Isolated 17,20-lyase activity has been reported in a small number of patients.²⁹⁸ These 46,XY individuals usually have genital ambiguity, normal secretion of glucocorticoids and mineralocorticoids, and marked reduction in sex steroid synthesis (see Table 23-12). The first two patients shown to have a molecular defect in P450c17 harbored homozygous point mutations in the enzyme (Arg347His, Arg358Gln) that specifically interfered with 17,20-lyase activity by changing the distribution of surface charges in the redox-partner binding site.²⁹⁹ Other patients have been reported with similar mutations or with a point mutation (Glu305Gly) that specifically alters the conformation of the substrate binding site.³⁰⁰

The diagnosis of 17 α -hydroxylase deficiency should be suspected in all cases of 46,XY DSD, and it is strongly supported by the discovery of hyporeninemic hypertension and hypokalemic alkalosis and by a lack of secondary sex characteristics at puberty. Plasma concentrations of corticotropin, DOC, corticosterone, and progesterone are high, and those of 17 α -OHP, cortisol, and gonadal steroids are low. Replacement therapy with physiologic doses of glucocorticoids suppresses DOC and corticosterone secretion and normalizes serum potassium levels, blood pressure, and plasma renin and aldosterone levels. Gonadectomy is usually performed in 46,XY patients who have a female gender assignment. Appropriate gonadal steroid replacement therapy is indicated at puberty.

Cytochrome b_5 Deficiency. A splice site mutation in the 17,20-lyase redox partner cytochrome b_5 was first reported in a 46,XY child with ambiguous genitalia and methemoglobinemia, although extensive endocrinologic data were not reported.³⁰¹ However, a homozygous nonsense mutation in this gene (*CYB5A*) was recently described in a 46,XY child with severe hypospadias and a biochemical profile consistent with isolated 17,20-lyase deficiency.³⁰² Methemoglobin was elevated above the normal range in this case, but it did not result in clinical signs.

P450 Oxidoreductase Deficiency. POR is a membrane-bound flavoprotein that plays a central role in electron transfer from NADPH to P450 enzymes (Fig. 23-27).³⁰³ POR is crucial in the 17,20-lyase reaction of P450c17, and it interacts with all 57 microsomal P450 enzymes, including P450c21 (21-hydroxylase) and P450c19 (aromatase), and with many others involved in hepatic drug metabolism.

A potential role for POR in human steroidogenesis emerged after the description of several patients with apparent combined deficiencies of CYP17 and CYP21.³⁰⁴ Ambiguous genitalia and unusual patterns of combined steroidogenic defects have been described in a subset of patients with Antley-Bixler syndrome, a form of skeletal dysplasia that is characterized by craniosynostosis, brachycephaly, midface hypoplasia, proptosis, choanal stenosis, radioulnar or radiohumeral synostosis, bowed femora, and arachnodactyly.

Figure 23-27 Role of P450 oxidoreductase (POR) in electron transfer to microsomal (type II) P450 enzymes. Reduced nicotinamide adenine dinucleotide phosphate (NADPH) interacts with POR, which is bound to the endoplasmic reticulum, and transfers a pair of electrons to the FAD moiety. This change in charge results in altered conformation, which allows the electrons to pass from the FAD to the FMN moiety. After further realignment, the FMN domain can interact with the redox partner binding site of the P450 enzyme (e.g., P450c17, P450c21, P450c19), permitting electron transfer to the active heme group of the enzyme, which results in substrate catalysis. The interaction of POR and the P450 enzymes is coordinated by negatively charged acidic residues on the surface of the FMN domain of POR and positively charged basic residues in the redox partner binding site of the P450 enzyme. In the case of human P450c17, this interaction is facilitated by the allosteric action of cytochrome b_5 and by serine phosphorylation of P450c17. (From Miller WL. Minireview: regulation of steroidogenesis by electron transfer. *Endocrinology*. 2005;146:2544-2550, with permission of The Endocrine Society, copyright 2005.)

The first recessively inherited human mutations in POR were described in 2004, and a significant number of changes have been described in patients with marked phenotypic variations (Table 23-13).^{170,305,306} At the most severe end of the spectrum are Antley-Bixler syndrome with ambiguous genitalia and apparent combined CYP17 and CYP21 deficiency with no skeletal phenotype. Milder defects in POR have also been seen in women with a form of polycystic ovary syndrome and in men with mild gonadal insufficiency. A range of POR activity is associated with this spectrum of phenotypes, and skeletal features can be subtle. Two common mutations are emerging: Arg-287Pro is the most prevalent mutation in patients of European ancestry, whereas the Arg457His mutation is common in Japan.^{170,306-307} Activating mutations in fibroblast growth factor receptor 2 (FGFR2) have also been reported in

TABLE 23-13

Clinical Features of P450 Oxidoreductase Deficiency in 46,XY Individuals

Karyotype	46,XY
Inheritance	Autosomal recessive; mutations in <i>POR</i> gene
Genitalia	Ambiguous; hypospadias or male
Wolffian duct derivatives	Absent or hypoplastic
Müllerian duct derivatives	Absent
Gonads	Testes
Habitus	Variable androgenization at birth; variable virilization at puberty; glucocorticoid deficiency; no severe mineralocorticoid deficiency; features of Antley-Bixler syndrome (craniosynostosis, skeletal dysplasia) in some cases
Hormone profile	Evidence of combined CYP17 and CYP21 insufficiency; normal or low cortisol with poor response to ACTH stimulation; elevated 17-OHP; T low

ACTH, adrenocorticotropin; CYP, cytochrome P450 enzyme; 17-OHP, 17-hydroxyprogesterone; POR, P450 oxidoreductase; T, testosterone.

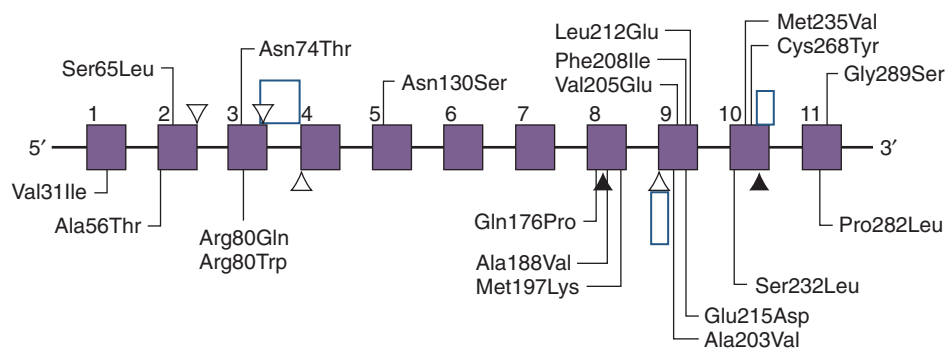

Figure 23-28 Diagram of the 17 β -hydroxysteroid dehydrogenase type 3 gene (*HSD17B3*) shows the mutations that result in deficiency of the enzyme. The numbered solid boxes depict the exons. The three-letter abbreviations for amino acids are used to indicate the position of missense mutations; X indicates a nonsense (stop) mutation; insertions and deletions resulting in frameshift mutations (solid triangles) and splice site mutations (open triangles) are shown.

association with Antley-Bixler syndrome; these patients do not have ambiguous genitalia or steroidogenic defects.

Most patients with POR deficiency have normal electrolytes and mineralocorticoid function (see Table 23-13).³⁰⁸ Cortisol insufficiency may be present, or if basal levels are adequate, the response to ACTH stimulation is reduced. The serum 17-OHP concentration is usually elevated, with a variable response to ACTH stimulation, and levels of sex steroids tend to be low, especially outside the early neonatal period. POR deficiency can be associated with ambiguous genitalia in both sexes (46,XY and 46,XX). Underandrogenization of 46,XY males can occur and may result from disturbed 17,20-lyase activity during fetal Leydig cell steroidogenesis. The partial androgenization of 46,XX infants is more prevalent and may be the result of a disturbance in aromatase activity, because POR is an electron donor for this enzyme and aromatase deficiency causes prenatal androgenization of the developing 46,XX fetus (see “Aromatase Deficiency”). Alternatively, a back-door pathway of androgen biosynthesis has been described in certain species, such as the fetal Tammar wallaby.^{170,171} In this model system, 17-OHP can be converted to DHT without the use of androstenedione or testosterone as an intermediate. Emerging data indicate that this pathway may also be functional during human development.

17 β -Hydroxysteroid Dehydrogenase Type 3 Deficiency.

The 17 β -hydroxysteroid dehydrogenase type 3 (*HSD17B3*) reaction in the human is mediated by isozymes that catalyze the reduction of androstenedione, DHEA, and estrone to testosterone, Δ^5 -androstenediol, and estradiol, respectively, as well as the reverse reaction (see Fig. 23-11).³⁰⁹ The *HSD17B3* enzyme uses NADPH as a cofactor. The *HSD17B3* gene contains 11 exons and is located on chromosome 9q22. The type 3 isoenzyme is expressed primarily in the testes, where it favors the conversion of the weak androgen substrate, androstenedione, to the more biologically active testosterone (see Fig. 23-11). The family of 17 β -HSDs comprise at least 14 isoenzymes that have physiologic relevance to a range of human disorders such as breast and prostate cancer, endometriosis, and disturbances in fatty acid metabolism, as well as 46,XY DSDs.³¹⁰

A deficiency of *HSD17B3*, which is also called 17-ketosteroid reductase, was first reported as one of the causes of 46,XY DSD by Saez and colleagues (Fig. 23-28).^{310,311} Many cases have been reported, and the phenotype is well characterized (Table 23-14).³¹²⁻³¹⁴ Most affected males have female external genitalia at birth, although a few infants present with ambiguous genitalia. The testes are usually located in the inguinal canal; the wolffian ducts are

stabilized to form epididymides, vas deferens, seminal vesicles, and ejaculatory ducts; and there is a blind vaginal pouch. Affected infants are invariably assigned a female sex and may mistakenly be assumed to have CAIS. Profound virilization occurs at puberty in the form of deepening of the voice, hirsutism, muscle development, and clitoromegaly. This is often how the condition must be distinguished from other causes of virilization arising at puberty in children raised female.

The pubertal increase in testosterone is mostly from extraglandular conversion from androstenedione. We have speculated that this is mediated by genetic or environmental induction of enzyme activities of the aldoketoreductase family 1C (AKR1C), such as the 17 β -HSD17B5 type 5 isoenzyme, also known as AKR1C3.^{315,316} The androstenedione substrate is increased at puberty, and the testes have partial *HSD17B3* activity in some cases. In a large cohort of patients from a consanguineous population in the Gaza Strip, the phallus was described as reaching lengths of 4 to 8 cm.³¹⁷ The *HSD17B3* mutation reported in this population (Arg80Gln) is associated with 15% to 20% retention of normal *HSD17B3* activity (see Fig. 23-28). The development of gynecomastia at puberty occurs because of estrogens derived from the conversion of androstenedione by aromatase in extraglandular tissue and the action of the *HSD17B1* or *HSD17B2* isoenzymes.

TABLE 23-14

Clinical Features of *HSD17B3* Deficiency in 46,XY Individuals

Karyotype	46,XY
Inheritance	Autosomal recessive; mutations in <i>HSD17B3</i> gene
Genitalia	Female → ambiguous; blind vaginal pouch
Wolffian duct derivatives	Present
Müllerian duct derivatives	Absent
Gonads	Testes (usually undescended)
Habitus	Virilization at puberty (phallus enlargement, deepening of voice, and development of facial and body hair); gynecomastia variable
Hormone profile	Increased plasma estrone and androstenedione; decreased ratio of plasma testosterone/androstenedione and estradiol after hCG stimulation test; increased plasma FSH and LH levels

FSH, follicle-stimulating hormone; hCG, human chorionic gonadotropin; *HSD17B3*, 17 β -hydroxysteroid dehydrogenase 3; LH, luteinizing hormone.

The striking virilization at puberty, similar to that of patients with 5 α -reductase type 2 deficiency, has resulted in gender role reassignment from female to male in some cases. Patients presenting as androgenized females at puberty usually undergo urgent gonadectomy, reduction clitoroplasty, and maintenance of female gender. In a series of women with diverse forms of DSD, there was evidence of significant psychological distress.³¹⁸ However, only two subjects with 17 β -HSD deficiency were included in this pilot study. The typical biochemical profile in HSD17B3 deficiency is an elevated androstenedione level relative to testosterone (see Table 23-14). Expressed as a ratio of testosterone to androstenedione (after an hCG stimulation test before puberty), values less than 0.8 are typically found in these patients.³¹⁹ Testicular vein sampling at the time of gonadectomy shows a markedly increased androstenedione gradient relative to that of testosterone.

Only mutations in the *HSD17B3* gene that encodes the testis-specific enzyme are a cause of this form of 46,XY DSD. The range of mutations reported in patients with HSD17B3 deficiency is shown in Figure 23-28. Most are missense mutations, and some patients are compound heterozygotes. Expression studies of the mutant enzymes in heterologous cells usually show complete absence of activity in the conversion of androstenedione to testosterone compared with the normal enzyme. A study of women with polycystic ovary syndrome showed no association with polymorphisms in the *HSD17B3* gene.³²⁰ Women homozygous or compound heterozygous for *HSD17B3* mutations are asymptomatic. The presence of Wolffian duct derivatives in the form of a normal vas deferens and epididymis in patients with homozygous mutations that result in complete absence of enzymatic activity is intriguing. A similar finding occurs in a significant number of patients with CAIS due to a missense mutation in the *AR* gene.³²¹ Androgens can diffuse directly into the adjacent Wolffian ducts to elicit a paracrine effect. Fetal androstenedione levels are expected to be increased. Although this is a weak androgen, a reporter gene assay indicated that it was almost as potent as testosterone and DHT when tested at concentrations greater than 10 nmol/L.³²²

Establishment of the diagnosis of HSD17B3 deficiency soon after birth, because of finding inguinal testes in a phenotypic female infant or because of ambiguity of the external genitalia, raises the question of sex assignment. Because of the experience of gender role change at puberty in affected families as reported in Gaza, it has been proposed that these patients be given male sex assignment at diagnosis.³²³ In this study, 46,XY males with female external genitalia were treated early with testosterone, followed later by first-stage genitoplasty. Most achieved a reasonable cosmetic result and a penile length within the normal range. No more recent studies have reported on outcomes for infants assigned a male sex of rearing. Phenotypic variability within affected families can also influence gender assignment.³¹⁵ Gender role changes at puberty were reported in 39% to 64% of patients raised as girls in one study, but the numbers of subjects on which these figures were based were fewer than for 5 α -reductase deficiency.¹⁹⁰

Steroid 5 α -Reductase Type 2 Deficiency. Steroid 5 α -reductase type 2 deficiency is a defect in androgen biosynthesis. As with 17 β -HSD deficiency, it is characterized by a 46,XY karyotype, normally differentiated testes, and male internal ducts but external genitalia that may be more ambiguous at birth. There is a striking degree of virilization at puberty in patients raised as female. Classic features of this enzyme deficiency are summarized in Table 23-15.

TABLE 23-15

Clinical Features of 5 α -Reductase Type 2 Deficiency in 46,XY Individuals

Karyotype	46,XY
Inheritance	Autosomal recessive; mutations in <i>SRD5A2</i> gene
Genitalia	Usually ambiguous with small, hypospadiac phallus; blind vaginal pouch
Wolffian duct derivatives	Normal
Müllerian duct derivatives	Absent
Gonads	Normal testes
Habitus	Decreased facial and body hair; no temporal hair recession; prostate not palpable
Hormone profile	Decreased ratio of 5 α /5 β C21 and C19 steroids in urine; increased T/DHT ratio before and after hCG stimulation; modest increase in plasma LH; decreased conversion of T to DHT in vitro

DHT, dihydrotestosterone; hCG, human chorionic gonadotropin; LH, luteinizing hormone; SRD5A2, steroid-5 α -reductase type 2; T, testosterone.

The description of a genetic isolate from villages in the southwestern part of the Dominican Republic and a subsequent review of the biochemical and molecular features underlines the importance of DHT in the development of the male phenotype.³²⁴⁻³²⁷ At birth, there is a bifid scrotum, a urogenital sinus, a blind vaginal pouch, and a clitoris-like, hypospadiac phallus. Testes differentiate normally and are located in the inguinal canal or in the labioscrotal folds. No Müllerian structures are present. The Wolffian ducts are stabilized so that the epididymides, vasa deferentia, and seminal vesicles are well differentiated; the ejaculatory ducts usually terminate in the blind vaginal pouch. The prostate is hypoplastic.

Affected males virilize to various degrees at puberty. The voice deepens, muscle mass increases, the phallus lengthens to 4 to 8 cm, the bifid scrotum becomes rugated and pigmented, and the testes enlarge and descend into the labioscrotal folds. Postpubertal affected males do not have acne, temporal hair recession, or enlargement of the prostate, and they do not develop gynecomastia. There is normal libido with penile erections. Histologic examination of the testes shows Leydig cell hyperplasia and decreased spermatogenesis. This is caused by failure to transform spermatogonia into spermatocytes, rather than associated cryptorchidism.³²⁸ Nevertheless, some members of the Dominican cohort had a normal sperm count. One man fathered a child after intrauterine insemination, and two affected brothers in a Swedish family were spontaneously fertile after hypospadias repair performed in childhood.^{329,330} Gender role changes occur frequently in 5 α -reductase deficiency, particularly where clusters of cases occur in geographic regions (e.g., Dominican Republic, New Guinea,³³¹ South Lebanon, Turkey). Overall, gender role is changed in 56% to 63% of cases.¹⁹⁰ Females (46, XX) homozygous for 5 α -reductase deficiency undergo normal puberty but delayed menarche, and fertility is normal.³³²

The biochemical profile in 5 α -reductase deficiency typically shows an elevated testosterone-to-DHT ratio, which needs to be determined after hCG stimulation when investigations are undertaken before puberty (see Table 23-15). A ratio exceeding 20:1 suggests the diagnosis. Serum LH and FSH levels may be normal or elevated after puberty. Analysis of a urinary steroid profile by gas chromatography and mass spectrometry is usually specific to demonstrate a diminished ratio of urinary 5 α - to 5 β -reduced C19 and C21

steroids.³³³ The diagnosis can still be confirmed biochemically after gonadectomy because of persistent effects on $5\alpha/5\beta$ -reduced C21 steroids. However, the results may not be sufficiently reliable in early infancy.

Early diagnosis of 5α -reductase type 2 deficiency is important because of its bearing on sex assignment. The natural history of this condition, with a tendency for change to a male gender role with virilization at puberty, indicates that male gender assignment must be an option when there is ambiguous or severely underandrogenized genitalia at birth.³³⁴ This enzyme deficiency can masquerade as PAIS in newborns.³³⁵ DHT, which may be applied topically as a cream, increases penile length and facilitates repair of the hypospadias.³³⁶

5α -reductase type 2 deficiency is transmitted as an autosomal recessive trait. Two microsomal 5α -reductase enzymes catalyze the NADPH-dependent conversion of testosterone to DHT. 5α -Reductase type 2 is a 254-amino-acid protein encoded by the *SRD5A2* gene on chromosome 2p23.³²⁶ The type 2 isozyme is expressed predominantly in the primordia of the prostate and external genitalia but not in the Wolffian ducts until after their differentiation into the male internal genital ducts.³³⁷ The type 1 isoenzyme is expressed in skin, including human genital skin fibroblasts. This isoenzyme may contribute to the virilization that occurs in 5α -reductase-deficient patients at puberty.³³⁸

The 5α -reductase type 2 deficiency is genetically heterogeneous, and the more than 50 mutations detected in the *SRD5A2* gene are distributed among all five exons (Fig. 23-29). Most are missense mutations, and a complete gene deletion is found in the New Guinea population. There is a predominance of mutations in exon 4, mostly localized between codons 197 and 230, where the effect is complete inactivation of the mutant enzyme. A stretch of 21 amino acids in this region probably functions as a transmembrane domain.³²⁷ There is little correlation between the severity

of the clinical phenotype and the nature of the mutation, although the highly prevalent proline-to-arginine mutation in the Mexican population is associated with severe undervirilization at birth and female sex assignment.³²⁷ A significant number of cases are compound heterozygotes, and consanguinity is common. Male heterozygotes are normal.

Disorders of Androgen Action

The key role of androgens in male sex differentiation cannot be better illustrated than by the consequence of total lack of response to androgens in target tissues—a complete female phenotype in a 46,XY individual with normally formed testes producing age-appropriate testosterone levels. This is the paradigm of a hormone resistance syndrome. The pathophysiology of clinical syndromes associated with complete or partial resistance to androgens is related to the mechanism of normal androgen action.^{339,340}

Male sex differentiation, the subsequent acquisition of secondary sex characteristics at puberty, and the onset of spermatogenesis are all mediated by androgens binding to a single intracellular AR ubiquitously expressed in target tissue. The AR is one of a quartet of nuclear receptors (i.e., glucocorticoid, mineralocorticoid, progesterone, and androgen) that are closely related within a large superfamily and activate gene transcription through hormone response elements. The single-copy eight exon gene encoding the AR is located on Xq11-q12; the AR is a protein of 919 amino acid residues. The major functional domains are an N-terminal transactivation domain (NTD) encoded by exon 1; a central, highly conserved DNA-binding domain (DBD) encoded by exons 2 and 3; a hinge region that connects the DBD to the ligand-binding domain; and a C-terminal ligand-binding domain (LBD) encoded by exons 4 through 8 (Fig. 23-30). The 70-amino-acid DBD is highly conserved among nuclear receptors and contains

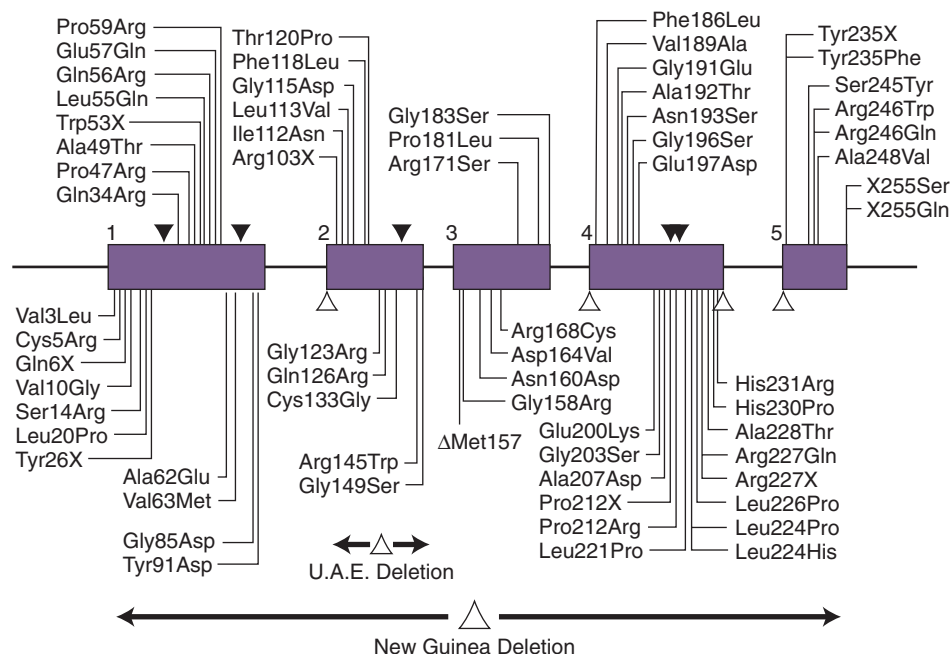

Figure 23-29 Diagram of the 5α -reductase type 2 gene (*SRD5A2*) shows the mutations that result in 5α -reductase deficiency. The numbered solid boxes depict the exons. The three-letter abbreviations for amino acids are used to indicate the position of missense mutations; X indicates a nonsense (stop) mutation; insertions and deletions resulting in frameshift and splice site mutations are shown by solid triangles and open triangles, respectively. Large deletions found in affected United Arab Emirates (UAE) and New Guinea populations are shown. (Adapted from Grumbach MM, Hughes IA, Conte FA. Disorders of sex differentiation. In: Larsen PR, Kronenberg HM, Melmed S, et al., eds. *Williams Textbook of Endocrinology*, 10th ed. Philadelphia, PA: Saunders, 2003, with additional data provided courtesy of Dr. Julianne Imperato-McGinley, Department of Medicine, Weill Medical College of Cornell University, Ithaca, NY.)

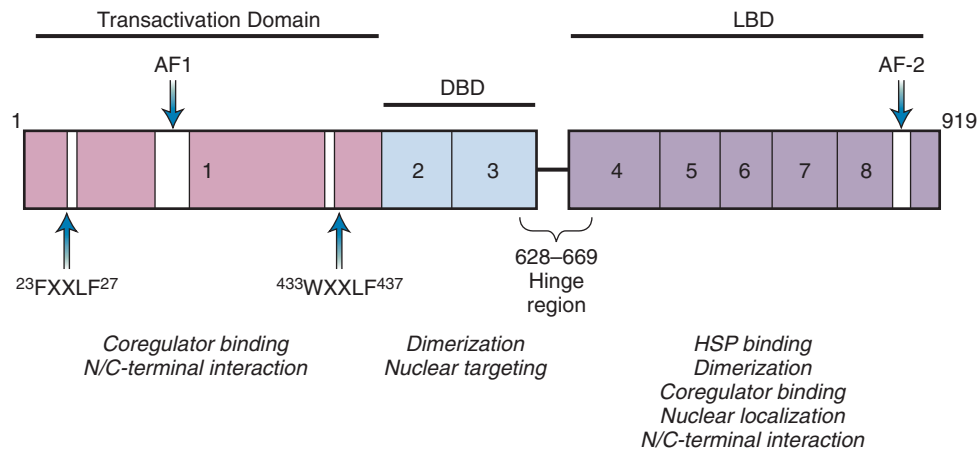

Figure 23-30 Schematic diagram of the androgen receptor (AR) shows the major functional domains and subsidiary functions. Single-amino-acid codes are used, and X represents any amino acid. Numbers outside the structure refer to amino acids (AR comprises 919 amino acid residues); numbers 1 through 8 inside the structure refer to AR exons. AF, activation function; DBD, DNA-binding domain; LBD, ligand-binding domain; HSP, heat shock protein.

cysteine residues that coordinate zinc atoms to form the zinc fingers characteristic of nuclear receptors and many other transcription factors. The first zinc finger contains a P box that enters the major groove of DNA to form specific base-pair contacts that are identical for all classic steroid receptors. The second zinc finger containing the D box is involved in protein-protein interactions and also stabilizes the unit for receptor dimerization. This requires recognition of selective androgen response elements.³⁴¹ The subsidiary functions operated by these domains are shown in Figure 23-30 and include dimerization, binding to coregulator proteins, interaction with HSPs, and transcriptional regulation.

The two subdomains most involved in activation of transcription are the motif activation function 1 (AF1) in the NTD and the motif activation function 2 (AF2) in the LBD. AF1 is ligand independent, whereas AF2 is ligand dependent and interacts with p160 steroid receptor coactivators such as NCOA1 (formerly called SRC1), NCOA2 (formerly SRC2 or TIF2), and NCOA3 (formerly SRC3).³⁴² For most nuclear receptors, there is a strong interaction between the AF2 subdomain and LXXLL motifs (in which L is leucine and X is any amino acid) in the coactivators. In the case of the AR, this interaction is weaker, and the AF2 subdomain interacts in an intramolecular manner with its cognate AF1 subdomain in the NTD. This N-terminal and C-terminal (N-C) interaction is a relatively unique feature of the AR and is mediated by interaction with the FXXLF motif (in which F is phenylalanine) in AF1 comprising amino acid residues 23 to 27. The N-C interaction stabilizes the AR and slows down the dissociation of the ligand from its receptor. Further modulation of AR function occurs posttranslationally by processes such as phosphorylation and sumoylation.

A unique feature of the AR is the homopolymeric stretches of amino acids within the NTD. A sequence of CAG repeats in exon 1 encodes for a stretch of glutamines that ranges from 11 to 31 repeats (mean, 21 repeats) in the general population. Another repeat ranges from 10 to 25 glycines (mean, 23 glycines) in the general population. In vitro studies show that the length of the CAG repeat is inversely proportional to the activity of the AR as a transcription factor.³⁴³

Figure 23-31 illustrates androgens interacting with the AR on entering target cells and subsequent activation of target genes. A single receptor binds all androgens;

testosterone is converted to DHT, which is biologically more potent because it dissociates from the AR at a slower rate. The AR in the unliganded state is located in the cytoplasm complexed to HSPs such as HSP70 and HSP90 and complexed to co-chaperone proteins such as FKBP4 (also called FKBP52). Binding of ligand to its receptor initiates dissociation from these complexes to allow translocation of the AR into the nucleus, where it binds as a homodimer to inverted repeats of 5'-AGAACA-2'-like motifs with a three-nucleotide spacer (nnn). The action of the AR is further modulated by interaction with coregulatory proteins that function as coactivators or corepressors.³⁴² Many coactivators act in a generic fashion (e.g., SRC and CBP/p300-interacting transactivator [CITED] family of proteins), but others, RAN (formerly called ARA24), RNF 14 (formerly ARA54), TGFB111 (formerly ARA55), and NCOA4 (formerly ARA70) are relatively specific to the AR.

The crystal structure of the AR LBD bound to natural and synthetic androgens is shown in Figure 23-32. The three-dimensional structure of a nuclear receptor LBD comprises 12 α -helices associated with antiparallel β -sheets arranged in the form of a tripartite sandwich. A hydrophobic pocket is formed by helices 3, 4, 5, 7, 11, and 12, to which the ligand is bound on contact with its cognate receptor. Helix 12, the outermost α -helix, folds back on top of the ligand hydrophobic pocket like a lid closing on a box. This has been referred to as the *mousetrap effect*; the ligand is captured and retained by slowing the rate of ligand-receptor dissociation. This trapping effect by helix 12 also permits interaction between the LBD and AF2 subdomain and the LXXLL motif in associated coregulator proteins. Information about the structural and functional aspects of the AR has been gathered from analysis of AR mutations that lead to various degrees of androgen resistance, which are clinically manifested as syndromes of androgen insensitivity that are classified as complete, partial, and minimal according to severity of hormone resistance.³³⁹

Complete Androgen Insensitivity Syndrome. The phenotype of CAIS is that of a female (Table 23-16). Estimates of the prevalence of this X-linked recessive disorder range from 1 case in 20,400 to 1 in 99,000 genetic males.³⁴⁴ The typical mode of presentation is that of an adolescent female who has breast development with a pubertal growth spurt but who has not had menarche. Pubic and axillary hair is

Figure 23-31 Androgen action in a target cell. Circulating testosterone bound predominantly to sex hormone-binding globulin (SHBG) enters the cell in free form, where it is converted to dihydrotestosterone (DHT), a more potent androgen. Both androgens bind to a single cytoplasmic androgen receptor (AR) complexed to heat shock proteins (HSPs) and other co-chaperones such as FKBP52. Androgen binding dissociates the AR from HSPs, and AR-bound androgen translocates to the nucleus, binding to DNA response elements as a homodimer. Coactivators such as NCOA4(ARA70) bind to the AR complex to mediate interaction with the general transcription apparatus (GTA). This results in transcription of androgen-responsive genes and pleiotropic biologic responses, including male sex differentiation, growth, muscle and bone development, spermatogenesis, and prostate growth. P, phosphorylation. (Adapted from Feldman BJ, Feldman D. The development of androgen-independent prostate cancer. *Nature Rev Cancer*. 2001;1:34-45, with permission of Nature Publishing Group, copyright 2001.)

Figure 23-32 **A**, Schematic diagram of the androgen receptor (AR) shows the tripartite sandwich arrangement of the helices, the position of the bound ligand in the pocket, and a coregulator FXXLF peptide bound to the activation function 2 (AF2) region. **B**, The DNA-binding domain structure of the AR binds through its two zinc fingers to DNA response elements.

TABLE 23-16

Clinical Features of Complete Androgen Insensitivity Syndrome

Karyotype	46,XY
Inheritance	X-linked recessive; mutations in <i>AR</i> gene
Genitalia	Female with blind vaginal pouch
Wolffian duct derivatives	Often present, depending on mutation type
Müllerian duct derivatives	Absent or vestigial
Gonads	Testes
Habitus	Scant or absent pubic and axillary hair; breast development and female habitus at puberty; primary amenorrhea
Hormone and metabolic profile	Increased LH and testosterone levels; increased estradiol (for male reference range); FSH levels often normal or slightly increased; resistance to androgenic and metabolic effects of testosterone

AR, androgen receptor; FSH, follicle-stimulating hormone; LH, luteinizing hormone.

usually absent or scanty. The uterus is absent as a result of normal AMH action, although there may be Müllerian remnants. The Wolffian ducts are stabilized in many patients, with well-developed vas deferens and epididymis observed when gonadectomy is performed.³²¹ The main differential diagnosis at this age is XY complete gonadal dysgenesis (i.e., Swyer syndrome), which is distinguished by poor breast development, taller stature, decreased ratio of upper to lower body segments, and a different hormone profile.³⁴⁵ CAIS may occur in early infancy with bilateral inguinal or labial swellings. 17 β -HSD deficiency may also manifest in this manner. Bilateral inguinal hernias are rare in girls, and it has been estimated that 1% to 2% of such patients have CAIS.³⁴⁶ A CAIS diagnosis should be considered in all girls with this type of hernia, and the presence of a Y chromosome should be checked by fluorescence in situ hybridization (FISH) or a full karyotype. If the hernial sac contains gonads, a biopsy should be performed in concert with the cytogenetic studies.³⁴⁷ It is not unusual to obtain the history of an older female sibling who had an inguinal hernia repair in infancy, and when the karyotype is subsequently checked, the sibling is also found to have CAIS.

It is increasingly common for the sex of the infant to be determined before birth by analysis of the fetal

karyotype because of maternal risk factors for congenital malformations. Fetal sexing is possible by three-dimensional ultrasound as early as the first trimester. Consequently, a mismatch between fetal sexing and birth phenotype may be the presentation.

Partial Androgen Insensitivity Syndrome. The terminology of PAIS implies some biologic response to androgens that results in incomplete masculinization (Table 23-17). The external genitalia may be ambiguous at birth, but the prototypic phenotype for PAIS is characterized by perineoscrotal hypospadias, micropenis, and a bifid scrotum. The testes may be undescended. The more severe form of PAIS, manifesting as isolated clitoromegaly, is only marginally different from CAIS. The milder end of the spectrum of PAIS includes isolated hypospadias; isolated micropenis does not appear to be a manifestation of PAIS.

The list of differential diagnoses within the 46,XY DSD category is lengthy for the PAIS phenotype. Causes include partial gonadal dysgenesis, a defect in androgen biosynthesis (e.g., LH receptor, SF1, 17 β -HSD, and 5 α -reductase deficiencies), mixed gonadal dysgenesis in association with 45,X/46,XY mosaicism, and ovotesticular DSD.

Minimal or Mild Androgen Insensitivity Syndrome. This category of androgen insensitivity syndrome (AIS) emerged after investigations for male factor infertility, which suggested a defect in androgen action in some cases.³⁴⁸ Studies of males who have oligospermia and normal testosterone levels with increased LH concentrations show that a small percentage have a mutation in the AR gene. High doses of androgens may overcome the spermatogenic defect. Minimal or mild androgen insensitivity syndrome (MAIS) may manifest with gynecomastia in young adulthood, and there may be a history of minor hypospadias repair in childhood. Cancer of the breast is rare in males, but the risk is increased in those with MAIS or PAIS, with an association between longer glutamine repeats in the AR and male breast cancer.³⁴⁹ Breast cancer has not been reported in women with CAIS.

Hormone Profiles in Androgen Insensitivity Syndromes. The typical hormone profile in a postpubertal

patient with CAIS and intact gonads comprises a testosterone level within or above the adult male range, an inappropriately increased concentration of LH, and a normal or slightly elevated FSH level. The serum estradiol level also is increased because of direct contributions from the testis and peripheral aromatization. A similar gonadotrophin and sex steroid profile occurs in PAIS.³⁵⁰ Concentrations of sex hormone-binding globulin (SHBG) are sexually dimorphic, with levels in patients with CAIS similar to those found in normal females. The SHBG response to a stanozolol, a nonaromatizable androgen, has been suggested as a biomarker of androgen responsiveness, but it is not sufficiently reliable for clinical use in PAIS.³⁵¹ The serum concentration of inhibin is normal, and the AMH concentration is even increased in CAIS, whereas these levels are low in gonadal dysgenesis.³⁵²

Male infants have an LH-induced surge in serum testosterone concentrations during the first few months of life, which manifests as some growth of the penis. Isolated case reports suggested that the surge does not occur in CAIS, and this was confirmed in a study of 10 infants with CAIS who proved to have an AR mutation.³⁵³ Testosterone levels did increase after hCG stimulation in these patients. In contrast, infants with PAIS have a spontaneous neonatal testosterone surge.

Such observations provide some insight into the control mechanisms of HPG cyclicity.³⁵⁴ Although a female infant with bilateral inguinal swellings and a 46,XY karyotype suggests a diagnosis of CAIS, measurement of baseline gonadotropins and sex steroids before and after hCG stimulation should be performed to exclude other causes.

Molecular Pathogenesis of Androgen Insensitivity Syndromes. Information about the various mutations that affect the AR and give rise to clinical disease is recorded on an International Mutation Database at McGill University (<http://www.androgendb.mcgill.ca>). A map that includes most of the reported mutations is shown in Figure 23-33. Most mutations are related to syndromes of androgen insensitivity, but somatic mutations identified in prostate carcinoma also are listed. The database comprises almost 1000 entries, encompassing more than 300 mutations that can cause AIS. There is no specific hot spot of mutations, but certain locations, such as exons 5 and 7, are affected more frequently. About two thirds of reported mutations are located in the LBD, approximately 20% in the DBD, and a few in the NTD encoded by the large first exon. The NTD has not been crystallized, but its distinct disordered molten-globular structure reflects a reduced spectrum of missense mutations found in the DBD and LBD.³⁴⁰ Nonsense mutations are evenly distributed throughout the AR gene, and all result in a CAIS phenotype.

Figure 23-34 illustrates the range of mutations recorded on the Cambridge DSD Database for CAIS and PAIS. The most common functional AR defect is a mutation that disrupts the hydrophobic ligand-binding pocket in the LBD. Repositioning of helix 12 generates the AF2 coregulator interaction surface. Most LBD mutations causing CAIS cluster within amino acid residues 688 to 712, 739 to 784, and 827 to 870. The first two clusters cover most of the ligand-binding pocket. One example is a mutation in helix 5, which changes the polar arginine to glutamine at codon 752. This results in a CAIS phenotype that is also found in the spontaneous *Tfm* rat model of CAIS.³⁵⁵

The phenotype can vary according to different substitutions at the same codon. Phenylalanine at codon 754 in helix 5 has a side chain that points away from the ligand-binding pocket. Figure 23-35 illustrates that when

TABLE 23-17

Clinical Features of Partial Androgen Insensitivity Syndrome

Karyotype	46, XY
Inheritance	X-linked recessive; mutations in AR gene
External genitalia	Ambiguous with blind vaginal pouch → undermasculinized → isolated hypospadias → normal male with infertility (mild AIS)
Wolffian duct derivatives	Often normal
Müllerian duct derivatives	Absent
Gonads	Testes (usually undescended)
Habitus	Decreased to normal axillary and pubic hair; beard growth, and body hair; gynecomastia common at puberty
Hormone and metabolic profile	Increased LH and testosterone concentrations; increased estradiol (for men); FSH levels may be normal or slightly increased Partial resistance to androgenic and metabolic effects of testosterone

AIS, androgen insensitivity syndrome; AR, androgen receptor; FSH, follicle-stimulating hormone; LH, luteinizing hormone.

Androgen receptor gene mutations, 30-7-03

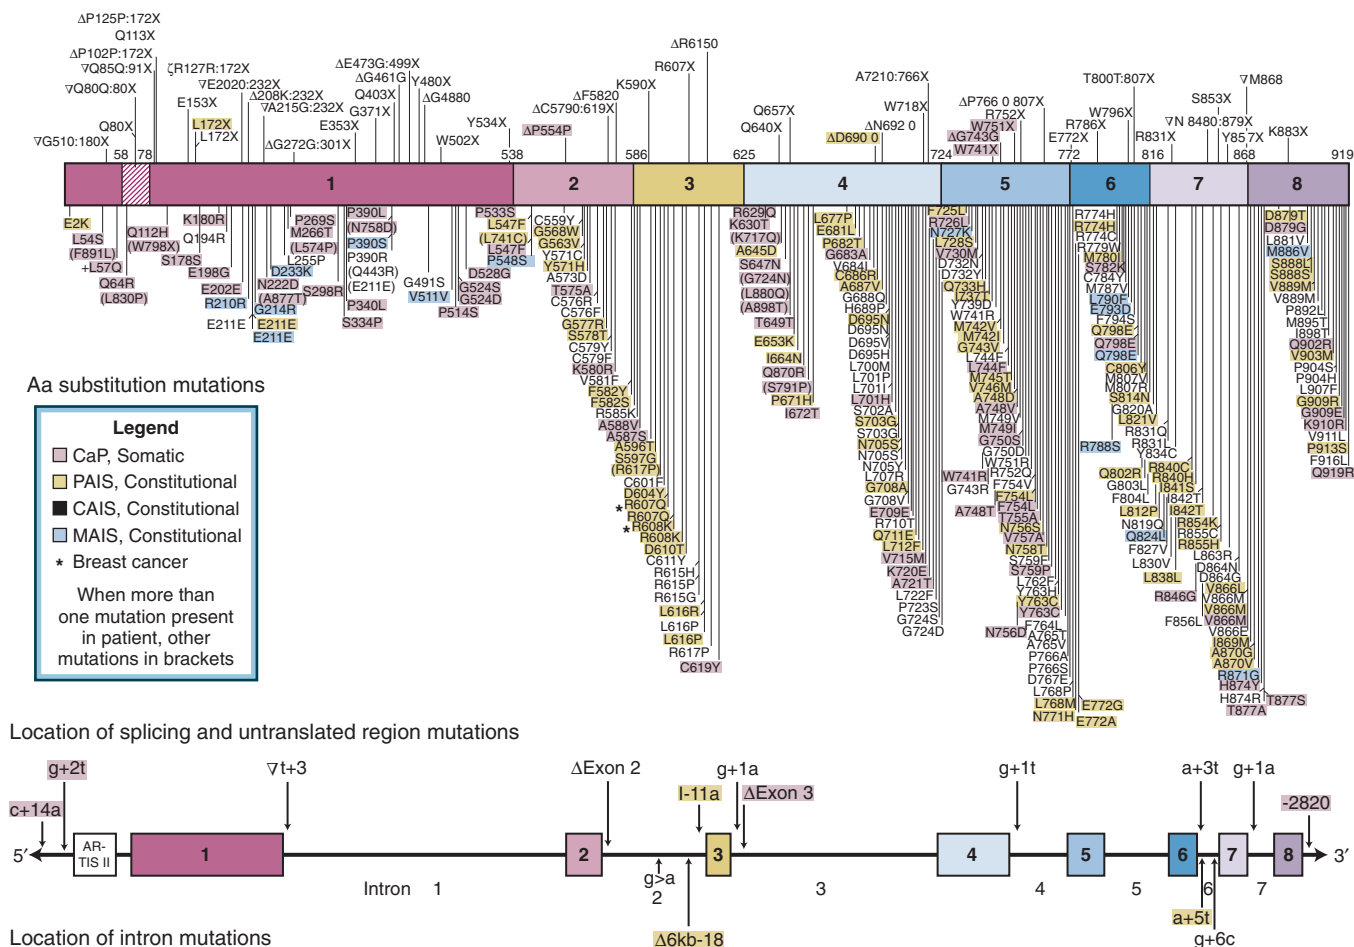

Premature termination mutations or 1–6 bp Δ or ∇ 

Figure 23-33 Overview of androgen receptor (AR) mutations that cause different forms of androgen insensitivity syndrome (AIS). CAIS, complete androgen insensitivity syndrome; MAIS, minimal or mild androgen insensitivity syndrome; PAIS, partial androgen insensitivity syndrome. (From the McGill Androgen Receptor Gene Mutation Database. Available at <http://www.androgendb.mcgill.ca> [accessed November 2010]).

phenylalanine is substituted for a valine, the mutant AR is transcriptionally inactive and causes CAIS.³⁵⁶ In contrast, serine and leucine substitutions result in a PAIS phenotype, explained by some residual transcriptional activity as measured in vitro. It is possible to rescue androgen action in vitro by administering high doses of androgens, as shown in Figure 23-35 in the case of an asparagine substituted for glutamic acid at codon 690. Linking the DBD to the LBD is a flexible hinge region defined by residues 628 to 669. This region stabilizes receptor interaction with selective androgen response elements and signals nuclear localization. Deletion of the hinge region by site-directed mutagenesis results in enhanced gene transcription, suggesting that it has a role in repression. This may not be the case in human studies, based on reduced N-C interactions as the sole explanation for the phenotype in PAIS subjects with an arginine-to-tryptophan substitution at codon 629 in the hinge region.³⁵⁷

There can be considerable heterogeneity in the phenotypic expression of a particular mutation, sometimes even within families. A mutation at codon 703 in exon 4 of the LBD, which changes a serine to a glycine, is reported in four individuals listed in the McGill Database. One patient had a normal female phenotype consistent with CAIS. The other three all had ambiguous genitalia consistent with

PAIS, but the degree of androgenization of the external genitalia was sufficiently variable that two were raised male and the other was raised female.³⁵⁸ X-linked disorders are associated with a high rate of de novo mutations; the rate in AIS is about 30%. Such mutations arise as a single mutational event in a parental germ cell (the mother in the case of AIS) or as germ cell mosaicism in the maternal gonad. When the mutation arises at the postzygotic stage, the index case is a somatic mosaic. This gives rise to expression of mutant and wild-type ARs in different target tissues, including the external genitalia. Perhaps one third of de novo mutations in AIS arise at the postzygotic stage, which could explain some of the variable phenotype in PAIS, whereas no somatic mosaicism is found in CAIS.^{359,360} Other modulatory factors include differences in 5 α -reductase type 2 expression and reduced AR transcription and translation.^{361,362}

Several in vitro assays are used to define mutant AR function. The techniques are particularly important to apply when a novel mutation associated with a PAIS phenotype is discovered and is located in the LBD. Measurement of androgen binding in genital skin fibroblasts derived from foreskin, scrotal, or labial skin obtained at surgery can provide information on AR number and binding affinity to ligand. Typically, binding is absent in CAIS, whereas the

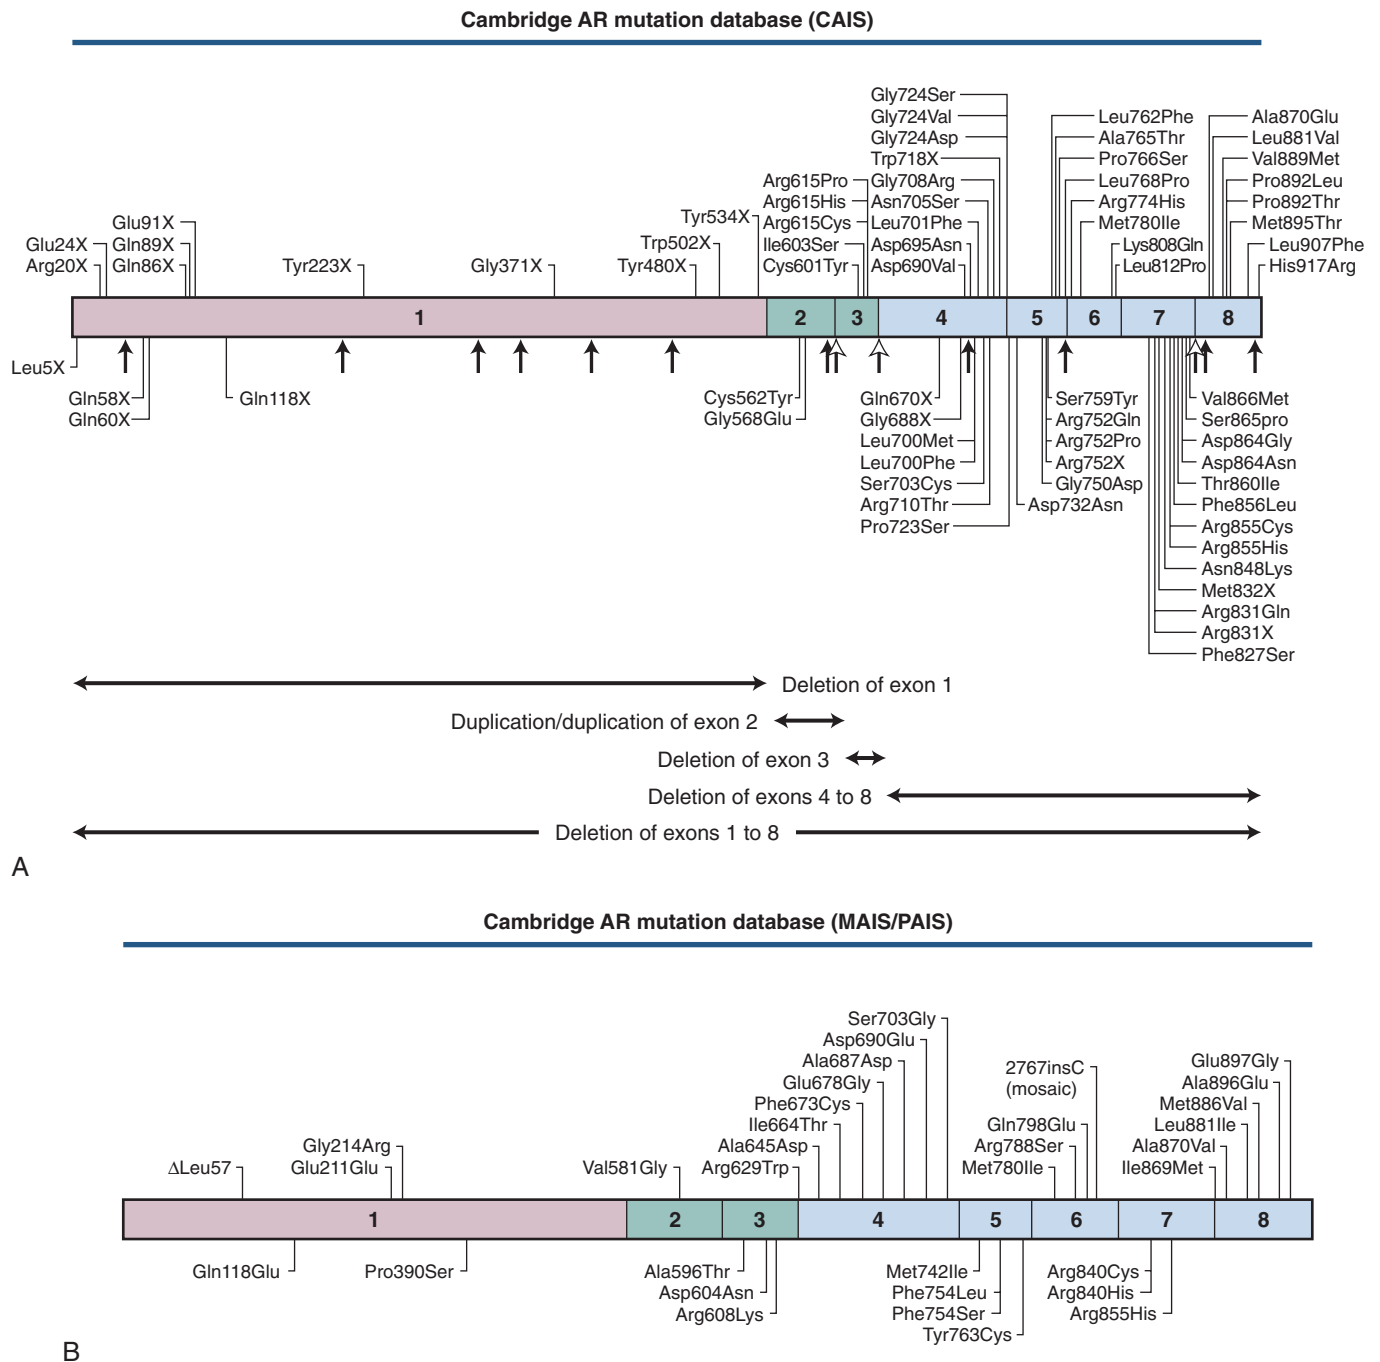

Figure 23-34 Androgen receptor (AR) mutations recorded in the Cambridge DSD Database. *Closed arrows indicate deletions; open arrows indicate splice site mutations.* **A**, Complete androgen insensitivity syndrome (CAIS). **B**, Partial androgen insensitivity syndrome (PAIS) or minimal or mild androgen insensitivity syndrome (MAIS). (Courtesy of Trevor Bunch, University of Cambridge, Cambridge, UK.)

kinetics of binding is altered in PAIS. Using this resource to analyze androgen-dependent gene expression, there is evidence that AR mutations induce lasting changes in genital skin fibroblast transcripts independent of biopsy site.³⁶³ Similar data from genome-wide profiling can be obtained from transcriptomes of blood leukocytes in a range of disorders affecting genital development.³⁶⁴

The standard assay used to study the function of a mutant AR is a promoter-luciferase assay applied after transient transfection into a receptor-negative cell line such as Cos-1, HeLa, CV-1, or the PC3 prostate cancer cell line. Figure 23-35 illustrates the application of such an assay for

analysis of four AR missense mutations. The data provide an indication of potential mutant AR recovery over a range of androgen concentrations. This has particular relevance for subjects with PAIS who are raised male and may require large doses of androgens to induce puberty or to stimulate spermatogenesis. The mammalian two-hybrid assay is particularly useful for functional analysis of AR mutants in view of the unique requirement for intramolecular N-C terminal interaction in the AR. Several mutations located in the LBD do not affect ligand binding, and AR dysfunction is explained by disruption of the androgen-induced interaction between the N-terminal FXXLF motif and the

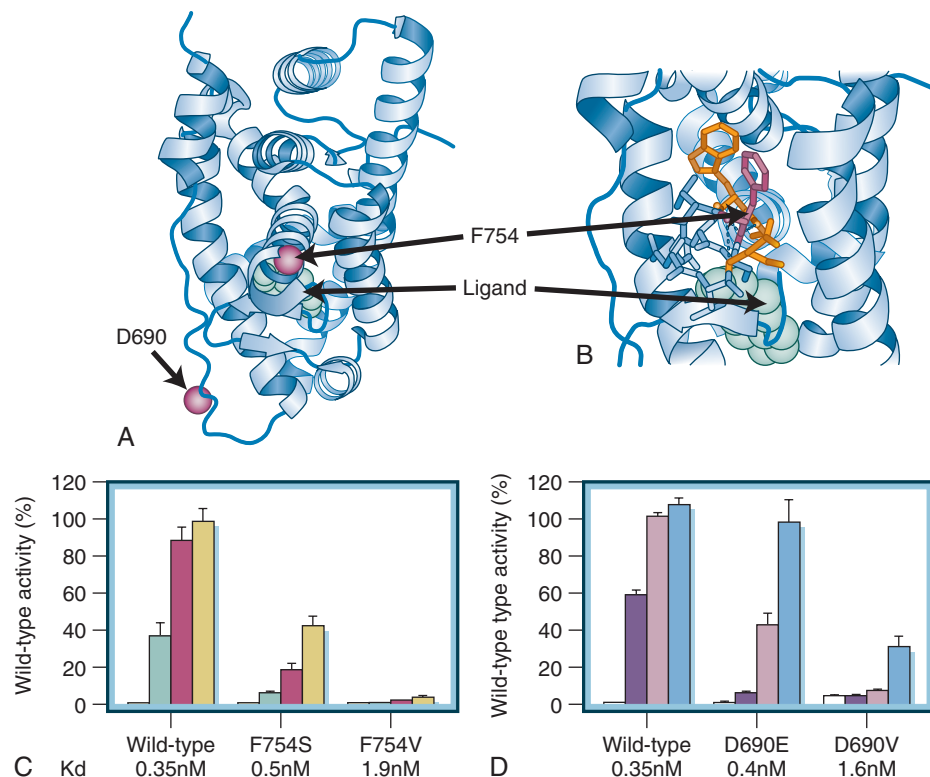

Figure 23-35 Schematic diagram of the androgen receptor (AR). **A**, Position of mutated residues Phe754 and Asp690 (pink). **B**, Residue Phe754 forms hydrogen bonds with neighboring residues (orange) that help to stabilize helices 5, 6, and 7. **C** and **D**, Luciferase reporter assays demonstrate mutant trans-activation activity relative to wild-type AR. The bars represent the responses to increasing concentrations of dihydrotestosterone (1, 3.3, and 10 nmol/L). Kd values for binding affinity are shown.

AF2 subdomain in the C-terminus.^{365,366} Other *in vitro* studies relevant to analysis of the AR include Western immunoblotting, ligand dissociation kinetics, oligonucleotide electrophoretic mobility shift assay, and use of the green fluorescent protein (GFP) technique to determine trafficking of the AR from the cytoplasm to the nucleus. Allied to functional studies *in vitro*, structure-guided modeling of the nuclear receptor can be used to predict the likely consequences of a mutant AR.^{356,365} As sequencing the entire AR gene has become more straightforward, discovery of novel mutations has become common.^{367,368} Nevertheless, it is necessary to undertake functional assays of the AR variant to determine its pathogenicity, particularly in cases of PAIS.

Androgen Insensitivity Syndromes without an Androgen Receptor Mutation. An AR gene mutation is identified in about 90% of subjects when the clinical and biochemical phenotype is consistent with CAIS. In contrast, the yield of mutations is less than 25% in PAIS, even when other causes of a similar phenotype have been excluded.³⁵⁸ In a study of two AR-related coactivators, RAN (formerly called ARA24) and NCOA4 (formerly ARA70), no substantive variations were found in amino acid residues in a series of patients with PAIS who had a normal AR.^{369,370} In studies relating to prostate cancer, NCOA3 (formerly SRC3) was identified as the preferred coactivator for the AR in the ligand-activated state.³⁷¹ The NCOA3 gene contains a variable tract of CAG/CAA triplets that encode a polyglutamine repeat. The lengths of glutamine repeats were found to be shorter in PAIS subjects compared with controls.³⁷² Variation in the NCOA3 protein may modulate or destabilize receptor-coactivator interactions. Targeted

disruption of Fkbp4 (also called Fkbp52), an AR co-chaperone, causes infertility and hypospadias in male mice.³⁷³ However, no mutations were found in a cohort of boys with nonsyndromic hypospadias.³⁷⁴ Hyperexpansion of the polyglutamine repeat in the N-terminus of the AR leads to toxic gain-of-function and Kennedy's disease or spinal and bulbar muscular atrophy (SBMA).³⁷⁵ Affected males have testicular atrophy, decreased spermatogenesis, gynecomastia, and elevated androgen levels in keeping with androgen resistance. An abnormally expanded CAG repeat to 44 residues was reported for one case of hypospadias.³⁷⁶ Variations in the length of the polyglutamine tract within the normal range have been found in a remarkable number of clinical scenarios, as summarized in Table 23-18. Even behavior in adolescent males and the physiologic response to hypoxic training in young men have been associated with the number of glutamine repeats.^{377,378} When CAG (glutamine) and GGN (glycine) lengths are analyzed together in the context of a missense mutation in the AR gene causing AIS, the combined effects appear to modulate the phenotypic expression of a given AR mutant in different affected individuals.³⁷⁹

Management of Androgen Insensitivity Syndromes. Gender assignment and sex of rearing is uniformly female in CAIS. However, one case was reported of male gender identity that resulted in complete sex reassignment involving androgen treatment and phalloplasty.³⁸⁰ An inactivating AR mutation was identified. Such an isolated case does not alter the premise that the sex of rearing is female in CAIS, but the observation raises the question of what role a functional AR plays in the development of male gender identity. Inguinal hernias need repair when patients present in

TABLE 23-18

Disease Associations with Variations in the Androgen Receptor Glutamine Repeat

Shortened (CAG)n	Increased (CAG)n
Prostate cancer	Above normal range
Ovarian hyperandrogenism	SBMA (Kennedy's disease)
Androgenetic alopecia	Hypospadias (one reported case)
Aspects of Klinefelter phenotype	Within normal range
Response to androgen treatment	Male infertility
Central obesity	Gynecomastia
Mental retardation	Hypospadias
Endometrial cancer	Aspects of Klinefelter phenotype
Coronary artery disease severity	Bone density
	Breast cancer

infancy, with an option at this stage to perform gonadectomy. There is no uniform practice concerning early versus late gonadectomy. There is merit in having spontaneous puberty from gonads in situ compared with induction of puberty with estrogen replacement. However, there is a small risk of a gonadal tumor if gonadectomy is delayed until adulthood. If early gonadectomy is undertaken, estrogen replacement should be started when the child is 10 to 11 years old with ethinyl estradiol (initially 2 µg (micrograms) daily and up to 20 to 30 µg daily by 14 to 15 years of age). Thereafter, adult estrogen replacement may continue orally with natural estrogens (1 mg daily) or changed to transdermal delivery (40 to 50 µg [micrograms]). Adjunctive replacement with progestins is seldom used because of the absence of a uterus, and depot estrogen is preferred by some women. Adults with CAIS report improved well-being with androgen replacement, particularly when it is introduced after gonadectomy. The mechanism of this androgenic effect is not understood. If gonads are left in situ, the onset of puberty occurs at the same age as in girls in their peer group.³⁸¹ Pubic hair occurs slightly later (median age, 14 years), and axillary hair usually is absent. Adult height of persons with CAIS is close to target male height and taller when gonadectomy is delayed.³⁴⁵ Bone mineral density is decreased in CAIS compared with 5α-reductase deficiency, illustrating the direct role of androgens in bone mineralization. Adult bone mineral density in CAIS is similar whether gonadectomy occurs before or after puberty.

There is an increased risk of gonadal tumors in DSDs, particularly in the presence of a Y chromosome.^{23,382,383} Seminoma, an invasive type II germ cell tumor, can develop in later adulthood in patients with AIS. This is preceded by an in situ neoplastic change called *intratubular germ cell neoplasia unclassified* (ITGNU). A more commonly recognized histologic term for this lesion is carcinoma in situ (CIS). The outcome of CIS is more likely to be a gonadoblastoma when the gonad is not well differentiated. The abundance of primordial germ cells in the tubules (i.e., ITGNU lesion) represents a delay in germ cell maturation into spermatogonia, and the arrested gonocyte underlies the cause of common germ cell cancer in young men.³⁸⁴ In the context of testicular germ cell tumors in young men, the presence of testicular microlithiasis strongly predicts concurrence of germ cell tumor and ITGNU.³⁸⁵ CIS cells originate from primordial germ cells (i.e., gonocytes) and express immunohistochemical markers such as placental-like alkaline phosphatase (PLAP), KIT (the receptor for the stem cell factor KITLG), TAFP2C (formerly called AP2G),

POU5F1 (formerly OCT 3/4), and NANOG.³⁸⁶ Immunohistochemical detection of POU5F1 and KITLG represents particularly informative markers for CIS.³⁸⁷

The initiating events for neoplastic transformation from the CIS state are not known. Normal androgen production and action are required for germ cell maturation. Environmental chemicals acting as endocrine disruptors on the mother and developing fetus may disrupt germ cell maturation in a particular genetic background.³⁸⁸ This theory aims to explain the increased incidence of testis tumors, which is often associated with abnormal spermatogenesis, undescended testes, and hypospadias. The prevalence of germ cell tumors among CAIS adults has been reported as 25% to 30%.³⁸⁹ However, later estimates from larger numbers of affected individuals have been as low as 0.8% for CAIS and 5.5% for AIS overall.^{23,390} Gonadectomy usually is performed in early adulthood, and some adults with CAIS decline gonadectomy.

Surgery in CAIS is confined to gonadectomy and perhaps to vaginoplasty procedures. Laparoscopic procedures are routine for removal of intra-abdominal testes. Those in the inguinal region can be removed during herniorrhaphy or by a laparoscopy-assisted transinguinal approach. The vagina in CAIS ends blindly and is shortened. The regular use of graded vaginal dilators during adolescence usually is successful.³⁹¹ The prepubertal girl with CAIS requires an examination under anesthesia at puberty to evaluate the vaginal anatomy.

The early management of PAIS centers on gender assignment and the subsequent plan and timing for surgery. The phenotypic heterogeneity seen in PAIS has been emphasized; most PAIS infants are raised male. Surgical procedures required include orchidopexy, chordee correction, and urethral reconstruction for the hypospadias. In some cases, several procedures implemented into adult life are required before full penile reconstruction is successful. Large doses of androgen may be required to promote phallic growth; the results of functional studies of any mutant AR that has been identified can be a useful predictor of the likely response. An approach involving high-content analysis of AR function at the cellular level by multiple assays has been proposed as a means to target androgen pharmacotherapy according to the type of AR mutation.³⁹² In practice, a course of androgen injections in early infancy is often used to assess androgen responsiveness. A monthly course of three 25-mg intramuscular injections of Sustanon (mixture of testosterone esters) is a common protocol. It is important to quantify the response, and an androgenization score, which takes account of penis size, testis position, and site of urethral orifice, is reliable and simple to apply.³⁹³

The risk of germ cell tumor of the testis is 15% or greater in patients with PAIS if the gonad is nonscrotal in position.³⁹⁴ A patient with PAIS who is raised male should have careful monitoring of scrotal testes. It is recommended that a biopsy be performed at puberty. If CIS is diagnosed, there is debate about whether the contralateral testis should be biopsied. Unilateral CIS is treated by gonadectomy; bilateral CIS, which is rare, is managed with local low-dose radiotherapy, which effectively eradicates CIS.³⁹⁵ Regular self-examination and testicular ultrasonography to screen for microliths is also recommended.³⁹⁶

The management of PAIS is complicated by the low incidence of proven AR mutations in cases that meet the phenotypic criteria consistent with incomplete resistance to androgens. In most reported series, which have included molecular analysis of the AR gene in a large number of cases, only about 25% of patients have a mutation in the

coding region of the gene.^{397,398} What causes the phenotype in most PAIS cases with a normal AR is not known, but there is a strong association between hypospadias and low birth weight linked to placental insufficiency, and the outcome of mutations in *NR5A1* may mimic PAIS in some cases.^{84,399,400} Information on outcome in adult life for parameters such as physical health, sexual function, fertility, quality of life, and social participation is scanty for males with PAIS. Some were dissatisfied with their gender assignment and had major impairment in sexual function.⁴⁰¹⁻⁴⁰³

Sex assignment in MAIS is male. Clinical presentation occurs in adolescence because of gynecomastia or for investigation of male factor infertility in adulthood. Reduction mammoplasty is required for the gynecomastia.

Counseling. AIS is an X-linked recessive condition; in 30% of cases, the mutation arises spontaneously. In cases with a PAIS phenotype, X linkage can be tested among family members by analysis of the CAG repeats. Even if a mutation has been identified, it is important to emphasize the phenotypic variability in the manifestation of a mutant receptor. An important component of counseling in AIS is disclosure of the diagnosis at an appropriate age and cognitive stage. Historically, the principles of beneficence (i.e., commitment by health care professionals to deliver care that provides the maximum benefit to the patient) and non-maleficence (i.e., duty to avoid causing harm) were applied to AIS in the mistaken belief that nondisclosure of the diagnosis was the appropriate management.⁴⁰⁴ Most clinicians now ensure that adults with AIS and the parents of affected children are fully informed about the condition and are apprised of the management options. Much of the enlightened change in practice has arisen from improved team networking with, and support from, advocacy groups.^{405,406}

Other Conditions Affecting 46,XY Sex Development

Persistent Müllerian Duct Syndrome. AMH is a glycoprotein homodimer that is secreted by the Sertoli cells of the developing testes from approximately 7 weeks' post-conception. It acts through the AMH type 2 receptor (AMHR2) between 8 and 12 weeks' post-conception to cause regression of the Müllerian duct (see "Development of Reproductive Systems").^{161,162}

AMH is encoded by a 2.75-kb gene containing five exons in the region of chromosome 19p13.3. The AMHR2 is a serine/threonine kinase with a single transmembrane domain that is encoded by an 11-exon gene on 12q13.¹⁶¹ Exons 1 to 3 code for the signal sequence and the extracellular domain of the AMHR2, exon 4 codes for the transmembrane domain, and exons 5 through 11 code for the intracellular serine/threonine domain.

Persistent Müllerian duct syndrome (PMDS), also known as herniae uteri inguinale, is a condition in which 46,XY males have well-developed testes and normal male ducts and external genitalia but also have Müllerian duct derivatives. The diagnosis is often not made until a fallopian tube and uterus are encountered in patients undergoing inguinal hernia repair, orchiopexy, or abdominal surgery. Because of the trend for early surgical repair of an inguinal hernia or undescended testis, more cases are detected in infancy or early childhood. There are two anatomic forms. In the more prevalent form, a hernia contains a partially descended or scrotal testis, and the ipsilateral tube and uterus are in the hernia. In some instances, the contralateral testis and tube also are present in the hernial sac. The presence of transverse testicular ectopia should suggest

PMDS. In the second form, the uterus, tubes, and testes are in the pelvis.

PMDS in normally differentiated males can result from failure of the testes to synthesize or secrete bioactive AMH or from a defect in the response of the duct to AMH because of an AMHR2 defect. Approximately one half of all genetically proven cases of PMDS result from defects in AMH, and half are caused by mutations in its receptor (Fig. 23-36).⁴⁰⁷ AMH gene mutations are most commonly found in Mediterranean, Northern African, and Middle Eastern countries,⁴⁰⁸ and most familial mutations are homozygous. In contrast, mutations in the gene encoding AMHR2 are more commonly found in France and Northern Europe and are often compound heterozygous mutations.⁴⁰⁹ In an extensive study of 69 families with PMDS, 28 different mutations in the AMH gene were detected in 31 families (see Fig. 23-36).^{407,408} Homozygous and compound heterozygous mutations were found in affected families, including splicing, missense, nonsense, and deletion mutations affecting the whole gene, but they mainly affected exon 1 and the 3' region of exon 5 (see Fig. 23-36). Deleterious mutations in AMHR2 were detected in 27 families and included deletion, missense, and nonsense mutations (see Fig. 23-36). The most common mutation was a 27-bp deletion in exon 10.⁴¹⁰ No abnormality in AMH or AMHR2 genes was detected in 11 families (16% of the total number). Measurement of serum AMH levels can provide a useful means for guiding genetic analysis; patients with PMDS caused by mutations of the AMH gene have low or undetectable levels of serum AMH, whereas AMH concentrations are often high normal or elevated in patients with mutations of AMHR2.

Treatment of PMDS includes an attempt to ensure fertility in males, which is a difficult issue because of the anatomic findings. Testicular differentiation and function are normal in these patients, but an increased prevalence of testicular degeneration has been described, which probably results from torsion of the testes. Anatomic abnormalities of the epididymis and the vas deferens are common. Infertility may result from late orchiopexy or from mechanical problems associated with entrapment of the vas deferens in the Müllerian derivatives. Early orchiopexy, proximal salpingectomy (leaving the epididymis attached to the fimbriae of the fallopian tube), dissection of the vas deferens from the lateral walls of the uterus, and a complete hysterectomy are recommended as a useful surgical approach. These structures can be left in place if there is risk of damage to the genital ducts. Men with high pelvic testes rarely have successful orchiopexy, and many of these individuals are androgen deficient.

Hypospadias. Hypospadias is incomplete fusion of the penile urethra defined by an arrest in development of the urethral spongiosum and ventral prepuce.⁴¹¹ The normal embryologic correction of penile curvature is also interrupted. It is a common congenital anomaly, with an estimated birth prevalence of 3 to 4 cases per 1000 live births. Although it has been suggested that the rates of hypospadias have been increasing, this is not borne out in contemporaneous studies.⁴¹¹⁻⁴¹⁷ The cause is unknown in most cases, but it is assumed that there is an interplay of genetic and environmental factors.⁴¹⁸ Mutations in the *MAMLD1* gene on chromosome Xq28 cause hypospadias in a minority of cases.^{146,419,420} Mutations in *HoxA13*, including expansion of polyalanine tracts, and in related fibroblast growth factors (FGFs) and bone morphogenetic proteins (BMPs) are found in the hand-foot-genital syndrome.⁴²¹⁻⁴²³ Hypospadias may also be a presenting

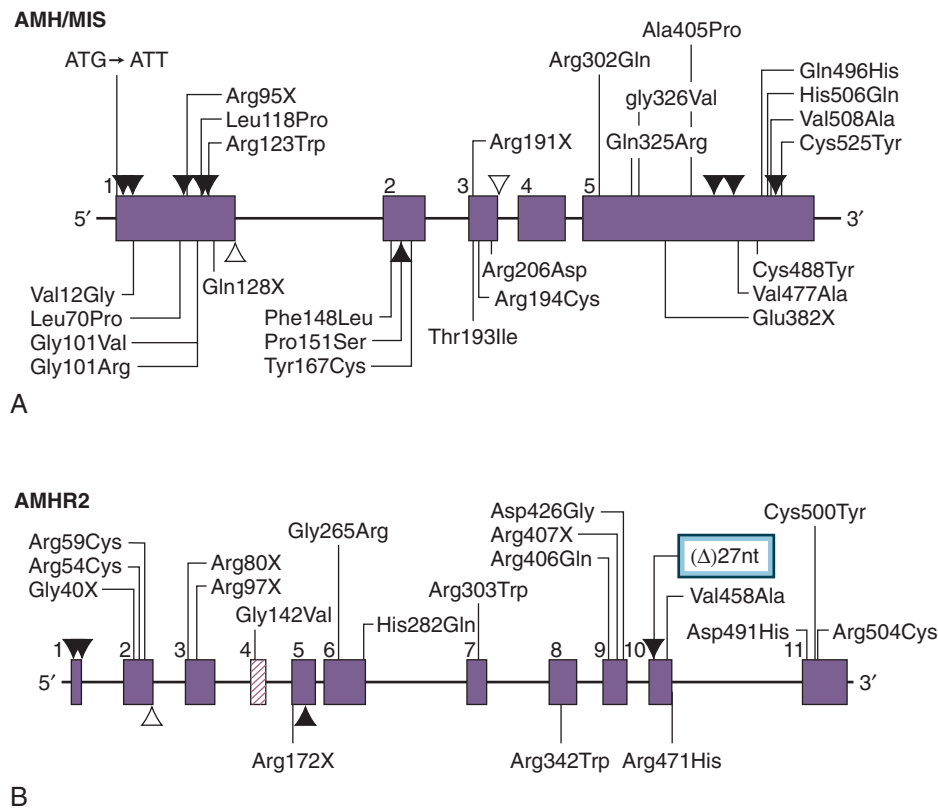

Figure 23-36 **A**, Diagram of the mutations in the anti-Müllerian hormone (AMH/MIS) gene that cause persistent Müllerian duct syndrome. The numbered solid boxes depict the exons. The three-letter abbreviations for amino acids are used to indicate the positions of missense mutations; X indicates a nonsense (stop) mutation; insertions and deletions resulting in frameshift and splice site mutations are shown by solid triangles and open triangles, respectively. **B**, Diagram of selected mutations in the gene for the AMH receptor type 2 (AMHR2). The numbered solid boxes depict the exons. Exons 1 to 3 encode the extracellular domain of the receptor. Exon 4 (diagonal lines) encodes the transmembrane domain, and exons 5 through 11 encode the intracytoplasmic domain. Different forms of mutation are depicted, as in part A. The $\Delta 27\text{nt}$ (open box) is a 27-nucleotide deletion, the most common AMHR2 mutation causing the persistent Müllerian duct syndrome. (**A**, Redrawn from Imbeaud S, Carré Eusebe D, Rey R, et al. Molecular genetics of the persistent müllerian duct syndrome: a study of 19 families. *Hum Mol Genet.* 1994;3:125-131, with permission of Oxford University Press. **B**, Redrawn from Imbeaud S, Belville C, Messike-Zeitoun L, et al. A 27 base-pair deletion of the antimüllerian type II receptor gene is the most common cause of the persistent müllerian duct syndrome. *Hum Mol Genet.* 1996;5:1269-1277, with permission of Oxford University Press.)

feature of milder forms of disorders of testicular dysgenesis or steroidogenic defects (e.g., mutated NR5A1), especially if the penis is small or the testes undescended.²⁴⁶ The prevalence of these conditions in isolated hypospadias is likely to be much lower. There is a familial clustering of cases in hypospadias, with a 7% incidence of one or more additional affected family members.⁴²⁴

Hypospadias is associated with increased maternal age, multiple births, maternal exposure to diethylstilbestrol in utero, paternal subfertility, maternal vegetarian diet, maternal smoking, assisted reproductive techniques, paternal exposure to pesticides, and fetal growth restriction.⁴²⁵ The association with low birth weight is remarkably consistent across all studies of idiopathic hypospadias.^{426,427}

Management is surgical. The urethral meatus is relocated to the glans, and the penis is straightened by correcting any chordee to give a normal, forward-directed urinary stream and the ability to have satisfactory sexual intercourse. Numerous techniques are described; repairs may require more than one stage, usually starting at 6 to 12 months of age. The true severity of the hypospadias may not be apparent until release of the chordee. Complications include fistula formation, meatal stenosis, urethral stricture, and residual chordee. Outcome data from large series are lacking, but there is evidence of satisfactory sexual function and cosmetic appearance after surgery.^{428,429}

Proximal hypospadias was associated with a lower maximum urinary flow outcome.

Anorchia and Cryptorchidism. The term *vanishing testis syndrome* was coined for the phenotype of bilateral anorchia in an otherwise normally developed male infant.² It recognizes the presence of normal testes in early gestation operating to induce Müllerian duct regression, stabilize Wolffian duct development, and differentiate male external genitalia. Any ambiguity of the external genitalia suggests a variant of the syndrome related to some form of XY gonadal dysgenesis. Bilateral anorchia with a normally differentiated but small phallus (micropenis) is also a recognized variant of the syndrome, and it may represent a milder variant of testicular dysgenesis in some cases.²⁴⁷ The cause of classic anorchia is unknown, but an interruption of the testis blood supply by a torsion or vascular occlusion event in utero has been proposed. Surgical exploration and histologic findings typically show testicular nubbins as remnants of gonads, which are associated with a vas deferens in most patients and with some epididymal tissue. The presence of hemosiderin-laden macrophages and dystrophic calcification is consistent with the vascular accident hypothesis in some cases.

The diagnosis of complete anorchia is based on a combination of biochemical tests, imaging studies, and surgical

exploration. An undetectable serum AMH level is a reliable marker when evaluating infants with nonpalpable gonads. This, coupled with elevated serum levels of gonadotropins and no testosterone response to hCG stimulation, predicts the absence of testes. A low inhibin B level is also supportive, although levels normally fall during childhood (see Fig. 23-16). Imaging with CT or MRI may be useful before laparoscopy. Most centers undertake surgical exploration to remove testicular remnants even though usually no evidence of malignancy is found. The procedure can be deferred until the time of insertion of prostheses.

Testes that have not descended at birth (i.e., cryptorchidism) is the most common congenital abnormality in boys, affecting 2% to 4% of term infants.^{173,430} There are geographic differences in prevalence, with the rate as high as 9% in Denmark and as low as 2.4% in Finland.⁴³¹ There is epidemiologic evidence of an increasing prevalence to 6% in populations studied in the United Kingdom.⁴³² Longitudinal studies demonstrated the expected decline in prevalence in early infancy to 2.4% but a subsequent rise to 7% by 2 years of age.

Ascending testis or acquired cryptorchidism is common and accounts for more than one half of cases of undescended testes seen in childhood.⁴³³ The strong association with low birth weight is well recognized, as are disorders of the pituitary-gonadal axis such as HH and the AIS. These observations are consistent with the role of androgens in the inguinoscrotal phase of testis descent. The first phase of transabdominal migration is under the control of *INSL3*, which is produced by Leydig cells.¹⁷⁴ Mutations in *INSL3* and the gene for its receptor, *RXFP2*, are found in a very small proportion of boys with cryptorchidism.⁴³⁴ Higher exposure to persistent endocrine-disrupting chemicals has been found in cryptorchid boys based on analyses of breast milk samples as a proxy for fetal exposure.⁴³⁵

Environmental Chemicals. The proposed increase in male reproductive tract disorders (testis cancer, abnormal spermatogenesis, cryptorchidism, and hypospadias) led to the concept that testicular dysgenesis syndrome (TDS) of fetal origin might be triggered by lifestyle factors and exposure to endocrine-disrupting chemicals operating during the fetal and perinatal periods.⁴³⁶ The clearest evidence that certain chemicals such as herbicides, fungicides, bisphenol A, and phthalates can act as endocrine disruptors is derived from observations of wildlife and laboratory animal experiments. It remains uncertain whether there is a new and emerging public health problem.⁴³⁷

Not all components of the quartet of male reproductive disorders can be assigned to TDS, particularly for cases of isolated hypospadias and men with solely impaired sperm quality.⁴³⁸ It has been questioned on epidemiologic grounds whether the TDS exists at all.⁴³⁹ Direct evidence of toxic effects in humans has not been established. The anogenital distance in newborn rodents is a sensitive index after maternal exposure to androgens and antiandrogens. Data on this anthropometric measure are available from normal male infants studied longitudinally from birth to 2 years of age.⁴⁴⁰ A preliminary study reported reduced anogenital distance in male infants related to prenatal phthalate exposure.⁴⁴¹ The U.S. Environmental Protection Agency (EPA) has recommended measurement of anogenital distance as one of the markers in reproductive toxicity studies in humans.⁴⁴²

The relevance of these epidemiologic and experimental findings to the assessment of an individual case of DSD remains uncertain.⁴⁴³ Major programs of research such as the Cluster of Research into Endocrine Disruption in

Europe (CREDO) supported by the European Commission and the endocrine-disrupting chemicals research program of the EPA are being conducted to determine the risks posed to human health by environmental chemicals. The maxim that exposure to chemicals should be reduced to as low a level as is reasonably practicable seems to be a sensible precautionary approach while further data are being gathered in humans.

46,XX Disorders of Sex Development

46,XX DSDs can be divided into disorders of ovary development, disorders of androgen synthesis, and other conditions affecting sex development (see Table 23-3).

Disorders of Ovary Development

Disorders of ovary development (i.e., ovarian dysgenesis or resistance) do not usually manifest until puberty, when a failure of estrogenization becomes apparent. In contrast, several well-defined but poorly understood disorders of gonadal development can result in a 46,XX individual with an ovary containing testicular tissue (i.e., 46,XX ovotesticular DSD) or even the development of a testis capable of producing enough androgen for a male phenotype and sufficient AMH to regress the uterus (i.e., 46,XX testicular DSD).

Ovarian Dysgenesis. Ovarian dysgenesis is most frequently seen in association with sex chromosome aneuploidy (e.g., Turner syndrome; 45,X and variants) when progressive ovarian apoptosis is evident. Ovarian resistance results from mutations in the FSH receptor and manifests at puberty.²⁰⁷ Ovarian dysfunction can also occur with a wide range of multisystem syndromes, often involving DNA-repair mechanisms (e.g., Perrault, Maximilian, Quayle and Copeland, Poher, Malouf, Nijmegen, Cockayne, Rothmund-Thompson, Werner syndromes; ataxia telangiectasia).¹⁵³ Several nonmetabolic causes of POI or POF have been described,⁴³⁻⁵¹ including POF1, Xq26-q28, *FMR* pre-mutations; POF2A, Xq22, *DIAPH2*; POF2B, Xq21, POF1B [actin-binding protein]; POF3, 3q22, *FOXL2*; POF4, Xp11.2, *BMP15*; POF5, 7q35, *NOBOX*; also 9q33, *NR5A1*), as well as mitochondrial disorders such as mutations in *POLG*.⁴⁴⁴ Although these conditions usually manifest with POI and early menopause, more severe forms of some of these disorders can interfere with earlier aspects of ovarian development and function and can manifest with absent puberty.

46,XX Ovotesticular and 46,XX Testicular Disorders of Sex Development. In rare conditions, the developing ovary may contain an element of testicular tissue (i.e., 46,XX ovotesticular DSD) or may even develop as a functioning testis (i.e., 46,XX testicular DSD). In 46,XX ovotesticular DSD, the patient usually presents with ambiguous genitalia at birth and progressive virilization at puberty if the gonad is not removed. In contrast, 46,XX testicular DSD is usually associated with a normal male phenotype and absence of Müllerian structures. However, the testis is not capable of supporting spermatogenesis because crucial genes on the Y chromosome are absent.

A detailed review of the presentation, endocrinology, and management of 46,XX ovotesticular DSD was given earlier (see “Sex Chromosome Disorders of Sex Development”) because many of the issues faced are similar to those with 46,XX/46,XY chimerism. However, a 46,XX karyotype is the most frequent finding in ovotesticular DSD, especially in patients from sub-Saharan Africa.²³⁸

Familial cases have been described, and it is likely that a genetic basis exists in some cases, although the exact cause is unknown. Translocation of a testis-determining gene (e.g., *SRY*, *SOX9*) has been found in rare cases.¹³¹ Partial dysfunction of the ovarian-testis repressor gene *RSPO1* has been described.²³⁹

Patients with 46,XX testicular DSD often present first with male factor infertility. In some cases, a family history is present. Because different family members can have different phenotypes, it is possible that 46,XX testicular DSD represents the most severe end of the spectrum of ovarian transdifferentiation phenotypes. Up to 80% of 46,XX males harbor translocations of Y-chromosomal material containing *SRY*, the testis-determining factor.^{27,101} This finding helped considerably in mapping the *SRY* gene in the first instance (see “Development of Reproductive Systems”), and in some situations, residual ovarian tissue (ovotestis) develops. Individuals with *SRY* translocations can be diagnosed by FISH analysis using a probe directed to that gene (see Fig. 23-3). A number of *SRY*-negative cases have been reported. Loss-of-function mutations in *RSPO1* (an ovarian gene encoding Respondin 1) have been reported in individuals with 46,XX testicular DSD with palmar-plantar hyperkeratosis and squamous cell carcinoma.¹⁵ This factor, which mediates the WNT4 signaling pathway, was the first ovarian-specific repressor of testis development to be described. Loss of function of Respondin 1 in the developing gonad of 46,XX individuals results in testis development and an infertile male phenotype. It is likely that additional factors may act as repressors of *SRY* and testis determination. Severe disruption of WNT4 can result in 46,XX sex reversal as part of the SERKAL syndrome, which consists of female-to-male sex reversal and renal, adrenal, and lung dysgenesis.⁴⁴⁵

Disorders of Androgen Excess

The steroid biosynthetic disorders causing androgen excess and 46,XX DSD are summarized in Table 23-6. Although CYP21 deficiency is by far the most common form of this condition, alternative diagnoses should be considered because approaches to counseling and management may vary.

3 β -Hydroxysteroid Dehydrogenase Type 2 Deficiency. 3 β -HSD/ $\Delta^4,5$ -isomerase catalyzes the conversion of Δ^5 -steroids to Δ^4 -steroids and is required for the generation of mineralocorticoids, glucocorticoids, and more potent androgens (e.g., testosterone, DHT) by the adrenal glands and gonads (see Fig. 23-11). The actions of 3 β -HSD and the consequences of deficiency of the type 2 enzyme (HSD3B2) were described earlier, because this deficiency results in adrenal insufficiency with variable defects in androgenization of the developing male fetus.

Defects in HSD3B2 also manifest in 46,XX females. Severe, recessively inherited defects in enzyme function can cause mild clitoral enlargement at birth in girls with glucocorticoid deficiency (with or without salt loss). This mild androgenization occurs not as a direct androgenic effect of the excess DHEA but as a result of its conversion and that of other Δ^5 -3 β -hydroxy-C19-steroids to testosterone by HSD3B1 in the placenta and in the peripheral tissues of the fetus. This conversion, coupled with the limited capacity of the placenta to aromatize androgens to estrogens early in gestation, can increase circulating levels of androgens in the female fetus and cause modest clitoromegaly in a minority of patients. Milder, nonclassic forms of HSD3B2 deficiency can cause premature pubarche in girls. Breast development can occur at puberty in affected

females, presumably by peripheral conversions of Δ^5 -C19 steroids to Δ^4 -C19 steroids by HSD3B1 expressed principally in peripheral tissues and by the subsequent aromatization of androgens to estrogens. The presence of menses has been reported in treated females with this condition.

The diagnosis of HSD3B2 deficiency can be challenging in nonclassic forms of this condition.²⁸⁸ The levels of Δ^5 -steroids (e.g., 17-hydroxypregnenolone, DHEA, and its sulfate, DHEAS) usually are increased, and the ratio of Δ^5 -steroids to Δ^4 -steroids (e.g., the ratio of 17-OHP to cortisol) is markedly increased, especially after stimulation with intravenous ACTH. The urinary steroid profile can also be informative, because 17-ketosteroids and especially DHEAS and 16-hydroxy-DHEAS are elevated. Basal plasma concentrations of 17-OHP can be increased as a result of peripheral conversion of Δ^5 -17-hydroxypregnenolone to 17-OHP by the type 1 enzyme. This finding may lead to confusion with alternative forms of CAH, such as CYP21 deficiency or POR deficiency. Mild forms of HSD3B2 deficiency may manifest in a fashion similar to that of virilizing adrenal tumors. Suppression of the increased plasma and urinary levels of C19 and C21 3 β -hydroxysteroids by glucocorticoids distinguishes 3 β -HSD deficiency in such cases. Treatment for 3 β -HSD deficiency is glucocorticoid, mineralocorticoid, and salt supplementation, as appropriate, and estrogen replacement to induce puberty.

21-Hydroxylase Deficiency. In the context of DSD, CYP21 deficiency (see Fig. 23-11) is the most common cause of ambiguous genitalia of the newborn. It is primarily a disorder of adrenal steroidogenesis (see Chapter 15).

A female fetus with CYP21 deficiency can become androgenized to various degrees, as illustrated by the Prader classification (Fig. 23-37). The fact that CYP21 deficiency can androgenize a female sufficiently to result in a male phenotype at birth (with nonpalpable testes) is indicative of exposure to extremely high circulating concentrations of androgens. Serum concentrations of testosterone are invariably within the adult male range and sometimes higher in CAH caused by CYP21 deficiency. Androgenization can be prevented if dexamethasone is administered to the mother early enough in gestation, indicating an intact fetal pituitary-adrenal axis that is responsive to negative-feedback regulation. This model is based on studies of human fetal adrenal explants that synthesize cortisol, androstenedione, and testosterone under ACTH regulation, which is subject to negative feedback by glucocorticoids.¹⁷² The route to increased adrenal production may be through the backdoor pathway to androgen synthesis.^{170,171} Nevertheless, high fetal concentrations of 17-OHP, androstenedione, and testosterone are the hallmark of androgenization in CAH due to CYP21 deficiency. More than 75% of patients are also salt losers because of their inability to synthesize sufficient mineralocorticoids. The two forms are readily explained by the nature of the mutation, which affects the *CYP21* gene on chromosome 6p21.3. The concordance

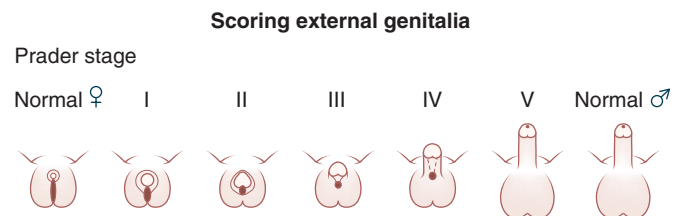

Figure 23-37 Prader classification of the degree of androgenization in a female with congenital adrenal hyperplasia.

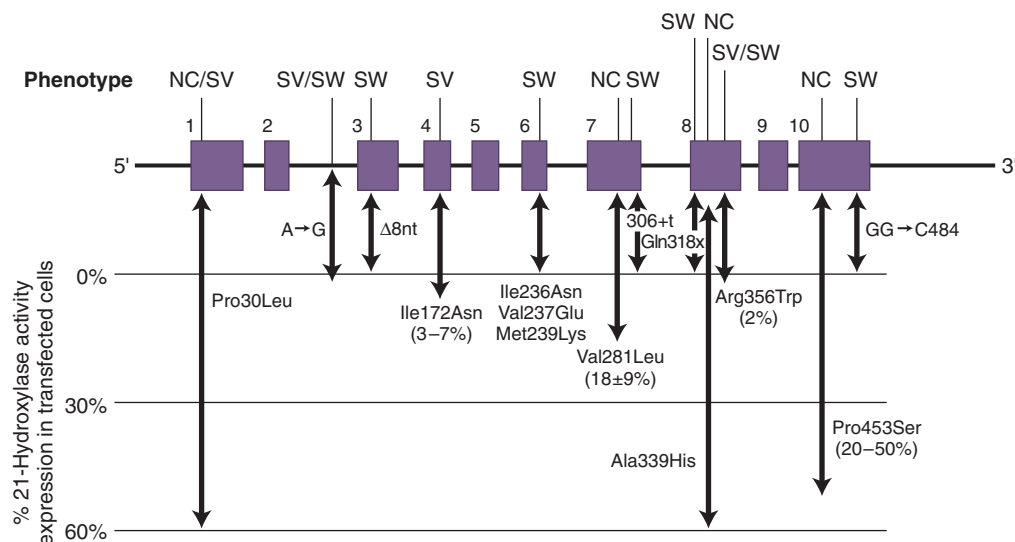

Figure 23-38 Diagram of the *CYP21* gene and locations of the mutations that cause more than 90% of cases of 21-hydroxylase deficiency. The numbered boxes depict the exons. The three-letter abbreviations for amino acids are used; X indicates a nonsense (stop) mutation. An adenine (A) to guanine (G) transition in intron 2 causes a common splice site mutation. Other mutations include an 8-nucleotide deletion (Δ nt) in exon 3, a thymidine insertion at codon 306 (306+T), and a guanine (G) to cytosine (C) transition at codon 484. The activities of the mutant enzymes, expressed as a percentage of the wild type, are indicated on the vertical axis and in parentheses for some missense mutations. NC, nonclassic form; SV, simple virilizing; SW, salt wasting.

between genotype and phenotype for the single-gene disorder is remarkably precise (Fig. 23-38). In patients who are compound heterozygotes, the phenotype usually is concordant with the milder allele. More than 90% of cases result from *CYP21* deletion or one of nine mutations derived from the nonfunctional pseudogene *CYP21P* (see Fig. 23-38). About 5% of *CYP21* mutations arise spontaneously.⁴⁴⁶ Worldwide, almost 100 non-pseudogene-derived mutations are reported for the *CYP21A2* allele.

The diagnosis of *CYP21* deficiency in a newborn with ambiguous genitalia is readily confirmed by markedly elevated serum 17-OHP concentrations (>300 nmol/L) after the first 48 hours. Sick, preterm infants can have moderately increased steroid levels, so ACTH stimulation may be needed to resolve any diagnostic confusion. The affected male usually has no alerting clinical signs at birth and, if a salt loser, does not decompensate with hypokalemia, hyperkalemia, and weight loss until 1 to 2 weeks after birth. Newborn screening programs to measure blood spot 17-OHP concentrations soon after birth have been introduced in some countries.^{447,448}

Of major relevance to DSD is the potential to prevent ambiguous genitalia of the newborn through prenatal treatment with dexamethasone.⁴⁴⁹ Treatment is effective if dexamethasone is started by 6 to 7 weeks' gestation. However, in current practice, karyotype analysis and *CYP21* genotype analysis is not available until approximately 5 weeks later. Seven unaffected or male fetuses would need to be treated with dexamethasone during this initial period for every one affected female fetus who might benefit.

Several concerns have been raised about the potential effects of dexamethasone on the developing fetus. Although no apparent somatic abnormalities have been observed in fetuses treated with dexamethasone to term and monitored through infancy and early childhood, and cognitive and motor development based on questionnaires appeared not to be adversely affected by exposure to dexamethasone, direct examination of 26 children who had been exposed to dexamethasone from gestational age 6 to 7 weeks did show adverse effects on verbal working memory compared with controls.⁴⁵⁰⁻⁴⁵³ All of these studies were observational,

and a meta-analysis emphasized the paucity of good-quality, long-term follow-up data to inform a risk/benefit analysis.⁴⁵⁴ This aspect should be considered when counseling families about prenatal treatment. Clinical practice guidelines have suggested that prenatal therapy should be undertaken using protocols approved by institutional review boards and at centers capable of collecting long-term outcome data as part of multicenter studies.⁴⁵⁵ Analysis of free fetal DNA in maternal blood for fetal sex determination using real-time quantitative polymerase chain reaction (PCR) techniques appears to be reliable at a median gestational age of 9 weeks.⁴⁵⁶ This would allow some reduction in unnecessary exposure to dexamethasone in male fetuses. It may be possible to reduce the dose of dexamethasone used later in gestation without altering efficacy,^{172,455} but significantly more research and long-term follow-up data are needed.

P450 Oxidoreductase Deficiency. POR is a membrane-bound flavoprotein that plays a central role in electron transfer from NADPH to all microsomal P450 enzymes, including CYP17, CYP21, and CYP19 (aromatase) (see Fig. 23-27). Defects in POR can cause apparent combined CYP17 and CYP21 deficiency, with or without Antley-Bixler syndrome, a form of craniosynostosis. These conditions were described earlier (see “Disorders of Androgen Synthesis”).^{170,305-308} POR deficiency can be associated with ambiguous genitalia in both 46,XX and 46,XY infants. The androgenization of 46,XX fetuses may result from a defect in aromatase activity or occur through a proposed backdoor pathway of DHT production that does not involve androstenedione or testosterone as intermediates.^{170,171} Children with this condition usually have cortisol deficiency, but mineralocorticoid function is relatively preserved.

11 β -Hydroxylase Deficiency. 11 β -Hydroxylase (CYP11B1) deficiency is a disorder of adrenal steroidogenesis. It can profoundly androgenize an affected female fetus and accounts for 5% to 8% of patients with CAH; there is a clustering of cases among Moroccan Jews. Apart from causing ambiguous genitalia in the newborn, 11 β -hydroxylase

deficiency manifests later with hypertension. Accumulation of 11-deoxycorticosterone leads to salt and fluid retention, and plasma renin is suppressed.

11 β -Hydroxylase is encoded by the *CYP11B1* gene, which is located on chromosome 8q21-22 in tandem with *CYP11B2*, which encodes aldosterone synthase, the enzyme catalyzing the conversion of deoxycorticosterone to corticosterone and then to aldosterone.⁴⁵⁷ Some *CYP11B1* mutations that cause 11 β -hydroxylase deficiency are shown in Figure 23-38. Fifty-three mutations are listed in the Human Gene Mutation Database at the Institute of Medical Genetics at Cardiff University, and most are missense mutations. Arg448 appears to be a relative hot spot for mutations, with Arg448His possibly a founder mutation in the Moroccan Jewish population. A null mouse model of 11 β -hydroxylase deficiency showed the expected phenotype of glucocorticoid deficiency, mineralocorticoid excess, hyperplastic adrenals, hypertension, and hypokalaemia.⁴⁵⁸ However, affected female mice were not virilized because rodent adrenals do not synthesize androgens.

Familial Glucocorticoid Resistance. Glucocorticoid resistance is a rare disorder that is usually caused by sporadic heterozygous mutations in the glucocorticoid receptor α -isoform (GR α).⁴⁵⁹ Partial end-organ insensitivity to glucocorticoid action coupled with impaired feedback mechanisms results in excess ACTH secretion and elevated circulating cortisol levels without the clinical features of Cushing's syndrome. In many cases, elevated levels of mineralocorticoids cause hypertension and hypokalemia, and elevated levels of adrenal androgens cause hirsutism and acne.

Most GR α mutations are heterozygous changes that cause a partial loss of function through altering ligand binding, nuclear localization, coactivator interactions, and target gene transcription, often with some degree of dominant negative activity. Complete loss of the GR α gene (*NR3C1*) is lethal in mice, and one case of complete glucocorticoid resistance has been described in a male infant with profound hypoglycemia and hypertension. One homozygous *NR3C1* mutation (Val571Ala) was reported in a Brazilian girl who had a large clitoris, posterior labioscrotal fusion, and a urogenital sinus at birth.⁴⁶⁰ This mutation

caused marked reduction in GR α function without complete loss of receptor activity. She also harbored a heterozygous mutation in *CYP21*. More severe GR α mutations may manifest as mild 46,XX DSD, although the phenotype might have been modified in this case by the coexistence of a heterozygous *CYP21* change.

Aromatase Deficiency. Aromatase (*CYP19A1*), formerly called estrogen synthetase, is the only cytochrome P450 enzyme known to catalyze the conversion of androgens (C19 steroids) to estrogens (C18 steroids) in vertebrate species.⁴⁶¹ Aromatase is expressed in many tissues, including the placenta, ovary, brain, bone, vascular endothelium, breast, and adipose tissue, where it is regulated by a number of tissue-specific promoters to convert testosterone to estradiol and androstenedione to estrone (Fig. 23-39). Aromatase plays a crucial role in the local production of estrogens and in the synthesis of circulating estrogens from the ovary at the time of puberty.

Aromatase deficiency due to recessively inherited mutations in *CYP19* has been described in approximately 13 girls with 46,XX DSD (see Fig. 23-40). The clinical and biochemical features of this condition underscore the key role aromatase plays in the fetoplacental unit, and this condition is sometimes referred to as *placental aromatase deficiency*. Aromatase plays a critical role in protecting the fetus from excessive androgen exposure in utero (Fig. 23-41). In the absence of aromatase, estrogen cannot be synthesized by the placenta, and large quantities of placental testosterone and androstenedione are transferred to the fetal and maternal circulation, resulting in androgenization of the female fetus and virilization of the mother during pregnancy.⁴⁶²

Females (46,XX) with aromatase insufficiency are born with clitoromegaly, various degrees of posterior fusion, scrotalization of the labioscrotal folds, and, in some infants with a urogenital sinus, a single perineal orifice.⁴⁶³⁻⁴⁶⁵ There is often a striking history of maternal virilization after the second trimester of pregnancy (e.g., acne, hair growth, voice changes) coupled with elevated maternal androgen levels, which usually resolve after the infant is born. As expected for a steroidogenic defect, affected girls (46,XX) have normal Müllerian structures. The histology of the ovaries in infancy is normal, but under increased FSH

Figure 23-39 Diagram of the *CYP11B1* gene and locations of the mutations causing 11 β -hydroxylase deficiency. The numbered solid boxes depict the exons. The three-letter abbreviations for amino acids are used; X indicates a nonsense (stop) mutation. A deletion of cytosine (C) at codon 32 and the addition of two nucleotides at codon 394 cause frameshift mutations; insertions and deletions resulting in a frameshift and splice site are shown by solid triangles and open triangles, respectively.

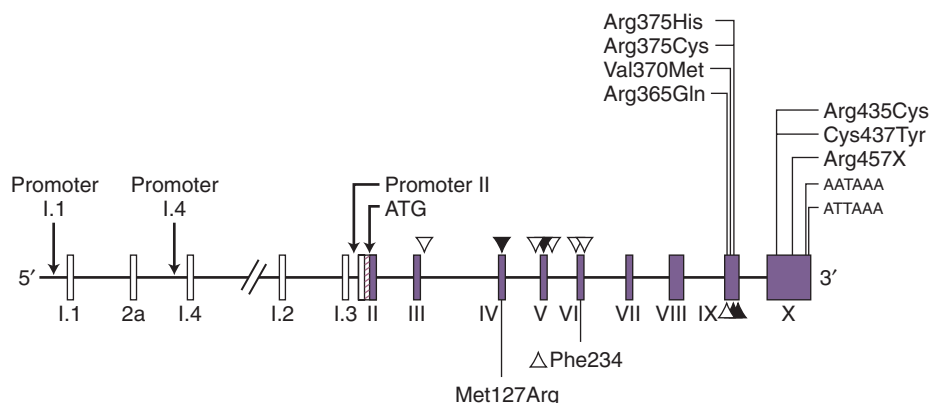

Figure 23-40 Diagram of the *CYP19* gene and selected mutations causing aromatase deficiency. The numbered solid boxes represent translated exons. The septum in the open box in exon II represents the 3' acceptor splice junction for the untranslated exons. Multiple alternative promoters and the untranslated exons (open boxes) are indicated. The three-letter abbreviations for amino acids are used to indicate the positions of missense mutations; X indicates a nonsense (stop) mutation; insertions and deletions resulting in frameshift and splice site mutations are shown by solid triangles and open triangles, respectively. In addition to the mutations causing classic aromatase deficiency, a homozygous Arg435Cys mutation and deletion of a phenylalanine residue at position 234 are both associated with a partial aromatase insufficiency phenotype. (Modified from Morishima A, Grumbach MM, Simpson ER, et al. Aromatase deficiency in male and female siblings caused by a novel mutation and the physiological role of estrogens. *J Clin Endocrinol Metab*. 1995;80:3689-3698, with permission of The Endocrine Society, copyright 1995.)

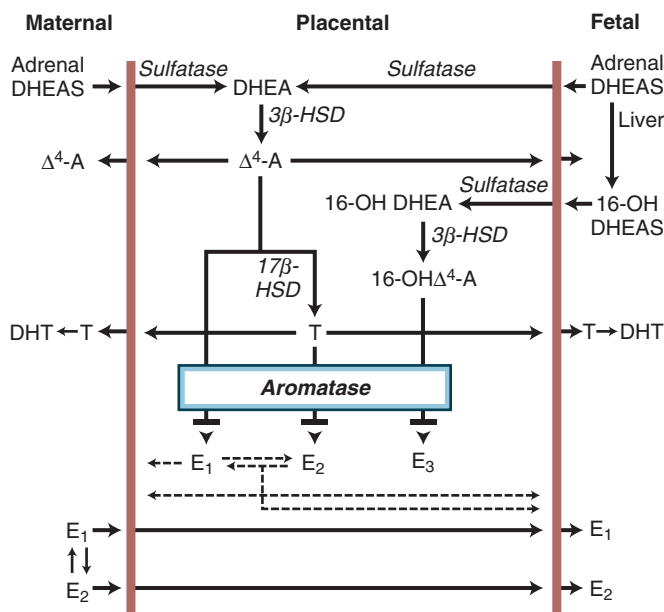

Figure 23-41 Aromatase plays a crucial role in protecting the fetus from excessive androgen exposure in utero. The placenta lacks *CYP17* enzymatic activity and cannot convert C21 steroids such as progesterone to C19 steroids and thereafter to estrogens. During gestation, large quantities of dehydroepiandrosterone sulfate (DHEAS) are produced in the fetal and maternal adrenal glands. DHEAS is 16 α -hydroxylated in the fetal adrenal and liver. The 16 α -hydroxy-DHEAS from the fetus and DHEAS from the mother are transferred to the placental unit, where the sulfate moiety is cleaved by placental sulfatase. These steroids can then be converted to androstenedione (A) and 16 α -hydroxyandrostenedione by 3 β -hydroxysteroid dehydrogenase (HSD) type I/ Δ^4 -isomerase; to testosterone and 16 α -hydroxytestosterone by 17 β -HSD; and to estrogens (mainly estrone from 16 α -hydroxy-DHEA) by placental aromatase. Androstenedione and 16 α -hydroxyandrostenedione may be aromatized directly to estrogens. DHT, dihydrotestosterone; E₁, estrone; E₂, estradiol; E₃, estriol; T, testosterone. (Modified and redrawn from Conte FA, Grumbach MM, Ito Y, et al. A syndrome of female pseudohermaphroditism, hypergonadotropic hypogonadism, and multicystic ovaries associated with missense mutations in the gene encoding aromatase (P450_{arom}). *J Clin Endocrinol Metab*. 1994;78:1287-1292, with permission of The Endocrine Society, copyright 1994.)

stimulation in the absence of ovarian aromatase, multiple, enlarged follicular cysts develop. At puberty, affected females have hypergonadotropic hypogonadism, typically fail to develop female secondary sexual characteristics, and exhibit progressive virilization. Plasma androstenedione and testosterone levels are elevated, and estrone and estradiol levels are low or not measurable. The ovaries enlarge and develop multiple cysts at puberty; in one affected female, polycystic ovaries were detected in infancy. The hypergonadotropism and the multiple ovarian cysts respond to estrogen replacement therapy, but in some cases, temporary treatment with an antiandrogen is necessary.⁴⁶⁶

In addition to a role in the reproductive axis, aromatase deficiency has implications for bone development, metabolism, and immune function, as determined by the long-term follow-up of the small numbers of women (46,XX) and men (46,XY) with aromatase deficiency and by studies of aromatase-knockout mice.⁴⁶¹ Males present only after puberty and have tall stature, delayed bone maturation and epiphyseal fusion, and osteopenia, suggesting that estrogens are essential for the prevention of osteoporosis in males and females and for normal skeletal maturation and proportions.⁴⁶⁷ This phenotype is similar to that of a man with an inactivating estrogen receptor- α mutation.⁴⁶⁸ Hyperinsulinemia and abnormal plasma lipids have also been reported in aromatase deficiency, which may in part reflect estrogen insufficiency but may also reflect specific actions of aromatase itself. The finding of apparently normal psychosexual development in the three aromatase-deficient adolescent or adult patients and in the man with an estrogen receptor defect suggests that estrogen does not play a critical role in sex differentiation of the human brain, as has been reported in nonprimate mammals.

Approximately 18 *CYP19A1* mutations have been described in males and females with aromatase deficiency (see Fig. 23-40). These changes are inherited in a recessive fashion and are present in a homozygous or compound heterozygous state. Functional assays of aromatase activity have shown severe loss of enzyme function (approximately 0.3%) in all cases associated with classic aromatase deficiency, other than approximately 1% activity for the Arg-435Cys change found in a compound heterozygote together with the null Cys437Tyr mutation.⁴⁶⁴ Although this patient

had a classic presentation at birth, maternal virilization during pregnancy was reportedly absent. A homozygous Arg435Cys change has been reported in a girl who presented with androgenized genitalia at birth but showed limited breast development during puberty.⁴⁶⁹ Deletion of a single phenylalanine residue (Phe234del) causing partial loss of aromatase activity was described in an androgenized 46,XX individual who showed significant breast development (Tanner stage 4) during puberty.⁴⁶⁹

A spectrum of phenotypes may be seen with aromatase insufficiency in humans. This important diagnosis should be considered in all androgenized 46,XX infants when more common forms of CAH (e.g., CYP21 deficiency) have been excluded. A history of maternal virilization in pregnancy should always be sought, and increased levels of Δ^4 -androstenedione, testosterone, and DHT and low levels of plasma estriol, urinary estriol, and amniotic fluid estrone, estradiol, and estriol may be detected.

Maternal Androgen Excess. Maternal sources of androgens that may virilize a female fetus may be endogenous from adrenal and ovarian tumors or exogenous from maternal ingestion of androgenic compounds. Danazol, a synthetic derivative of ethisterone with androgenic, anti-estrogenic, and antiprogesterogenic activities, is used in diverse conditions such as endometriosis, benign fibrocystic breast disease, and hereditary angioedema and in women with unexplained subfertility. It crosses the placenta and is contraindicated in pregnancy in view of reports that a female fetus may become androgenized.⁴⁷⁰ Ovarian causes of virilization include primary malignancy, benign lesions such as luteoma and hyperreactio luteinalis, and polycystic ovary syndrome. Recurrence in subsequent pregnancies and maternal virilization can occur with luteomas.⁴⁷¹ As in fetal aromatase deficiency, a similar pattern of recurrent hyperandrogenization without evidence of placental aromatase deficiency has been reported.⁴⁷²

Other Conditions Affecting 46,XX Sex Development

Several syndromic associations can cause developmental genital abnormalities in 46,XX females, although these are less common than the syndromic associations resulting in underandrogenization in 46,XY males. Complex urogenital anomalies such as cloacal extrophy can affect both sexes and require major reconstructive surgery for bladder and bowel function and for the lower genital system.

Abnormalities in uterine development can result in bicornate uterus (i.e., Fryns syndrome), uterine hemiagenesis or hypoplasia, or uterine agenesis. These conditions can be associated with renal, cardiac, and cervical spinal abnormalities as part of Mayer-Rokitansky-Küster-Hauser (MRKH) syndrome or MURCS (Müllerian, renal, and cervical spine syndrome).⁴⁷³ The cause of these conditions is unknown for most women, although some familial cases have been described, and a mutation in *WNT4* was reported in a patient with absent Müllerian structures (uterus and upper vagina), unilateral renal agenesis, and mild hyperandrogenemia.⁴⁷⁴ Uterine abnormalities have also been associated with maturity-onset diabetes of the young type 5 (MODY5, *HNF1B*) and with vaginal abnormalities in patients with hand-foot-genital syndrome (*HOXA13*) and McKusick-Kaufman syndrome (MKKS, formerly called BBS6). Because a prominent clitoris can be associated with conditions such as Fraser syndrome or neurofibromatosis, careful evaluation is necessary before a hyperandrogenic cause is diagnosed.

Other common conditions that may be mistaken for a more serious underlying disorder include apparent clitoromegaly seen in premature or former premature babies or when little labial adipose tissue is present. Assessment by a surgeon or physician with experience of normal variability in clitoral size is important. Labial adhesions are a common finding in female newborns. They often resolve spontaneously, although estrogen cream can be used to accelerate the process. Transient menstrual bleeding during the first week of life can be seen frequently in female infants with the withdrawal of large amounts of estrogens and progesterones after birth. This finding can be alarming for parents, but it rapidly resolves, and no treatment is needed.

INVESTIGATION AND MANAGEMENT OF DISORDERS OF SEX DEVELOPMENT

The general principles of the approach to the management of DSD apply regardless of the underlying diagnosis. In the case of presentation in the newborn period, the prototypical example of DSD is ambiguous genitalia for which instantaneous sex assignment is not possible. Although final assignment will be delayed pending the results of investigations, the principle applies that all infants should be designated as male or female. DSD presentations in the newborn period may be less overtly ambiguous when there is less doubt about the sex, but there is significant under-masculinization of a male infant or masculinization of a female infant. An apparent male with nonpalpable testes (possible CAH) or an apparent female with inguinal hernias (possible CAIS or 17 β -HSD deficiency) also should be investigated. A family history of DSD or a mismatch between prenatal genotype and the birth phenotype should prompt investigation. Problems in infants that merit investigation are listed in Table 23-19.

It is debatable whether deviation from the genital anatomy of the typical male or female, estimated to occur in 1.7% of live births, should be a guide for investigation. More realistic evidence suggests that some form of genital anomaly at birth may have a prevalence as high as 1 in 300,⁴⁷⁵ whereas ambiguity of the external genitalia has a prevalence of approximately 1 in 5000 births.⁴⁷⁶ Against such a background, it is useful to provide reference to normative data on measurements of the genitalia in infants (Table 23-20) and to methods to assess the degree of external virilization in CAH (Fig. 23-37) or as an external masculinization score³⁹³ (Fig. 23-42). The latter system has the merit of providing a quantitative score for four

TABLE 23-19

Problems in Newborns That Merit Investigation for DSDs

Ambiguous genitalia
Apparent female genitalia
Enlarged clitoris
Posterior labial fusion
Inguinal/labial mass
Apparent male genitalia
Nonpalpable testes

components of male genital development, and it can be applied objectively when assessing the response to androgen treatment. The score is also useful as a guide to decide which infants require further evaluation and investigation. The diagnostic yield in terms of finding chromosomal abnormalities in isolated mild hypospadias or isolated cryptorchidism ranges from 2% to 7%; the rate increases to 12.5% when both conditions are present.⁴⁷⁷ A cause was identified for more than one third of severe cases when hypospadias was comprehensively investigated.⁴⁷⁸

Investigations

Before embarking on a process of investigation that may be complex and lengthy, an adequate history should be obtained and a thorough physical examination should be performed. The information obtained may add urgency to complete initial investigations and start treatment if a life-threatening condition affecting the adrenal is suspected. The history should cover facets such as family history of DSD, adrenal disorders, or infertility and details of the current pregnancy, such as the need for assisted reproductive technologies, maternal exposure to medications, maternal virilization during pregnancy, and birth weight.⁴⁷⁹ The examination should take note of features suggesting particular DSD-related syndromes or indications of metabolic decompensation or hyperpigmentation. Specific examination of the external genitalia should assess the appearance and size of the phallus, the location of a urethral opening, the presence of a vaginal opening, the nature of the scrotum or labioscrotal folds, and the site of any palpable gonads. If possible, the phallic length along its dorsal surface should be documented (see Table 23-20). Often, the sex of the infant is not easily determined after the examination, and investigations are needed urgently.

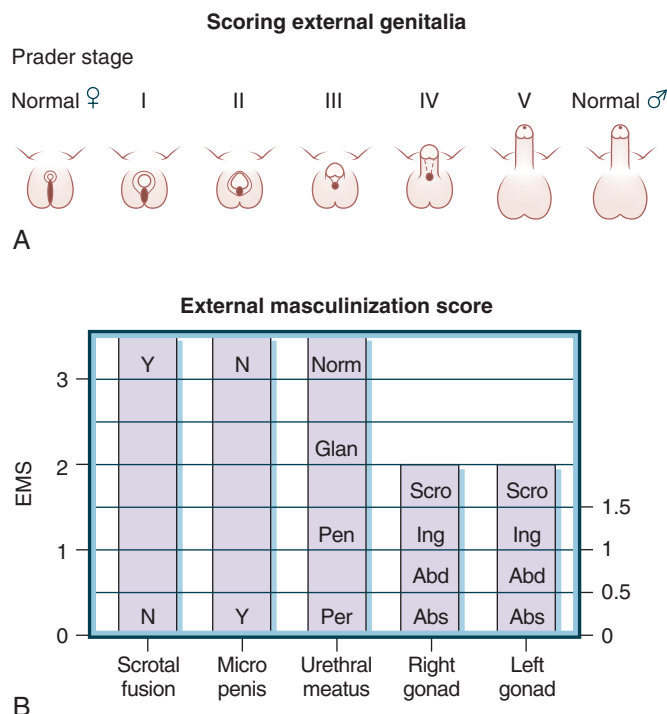

Figure 23-42 A, Prader staging for scoring the degree of androgenization of the external genitalia in a female infant with congenital adrenal hyperplasia. **B**, The external masculinization score (EMS) is used to assess degree of underandrogenization in an individual with 46,XY disorder of sex development. The score is based on the presence or absence of a micropenis and bifid scrotum, the location of the urethral meatus, and the position of the testes. (From Ahmed SF, Khwaja O, Hughes JA. The role of a clinical score in the assessment of ambiguous genitalia. *BJU Int*. 2000;85:120-124.)

ACTH, adrenocorticotrophic hormone; AMH, anti-Müllerian hormone; CT, computed tomography; DHT, dihydrotestosterone; FISH, fluorescent in situ hybridization; GC-MS, gas chromatography–mass spectrometry; hCG, human chorionic gonadotropin; MRI, magnetic resonance imaging.

Investigations should be targeted initially to answer specific questions that would be informative about sex assignment, even though a definitive diagnosis may not be achieved until another batch of tests are undertaken. A first-line set of investigations, as listed in Table 23-21, usually achieves the first target. Obtaining an indication of the sex chromosomes by FISH using X- and Y-specific probes within hours after birth has been a major advance in management. A definitive karyotype is necessary, but the result is often available within days. Concomitant endocrine tests include measurement of serum 17-OHP, testosterone, and AMH. The latter peptide is proving to be a highly reliable indicator of the presence of testicular tissue.⁴⁸⁰ Urine should be collected and stored pending a later decision about analysis by specific gas chromatography and mass spectrometry. For the more uncommon forms of CAH, this test can provide the definitive diagnosis.³³³ Imaging by pelvic ultrasound may be most informative when a cervix or uterus is clearly visualized in the context of a 46,XX karyotype and elevated serum 17-OHP concentration. In a term infant, the diagnosis is CAH, the most common cause of ambiguous genitalia of the newborn. Ultrasound imaging alone should not always be relied on to delineate the internal genital anatomy or to locate the site of gonads. MRI or laparoscopy may be a more definitive investigation to answer such questions. An ACTH stimulation test may be required to confirm a diagnosis of CAH in some cases and to verify adequate cortisol production in some rare forms of 46,XY DSD.

Second-line investigations usually are required when the karyotype is 46,XY or perhaps 45,X/46,XY. In this instance, the question is whether testes are present and, if so, whether they are capable of producing normal, age-related levels of androgens. The lynchpin of this assessment is the hCG stimulation test, for which several protocols have been employed. We are most familiar with the 3-day stimulation test comprising 1500 units daily,

with samples for steroid analysis collected before the first injection and 24 hours after the last injection.⁴⁸¹ Measurement of testosterone is essential, but in addition, androstenedione and DHT are measured when an androgen biosynthetic defect is suspected. The stimulation test may be prolonged for another 2 weeks (using twice-weekly hCG injections) to determine whether the gonads are dysgenetic. The hCG stimulation test is often preceded by an acute LHRH stimulation test, which occasionally may be useful for suggesting primary gonadal dysgenesis (i.e., exaggerated peak LH and especially peak FSH levels) or some hypothalamic-pituitary dysfunction (i.e., absent LH and FSH responses). Analysis of DNA for specific gene mutations and androgen-binding assays using genital skin fibroblasts are investigations that may be required later. At this stage, an underlying diagnosis of DSD is often not established, particularly for phenotypes similar to PAIS (but with no AR mutation detected), partial gonadal dysgenesis, or a phenotype associated with an unknown dysmorphic syndrome. Laparoscopy and gonadal biopsy for histology and karyotyping may be needed in some cases to obtain a definitive diagnosis. In rare cases of possible 46,XX ovotesticular DSD manifesting at birth, measurement of estradiol and inhibin A levels after recombinant FSH stimulation may provide an assessment of ovarian tissue.²⁴²

Management

The pillars of management are effective communication with the family from the outset of having a newborn with a DSD, clear explanation of the steps to be taken to investigate their child, joint discussion about sex assignment, and description of the sequential road map for management through childhood, through puberty, and into young adulthood. The information provided and the manner with which it is delivered has a long-lasting effect on how parents perceive and understand their child's problem. Providing appropriate written information, adapted to local circumstances, is essential, and audiotaping consultations and providing edited transcripts can be valuable. Later, families find support from patient advocacy groups or benefit from being put in touch with another family affected by DSD.

Who should act as the key contact for affected families and be the conduit for communication among the multidisciplinary team? The team may include a pediatric endocrinologist, a pediatric surgeon/urologist, a clinical psychologist, a specialist in pediatric and adolescent gynecology, a clinical geneticist, a neonatologist, a social worker, and a medical ethicist. Not all of these professionals are routinely involved from the outset, but the mechanism must be in place for all to engage in management discussions as part of regular meetings of the multidisciplinary team. Each team member should be trained in the skills of communication relevant to the management of an infant with DSD. In reality, the trio of the pediatric endocrinologist, pediatric surgeon/urologist, and clinical psychologist take a major share of this responsibility and make themselves readily available. The family's primary care physician must be constantly informed of developments.

How a multidisciplinary team operates in practice in the management of DSD is exemplified by the 20 years of experience gleaned at the Great Ormond Street Hospital for Children in London and transitional care in the Adolescent Unit at the neighboring University College Hospital.⁴⁸² Although many DSD centers can report their own practice, the London model provides a comprehensive report of a holistic approach to the management of DSD

from birth through adolescence. Each member of the multidisciplinary team understands his or her responsibilities and what is required for input, but success depends on well-organized, regular meetings of the multidisciplinary team. This provides an opportunity to review the results of investigations across a range of disciplines (e.g., biochemistry, imaging, genetics, histopathology), opinions on diagnosis and sex assignment, and the action plans in the immediate and longer term. The factual information should be presented in a formal manner (e.g., PowerPoint) and in the context of an up-to-date review of the relevant literature. An electronic record must be secured appropriately and medical confidentiality ensured. A gathering of the multidisciplinary team in this manner may provide an opportunity for an educational exercise to a wider audience, perhaps supplemented at the end of the meeting with formal talks stemming from a syllabus of DSD topics.

Management of DSD is an ongoing process in which the team meeting can review newly obtained information, including feedback on the outcome of consultations with each of the team professionals. Over a 2-year period, the multidisciplinary team in London reviewed more than 100 cases of DSD, with approximately two thirds categorized as 46,XY DSDs.⁴⁸² Within this category were disorders of gonadal development, disorders of androgen synthesis or action, and a significant number of syndromic disorders. As expected, various forms of CAH predominated within the 46,XX category, and there were a significant number of cases of isolated clitoromegaly of unknown cause. Mixed gonadal dysgenesis (45,X/46,XY mosaicism) predominated in the sex chromosome DSD category when classic Turner syndrome was excluded.

Outcomes

Several issues should be considered after the initial assessment, attempted diagnosis, and decisions about sex assignment are completed. Sex assignment is based on several factors, including the underlying diagnosis, likely gender identity, appearance of the genitalia and options for urologic and sexual function, the probable need for hormone

replacement, potential for fertility, and tumor risk (Table 23-22). These factors should be considered within the context of the views of the family and social and cultural circumstances. Female sex assignment is assumed in 46,XX DSD due to CAH on early diagnosis and in 46,XY due to CAIS. However, such decisions are not as straightforward for mixed gonadal dysgenesis (45,X/46,XY mosaicism), ovotesticular DSD, partial gonadal dysgenesis, severe PAIS, or the androgen biosynthetic defects (i.e., 17 β -HSD and 5 α -reductase enzyme deficiencies).

Exposure to androgens in the prenatal and postnatal periods is considered to be a factor that leads to brain masculinization and increased male-typical behavior. The evidence that this may be the case is more persuasive for prenatal androgen exposure, based on studies of girls with CAH⁴⁸³ and on play behavior in normal children.⁴⁸⁴ In contrast, studies in infant rhesus macaques treated with a GnRH agonist after birth showed that expression of infant sex differences in behavior was not altered by manipulation of the postnatal surge in testosterone.⁴⁸⁵ Boys with congenital anorchia and otherwise normal development of the external genitalia at birth showed no difference in male-typical sex behavior in young adulthood compared with controls.⁴⁸⁶ Consequently, the relevance of the postnatal testosterone surge to brain masculinization is unsubstantiated. The sex difference in toy preferences in early childhood may relate more to socialization and cognitive gender development than to inborn factors.⁴⁸⁷

The surgical options are a function of sex assignment, and procedures are planned accordingly. The timing of surgery may be delayed, allowing the child to engage in discussions at the appropriate time. This is increasingly the practice adopted for female sex assignment for conditions such as CAH. In some cases, surgery may not be considered necessary. Outcome studies involving assessment of genital sensitivity and sexual function in women with CAH show clear impairment related to previous feminizing genital surgery.^{488,489} Although surgical procedures have changed, these data have had a profound bearing on decisions taken during infancy and childhood for the surgical management of conditions such as CAH. It is generally accepted that clitoroplasty should be reserved only for the most

severe degree of clitoromegaly, and vaginal surgery is deferred until after puberty. The long-term outcome of vaginal reconstruction procedures performed before puberty for a variety of conditions (e.g., CAH, AIS, mixed gonadal dysgenesis, persistent cloaca) suggests that complications may be reduced by undertaking the surgery later.⁴⁹⁰ In adulthood, vaginal length in conditions such as CAIS and the MRKH syndrome can be normalized by dilator treatment alone.^{391,491}

Subjects with DSD raised male require surgery to correct hypospadias and orchidopexy for testis maldescent.^{492,493} Hypospadias repair usually is scheduled for between 6 and 24 months of age. More than one procedure is often required. It is the surgeon's responsibility to map out these procedures for the parents and to ensure that their expectations are realistic when questions are raised later about the role of phalloplasty in adulthood.⁴⁹⁴ The topic of gonadectomy planned before puberty in 46,XY individuals raised female to prevent virilization and in others with DSD to avoid gonadal tumors was covered earlier. The irreversible nature of such a procedure has created uncertainty among professionals, particularly when the procedure is performed before the affected child can be engaged in discussions. This is another issue that requires the collective discussion of the multidisciplinary team and often includes input from an ethicist. The practice of cryopreserving excised gonads with unrealistic expectations for preservation of reproductive potential should be viewed cautiously, especially because current knowledge is based primarily on the gonadal effects of cancer therapies.⁴⁹⁵⁻⁴⁹⁷

Disclosure policies about sharing diagnostic information in relation to the karyotype, gonads, internal and external genital anatomy, and levels of circulating sex hormones are relevant across the spectrum of DSD presentations. It is germane whether the problem is congenital anorchia, undescended testes, micropenis, isolated hypospadias or ambiguous genitalia, or a phenotype completely at variance with the karyotype or gonadotype. The need for planned disclosure is most apparent for the girl who has had previous gonadectomy, has an XY karyotype, and is now in late childhood. Counseling in this setting should be undertaken only by a psychologist skilled in DSD management and should be provided in a stepwise manner. A more immediate need for professional input occurs in adolescence when, for example, investigations for primary amenorrhea reveal a diagnosis such as CAIS or complete gonadal dysgenesis. The historical practice of concealment is no longer acceptable.⁴⁰⁴ It is encouraging that younger adults with DSD who participated in a survey of disclosure experiences reported more positively about appropriate information sharing, compared with participants of an older age.⁴⁹⁸ Nevertheless, there remains considerable scope for improving communication and investing in more resources for psychosocial support.

Transitional Care and Adulthood

Various forms of transitional care have been reported for chronic endocrine-related disorders such as CAH, Turner syndrome, and growth hormone deficiency.⁴⁹⁹⁻⁵⁰¹ A model of transitional care is of paramount importance in DSD, as exemplified by the increasing role of gynecologists and adult endocrinologists in the management of female adolescents, urologists for young men, and, above all, clinical psychologists for many patients. Transition is an opportunity to take stock of the diagnosis, the appropriateness of hormone replacement therapy, and the need for further surgical interventions. The accuracy of the diagnosis may

AIS, androgen insensitivity syndrome; CYP, cytochrome P450 enzyme; DSD, disorders of sex development; 17 β -HSD, 17 β -hydroxysteroid dehydrogenase.

be questionable for many individuals, particularly females with an XY karyotype.⁵⁰² The hinterland between pediatric and adult practice may be the time when DSD comes to light, that is, in the adolescent girl with primary amenorrhea or with virilization and in the boy with gynecomastia (Table 23-23). An appropriately constituted multidisciplinary team is as important at this stage in the DSD management process as it is at birth and is vital for coordinating the long-term endocrine, gynecologic, urologic, and psychological issues related to DSD into adult life.⁵⁰³

Future Development

The Chicago Consensus has been the catalyst for a sea change in the approach to management of DSD. The change in nomenclature and the development of a new classification system has incited a quiet revolution in this branch of medicine.⁵⁰⁴ DSD centers are incorporating the changes in their clinical practice and the new nomenclature is being used abundantly in the biomedical literature.⁵⁰⁵ There is a consensus among professionals working in the field of DSD to make progress in tackling the challenges that the multidisciplinary team face in management. Disclosure strategy merits research that can draw on experiences in other areas of practice, such as adoption and studies of donor conception.⁵⁰⁶ No single center is able to gather sufficient numbers of cases and experience in management to make strides in elucidating the genetic and endocrine mechanisms causing gonadal dysgenesis, PAIS-like phenotypes, or isolated hypospadias and in gathering more data to interpret age-related changes in steroid production and metabolism. National and international forms of collaboration are essential for progress.

ACKNOWLEDGMENTS

We recognize the major contributions made to this chapter by previous editors Melvin Grumbach, MD, and Felix Conte, MD. John C. Achermann holds a Wellcome Trust Senior Research Fellowship in Clinical Science (079666). Ieuan A. Hughes is supported by the NIHR Cambridge Biomedical Research Centre for his work on disorders of

sexual development, and both authors acknowledge the support of the European Commission-funded EuroDSD Programme.

NORMAL GROWTH

Overview

Growth is a fundamental, intrinsic aspect of childhood health. It is also a complex yet tightly regulated process. An individual's final height and the path taken to reach that end point are significantly determined by that person's genetic composition. But growth and final height can also be affected by external factors, including the quality and quantity of nutrition, and by psychosocial factors. This process is regulated by multiple hormones and growth factors interacting with an array of membrane receptors that activate seemingly redundant intracellular signaling cascades. And yet, as complex as this process is, 1 standard deviation (SD) of adult height represents about only 4% of the mean adult height.

Whether linear growth occurs as a continuous process or with periodic bursts of growth and arrest¹⁻⁴ has been hard to characterize definitively. There do appear to be seasonal variations of growth, with slower growth in autumn and winter and greater growth in spring and early summer.^{5,6} Some normal children have a broad growth channel, with many showing diverse but characteristic growth tracks.⁷ Nonetheless, even though the process of growth is multifactorial and complex, children usually

grow in a remarkably predictable manner. Deviation from such a normal pattern of growth can be the first manifestation of a wide variety of disease processes, including endocrine and nonendocrine disorders and involving virtually any organ system of the body. Therefore, frequent and accurate assessment of growth is of primary importance in the care of children.

Measurement

Assessment of growth requires accurate and reproducible determinations of height. Supine length is routinely measured in children younger than 2 years of age, and erect height is assessed in older children. It can be useful to measure both length and height in children between 2 and 3 years of age, to allow comparisons to prior length measurements and to begin to record height measurement for ongoing comparisons. The inherent inaccuracies involved in measuring length in infants are often obscured by the rapid skeletal growth during this period. For measurement of supine length (Fig. 24-1), it is best to use a firm box with an inflexible board, against which the head lies, and a movable footboard, on which the feet are placed perpendicular to the plane of the supine length of the infant. Optimally, the child should be relaxed, the legs should be fully extended, and the head should be positioned in the

Figure 24-1 Technique for measuring recumbent length. (A device suitable for measurement of length of infants can be purchased from Raven Equipment Limited, Essex, United Kingdom.) (Photograph courtesy of Noel Cameron.)

Frankfurt plane, with the line connecting the outer canthus of the eyes and the external auditory meatus perpendicular to the long axis of the trunk.

When children are old enough (and physically capable) to stand erect, it is best to employ a wall-mounted Harpenden stadiometer similar to that designed by Tanner and Whitehouse for the British Harpenden Growth Study. The traditional measuring device of a flexible arm mounted to a weight balance is notoriously unreliable and does not provide accurate serial measurements.

As with length measurements in infants, positioning of the child in the stadiometer is critical (Fig. 24-2). The child should be fully erect, with the head in the Frankfurt plane; the back of the head, thoracic spine, buttocks, and heels should touch the vertical axis of the stadiometer, and the heels should be together. Every effort should be made to correct discrepancies related to lordosis or scoliosis. Ideally, serial measurements should be made at the same time of day, because standing height may undergo diurnal variation.

Height determinations should be performed by a trained individual rather than an inexperienced member of the staff. We recommend that lengths and heights be measured in triplicate, that variation should be no more than 0.3 cm, and that the mean height should be recorded. For determination of height velocity when several measurements are being made within a short period, the same individual should perform the determinations to eliminate interobserver variability. Even when every effort is made to obtain accurate height measurements, a minimum interval of 6 months is necessary for meaningful height velocity computation. Nine to 12 months' data are preferable so that errors of measurement are minimized and the seasonal variation in height velocity is assimilated into the data.

Growth Charts

Evaluation of a child's height must be done in the context of normal standards. Most American pediatric endocrine clinics use the cross-sectional data provided by the National Center for Health Statistics (NCHS), which were originally introduced in 1977. Revised and updated growth charts have been available on the Centers for Disease Control (CDC) web site since 2000 (www.cdc.gov/growthcharts; Figs. 24-3 through 24-8).⁸ The data for these charts encompass measurements obtained in the United States between 1963 and 1995, and they include a broader representation of the U.S. population for all measures than was available in earlier charts.

These charts allow comparison of individual children with the 3rd, 10th, 25th, 50th, 75th, 90th, and 97th percentiles of normal American children. There are, however, two limitations of these charts when applied to the

individual child. First, they do not satisfactorily define children below the 3rd or above the 97th percentiles—the very children in whom it is most critical to define the degree to which they deviate from the normal growth centiles. However, the NCHS data tables (also available on the CDC web site) can be used to compute standard deviation scores (SDS). For example, a short child below the 3rd percentile can be described more precisely as being

Figure 24-2 Technique for measuring erect height using the Harpenden stadiometer with direct digital display of height. (Devices of this type are available from Holtain Ltd, Wales, United Kingdom, and Seritex Inc, Carlstadt, NJ.)

Figure 24-3 Length-for-age and weight-for-age percentiles for boys (birth to 36 months) developed by the National Center for Health Statistics in collaboration with the National Center for Chronic Disease Prevention and Health Promotion (2000). Available at <http://www.cdc.gov/growthcharts> (accessed October 2010).

approximately 4.2 SDS below the mean for age. A height SDS for age is calculated as follows: the SDS equals the child's height, minus the mean height for normal children of the child's age and gender, divided by the SD of the height for normal children of this age and gender. Second, cross-sectional data are of greater value during infancy and childhood than in adolescence, because differences in the timing of pubertal onset can considerably influence normal growth rates. To address this issue, Tanner and colleagues⁹ developed longitudinal growth charts, in an effort to construct the curve shapes with centile widths obtained from a large cross-sectional survey, thus accounting for variability in the timing of puberty. Such charts are of particular value in assessing growth during adolescence and puberty and for plotting sequential growth data for any individual child.

The data from cross-sectional and longitudinal growth studies have been employed to develop *height velocity* standards (Figs. 24-9 and 24-10). It is important to emphasize that carefully documented height velocity data are invaluable in assessing a child with abnormalities of growth. There is considerable variability in normal height velocity of children at different ages; however, between the age of 2 years and the onset of puberty, children grow with remarkable fidelity relative to the normal growth curves. Any crossing of percentile curves on the height chart

during this age period should be considered abnormal and warrants further evaluation.

Syndrome-specific growth curves have been developed for a number of clinical conditions associated with growth failure, such as Turner syndrome (TS),¹⁰ achondroplasia,¹¹ and Down syndrome.¹² Such growth profiles are invaluable for tracking the growth of children with these clinical conditions. Deviation of growth from the appropriate disease-related growth curve suggests the possibility of a second underlying cause, such as acquired autoimmune hypothyroidism in children with Down syndrome or TS.

Body Proportions

Many abnormal growth states, including both short stature and excessive stature, are characterized by *disproportionate* growth. The following determinations should be made as part of the evaluation of short stature:

1. Occipitofrontal head circumference
2. Lower body segment: distance from top of pubic symphysis to the floor
3. Upper body segment: the difference between total height and lower body segment (it can also be measured as the sitting height, subtracting the height of the chair or stool)
4. Arm span

Figure 24-4 Head circumference-for-age and weight-for-length percentiles for boys (birth to 36 months) developed by the National Center for Health Statistics in collaboration with the National Center for Chronic Disease Prevention and Health Promotion (2000). Available at <http://www.cdc.gov/growthcharts> (accessed October 2010).

Figure 24-5 Length-for-age and weight-for-age percentiles for girls (birth to 36 months) developed by the National Center for Health Statistics in collaboration with the National Center for Chronic Disease Prevention and Health Promotion (2000). Available at <http://www.cdc.gov/growthcharts> (accessed October 2010).

Published standards exist for these body proportion measurements, which must be evaluated relative to the patient's age.¹³ The ratio of upper segment to lower segment ranges from 1.7 in the neonate to slightly less than 1.0 in the adult (Fig. 24-11).

Parental Target Height

Genetic factors are important determinants of growth and height potential. Therefore, it is useful to assess a patient's stature relative to that of siblings and parents. Tanner and associates developed a growth chart that factored parents' heights into the evaluation of the heights of children ages 2 to 9 years.¹⁴ One can also calculate a child's expected final height based on the parents' heights by calculating the midparental height. This is the average of the parents' heights, after accounting for the average difference in height between adult men and women (13 cm). In other words, a boy's midparental height equals the average of his parents' heights plus 6.5 cm, and a girl's midparental height equals the average of her parents' heights minus 6.5 cm.

Because of regression to the mean,^{15,16} children of short parents are likely to be less short than their parents, and children of tall parents are likely to be less tall than their parents. Therefore, a child's genetic *target height range*

centers on the point that represents 80% of the difference between the child's midparental height and the mean adult height for the child's gender.¹⁵ For example, if a boy's father is 168 cm tall and his mother is 153 cm tall, his midparental height is 167 cm, which is 10 cm below the mean height of adult men (177 cm). Therefore, the boy's target height range centers on 169 cm, which is 8 cm below the mean adult height for men. In more than 95% of children, the adult height falls within 10 cm of the point thus calculated.^{14,15} In children with extremely short stature (>-3 SD), the father's height may more strongly correlate with the patient's height, and the mother's height may more greatly influence birth length.¹⁷

Skeletal Maturation

The growth potential in the tubular bones can be assessed by evaluation of the progression of ossification within the epiphyses. The ossification centers of the skeleton appear and progress in a predictable sequence in normal children, and this skeletal maturation can be compared with normal age-related standards. This forms the basis of the *bone age* or *skeletal age*, a quantitative determination of net somatic maturation that serves as a mirror of the tempo of growth and maturation. The bone age also reflects the degree of growth plate senescence and therefore is a useful adjunct

Figure 24-6 Head circumference-for-age and weight-for-length percentiles for girls (birth to 36 months) developed by the National Center for Health Statistics in collaboration with the National Center for Chronic Disease Prevention and Health Promotion (2000). Available at <http://www.cdc.gov/growthcharts> (accessed October 2010).

Figure 24-7 Stature-for-age and weight-for-age percentiles for boys (2 to 20 years) developed by the National Center for Health Statistics in collaboration with the National Center for Chronic Disease Prevention and Health Promotion (2000). Available at <http://www.cdc.gov/growthcharts> (accessed October 2010).

in estimating growth opportunity (i.e., the ultimate adult height), as discussed later in this chapter.

Not all of the factors that determine the normal pattern of skeletal maturation have been identified, but genetic factors and multiple hormones, including thyroxine, growth hormone (GH), and gonadal steroids, are involved.¹⁸ Ultimately, growth cessation occurs after exhaustion of the proliferative capacity of the growth plate chondrocyte.¹⁹ Estrogen plays an important role in this process: animal studies have indicated that estrogen accelerates growth plate senescence,²⁰ and studies in patients with mutations of the gene for the estrogen receptor²¹ or for the aromatase enzyme²²⁻²⁴ demonstrated that estrogen is primarily responsible for epiphyseal fusion.²⁵

Phases of Normal Growth

Growth occurs at differing rates during intrauterine life, early and middle childhood, and adolescence, then ceases after fusion of long bone and vertebral epiphyseal growth plates. Karlberg and associates resolved the normal linear growth curve into three additive, partially superimposable phases^{26,27}: an “infancy” phase, starting in midgestation and then rapidly decelerating until about 3 to 4 years of age; a “childhood” phase, slowly decelerating during early adolescence; and a sigmoid-shaped “puberty” phase that

comprises the adolescent growth spurt. Prenatal growth averages 1.2 to 1.5 cm per week but varies dramatically (Fig. 24-12); the midgestational length growth velocity of 2.5 cm per week falls to almost 0.5 cm per week immediately before birth. Growth velocity (see Figs. 24-2 and 24-3) averages about 15 cm per year during the first 2 years of life; it then slows to approximately 6 cm per year during middle childhood. During this time, a normal child's height, plotted on a growth curve, typically remain within a given growth channel; that is, it does not cross percentile lines on the growth curve.

Prepubertal growth is similar between boys and girls. The height difference between men and women, an average of 13 cm, is accounted for by two factors. First, boys grow for an average of 2 years longer than girls do, because girls have an earlier onset of puberty and, consequently, earlier cessation of growth. Therefore, prepubertal growth is greater for boys; they are 8 to 10 cm taller when their puberty starts, compared with girls' heights when their puberty starts.¹⁵ Second, boys achieve a greater maximal pubertal growth velocity than girls do, giving them 3 to 5 cm greater pubertal growth. The time of onset of puberty varies in normal children, resulting in a normal variation in the timing of the pubertal growth spurt. However, in most normal children, the final height is not influenced by the chronologic age at onset of the pubertal growth spurt,

Figure 24-8 Stature-for-age and weight-for-age percentiles for girls (2 to 20 years) developed by the National Center for Health Statistics in collaboration with the National Center for Chronic Disease Prevention and Health Promotion (2000). Available at <http://www.cdc.gov/growthcharts> (accessed October 2010).

Figure 24-9 Height velocity chart for boys constructed from longitudinal observations of British children. The 97th, 50th, and 3rd percentile curves define the general pattern of growth during puberty. Shaded areas indicate velocities in those children with peak velocities occurring up to 2 standard deviations before or after the average age depicted by the percentile lines (Up arrows, diamonds, and down arrows mark, respectively, the 97th, 50th, and 3rd percentiles of peak velocity when the peak occurs at these early or late limits.) (Modified from charts prepared by Tanner JM and Whitehouse RH from data published in references 9, 1211, and 1899. Reproduced with permission of J.M. Tanner and Castlemead Publications, Ward's Publishing Services, Herts, United Kingdom.)

Figure 24-10 Height velocity chart for girls constructed from longitudinal observations of British children. The 97th, 50th, and 3rd percentile curves define the general pattern of growth during puberty. Shaded areas indicate velocities in those children with peak velocities occurring up to 2 standard deviations before or after the average age depicted by the percentile lines (Up arrows, diamonds, and down arrows mark, respectively, the 97th, 50th, and 3rd percentiles of peak velocity when the peak occurs at these early or late limits.) (Modified and reproduced with permission of J.M. Tanner and Castlemead Publications, Ward's Publishing Services, Herts, United Kingdom.)

because the additional time for prepubertal growth that occurs when puberty is late is balanced by the fact that pubertal growth is smaller the later it occurs (see Figs. 24-2 and 24-3). After puberty, chondrocyte proliferation in the growth plate slows and senescence occurs due to depletion of stem-like cells in the resting zone of the growth plate.^{28,29}

There are two variants of normal growth whose characteristic patterns are such that children exhibiting these growth variants are often evaluated for a growth disorder. These two variants are crossing linear percentiles of infancy, and constitutional delay of growth and development (CDGD). In many cases, it is difficult to differentiate children with these normal growth variants from children with a growth disorder.

Crossing Linear Percentiles of Infancy

As in postnatal growth, genetic and environmental factors are important determinants of fetal growth and of the size of an infant (weight and length) at birth. However, there are significant differences between the factors affecting birth size and those affecting childhood growth and adult stature. There is much less correlation between length at birth and ultimate adult height than between length at birth and height in the later years of childhood.³⁰

Parental stature affects birth length, as it does adult stature; this is an indicator of the genetic influence on

Figure 24-11 Ratio of upper to lower body segment from birth to 18 years of age. (From data in Wilkins L. *The Diagnosis and Treatment of Endocrine Disorders in Childhood and Adolescence*. Springfield, IL: Charles C Thomas; 1957.)

Figure 24-12 Rate of linear growth and weight gain in utero and during first 40 weeks after birth. Length velocity is expressed in centimeters per week. The solid line depicts the actual linear growth rate; the dashed line connecting the prenatal and postnatal length velocity lines depicts the theoretical curve for no uterine restriction late in gestation. The lighter dashed line depicts weight velocity. (From data in Tanner JM. *Fetus into Man*. Cambridge, MA: Harvard University Press; 1978.)

growth. Although maternal and paternal stature contribute equally to childhood growth and adult stature, the effect of maternal stature may predominate over that of paternal stature on length at birth.^{31,32} However, some studies have found equal effects of maternal and paternal stature on birth size.³³ Maternal nutrition and health have significant effects on fetal growth. Maternal weight has a positive effect, and smoking during pregnancy has a negative effect. Maternal diabetes has a strong positive effect on fetal growth. It is possible for the prenatal determinants of growth to result, for example, in a child who will ultimately grow to below-average stature but is above average size at birth. For this reason, it is common for infants' lengths to cross percentiles on the growth curve. Indeed, it is more common for the growth of an infant to cross percentiles than to follow a single percentile from birth into childhood: approximately one third of infants have lengths that cross percentiles moving upward on the growth curves, and approximately one third have lengths that cross percentiles moving downward.^{32,34} Most normal infants crossing percentiles do so in the first 6 to 12 months, although some normal infants cross percentiles after 1 year of age.

Infants who are small at birth can be divided into (1) those who are small only because of prematurity and are therefore of a size appropriate for gestational age (AGA) and (2) those who are small for gestational age (SGA). SGA is usually defined as a birth weight or length (or both) below the 3rd percentile (or, sometimes, below the 10th percentile) for gestational age.³⁵ Some infants born SGA represent the small percentage of individuals whose genetic potential leads to small size at birth, and they can be expected to remain small throughout childhood and adulthood. However, many infants are SGA due to intrauterine growth retardation (IUGR) and have a genetic potential that would not be expected to result in small adult stature. Most infants who are born small, either AGA or SGA, have catch-up growth and achieve lengths greater than the 3rd percentile within the first 2 years of life. However, up to 10% of SGA infants do not show such catch-up growth.^{36,37} The pathologic aspects of IUGR and of SGA in infants who do not have catch-up growth are discussed later.

Constitutional Delay of Growth and Development

CDGD is a normal variant of growth.³⁸ It describes the growth pattern of children who will experience a later than average timing of puberty. Their birth size is normal, and their final height is within their genetic potential. However, during most of their childhood, they grow at a height percentile below that expected based on their genetic potential. Typically, these children have a low growth velocity during the first years of life, crossing downward on the length percentile growth curves, so that by 2 years of age their heights are at or slightly below the 5th percentile. After age 3 years, their growth rate is typically normal, so that their height growth usually remains parallel to the 5th percentile until adolescence, although the height SDS may gradually drift slightly lower during the middle childhood years in some cases.^{38,39} Their height diverges even further from that of average children during the early teen years due to the declining prepubertal growth velocity of these children compared with the accelerating growth rate of average children with onset of puberty.

Ultimately, children with CDGD have a late growth spurt, consistent with their late puberty, and this brings their height into the normal adult range. Final height is often in the lower part of the parental target height range, and few patients exceed the parental target height,⁴⁰⁻⁴² although this finding is probably, at least in part, the result of a selection bias of the children examined for such studies. However, there is evidence that a delayed growth spurt may adversely affect growth of the spine, resulting in a decrease in the final ratio of the upper to the lower segment and perhaps contributing to a limited final height.⁴³ Studies have also reported that prepubertal boys with CDGD have decreased bone mineral density (BMD),⁴⁴ and this decreased BMD may persist into adulthood, although not all studies have confirmed this finding.⁴⁵

Secular Changes in Height

There are surprisingly few data concerning the stature of modern humans before the measurement of military recruits became customary in the 18th century. Skeletal remains from the last ice age appear to indicate that adult stature 10,000 to 20,000 years ago was not substantially different from that of contemporary adults, although this record is obviously fragmentary.⁴⁶ It has been suggested that a reduction in stature was observed with the introduction of agriculture approximately 5000 years ago, with growth attenuation resulting from the combined effects of nutrient deficiency, population growth, and spread of infectious diseases.

Military recruits in the 18th and 19th centuries were clearly shorter than those of today, although it must be recognized that soldiers were commonly recruited from the lower socioeconomic classes, and poor health and nutrition would have contributed to both poor growth and late maturity.⁴⁷ Whereas men in the 20th century averaged 5 to 10 cm greater in height than those in the 18th century for whom we have records, much of this height gain has occurred over the last 100 years and probably reflects the dramatic improvement in overall nutrition and health seen in the Western world.

Therefore, secular changes in height appear to reflect fundamental alterations in the standard of living rather than major genomic differences among populations; future economic advances in developing countries can be predicted to lead to improvement in adult stature and a reduction in international differences in growth.

ENDOCRINE REGULATION OF GROWTH

The Hypothalamic-Pituitary Axis: Embryogenesis and Anatomy

The pituitary gland is central to the regulation of mammalian growth. The pituitary gland develops from oral ectoderm in response to inductive signals from the neuroepithelium of the ventral diencephalon and intrinsic signaling gradients determining expression patterns of pituitary-specific transcription factors in the developing anterior pituitary gland.⁴⁸ The primordium of the anterior pituitary, Rathke's pouch, forms as an upward invagination of a single-cell-thick layer of ectoderm that contacts the neuroectoderm of the primordium of the ventral hypothalamus at embryonic day 8.5 (E8.5) in the mouse embryo^{49,50} and can be identified by the third week of pregnancy in humans.⁵¹ The neurohypophysis (posterior pituitary) originates in the neural ectoderm of the floor of the forebrain, which also develops into the third ventricle. During anterior pituitary development, overlapping but regionally specific and temporally distinct patterns of homeobox transcription factor expression lead to the sequential appearance of the terminally differentiated cell types from E12.5 to birth.⁵⁰

The initiation of anterior pituitary gland development depends on the competency of the oral ectoderm to respond to inducing factors from the neural epithelium of the ventral diencephalon.⁵² The bone morphogenic protein 4 (BMP4) signal from the ventral diencephalon is the critical dorsal neuroepithelial signal required for organ commitment of the anterior pituitary gland. Wnt5a and fibroblast growth factor 8 (FGF8) are also expressed in the diencephalon in distinct overlapping patterns with BMP4. Subsequently, a BMP2 signal arises from the boundary of a region of oral ectoderm in which Sonic hedgehog (SHH) expression, initially expressed uniformly in the oral ectoderm, is selectively excluded from the developing Rathke's pouch. The ventral-dorsal BMP2 signal and the dorsal-ventral FGF8 signal appear to create opposing activity gradients that are suggested to dictate overlapping patterns of specific transcription factors underlying cell lineage specification. The various extensions of these transcription factors in their fields are theorized to combinatorially determine the specific cell types. The FGF8 gradient determines the dorsal cell phenotypes,^{52,53} and dorsally expressed transcription factors include Nkx-3.1, Six3, Pax6,⁵⁴ and prophet of PIT1 (PROP1).⁵⁵ Temporally specific attenuation of the BMP2 signal is required for terminal differentiation of the ventral cell types, and ventrally expressed transcription factors include islet-1 (Isl1), Brn4, P-Frk, and GATA2.^{52,55,56} PIT1 (encoded by the gene *POU1F1*) is required for somatotroph, lactotroph, and thyrotroph development,^{57,58} whereas the orphan nuclear receptor steroidogenic factor 1 (SF1) is selectively expressed in the gonadotrophs.^{59,60}

The ventral-dorsal gradient induces GATA2 in a corresponding gradient in presumptive gonadotrophs and thyrotrophs, and high levels of GATA2 in the most ventral aspect of the developing anterior pituitary directly or indirectly restrict expression of *POU1F1* out of the presumptive gonadotrophs. In the absence of PIT1, GATA2 expression appears sufficient to induce the entire set of transcription factors that are typical of the gonadotroph cell type, including SF-1, P-Frk, and Isl-1. Conversely, the absence of GATA2 dorsally is critical for differentiation of PIT1-positive cells

to somatotroph/lactotroph fates. It is hypothesized that the level of GATA2 expression in the thyrotrophs is below the threshold required to inhibit activation of the *POU1F1* gene early enhancer, permitting the emergence of a PIT1+, GATA2+ cell that results in the thyrotroph fate.⁵⁶ Pax6 has a role in the sharp boundary of attenuation of the ventral signals that dictate thyrotroph and gonadotroph cell lineages. In the absence of Pax6, the ventral lineages, particularly thyrotrophs, become dorsally extended at the expense of somatotroph and lactotroph cell types,⁵⁴ and Pax6 mutant mice are GH and PRL deficient.⁶¹

The earliest marker of the anterior pituitary is expression of the glycoprotein α -subunit (α GSU), which appears at E11.5 in the mouse. These α GSU-positive cells also express the transcription factor Isl1 and mark a population of differentiating thyrotrophs that disappears after birth.^{53,57,62,63} α GSU is expressed in mature thyrotrophs and gonadotrophs. At E12.5, corticotrophs start to differentiate and produce pro-opiomelanocortin (POMC).^{53,63} Intensified cell proliferation within Rathke's pouch results in formation of a visible nascent anterior pituitary lobe on E12.5.⁵⁰ Definitive thyrotrophs are observed at 14.5 dpc, characterized by the expression of *Tshb* at E14.5 and followed by the expression of GH and prolactin (PRL) in somatotrophs and lactotrophs, respectively, at E15.5. The gonadotrophs are the last cell type to develop, at E16.5, marked by expression of luteinizing hormone (LH) and later by follicle-stimulating hormone (FSH). Eventually, the mature gland is populated by at least five highly differentiated cell types; ventrally to dorsally, they are the gonadotrophs, thyrotrophs, somatotrophs, lactotrophs, and corticotrophs.⁵² Ultimately, some of these same transcription factors are also involved in the cell-specific expression and regulation of the gene products of these pituitary cell types, with corticotrophs producing adrenocorticotropin (ACTH), thyrotrophs producing thyrotropin (thyroid-stimulating hormone, TSH), gonadotrophs producing gonadotropins (LH and FSH), somatotrophs producing GH, and lactotrophs producing PRL. The developmental factors that play an in vivo role in pituitary gland development and differentiation are shown in Fig. 24-13.

In humans, GH-producing cells can be found in the anterior pituitary gland by 9 weeks of gestation,⁶⁴ and vascular connections between the anterior lobe of the pituitary and the hypothalamus develop at about the same time,^{65,66} although hormone production can occur in the pituitary in the absence of connections with the hypothalamus. Somatotrophs can be demonstrated in the pituitary in anencephalic newborns.⁶⁷

In the newborn, the pituitary weighs about 100 mg. In the adult, the mean weight is about 600 mg, with a range of 400 to 900 mg; the pituitary is slightly heavier in women than in men and increases during pregnancy.⁶⁸ The mean adult pituitary size is 13 × 9 × 6 mm.⁶⁹ The anterior pituitary normally constitutes 80% of the weight of the pituitary. The pituitary resides in the sella turcica, immediately above and partially surrounded by the sphenoid bone. The volume of the sella turcica is a good index of pituitary size and may be reduced in the child with pituitary hypoplasia. The optic chiasm is located superior to the pituitary gland, so suprasellar growth of a pituitary tumor may initially manifest with visual complaints or evidence of decreases in peripheral vision. Furthermore, development of the neurohypophysis and the pituitary are intimately related, leading to potential anatomic associations of central nervous system (CNS) abnormalities with pituitary hypoplasia. For example, septo-optic dysplasia is associated with several CNS anatomic abnormalities and pituitary hormone

Figure 24-13 Development of pituitary cell lineages. **A**, Schematic representation of pituitary cell precursors shows the expression of prevalent transcription factors at each stage of development. Terminally differentiated cells are shown as larger and shaded circles together with the hormones produced (lineage-specific transcription factors are highlighted in bold in these cells). The interaction with transcription factors and signaling molecules in the hypothalamus is also depicted. Transcription factors are represented in lower case (except for SF1 and GATA2), whereas signaling molecules appear in upper case. **B**, The timing of appearance and disappearance of pituitary transcription factors during mouse embryogenesis. *BMP4*, bone morphogenic protein 4; e, embryonic day; ER, estrogen receptor; *FGF8*, fibroblast growth factor 8; *FSH*, follicle-stimulating hormone; *GHRH*, growth hormone-releasing hormone; *GnRH*, gonadotropin-releasing hormone; *αGSU*, glycoprotein α-subunit; *LH*, luteinizing hormone; *POMC*, pro-opiomelanocortin; *PRL*, prolactin; *SF1*, steroidogenic factor 1; *TRH*, thyrotropin-releasing hormone; *TSH*, thyroid-stimulating hormone; *Wnt5a*, wingless type MMTV integration site family, member 5A; *Hesx1*, homeobox expressed in ESI cells (Rathke's pouch homeobox, Rpx). deficiencies.⁷⁰ For this reason, children with congenital blindness or nystagmus should be monitored for hypopituitarism.

The anterior pituitary receives controlling signals from the hypothalamus through the portal circulatory system (Fig. 24-14).^{65,66} The hypothalamus integrates signals from other brain regions and the environment, resulting in the release of factors that control pituitary hormone synthesis and secretion. Hypothalamic neurons that synthesize peptides terminate in the infundibulum, enter the primary plexus of the hypophyseal portal circulation, and are transported via the hypophyseal portal veins to the capillaries of the anterior pituitary. This portal system in the pituitary stalk provides a means of communication between the neurons of the hypothalamus and the anterior pituitary. Magnetic resonance imaging (MRI) of the pituitary stalk conveys important anatomic information in patients with hypopituitarism.

Growth Hormone

Human GH is produced as a single-chain, 191-amino-acid, 22-kD protein containing two intramolecular disulfide bonds (Fig. 24-15).⁷¹ GH shares sequence homology with

Figure 24-14 The main components of the hypothalamic-pituitary portal system. (From Guyton AC, Hall JC. *Human Physiology and Mechanisms of Disease*, 6th ed. Philadelphia, PA: WB Saunders; 1997:600, with permission.)

PRL, chorionic somatomammotropin (CS, placental lactogen), and a 22-kd GH variant (GH-V) that is secreted only by the placenta and differs from pituitary GH by 13 amino acids.⁷² The genes encoding these proteins most likely evolved from a common ancestral gene, despite being located on different chromosomes (chromosome 6 for PRL and chromosome 17 for GH).⁷³ The genes for GH, PRL, and placental lactogen share a common structural organization, with four introns separating five exons. The GH subfamily contains five members, with genes located on a 78-kilobase (kb) section of chromosome 17; the 5' to 3' order of the genes is GH, a CS pseudogene, CS-A, GH-V, and CS-B.⁷⁴ Normally, about 75% of GH produced by the pituitary is of the mature, 22-kd form. Alternative splicing of the second codon results in deletion of amino acids 32 through 46, yielding a 20-kd form that normally accounts for 5% to 10% of pituitary GH.⁷³ The remainder of pituitary GH includes desamidated and N-acetylated forms and various GH oligomers.

The pulsatile pattern characteristic of GH secretion reflects the interplay of two hypothalamic regulatory peptides, growth hormone–releasing hormone (GHRH) and somatostatin (also called somatotropin release-inhibiting factor, or SRIF), with modulation by other putative GH-releasing factors.⁷⁵ GHRH is secreted from nerve cells within the hypothalamus binds to receptors in the anterior pituitary to stimulate somatotroph cell proliferation, differentiation, and growth⁷⁶⁻⁷⁸ and to stimulate the secretion and synthesis of GH.⁷⁹⁻⁸⁴ Regulation of GH production by GHRH is mediated largely at the level of transcription and is enhanced by increases in intracellular cyclic adenosine monophosphate (cAMP) levels. The GHRH receptor is a member of the G protein–coupled receptor family B-III.^{85,86} In a dwarf transgenic mouse model with diminished GHRH production, pituitary somatotroph proliferation is markedly decreased.^{87,88} Transgenic mice that overexpress GHRH grow at a faster rate than control mice.⁸⁹

Somatostatin appears to have its major effect on the timing and amplitude of pulsatile GH secretion and lesser

effects on the regulation of GH synthesis. The pulsatile secretion of GH in vivo is believed to result from a simultaneous reduction in hypothalamic somatostatin release and increased GHRH release.⁹⁰ Conversely, a trough of GH secretion occurs when somatostatin is released in the face of diminished GHRH activity.

Regulation of the reciprocal secretion of GHRH and somatostatin is imperfectly understood. The hypothalamus integrates signals for stress, sleep, hemorrhage, fasting, hypoglycemia, and exercise through the secretion of multiple neurotransmitters and neuropeptides to regulate the release of these hypothalamic factors and ultimately to influence GH secretion. This physiologic phenomenon forms the basis for a number of GH-stimulatory tests employed in the evaluation of GH secretory capacity or reserve. GH secretion is also influenced by a variety of nonpeptide hormones, including androgens,^{91,92} estrogens,⁹³ thyroxine,⁹⁴ and glucocorticoids.^{95,96} The mechanisms by which these hormones regulate GH secretion may involve actions at the hypothalamus and the pituitary. For example, hypothyroidism and glucocorticoid excess may each blunt spontaneous and provocative GH secretion. Gonadal steroids appear to be responsible for the rise in GH secretion that characterizes puberty.

Synthetic hexapeptides capable of stimulating GH secretion are termed GH secretagogues.^{97,98} These peptides stimulate GH release and enhance the GH response to GHRH, although they work at receptors distinct from those for GHRH, at hypothalamic and pituitary sites.^{97,98} Kojima and colleagues⁹⁹ identified a natural ligand called *ghrelin*, a 28-amino-acid protein with the serine 3 residue *n*-octanoylated. It is produced mainly by the oxyntic cells of the stomach (and throughout the gastrointestinal tract¹⁰⁰) and in the hypothalamus, heart, lung, and adipose tissue. Ghrelin has a potent, dose-related, GH-releasing effect¹⁰¹ and potentiates the GHRH-dependent secretion of GH.¹⁰² GH release results from the binding of ghrelin to the growth hormone secretagogue 1a receptor (GHSR-1a) on somatotrophs in the pituitary¹⁰¹ and on GHRH-containing

neurons in the hypothalamus.¹⁰³ Many studies have demonstrated that ghrelin has a wide range of effects, including immune function, cognition, gonadal axis regulation, bone metabolism, gastrointestinal motility, cell proliferation, and effects on the cardiovascular system.¹⁰⁴ However, it is difficult to separate the direct effects of ghrelin from those related to GH secretion. Although ghrelin has documented physiologic effects in vivo, Ghrelin-1a knockout mice have a phenotype similar to that of wild-type animals, suggesting that ghrelin does not have a role in growth. However, compensatory mechanisms may provide an explanation for these findings.^{105,106}

More recently, studies have documented a positive correlation between ghrelin and anthropometric parameters in the first months of life, which strengthens the hypothesis that ghrelin exerts an influence on growth.¹⁰⁷ Two reports of mutations in GHSR-1a in familial short stature provide evidence to the contrary.^{108,109} Further studies indicate that the aging process may be associated with decreased expression of GHSRs in the hypothalamus¹¹⁰ and with systemic concentration of ghrelin.¹¹¹ In addition to direct effects on linear growth, ghrelin has been shown to increase energy stores by stimulating appetite and affecting peripheral glucose and lipid metabolism.¹¹²⁻¹¹⁴ These data suggest that ghrelin is an important stimulus for nutrient allocation for growth and metabolism and a central component of the GH regulatory system. Orally active ghrelin analogues have been considered as therapeutic agents in the treatment of GH deficiency (GHD), because they may provide a more physiologic approach to increasing the pulsatile release of endogenous GH compared with a single daily dose of recombinant human GH. However, there has been no definite evidence of the therapeutic efficacy of ghrelin analogues in the treatment of GH-deficiency states.

Pituitary adenylate cyclase-activating polypeptide (PACAP) is a hypothalamic peptide that has been shown to be effective in releasing GH from cultured pituitary cells. It belongs to a superfamily of hormones that includes glucagon, secretin, glucagon-like peptide 1 (GLP1), GLP2, GHRH, vasoactive intestinal polypeptide (VIP), peptide histidine methionine (PHM), and glucose-dependent insulinotropic polypeptide (GIP). Gene knockout of the specific PACAP receptor (PAC1R) resulted in 60% mortality in the PAC1R null mice in the first 4 weeks after birth, providing insight into the importance of PACAP even though other superfamily members may compensate some of its functions.¹¹⁵ The surviving knockout mice showed reduced glucose-stimulated insulin release and glucose intolerance. This observation suggests that PACAP is important in carbohydrate metabolism, potentially through GH.

The synthesis and secretion of GH is also regulated by the insulin-like growth factor (IGF) peptides. Receptors specific for IGF1 and IGF2 have been identified in the hypothalamus and pituitary.^{116,117} Inhibition of GH secretion by IGF1 or IGF2 or both has been demonstrated,¹¹⁸ and spontaneous GH secretion is diminished in humans treated with synthetic IGF1.¹¹⁹

Growth Hormone Secretion in Humans

The episodic release of GH from the pituitary somatotrophs results in intermittent increases in serum levels of GH separated by periods of low or undetectable levels, during which time GH secretion is minimal.^{120,121} The pulsatile nature of GH secretion has been demonstrated by frequent serum sampling coupled with the use of sensitive immunofluorometric or chemoluminescent assays of GH.¹²¹ Under normal circumstances, serum GH levels are less than 0.04 mg/L between secretory bursts. It is impractical to

assess GH secretion by random serum sampling. Extensive sampling studies at different ages in normal persons and in many abnormal conditions have defined GH pulses, basal secretion, and diurnal variability. Computer programs have been developed to indicate whether changes in GH levels in various life periods and under diverse clinical circumstances occur because of a change of secretory mass or pulse frequency, altered clearance, or a combination of these processes.¹²⁰⁻¹²³ Deconvolution techniques allow accurate estimates of the quantity of GH secreted per burst, GH clearance kinetics, and pulse amplitudes and frequencies, as well as an overall calculation of endogenous GH production. Approximate entropy, a model-free measure, is applied to quantify the degree of orderliness of GH release patterns.^{124,125} The impact of the specific nature of pulsatile GH secretion on its biologic actions is under study.^{120,121} For example, it appears that better statural growth is associated with large swings of GH output of relatively uniform magnitude in an irregular sequence (high approximate entropy).^{126,127}

GH-secreting cells have been identified by 9 to 12 weeks of gestation, and immunoreactive pituitary GH is present by 7 to 9 weeks of gestation.^{128,129} Fetal pituitary cells secrete GH in vitro by 5 weeks,¹³⁰ before the hypothalamic-portal vascular system is differentiated.¹³¹ PIT1 mRNA and PIT1 protein are expressed by at least 6 weeks of gestation; their abundant presence early in gestation suggests an important role in cytodifferentiation and cell proliferation.¹³² GH can be identified in fetal serum by the end of the first trimester, with peak levels of approximately 150 mg/L in midgestation.^{128,129} Serum levels fall throughout the latter part of pregnancy and are lower in full-term than in premature infants, perhaps reflecting feedback by the higher serum levels of IGF peptides that characterize the later stages of gestation.^{133,134}

Mean levels of GH decrease from values of 25 to 35 mg/L in the neonatal period to approximately 5 to 7 mg/L through childhood and early puberty.^{129,135,136} Twenty-four hour GH secretion peaks during adolescence, undoubtedly contributing to the high serum levels of IGF1 that are characteristic of puberty. The increase in GH production during middle to late puberty is caused by enhanced pulse amplitude and increased mass of GH per secretory burst, rather than by a change in pulse frequency (Figs. 24-16 and 24-17).^{120,124,135,136} Greater irregularity in GH secretion corresponds to greater linear growth.¹³⁷ In the face of stable levels of the growth hormone-binding protein (GHBP),^{138,139} the enhanced pubertal GH production appears to be associated with higher levels of "free" GH (Fig. 24-18), potentially facilitating the delivery of IGF1 to target tissues. This enhanced activity of the GH-IGF axis contributes to the insulin resistance that occurs during puberty.¹⁴⁰ Production of GH and IGF begins to decline by late adolescence¹²² and continues to fall throughout adult life. Normal young adult men experience 6 to 10 GH secretory bursts per 24 hours, a value similar to that observed in younger children and adolescents.^{121,135} On the other hand, 24-hour GH production rates for normal men range from 0.25 to 0.52 mg/m² surface area,^{96,141} about 20% to 30% of pubertal levels; this is largely due to decreased GH pulse amplitude with age.¹³⁵ Indeed, puberty may be considered, with some justification, a period of "physiologic acromegaly," whereas aging, with its decrease in GH secretion, has been termed "the somatopause."^{93,142}

Physiologic states that affect GH secretion, in addition to maturation and aging, include sleep,¹⁴³ nutritional status,¹⁴⁴ fasting, exercise,¹⁴⁵ stress,¹⁴⁵ and gonadal steroids.⁹¹ Maximal GH secretion occurs during the night,

Figure 24-16 Relation between 24-hour mean growth hormone (GH) levels and age in boys and men. The bars represent the 24-hour mean and standard error (+SE) values of GH (left axis) obtained from 60 24-hour GH profiles of healthy boys and men subdivided according to chronologic age. An idealized growth velocity curve reproduced from the 50th percentile values for whole-year height velocity of North American boys¹⁵ is superimposed. (From Martha PM Jr, Rogol AD, Veldhuis JD, et al. Alterations in the pulsatile properties of circulating growth hormone concentrations during puberty in boys. *J Clin Endocrinol Metab.* 1989;69:563-570.)

Figure 24-17 **A**, The 24-hour and standard error (+SE) levels of growth hormone (GH) for groups of normal boys at varied stages of pubertal maturation. **B**, The mean (+SE) area under the GH concentration-versus-time curve for individual GH pulses, as identified by the cluster pulse detection algorithm. **C**, The number of GH pulses (+SE), as detected by the cluster algorithm, in the 24-hour GH concentration profiles for boys in each of the pubertal study groups. Notice that the mean 24-hour GH concentration changes are largely mediated by changes in the amount of GH secreted per pulse, rather than the frequency of pulses. In each panel, bars bearing the same letter are statistically indistinguishable. (From Martha PM Jr, Rogol AD, Veldhuis JD, et al. Alterations in the pulsatile properties of circulating growth hormone concentrations during puberty in boys. *J Clin Endocrinol Metab.* 1989;69:563-570.)

Figure 24-18 Levels of growth hormone (GH) and growth hormone-binding protein (GHBP) measured in normal pubertal boys throughout adolescence. The GHBP levels do not significantly change during puberty, but there is a significant increment of GH production and, therefore, of GH levels during this same time. These data suggest that there may be greater amounts of “free GH” during this period, leading to greater production of insulin-like growth factor I. (Based on data from references 136 and 138.)

especially at the onset of the first slow-wave sleep period (stages III and IV). Rapid eye movement (REM) sleep, on the other hand, is associated with low GH secretion.^{143,146} A circadian rhythm of somatostatin secretion, upon which is superimposed episodic bursts of GHRH release, may help explain the nocturnal augmentation of GH production.¹⁴⁷

When testosterone was administered to boys with delayed puberty, spontaneous GH release was enhanced, but such a change was not duplicated by administration of nonaromatizable androgens, emphasizing the possible unique importance of estrogen in GH secretion.^{122,148-150} The effects of testosterone on serum IGF1 levels may in part be independent of GH, because individuals with mutations of the GH receptor (GHR) still experience a modest rise in serum IGF1 during puberty.¹⁵¹ With a combination of deconvolution analysis, approximate entropy, and cosine regression analysis, Veldhuis and associates^{124,150} carefully evaluated intensive GH sampling data derived from measurements in sensitive GH assays in prepubertal and pubertal children of both genders. In addition to the amplified secretory burst mass caused by jointly increased GH pulse amplitude and duration, they found that sex steroids selectively affect facets of GH neurosecretory control: estrogen increases the basal GH secretion rate and the irregularity of GH release patterns, whereas testosterone stimulates greater GH secretory burst mass and greater IGF1 concentrations.

Obesity is characterized by lowered GH production, reflected by a diminished number of GH secretory bursts and shorter half-life duration.^{144,152} Obesity in childhood and adolescence is characterized by decreased GH production with normal IGF and increased GHBP levels and often by increased linear growth.¹⁵² The hyperinsulinism associated with obesity causes lowered levels of IGF-binding protein 1 (IGFBP1) and, perhaps, higher levels of “free” IGF1.¹⁵³ Endogenous GH secretion and levels achieved during provocative tests in obese subjects¹⁵⁴ approximated the diagnostic range of GHD. Fasting increased both the number and the amplitude of GH secretory bursts, presumably reflecting decreased somatostatin secretion and enhanced GHRH release, while lowering GHBP concentrations. Rapid changes in levels of IGFBPs in response to altered nutrition and changes in insulin levels may modify

the effect of IGF1 on its negative feedback and effector sites.^{121,152} Body mass also influences GH production in normal prepubertal and pubertal children and adults.^{135,155,156}

The Growth Hormone Receptor and Growth Hormone Binding Protein

The gene for the human GHR is located on chromosome 5p13.1-p12, where it spans more than 87 kb.¹⁵⁷ The GHR gene (*GHR*) contains 10 exons: exon 1 contains the 5' untranslated region, whereas exons 2 through 10 encode the three domains of the GHR—the extracellular ligand-binding domain, a single transmembrane domain, and a cytoplasmic domain for signal transduction.¹⁵⁸ The highest level of *GHR* expression is in the liver, followed by muscle, fat, kidney, and heart. Although ubiquitously expressed transcription factors have been found to bind the *GHR* promoter, little is known about how these transcription factors coordinate regulation of *GHR* expression. The receptor is 620 amino acids long, with a predicted molecular weight of 70 kd before glycosylation. It is a member of the class I hematopoietic cytokine family¹⁵⁹ and has sequence homology to PRL, erythropoietin, granulocyte-macrophage colony-stimulating factor, and interferon receptors as well as the interleukin 2 (IL2), IL3, IL4, IL6, and IL7 receptors.¹⁵⁸

Two isoforms of the *GHR* have been found in humans—a full-length form and a form that has a deletion of exon 3 (*GHRd3*) with a loss of a 22-amino-acid segment of the extracellular domain of the receptor.¹⁶⁰ The *GHRd3* allele is present in approximately 33% of a general population.¹⁶⁰ Several studies have investigated the clinical significance of the *GHRd3* allele on growth and GH responsiveness in specific disease states.

GH must bind to a homodimer complex of GHR to activate its intracellular signaling pathways (Fig. 24-19). Whether dimerization of the GHR subunits occurs before or after GH binding is a matter of debate. It was initially thought that dimerization would occur only after GH binding; GH would bind to the first subunit, after which the GH-GHR complex would diffuse within the membrane

until contacted by a second subunit, leading to receptor activation.^{161,162} However, it was shown in live cells that the subunits of the GHR are constitutively dimerized in an inactive (i.e., unbound) state.^{163,164} The two subunits are joined by their transmembrane domains through leucine zipper interactions, with steric hindrance from extracellular domains preventing interactions between identical receptor partners. The GH binding sites on the extracellular domains of the two subunits are placed asymmetrically. Therefore, once GH binds to the constitutive dimer, it induces rotation of the two subunits of the dimer that is transmitted via the transmembrane domain to the intracellular domain, allowing downstream kinase activation by transphosphorylation.

After binding to its receptor, GH stimulates phosphorylation of JAK2 (Janus kinase 2), a tyrosine kinase associated with the GHR (see Fig. 24-19). On recruitment or activation, the JAK2 molecule causes phosphorylation of critical tyrosines on the intracellular portion of the GHR, a sort of transphosphorylation. The phosphorylated tyrosines on the GHR provide docking sites for critical intermediary STAT proteins (signal transducers and activators of transcription).^{161,165} STAT proteins dock, via their SRC homology 2 (SH2) domain to phosphotyrosines on ligand-activated receptors, such as the GHR. After docking, phosphorylation occurs on single tyrosines at the carboxyl-terminus of the protein. Then STATs dissociate from the GHR, dimerize, translocate to the nucleus, and bind to DNA through their DNA-binding domain to regulate gene transcription. There are seven known mammalian STATs; of these, STAT5B appears to be most critically involved in mediating the growth-promoting actions of the GHR, as was indicated by several gene disruption studies in rodent models.¹⁶⁶⁻¹⁶⁹ GH- and JAK2-dependent phosphorylation and activation have been demonstrated for many cytoplasmic signaling molecules which, after forming homodimers or heterodimers, translocate into the nucleus, bind DNA, and activate transcription.¹⁷⁰⁻¹⁷²

It has been shown that GHR signaling can also lead to activation of extracellular related kinase 1 (ERK1) and ERK2 to increase transcription.¹⁷³ How GHR activation leads to ERK1/2 activation is a matter of debate. A JAK2-independent but SRC-dependent phosphorylation has been modeled,^{174,175} as has a JAK2-dependent but SRC-independent mechanism.¹⁷⁶ Experiments were conducted in different cell lines, so it is possible that the mechanisms of ERK1/2 activation by GHR are different in different cell lines. It is unclear what role these pathways play in the GH stimulation of growth.

Inhibition of GH signaling by several members of the GH-inducible suppressor of cytokine signaling (SOCS) family has been reported.¹⁷⁷ The importance of SOCS proteins in controlling growth is demonstrated by the finding of gigantism in *Socs-2* knockout mice,¹⁷⁸ an effect that appears to require the presence of GH and activation of STAT5B.¹⁷⁹ Endotoxin and the proinflammatory cytokines IL1 and tumor necrosis factor- α (TNF- α) can induce SOCS proteins¹⁸⁰ and GH insensitivity. It has been proposed that IL1 and TNF- α are factors that play a role in the GH insensitivity of sepsis by inducing SOCS3.¹⁸¹

GHBP prolongs the half-life of GH, presumably by impairing glomerular filtration, and modulates its binding to the GHR. It binds GH with high specificity and affinity but with low capacity; only about 45% of circulating GH is bound.^{139,182,183} GHBP is derived from proteolytic cleavage of the extracellular domain of the receptor.¹⁸⁴ GHBP levels reflect GHR levels and activity; that is, low levels are associated with states of GH insensitivity.¹³⁹ Levels of GHBP are

Figure 24-19 A model depicting intracellular signaling intermediates induced by binding of growth hormone (GH) with the GH receptor (GHR). Jak, Janus kinase; P, phosphorylation; STAT, signal transducer and activator of transcription. (From Le Roith DC, Bondy S, Yakar J-L, et al. The somatomedin hypothesis: 2001. *Endocrine Rev.* 2001;22:53-74.)

low early in life, rise through childhood, and plateau during the pubertal years and adulthood.^{138,185,186} Levels are constant for an individual once puberty is reached and correlate inversely with 24-hour GH production.¹³⁸ Impaired nutrition, diabetes mellitus, hypothyroidism, chronic liver disease, and inherited abnormalities of the GHR are associated with low levels of GHBP, whereas obesity, refeeding, early pregnancy, and estrogen treatment are associated with elevated levels of GHBP.¹³⁹ In general, GHBP levels reflect GHR levels and activity. Patients with GH insensitivity due to defects of the extracellular domain of the GHR have low GHBP levels, and GHBP levels therefore can be useful in identifying these individuals. Patients with GH insensitivity due to nonreceptor abnormalities, defects of the intracellular domain of the GHR, or inability of the receptor to dimerize may have normal levels of GHBP.^{151,187-189}

GHR signaling affects the transcription of many genes immediately (<3 hours after stimulation) and other genes over a longer period of stimulation. After acute GH stimulation in GH-deficient rats, hepatic genes immediately induced by GH included signal transducers (STAT3, gp130, p38), DNA repair proteins, receptor proteases, and metabolic regulators such as Igf1, Igfbp3, and Mct1.¹⁹⁰ Studies using *Ghr*^{-/-} mice or mice overexpressing *Gh* indicate that *Ghr* signaling is involved in regulation of expression of genes involved in carbohydrate, fat, and steroid metabolism.^{168,191-193}

The development of mice that lack *Ghr* or downstream components of *Ghr* signaling has shed light on the role of GH in normal physiology. *Ghr*^{-/-} mice exhibit normal size at birth but have attenuated postnatal growth, with body weight about half of normal and length about two-thirds of normal.¹⁹⁴ *Ghr*^{-/-} mice also exhibit delayed pubertal maturation, longer life span, and increased insulin sensitivity compared with controls.

To determine which cytoplasmic regions of the GHR are involved in growth-promoting actions, mice with truncated *Ghr* were engineered via homologous recombination (so-called knock-in mice). One knock-in mouse had a mutation that resulted in removal of the C-terminal region of the receptor (mutant 569), including some recognized Stat5 and Socs2 recruitment sites; a second knock-in mouse had a mutation that resulted in truncation of the receptor downstream from the Jak2, mitogen-activated protein (MAP) kinase, and phosphatidylinositol 3 (PI3) kinase interaction sites, a region that included the majority of Stat5 recruitment sites (mutant 391).¹⁶⁸ Homozygous mutant 569 mice exhibited a body size 44% of that of wild-type mice on loss of 70% of Stat5 signaling and with IGF1 levels 80% lower than in the wild-type mouse. As expected, homozygous mutant 391 mice had more severe growth attenuation, with a body size 11% of that of wild-type mice on complete loss of Stat5 signaling. The fact that these mice had some growth implicates other signaling pathways, such as MAP kinase, in growth-promoting roles.

Mice with *Ghr* deleted only in the liver were produced and were found to have low IGF1 levels and high GH levels. These mice exhibited normal growth but had significantly lower bone density than controls. They also exhibited liver steatosis with insulin resistance and elevated serum free fatty acid levels.¹⁹⁵ This mouse model sheds light on the metabolic function of excessive GHR signaling independent of IGF1 signaling.

Deletion of *Jak2* in mice is embryonically lethal,¹⁹⁶ as is deletion of *Stat3*. Deletion of *Stat1* or *Stat5a* does not affect body size. However, deletion of *Stat5b* leads to decreased size in male but not female mice. The *Stat5a/b*^{-/-} mouse is

smaller than the *Stat5b*^{-/-} mouse.¹⁹⁷ Deletion of *Socs2*,¹⁷⁸ but not of other *Socs* genes,¹⁷⁹ produced gigantism in mice, indicating the specific role of *Socs2* in the negative regulation of GHR action. The combined *Igf1* and *Ghr*^{-/-} mouse had a more severe attenuation of postnatal growth than mice with knockout of either gene alone, indicating that GH and IGF1 promote growth by both common and independent functions.¹⁹⁸ The liver-specific IGF1 knockout mouse with extremely low serum IGF1 levels has normal linear growth, suggesting IGF-independent actions of GH or paracrine production and effects of IGF1, or both.¹⁹⁹

Historically, the anabolic actions of GH were thought to be mediated entirely by the IGF peptides (the so-called somatomedin hypothesis).^{200,201} Although a majority of GH actions are mediated by IGFs, the opposite effects of GH and IGFs on metabolism and in knockout mouse models suggest that there are IGF-independent actions of GH. Indeed, the “diabetogenic” actions of GH are contradictory to the glucose-lowering effects of IGFs. In vitro studies suggest potential IGF-independent action of GH in the following tissues:

1. Epiphysis—stimulation of epiphyseal growth
2. Bone—stimulation of osteoclast differentiation and activity, stimulation of osteoblast activity, and increase in bone mass through endochondral bone formation
3. Adipose tissue—acute insulin-like effects, followed by increased lipolysis, inhibition of lipoprotein lipase, stimulation of hormone-sensitive lipase, decreased glucose transport, and decreased lipogenesis²⁰²⁻²⁰⁴
4. Muscle—increased amino acid transport, increased nitrogen retention, increased lean tissue, and increased energy expenditure^{205,206}

The concept of IGF-independent actions of GH is supported by results of in vivo studies in which IGF1 could not duplicate all of the effects of GH, such as nitrogen retention and insulin resistance.²⁰⁷

Insulin-Like Growth Factors

Historical Background

The IGFs (somatomedins) are a family of peptides that are, in part, GH dependent and mediate many of the anabolic and mitogenic actions of GH. They were originally identified in 1957 by their ability to stimulate [³⁵S]-sulfate incorporation into rat cartilage and were called *sulfation factors*.²⁰⁰ In 1972, that term was replaced with *somatomedin*,²⁰⁸ and purification of somatomedin from human serum yielded a basic peptide (somatomedin-C) and a neutral peptide (somatomedin-A).^{209,210} In 1978, Rinderknecht and Humbel^{211,212} isolated two active somatomedins from human plasma and, after demonstrating a striking structural resemblance to proinsulin, renamed them *insulin-like growth factors* (IGFs).

IGF Genes and Protein Structure

There are two IGFs circulating in humans, IGF1 and IGF2. IGF1 is a basic peptide of 70 amino acids, and IGF2 is a peptide of 67 amino acids. The two peptides share 45 of 73 possible amino acid positions and have 50% amino acid homology to insulin.^{200,211,212} Like insulin, both IGFs have A and B chains connected by disulfide bonds. The connecting C-peptide region is 12 amino acids for IGF1 and 8 amino acids for IGF2, bearing no homology for the C-peptide region of proinsulin. The D-peptide region contains C-terminal extensions of 8 amino acids for IGF1 and 6 amino acids for IGF2. The E-peptide is a trailer peptide

Figure 24-20 Structure and expression of the human insulin-like growth factor I (IGF-I) gene. The structure of the different human IGF-I messenger RNAs (mRNAs) is displayed below the map of the gene. Sites of pre-mRNA processing are indicated by the thin lines. Sites of differential polyadenylation are marked at the 3' end of the gene by vertical arrows and in the mRNAs by horizontal boxes of varying length. (From Rotwein P. Structure, evolution, expression and regulation of insulin-like growth factors I and II. *Growth Factors*. 1991;5:3-18.)

that is cleaved in post-translational processing. The structural similarity explains the ability of both IGFs to bind to the insulin receptor and the ability of insulin to bind to the type I IGF receptor (encoded by *IGF1R*). On the other hand, structural differences probably explain the failure of insulin to bind with high affinity to the IGFBPs.

Insulin-Like Growth Factor I

Gene Regulation. The human IGF1 gene (*IGF1*) is located on the long arm of chromosome 12²¹³⁻²¹⁵ and contains at least six exons (Fig. 24-20). Exons 1 and 2 encode alternative signal peptides, each containing several transcription start sites; that is, the multiple existing *IGF1* transcripts consist of either exon 1 or exon 2. Two different promoters regulated in a tissue-specific manner^{216,217} control the use of exon 1 or 2. Exons 3 and 4 encode the remaining signal peptide, the remainder of the mature IGF1 molecule, and part of the trailer peptide (E peptide). Exons 5 and 6 encode alternatively used segments of the trailer peptide and 3' untranslated sequences with multiple different polyadenylation sites. As a result, multiple mRNA species exist, allowing for tissue-specific, developmental, and hormonal regulation of *IGF1* gene expression.

GH appears to be the primary regulator of *Igf1* transcription, which begins as early as 30 minutes after intraperitoneal injection of GH into hypophysectomized rats.²¹⁸ Transcriptional activation by GH results in a 20-fold rise in *Igf1* mRNA, but there may be tissue-to-tissue variability in extent of GH-induced expression of *Igf1* mRNA.²¹⁹ Another influential factor is estrogen, which stimulates *Igf1* mRNA expression in the uterus but inhibits GH-stimulated *Igf1* transcription in the liver.²²⁰ Estradiol administration to a *Ghr*^{-/-} mouse can stimulate hepatic *Igf1* synthesis and growth.²²¹ The sex-steroid effects on *IGF1* transcription plays a role in the pubertal rise of IGF1 levels in humans (see later discussion).

The mechanisms involved in regulation of IGF gene expression include the existence of multiple promoters, heterogeneous transcription initiation within each of the promoters, alternative splicing of various exons, differential RNA polyadenylation, and variable mRNA stability. Translation of *IGF1* may also be under complex control.

The transcription factor STAT5B is the most critical mediator of GH-induced activation of IGF1 transcription, as detailed earlier. Two adjacent STAT5B binding sites have been identified in the second intron of the rat *Igf1* gene, within a region previously identified as undergoing acute changes in chromatin structure after GH treatment.¹⁶⁹

Once translated, IGF1 pre-propeptides require processing to form the mature IGF1 peptide (Fig. 24-21). After processing, all transcript isoforms result in an identical 70-amino-acid protein containing the A, B, C, and D domains. Pro-IGF1 also contains the E peptide. Proteases from the subtilisin-related proprotein convertase family (SPC) cleave pro-IGF1 at Arg71, located in the D portion of the peptide.²²² Several reports have demonstrated the secretion of pro-IGF1 from fibroblasts and other cells,^{223,224} although the biologic significance of the pro-IGF1 peptide is unclear. It has been shown that the *IGF1* splice variant (see Fig. 24-20) that includes exon 5 increases in rabbit muscle subjected to stretch.²²⁵ The ability to express this transcript diminishes with age.^{226,227} This transcript, when injected into rabbit muscle, promoted increased muscle mass within 2 weeks.²²⁸ However, viral delivery of this transcript to skeletal muscle did not cause a greater increase

Figure 24-21 Structure of the insulin-like growth factor IGF-I peptide. (Reproduced from Yakar S, Wu Y, Setser J, et al. The role of circulating IGF-I. *Endocrine*. 2002;19:239-248.)

Figure 24-22 Structure and expression of the human insulin-like growth factor 2 (IGF2) gene. The structure of different human IGF2 messenger RNAs (mRNAs) is displayed below the map of the gene. The patterns of mRNA processing are indicated by the thin lines. Sites of differential polyadenylation are marked at the 3' end of the gene by vertical arrows and in the mRNAs by horizontal boxes of varying length. (From Rotwein P. Structure, evolution, expression and regulation of insulin-like growth factors I and II. *Growth Factors*. 1991;5:3-18.)

in muscle mass over other IGF1 transcripts. It was postulated that muscle damage, caused by injection but not by viral delivery of the transcript, must occur for the transcript to have a differential effect on muscle mass.²²⁹ These studies demonstrate potential roles of the various *IGF1* transcripts.

Serum Levels. In human fetal serum, IGF1 levels are relatively low and are positively correlated with gestational age.^{230,231} There is a reported correlation between fetal cord serum IGF1 levels and birth weight,²³⁰⁻²³² but this relationship is controversial.²³³ IGF1 levels in newborn serum are typically 30% to 50% of adult levels. Serum levels rise during childhood. During puberty, IGF1 levels rise to 2 to 3 times the adult range. Levels during adolescence correlate better with Tanner stage or bone age than with chronologic age.^{234,235} The pubertal rise in gonadal steroids may stimulate IGF1 production indirectly by contributing to a rise in GH secretion and directly by augmenting liver synthesis and secretion of IGF1. Girls with gonadal dysgenesis show no adolescent increase in serum IGF1, providing evidence of the association of the pubertal rise in IGF1 with the production of gonadal steroids.²³⁶⁻²³⁸ As further evidence, patients with GH insensitivity due to GHR mutations exhibit a modest rise in IGF1 during puberty despite a decline in GH levels. After 20 to 30 years of age, serum IGF1 levels gradually and progressively fall.^{239,240} The age-associated decline in IGF1 levels has been implicated in the negative nitrogen balance, decrease in muscle mass, and osteoporosis of aging.²³⁹

Insulin-Like Growth Factor 2

Gene Regulation. The gene for IGF2 (*IGF2*) is located on the short arm of chromosome 11,²¹³⁻²¹⁵ adjacent to the insulin gene, and contains 9 exons (Fig. 24-22). Exons 1 through 6 encode 5' untranslated RNA, exon 7 encodes the signal peptide and most of the mature protein, and exon 8 encodes the C-terminal portion of the protein. As with *IGF1*, multiple mRNA species exist to allow for developmental and hormonal regulation of expression. *IGF2* mRNA expression is high in fetal life and has been detected as early as the blastocyst stage in mice.²⁴¹ Fetal tissues

generally have high *IGF2* mRNA levels that decline postnatally.

IGF2 is imprinted—that is, only one allele is active, depending on parental origin. In the case of *IGF2*, only the paternally expressed allele is active. Most imprinted genes occur in clusters with reciprocally imprinted genes, and *IGF2* is no exception. The noncoding gene *H19* is downstream from *IGF2* and is oppositely imprinted, meaning that only the maternal allele is expressed and the paternal allele is inactive. The promoters of *IGF2* and *H19* share a set of enhancers that act on either gene. On the paternal allele, the *H19* promoter region is methylated and thus inactivated (so-called epigenetic regulation of expression).²⁴² The *IGF2* promoter does not contain regions that can be methylated. Instead, upstream from the *H19* and *IGF2* promoter region is a so-called differentially methylated region (DMR). When it is methylated, binding of CCCTC binding factor (CTCF) is prevented, allowing enhancers to act on the *IGF2* promoter to activate transcription.²⁴³ On the maternal chromosome, the DMR region is not methylated, allowing CTCF to bind and preventing transcription (Fig. 24-23).²⁴⁴

The fact that *IGF2* is monoallelically expressed emphasizes the importance of gene dosage to normal physiology and development. Loss of imprinting of *IGF2* can lead to

Figure 24-23 Schematic of the imprinted region of the insulin-like growth factor 2 (*IGF2*)-*H19* locus. CTCF, CCCTC binding factor; CH₃, methylation; DMR, differentially methylated region. (Adapted from Chao W, D'Amore P. IGF2: epigenetic regulation and role in development and disease. *Cytokine Growth Factor Rev*. 2008;19:111-120.)

constitutively expressed *IGF2* mRNA and excessive IGF2. *IGF2* mRNA is expressed constitutively in a number of mesenchymal and embryonic tumors, including Wilms' tumor,^{245,246} rhabdomyosarcoma, neuroblastoma, pheochromocytoma, hepatoblastoma, leiomyoma, leiomyosarcoma, liposarcoma, and colon carcinoma.²⁴⁷⁻²⁵¹ Loss of imprinting has been demonstrated as the cause for dysregulated expression in some of these tumors. Production of *IGF2* variants by these tumors can cause non-islet cell tumor hypoglycemia (NICTH).²⁵² Loss of imprinting of *IGF2* resulting in biallelic gene expression has also been found in Beckwith-Wiedemann syndrome (BWS), which is characterized by fetal and neonatal overgrowth and an increased risk of childhood cancers. Loss of imprinting in BWS can result from mutations that effect imprinting in the region of chromosome 11 that contains *IGF2*,²⁵³ methylation defects that cause hypermethylation of the region or duplication of the expressed paternal allele resulting in increased *IGF2* expression, or paternal uniparental disomy (i.e., inheritance of only the expressing paternal allele).

Variant peptides of IGF2 have been identified in normal human serum, the significance of which is uncertain. Up to one quarter of the IGF2 isolated from normal human plasma lacked the amino-terminal alanine.²¹² Another variant peptide with the Ser29 replaced by Arg-Leu-Pro-Gly has also been identified in human plasma,²⁵⁴ presumably from the liver.²⁵⁵ Other IGF2 variants have been identified that are longer than the predominant IGF2 species.²⁵⁶ The significance of these larger forms of IGF2 is uncertain. In general, these variants appear capable of binding to IGF and insulin receptors and to IGFs, and they can participate in formation of the 150-kD IGF-IGFBP3-acid-labile subunit (ALS) ternary complex (discussed later). Large IGF2 variants have been shown to be produced by mesenchymal tumors and cause NICTH. In a patient with leiomyosarcoma and recurrent hypoglycemia, 70% of serum IGF2 consisted of the higher-molecular-weight forms.²⁵² Removal of the tumor decreased the fraction of the large IGF2 forms and serum and corrected the hypoglycemia. It has been documented that the total serum IGF2 in NICTH is normal, yet the fraction of the larger forms is larger. Zapf²⁵⁷

proposed that NICTH occurs when secretion of large IGF2 forms results in suppression of GH, insulin, and the normal 7-kD IGF2, leading to decreased production of IGF1, IGFBP3, and the ALS and increased production of IGFBP2. This produces a shift in the distribution of IGF2 from the IGF2-IGFBP ternary complex to the lower-molecular-weight complex. The results is increased bioavailability of IGF2 to target tissues, enhanced glucose consumption, and decreased hepatic glucose production.

Serum Levels. Human newborn levels of IGF2 are typically 50% of adult levels. By 1 year of age, adult levels are attained, and there is little, if any, subsequent decline, even up to the seventh or eighth decade.²⁵⁸

Insulin-Like Growth Factor Receptors

There are two types of IGF receptors, type I and type II (Fig. 24-24). Structural characterization of these receptors has provided documentation of the differences between these two forms.^{259,260} The type I IGF receptor is closely related to the insulin receptor; both are heterotetramers comprising two membrane-spanning α -subunits and two intracellular β -subunits. The α -subunits contain the binding sites for IGF1 and are linked by disulfide bonds. The β -subunits contain a transmembrane domain, an adenosine triphosphate (ATP)-binding site, and a tyrosine kinase domain, which constitute the presumed signal transduction mechanism for the receptor. One mole of the full heterotetrameric receptor appears to bind 1 mole of ligand.

Although the type I IGF receptor has been commonly termed the "IGF1 receptor," this receptor binds both IGF1 and IGF2 with high affinity, and both IGF peptides can activate tyrosine kinase by binding to the type I receptor. In studies involving transfection and overexpression of the type I IGF receptor complementary DNA (cDNA), the dissociation constant for IGF1 is typically 0.2 to 1.0 nmol/L, whereas the affinity for IGF2 is usually slightly less, although it varies from study to study.²⁶⁰ The affinity of the type I IGF receptor for insulin is usually 100-fold less, explaining the relatively weak mitogenic effect of insulin.

Figure 24-24 Structure of the insulin-like growth factor (IGF) receptors. The insulin receptor and the IGF1 receptor are both heterotetrameric complexes composed of extracellular α -subunits that bind the ligands and β -subunits that anchor the receptor in the membrane and contain tyrosine kinase activity in their cytoplasmic domains. The tyrosine kinase domain of the insulin receptor-related receptor (IRR) is homologous to the tyrosine kinase domains of the insulin and IGF1 receptors. The carboxyl-terminal domain is deleted in the IRR. Hybrids consist of a hemireceptor from both insulin and IGF1 receptors. The IGF2/mannose-6-phosphate (M6P) receptor is not structurally related to the IGF1 and insulin receptors or to the IRR, having a short cytoplasmic tail and no tyrosine kinase activity. (From LeRoith D, Werner H, Geitner-Johnson D, et al. Molecular and cellular aspects of the insulin-like growth factor I receptor. *Endocr Rev*. 1995;16:143-163.)

Figure 24-25 Structure of the human insulin-like growth factor type I (IGF1) receptor precursor. Molecular cloning of human IGF1 receptor complementary DNAs isolated from a placental library revealed the presence of an open reading frame of 4101 nucleotides. The 1367-amino-acid polypeptide contains, at its amino terminus, a 30-amino-acid hydrophobic signal peptide that is responsible for the transfer of the nascent protein chain into the endoplasmic reticulum. After digestion by endopeptidases at a proteolytic cleavage site (Arg-Lys-Arg-Arg) located at residues 707 through 710, α - and β -subunits are released and linked by disulfide bonds to yield the configuration of the mature heterotetrameric receptor. Also shown are the cysteine-rich domain of the α -subunit and the transmembrane and tyrosine kinase domains of the β -subunit. (From LeRoith D, Werner H, Beitner-Johnson D, et al. Molecular and cellular aspects of the insulin-like growth factor I receptor. *Endocr Rev.* 1995;16:143-163.)

The structure of the human type I IGF receptor has been deduced from cDNA.²⁶¹ The mature peptide has 1337 amino acids with a predicted molecular mass of 151,869 kD (Fig. 24-25). The translated $\alpha\beta$ heterodimer is cleaved at an Arg-Lys-Arg-Arg sequence at positions 707 through 710. The released α - and β -subunits, linked by disulfide bonds, then form the mature ($\alpha\beta$)₂ receptor, in which two α chains are joined by secondary disulfide bonds. The α -subunits are extracellular and contain a cysteine-rich domain that is critical for IGF binding. The β -subunit has a short extracellular domain, a hydrophobic transmembrane domain, and the intracellular tyrosine kinase domain with the ATP-binding site.

The gene for the type I IGF receptor (*IGF1R*) spans more than 100 kb of genomic DNA, with 21 exons; the genomic organization resembles that of the insulin receptor gene.²⁶¹⁻²⁶³ Exons 1 through 3 encode for the 5' untranslated region and the cysteine-rich domain of the α -subunit that is involved in ligand binding. The remainder of the α -subunit is encoded by exons 4 through 10. The peptide cleavage site involved in generation of the α - and β -subunits is encoded by exon 11, and the tyrosine kinase domain of the β -subunit is encoded by exons 16 through 20. It is in the latter region that *IGF1R* and the insulin receptor gene share the greatest sequence homology, ranging from 80% to 95%. Exon 21 encodes the 3' untranslated sequences.

IGF1R mRNA has been identified in virtually every tissue except liver.^{264,265} The mRNA is most abundant in embryonic tissues and appears to decrease with age. *IGF1R* expression is present at the embryonic 8-cell stage, whereas expression of the type II IGF receptor gene is first demonstrable at the 2-cell stage. *IGF1R* becomes widely expressed after implantation, consistent with the observation that this receptor is essential for normal fetal growth.

As with other growth factor receptor tyrosine kinases, binding of ligand (IGF1 or IGF2) induces receptor autophosphorylation of critical tyrosine residues in the type I IGF receptor.²⁶⁶⁻²⁶⁹ Specifically, ligand binding to the α -subunits leads to activation of the tyrosine kinase domain of the β -subunits. Mutations of the ATP-binding site or of critical tyrosine residues (Tyr1131, Tyr1135, and Tyr1136)²⁶⁶⁻²⁶⁹ in the tyrosine kinase domain of the β -subunit result in loss of IGF-stimulated thymidine

incorporation and glucose uptake. Autophosphorylation appears to occur by transphosphorylation of sites on the opposite β -subunit.^{270,271} A tyrosine proximal to the tyrosine kinase domain, Tyr 950, is part of a motif that, when deleted, reduces receptor autophosphorylation, affects receptor internalization, and inhibits postreceptor signaling. The adapter proteins Shc and insulin receptor substrate 1 (IRS1) bind to this domain.

Autophosphorylation and activation of the cytoplasmic region of the IGF type I receptor promotes recruitment or activation of several docking proteins, each of which activate distinct signaling pathways, with some overlap (Fig. 24-26). Proteins that can dock onto the activated IGF type I receptor include members of the IRS family, Shc, 14-3-3e, p85 subunit of PI3 kinase, tyrosine phosphatase PTP1D, and mGRB10. Of these docking proteins, the pathways involving IRS and Shc are best characterized. IRS1 is a 185-kD protein²⁷² that, when phosphorylated, contains specific phosphotyrosine motifs that can associate with proteins containing SRC homology 2 (SH2) domains such as the p85 subunit of PI3 kinase,²⁷³ growth factor receptor-bound protein 2 (Grb2),²⁷⁴ Syt (a phosphotyrosine phosphatase),²⁷⁵ and Nck (an oncogenic protein).²⁷⁵ Activation of Shc²⁷⁶ and Grb2 results in activation of the Ras, Raf, MAP kinase kinase, and S6 kinase pathways.²⁷⁷⁻²⁷⁹

Phosphorylation of IRS1 by either the type I IGF receptor or the insulin receptor activates multiple signaling cascades that ultimately influence nuclear transcription and gene expression. Mice with a null deletion for the IRS1 gene have poor growth in addition to insulin resistance.²⁸⁰ Binding of the p85 subunit of PI3 kinase leads to activation of the p110 subunit of PI3 kinase. This process then activates downstream phospholipid signal transduction pathways that includes Akt. Activation of Akt leads to regulation of diverse cellular processes including apoptosis, glucose transport and metabolism, protein synthesis, mitosis, and differentiation.²⁸¹ Activation of the type I IGF receptor leads to phosphorylation of Shc, which then acts as a docking site for the SH2 domain of Grb2. Grb2 then binds SOS, a guanine nucleotide exchange factor that converts inactive Ras guanosine diphosphate (GDP) into guanosine triphosphate (GTP). GTP-bound Ras then recruits Raf, and Raf subsequently activates MAP kinase and mitogen and extracellular signal-related kinases (MEK) 1 and 2. Activation of these proteins ultimately regulates gene transcription. Given that insulin and IGF peptides activate similar signaling pathways through their own specific receptors, it is unclear how the cell distinguishes among these overlapping ligands. Whether the consequences merely reflect the relative levels of receptors or whether divergent downstream pathways exist for insulin and IGF action remain questions for future investigation.²⁸²

Although targeted disruption *Igf1r* causes fetal growth retardation, a clear role for this receptor in the cell cycle has not been established. Fibroblast cell lines derived from mouse embryos homozygous for the type I IGF receptor null mutation still undergo cell cycle-dependent division, although at a slower rate.²⁸³⁻²⁸⁵ However, the transformed nature of some cells in culture may be critically depend on expression of the type I IGF receptor. The simian virus SV40Tg is capable of inducing a transformed phenotype in a cell only in the presence of intact type I IGF receptors.²⁸⁵ NIH3T3 cells that are made to overexpress the type I IGF receptor develop IGF1-dependent neoplastic transformation with tumor formation in nude rats.²⁸⁶

Variants of the α - and β -subunits are present in placenta,²⁸⁷ muscle,^{287,288} and brain.²⁸⁹ These variants may explain seemingly anomalous competitive binding sites.²⁹⁰⁻²⁹² The molecular mechanisms for the formation of

Figure 24-26 Schematic representation of intracellular signaling pathways of the insulin-like growth factor type I (IGF1) receptor. On binding of IGF1, the IGF receptor undergoes autophosphorylation at multiple tyrosine residues. The intrinsic kinase activity of the receptor also phosphorylates IRS1 at multiple tyrosine residues. Various SH domain-containing proteins, including phosphatidylinositol 3 (PI) kinase, Syp, Fyn, and Nck associate with specific phosphotyrosine-containing motifs within IRS1. These docking proteins recruit diverse other intracellular substrates, which then activate a cascade of protein kinases including Raf-1 and one or more related kinases including mitogen-activated protein kinase (MAPK), mitogen and extracellular signal-related kinase (MEK), and others. These protein kinases, in turn, activate various other elements, including nuclear transcription factors. Alterations in expression of various IGF1-responsive genes result in longer-term effects of IGF1, including growth and differentiation. This model of signal transduction cascades also shows a potential mechanism for inhibition of apoptosis. BAD, BCL2-associated agonist of cell death; Erk, Extracellular signal-regulated kinase; GDP, guanosine diphosphate; GLUT4, glucose transporter 4; GTP, guanosine triphosphate; JNK, c-Jun N-terminal kinase; KD, catalytic kinase domain of Akt; MEK, mitogen-activated protein kinase; P, phosphorylation; PH, pleckstrin homology domain of Akt; PP2A, protein phosphatase 2A; RD, regulatory C-terminal tail of Akt; SEK1, Serum- and glucocorticoid-inducible protein kinase 1. (From Le Roith D, Bondy C, Yakar S, et al. The somatomedin hypothesis: 2001. *Endocr Rev*. 2001;22:53-74.)

such receptor variants have not been identified, nor is it known whether they differentially bind IGF1, IGF2, or insulin. The formation of IGF-insulin receptor hybrids that contain an α -IGF hemireceptor disulfide-linked to an α -insulin hemireceptor (see Fig. 24-24)²⁹³⁻²⁹⁵ appears to be ligand dependent,²⁹⁶ and studies with monoclonal antibodies specific for the insulin receptor or the type I IGF receptor suggest that such receptors develop in cells with abundant native receptors, such as muscle or placenta.^{297,298} Such hybrids have near-normal affinity for IGF1 but decreased affinity for insulin. The physiologic significance of such hybrid receptors is unknown. Studies in cells are complicated by simultaneous variable expression of insulin receptors, IGF type I receptors, and hybrid receptors. The lack of specific antibodies to hybrid receptors also hinders investigation.

The type II IGF receptor bears no structural homology with either the insulin receptor or type I IGF receptors (see Fig. 24-24). The receptor does not contain an intrinsic tyrosine kinase domain or any other recognized signal transduction mechanism. The type II IGF receptor is identical to the cation-independent mannose-6-phosphate (M6P) receptor, a protein involved in the intracellular lysosomal targeting of acid hydrolases and other mannolyated proteins.^{299,300} This common receptor is often referred to as the

IGF2/M6P receptor. The gene for the IGF2/M6P receptor (*IGF2R*) is located on the long arm of chromosome 6.³⁰¹ Exons 1 through 46 encode the extracellular region of the receptor, which contains 15 repeat sequences of 147 residues each. Exons 47 and 48 encode the 23-residue transmembrane domain and a small cytoplasmic domain consisting of only 164 residues.³⁰² In mice, gene expression is maternally imprinted, but for humans the expression is biallelic.³⁰³ Like *IGF2*, the *IGF2R* gene is expressed at highest levels early in fetal development and declines to lower levels postnatally.³⁰⁴

The IGF2/M6P receptor has an apparent molecular weight of 220,000 under nonreducing conditions and 250,000 after reduction, indicating that it is a monomeric protein.³⁰⁵ The 15 repeat sequences contain cysteines to form intramolecular disulfide bonds necessary for receptor folding.^{306,307} Repeat 11 binds IGF2, whereas repeats 3, 5, and 9 bind M6P.^{306,308-310} Because of receptor folding, it appears that the IGF2 binding site is on the opposite face to the M6P binding site.³¹¹ A truncated form of the receptor, missing the cytoplasmic domain, has been observed to be soluble in serum.³¹²⁻³¹⁴ The soluble form is able to bind IGF2^{315,316} and is able to inhibit cell responses to IGF2 in vitro.^{317,318}

The IGF2/M6P receptor binds a variety of M6P-containing proteins, including lysosomal enzymes,

transforming growth factor- β (TGF- β),³¹⁹ and leukemia inhibitory factor (LIF).³²⁰ Unlike the type I IGF receptor, which binds both IGF peptides with high affinity and insulin with 100-fold lower affinity, the IGF2/M6P receptor binds only IGF2 with high affinity, the dissociation constant ranging from 0.017 to 0.7 nmol/L; IGF1 binds to this receptor with lower affinity, and insulin does not bind at all.³²¹ One mole of IGF2 binds 1 mole of receptor. It participates in lysosomal enzyme trafficking between the trans-Golgi network and the extracellular space, regulates extracellular IGF2 and LIF levels, and plays a role in TGF- β activation (reviewed by El-Shewy and colleagues³²²). In addition, the IGF2/M6P binds retinoic acid and may mediate some of the growth-inhibitory effects of retinoids.³²³ Mice null for the type II IGF receptor have macrosomia and fetal death, consistent with a potential role in IGF2 degradation.³²⁴

The mitogenic and metabolic actions of IGF1 and IGF2 appear to be mediated through the type I IGF receptor, because monoclonal antibodies directed against the IGF1 binding site on the type I IGF receptor inhibit the ability of both IGF1 and IGF2 to stimulate thymidine incorporation and cell replication.^{325,326} Polyclonal antibodies that block IGF2 binding to the IGF2/M6P receptor do not block IGF2 actions.³²⁷⁻³²⁹ IGF2 analogs with decreased affinity for the type I IGF receptor but reserved affinity for the IGF2/M6P receptor are less potent than IGF2 in stimulating DNA synthesis.²¹¹ However, there is evidence that some of the mitogenic actions of IGF2 may be mediated by the IGF2/M6P receptor.³²² The IGF2/M6P receptor may be involved in production of inositol triphosphate and diacylglycerol in proximal tubules and canine kidney membranes.³³⁰ IGF2 may stimulate the growth of a human erythroleukemia cell line, an action not duplicated by either IGF1 or insulin.²⁹⁰ IGF2 may be able to act as an autocrine growth factor and cell motility factor for human rhabdomyosarcoma cells, actions apparently mediated through the type II receptor.²⁹¹ Additionally, it has been reported that IGF2 activates a calcium-permeable cation channel via the IGF2/M6P receptor, perhaps through coupling to a pertussis toxin-sensitive guanine nucleotide binding protein (G_i protein).^{292,296,331-334}

Insights into Function-Targeted Disruption of IGF and IGF Receptor Genes

The role of the IGF axis in prenatal and postnatal growth was firmly established by a series of studies involving IGF and IGF receptor gene null mutations.³³⁵ Unlike *Gh* or *Ghrh* null mice^{194,336} which are near-normal at size at birth, mice with deletions of *Igf1* or *Igf2* have birth weights approximately 60% of normal.³³⁷⁻³³⁹ Fetal size is proportionately reduced, but mice with deletion of *Igf1* have a higher neonatal death rate. *Igf2* null mice also exhibit smaller placentas. Growth delay begins on day E11 for mice with deletion of *Igf2* and on day E13.5 for mice with deletion of *Igf1*. Postnatally, mice with deletion of *Igf1* who survive the neonatal period continue to have growth failure, with weights 30% of normal by 2 months of age. A similar prenatal and postnatal growth phenotype was observed in the reported case of an *Igf1* deletion³⁴⁰ and in the case of a bioinactive IGF1 molecule resulting from a missense mutation.³⁴¹ When both *Igf1* and *Igf2* were disrupted, weight at birth was only 30% of normal and all animals died shortly after birth, apparently from respiratory insufficiency secondary to muscular hypoplasia (Fig. 24-27).

Mice lacking *Igf1* and the *Ghr* are only 17 % of normal size.¹⁹⁸ Therefore, both IGF1 and IGF2 are important in fetal growth, but GHR signaling may have IGF-independent actions on growth as well. The postnatal growth of *Igf1*^{-/-}

Figure 24-27 Effects of the disruption of one or more genes of the insulin-like growth factor (Igf) system on fetal growth in mice, expressed as percentage of normal body weight. *Igf1*^{-/-}, *Igf1* gene null mice; *Igf2*^{p-/-}, *Igf2* paternal allele null mice; *Igf1r*^{-/-}, *Igf2* gene null mice; *Igf2rm*^{-/-}, *Igf2r* maternal allele null mice. Mice with two source arrows are the combined genotype of the source arrow mice. (Reproduced from Giquel and LeBouc. Hormonal regulation of fetal growth. *Horm Res.* 2006;65:28-33.)

mice was poorer than that observed in mice with *Ghr* or *Ghrh* receptor mutations, indicating that both GH-dependent and GH-independent effects of IGF1 are necessary for normal growth.

Specific ablation of hepatic IGF1 production through the Cre/LoxP recombination system confirmed that the liver is the principal source of circulating IGF1, but the resulting 80% reduction in serum IGF1 levels had no effect on postnatal growth,^{199,342-344} suggesting that postnatal growth is relatively independent of hepatic IGF1 production. Presumably, production of IGF1 from local chondrocytes or other tissues maintains adequate endocrine sources of IGF1 to account for growth preservation. Supportive data for the predominant role in growth of locally produced IGF1 include the fact that only modest decrement of postnatal growth is seen in mice null for *Igfals* (the gene encoding ALS).³⁴⁵ The hormonal profile of the murine models is complex, with reduced IGFBP3 levels despite increased GH. Free IGF1 levels have been reported to be normal in these animals, even though GH levels are elevated.^{343,346}

By crossing the liver-derived IGF1 gene-deleted mice with ALS gene-deleted mice, 85% to 90% reduction in serum IGF1 was achieved, and early postnatal growth retardation was observed.³⁴⁷ These findings suggest that postnatal growth is dependent on both hepatic and tissue IGF1, although definite conclusions are problematic in the face of elevated GH production and perturbations of the IGFBP system observed in these studies.

Deletion of *Igf1r* resulted in birth weights 45% of normal with 100% neonatal lethality.³⁴⁸ In humans, two cases of mutations in the *IGF1R* gene have been reported; these patients had IUGR and postnatal growth failure with elevated IGF1 levels. One patient had a compound for point mutations in exon 2 of the *IGF1R* gene, leading to decreased receptor affinity for IGF1, whereas the other patient had a nonsense mutation of one allele, resulting in reduced numbers of IGF type I receptors.³⁴⁹ Concurrent deletion of *Igf1* and the *Igf1r* resulted in no further reduction in birth size compared with deletion of *Igf1r* alone; this is consistent with the hypothesis that all IGF1 actions are mediated via the IGF type I receptor.³³⁵

Figure 24-28 Schematic representation of the insulin-like growth factor (IGF) system, including IGF ligands (IGF-I and -II), binding proteins (both high- and low-affinity binders), IGF-binding protein (IGFBP) proteases, type I and type II IGF receptors, and potential receptors for other IGFBPs and IGFBP-related proteins (IGFBP-rPs). MCP, mannose-6-phosphate. (From Hwa V, Oh Y, Rosenfeld RG. The insulin-like growth factor-binding protein [IGFBP] superfamily. *Endocr Rev.* 1999;20:761-787, copyright Endocrine Society.)

Deletion of *Igf2r* in mice causes an increase in birth weight but death in late gestation or at birth.³²⁴ Because this receptor normally degrades IGF2, increased growth reflects excess IGF2 acting through the IGF type I receptor, with variable accumulation of IGF2 in tissues.³⁵⁰ Deletion of *Igf2r* plus *Igf2* results in a birth weight 60% of normal, similar to the size of mice with knockout of *Igf2* alone, with no effect on neonatal survival.³⁵¹ Simultaneous knockout of the genes for *Igf2* and *Igf1r* causes further reduction of birth size to 30% of normal, suggesting that some of the fetal anabolic actions of IGF2 are mediated by another mechanism such as via placental growth or interactions with the insulin receptor. Indeed, specific deletion of *Igf2* in the placenta causes small placenta and growth retardation.³⁵²

These studies allow the following conclusions: (1) IGF1 is important for both fetal and postnatal growth; (2) IGF2 is a major fetal growth factor but has little, if any, role in postnatal growth; (3) the IGF type I receptor mediates anabolic actions of both IGF1 and IGF2; (4) the IGF type II receptor is bifunctional, serving to target lysosomal enzymes and to enhance IGF2 turnover; (5) IGF2 deletion results in impaired placental growth; (6) IGF1 is the major mediator of GH effects on postnatal growth, although GH and GHR may have small IGF1-independent effects. Whether these effects apply to humans is not yet known.

Insulin-Like Growth Factor-Binding Proteins

In contrast to insulin, the IGFs circulate in plasma complexed to a family of binding proteins that extend the serum half-life of the IGF peptides, transport the IGFs to target cells, and modulate the interactions of the IGFs with surface membrane receptors.^{353,354} In addition to these effects, the IGFBPs have been found to have effects on cells

independent of IGFs. The presence and various actions of the IGFBPs provide layers of regulation to the GH-IGF axis, greatly increasing its complexity (Fig. 24-28). In the following paragraphs, the structure of the IGFBP family is described first, followed by the role of IGFBPs in IGF physiology and the characteristics of individual IGFBPs.

Structure of IGFBPs. Six distinct human IGFBPs have been cloned, and their highly conserved amino acid sequences have been determined. The six IGFBPs share structural homology in the N-terminal and C-terminal domains but have highly variable midsections, which probably accounts for the more specialized properties of the individual IGFBPs, such as cell dissociation, IGF-binding enhancement, and IGF-independent actions. In each of the conserved N- and C-terminal domains, there are a high number of cysteine-rich residues with a conserved spatial order, implying that the disulfide bond-dependent secondary structure of the IGFBPs is also conserved.³⁵⁵ Reduction of the disulfide proteins results in loss of IGF binding, further demonstrating the importance of the cysteine-rich region.

The N-terminal domain contains residues that have been shown to be essential for IGF binding to IGFBPs 1, 3, and 4.^{356,357} Whether this binding is important for IGF-independent effects of the IGFBPs is unknown. The cysteine-rich C-terminal region also contains regions important in IGFBP binding to proteins such as heparin, fibrinogen, fibrin, and plasminogen.^{358,359} The exact sequences in the C-terminal domain that are responsible for binding may differ among the IGFBPs; for example, the arginine-glycine-aspartic acid sequence in the C-terminal of IGFBPs 1 and 2, which is putatively necessary for binding to cellular surfaces,^{360,361} is not present on IGFBP3, which

Figure 24-29 Schematic representation of the effect of insulin-like growth factor (IGF)-binding protein (IGFBP) proteases on IGF action. In this model, proteolysis of IGFBPs results in a reduction in their affinity for IGF ligands, leading to enhanced binding of IGF peptides by IGF receptors. (From Cohen P, Rosenfeld RG. The IGF axis. In Rosenbloom AL, ed. *Human Growth Hormone: Basic and Scientific Aspects*. Boca Raton, FL: CRC Press; 1995:43-58.)

can also bind cell membranes.^{362,363} The highly variable midregion segment of the IGFBPs is the site of post-translational modifications such as glycosylation and phosphorylation and of proteolysis. Both the primary structure of IGFBPs and their post-translational modifications are responsible for the differential targeting to tissues: glycosylation can affect cell interactions, phosphorylation can affect IGF1 binding affinity and susceptibility to proteases, and proteolysis can affect IGF/IGF receptor-dependent and -independent actions.³⁶⁴

The three-dimensional structure of IGFBPs 1, 2, 4, and 5 have been determined, confirming the presence of IGF-binding sites in the N- and C-terminal domains. Crystallography has shown that the structure of the N-terminal domain is critical for IGF binding, whereas the C-terminal domain is important for inhibiting interactions between IGF1 and its receptor.³⁶⁵⁻³⁶⁹

Several groups of cysteine-rich proteins that contain domains similar to the IGFBPs have been discovered, leading to the proposal of an IGFBP superfamily.³⁷⁰ This superfamily includes the six high-affinity IGFBPs and a number of IGFBP-related proteins (IGFBP-rPs). Three of these proteins—Mac25 (IGFBP-rP1), connective tissue growth factor (CTGF/IGFBP-rP2), and NovH (IGFBP-rP3)—have been shown to bind IGFs, although with considerably lower affinity than the IGFBPs. The role, if any, of IGFBP-rPs in normal IGF physiology is unclear.

Analysis of IGFBPs is complicated by the presence of IGFBP proteases that degrade IGFBP (Fig. 24-29).^{371,372} Proteolysis of IGFBPs complicates their assay and must be taken into consideration when measuring the various IGFBPs in biologic fluids.³⁷³ Proteases for IGFBPs 2, 3, 4, and 5 are present in serum, seminal plasma, cerebrospinal fluid, and urine.³⁷⁴⁻³⁷⁶ It is likely that multiple IGFBP proteases exist, including calcium-dependent serine proteases, kallikreins, cathepsin, and matrix metalloproteases.^{377,378} It is postulated that proteolysis of IGFBPs releases IGFs to interact with cell surface receptors, thereby enhancing the mitogenic and anabolic effects of IGF peptides. There is some evidence that the proteolytic fragments of IGFBP3 and IGFBP5 have IGF1-independent effects.^{379,380}

Role of IGFBPs in IGF Physiology

IGFBPs as Carrier Proteins. The IGFBPs complex almost all of the circulating IGF1 and IGF2 secondary to their high affinity for the IGFs (10^{-10} to 10^{-11} mol/L).³⁸¹ In adults, 75% to 80% of IGFs are carried in a ternary complex consisting of 1 molecule of IGF plus 1 molecule of IGFBP3 plus 1 molecule of the protein ALS.^{382,383} This 150-kd ternary complex is too large to leave the vascular compartment and extends the half-life of IGF peptides from approximately 10 minutes for IGF alone to 12 to 15 hours for IGF in the ternary complex.³⁸⁴ Binding of IGF to IGFBP3 in a binary complex extends the half-life of IGF to 1 to 2 hours. When IGFs bind as a binary complex to the IGFBPs, diffusion out of the vascular compartment may occur; this has been observed for IGF-binding proteins 1, 2, and 4.³⁸⁵

Both IGFBP3 and ALS are GH dependent, providing an additional mechanism for GH regulation of the IGF axis. Whereas GH administration to GH-deficient patients shifts IGF from a 40- to 50-kd form to the ternary complex,^{386,387} this shift does not occur after IGF1 treatment. No sustained increase in levels of IGFBP3 occurs after administration of IGF1,^{121,388} but ALS levels may decrease after IGF1 administration, possibly reflecting IGF feedback inhibition of pituitary GH secretion.^{388,389} In serum of patients with GHD or GH insensitivity, little IGF is present in the 150-kd ternary complex; the IGF present is in the IGF-IGFBP3 binary complex or is bound by other IGFBPs such as IGFBPs 1, 2, 4, or 5.^{258,371,386}

IGFBPs as Modulators of IGF Action. IGFBPs also regulate biologic actions by modulating the availability of IGFs (Fig. 24-30). The binding affinity of IGFs for IGFBPs is higher than for IGF receptors, and dissociation of IGFs from IGFBPs is required for IGFs to interact with IGF receptors.³⁸¹ Additionally, the concentration of IGFBPs is in excess, compared with IGFs, in many bodily fluids.^{390,391} Dissociation of IGFs from IGFBPs is achieved by mass action, proteolysis, or other unknown mechanisms. Alterations in the interaction between IGF1 and its receptor can result in inhibition or potentiation of IGF effects on cell proliferation.^{392,393} Inhibition of IGF1 action by the presence of IGFBP4 has been demonstrated in vitro and in vivo,^{394,395} because IGF analogs with decreased affinity for IGFBP4 have increased biologic potency. IGFBPs 1, 3, and 5 have been shown to have potentiating effects on IGF action, perhaps by facilitating the delivery of IGF to target receptors, as has been shown for IGFBP3.³⁹⁶

The enhancing effects of IGFBP5 were shown to involve binding of IGFBP5 to extracellular matrix proteins, which

Figure 24-30 Theoretical mechanisms of cellular actions of insulin-like growth factor (IGF)-binding proteins (IGFBPs). See text for details.

reduces the affinity of IGFBP5 for IGF.³⁹⁷ Possibly, IGFBP5 binding to the extracellular matrix brings IGF close to the cell surface in a low-affinity complex, from which it can be released slowly to bind neighboring IGF receptors.³⁹⁸ To complicate matters, it appears that the same IGFBP can potentiate or inhibit IGF action in vitro, depending on cell culture conditions, cell type, IGFBP dose, and post-translational modifications such as phosphorylation state.³⁹³ It has been proposed that IGFBP3 and IGFBP5 may have their own receptors that, when activated, interact with IGF receptor signaling pathways.³⁹⁴

It has also been proposed that IGFBP-IGF complexes can be stored in tissues to act in a paracrine manner. This has been demonstrated for IGFBP5 and bone matrix. IGFBP5 is produced by osteoblasts, and the IGFBP5-IGF complex can bind hydroxyapatite. It has been proposed that the complex participates in bone turnover.³⁹⁹

IGFBP proteases, which degrade IGFBPs, are postulated to play a role in altering IGF availability by lowering affinities of IGFBPs for their ligand, thereby increasing the availability of IGFs to cell membrane receptors.^{400,401}

IGF-Independent Actions of IGFBPs. IGFBPs also have IGF-independent actions, such as growth inhibition of certain cell types,⁴⁰² growth stimulation of tissues,⁴⁰³ direct induction of apoptosis,⁴⁰⁴ and modulation of the effects of other, non-IGF growth factors. The mechanisms of IGF-independent actions are slowly being unraveled and include binding to IGFBP-specific cell surface receptors, binding to other cell surface receptors, and interaction with nuclear receptors (Fig. 24-31).

IGF-independent actions have been characterized for IGFBPs 1, 3, and 5. IGFBP1 has been shown to increase ovarian cell migration via binding to the fibronectin receptor independent of IGF1.³⁶¹ IGFBP3 also appears to have intrinsic inhibitory effects on cells. In in vitro studies, IGFBP3 administration or overexpression inhibits DNA synthesis and cell proliferation in conditions in which IGF1 or the IGF type I receptor is neutralized, suggesting IGF-independent inhibition by IGFBP3.⁴⁰⁵ Stimulation of DNA synthesis by basic FGF is inhibited by simultaneous treatment with IGFBP3, even in the presence of insulin, suggesting that sequestration of IGF peptides from IGF receptors is not the only means by which IGFBP3 inhibits cell growth.⁴⁰⁶ IGFBP3 is more effective than immunoneutralization of IGF1 in inhibiting serum-stimulated DNA synthesis in cultured ovarian granulosa cells, with or without added IGF.⁴⁰⁷ Both overexpression studies and gene knockdown studies suggest that IGFBP3 alone can

inhibit DNA synthesis and that it plays a role in the signaling of p53, a potent tumor-suppressor gene. Additionally, IGFBP3 has been demonstrated to induce apoptosis in fibroblasts lacking functional IGF receptors,³⁷⁹ an IGFBP3 that does not bind IGF stimulates apoptosis in these fibroblasts and in wild-type fibroblasts.⁴⁰⁸ IGFBP5 also has IGF-independent effects on osteoblasts. In osteoblasts cultured from mice null for the IGF1 gene, the presence of IGFBP5 increased cell growth, alkaline phosphatase activity, and osteocalcin expression to levels similar to those of wild-type osteoblasts.⁴⁰⁹ In addition, IGFBP5 administered to bone of *IGF1* null mice was associated with an increase in markers of bone formation.

The IGFBPs have IGF-independent effects via binding to IGFBP-specific membrane receptors for IGFBP3^{405,410} IGFBP5,⁴¹¹ or other receptors such as the TGF- β receptor type V.⁴¹² The downstream signaling pathways activated by the IGFBP-specific receptors are unknown, as are the possible interactions with IGF receptor signaling. IGFBP3 and IGFBP5 also contain nuclear localization signals, and these proteins have been localized to the nucleus in vitro.^{413,414} IGFBP3 has been shown to interact with the retinoic acid receptor- α (RXR α), modulating its ability to act as a transcription factor and ultimately affecting apoptosis in cancer cells.⁴¹⁵ IGFBP proteases can also generate IGFBP3 fragments with enhanced affinity for cell surface IGFBP3 receptors.⁴¹⁶

Characteristics of IGFBPs 1 through 6. IGFBP1 was the first of the IGFBPs to be purified and to have its cDNA cloned.⁴¹⁷ Its gene is 5.2 kb long, is located on the short arm of chromosome 7, and comprises four exons.⁴¹⁸ The mature protein is 30 kd and is not glycosylated. Messenger RNA is strongly expressed in decidua, liver, and kidney. It is the major IGFBP in fetal serum in early gestation, reaching levels as high as 3000 μ g/L by the second trimester. Levels of IGFBP1 in newborn serum are inversely correlated with birth weight, suggesting an inhibitory role on fetal IGF action.

IGFBP1 may be involved in reproductive function, including endometrial cycling,⁴¹⁹ oocyte maturation,⁴²⁰ and fetal growth.^{371,421} It also appears to have an important metabolic role, in that its gene expression is enhanced in catabolic states^{258,422,423} and serum levels undergo diurnal variation.⁴²⁴ Insulin suppresses and glucocorticoids enhance IGFBP1 mRNA levels.^{422,425}

Although most in vitro studies consistently show an inhibitory effect of IGFBP1 on IGF action, presumably reflecting interference with IGF ligand-receptor interactions,³⁵⁴ IGFBP1 potentiates IGF effects in certain cell systems,⁴²⁶ possibly as a result of the binding of IGFBP1 to cell membranes through its Arg-Gly-Asp sequence.³⁶¹ The ability of IGFBP1 to inhibit or potentiate IGF action may depend on post-translational modifications of IGFBP1, such as phosphorylation, which appears to enhance the affinity of IGFBP1 for IGF1, thereby inhibiting IGF action.⁴²⁷

The *IGFBP2* gene is located on the long arm of chromosome 2^{428,429} and encodes for a mature protein of 34 kd.⁴³⁰ Like IGFBP1, IGFBP2 is highly expressed in fetal tissues, particularly in the CNS.⁴³¹ It is also expressed in secretory endometrium and endometrial tumors⁴²⁸ and is the major IGFBP in seminal fluid and in the conditioned media of prostatic epithelial cells.⁴³² Like IGFBP1, IGFBP2 does not have N-glycosylation and has the amino acid sequence, perhaps allowing association with cell surfaces.⁴³³

The *IGFBP3* gene is located on chromosome 7.⁴³⁴ It contains four exons homologous to *IGFBP1* and *IGFBP2* and a fifth exon consisting of 3' untranslated sequences. Messenger RNA levels are high in the liver, most notably

Figure 24-31 Schematic diagram of insulin-like growth factor (IGF)-dependent and IGF-independent actions of IGF-binding protein 3 (IGFBP3), the latter being mediated through a putative membrane-associated IGFBP3 receptor.

in the hepatic endothelia and Kupffer cells, compared with ALS, which is high in hepatocytes.^{435,436} The mature, unglycosylated IGFBP3 protein has a molecular weight of approximately 29 kd and comprises 264 amino acids. IGFBP3 is composed of the conserved N-terminal and C-terminal domains and the variable midsection. The midsection is the site of N-linked glycosylation,⁴³⁷ which is not present in IGFBP1 or IGFBP2, and this is why it normally migrates as a doublet-triplet of 40 to 46 kd. Glycosylation does not appear to alter its affinity for IGF1 or IGF2.⁴³⁸ The midsection is also the site of phosphorylation. Studies have shown that this midsection is the site responsible for interaction with cell surfaces.⁴³⁹ Smaller-molecular-weight fragments of IGFBP3 can be found in patients who are catabolic or have undergone surgery and in patients with non-insulin-dependent diabetes mellitus (NIDDM).^{440,441}

IGFBP3 is the predominant IGFBP in adult serum, where it carries approximately 75% of the total IGF, primarily as part of the 150-kd ternary complex consisting of IGF1, IGFBP3, and ALS. IGFBP3 and IGFBP5 are the only IGFBPs to form this complex. It is believed that formation of this ternary complex limits IGF access to target cells, while at the same time prolonging serum half-lives of both the IGF peptide and its binding protein.⁴⁴² Serum levels of IGFBP3 and ALS are reduced in patients with GHD or GH insensitivity, conditions in which assays for serum IGFBP3 have important diagnostic value. IGFBP3 is increased in states of GH excess and acromegaly.

IGFBP3 action is GH dependent, either directly or through regulation by IGF. IGF1 administration to hypophysectomized rats increases serum levels of IGFBP3.⁴⁴³⁻⁴⁴⁵ IGF1 treatment of patients with GH insensitivity, however, does not greatly alter serum IGFBP3 levels,^{119,361,377} and GH treatment of GH-deficient patients does not increase serum levels. Whether these observations mean that GH has a direct effect on IGFBP3 or reflects GH regulation of ALS and ternary complex formation is unclear, although it appears likely that both factors are contributory.

IGFBP3 associates with cell membrane proteins in a specific, cation-dependent manner and with high affinity.⁴⁴⁶ Whether the cell membrane proteins constitute genuine IGFBP3 receptors remains to be determined, although they may mediate IGF-independent actions of IGFBP3. Alternatively, IGFBP3 may associate with heparin-containing proteoglycans in the extracellular matrix and in the cell membrane, because it contains heparin-binding consensus sequences in the C-terminus.⁴⁴⁷ It has been suggested that IGFBP3 is a ligand of the serine/threonine kinase type V TGF- β receptor, with the resultant interaction leading to cell growth inhibition.^{412,448}

IGFBP3 can also translocate to the cell nucleus from the extracellular compartment. It has a consensus nuclear translocation sequence,⁴⁴⁹ and translocation is facilitated by importin-B.⁴⁵⁰ IGFBP3 can bind the nuclear RXR α .^{451,452} This interaction has been shown to be important in the IGFBP3 effect on apoptosis.⁴¹⁵

IGFBP3 expression can be induced by cell cycle regulators and growth-inhibitory factors such as TNF- α , TNF- β , retinoic acid, vitamin D, antiestrogens, and antiandrogens.⁴⁵³ In many cases, modulation of IGFBP3 expression has been shown to be crucial to the antiproliferative effects of factors in vitro.⁴⁵³ IGFBP3 expression is also activated by the tumor suppression gene p53^{454,455} in tumor cell lines treated with chemotherapeutic agents.⁴⁵⁶ Like many genes, IGFBP3 expression is affected by methylation and histone modification. Numerous studies have shown that abnormal methylation or histone modification of the IGFBP3 gene is present in many different types of human cancer (reviewed by Jogie-Brahim and colleagues⁴⁵³).

The IGFBP4 gene is located on chromosome 17 and contains four exons.⁴⁵⁷ It is present mostly as a nonglycosylated form of 24 kd, with the glycosylated form being 29 kd. Similar to IGFBP3, its glycosylation site is in the highly variable midregion of the protein. It is widely expressed in embryonic tissues, fibroblasts, osteoblastic cells, prostatic cells, ovarian cells, and liver. The circulating form is derived mostly from the liver. Evidence suggests that IGFBP4 is the only IGFBP that does not have IGF-independent effects. In vitro, IGFBP4 inhibits IGF action, and in vivo studies have demonstrated that the inhibitory action of IGFBP4 on cellular processes is IGF1-dependent.⁴⁵⁸ The inhibitory effects of IGFBP4 are reduced by proteolysis, similar to IGFBP3. IGFBP4 proteases are present in a wide variety of cells, including neuroblastoma, smooth muscle, fibroblasts, osteoblasts, and prostatic epithelium.⁴⁵⁹⁻⁴⁶³ Activation of IGFBP4 proteolysis occurs in the presence of IGF1 or IGF2, presumably reflecting a conformational change in IGFBP4 resulting from IGF occupancy.^{464,465} The protease pregnancy-associated plasma protein-A (PPAP-A) has been shown to degrade IGFBPs 2, 4, and 5, but not IGFBP3,⁴⁶⁶⁻⁴⁶⁸ and it has been associated with the decline of IGFBP4 during ovarian follicular growth.⁴⁶⁹ Proteolysis of IGFBP4 by PPAP-A in developing ovarian follicles has been postulated to play a role in the development of dominant follicles.⁴⁶⁹

The IGFBP5 gene is located on chromosome 5 and contains four exons. It is 28 kd and also contains a glycosylation site in the highly variable midregion of the protein.⁴⁷⁰⁻⁴⁷² In contrast to the other glycosylated IGFBPs, IGFBP5 is O-glycosylated rather than N-glycosylated. IGFBP5 has been shown to bind extracellular matrix proteins such as types III and IV collagen, laminin, and fibronectin, and it does so in response to binding of IGF1.³⁹⁷ The affinity of IGFBP5 is reduced about sevenfold when the binding protein is associated with extracellular matrix, providing a potential mechanism for release of IGFs to cell surface receptors. Association of IGFBP5 with extracellular matrix also appears to protect it from proteolysis.⁴⁷³ Unlike proteolysis of IGFBP4, which is enhanced by the addition of IGFs, degradation of IGFBP5 is inhibited by the binding of IGF peptides.^{470,474} Proteolytic fragments of IGFBP5 have been shown to have IGF-independent effects on mitogenesis, possibly by binding an IGFBP5-specific cell surface receptor.⁴⁷⁵

The IGFBP6 gene is located on chromosome 12 and contains four exons. The mature peptide contains 216 amino acids and is 23 kd, although it may undergo O-glycosylation, similar to IGFBP5.⁴⁷⁶ Although IGFBP6 binds both IGF1 and IGF2, it has a significantly greater affinity for IGF2.⁴⁷⁷ IGFBP6 is found in high levels in cerebrospinal fluid, as is IGFBP2, which also binds IGF2 with high affinity. IGFBP6 may have a role in regulating ovarian activity, perhaps by functioning as an antagonodotropin.⁴⁷⁸

Mice null for the individual IGFBPs have been generated. Only modest, if any, effects on growth have been found. Modest decreases in organ size have been noted in IGFBP2 null mice,⁴⁷⁹ whereas growth in IGFBP4 null mice is 85% to 90% of normal. Increases in other IGFBP levels were noted in these mice. Triple knockout mice null for IGFBPs 3, 4, and 5 have been generated,⁴⁸⁰ and they exhibit lengths 80% of normal with IGF1 levels 45% that of the wild type. Transgenic mice overexpressing the IGFBPs 1, 2, 3, and 4 have also been generated,⁴⁸¹ and they exhibit growth retardation to varying degrees, demonstrating the role of the IGFBPs in sequestering IGF1 or inhibiting its actions. In addition, mice overexpressing IGFBP1 and IGFBP3 also exhibit impaired glucose tolerance and

decreased fertility, further implicating a role for IGF1 or a separate role for these IGFBPs in glucose metabolism and reproduction.

Gonadal Steroids

Androgens and estrogens affect growth predominantly through two mechanisms: regulation of the GH-IGF1 axis and maturation of the epiphyseal growth plates. The adolescent rise in serum gonadal steroid levels is an important part of the pubertal growth spurt. In addition, it is the stimulation of epiphyseal fusion by the pubertal rise of gonadal steroid production that results in the ultimate cessation of linear growth. The details of the roles of androgens and estrogens in enhancing GH secretion and directly stimulating IGF1 production were discussed earlier.

Both androgens and estrogens increase skeletal maturation and accelerate growth plate senescence. However, most of these effects are due to the action of estrogen, with androgens acting indirectly after their conversion to estrogens by aromatase in extraglandular tissues, including locally within the growth plate. The primacy of the role of estrogen comes from animal studies²⁰ as well as reports of human subjects with mutations. A mutation of the estrogen receptor in a man was associated with tall stature and open epiphyses,²¹ and similar findings were reported in patients with mutations of the gene encoding the aromatase enzyme.^{22,23} In addition, variants of the estrogen receptor have been associated with height in males⁴⁸² and in females,⁴⁸³ and increased aromatase expression results in short adult stature in males.^{484,485}

Whereas most of the effects of androgen on growth are mediated through actions that occur after their aromatization to estrogen, there is evidence of androgen-specific effects. Notably, dihydrotestosterone, a nonaromatizable androgen, can accelerate linear growth in boys. This effect of androgen does not appear to be mediated by either GH or circulating IGF1, but it may be mediated by an increase in local IGF1 production.⁴⁸⁶

Gonadal steroids, along with GH and IGF1, contribute to the attainment of peak bone mass in adults. Again, this sex hormone effect is largely mediated by estrogen action.⁴⁸⁷⁻⁴⁸⁹

Thyroid Hormone

Thyroid hormone is of relatively little importance in the growth of the fetus, but it has significant effects on postnatal growth and bone maturation. Patients with hypothyroidism have decreased spontaneous GH secretion and blunted responses to GH provocative tests. Thyroid hormone also has a direct effect on chondrocytes and osteoblasts, which both express thyroid hormone receptors. Thyroid hormone regulates chondrocyte proliferation and stimulates terminal differentiation, mineralization, and angiogenesis.^{490,491} In particular, thyroid hormone is essential for hypertrophic chondrocyte differentiation.⁴⁹² Postnatally, hypothyroidism can cause growth failure and delayed skeletal maturation, whereas hyperthyroidism can accelerate linear growth and skeletal maturation.

Glucocorticoids

Supraphysiologic doses of glucocorticoids can acutely increase GH secretion.⁴⁹³ However, prolonged exposure to excess glucocorticoids severely impairs growth. This occurs through multiple mechanisms that act through the GH-IGF1 axis. Chronic glucocorticoid treatment attenuates pituitary secretion of GH through an increase in

somatostatin tone.^{494,495} Glucocorticoids can also impair growth through direct actions at the growth plate, by inhibiting local IGF1 production through suppression of chondrocyte GHR expression and impairment of chondrocyte IGF1 receptor expression.⁴⁹⁶ In addition, IGF1 action at the chondrocyte may be impaired through alterations in IGFBP levels and impairment of intracellular signaling.⁴⁹⁷ Finally, glucocorticoids may stimulate apoptosis of growth plate chondrocytes.⁴⁸⁶

Additional indirect effects of excess glucocorticoids on growth can result from glucocorticoid inhibition of calcium absorption and reabsorption, with the development of secondary hyperparathyroidism.⁴⁹¹ In pubertal children, glucocorticoid excess can induce sex hormone deficiency, causing a loss of the normal growth stimulatory effect of these hormones.⁴⁹¹

PATHOLOGIC BASIS OF GROWTH RETARDATION

A classification of growth retardation is presented in Table 24-1. Growth disorders are subdivided into (1) disorders of the hypothalamic-pituitary axis resulting in deficiency of GH, (2) disorders resulting in deficiency or resistance to the action of IGF1, (3) growth disorders that primarily affect the growth plate or are caused by chronic disease, and (4) idiopathic short stature (ISS), which is considered separately but may have a pathogenic basis in the GH-IGF1 axis or at the growth plate. A schematic diagram of known defects in the GH-IGF1 axis is shown in Fig. 24-32, and the known involved genes are listed in Table 24-2.

Disorders of the GH/IGF1 Axis

Growth Hormone Deficiency

Although it is not always possible to establish definitively whether hypothalamic or pituitary dysfunction is responsible for the hormone deficiency, these compartments are

differentiated to facilitate discussion of the pathology. Table 24-3 indicates possible etiologies for deficiency in the GH-IGF axis. The term *idiopathic* is often used to designate lack of understanding of the basis for the GHD. Developmental or functional abnormalities of the hypothalamus account for most “idiopathic” cases of hypopituitarism, and recent molecular studies have begun to elucidate the molecular bases of these disorders. It is anticipated that most cases of idiopathic hypopituitarism will be defined at the genetic level in the future.

The Hypothalamus

Congenital Disorders. The primary hypothalamic neuropeptide responsible for synthesis and release of GH is GHRH. Somatostatin plays an antagonistic role in GH release. Synthesis of these two hypothalamic proteins is controlled by a series of neurochemicals, and it is the balance between them that is responsible for the tight neuroendocrine control of GH biosynthesis. Mutations of some of the genes encoding hypothalamic peptides explain some cases of GHD due to hypothalamic dysfunction.

As noted earlier, patients with early-diagnosed congenital GHD frequently have an abnormal pituitary stalk, ectopia of the posterior pituitary, and hypoplasia of the anterior pituitary (Fig. 24-33). Anencephaly results in a pituitary gland that is small or abnormally formed and is frequently ectopic.^{127,498,499} Despite the loss of hypothalamic regulation, somatotrophs differentiate and proliferate, although in diminished overall mass.⁶⁷ During intrauterine life, serum GH and IGF1 levels are 30% to 50% of the normal range,¹³⁴ and pituitary GH content at birth is about 15% to 20% of normal,^{128,134} with similarly low neonatal plasma GH levels.^{129,500,501}

Figure 24-33 Magnetic resonance imaging of infundibular dysgenesis. **A**, T1-weighted sagittal and coronal images of the hypothalamic-pituitary area in a normal 8-year-old girl. The anterior (AP) and posterior pituitary (PP) lobes and the pituitary stalk (PS) are marked. **B**, T1-weighted sagittal and coronal images of the hypothalamic-pituitary area of a 17-year-old boy with isolated growth hormone deficiency. The anterior pituitary lobe (AP) is hypoplastic, the posterior pituitary (PP) is ectopic, and the pituitary stalk is absent. (Reprinted from Root AW, Martinez CR. Magnetic resonance imaging in patients with hypopituitarism. *Trends Endocrinol Metab.* 1992;3:283-287.)

POU1F1 (PIT1)	<ul style="list-style-type: none"> Member of the POU transcription factor family Important for activation of GH1, PRL, and TSHβ genes 	Somatotrophs, lactotrophs, thyrotrophs	<ul style="list-style-type: none"> Combined pituitary deficiencies (GH, TSH, PRL, and late-onset ACTH reported); TSH secretion may initially be normal Pituitary hypoplasia 	AD, AR
Otx2	<ul style="list-style-type: none"> Bicoid-type homeodomain gene required for forebrain and eye development Antagonizes <i>FGF8</i> and <i>SHH</i> expression May have importance in activation of Hesx1 	Somatotrophs, thyrotrophs, corticotrophs, and probably gonadotrophs	<ul style="list-style-type: none"> Severe ocular malformation including anophthalmia Combined pituitary hormone deficiencies with LH/FSH deficiency Anterior pituitary hypoplasia with ectopic posterior pituitary 	Unknown
SOX2	<ul style="list-style-type: none"> Member of SOXB1 subfamily as SOX1 and SOX3 expressed early in development 	Somatotrophs, gonadotrophs (and, in animal models, thyrotrophs)	<ul style="list-style-type: none"> Hypogonadotropic hypogonadism Anterior pituitary hypoplasia Bilateral anophthalmia/microphthalmia Midbrain defects including corpus callosum and hippocampus Sensorineural defects Esophageal atresia and learning difficulty 	De novo
SOX3	<ul style="list-style-type: none"> Member of SOX (SRY-related HMG box) Developmental factor expressed in developing infundibulum and hypothalamus 	Somatotrophs and/or additional anterior pituitary cell types	<ul style="list-style-type: none"> Duplications of Xq26-27 in affected males (female carriers unaffected) Variable mental retardation Hypopituitarism with abnormal MRI Anterior pituitary hypoplasia Infundibular hypoplasia Ectopic/undescended posterior pituitary Abnormal corpus callosum Murine studies suggest SOX3 dosage critical for normal pituitary development 	X-linked

Table continued on following page

TABLE 24-2

Genetic Defects of the GH-IGF Axis Resulting in Somatotroph Dysfunction and GH Deficiency (Continued)

Factor	Gene Function	Affected Cell Types	Clinical Phenotype	Mode of Inheritance
Isolated Growth Hormone Deficiency				
GLI2	• Member of the GLI gene family; transcription factors that mediate SHH signaling	Somatotrophs	• Heterozygous loss-of-function mutations in patients with holoprosencephaly • Penetrance variable • Pituitary dysfunction accompanied by variable craniofacial abnormalities.	Unknown
GHRHR	• Encodes GHRH receptor	Somatotrophs	• Short stature • Anterior pituitary hypoplasia	AR
GH1	• Encodes GH peptide • Several mutations shown to affect GH secretion or function	Somatotrophs	• Short stature • Abnormal facies • Presentation includes bioinactive GH	AR, AD, or X-linked

ACTH, adrenocorticotrophic hormone; AD, autosomal dominant; AR, autosomal recessive; FSH, follicle-stimulating hormone; GH, growth hormone; GHRH, growth hormone–releasing hormone; α GSU, glycoprotein α -subunit; HMG, high mobility group; LH, luteinizing hormone; MRI, magnetic resonance imaging; PRL, prolactin; SHH, Sonic hedgehog; TSH, thyroid-stimulating hormone.

In most patients, so-called idiopathic hypopituitarism or GHD is presumed to be due to abnormalities of synthesis or secretion of hypothalamic hypophysiotropic factors.^{97,502,503} In a number of reports, idiopathic GHD is associated with MRI findings of an ectopic neurohypophysis, pituitary stalk dysgenesis, and hypoplasia or aplasia of the anterior pituitary. In series involving 397 children with isolated growth hormone deficiency (IGHD) or with combined pituitary hormone deficiencies (CPHD), 54% had the characteristic MRI findings, and 93% of CPHD patients were abnormal, in contrast to 32% of patients with IGHD.^{504–508} Abrahams and colleagues⁵⁰⁹ studied 35 patients with idiopathic GHD and found that those with MRI abnormalities could be divided into two groups: (1) 43% had an ectopic neurohypophysis (neurohypophysis located near the median eminence), absent infundibulum, and

absence of the normal posterior pituitary bright spot; (2) 43% had a small anterior pituitary, either as an isolated finding or combined with an ectopic neurohypophysis. Overall, those patients with the most striking abnormalities of the hypothalamic-pituitary region, largely those with CPHD, had the smallest anterior pituitary glands.^{505,510} Patients with more severe deficiencies of GH have greater frequency of significant morphologic abnormalities.^{511,512}

Although the increased incidence of breech presentation and birth trauma with neonatal asphyxia in congenital idiopathic hypopituitarism has led some to suggest an etiologic role for these occurrences,^{513,514} the syndrome of pituitary stalk dysgenesis with congenital hypopituitarism is probably the result of abnormal development, and the perinatal difficulties are likely the consequence rather than the cause of the abnormalities. Findings of a similar MRI appearance in patients with septo-optic dysplasia,^{128,515} in association with type I Arnold-Chiari syndrome and syringomyelia,^{128,510,516} and possibly in holoprosencephaly¹²⁸ and the occurrence of micropenis with congenital hypopituitarism^{128,517–520} all support the concept that congenital hypopituitarism is a genetic or developmental malformation, not a birth injury. A single report of an apparent autosomal dominant mutation of early brain development with infundibular dysgenesis associated with GHD supports the primary nature of the anomaly.⁵²¹ Further indirect evidence in studies⁵²² of isolated, complete anterior pituitary aplasia indicates that hypothalamic hypopituitarism and breech delivery are consequences of congenital midline brain defects, although perinatal residua of breech delivery may exacerbate ischemic damage to the hypothalamic-pituitary unit.

The MRI findings described for early-diagnosed patients with hypopituitarism are also found in children diagnosed at a later age. Most of these children have hypothalamic dysfunction as the cause of diminished pituitary hormone secretion. In the older group, as in the infants, structural, acquired hypothalamic, stalk, or pituitary abnormalities must be considered.

Holoprosencephaly. Holoprosencephaly, which is caused by abnormal midline development of the embryonic forebrain, usually results in hypothalamic insufficiency^{523,524} and has been associated with mutations in developmental proteins.^{525,526} These mutations are associated with diminished signaling by SHH, a critical factor in forebrain development.⁵²⁷ Hedgehog ligands bind to and

TABLE 24-3

GH/IGF1 Deficiency Syndromes**Congenital Growth Hormone Deficiency**

GH deficiency resulting from hypothalamic dysfunction
Holoprosencephaly and septo-optic dysplasia
GH deficiency resulting from pituitary dysfunction
GH deficiency resulting from mutations of the GHRH receptor and GH
GH deficiency resulting from CPHD
Bioinactive GH

Acquired Growth Hormone Deficiency

GH deficiency resulting from CNS tumors, trauma, or inflammation
Circulating antibodies to GH that inhibit GH action

Congenital IgfI Deficiency

Abnormalities of the GHR
STAT5 mutations
ALS mutations
IGF1 gene mutations
IGF type I receptor mutations

Acquired IgfI Deficiency

Circulating antibodies to the GHR
Chronic disease states

ALS, acid-labile subunit; CPHD, combined pituitary hormone deficiencies; CNS, central nervous system; GHR, growth hormone receptor; GHRH, growth hormone–releasing hormone; IGF1, insulin-like growth factor I.

activate the transmembrane receptor Patched (PTCH), which results in release of the coreceptor, Smoothened (SMO), activating GLI transcription factors. SHH and FGF8 play a role in the induction of BMP2 and LHX, which are important for proliferation in the developing pituitary gland and are influenced by loss-of-function mutations of the *GLI2* gene.^{527,528}

Facial dysmorphism of holoprosencephaly ranges from cyclopia to hypertelorism and is accompanied by absence of the nasal septum, midline clefts of the palate or lip, and sometimes a single central incisor. GHD may be accompanied by other pituitary hormone insufficiencies. The incidence of GHD is increased in cases of simple clefts of the lip or palate (or both),^{529,530} and children with cleft palates who grow abnormally require further evaluation.

Septo-Optic Dysplasia. In its complete form, the rare syndrome of *septo-optic dysplasia* combines hypoplasia or absence of the optic chiasm or optic nerves (or both), agenesis or hypoplasia of the septum pellucidum or corpus callosum (or both), and hypothalamic insufficiency.^{515,531,532} The extent of the anatomic and functional abnormalities can vary but usually in parallel to each other.^{531,532} GHD can occur by itself or in combination with deficiencies of TSH, ACTH, or gonadotropins. About 50% to 70% of children with severe anatomic defects have hypopituitarism or, at least, identifiable abnormalities of the GH-IGF axis,^{128,533,534} and the diagnosis should be considered in any child who has growth failure associated with pendular or rotatory nystagmus or impaired vision and a small optic nerve disc. In some patients, a hypoplastic or interrupted pituitary stalk and ectopic posterior pituitary placement have been identified by MRI.^{128,515,535} It is not clear whether this disorder is inherited, but there is an increased incidence in offspring of young mothers, in first-born children, in areas of high unemployment, and in babies exposed to intrauterine medications, smoking, alcohol, or diabetes.^{536,537}

HESX1. Mutations of *HESX1*, a paired-like homeodomain gene that is expressed early in pituitary and forebrain development, are associated with familial forms of *septo-optic dysplasia*.⁵³⁸⁻⁵⁴⁰ *HESX1*, also referred to as *RPX* (Rathke's pouch homeobox), is a member of the paired-like class of homeobox genes and is essential for normal forebrain and pituitary formation.⁵⁴¹ It is one of the earliest known specific markers for the pituitary primordium and encodes for a developmental repressor with localization to the Rathke's pouch.⁵⁴² TLE1 (the mammalian ortholog of the *Drosophila* protein Groucho) and the nuclear corepressor NCOR1, bind to *HESX1* to exert repression.^{543,544} *HESX1* downregulation is required for cell determination mediated by PROP1 to occur. The LIM homeodomain proteins LHX1 and LHX3 are required for activation of the *HESX1* promoter.⁵⁴⁵

Hesx1 null mutant mice display abnormalities in the forebrain, eyes, and other anterior structures such as the pituitary.⁵⁴⁶ Mouse embryos heterozygous for both *Hesx1* and *Six3* null mutations have a mild phenotype, suggesting that these developmental factors control a switch in progenitor proliferation between repression by *HESX1* and activation of PROP1.⁵⁴⁷ These defects have similarity with human phenotypes such as *septo-optic dysplasia* and CPHD. Patients with *septo-optic dysplasia* may present with a wide spectrum of phenotypes associated with congenital hypopituitarism. Several homozygous and heterozygous mutations have been identified in *HESX1* (Online Mendelian Inheritance in Man [OMIM] no. 601802) in patients with hypopituitarism with variable phenotypes.^{540,542,546,548-554}

Two siblings (born to consanguineous parents) with a severe *septo-optic dysplasia* phenotype including anterior pituitary hypoplasia, an ectopic posterior lobe, agenesis of the corpus callosum, absent septum pellucidum, and optic nerve hypoplasia were found to have a homozygous mutation at a highly conserved arginine residue of the homeodomain (p.R160C) that resulted in loss of DNA binding of the mutant protein. Another homozygous mutation, a threonine/isoleucine substitution at residue 26 (p.I26T), was identified in a child with GH and gonadotropin deficiency that later evolved to deficiencies of ACTH and TSH. She had no forebrain abnormalities and normal optic nerves, but on MRI had hypoplasia of the anterior pituitary and an undescended posterior pituitary. This mutation lies in a highly conserved engrailed homology domain that is required for transcriptional repression. Loss of repressor function was found to be caused by impaired interaction with the TLE1 corepressor. To determine the mechanisms by which these mutations cause the disorder, mice homozygous for these mutations were generated.⁵⁵⁵ Mice homozygous for the p.R160C mutation displayed pituitary and forebrain defects similar to those in the *Hesx1* null embryos, indicating the critical role of *HESX1* interactions with DNA in transcriptional repression during development. Mice homozygous for the p.I26T allele displayed pituitary defects and ocular abnormalities suggestive of a hypomorph allele, indicating the important role of TLE interaction in pituitary and ocular development.

Heterozygous mutations of *HESX1* have been identified in patients with hypopituitarism and *septo-optic dysplasia* and are usually associated with less affected phenotypes. Approximately 850 patients were studied for mutations in *HESX1*, including more than 300 patients with *septo-optic dysplasia*; 410 with isolated pituitary dysfunction, optic nerve hypoplasia, or midline neurologic abnormalities; and 126 with familial inheritance. The incidence of coding region mutations in *HESX1* within this population was about 1%, suggesting that mutations in *HESX1* are a rare cause of hypopituitarism and *septo-optic dysplasia*.⁵⁴⁹

OTX2. Mutations in other genes have been associated with CNS anatomic abnormalities and hypopituitarism. *OTX2* is a homeobox gene that is expressed earliest in the neuroectoderm⁵⁵⁶ cells of the forebrain and midbrain and encodes a transcription factor belonging to the orthodenticle family. This factor also plays a role in ocular development. Murine models harboring mutant *Otx2* genes demonstrate abnormal primitive streak organization and a headless phenotype.⁵⁵⁶ *OTX2* has a role in regulating early expression of *HESX1* and is expressed in the pituitary to regulate POU1F1 (PIT1). Dateki and colleagues⁵⁵⁷ identified a frameshift *OTX2* mutation in a patient with bilateral anophthalmia and partial IGHD with minimal transactivation activity. A heterozygous *OTX2* mutation was described in two unrelated patients with hypopituitarism; although initial studies demonstrated normal binding to *HESX1* binding sites, the mutant *OTX2* gene was demonstrated to have decreased activation of the *HESX1* promoter, suggesting a dominant negative effect leading to CPHD.⁵⁵⁸ This relationship between the transcription factors *OTX2* and *HESX1* emphasizes the complexities of pituitary development and suggests that genetic etiologies may be multifactorial. Further studies have revealed two frameshift mutations, a nonsense mutation in two unrelated patients, and a heterozygous microdeletion in a fifth patient.⁵⁵⁷

SOX3. A syndrome of X-linked hypopituitarism and mental retardation involving duplications of Xq26-27 encompassing *SOX3* (OMIM 313430) has been described in several pedigrees. The affected males have anterior

pituitary and infundibular hypoplasia with an undescended posterior pituitary and abnormalities of the corpus callosum. The GHD may also be associated with deficiencies of ACTH, TSH, or gonadotropins. Because *Sox3* is not expressed in Rathke's pouch in the mouse, the anterior pituitary developmental defects are probably secondary to disruption of infundibular development.⁵⁵⁹⁻⁵⁶² Female carriers appear to be clinically unaffected, and no mutations have been found in patients with sex reversal, gonadal dysgenesis, or infertility.^{563,564}

SOX2. Heterozygous mutations within *SOX2* in males have been associated with anophthalmia or microphthalmia and anterior pituitary hypoplasia. The resulting hormonal abnormalities include GH and gonadotropin deficiency. Some patients also present with genital abnormalities.⁵⁶⁵⁻⁵⁶⁹ A wide variety of additional abnormalities may be present, including hypoplasia of the corpus callosum, hypothalamic hamartoma, hippocampal malformation, esophageal atresia, sensorineural hearing loss, and learning difficulties.⁵⁶⁷⁻⁵⁷⁶ In addition to de novo heterozygous mutations, nonsynonymous changes have been identified in individuals who inherited the variant from a clinically unaffected parent.^{565,577} A perplexing case of a patient with isolated hypogonadotropic hypogonadism but without anterior pituitary hypoplasia suggests that *SOX2* may be independently involved in hypothalamic neuronal development.⁵⁶⁹ The expression of *SOX2* has been found to overlap with that of *LHX3* and *HESX1* within Rathke's pouch.^{555,566,578,579}

Acquired Disorders

Inflammation of the Brain or Hypothalamus. Bacterial, viral, or fungal infections may result in hypothalamic/pituitary insufficiency,^{580,581} and the hypothalamus or pituitary or both may also be involved in sarcoidosis.⁵⁸²

Tumors of the Brain or Hypothalamus. Brain tumors are a major cause of hypothalamic insufficiency,⁵⁸³ especially midline brain tumors such as germinomas, meningiomas, gliomas, ependymomas, and gliomas of the optic nerve. Although short stature and GHD are most often associated with suprasellar lesions in neurofibromatosis, they may also exist without such lesions. Whether growth impairment antedates the pathologic findings is not yet clear.^{584,585} Metastases from extracranial carcinomas are rare in children, but hypothalamic insufficiency can result from local extension of craniopharyngeal carcinoma or Hodgkin's disease of the nasopharynx. The laboratory diagnosis of GHD in children with brain tumors can be difficult because levels of IGF1 and IGFBP3 are poor predictors, especially in pubertal patients.⁵⁸⁶ Craniopharyngiomas and histiocytosis can cause hypothalamic dysfunction (see later discussion).

Trauma of the Brain or Hypothalamus. Head trauma, resulting from boxing and various injuries, can cause IGHD or multiple anterior pituitary deficiencies.⁵⁸⁷⁻⁵⁹¹ Some series of patients with GHD have indicated an increased incidence of birth trauma, such as breech deliveries, extensive use of forceps, prolonged labor, or abrupt delivery. Although GHD can be a consequence of a difficult delivery or hypoxic-perinatal period, it is more commonly associated with developmental deficiencies (discussed previously) or head trauma later in life. In a series of 22 head-injured adolescents and adults, almost 40% had some degree of hypopituitarism.⁵⁸⁸

Psychosocial Dwarfism. An extreme form of failure to thrive is termed *psychosocial dwarfism* or *emotional deprivation dwarfism*.^{579a-579c} Most cases of failure to thrive can be traced back to a poor home environment and inadequate parenting, with improved weight gain and growth upon

removal of the infant from the dysfunctional home. Some children have been reported, however, to show dramatic behavioral manifestations beyond those in the typical failure-to-thrive infant, namely bizarre eating and drinking habits, such as drinking from toilets, social withdrawal, and primitive speech.^{579b} Hyperphagia and abnormalities of GH production may be associated.^{579d} GH secretion is low in response to pharmacologic stimuli but returns to normal upon removal from the home. Concomitantly, eating and behavioral habits returned to normal, and a period of catch-up growth ensued. Careful assessment of endogenous GH secretion showed reversal of the GH insufficiency within 3 weeks, including enhancement of GH pulse amplitude and a variable increase of pulse frequency.^{579d-579f} The reversibility of GH secretory defects and the later growth increment in the context of the clinical findings described previously confirm the diagnosis of psychosocial dwarfism.^{579c,579f-579h}

The neuroendocrinologic mechanisms involved in psychosocial dwarfism remain to be elucidated. GH secretion is abnormal and ACTH and TSH levels may also be low, although some patients have high plasma cortisol levels.^{579c} Even when GH secretion is reduced, treatment with GH is not usually of benefit until the psychosocial situation is improved.^{579c} Management of the environmental causes of the growth failure is imperative and often associated with substantial growth. In our experience, although psychosocial dysfunction is a common cause of failure to thrive in infancy, the constellation of bizarre behaviors described in psychosocial dwarfism is rare.

The fact that GH production is impaired in adults with varied psychiatric disorders^{579i,579j} and given the growth aberrations of functional GHD with psychosocial dwarfism together suggest that children with emotional problems may have impaired GH secretion and growth.^{579k} Indeed, depression in children, as adults, can lower GH production,^{579l} and in girls, anxiety disorders predict a modest height loss in adults.^{579k}

The Anterior Pituitary

As discussed earlier, many of the disease processes that impair hypothalamic regulation of GH secretion also impair pituitary function. Another group of abnormalities specifically affect pituitary somatotroph development and function.

Congenital Disorders. As many as 3% to 30% of patients with GHD have an affected parent, sibling, or child.⁵⁹²⁻⁵⁹⁴ Inborn errors of the genes for nuclear transcription factors affecting hypothalamic-pituitary development, the GHRH receptor, or the GH gene can cause GHD and IGF deficiency.

Combined Pituitary Hormone Deficiency. During pituitary development, a series of transcription factors are expressed in a specific timeframe and in a spatial context. The result of cell differentiation and proliferation is a mature anterior pituitary gland with five distinct cell types (see Chapter 8).

PITX2. *PITX2* (also known as *RIEG*) is a member of the bicoid-like homeobox transcription factor family that is closely related to the mammalian *OTX* genes expressed in the rostral brain during development; it is required at many stages of pituitary development.⁵⁹⁵ Studies have shown that activation of the WNT signaling pathway or constitutive activation of β -catenin can induce *PITX2* expression. *PITX2* is expressed in thyrotrophs, gonadotrophs, somatotrophs, and lactotrophs but not in corticotrophs.⁵⁹⁶

PITX2 acts to activate the promoters of pituitary hormone target genes.⁵⁹⁷⁻⁵⁹⁹ Homozygous loss of *PITX2* results in early embryonic lethality with pituitary development severely affected.⁶⁰⁰⁻⁶⁰³ This is thought to be related to the control of cell cycle regulatory genes by PITX2.^{604,605} Furthermore, the lack of *PITX2* also results in excessive cell death during early pituitary development, suggesting a role in cell survival.⁶⁰⁶ A mouse line expressing a hypomorphic allele of *Pitx2* provided evidence that the extent of pituitary hypoplasia and cellular differentiation is proportional to the reduced dosage of *Pitx*.^{603,607} In this model, the gonadotroph lineage was primarily affected and the numbers of differentiated somatotrophs and thyrotrophs were reduced, but the corticotroph population was unaffected.⁶⁰⁷

In a *Pitx2* overexpression model, the gonadotroph population was expanded, probably because of the role of *Pitx2* in the expression of gonadotroph-specific transcription factors GATA2, EGR1, and NR5A1 (SF1).⁶⁰⁶ Mutations of *PITX2* have been described in patients diagnosed with Rieger syndrome, an autosomal dominant condition with variable manifestations including anomalies of the anterior chamber of the eye, dental hypoplasia, a protuberant umbilicus, mental retardation, and pituitary abnormalities. Six point mutations of *PITX2*, located within the homeodomain responsible for DNA binding have been described, and several of these mutations show loss of DNA binding capacity.⁶⁰⁸ A heterozygous mutation that changes the lysine at position 50 to glutamic acid in the homeodomain has been found to impart a dominant negative effect leading to a pronounced phenotype.⁶⁰⁹

LHX3. LHX3 is a member of the LIM-type homeodomain protein family of transcription factors that feature two LIM domains in their amino terminus and a centrally located homeodomain used to interact with specific DNA elements on target genes. During development, expression of *LHX3*, which persists in the adult pituitary, is seen in the anterior and intermediate lobes of the pituitary, spinal cord, and medulla.⁶¹⁰ Murine models with targeted disruption of *Lhx3* show depletion of thyrotrophs, gonadotrophs, and somatotrophs, suggesting that *Lhx3* is important for cell specification and proliferation.⁶¹¹ Three LHX3 isoforms have been identified in humans: LHX3a, LHX3b, and M2-LHX3.⁶¹² Of these, LHX3a displays the greatest ability to activate the promoters of pituitary genes. Patients with reported mutations in *LHX3* have deficits of GH, PRL, TSH, and gonadotropins, as well as abnormal pituitary morphology along with a rigid cervical spine that limits head rotation.⁶¹³ *LHX3* mutations are a rare cause of reported hypopituitarism, and one study reported that the incidence of a homozygous *LHX3* mutation in patients studied with CPHD was 2.2%.⁶¹³ Several other novel *LHX3* mutations in patients with CPHD demonstrating autosomal recessive inheritance have been reported and characterized.^{579,614} There is also evidence to demonstrate that SOX2 is capable of binding and activating transcription of the *LHX3* promoter and therefore may be important in pituitary development.⁵⁷⁹

LHX4. LHX4 is another LIM homeodomain protein with homology to LHX3, and it is also expressed in the developing brain, including the cortex, pituitary, and spinal cord.⁶¹⁵ Despite similarities in protein structure, the role of LHX4 in development is distinct from that of LHX3, as demonstrated by single and combined gene-deletion targeting in mice. Murine models with targeted deletion of *Lhx4* form a definitive Rathke's pouch that arrests and results in a hypoplastic pituitary. In contrast to *Lhx3* gene knockout mice, *Lhx4*^{-/-} mice contain all five differentiated cell types.^{616,617} *Lhx3* expression is impaired in the *Lhx4* mutants, suggesting that *Lhx4* is required for cell survival,

expansion of the pouch, and differentiation of pituitary-specific cell lineages.

Several reports have described CPHD patients with evidence of a hypoplastic pituitary who harbored *LHX4* mutations.⁶¹⁸⁻⁶²⁰ These heterozygous mutations have been shown to result in proteins that are unable to bind DNA and activate pituitary gene expression.⁶²⁰ Further studies have demonstrated a functional relationship between POU1F1 and LHX4 in the regulation of POU1F1 expression in specific pituitary cell types.⁶¹⁸ Also, several studies have suggested that LHX4 and PROP1 have overlapping functions in pituitary development.⁶¹⁶ Finally, in addition to pituitary hormone deficiencies, *LHX4* mutations have been implicated in structural abnormalities; patients with an *LHX4* mutation have been reported with abnormal MRI findings including a hypoplastic anterior pituitary, ectopic posterior lobe, poorly developed sella turcica, and Chiari malformation.⁶²¹

SIX6. *SIX6* is a member of the SIX/sine oculis family of homeobox genes that is expressed in retina, optic nerve, hypothalamus, and pituitary.⁶²² Murine expression studies of the TCF/LEF family of transcription factors during pituitary development demonstrated that *Six6* plays a role in proliferation of cells during early formation of Rathke's pouch.⁶²³ *SIX6* has also been shown to interact with the Groucho family of transcriptional repressors.^{624,625} *SIX6* has been mapped to chromosome 14q22-23, and patients with deletions of this chromosomal region display bilateral anophthalmia and pituitary anomalies.⁶²⁶ Patients with anophthalmia/microphthalmia were shown to have several frequent polymorphisms of *Six6* and one potential causative missense mutation.⁶²² One case report implicated *SIX6* haploinsufficiency as being responsible for ocular and pituitary maldevelopment. Despite its importance in early development, further studies are required to determine whether *SIX6* mutations are present in patients with pituitary hormone deficiency.

ISL1. *ISL1* is a member of the LIM homeodomain family of transcription factors, which are characterized by two tandemly repeated cysteine/histidine-rich LIM domains that are involved in protein-protein interactions. Its expression is restricted to cells that will express CGA and subsequently *TSHB*.^{627,628} Homozygous loss of *Isl1* in mice results in developmental arrest with no pouch formation.⁶²⁹ To date, no human mutations in *ISL1* have been identified.

PROP1. Mutations in *PROP1*, a paired-like homeodomain transcription factor with expression restricted to the anterior pituitary during development, have also been found to result in CPHD.⁶³⁰ Mutation of this gene is responsible for a form of murine pituitary-dependent dwarfism known as the Ames mouse.^{55,631,632} The pituitary gland appears to be enlarged in mice bearing mutations in *Prop1*, although the mechanism is unclear.⁶³³⁻⁶³⁶ In the end, a decrease in proliferation and apoptosis result in pituitary hypoplasia, similar to that seen in humans.⁶³⁶⁻⁶³⁸ The switch from repression of target gene expression by HESX1 to activation by PROP1 is important for development of the POU1F1 (GH, PRL, and TSH) and gonadotroph lineages.^{544,635,639} PROP1 and β -catenin have been shown to form a complex that represses *Hesx1* while activating *Pou1f1* expression.⁶⁴⁰ The gonadotropin deficiency in the Ames dwarf remains unexplained, although treatment with thyroxine (T₄) or GH (or both) restored fertility in some male mice and sexual maturation, but not fertility, in female mice.^{641,642}

Mutations of *PROP1* in humans result in GH, PRL, and TSH deficiencies, although failure in all cell lineages, including gonadotrophs and corticotrophs, has been reported.^{632,643,644} The characterization of *PROP1* mutations

is complex, because the phenotypes are variable and dynamic and hormone deficiencies may develop over time even in patients with similar genetic backgrounds.^{643,645,646} Gonadotropin abnormalities are particularly diverse in that approximately 30% of patients have spontaneous pubertal development, including menarche, before ultimately developing hypogonadotropic hypogonadism.^{643,647} Apparently normal growth without GH has also been found in a child with *PROP1* deficiency.^{648,649} The ACTH deficiency may develop in the fourth or fifth decade of life.⁶⁵⁰ Striking variability has been described in pituitary size, with very large glands, possibly arising from the intermediate lobe,⁶⁵¹ producing a hyperintense T1 signal occasionally demonstrated by MRI.^{632,644,652,653} These glands may undergo involution, leaving a large empty sella in patients with complete anterior hypopituitarism including ACTH deficiency.⁶⁵⁴⁻⁶⁵⁶

Many *PROP1* (chromosome 5q35, OMIM 601538) abnormalities have been identified, including missense, frameshift, and splicing mutations. A GA repeat in exon 2 (295-CGA-GAG-AGT-303) has been reported to be a "hot spot" in *PROP1*; any combination of a GA or AG deletion in this repeat region results in a frameshift in the coding sequence and premature termination at codon 109.^{647,657} Similar abnormalities result from homozygous lesions at other sites on exon 2 and affect codons 73, 88, and 149.^{644,658,659} Compound heterozygosity for two mutations was detected in 36% of children from four families; two different common deletions both led to a stop codon at position 109.⁶⁵⁹ These mutations are predicted to result in loss of the DNA-binding and C-terminal transactivating domains of *PROP1*. Some missense mutations have been shown to retain partial activity.^{644,660,661}

There does not appear to be strong correlation between phenotype and genotype.⁶⁴⁷ A screen of 73 subjects (36 families) diagnosed with CPHD by Deladoey and associates identified 35 patients with *PROP1* gene defects, including three different missense mutations, two frameshift mutations, and one splice site mutation. In 12 of 36 unrelated families, defects were located in the region nt296 through nt302, suggesting a possible hot spot for *PROP1* mutations in CPHD.⁶⁴⁷ Although *PROP1* mutations appear to be rare in sporadic cases, their prevalence is 29.5% in familial cases of CPHD, as reported by Turton and colleagues.^{662,663}

POU1F1. The *POU1F1* gene (chromosome 3p11, OMIM 173110) encodes PIT1, a member of a large family of transcription factors referred to as POU-domain proteins that is responsible for pituitary-specific transcription of genes for GH, PRL, TSH, and the GHRH receptor.^{58,664-667} PIT1, a 290-amino-acid protein, contains two domains, the POU-specific and the POU-homeo domains; both are necessary for DNA binding and activation of GH and PRL genes and for regulation of the PRL, TSH- β , and *POU1F1* genes.⁶⁶⁸ Its expression is restricted to the anterior pituitary to control differentiation, proliferation, and survival of somatotrophs, lactotrophs, and thyrotrophs.^{593,667-670} PIT1 regulates target genes by binding to response elements and recruiting coactivator proteins, such as cAMP response element-binding protein (CREB)-binding protein (CBP).⁶⁷¹

Two mouse models were first reported to have GH, PRL, and TSH deficiencies associated with mutations or rearrangements of the *Pit1* gene; these were the Snell (dw/dwS) and the Jackson (dw/dwJ) dwarf mice.^{672,673} Many different mutations of the *POU1F1* gene have been found internationally in families with GHD and PRL deficiency and variable defects in TSH expression.^{631,664,669,674-682} These mutations are transmitted as autosomal recessive or dominant traits and cause variable peptide

hormone deficiencies with or without anterior pituitary hypoplasia.^{663,664,669,674,676-679,683,684}

The most common mutation is an R271W substitution that affects the POU homeodomain, encoding a mutant protein that binds normally to DNA and acts as a dominant inhibitor of transcription.^{663,685-688} Evidence from a patient with the R271W mutation suggests that PIT1 may have a role in cell survival.⁶⁸⁹ A patient diagnosed with GHD, along with dysregulation of PRL and TSH was reported to have a lysine-to-glutamic acid mutation at codon 216 (K216E).⁶⁶⁸ This mutant PIT1 binds to DNA and appears not to inhibit basal activation of GH and PRL genes; however, the mutant is unable to support retinoic acid induction of *POU1F1* gene expression. Another report suggested that CBP (p300) recruitment and PIT1 dimerization are necessary for target gene activation and that disruption of this process may account for the pathogenesis of CPHD.⁶⁹⁰ All of the reported mutations involve sites affecting *POU1F1* DNA-binding, dimerization, or target gene transactivation.

Phenotypic variability occurs among patients with apparently similar genotypes.⁶⁸⁴ It does not appear that ACTH or gonadotropin deficiencies occur, as is frequently the case with *PROP1* defects,⁶⁶³ but adrenarche has been reported to be absent or delayed in patients with a *POU1F1* mutation.⁶⁹¹

Isolated Growth Hormone Deficiency. The incidence of IGHD is estimated to be 1 of every 3,480 to 10,000 live births.^{88,692-694} In most children with IGHD, no cause can be identified, and this group is often referred to as having idiopathic GHD. However, there is increasing recognition of genetic defects in idiopathic GHD. Four forms of IGHD have been reported (see Table 24-2).^{593,664,695} The classification system is based on clinical characteristics, inheritance patterns, and GH secretion but not necessarily on disease causation.

The gene encoding GH (*GH1*) is located on chromosome 17q23 in a cluster that includes two genes for placental lactogen (hPL), a pseudogene for hPL, and the *GH2* gene that encodes placental GH.^{592,594} *GH1* and *GH2* differ in mRNA splicing pattern: *GH1* generates 20- and 22-kd proteins (of approximately equal bioactivity), whereas *GH2* yields a protein that differs from GH1 in 13 amino acid residues.

IGHD Type I. IGHD type IA results primarily from large deletions, with rare microdeletions and single base-pair substitutions of the *GH1* gene that prevent synthesis or secretion of the hormone.⁶⁹⁶ IGHD IA is inherited as an autosomal recessive trait, and affected individuals have profound congenital GHD. Because GH is not produced even in fetal life, patients are immunologically intolerant of GH and typically develop anti-GH antibodies when treated with either pituitary-derived or recombinant DNA-derived GH. When antibodies prevent patients from responding to GH, IGHD IA can be viewed as a form of GH insensitivity, and such patients are candidates for IGF1 therapy.

The less severe form of autosomal recessive GHD, termed IGHD type IB, also may result from mutations or rearrangements of the *GH1* gene that cause production of an aberrant GH molecule that retains some function or at least generates immune tolerance. The phenotypic variability is greater than in IGHD IA.⁶⁹⁵ These patients usually respond to exogenous GH therapy without antibody production. The very low frequency (1.7%) of *GH1* gene mutations in familial type IB IGHD suggests the importance of studying the *GH1* gene promoter region in patients with unexplained GHD.^{664,697} In a group of 65 children with IGHD IB, the GHRH receptor gene (*GHRHR*) was normal in domains coding for the extracellular region,⁶⁹⁸ but

mutations in transmembrane and intracellular gene domains were found in 10% of families with IGHD IB.⁶⁹⁹

IGHD Type II. IGHD type II is inherited as an autosomal dominant trait. The most common cause appears to be mutations that inactivate the 5' splice donor site of intron 3 of the *GH1* gene, resulting in skipping of exon 3^{631,664} and producing a molecule that cannot fold normally. It is likely that the 17.5-kd GH isoform mutant functions in a dominant-negative manner to suppress intracellular accumulation and secretion of wild-type GH.⁷⁰⁰⁻⁷⁰³ In patients with missense mutations in exon 4 or 5, clinical presentation is quite variable, with some evidence for reversibility of the impairment of intracellular GH storage and secretion by GH treatment.⁷⁰⁴ Mullis and coworkers⁷⁰⁵ studied 57 subjects from 19 families and found that patients with IGHD type II not only have a variable phenotype in terms of onset, severity, and progression of GHD but also may demonstrate later onset of ACTH or TSH deficiencies and pituitary hypoplasia. An extensive assessment of *GH1* gene mutations in short children with and without GHD did reveal a substantial number of heterozygous mutations.⁷⁰⁵ Even though these are not primary explanations for the growth impairment, they may contribute to the observed variation in the growth process.

Mutations in *GHRHR* are also classified as IGHD type IB. The GHRH receptor is G-protein coupled with seven transmembrane domains and is found predominantly in the pituitary gland. Mutation of the gene for *Ghrhr* in its ligand-binding domain has been identified in the *little mouse (lit/lit)*⁷⁰⁶ and results in dwarfism and decreased numbers of somatotrophs.^{667,707,708} In this model, the fetal somatotroph mass is normal, and hypoplasia (but not absence) of the somatotrophs is evident only postnatally.^{667,670,707,708} Such data suggest that GHRH is not an essential factor for fetal differentiation of the somatotrophs and that GHRH-independent cells persist or that mutation does not cause total loss of GHRH function. The human *GHRHR* gene is 15 kb with 13 exons. The GHRHR protein is encoded by a 1.3 kb cDNA.^{77,709-711}

Wajnrajch and colleagues reported the first human cases of a mutation in the *GHRHR* gene in two cousins in a consanguineous Indian Muslim family with IGF deficiency and profound growth failure.⁷¹² The gene defect, a nonsense mutation that introduced a stop codon at position 72 (E72X), resulted in a markedly truncated GHRHR protein that lacked the membrane-spanning regions and the G-protein-binding site. The affected children had undetectable GH release during standard provocative tests and after exogenous GHRH administration but responded to GH treatment. The same mutation was also identified in a reportedly unrelated Tamoulean kindred in Sri Lanka,⁷¹³ in a consanguineous kindred in Pakistan ("dwarfism of Sindh"),^{714,715} and in 17 patients from one Muslim and four Hindu families in Western India.⁷¹⁶ The largest kindred with a mutation of *GHRHR* was identified a Brazilian family with a homozygous donor splice mutation (G to A at position +1) of exon 1.⁸⁸ This mutation disrupts the highly conserved consensus GT of the 50-donor splice site, generating a truncated GHRHR.^{717,718}

A *GHRHR* missense mutation in exon 11 (R357C) was described in two consanguineous Israeli Arab families.⁷¹⁹ Patients in all of the groups had early growth failure with short stature (−4.5 to −8.6 SD), a high-pitched voice, and increased abdominal fat accumulation.^{714,718} As expected, all of the patients demonstrated severely reduced or undetectable serum concentrations of GH in response to provocative GH stimulation, as well as very low serum concentrations of IGF1, IGFBP3, and ALS.⁷¹⁸ The adults manifest an

unfavorable cardiovascular risk profile, which includes increased levels of low-density lipoprotein cholesterol and total cholesterol, elevated C-reactive protein, elevated blood pressure, and abdominal obesity. However, a perplexing study found no evidence of premature atherosclerosis or premature myocardial ischemia in these patients with *GHRHR* mutations.⁷²⁰ The patients respond well to exogenous GH without antibody formation. Heterozygotes may have minimal height deficits and may show moderate biochemical deficiencies of the GH-IGF axis.⁷¹⁴ Despite extensive study, the geographic separation and ethnic differences among these patient groups do not suggest recent (>200 years) contact among the families from the Indian subcontinent. At present, the likely explanation for all four families is that of a "founder effect" or one-time mutation in each group followed by propagation within a geographically isolated gene pool.⁸⁸ In an analysis of 30 families with IGHD type IB, Salvatori and colleagues⁶⁹⁹ found new missense mutations in transmembrane and intracellular domains of the *GHRHR* in three families (10%), with two affected members in each. Transfection experiments indicated normal cellular expression of these mutant receptors.

IGHD Type III. IGHD type III, transmitted as an X-linked trait with associated hypogammaglobulinemia,⁷²¹ has not yet been related to a mutation of the *GH1* gene. A large Australian kindred demonstrated GHD with a variable spectrum of pituitary hormonal deficiencies that may have been caused by duplication of the Xq25-Xq28 region.⁷²²

Bioinactive GH. Serum GH exists in multiple molecular forms, reflecting the consequences of alternative post-transcriptional or post-translational processing of the mRNA or protein, respectively. Some of these forms are presumed to have defects in the amino acid sequences required for binding of GH to its receptor, and different molecular forms of GH may have varying potencies for stimulating skeletal growth, although this remains to be rigorously proved. Short stature with normal GH immunoreactivity but reduced biopotency has been suggested,^{723,724} but the molecular abnormalities have been characterized in relatively few patients, and many cases of suspected bioinactive GH have not been rigorously proven.^{725,726}

In one child with extreme short stature (−6.1 SDS), a mutant GH caused by a single missense heterozygous mutation (cysteine to arginine, codon 77 of *GH1*) bound with greater affinity than normal to GHBP and the GHR and inhibited the action of normal GH. The child grew more (6 versus 3.9 cm/year) during a period of exogenous GH in moderate dosage. The father was found to have the same genetic abnormality but did not express the mutant hormone. In a second patient⁷²⁶ with marked short stature (−3.6 SDS), a heterozygous alanine-to-glycine substitution in exon 4 of GH led to a substitution of glycine for arginine. This mutation was located in site 2 of GH molecular binding with its receptor and apparently led to failure of appropriate molecular rotation of the dimerized receptor and subsequent diminished tyrosine phosphorylation and the GH-mediated intracellular cascade of events. Bioactivity determined in a mouse B-cell lymphoma line was about 33% of immunoreactivity.⁷²⁷ Exogenous GH substantially increased growth velocity (from 4.5 to 11.0 cm/year).

An Ile179Met substitution found in a short child was characterized by normal STAT5 activation but a 50% decrement in ERK activation.¹⁷³ This novel finding demonstrated the complexity of the functional interaction of GH with its receptor, but because STAT5B is clearly the major (if not the sole) GH-dependent mediator of IGF1 gene transcription, the role of this mutation is not clear. Six GH heterozygous variants with evidence of impairment of JAK/

STAT activation were found by screening of short children, suggesting that further studies are needed to determine the mechanism of interaction of GH with its receptor.⁷²⁸ Because these variants occur in heterozygotes, the genotype-phenotype correlations are unclear. In one of the more convincing cases of bioinactive GH reported to date, Besson and associates⁷²⁹ found a homozygous missense mutation (G705C) in a short child (−3.6 SDS) that resulted in absence of two disulfide bridges. Both GHR binding and JAK2/STAT5 signaling activity were markedly reduced.

Some patients demonstrate a decrease in bioactivity (when measured by sensitive *in vitro* assays) but not in immunoreactivity. The absence of mutations suggests that abnormal post-translational modifications of GH or other peripheral mechanisms may be responsible.^{730,731}

Acquired Disorders

Craniopharyngiomas and Other Tumors. Many tumors that impair hypothalamic function also affect pituitary secretion of GH. In addition, *craniopharyngiomas* are a major cause of pituitary insufficiency.⁷³²⁻⁷³⁴ These tumors arise from remnants of Rathke's pouch, the diverticulum of the roof of the embryonic oral cavity that normally gives rise to the anterior pituitary. Genetic defects in this condition, although certainly reasonable to suspect, have not yet been identified. This tumor is a congenital malformation present at birth and gradually grows over the ensuing years. The tumor arises from rests of squamous cells at the junction of the adenohypophysis and neurohypophysis and forms a cyst as it enlarges; the cyst contains degenerated cells and may calcify but does not undergo malignant degeneration. The cyst fluid ranges from the consistency of machine oil to a shimmering, cholesterol-laden liquid, and the calcifications may be microscopic or gross.⁷³⁵ About 75% of craniopharyngiomas arise in the suprasellar region; the remainder resemble pituitary adenomas.⁷³⁵⁻⁷⁴⁰

Craniopharyngiomas can cause manifestations at any age from infancy to adulthood but usually manifest in middle childhood. The most common presentation results from increased intracranial pressure and includes headaches, vomiting, and oculomotor abnormalities. Visual field defects result from compression of the optic chiasm, and papilledema or optic atrophy may be present. Visual and olfactory hallucinations have been reported, as have seizures and dementia. Most children with craniopharyngiomas have evidence of growth failure at the time of presentation, and they are often found retrospectively to have had reduced growth since infancy.⁷⁴¹ GH and the gonadotropins are the most commonly affected pituitary hormones in children and adults, but deficiency of TSH, ACTH, may also occur, and diabetes insipidus is present in 25% to 50% of patients.^{735-737,742} Between 50% and 80% of patients have abnormalities of at least one anterior pituitary hormone at diagnosis.^{736,742}

Cystic and solid components can be identified by MRI, and anatomic relationships can be delineated to help plan a rational operative approach. Operative intervention via craniotomy or transsphenoidal resection may result in partial or almost complete removal of the lesion. Postoperative irradiation is commonly used, especially if tumor resection was incomplete. In some patients, particularly those who become obese, a syndrome of normal linear growth without GH may occur. The metabolic syndrome, with evidence of insulin insensitivity and increased body mass index (BMI), is common and is a predictor of potential major long-term morbidity.^{741,743,744} The long-term childhood and adolescent consequences of craniopharyngioma are substantial, with many quality-of-life issues exacerbating the hypopituitarism.

Pituitary adenomas (see Chapter 8) are infrequent during childhood and adolescence, accounting for fewer than 5% of patients undergoing surgery at large centers.^{739,740,745} Almost two thirds of tumors immunochemically stain for PRL, and a small number stain for GH. GH-secreting pituitary adenomas are exceedingly unusual in youth. There is a variable experience as to the invasive nature of pituitary adenomas, but the prevailing opinion is that they are less aggressive in children than in adults.^{739,745} In 56 patients at the Mayo Clinic with non-ACTH-secreting adenomas removed transsphenoidally, macroadenomas were about one third more frequent than microadenomas, with cases in girls outnumbering those in boys 3.3 to 1.⁷³⁹ The patients with macroadenoma had an approximately 50% incidence of hypopituitarism, compared with zero incidence in those patients with microadenomas; long-term cure rates were between 55% and 65% for both tumor sizes.

Histiocytosis X. The localized or generalized proliferation of mononuclear macrophages (histiocytes) characterizes Langerhans cell histiocytosis, a diverse disorder that occurs in patients of all ages, with a peak incidence at ages 1 to 4 years.⁷⁴⁶ Endocrinologists are more familiar with the term *histiocytosis X*, which includes three related disorders: solitary bony disease (eosinophilic granuloma), Hand-Schüller-Christian disease (chronic disease with diabetes insipidus, exophthalmos, and multiple calvarial lesions), and disseminated histiocytosis X (Letterer-Siwe disease, with widespread visceral involvement). These syndromes are characterized by an infiltration and accumulation of Langerhans cells in the involved areas, such as skull, hypothalamic-pituitary stalk, CNS, and viscera. Although these disorders, especially Hand-Schüller-Christian disease, are classically associated with diabetes insipidus, approximately 50% to 75% of patients in selected series have growth failure and GHD at the time of presentation.⁷⁴⁷⁻⁷⁴⁹ In contrast, a French national registry ($n = 589$) found GHD in 61 subjects, with overall endocrine dysfunction in 148. In the latter group, an evolving neurodegenerative syndrome (identified in 10% of patients with 15-year follow-up) seemed to be associated with pituitary involvement.⁷⁵⁰ Only 1% of unselected children with Langerhans cell histiocytosis living in Canada during a 15-year period had GHD.⁷⁵¹

Growth Hormone Insensitivity

Mutations in GHR Signaling Proteins and ALS. Conditions of GH insensitivity, also referred to as primary IGF1 deficiency, encompass a variety of genetic conditions characterized by growth failure, high serum GH levels, and very low serum IGF1 levels.⁷⁵² These findings, first described in siblings in 1966 by Laron and colleagues,⁷⁵³ are also known collectively as *Laron syndrome*. Fewer than 500 cases of true GH insensitivity have been identified worldwide, with most individuals from pedigrees of Mediterranean or Middle Eastern descent. Members of a well-described pedigree from Ecuador were from an inbred population with Mediterranean origins.⁷⁵⁴

The phenotypic characteristics of GH insensitivity include growth failure evident at birth⁷⁵³ with postnatal subnormal growth velocities and stature −4 to −10 SD below the mean (Fig. 24-34).⁷⁵² Patients also have a subnormal head circumference, protruding forehead, abnormal upper- to lower-body ratio, short extremities, and sparse hair (Table 24-4). There is delayed motor development, indicating the importance of IGF1 in cerebral development. The genitalia are small, and puberty is delayed, but fertility is normal. Metabolically, the most striking feature of IGF1 deficiency is hypoglycemia with later development of obesity, relative hyperinsulinemia, and insulin resistance.⁷⁵⁵ Individuals do not respond to exogenous GH, as

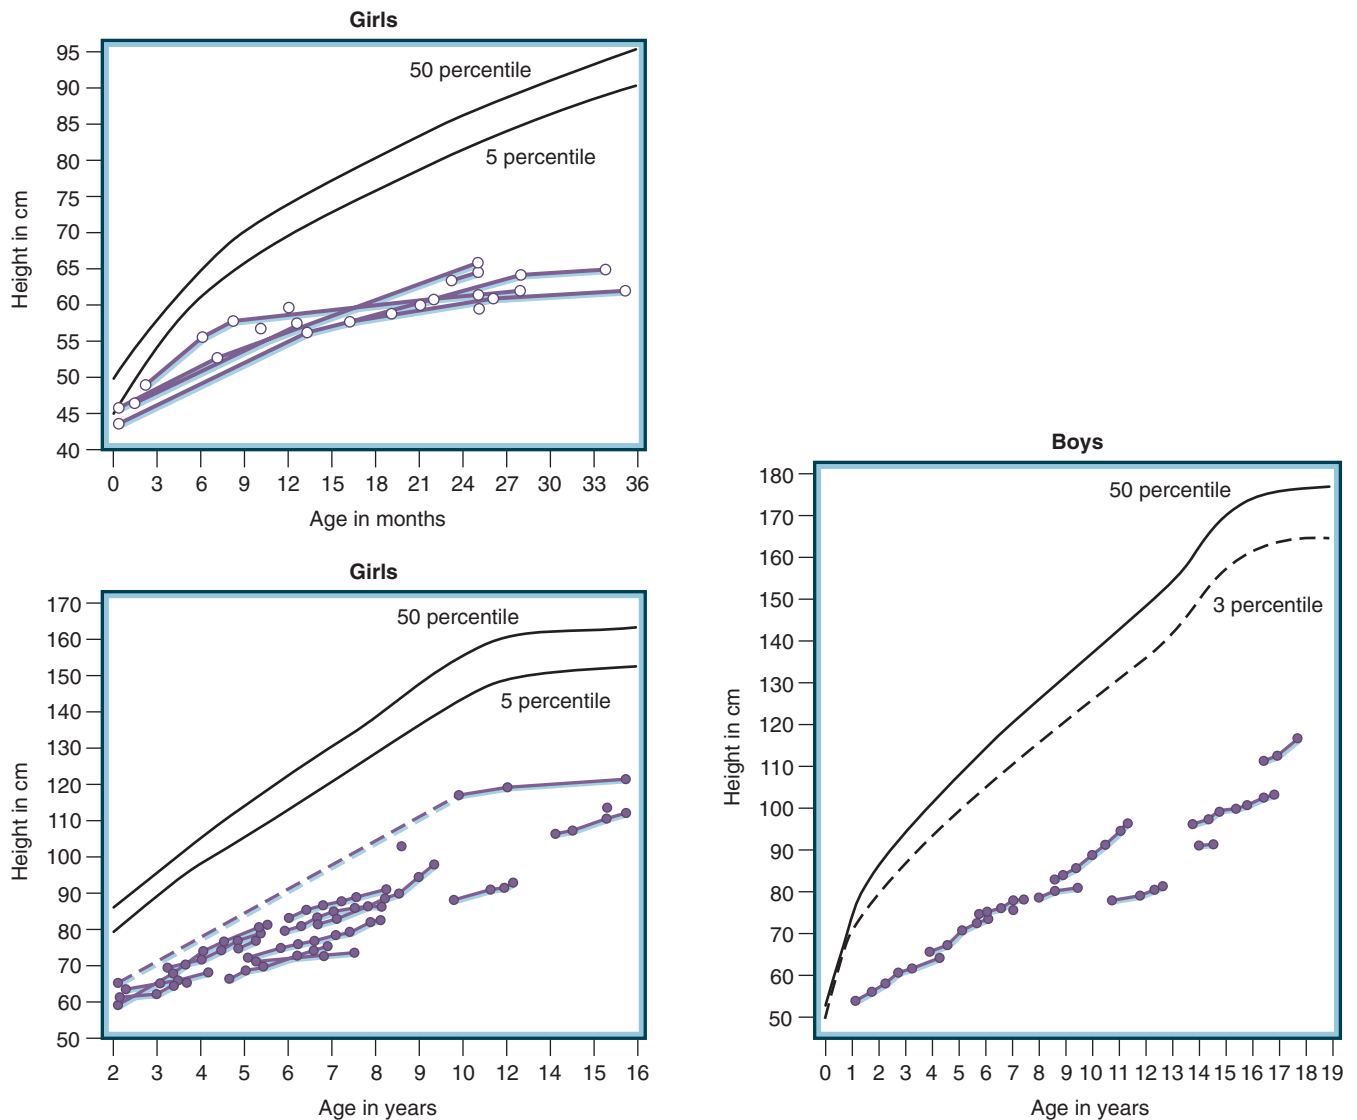

Figure 24-34 Height measurements for Ecuadorian children with insulin-like growth factor (IGF) deficiency resulting from growth hormone (GH) insensitivity. (From Rosenfeld RG, Rosenbloom AL, Guevara-Aguirre J. Growth hormone [GH] resistance due to primary GH receptor deficiency. *Endocr Rev.* 1994;15:369-390.)

determined by growth velocity, hypoglycemia incidence, or serum IGF1 or IGFBP1 levels.⁷⁵⁶ In addition, GHBP activity is usually undetectable in sera of these patients,^{757,758} but measurable levels correspond to higher final heights.

Almost 20 years after the original description of GH insensitivity, liver biopsy performed on two affected patients demonstrated that microsomal cells did not bind recombinant GH, suggesting a defect in the GHR.⁷⁵⁹ Subsequently, both deletions and homozygous point mutations (missense, nonsense, and abnormal splicing) in the GHR were described in persons with GH insensitivity.^{702,760,761} The initial described gene deletion involved exons 3, 5, and 6.⁷⁶² Deletion of exons 5 and 6 results in a frameshift and a premature translational stop signal with consequent encoding of a receptor lacking most of the extracellular GH-binding domain.

More than 60 distinct mutations of the GHR gene resulting in GH insensitivity have been reported to date.⁷⁶³ Most of the mutations are in the extracellular (GH-binding) domain of the receptor and result in impaired ability of GH to bind to the receptor; this leads to a deficiency of circulating GHBP, which is derived from the extracellular

domain of the receptor. One reported mutation of the extracellular domain does not affect GH binding to the receptor but prevents dimerization of the receptor.¹⁸⁸ Homozygous mutations have also been reported in the transmembrane domain.^{189,764} These mutations result in GH insensitivity with normal GH binding but lack of receptor transduction. Because the extracellular domain is intact and the mutant receptor protein apparently becomes detached from the cell receptor surface, GHBP levels are normal to elevated.

Mutations affecting the intracellular domain of the GHR have also been found. Two defects directly involving the intracellular domain have been reported to result in dominantly inherited GH insensitivity.⁷⁶⁵⁻⁷⁷⁰ In the two heterozygous mutations reported, truncation of the GHR results in absence of the intracellular domain. In vitro, the GHR molecule behaves in a dominant negative manner, presumably by retaining an ability to dimerize with the normal GHR and thereby inhibiting GH-induced tyrosine phosphorylation of STATs.⁷⁶⁹⁻⁷⁷¹ Mutations resulting in C-terminal deletions of the intracellular domain of the GHR have been shown to exhibit normal GH binding and

TABLE 24-4

Clinical Features of Classic Growth Hormone Insensitivity

Parameter	Clinical Finding
Growth and Development	
Birth weight	Near-normal
Birth length	May be slightly decreased
Postnatal growth	Severe growth failure
Bone age	Delayed, but may be advanced relative to height age
Genitalia	Micropenis in childhood; normal for body size in adults
Puberty	Delayed 3 to 7 years
Sexual function and fertility	Normal
Craniofacies	
Hair	Sparse before age 7 years
Forehead	Prominent; frontal bossing
Skull	Normal head circumference; craniofacial disproportion due to small facies
Facies	Small
Nasal bridge	Hypoplastic
Orbits	Shallow
Dentition	Delayed eruption
Sclerae	Blue
Voice	High-pitched
Musculoskeletal/Metabolic/Miscellaneous	
Blood glucose	Hypoglycemia in infants and children; fasting symptoms in some adults
Walking and motor milestones	Delayed
Hips	Dysplasia; avascular necrosis of femoral head
Elbow	Limited extensibility
Skin	Thin, prematurely aged
Bone mineral density	Osteopenia

JAK2 phosphorylation but impaired phosphorylation of STAT5B.^{772,773}

That a dominant negative effect has been described for some mutations raises the question of whether heterozygosity for defects of the extracellular domain can also result in short stature. Heterozygosity for defects of the GHR has been reported to cause some degree of relative GH insensitivity, with modest growth improvement occurring only with high doses of GH.⁷⁷⁴⁻⁷⁷⁷ In addition, a truncated GHR splice variant has been described that functions as a dominant negative inhibitor of the full-length receptor and results in large amounts of GHBP, further downregulating GHR function.⁷⁷⁸

The most extensively studied polymorphism in the GHR gene is the deletion of exon 3 (*GHRd3*), which is present in up to 50% of Caucasians. It has been proposed that GHRs without exon 3 bind GH with comparable affinity^{779,780} but may transduce the signal with a different intensity *in vitro*.⁷⁸¹ In an observational study, GH treatment of short children with GHD found that those with one or two copies of the *GHRd3* variant grew faster than other children after correction for GH dosing.⁷⁸¹ Similar observations were reported in studies of patients with TS and children with SGA.⁷⁸² Different studies reported different findings on whether GH-deficient children with the *GHRd3* variant experience faster growth.⁷⁸³⁻⁷⁸⁵ Different GH dosing between studies and differences among the populations studied could account for the varying results.

Some patients with the phenotype of GH insensitivity but without mutations of the GHR gene have been found to have mutations in downstream GHR signaling molecules. Homozygous mutations in the *Stat5B* gene have been found to cause GH insensitivity.^{786,787} The first mutation characterized was a point mutation that causes a marked decrease in phosphorylation of tyrosine,⁶⁹⁹ a critical step in the pathway to STAT activation of IGF1 gene transcription. The mutant *Stat5B* did not have the ability to dock with phosphotyrosines on GH-activated receptors or to stably bind DNA⁷⁸⁸ and exhibited aberrant folding and diminished solubility with aggregation and inclusion body formation.⁷⁸⁹ The second characterized mutation was an insertion in exon 10 that leads to early protein termination.⁷⁸⁷ Both patients had evidence of immune dysfunction and recurrent pulmonary infections, presumably because *Stat5B* is involved in downstream signaling for multiple cytokines. To date, no mutations of the genes for JAK2 or MAP kinase have been implicated in GH insensitivity. Deletion of *Jak2* in mice is embryonically lethal, as detailed earlier.

Markedly reduced serum concentrations of IGF1 and IGFBP3 have been observed in two cases involving mutations of the *ALS* gene.^{790,791} Even though IGF1 and IGFBP3 were as low as in patients with classic GH insensitivity, the index case attained an adult height within the normal range. Whether the relatively normal growth of these patients reflects the greater importance of locally produced IGF1 or altered kinetics of serum IGF1 in the face of reduced concentrations of binding proteins remains uncertain.

Abnormalities of IGF1 and IGF1 Receptor Signaling. Woods and colleagues⁷⁹² described a 15-year-old boy with deletion of exons 4 and 5 of the IGF1 gene that resulted in a truncated IGF1 molecule. The boy exhibited severe prenatal and postnatal (approximately -7 SDS) growth retardation unresponsive to GH in addition to sensorineural deafness, mental retardation, and microcephaly. He had normal IGFBP3 and GHBP levels, undetectable IGF1 levels, and hyperinsulinism. On treatment with IGF1, the child experienced growth and improved metabolic parameters.⁷⁹³

Inactivating Mutation of the IGF1 Gene. An adult was identified who had the same phenotype as the boy with the IGF1 deletion but with markedly elevated serum IGF1 levels.³⁴¹ A homozygous point mutation in the IGF1 gene was found. This mutation resulted in an IGF1 molecule with markedly reduced affinity for the IGF1 receptor that poorly stimulated autophosphorylation of the IGF1 receptor and activation of AKT or ERK.⁷⁹⁴ Family members heterozygous for this mutation were found to have significantly lower birth weight, final height, and head circumference, suggesting an effect of heterozygosity for this mutation on IGF1 function.

Primary Defects of IGF Transport and Clearance. An extremely short boy (-6 SDS) with increased GH, normal IGF1, and 20- to 30-fold elevated IGFBP1 levels had improvement in growth and suppression of IGFBP1 levels with GH administration. The growth failure was hypothesized to result from inhibition of IGF1 action by IGFBP1. Tollefson and colleagues identified a child with growth failure whose fibroblasts were resistant to IGF1.⁷⁹⁵ The fibroblasts were able to be stimulated with an IGF variant that exhibited a 600-fold lower binding affinity for IGFBPs and secreted more IGFBPs than normal, suggesting an IGFBP inhibition of IGF1 action.

Primary Defects of IGF1 Receptor Production or Responsiveness. In mouse knockout models, homozygous mutations of the IGF1 receptor resulted in profound growth

failure and neonatal mortality, so it is doubtful that significant mutations of the IGF1 receptor will be found in patients. Patients with IUGR and postnatal growth failure, microcephaly, and mental retardation with normal to elevated serum IGF1 levels have been reported to have reduced binding of IGF1 to its receptor.^{349,796} Studies in the African Efe pygmies demonstrated extreme insensitivity to the in vitro growth-enhancing effects of IGF1.⁷⁹⁷ Explanations for these findings include reduced IGF1 receptor transcripts and sites with resultant diminished tyrosine phosphorylation and postreceptor signaling.

In leprechaunism, a syndrome of growth failure and insulin receptor dysfunction, there is variable IGF1 insensitivity.^{798,799} The profound abnormality of the insulin receptor suggests that heterodimeric insulin and IGF1 receptor combinations might lead to failed activation of the IGF1 signaling cascade. The IGF1 receptor gene resides on 15q, so persons with deletions of the distal long arm of chromosome 15 or ring chromosome 15 have heterozygosity of the IGF1 receptor.^{798,800} These patients may have IUGR and postnatal growth failure, but lack of a biologic response to IGF1 has not been conclusively demonstrated.⁸⁰⁰ Therefore, whether the growth failure is caused by altered levels of IGF1 receptor or is a result of the loss of other genes located on 15q remains to be determined.

Disorders outside the Growth Hormone-IGF Axis

Many systemic disorders, if severe enough, can cause growth failure in children. Those that primarily alter hormones that directly regulate growth (e.g., thyroid hormone, glucocorticoids) can be understood based on the known actions of those hormones. Even in those disorders in which the pathology is not primarily within the endocrine system, there is often an underlying hormonal abnormality contributing to the growth failure. In some cases, the underlying disorder produces a secondary hormone deficiency. Those disorders in which a hormone deficiency cannot be identified may be thought of as demonstrating hormone resistance, because these children have growth failure in the presence of normal GH production.

Malnutrition

Given the worldwide presence of undernutrition, it is not surprising that inadequate intake of energy (calories) or protein or both is the most common cause of growth failure.⁸⁰¹ *Marasmus* refers to an overall deficiency of calories including protein malnutrition. Subcutaneous fat is minimal, and protein wasting is marked. *Kwashiorkor* refers specifically to inadequate protein intake, although it may also be characterized by some caloric undernutrition. In both conditions, multiple deficiencies of vitamins and minerals are apparent.⁸⁰² Frequently, the two conditions overlap. Decreased weight growth usually precedes the failure of linear growth by a very short time in the neonatal period and by several years at older ages. Stunting of growth due to caloric or protein malnutrition in early life often has lifelong consequences, including diminished skeletal growth.⁸⁰³

Both acute and chronic malnutrition affect the GH/IGF1 system. The impaired growth seen in malnutrition is usually associated with elevated basal or stimulated serum GH levels,⁸⁰⁴⁻⁸⁰⁶ although in some cases of generalized malnutrition (*marasmus*) the GH levels are normal or low.⁸⁰⁷ In both conditions, serum IGF1 levels are reduced.^{808,809} The increase in GH levels is caused by a decrease in negative feedback by IGF1 and a decrease in somatostatin

Figure 24-35 Curves of weight and height for a child who had growth failure resulting from prolonged self-imposed caloric restriction due to a fear of becoming obese. Notice that crossing of percentiles on the weight curve preceded that on the height curve, and that, after caloric intake was normalized (arrow), gain in weight occurred before improvement in linear growth. At the end of the prolonged period of caloric restriction, weight age (10.2 years) was less than height age (12 years). (From Pugliese MT, Lifshitz F, Grad G, et al. Fear of obesity: a cause of short stature and delayed puberty. *N Engl J Med.* 1983;309:513-518. Reprinted by permission of the *New England Journal of Medicine.*)

tone.⁸¹⁰ Malnutrition also results in increased ghrelin levels,^{811,812} which could also contribute to an increase in GH secretion, although the role of ghrelin in regulating GH secretion remains unclear.⁸¹³ With serum IGF1 levels reduced despite normal or elevated GH levels, malnutrition is a form of GH insensitivity. One cause of this insensitivity is a decrease in GHR expression, which is reflected in decreased serum GHBP levels.^{423,805} This GH insensitivity may be an adaptive response, diverting scarce energy resources from growth toward use for acute metabolic needs. The low IGF1 minimizes stimulation of anabolism, whereas the direct actions of the elevated GH levels (e.g., lipolysis, insulin antagonism) may increase the availability of energy substrates.^{814,815} These adaptive mechanisms are accompanied by changes in serum IGF1 levels that further limit IGF action during periods of malnutrition.^{805,816}

Inadequate calorie or protein intake complicates many chronic diseases that are characterized by growth failure. Anorexia is a common feature of renal failure and inflammatory bowel disease, and it also occurs with cyanotic heart disease, congestive heart failure, CNS disease, and other illnesses. Some of these conditions may be further characterized by deficiencies of specific dietary components, such as zinc, iron, and vitamins necessary for normal growth and development.

Undernutrition may also be voluntary, as with dieting and food fads (Fig. 24-35).⁸¹⁷ Caloric restriction is especially common in girls during adolescence, in whom it may be

associated with anxiety concerning obesity, and in gymnasts and ballet dancers. Anorexia nervosa and bulimia are extremes of “voluntary” caloric deprivation that are commonly associated with impaired growth before epiphyseal fusion, which may result in diminished final adult height.⁸¹⁸⁻⁸²⁰ Adolescent bone mineral accretion is impaired, and significant osteopenia may persist into adulthood.⁸²¹ Later in adolescence, malnutrition may cause delayed puberty or menarche or both, as well as a variety of metabolic alterations. In anorexia nervosa, hormonal profiles are similar to those in protein-energy malnutrition,^{818-820,822} with high basal levels of GH. However, in contrast to chronic critical illness, in which there is an increase in nonpulsatile secretion but a decrease in pulsatile GH secretion, in anorexia both nonpulsatile and pulsatile secretion of GH are increased.⁸¹⁰ The GH secretion stimulated by insulin-induced hypoglycemia, dopaminergic agents, or acute administration of dexamethasone is impaired in patients with anorexia nervosa, whereas clonidine and arginine elicit normal GH responses. Finally, a paradoxical increase in GH release to intravenous glucose infusion has been described.⁸¹⁰ As in malnutrition in general, low levels of IGF1 and IGFBP3 are found in anorexia nervosa, indicating GH resistance. Similarly, GHBP levels are decreased,⁸¹⁰ indicating a decrease in GHR expression as a contributing factor to the GH resistance. The hormones of the GH-IGF1 axis return to normal levels with refeeding.^{805,818,823}

A rare cause of failure to thrive in infants and young children is the diencephalic syndrome.⁸²⁴ This syndrome is characterized by a marked impairment of weight gain, or even weight loss, but with normal linear growth (at least initially). It is caused by hypothalamic tumors. Similar to the findings in other causes of low weight for length or height, increased GH levels have been found in patients with diencephalic syndrome. As in patients with anorexia nervosa, GH levels paradoxically increase in response to a glucose load. However, in contrast to the increased GH secretion seen in malnutrition or anorexia nervosa, IGF1 levels are normal rather than decreased.⁸²⁴ Therefore, diencephalic syndrome does not demonstrate GH resistance in the way that these other disorders do.

Chronic Diseases

Malabsorption and Gastrointestinal Diseases. Intestinal disorders that impair absorption of calories or protein cause growth failure, for many of the same reasons as malnutrition per se.^{814,825-827} Growth retardation may predate other manifestations of malabsorption or chronic inflammatory bowel disease. Celiac disease (gluten-induced enteropathy) and regional enteritis (Crohn's disease) should be considered in the differential diagnosis of unexplained growth failure. Serum levels of IGF1 may be reduced,^{814,828} reflecting the malnutrition, and it is critical to discriminate between these conditions and disorders related to GHD. Documentation of malabsorption requires demonstration of fecal wasting of calories, especially fecal fat, along with other measures of gut dysfunction such as the D-xylose or breath hydrogen studies.

In celiac disease, an immune-mediated disorder in which the intestinal mucosa is damaged by dietary gluten (Fig. 24-36), impaired linear growth may be the first manifestation of disease.^{814,829-832} The degree of growth impairment may be similar in patients with or without gastrointestinal symptoms.⁸¹⁴ Celiac disease has an increased incidence in individuals with TS, insulin-dependent (type 1) diabetes mellitus (IDDM), Down syndrome, or Williams' syndrome. In European studies, celiac disease is the cause of unexplained growth impairment in 5% to 20% of unselected patients, although this high

Figure 24-36 Catch-up growth in a girl with gluten-induced enteropathy (celiac disease). After 8 years of growth impairment, the patient was placed on a gluten-free diet and demonstrated substantial catch-up growth, returning to the previous growth percentiles. (Courtesy of J.M. Tanner.)

frequency does not hold true in many centers and may reflect varying stringency in the diagnostic criteria employed.⁸³⁰⁻⁸³² The onset and progression of puberty may be delayed, and menarche may be late.⁸²⁹ Measurement of an immunoglobulin A (IgA) tissue transglutaminase antibody (tTG-IgA)⁸³³ is the currently recommended screening test. This test has a sensitivity of up to 99%, with much higher specificity than IgA gliadin antibodies (AGA-IgA). However, tTG-IgA has significantly lower sensitivity in children less than 18 months of age,⁸³⁴ where it may be preferable to also measure AGA-IgA. When measuring IgA antibodies, it is necessary to measure total IgA levels to exclude IgA deficiency, particularly because IgA deficiency has an increased incidence in patients with celiac disease.⁸³⁵ (In subjects with IgA deficiency, tTG-IgG may be used.⁸³⁵) Nonetheless, the diagnosis of celiac disease ultimately requires demonstration of the characteristic mucosal flattening in small bowel biopsy. The incidence of childhood celiac disease in the United States is about 0.9%.⁸³⁶ Gluten withdrawal is a highly effective treatment for celiac disease and results in rapid catch-up growth and decreased clinical symptoms during the first 6 to 12 months of treatment.^{814,829} Low IGF1 and IGFBP3 levels return to normal during this period.^{828,837} Most children who receive appropriate dietary management ultimately achieve a normal final height.^{838,839}

Growth failure in Crohn's disease, which correlates with disease severity,^{840,841} is probably due to a combination of malnutrition from malabsorption, anorexia, nutrient loss, chronic inflammation,^{826,827,841} inadequacy of trace minerals in the diet, and use of glucocorticoids. IGF1 levels are low, especially with impaired growth.^{814,827} In an animal model, approximately one half of the decrease in IGF1 levels was accounted for by undernutrition, with the other half attributable to the effects of inflammation.⁸⁴² One

third to two thirds or more of children with Crohn's disease have impaired growth at diagnosis. In some patients, the growth failure precedes clinical symptoms of bowel disease by a few years, with a significant number showing linear growth failure before any weight loss.^{814,827,841,843,844} Adequate nutritional supplementation and surgical resection of the diseased intestine can lead to improved growth, but surgery is not always an option.⁸⁴⁵⁻⁸⁴⁸ Osteopenia is common.^{849,850} An elevated erythrocyte sedimentation rate, anemia, and low serum albumin are useful clues, but diagnosis of Crohn's disease ultimately requires colonoscopy and biopsy, along with gastrointestinal imaging studies. Permanent impairment of linear growth and deficits of final height may occur in 30% of patients.⁸⁵¹ Approximately 20% of patients at adult height are more than 8 cm below the midparental target height.⁸⁵² Small, mostly uncontrolled trials of GH treatment in children with Crohn's disease have had conflicting results: some have shown improved growth velocity,^{853,854} but others have not.⁸⁵⁵ Some have shown improved body composition and BMD.⁸⁵³ None of the reports, however, has extended beyond 2 years of treatment to determine whether there is a long-term benefit.

Chronic Liver Disease. Chronic liver disease in childhood can cause impaired linear growth. Decreased food intake, fat and fat-soluble vitamin malabsorption, and trace element deficiencies contribute to growth failure.⁸⁵⁶⁻⁸⁶⁰ In addition, these children show evidence of GH resistance, having decreased levels of IGF1 and IGFBP3 and increased GH secretion.⁸⁶¹⁻⁸⁶⁴ IGF2 levels are also decreased, and IGFBP1 levels are increased.⁸⁶¹⁻⁸⁶³ Although the low IGF1 levels might be due to the impaired synthetic capacity of the liver, there is decreased expression of the GHR in cirrhotic liver, just as in malnutrition.⁸⁶⁵ However, despite provision of adequate calories, insensitivity to the action of GH persists,^{859,862} suggesting that the GH resistance of liver failure is not due solely to malnutrition. Liver transplantation prolongs life expectancy, and linear growth is variably improved in the early post-transplantation years.^{858,863,866,867} Exogenous glucocorticoid administration presumably plays a major role in the continued growth retardation^{858,867}; GH and IGF1 production are normal, but the amount of "free IGF" may be decreased, because IGFBP3 levels are relatively high.^{863,866} Post-transplantation growth is inversely correlated with age and directly correlated with the degree of growth impairment at transplantation.^{857,858,866} Exogenous GH treatment enhances growth rates and increases median height SDS by 0.3 to 0.6 units after 1 year of treatment,⁸⁶⁸⁻⁸⁷⁰ with continued increases in height SDS for up to 5 years during treatment.⁸⁶⁸

Cardiovascular Disease. Congenital heart disease with cyanosis or chronic congestive heart failure can cause growth failure.⁸⁷¹⁻⁸⁷³ As many as 27% of children with varied cardiac lesions were below the 3rd percentile for height and weight in one survey,⁸⁷⁴ and 70% were lower than the 50th percentile in another.⁸⁷⁵ Because cardiac defects are usually congenital, many infants have dysmorphic features and IUGR. Inadequate caloric intake is the most common cause of growth impairment in children with congenital heart disease^{873,875,876} and is frequently associated with anorexia and vomiting. Chronic congestive heart failure is associated with malabsorption that includes protein-losing enteropathy, intestinal lymphangiectasia, and steatorrhea. Greater cardiac and respiratory work requirement and the relatively higher ratio of metabolically active, energy-utilizing brain and heart tissue to the growth-retarded body mass (cardiac cachexia⁸⁷⁷) cause an

increased basal metabolic rate in these children.⁸⁷⁸⁻⁸⁸⁰ Food intake that appears adequate for the child's weight is often inadequate for normal growth. The degree of cyanosis or hypoxia does correlate with the degree of growth impairment.^{873,875,881} Decreased levels of IGF1 and IGFBP3^{880,882,883} and normal levels of GH and hepatic GHRs in chronically hypoxemic newborn sheep⁸⁸³ suggest GH insensitivity distal to the GHR. Linear growth and pubertal maturation depend on left ventricular function in children and adolescents with complicated rheumatic heart disease.⁸⁸⁴

Corrective surgery may restore normal growth, frequently after a phase of catch-up growth with normalization of energy expenditure.^{879,885} Surgery must, on occasion, be delayed until the infant reaches an appropriate size, resulting in the conundrum that surgery corrects growth failure but cannot be performed because the infant is too small. In these situations, meticulous attention to caloric support and alleviation of hypoxia and heart failure are necessary to promote growth before surgery. This problem has diminished over time because of operative successes in the neonatal period. The nutritional management of these infants includes calorie-dense feedings because of the need to restrict fluids, calcium supplementation because of the use of diuretics that can cause calcium loss in the urine, and iron to maintain an enhanced rate of erythropoiesis.

Renal Disease. All conditions that impair renal function can impair growth.⁸⁸⁶⁻⁸⁹⁰ Uremia and renal tubular acidosis can cause growth failure before other clinical manifestations become evident. The growth impairment results from multiple mechanisms, including inadequate formation of 1,25-dihydroxycholecalciferol (1,25-dihydroxyvitamin D₃, calcitriol) with resultant osteopenia, decreased caloric intake, loss of electrolytes necessary for normal growth, metabolic acidosis, protein wasting, insulin resistance, chronic anemia, compromised cardiac function, and impairment of GH and IGF production and action. In nephropathic cystinosis, acquired hypothyroidism contributes to the inadequate growth.⁸⁹¹ Between 60% and 75% of patients with chronic renal failure treated before the GH therapeutic era had final adult heights more than 2 SD below the mean.⁸⁹²

The effects of renal failure on the GH-IGF1 axis are complex, and there is evidence for both GH and IGF1 resistance. Children and adolescents have normal or elevated circulating levels of GH, depending on the degree of renal failure.^{887,888,893-897} The increased GH levels result from both an increase in GH secretory bursts and a decrease in renal GH clearance.⁸⁹⁸ Serum IGF1 and IGF2 levels are usually normal in patients with renal failure.^{887,893,894,899,900} Early reports of decreased serum IGF levels in uremia were an artifact caused by inadequate separation of IGF from IGFBPs before assay.⁹⁰¹ However, the normal IGF1 levels in the face of elevated GH levels denotes GH resistance, which is also indicated by the finding of decreased hepatic IGF1 production.⁹⁰² The mechanism for GH resistance includes decreased GHR gene expression in the liver and in the growth plate.^{899,903} There is also evidence that the uremic state causes a postreceptor defect in GH signal transduction by diminishing phosphorylation and nuclear translocation of GH-activated STAT proteins.^{898,904,905} Although a defect in IGF1 receptor signaling has been demonstrated in renal failure,⁹⁰³ the more important mechanism for decreased IGF1 action in renal failure is alterations in the serum level of IGFBPs that decrease the bioavailability of IGF1. IGFBPs 1, 2, 4, and 6 are increased.^{887,888,903,906-910} In addition, low-molecular-weight IGFBP3 fragments, which have decreased affinity for IGF1, accumulate due to reduced renal clearance.⁹⁰³ In nephrotic syndrome, an additional contribution

to growth failure may come from reduced serum levels of IGF1 and IGFBP3 resulting from urinary loss of IGF-IGFBP complexes.⁸⁸⁹ Finally, glucocorticoid therapy that may be used for treatment of the renal disease can exacerbate growth retardation by diminishing GH release and blunting IGF1 action at growth plates.^{909,911-913}

Even after successful renal transplantation, growth may not be normal.⁹¹⁴⁻⁹¹⁸ In the large cohort of patients in the North American Pediatric Renal Transplant Cooperative Study,^{916,918,919} mean height increased after transplantation by only 0.11 SD in the first 4.5 years. The youngest age group (<2 years) had the largest deficit and the most catch-up growth (0.94 SD); children between 6 and 17 years of age had no improvement in height SD score. Although the younger age group had a 16% mortality rate,⁹¹⁶ more recent studies^{920,921} suggest that transplantation may have an acceptable high risk in such patients. Growth-retarded post-transplantation children receiving daily or alternate-day glucocorticoid treatment have decreased GH secretion, normal levels of IGF1 and IGFBP1, and elevated levels of IGFBP3. They differ from patients with end-stage renal disease in that IGFBP1 levels are not strikingly elevated, perhaps because of altered glucose tolerance and hyperinsulinism due to chronic glucocorticoid therapy.⁹⁰⁹ Overall, height SDS at the time of transplantation and use of alternate-day glucocorticoid therapy after transplant correlate positively with final height, and longer duration of reduced GFR and a higher cumulative dose of prednisone have a negative impact; other factors such as gender, age at transplantation, diagnosis, and number of transplants do not seem to have significant impact on adult height.⁹¹⁴ The importance of height at the time of transplantation in determining final adult height, despite the complex post-transplantation health issues, confirms the value of improving growth velocity and absolute height before transplantation. Children who receive tacrolimus (FK-506)-based immunosuppression, allowing discontinuation of glucocorticoids, have normal growth and absence of obesity.⁹²²

Although the growth failure of renal disease in the pre-transplantation period is not specifically caused by GHD, GH therapy accelerates skeletal growth and is approved by the U.S. Food and Drug Administration (FDA) for use. Such treatment probably increases the molar ratio of IGF peptides to IGFBPs and may override the inhibitory actions of IGFBPs.

Hematologic Disorders. Chronic anemias, such as sickle cell disease, are characterized by growth failure.^{923,924} In general, the decrease in height and weight is greater in adolescent years than earlier, because the onset of the adolescent growth spurt is delayed and menarche is late.⁹²³⁻⁹²⁵ However, the adolescent growth and final adult height in patients with sickle cell disease may be normal.⁹²⁵ The causes of growth retardation probably include impaired oxygen delivery to tissues, increased work of the cardiovascular system, energy demands of increased hematopoiesis, and impaired nutrition. Long-term chronic transfusion therapy as part of stroke prevention treatment is associated with enhanced growth.⁹²⁶ The GH/IGF1 system probably does not have an important role in the growth impairment of sickle cell anemia.

In thalassemia, in addition to the consequences of chronic anemia, endocrine deficiencies can result from chronic transfusions and accompanying hemosiderosis.⁹²⁷ Despite vigorous efforts to maintain hemoglobin levels near normal and to avoid iron overload, growth failure is still a common feature of thalassemia, especially in male

adolescents.⁹²⁸ The patients tend to show body disproportion, with truncal shortening but normal leg length. It is likely that anemia, impaired IGF1 synthesis, hypothyroidism, gonadal failure, and hypogonadotropic hypogonadism all contribute to growth failure in this disorder. GH insensitivity in some cases is suggested by generally adequate GH production with low IGF1 levels.^{929,930} Several groups have reported data on treatment of thalassemia patients in whom GH production seemed diminished. In most patients, GH treatment increased growth, at least initially.^{929,931} In a longer-term study (average duration, 59 months) starting with young patients (7.2 years of age), an increased growth velocity was maintained throughout the treatment period⁹³²; when treatment was initiated at an older age (13.6 years), final height was not improved.⁹³³ A small number of adults with thalassemia are found to have continued GHD, so GH treatment for cardiac and bone health reasons may be important in this disease.⁹³⁴

About half of the patients in the International Fanconi Anemia Registry have short stature. GHD was demonstrated by provocative testing (22 of 48 patients) or with assessment of endogenous secretion (13 of 13) in a group with a mean height of -2.23 SDS.⁹³⁵ In pure red-cell aplasia,⁹³⁶ approximately 30% of patients demonstrated growth retardation. The frequency increased with age (42% in individuals >16 years) and with treatment programs such as chronic transfusions or glucocorticoids.

Inborn Errors of Metabolism. Inborn errors of metabolism are often accompanied by growth failure that may be pronounced. Glycogen storage disease, the mucopolysaccharidoses, glycoproteinoses, and mucopolipidoses are characterized by poor growth. Many inborn metabolic disorders are also associated with significant skeletal dysplasia. In a small number of patients with organic acidoses, such as methylmalonic and propionic acidurias, IGF1 levels are low and GH levels are normal, suggesting a possible state of GH insensitivity related to nutritional status.⁹³⁷ Preliminary data suggest that exogenous GH treatment may improve the metabolic status of such children.^{937,938}

Pulmonary Disease. Growth can be retarded in children with asthma who have not received glucocorticoid therapy.^{939,940} Mean height and growth velocity and degree of growth failure are related to the severity of the asthma.^{939,940} Delayed pubertal maturation in such patients is also associated with growth deceleration in early teenage years.^{939,941} Impaired nutrition and increased energy requirements, along with chronic stress, especially with nocturnal asthma and enhanced endogenous glucocorticoid production, cause poor linear growth. The lowered growth in asthmatic children does not appear to be associated with abnormalities of the GH-IGF1 axis.⁹⁴² Glucocorticoid therapy, which is typically given to more severely affected patients, further impairs growth throughout childhood.⁹⁴³⁻⁹⁴⁵

Synthetic glucocorticoids, such as prednisone or dexamethasone, may have a greater growth-suppressive effect than equivalent therapeutic doses of cortisol, presumably because the biopotency of the synthetic agents may be underestimated. Alternate-day or aerosolized glucocorticoid therapy often ameliorates growth retardation and can be associated with an accelerated catch-up phase.^{939,944} Intermittent glucocorticoid therapy is usually not associated with impaired final height. The use of spacer devices and effective nebulizer solutions may permit use of inhaled glucocorticoids in young children without growth impairment.⁹⁴⁶⁻⁹⁴⁸ Clearly, however, sufficient glucocorticoid delivered by any route can diminish growth and

impede the function of the adrenal gland.⁹⁴⁹ Nonetheless, judicious use of inhaled glucocorticoid results in normal adult height despite long-term exposure and an initial decrement of linear growth velocity.^{950,951} Indeed, examination of near-adult heights of Swedish men with asthma demonstrated an improvement in the mean difference between "severe" asthmatics and normal controls in the era of inhaled corticosteroid use.⁹⁵² Overall, normal adult height is usually achieved.^{953,954}

Bronchopulmonary dysplasia (BPD), a sequela of neonatal respiratory distress syndrome and prematurity, has an incidence as high as 35% in infants with very low birth weight (<1500 g).⁹⁵⁵ The use of dexamethasone in the treatment of BPD in neonates causes a transient cessation of growth⁹⁵⁶ and has engendered long-term concern for neurodevelopment and somatic growth.⁹⁵⁷ Growth in surviving infants is poor through early childhood,⁹⁵⁸⁻⁹⁶⁰ but the defect usually disappears by 8 years of age.⁹⁶¹⁻⁹⁶³ Long-term hypoxemia, poor nutrition, chronic pulmonary infections, and reactive airway disease are responsible for the poor early growth.

In patients with cystic fibrosis, chronic pulmonary infection with bronchiectasis, pancreatic insufficiency with exocrine and endocrine inadequacy, malabsorption, and malnutrition all contribute to decreased growth and late sexual maturation. In 17,857 patients with cystic fibrosis, mean height was at the 21st percentile and mean weight was at the 9th percentile.⁹⁶⁴ Early impairment of height and weight growth and retardation of skeletal maturation may progress or plateau during middle childhood years but become most marked in the preadolescent period, when growth and maturational changes are frequently delayed.⁹⁶⁴⁻⁹⁶⁶ The degree of growth retardation is related most closely to the severity and variability of the pulmonary disease rather than to pancreatic dysfunction.^{967,968} The degree of steatorrhea does not correlate well with growth impairment, although improved nutrition programs enhance the overall clinical picture.^{969,970} Adult heights in surviving patients with cystic fibrosis approach the normal range⁸²⁵ but remain lower than average.⁹⁷¹ Endocrine abnormalities, such as failure of both alpha and beta islet cells with decreased glucagon and insulin production, do not seem to influence prepubertal growth patterns in children with cystic fibrosis. The incidence of diabetes mellitus increases as patients live past the second decade.⁹⁶⁴ Alterations of vitamin D metabolism, while potentially affecting skeletal mineralization, do not diminish growth.⁹⁷² Delayed sexual maturation, in which administration of gonadotropin-releasing hormone (GnRH) evokes a prepubertal pattern of pituitary gonadotropin secretion in adolescent patients, is similar to that in patients with CDGD.^{973,974}

The GH-IGF1 axis in cystic fibrosis patients shows evidence for some degree of acquired GH insensitivity with lowered mean IGF1 and elevated GH levels.⁹⁷⁵ Treatment of prepubertal cystic fibrosis patients with GH for 1 year resulted in an anabolic effect, with greater growth velocity and nitrogen retention and increased protein and decreased fat stores.^{976,977} In a separate study, 1 year of GH treatment increased the gain in height, weight, and bone mineral content, improved the clinical status, and decreased hospitalizations.⁹⁷⁸ In a 2-year GH treatment program for cystic fibrosis patients who received enteral nutrition before and during GH therapy, auxologic parameters continued to improve.⁹⁷⁹ Pulmonary function improved in most patients. A 4-year longitudinal study using the National Cystic Fibrosis Foundation registry found that improved nutrition status and growth were associated with a slower age-related decrement of pulmonary function.⁹⁸⁰

Current perspective suggests that GH treatment should be considered for adjunctive use as part of therapy with an aggressive nutritional program, appropriate pulmonary care without glucocorticoid administration, and careful assessment of carbohydrate metabolism.⁹⁸¹

Chronic Inflammation and Infection. Poor growth is a characteristic feature of chronic inflammatory disease and recurrent serious infection. The impaired growth associated with such disorders as Crohn's disease, cystic fibrosis, and asthma, in which inflammatory processes may be significant, has already been discussed. Inflammatory states are associated with increased levels of numerous cytokines. IL6, specifically, has been implicated in this growth impairment. De Benedetti and colleagues,⁹⁸² studying juvenile rheumatoid arthritis in humans and in a transgenic murine model expressing excessive IL6, demonstrated an IL6-mediated decrease in IGF1 production. IL6 has been demonstrated to activate SOCS3; this provides a pathway for inflammation to inhibit IGF1 production, because SOCS3 is a negative regulator of the JAK2/STAT5 GH signal transduction pathway.^{159,842,983} IL6 may also cause a decrease in serum IGF1 levels by increasing its clearance through a decrease in IGFBP3 levels.⁸⁴² In addition, cytokines can affect the endocrine system at many other levels,^{984,985} impairing mineral and nutrient metabolism and the growth and remodeling of bone.⁹⁸⁶

Exposure to human immunodeficiency virus (HIV) in children and adolescents occurs through perinatal transmission, blood transfusions, drug usage, and sexual contact. Growth failure is a cardinal feature of childhood acquired immunodeficiency syndrome (AIDS).⁹⁸⁷⁻⁹⁹² However, HIV-infected infants and children show growth failure even before demonstrating severe immune dysfunction.^{993,994} Weight, length, and head circumference are all affected, although weight-for-height may be normal.^{990,992,995} Before the era of highly active antiretroviral therapy (HAART), height growth velocity was associated with survival, independent of either CD4⁺ T-cell lymphocyte count or viral load, with HAART therapy normalizing growth in most studies.⁹⁹⁵ Studies of the GH-IGF1 axis in HIV-infected children have shown evidence of decreased GH secretion, GH resistance, and IGF1 resistance; both normal and low levels of GH and IGF1 are seen.⁹⁹³ Lipodystrophy associated with HAART therapy occurs in children, although less commonly than in adults, and decreased GH secretion has been demonstrated in HIV-associated lipodystrophy,⁹⁹³ potentially contributing to impaired growth. HIV-infected children frequently have delayed puberty, which could contribute to their linear growth failure. In a short-term treatment trial with standard doses of GH, height and weight growth increased and protein catabolism diminished, without any adverse effect on viral burden.⁹⁹⁶

Endocrine Disorders

Hypothyroidism. Untreated severe congenital hypothyroidism results in profound growth failure. With proper treatment, however, children with congenital hypothyroidism reach a height appropriate for their genetic potential.⁹⁹⁷

Acquired hypothyroidism during childhood may also result in growth failure that can range from subtle to profound, depending on the severity and duration of the hypothyroidism. Growth failure may be the most prominent manifestation of hypothyroidism in children.⁹⁹⁸ The poor growth is more apparent in height than in weight gain, so these children tend to be overweight for height. Rivkees and coworkers⁹⁹⁸ reported a mean 4.2-year delay

between slowing of growth and the diagnosis of hypothyroidism; at diagnosis, girls were 4.04 SD below and boys 3.15 SD below the mean height for their age. Skeletal maturation is delayed in those children in whom the hypothyroidism was sufficient to retard growth, with the bone age at diagnosis corresponding to the age at onset of the hypothyroidism.⁹⁹⁸ Body proportion is immature, with an increased upper-to-lower body segment ratio. Although chronic hypothyroidism is usually associated with delayed puberty, precocious puberty and premature menarche can occur in hypothyroid children (see Chapter 13).

In those children with severe growth failure, treatment with thyroid hormone results in rapid catch-up growth. This is typically accompanied by marked skeletal maturation. In cases of prolonged severe hypothyroidism, the advancement of skeletal maturation with treatment can exceed the growth acceleration, resulting in a compromised adult height.⁹⁹⁸ The deficit in adult stature correlates with the duration of hypothyroidism before initiation of treatment. Catch-up growth may be particularly compromised if therapy is initiated near puberty.⁹⁹⁹

As expected, hyperthyroidism has effects on growth opposite to those of hypothyroidism: it results in accelerated growth and epiphyseal maturation. Children with hyperthyroidism present with an increased height and advanced bone age. In neonates, hyperthyroidism can result in craniosynostosis. However, despite the advanced bone age at diagnosis, the final height of children treated for hyperthyroidism remains normal in relation to genetic potential.¹⁰⁰⁰

Diabetes Mellitus. Although weight loss may occur immediately before the onset of clinically apparent IDDM, children with new-onset diabetes are frequently taller than their peer group, possibly because GH and insulin levels are increased during the preclinical evolution of the disease.¹⁰⁰¹⁻¹⁰⁰³ Most children with IDDM, even those with marginal control,¹⁰⁰⁴ grow quite normally, especially in prepubertal years, although growth velocity may decrease during puberty.¹⁰⁰⁵ However, growth failure can occur in diabetic children with long-standing poor glycemic control.^{1006,1007} The Mauriac syndrome¹⁰⁰⁸ describes children with poorly regulated IDDM, severe growth failure, and hepatosplenomegaly due to excess hepatic glycogen deposition. This type of growth retardation has become increasingly rare with modern diabetes care.

Many pathophysiologic processes, including malnutrition, chronic intermittent acidosis, increased glucocorticoid production, hypothyroidism, impaired calcium balance, and end-organ unresponsiveness to either GH or IGF, may contribute to growth failure in IDDM.^{1001,1009-1011} IGF1 and IGFBP3 levels are diminished in the face of enhanced GH production,¹⁰¹²⁻¹⁰¹⁶ reflecting acquired GH insensitivity. GHBP levels are decreased,^{1009,1015} supporting the concept of impaired GHR number or function. Furthermore, IGFBP1 is normally suppressed by insulin, and hypoinsulinemia results in elevated serum IGFBP1 levels that may inhibit IGF action.^{1015,1017-1020} In contrast to the situation in adolescents and adults, IGFBP1 levels are not elevated in well-growing prepubertal children.¹⁰¹⁹ On the contrary, increased IGFBP3 proteolysis may enhance the bioactivity of the available IGF1.^{1016,1021} Most children with IDDM attain normal cellular nutrition and growth factor action despite intermittent hypoinsulinemia and derangements of peripheral indices of the GH/IGF1 system.

Even though glycemic control is inversely correlated with IGF I levels,^{1010,1012,1015,1022} the correlation between glycemic control and growth is weak. After conflicting reports as to the influence of glycemic regulation on

growth,^{1001,1002,1023,1024} a longitudinal study¹⁰²⁴ of 46 children whose diabetes began before age 10 indicated that initial heights at diagnosis were normal and that the final height SDS was minimally reduced from that at onset. In boys, despite a delay of about 2.5 years in onset of puberty, total pubertal height gain was normal. In girls with diabetes, however, total pubertal height gain was diminished and the age at menarche was delayed; the effects of altered insulin and IGF1 levels on ovarian function have not been assessed in such patients. Chronic metabolic control did not correlate with the pubertal height gain or with the normal final height. Nevertheless, good glycemic control may improve growth at certain maturational periods such as puberty.^{1001,1014,1025}

Cushing's Syndrome: Glucocorticoid Excess. Glucocorticoid excess impairs skeletal growth, interferes with normal bone metabolism by inhibiting osteoblastic activity, and enhances bone resorption.¹⁰²⁶⁻¹⁰²⁸ These effects are related to the duration of steroid excess,¹⁰²⁹ regardless of whether the Cushing's syndrome is due to ACTH hypersecretion, adrenal tumor, or glucocorticoid administration.

Even modest doses of oral glucocorticoids can inhibit growth; these doses may be as low as 3 to 5 mg/m² per day of prednisone or 12 to 15 mg/m² per day of hydrocortisone (i.e., only slightly above what is considered physiologic replacement).¹⁰³⁰ The "toxic" effects of glucocorticoids on the epiphysis may persist to some degree after correction of chronic glucocorticoid excess, and patients frequently do not attain their target height.^{685,1031} The longer the duration and the greater the intensity of glucocorticoid excess, the less likely is catch-up growth to be completed. Alternate-day glucocorticoid treatment decreases but does not eliminate the risk of growth suppression.¹⁰³²⁻¹⁰³⁴ Inhaled glucocorticoids given for the treatment of asthma have an even lower risk of growth suppression, but even at modest doses (e.g., 400 µg/day of beclomethasone,¹⁰³⁵ 200 µg/day of fluticasone,^{951,1035} or 400 µg/day of budesonide⁹⁵¹) they can cause at least temporary slowing of growth. However, inhaled corticosteroids do not appear to impair final height.^{950,951}

GH therapy can overcome some of the growth-inhibiting effects of excess glucocorticoids. The GH-induced increase in growth rate is inversely related to the glucocorticoid dose,¹⁰³⁶ with one small study finding no benefit of GH treatment for prednisone doses greater than 0.35 mg/kg per day.¹⁰³⁷ GH or IGF1 administration can diminish many of the catabolic effects of excess glucocorticoids.^{1027,1038,1039}

Adrenal tumors secreting large amounts of glucocorticoids can produce excess androgens, which may mask the growth-inhibitory effects of glucocorticoids. In addition, Cushing's syndrome in children may not cause all the clinical signs and symptoms associated with the disorder in adults and may manifest with growth arrest. However, Cushing's syndrome is an unlikely diagnosis in children with obesity, because exogenous obesity is associated with normal or even accelerated skeletal growth and growth deceleration is usually evident by the time other signs of Cushing's syndrome appear (Fig. 24-37). In a series of 10 children and adolescents treated for Cushing's disease with surgery and cranial irradiation, post-therapy GHD was common and mean final height was -1.36 SDS.¹⁰⁴⁰

Pseudohypoparathyroidism: Albright's Hereditary Osteodystrophy. Albright's hereditary osteodystrophy (AHO) is caused by mutations in the stimulatory GTP-binding protein, G_sα. It exists both with and without multihormone resistance—termed pseudohypoparathyroidism type 1A (PHP-1A) and pseudo-pseudohypoparathyroidism

Figure 24-37 Growth curves of two boys with obesity. The boy depicted by the circles had cortisol excess related to Cushing's disease. He had onset of rapid weight gain associated with a decrease in linear growth velocity at age 7. The diagnosis was made, and an adrenalectomy (arrow) was performed at age 9½ years, with an almost immediate increase in growth rate and striking catch-up growth. The boy whose growth is depicted by triangles had exogenous obesity. At age 9½, his weight was approximately the same as that of the patient with Cushing's disease, but his height was at the 97th percentile, reflecting the enhancement of linear growth in individuals with exogenous obesity.

(pseudoPHP). This condition is discussed in detail in Chapter 25 but is included here because short adult height is a common feature.¹⁰⁴² AHO is characterized by obesity (more marked in PHP-1A than in pseudo-PHP¹⁰⁴³), short metacarpals, subcutaneous ossifications, round facies, and cognitive impairments. Patients with AHO, whether they have PHP-1A or pseudo-PHP, typically have short adult stature. Many patients with PHP-1A demonstrate GHD due to resistance to GHRH.^{1044,1045} However, the growth pattern of patients with AHO suggests that there is another contributor to growth failure, because they often have only modest growth failure in early and middle childhood, with early epiphyseal fusion contributing to their short final height.^{1046,1047}

Rickets. In the past, hypovitaminosis D was a major cause of short stature and was often associated with other causes of growth failure, such as malnutrition, prematurity, malabsorption, hepatic disease, or chronic renal failure (see Chapter 28). In isolated vitamin D deficiency, breast-fed infants typically have poor exposure to sunlight and are not nutritionally supplemented with vitamin D. Characteristic skeletal manifestations of rickets include frontal bossing, craniotabes, rachitic rosary, and bowing of the legs. Such children usually begin to synthesize 1,25-dihydroxyvitamin D₃ as they become older, broaden their diet, and have increased exposure to sunlight, with amelioration of the transient early decrease of linear growth velocity. The association of vitamin D receptor gene polymorphism with

birth length, growth rate, adult stature, and BMD¹⁰⁴⁸⁻¹⁰⁵² further emphasizes the importance of vitamin D in normal growth. Additionally, vitamin D and estrogen receptor genotypes appear to interactively affect infant growth, especially in males.^{1050,1053} The presence of high-affinity binding sites for the vitamin D receptor DNA-binding domain in the GH promoter suggests that the vitamin D receptor may actually modulate GH expression.¹⁰⁵⁴

Hypophosphatemic Rickets. Hypophosphatemic rickets is an X-linked dominant disorder caused by decreased renal tubular reabsorption of phosphate related to mutations in the phosphate regulating endopeptidase gene, *PHEX*, located on chromosome Xp22.1. Other hypophosphatemic syndromes include autosomal-dominant hypophosphatemic rickets, hereditary hypophosphatemic rickets with hypercalciuria, and tumor-induced osteomalacia (see Chapter 28).¹⁰⁵⁵ In all of these conditions, there are increased levels of FGF23, perhaps a major phosphaturic agent.¹⁰⁵⁶ The features are usually more severe in boys and include short stature,^{936,1057} prominent bowing of the legs, and, sometimes, rachitic signs.¹⁰⁵⁸ The metabolic and skeletal abnormalities cannot be overcome by vitamin D therapy alone.

Treatment of hypophosphatemic rickets requires oral phosphate replacement, but such therapy may result in poor calcium absorption from the intestine. The addition of calcitriol to oral phosphate increases intestinal phosphate absorption and prevents hypocalcemia and secondary hyperparathyroidism. Such combined therapy improves the rickets but does not necessarily correct growth.^{1055,1059,1060,1061} Potential growth-related benefits of this regimen appear to be dependent on the initiation of therapy in early infancy, which leads to achievement of greater childhood and adult height.¹⁰⁵⁷ There is no clear association between endogenous GH secretion, IGF1, or phosphate levels and height in this disorder.¹⁰⁶²⁻¹⁰⁶⁴ Nevertheless, GH therapy in eight trials including 83 patients resulted in an enhancement of skeletal growth and improvement in BMD.¹⁰⁶⁵⁻¹⁰⁶⁷ In 14 of those patients, treatment for 4 to 5 years resulted in a height gain of up to 1.2 SDS. One report cautioned that GH treatment appeared to exaggerate disproportionate truncal growth.¹⁰⁶⁸

Osteochondrodysplasias

The osteochondrodysplasias encompass a heterogeneous group of disorders characterized by intrinsic abnormalities of cartilage and bone.^{1069,1070} These disorders include abnormalities in the size or shape of bones in the limbs, spine, or skull, often with abnormalities seen on radiographic evaluation. More than 100 osteochondrodysplasias have been identified based on physical characteristics and radiographic characteristics (Table 24-5). An international classification for the osteochondrodysplasias was developed in 1970¹⁰⁷¹ and revised in 1978,¹⁰⁷² 1992,¹⁰⁷³ 1997,¹⁰⁷⁴ and 2001.¹⁰⁷⁵

Diagnosis of osteochondrodysplasias can be difficult, with clinical and radiologic evaluation central to the diagnosis. The family history is critical, although many cases are caused by de novo mutations, and this is generally the case in autosomal-dominant achondrodysplasia and hypochondrodysplasia. Measurement of body proportions should include arm span, sitting height, upper and lower body segments, and head circumference. Radiologic evaluation should be used to determine whether involvement is of the long bones, skull, or vertebrae and whether abnormalities are primarily at the epiphyses, metaphyses, or diaphyses. The osteochondrodysplasias most commonly encountered in endocrine practice are discussed in the following paragraphs.

TABLE 24-5

Classification of Osteochondrodysplasias**I. Defects of the Tubular (and Flat) Bones and/or Axial Skeleton**

- A. Achondroplasia group
- B. Achondrogenesis
- C. Spondylodysplastic group (perinatally lethal)
- D. Metatropic dysplasia group
- E. Short rib dysplasia group (with or without polydactyly)
- F. Atelosteogenesis/diastrophic dysplasia group
- G. Kniest-Stickler dysplasia group
- H. Spondyloepiphyseal dysplasia congenita group
- I. Other spondylo epiphyseal/metaphyseal dysplasias
- J. Dysostosis multiplex group
- K. Spondylometaphyseal dysplasias
- L. Epiphyseal dysplasias
- M. Chondrodysplasia punctata (stippled epiphyses) group
- N. Metaphyseal dysplasias
- O. Brachyrachia (short spine dysplasia)
- P. Mesomelic dysplasias
- Q. Acro/acromesomelic dysplasias
- R. Dysplasias with significant (but not exclusive) membranous bone involvement
- S. Bent bone dysplasia group
- T. Multiple dislocations with dysplasias
- U. Osteodysplastic primordial dwarfism group
- V. Dysplasias with increased bone density
- W. Dysplasias with defective mineralization
- X. Dysplasias with increased bone density

II. Disorganized Development of Cartilaginous and Fibrous Components of the Skeleton**III. Idiopathic Osteolyses**

Achondrodysplasia is the most common of the osteochondrodysplasias, with a frequency of 1 in 26,000 individuals. Characteristic abnormalities of the skeleton include megaloccephaly, low nasal bridge, lumbar lordosis, short trident hand, and rhizomelia (shortness of the proximal legs and arms) with skin redundancy. Radiologic findings include small, cuboid-shaped vertebral bodies with short pedicles and progressive narrowing of the lumbar interpedicular distance. The small foramen magnum may lead to hydrocephalus, and spinal cord and root compression may result from kyphosis, stenosis of the spinal canal, or disc lesions.^{1076,1077} Diminished growth velocity is present from infancy, although short stature may not be evident until after 2 years of age. Mean adult heights in males and females are 130 and 120 cm, respectively.¹⁰⁷⁸ GH secretion is comparable to that in normal subjects.¹⁰⁷⁹

Achondrodysplasia is caused by mutations in the transmembrane domain of the FGF receptor 3 gene (*FGFR3*).^{1073,1080-1083} It is transmitted in an autosomal dominant manner, but 80% to 90% of cases are caused by de novo mutations. Most of the cases are the result of activating mutations at nucleotide 1138 of the *FGFR3* gene, which creates new recognition sites for restriction enzymes, thus easing the molecular diagnosis. The mutation rate reported at this site is very high, and *FGFR3* has been labeled the most mutable gene in the genome. As a result of the upregulation of receptor activity, there is abnormal chondrogenesis and osteogenesis during endochondral ossification, leading to the typical phenotypic findings. The homogeneity of the mutation in achondroplasia probably explains the minimal heterogeneity in the phenotype. Infants homozygous for the mutation have severe disease, typically dying in infancy from respiratory insufficiency due to a small thorax. In mice with the equivalent *Fgfr3* mutation, there is ligand-independent dimerization and

phosphorylation of *Fgfr3* with activation of Stat proteins and upregulation of cell cycle inhibition.¹⁰⁸⁴ Expression of the Indian hedgehog and parathyroid hormone-related protein (PTHrP) receptor genes is downregulated.¹⁰⁸⁵

Hypochondroplasia is also autosomal dominant, and 70% of affected individuals are heterozygous for mutations in the *FGFR3* gene, frequently at amino acid position.¹⁰⁸⁶ The facial features of achondroplasia are absent, and both short stature and rhizomelia are less pronounced. Adult heights are typically in the 120- to 150-cm range. Poor growth may not be evident until after 2 years of age, but stature then deviates progressively from normal. Occasionally, the disproportionate short stature is not apparent until adulthood. Outward bowing of the legs may be accompanied by genu varum. On radiologic evaluation, lumbar interpedicular distances are diminished between L1 and L5, and there may be flaring of the pelvis and narrow sciatic notches. The diagnosis can be difficult to make, with mild variants of the syndrome difficult to distinguish from normal.

The short stature homeobox-containing (*SHOX*) gene is located in the pseudoautosomal region of distal Xp and Yp. Mutations or deletion of *SHOX* is associated with syndromes of poor growth and skeletal dysplasia, including Léri-Weil dyschondrosteosis (LWD), TS, and Langer mesomelic dysplasia (LMD).¹⁰⁸⁷ Findings include short stature, Madelung deformity, increased carrying angle, tibial bowing, scoliosis, and high arched palate. The auxologic finding of relatively short limbs suggests a defect in *SHOX*, because the *SHOX* protein may affect cellular proliferation and apoptosis of chondrocytes at the growth plate.¹⁰⁸⁸ Indeed, the skeletal manifestations have been associated with areas in which there is intrauterine expression of *SHOX*.^{1088,1089} LWD is caused by homozygous gene defects, whereas TS and LMD are caused by haploinsufficiency. In LWD, most patients share a distinct 5-kb region for break-points, indicating a hot spot for mutations.¹⁰⁹⁰ The profound findings in LWD, compared with TS, may reflect the impact of pubertal estrogen exposure in LWD.¹⁰⁹¹

Endochondral growth is regulated by multiple endocrine, paracrine, and autocrine factors, and many inborn errors have been identified. In the syndrome of acromesomelic dysplasia, growth is remarkably impaired, leading to adult heights that may be more than 5 SD below the mean. A homozygous mutation in the homodimeric transmembrane natriuretic receptor B (NPR-B) that impairs binding of the ligand C-type natriuretic peptide has been found in some affected individuals.¹⁰⁹¹ Obligatory heterozygotes are significantly shorter than normal but have normal skeletal anatomy.¹⁰⁹² Therefore, heterozygous mutations of NPR-B demonstrate that a subset of children with unexplained short stature may, in fact, have mild forms of osteochondrodysplasias.

Chromosomal Abnormalities

Abnormalities of autosomes or sex chromosomes can cause growth retardation without evidence of skeletal dysplasia, frequently with somatic abnormalities and developmental delay. In many cases, the precise cause of growth failure is not clear because the genetic defects do not affect known components of the GH/IGF1 system. Chromosomal lesions may directly influence normal tissue growth and development or indirectly modulate local responsiveness to IGF or other growth factors at the growth plate.

Down Syndrome. Trisomy 21, or Down syndrome, is probably the most common chromosomal disorder associated with growth retardation, affecting approximately 1 in 600 neonates. On average, newborns with Down syndrome

have birth weights 500 g below normal and are 2 to 3 cm shorter than normal. Growth failure continues postnatally and is typically associated with delayed skeletal maturation and a delayed and incomplete pubertal growth spurt. Adult heights range from 135 to 170 cm in men and 127 to 158 cm in women.¹² The etiology of growth failure in Down syndrome is unknown, and attempts to find underlying hormonal explanations for growth retardation have been unsuccessful. Marginal levels of GH secretion and low-normal serum levels of IGF1 has been reported in patients with Down syndrome. Exogenous GH has been tried in some of these patients and have produced short-term increases in growth velocity, but the long-term effects on final adult height have not been studied. In addition, no improvement in gross motor or mental development was noted.^{1093,1094} Hashimoto's thyroiditis is common in individuals with Down syndrome and should be sought and treated promptly. Because of the concern for development of leukemia, which is more common in individuals with Down syndrome, GH use is generally not recommended.

Turner Syndrome. In girls with TS, short stature is the single most common feature, occurring more frequently than delayed puberty, cubitus valgus, or webbing of the neck.¹⁰⁹⁵⁻¹⁰⁹⁷ Short stature occurs in 95% to 100% of girls with a 45,X karyotype.¹⁰⁹⁸⁻¹¹⁰⁰ Mean adult heights in the United States and Europe range from 142.0 to 146.8 cm, with important genetic and ethnic influences on growth of girls in different regions. Parental height correlates well with final adult height,^{1101,1102} and a cross-cultural study in 15 countries demonstrated a very strong correlation between final height in TS and in the normal population, with an approximate 20-cm deficit.¹⁰⁹⁸ Several distinct phases of growth have been identified in girls with TS¹¹⁰³⁻¹¹⁰⁴:

1. Mild IUGR with a mean birth weight of 2800 g and a mean birth length of 48.3 cm
2. Slow growth recognized during early infancy and reaching -3 SD by 3 years of age¹¹⁰⁶
3. Delayed onset of the "childhood" phase of growth^{26,27,1105} and progressive decline in height velocity from age 3 years until approximately 14 years, resulting in further deviation from normal height percentiles
4. A prolonged adolescent growth phase, characterized by a partial return toward normal height, followed by delayed epiphyseal fusion

These girls have many features of skeletal dysplasia such as Madlung's deformity and are haploinsufficient for the *SHOX* gene, which is located in the pseudoautosomal region of the short arm of the X chromosome.¹¹⁰⁷ When heights of girls with TS are compared with those of girls with LWD, which involves a *SHOX* deletion, it appears that the *SHOX* defect may account for about two thirds of the height deficit in TS.¹¹⁰⁸ Girls with TS have normal GH and IGF levels during childhood; reports of low levels of GH or IGF, or both, in adolescents are likely due to low serum levels of gonadal steroids.¹¹⁰⁹ Multiple studies have shown that GH therapy is capable of accelerating short-term growth and increasing final adult height.^{1100,1110,1111} GH treatment in TS is discussed in detail later in the chapter.

Noonan Syndrome. Individuals with Noonan syndrome have postnatal growth failure, right-sided cardiac abnormalities (most often pulmonary valve abnormalities), webbing of the neck, low posterior hairline, ptosis, cubitus valgus, and malformed ears. Microphallus and cryptorchidism are common, and puberty may be delayed or incomplete. Cognitive delay of variable degrees is present in about

25% to 50% of patients. Although this disorder shares phenotypic features with TS, the two are clearly distinct.^{1112,1113} Therefore, oft-used terms such as "Turner-like syndrome" or "male Turner syndrome" are misleading. In Noonan syndrome, the sex chromosomes are normal and transmission is autosomal dominant, although about 50% of cases are sporadic. Approximately half of patients have heterozygous missense mutations of *PTPN11* leading to a gain-of-function mutation in a nonreceptor type 2 tyrosine phosphatase (SHP2) that enhances intracellular dephosphorylation.¹¹¹⁴⁻¹¹¹⁶ Through much of childhood, mean growth in length and weight is below the third percentile.¹¹¹⁷⁻¹¹¹⁹ GH secretory abnormalities do not account for the short stature, although endogenous GH production may be slightly reduced.^{1119,1120} It is postulated that the enhanced intracellular phosphatase activity diminishes the effectiveness of GH-induced IGF production.¹¹²¹⁻¹¹²³ GH therapy has been used in the treatment of patients with Noonan syndrome who have short stature, as discussed in detail later.

Prader-Willi Syndrome. In Prader-Willi syndrome (PWS), growth failure may be evident at birth but is more pronounced postnatally.¹¹²⁴ This syndrome is discussed at length in a later section of this chapter.

Other Syndromes. Other syndromes associated with moderate to profound growth failure include Bloom's syndrome, de Lange syndrome, leprechaunism, Ellis-van Creveld syndrome, Aarskog's syndrome, Rubenstein-Taybi syndrome, mulibrey nanism, Dubowitz syndrome, progeria, Cockayne's syndrome, and Johanson-Blizzard syndrome.¹¹²⁵

Small for Gestational Age

Historically, infants born SGA have comprised a heterogeneous group with birth weight or length below the 3rd, 5th, or 10th percentile for gestational age, depending on the study.³⁵ As the growth and metabolic consequences of being born SGA have been observed and characterized, studies have more consistently used the definition of SGA as birth weight or length (or both) at least 2 SD below the mean for gestational age (usually at or below the 2.3 percentile for a population). The term IUGR has been used interchangeably with SGA to describe these infants. However, it has been proposed that, because IUGR implies a known underlying pathologic process, that term should be reserved for infants whose abnormal prenatal growth has been confirmed by intrauterine growth assessments and whose growth restriction can be attributed to a specific cause.^{1125A} The reason for abnormal fetal growth is unclear in up to 40% of cases¹¹²⁶; known underlying reasons are listed in Table 24-6. Accurate assessment of an infant as SGA depends on accurate gestational dating and weight and length measurements, which can be difficult in both developed and developing countries.

Most SGA infants exhibit catch-up growth (as defined by a growth velocity greater than the median for chronological age and gender) by 2 years of age. Catch-up growth occurs during the first 6 months of life in approximately 80% of infants born SGA.¹¹²⁷ Approximately 10% to 15% of infants born SGA exhibit slow, attenuated growth with persistent height deficits in childhood and adolescence. The remaining 5% to 10% exhibit a slower catch-up growth pattern, reaching heights 2 SD below the mean between 3 and 5 years of age. These estimations vary by study; in a population of severely affected infants with SGA who required care in a neonatal intensive care unit, 27% had not achieved catch-up growth by 6 years of age.¹¹²⁸

TABLE 24-6

Factors Associated with Small for Gestational Age (SGA) Births

I. Intrinsic Fetal Factors

- A. Chromosomal Disorders
- B. Syndromes
 - 1. Russell-Silver Syndrome
 - 2. Seckel Syndrome
 - 3. Progeria
 - 4. Cockayne Syndrome
 - 5. Bloom Syndrome
 - 6. Rubenstein-Taybi Syndrome

II. Placental Abnormalities

- A. Abnormal Implantation of the Placenta
- B. Placental Vascular Insufficiency; Infarction
- C. Vascular malformations

III. Maternal Disorders

- A. Malnutrition
- B. Constraints on Uterine Growth
- C. Vascular Disorders
 - 1. Hypertension
 - 2. Toxemia
 - 3. Severe Diabetes Mellitus
- D. Uterine Malformations
- E. Drug Ingestion
 - 1. Tobacco
 - 2. Alcohol
 - 3. Narcotics

Low birth-weight premature babies who are appropriate for gestational age (AGA) invariably experience catch-up growth in the first 2 years of life. Final adult height of all children born SGA is -0.8 to -0.9 SD, a mean deficit of 3.6 to 4 cm when adjusted for family stature.¹¹²⁹ It has been estimated that the 10% to 15% of SGA children with short stature account for as much as 20% of all short children. In the United States, 2.3% of the population fitting the definition of SGA represents roughly an incidence of 1 in 43 neonates. Therefore, SGA children have a fivefold to sevenfold greater possibility of short stature than AGA children.³⁵

Normal fetal growth depends on a complex interplay of maternal and fetal genetic and external environmental influences. Abnormal intrauterine growth can result from pathologic processes in the fetus, the placenta, or the mother. Growth in length occurs early in fetal life, whereas weight gain occurs later in fetal life¹¹³⁰; first-trimester growth failure has been closely associated with low birth weight and low birth weight percentile.¹¹³¹ Because there is a differential effect on weight and length depending on the fetal period when the pathologic processes occur, IUGR has been subclassified into symmetric and asymmetric types. The symmetric type of IUGR results from an insult early in the pregnancy, often due to fetal genetic factors or syndromes, congenital infections, or toxic effects; asymmetric IUGR results from an insult occurring late in gestation, often due to fetoplacental insufficiency. Historically, it was thought that infants with symmetric IUGR do not experience catch-up growth whereas those with asymmetric IUGR who have normal head circumference and length yet low birth weight usually experience catch-up growth postnatally.¹¹³⁰ However, studies have suggested that infants with asymmetric IUGR have worse perinatal outcomes than those with symmetric IUGR^{1132,1133} and that both types of growth restriction can arise in the second trimester of pregnancy.^{1134,1135} Therefore, the subclassification of IUGR, like the term IUGR itself, is controversial.

Endocrine-related causes account for a small fraction of the many contributors to fetal growth abnormalities, but hormonal disorders associated with fetal and neonatal growth restriction shed light on the endocrine mechanisms of growth in the fetus. Although GH plays a major role in postnatal growth, it has a minimal role in fetal growth; infants with neonatal GHD are typically -0.5 to -1.5 SD below the mean in length and are heavy for this length.^{518,519,1136} An adequate nutrient supply is the main determinate of fetal growth, but growth factors such as insulin, IGF1, and IGF2 also play a role. Defects of insulin secretion or action are associated with impaired fetal growth.¹¹³⁰ Congenital defects of insulin secretion such as glucokinase deficiency¹¹³⁷ or pancreatic agenesis¹¹³⁸ are associated with severe IUGR. Leprechanism is caused by defects in the insulin receptor and is associated with severe insulin resistance and IUGR.²⁶ The initial case of a deletion of the IGF1 gene had profound intrauterine growth failure.^{340,792} Polymorphisms of the IGF1 gene have also been reported to be associated with IUGR.^{340,1139,1140}

Neonates with SGA exhibit hormonal patterns consistent with insensitivity to GH and IGF1 and/or insulin action. In neonates with IUGR, GH levels are elevated¹¹⁴¹ and IGF1 and IGFBP3 levels are low.^{134,1142-1144} IGFBP1 and IGFBP2 levels have been reported to be higher than in AGA infants,³⁷¹ a pattern seen in individuals with insulin resistance. Similar patterns are found in the first week of life after severe fetal malnutrition.¹¹⁴⁵ Exogenous GH treatment has little or no effect on growth, body composition, or energy expenditure^{1146,1147} in the neonatal period. In most infants with SGA, normalization of GH, IGF1, and IGFBP3 levels occurs by 3 months of age, with normal response to GH stimulation testing in childhood.¹¹⁴⁸ In measurement of spontaneous GH secretion, high pulse frequency with attenuated pulse amplitude and elevated trough values of GH have been noted in SGA children.¹¹⁴⁹⁻¹¹⁵¹ Serum IGF1 levels in children with short stature born SGA are slightly but significantly lower than in children with catch-up growth.^{1148,1151}

SGA children who have striking weight gain during the first several years of life can develop endocrine disorders later in childhood, including premature adrenarche, insulin resistance, polycystic ovary syndrome, and an attenuated growth spurt.¹¹⁵² This subset of SGA children have increased risks of hypertension, maturity-onset diabetes, and cardiovascular disease later in life.¹¹⁵³⁻¹¹⁵⁶ This is consistent with the Barker hypothesis, which states that fetal metabolic responses to a nutritionally hostile intrauterine environment may lead to inappropriate extrauterine consequences.¹¹⁵⁷⁻¹¹⁵⁹ These problems do not appear to occur in SGA babies without catch-up growth, although insulin resistance has been described.¹¹⁶⁰ Whether SGA is causally related to these disorders or is a symptom of an underlying inborn metabolic disorder is not yet known.

Russell-Silver syndrome (RSS) was independently described by Russell¹¹⁶¹ and by Silver and associates.¹¹⁶² Findings include IUGR with postnatal growth failure, congenital hemihypertrophy, and small, triangular facies.¹¹⁶³⁻¹¹⁶⁶ Other nonspecific findings include clinodactyly, delayed closure of the fontanelle, delayed bone age, and precocious puberty.¹¹⁶³⁻¹¹⁶⁵ Adults are short, with final heights approximately -4 SD below the mean.^{1164,1166} The incidence is between 1 in 50,000 and 1 in 100,000 live births. Endogenous GH secretion in prepubertal RSS children is similar to that in other short IUGR children and less than in AGA short children.^{1149,1167} Maternal uniparental disomy of chromosome 7 is present in 7% to 10% of cases.¹¹⁶⁸⁻¹¹⁷¹ Although there are a number of imprinted genes or factors involved in growth and development on chromosome 7, numerous studies have not detected any

Figure 24-38 Schematic representation of the 11p15 region and the epigenetic mutations associated with Russell Silver syndrome and Beckwith-Wiedemann syndrome. Red and pink boxes represent genes of imprinting control region I (ICR1), and green boxes represent genes of ICR2. The arrow represents the presence of gene transcription. Dark triangle(s) represent anti-sense transcripts that can repress transcription of ICR2 genes. When methylated, the transcripts cannot be formed, allowing transcription of ICR2 genes and reciprocal suppression of transcription of downstream genes (i.e., *IGF 2*). (Adapted from Eggerman T. Silver-Russell and Beckwith-Wiedemann syndromes: opposite (epi)mutations in 11p15 result in opposite clinical pictures. *Horm Res.* 2009;71(suppl 2):30-35.)

pathologic mutations in the candidate genes. A gene on chromosome 7p, *GRB10*, is involved in regulation of insulin and IGF1 receptor signaling and is mainly expressed from the maternal allele; loss of the maternal allele results in fetal and placental overgrowth.^{1171,1172} Mutations that could cause overexpression of *GRB10* have not been found in patients with RSS.

A small number of patients with RSS have duplication of the maternal allele of the 11p15 region¹¹⁷³; duplication of the paternal allele in this region is associated with BWS and overexpression of *IGF2*. The 11p15 region contains two imprinting control regions (ICR), ICR1 and ICR2 (Fig. 24-38). ICR1 comprises the *IGF2* and *H19* genes. The non-coding gene *H19* is downstream from *IGF2* and is oppositely imprinted, meaning that only the maternal allele is expressed and the paternal allele is inactive. The promoters of the *IGF2* and *H19* genes share a set of enhancers that act on either gene. On the paternal allele, the *H19* promoter region is methylated and therefore inactivated.²⁴² Upstream from the *H19* and *IGF2* promoter region is a paternally methylated region that prevents binding of CTCF, allowing enhancers to act on the *IGF2* promoter to activate transcription.²⁴³ On the maternal chromosome, this region is not methylated, allowing CTCF to bind and preventing transcription.²⁴⁴ In this ICR1 region, mutations causing hypomethylation of the *H19* promoter region has been described in approximately 40% of patients with RSS.¹¹⁷⁴ Oppositely, hypermethylation of the ICR1 region has been associated with BWS. Disruption of ICR2 has been described in BWS (described later) but not in RSS. Reduced *IGF2* expression has been demonstrated in fibroblasts of patients with RSS in vitro,¹¹⁷⁴ but serum levels of *IGF2* in patients with RSS are normal.¹¹⁷⁵ Mice with a null mutation of *IGF2* have prenatal

growth retardation but normal postnatal growth; how reduced expression of *IGF2* contributes to postnatal growth failure in RSS has yet to be elucidated.

Maternal and Placental Factors

Maternal factors and placental insufficiency can impair fetal growth and likely account for most cases of asymmetric IUGR. Maternal nutrition is an important contributor to fetal growth and to growth during the first year of life.¹¹⁷⁶ Fetal growth retardation may result from use of alcohol,¹¹⁷⁷⁻¹¹⁷⁹ cocaine,¹¹⁸⁰ marijuana,¹¹⁸⁰ or tobacco¹¹⁸¹ during pregnancy. The mechanisms for drug-induced fetal growth retardation are unclear but may include uterine vasoconstriction and vascular insufficiency, placental abruption, or premature rupture of membranes. The maternal hormonal milieu is affected by placental steroids and peptides. Maternal *IGF1* affects placental function and may facilitate transport of nutrients to the fetus. Maternal *IGF1* levels have been found to correlate with fetal growth.^{1182,1183} Increased levels of free *IGF1* are found during normal human pregnancy.¹¹⁸⁴

The placenta has multiple functions, including the transport of nutrients, oxygen, and waste and the production of hormones. It consumes oxygen and glucose brought by the uterine circulation. Placental GH affects maternal *IGF* production, which in turn affects placental function. A woman with GHD due to PIT1 mutation exhibited normal levels of placental GH and *IGF1*, demonstrating the independent production of GH and *IGF1* by the placenta.¹¹⁸⁵ Human placental lactogen (hPL) is a major regulator of glucose, amino acid, and lipid metabolism in the mother, aiding in the mobilization of nutrients for transport to the fetus. Damage to the placenta resulting from

vascular disease, infection, or intrinsic abnormalities of the syncytiotrophoblasts can impair these important functions. At times, examination of the placenta may yield causal information about fetal growth retardation.

An X-linked homeobox gene, *ESX1*, detected only in extraembryonic tissues and human testes, is a chromosomally imprinted regulator of placental morphogenesis.¹¹⁸⁶⁻¹¹⁸⁸ Heterozygous and homozygous mutant mice are born 20% smaller than normal and have large edematous placentas.¹¹⁸⁶ Vasculature is abnormal at the maternal-fetal interface, presumably causing the growth retardation.

PATHOLOGIC BASIS OF EXCESS GROWTH

Although, by definition, there are as many children with heights greater than 2 SD above the mean as with heights less than 2 SD below the mean, tall stature as a chief complaint is encountered much less often in endocrine practice. Nevertheless, it is critical to identify those situations in which tall stature or an accelerated growth rate provides clues of an underlying disorder (Table 24-7).

Statural Overgrowth in the Fetus

Maternal diabetes mellitus is the most common cause of large-for-gestational age (LGA) infants. LGA is defined as length or weight greater than the 90th percentile for gestational age. Even in the absence of clinical symptoms or family history, the birth of an excessively large infant should lead to evaluation for maternal or gestational diabetes.

Two relatively rare syndromes, Sotos syndrome and BWS, can also cause LGA infants.

TABLE 24-7
Differential Diagnosis of Statural Overgrowth
Fetal Overgrowth
Maternal diabetes mellitus
Cerebral gigantism (Sotos syndrome)
Weaver's syndrome
Beckwith-Wiedemann syndrome
Other insulin-like growth factor 2 (IGF2) excess syndromes
Postnatal Overgrowth Leading to Childhood Tall Stature
Familial (constitutional) tall stature
Cerebral gigantism
Beckwith-Wiedemann syndrome
Exogenous obesity
Excess growth hormone (GH) secretion (pituitary gigantism)
McCune-Albright syndrome or multiple endocrine neoplasia (MEN) associated with excess GH secretion
Precocious puberty
Marfan's syndrome
Klinefelter's syndrome (XXY)
Weaver's syndrome
Fragile X syndrome
Homocystinuria
XXY
Hyperthyroidism
Postnatal Overgrowth Leading to Adult Tall Stature
Familial (constitutional) tall stature
Androgen or estrogen deficiency/estrogen resistance (in males)
Testicular feminization
Excess GH secretion
Marfan's syndrome
Klinefelter's syndrome (XXY)
XXY

Sotos Syndrome

Children with cerebral gigantism (Sotos syndrome) are typically above the 90th percentile for length and weight at birth.¹¹⁸⁹⁻¹¹⁹¹ Clinical features also include a prominent forehead; dolichocephaly; macrocephaly; high arched palate; hypertelorism with unusually slanting eyes; prominent ears, jaw, and chin; large hands and feet with thickened subcutaneous tissue; cognitive delay; and motor incoordination. Children continue to grow rapidly during early childhood, but puberty is usually early, with premature epiphyseal fusion. Therefore, most children with Sotos syndrome have a final height within the normal range.¹¹⁹¹ GH secretion and serum IGF levels are normal, and no specific cause of the overgrowth has been identified. About 80% of patients have a loss-of-function mutation in the *NSD1* gene whose product is a nucleus-localized basic transcription factor.¹¹⁹²

Beckwith-Weidemann Syndrome

BWS is the most common (1 of every 13,700 live births) of the overgrowth disorders, the group of disorders associated with excessive somatic and specific organ growth. It is characterized by fetal macrosomia with omophalocele¹¹⁹³ and other clinical features secondary to organomegaly, such as macroglossia, renal medullary hyperplasia, and neonatal hypoglycemia due to islet cell hyperplasia.¹¹⁹⁴ Excessive childhood growth ultimately leads to earlier puberty and early epiphyseal fusion with resultant normal adult height.¹¹⁹⁵ BWS is postulated to be caused by excess availability of IGF2.¹¹⁹⁶ Although an association between BWS and disordered regulation of *IGF2* gene transcription has been documented, no consistent postnatal abnormality of the GH-IGF axis has been identified to date.^{1197,1198}

Various lines of evidence have shown that BWS is associated with loss of imprinting of the genes on chromosome 11p15.5, home of the *IGF2* gene (see Fig. 24-38). Under normal conditions, the paternally derived *IGF2* gene is expressed and the maternally transmitted gene is not active, as described in detail earlier in this chapter. BWS has been associated with uniparental disomy or duplication of the paternal 11p15 region and resultant overexpression of the *IGF2* gene.¹¹⁹⁹ The ICR1 region of 11p15 contains the *IGF2* and *H19* genes; the noncoding gene *H19* is located downstream from *IGF2* and is oppositely imprinted. The promoters of the *IGF2* and *H19* genes share a set of enhancers that act on either gene. On the paternal allele, the *H19* promoter region is methylated and therefore inactivated.²⁴² Upstream from the *H19* and *IGF2* promoter region is a paternally methylated region that prevents binding of CTCF, allowing enhancers to act on the *IGF2* promoter to activate transcription.²⁴³ On the maternal chromosome, this region is not methylated, allowing CTCF to bind and preventing transcription.²⁴⁴ Hypermethylation of the *H19* promoter region with resultant loss of imprinting and biallelic expression of *IGF2* has been associated with fewer than 10% of the cases of BWS.^{253,1200} Hypomethylation of this region is associated with RSS, a syndrome associated with prenatal and postnatal growth failure (see earlier discussion).

ICR2, located 5' of *ICR1*, contains the genes for cyclin-dependent kinase inhibitor 1C (CDKN1C) and potassium channel KQT family member 1 (KCNQ1), among others that are methylated on the maternal allele. Associated with these two genes is an antisense transcript with paternal expression that may suppress transcription; it has been postulated that this cluster of genes is in "expression competition" with the *IGF2*/*H19* cluster.¹²⁰¹ Up to 25% of familial cases of BWS are associated with mutation in the

CDKN1C or *KCNQ1* gene,¹²⁰² but there is debate about whether loss of imprinting of the *IGF2* gene convincingly occurs with most of the mutations. Four children with somatic overgrowth but not the diagnostic features of BWS had *IGF2* gene overexpression.¹¹⁹⁶ Additionally, mutations in *GPC3*, a glypican gene that codes for an IGF2 neutralizing membrane receptor, cause the related Simpson-Golabi-Behmel overgrowth syndrome.^{1203,1204}

Postnatal Statural Overgrowth

As in the case of the child with growth failure, crossing of height percentiles between infancy and the onset of puberty is an indication for further evaluation because it can indicate serious underlying pathology. As with short stature, children with tall stature must be evaluated in the context of familial growth and pubertal patterns.

Tall Stature

GH secretion and levels of IGF1 and IGFBP3 in familial tall stature are often in the upper-normal range.¹²⁰⁵ Tauber and colleagues¹²⁰⁶ divided 65 children with familial tall stature into a subset with high GH secretion rates and frequent secretory bursts and another subset with lower GH secretion and fewer episodic spikes. IGF1 levels were higher among those producing more GH and normal in the low-GH group. The authors postulated that both enhanced secretion of GH and greater efficiency of GH-mediated IGF1 production might be potential causes of familial tall stature.

Tall stature is also a characteristic of certain syndromes. Marfan syndrome, an autosomal dominant disorder of collagen metabolism, is characterized by hyperextensible joints, dislocation of the lens, kyphoscoliosis, dissecting aortic aneurysm, and long, thin bones that result in arachnodactyly and moderately tall stature. It is caused by mutations in the fibrillin-1 gene (*FBN1*). The abnormal *FBN1* monomers from the mutated gene disrupt the normal aggregation of *FBN1*, impairing microfibril formation. Homocystinuria is an autosomal recessive disorder that phenotypically resembles Marfan syndrome, but patients also have cognitive disabilities. Tall stature has also been found in patients with familial ACTH resistance due to a defective ACTH receptor.¹²⁰⁷

Dosage effects of the *SHOX* gene may result in tall stature.¹²⁰⁸ In females with three copies of the *SHOX* gene and gonadal dysgenesis, adult stature was +2 to +2.9 SDS.¹²⁰⁹ In women with 47,XXX karyotype, mean final heights are 5 to 10 cm taller than population means, and men with 47,XXY karyotype (Klinefelter's syndrome) are about 3.5 cm taller than population means.^{30,1210,1211} Males with an XYY karyotype may also have moderately tall stature. In addition to *SHOX* effects, the variable degree of estrogen production in these syndromes may also influence skeletal maturation and final height.²⁵

Failure to enter puberty and complete sexual maturation may result in sustained growth during adult life with ultimate tall stature and a characteristic eunuchoid habitus. The description of tall stature with open epiphyses resulting from mutation of the estrogen receptor or from aromatase deficiency²¹⁻²³ underscores the fundamental role of estrogen in promoting epiphyseal fusion and termination of normal skeletal growth.

Obesity

Obesity is frequently associated with rapid skeletal growth and early onset of puberty.¹²¹² Rapid early postnatal weight gain has been associated with taller stature at 8 years of age than that predicted from the midparental target height.¹²¹³

Others have shown that early postnatal growth is associated with altered tempo of development, but sudden weight gain in middle childhood has little effect on height trajectory.¹²¹⁴ Patients with obesity tend to have diminished overall GH production but normal to high GHBP, and IGF1 levels appear to be capable of maintaining adequate or enhanced linear growth velocity. Bone age is usually modestly accelerated, so that both puberty and epiphyseal fusion occur early and adult height is normal. This association between obesity and rapid growth is so characteristic that a child with obesity and short stature should always be evaluated for underlying pathology, such as hypothyroidism, GHD, Cushing's syndrome, or PWS.

Tumors

Pituitary gigantism is a rare condition, analogous to acromegaly in the adult (see Chapter 9).¹²¹⁵⁻¹²¹⁷ GH-secreting tumors of the pituitary are typically eosinophilic or chromophobic adenomas. Their etiology is uncertain, although many result from somatic mutations that generate constitutively activated G proteins with reduced GTPase activity (see Chapter 9).¹²¹⁸ The resulting increase in intracellular cAMP in the pituitary leads to increased GH secretion. Somatotrophic tumors with excess GH secretion may occur in McCune-Albright syndrome, which is caused by mutations resulting in constitutive activation of G proteins.^{1219,1220} GH-secreting tumors have also been reported in multiple endocrine neoplasia (MEN) and in association with neurofibromatosis and tuberous sclerosis.¹²²¹

GH excess that occurs before epiphyseal fusion results in rapid growth and attainment of adult heights above expected adult potential. When GH hypersecretion is accompanied by gonadotropin deficiency, accelerated linear growth may persist for decades, as was the case for the Alton giant, who reached a height of 280 cm by the time of his death in his 20s.¹²²² Manifestations typical of acromegaly may also appear, such as soft tissue swelling; enlargement of the nose, ears, and jaw with coarsening of facial features; pronounced increases in hand and foot size; diaphoresis; galactorrhea; and menstrual irregularity.

EVALUATION AND TREATMENT OF GROWTH ABNORMALITIES

Clinical Evaluation of Growth Retardation

The most important parameter in assessing children with growth failure is careful clinical evaluation, including accurate serial assessment of height and height velocity. Consideration of a growth disorder is raised when a child's length or height falls below the normal range (<3rd percentile), the growth velocity is subnormal (indicated by length or height measurements that cross percentiles on the growth curve or by an annual growth velocity less than the 3rd percentile for age), or the child's height is below the range expected based on the parents' heights. To grow along the 3rd percentile for height, a child must maintain a height velocity at the 25th percentile for age.¹²²³ Therefore, a height velocity below the 25th percentile in a short child suggests abnormal growth. However, because of the greater error intrinsic to assessment of growth velocity compared with height velocity,¹²²⁴ a single height velocity measurement above the 25th percentile for age, even based on annual height data, cannot fully exclude a growth abnormality in a short child.¹²²⁴

Figure 24-39 provides an algorithm for evaluation of the child with growth failure. Although one third of healthy

CRH, corticotropin-releasing hormone; GH, growth hormone; GHD, growth hormone deficiency; GHIS, growth hormone insensitivity; GHR, growth hormone receptor; GHRHR, growth hormone-releasing hormone receptor; HPA, hypothalamic-pituitary axis; IGF-I, insulin-like growth factor 1; IGFBP-3, IGF-binding protein 3; ITT, insulin tolerance test; MRI, magnetic resonance imaging; SD, standard deviation; SDS, standard deviation score; T₄, thyroxine; TSH, thyroid-stimulating hormone.

infants will cross downward on the length percentile growth curve (discussed previously), this is normal only in relatively large infants born to small parents or in those infants who are following a growth pattern of CDGD (see later discussion). In other situations, the infant who is crossing downward on the length percentile curve should be investigated in the same way as other children with subnormal growth velocities.

History and Physical Examination

The many illness-related causes of diminished growth were discussed in earlier sections of this chapter. A growth pattern in which weight gain is impaired before linear growth or in which there is greater impairment of weight gain than of length/height gain suggests an impairment of nutrition, such as inadequate intake, malabsorption, or increased energy requirements. Nonhormonal causes of growth failure should be investigated based on data obtained from a careful history and physical examination. In addition, careful evaluation of the growth curve in the context of the family history may suggest a normal variant growth pattern, such as crossing linear percentiles of infancy, familial short stature, or CDGD. In such cases, careful observation may be all that is required. One third of all infants have growth parameters that cross percentiles downward on the growth curve, and 3% of the all children have a length or height below the 3rd percentile. Most of these children have no disease or growth disorder and will demonstrate this by having a normal growth velocity on continued observation.

The physical examination should look for evidence of an underlying organ-specific or systemic disease. It should also evaluate for clues specific to growth disorders, such as findings suggestive of genetic disorders such as Noonan syndrome, RSS, or TS. In addition, body proportions should be measured, because skeletal disproportion suggests a skeletal dysplasia.

Findings on the history and examination may point to an increased likelihood of the presence of GHD (Table 24-8). Micropenis in a male newborn should always lead to an evaluation of the GH-IGF1 axis. Nystagmus, indicating neonatal blindness, suggests hypopituitarism due to its association with optic nerve hypoplasia in the syndrome of septo-optic-dysplasia. A history of other midline defects, such as cleft lip and cleft palate,⁵²⁹ or a single central incisor increases concern for hypopituitarism. Unexplained neonatal hypoglycemia, hepatitis, or prolonged jaundice should prompt an evaluation of pituitary function. Older children with GHD have less impaired weight gain than height gain, resulting in an increased weight for height; they are often described as having a “cherubic” appearance. Increased weight for height with growth failure is also characteristic of hypothyroidism. If the weight gain is dramatic, Cushing’s syndrome should be considered. (However, linear growth acceleration with excess weight gain is not consistent with Cushing’s syndrome.) Finally, GHD should be suspected in children with known or suspected CNS pathology (e.g., tumors, prior radiation therapy to the CNS, malformations, infection, trauma) or with documented deficiency of TSH, ACTH, antidiuretic hormone, or gonadotropin.

Laboratory Testing

If the history and physical examination do not suggest a specific disorder causing growth failure and the growth pattern and family history do not provide sufficient reassurance that the growth is following a normal variant growth pattern, it is necessary to perform laboratory testing. In many cases, the testing does not identify an

TABLE 24-8

Key History and Physical Examination Findings That Suggest the Diagnosis of Growth Hormone Deficiency (The Growth Hormone Research Society 2000 Criteria)

Findings That Suggest the Diagnosis of GHD

In the Neonate

Hypoglycemia
Prolonged jaundice
Hepatitis
Microphallus
Traumatic delivery

In a Child with Short Stature or Growth Failure

Cranial irradiation
Head trauma or central nervous system infection
Consanguinity and/or an affected family member
Craniofacial midline abnormalities

Findings That Support Immediate Investigation for GHD

In a Child with Short Stature

Signs indicative of an intracranial lesion
Neonatal symptoms and signs of GHD
Auxologic findings
Severe short stature (≤ -3 SD)
Height ≤ -2 SD and height velocity over 1 yr of ≤ -1 SD
A decrease in height SD of >0.5 over 1 yr in children >2 yr of age
A height velocity below -2 SD over 1 yr
A height velocity >1.5 SD below the mean sustained velocity over 2 yr
Signs of multiple pituitary hormone deficiency (MPHD)

GHD, growth hormone deficiency; SD, standard deviation.

From Growth Hormone Research Society. Consensus guidelines for the diagnosis and treatment of growth hormone (GH) deficiency in childhood and adolescence: summary statement of the GH research society. *J Clin Endocrinol Metab.* 2000;85:3990-3993.

abnormality, and the child either is ultimately found to have a normal variant growth pattern or falls into the classification of ISS. The laboratory tests can be divided into those screening for disorders outside the GH-IGF1 axis and those evaluating that axis.

Screening Tests

Because a number of illnesses can cause growth failure either before or in the absence of other signs or symptoms, it is necessary to screen for these disorders in children with abnormal growth. A complete blood count looks for evidence of anemia, chronic infection, or inflammation. A complete blood chemistry panel provides evidence for silent renal disease (including renal tubular acidosis), liver disease, and disorders of calcium and phosphorus. The erythrocyte sedimentation rate is measured to look for evidence of disorders involving chronic inflammation, such as presymptomatic juvenile idiopathic arthritis and inflammatory bowel disease. A urinalysis is obtained to look for renal disease and chronic urinary tract infection. Tissue transglutaminase IgA (and total serum IgA) is measured to screen for celiac disease. In girls in whom no other explanation for short stature is found, a karyotype should be obtained to exclude TS. This is done even in the absence of other physical features of TS, because growth failure may be the only evident feature, particularly in cases of significant mosaicism.

Hypothyroidism should be sought by screening in children with growth failure and may be the cause of the growth failure. Because of the importance of thyroid hormone on brain development in infants, this possibility

should be considered early in the evaluation of an infant with growth failure in order to correct identified hypothyroidism quickly. In addition, hypothyroidism results in lower serum IGF1 levels and decreases GH levels during provocative testing.¹²²⁵⁻¹²²⁷ Therefore, it is necessary to ensure that thyroid function is normal before evaluating for GHD. TSH is measured because it is the most sensitive indicator of primary hypothyroidism. However, because central hypothyroidism must also be considered as a cause for growth failure in children, the thyroxine level should also be measured.

Bone Age. After the neonatal period, a bone age determination can be useful in the evaluation of children with growth disorders. A radiograph of the left hand and wrist is commonly used for comparison with the published standards of Greulich and Pyle.¹²²⁸ An alternative method for assessing bone age from radiographs of the left hand involves a scoring system for developmentally identified stages of each of 20 individual bones,¹²²⁹ a technique that has been adapted for computerized assessment.^{1230,1231} The left hand is used because radiographs of the entire skeleton would be tedious and expensive and would involve additional radiation exposure. However, the hand does not contribute to height, and accurate evaluation of growth potential may require radiographs of the legs and spine.

Although the bone age result does not identify a specific diagnosis in a child with a growth disorder, it can be used to classify the child's growth in relation to groups of diagnoses. Growth disorders caused by an underlying illness or hormone disorder (e.g., renal disease, malnutrition, glucocorticoid excess) are associated with a delayed bone age—that is, a bone age that is younger than the patient's chronologic age. Similarly, hypothyroidism and GHD are associated with a delayed bone age. If short stature is intrinsic to the condition, however, bone age is not delayed and is within the range of normal for the chronologic age. This is true for genetic disorders such as TS, Noonan syndrome, and RSS and also for familial short stature. In CDGD, the bone age is delayed, consistent with the future delay in puberty and late epiphyseal fusion. Given the lack of precise diagnostic laboratory tests for GHD, a lack of bone age delay argues against this diagnosis. On the other hand, the fact that patients with CDGD have a delayed bone age does not help in the sometimes difficult discrimination between this condition and GHD.

A number of important caveats concerning bone age must be considered. Experience in determination of bone age is essential to minimize intraobserver variance, and clinical studies involving bone age benefit from having a single reader perform all interpretations. The normal rate of skeletal maturation differs between boys and girls and among different ethnic groups. The standards of Greulich and Pyle are separable by sex but were developed in American white children between 1931 and 1942. Both those and the Tanner and Whitehouse standards are based on normal children¹²³² and may not be applicable to children with skeletal dysplasias, endocrine abnormalities, or other forms of growth retardation or acceleration.

Prediction of Adult Height. The extent of skeletal maturation observed in an individual can be used to predict the ultimate height potential. Such predictions are based on the observation that the more delayed the bone age (relative to the chronologic age), the longer the time before epiphyseal fusion prevents further growth. The most commonly used method for height prediction, based on Greulich and Pyle's *Radiographic Atlas of Skeletal Development*,¹²²⁸ was developed by Bayley and Pinneau¹²³³ and relies on bone age, height,

and a semiquantitative allowance for chronologic age (Table 24-9). The system of Tanner and colleagues¹²²⁹ uses measurements of height, bone age, chronologic age, and, during puberty, height and bone age increments during the previous year, as well as menarchal status. Roche, Wainer, and Thissen¹²³⁴ used the combination of height, bone age, chronologic age, midparental height, and weight (RWT method). Attempts have been made to calculate final height predictions without requiring the determination of skeletal age¹²³⁵ by using multiple regression analyses with available data such as height, weight, birth measurements, and midparental stature. All of these systems are, by nature, empiric and are not absolute predictors. Indeed, the 90% confidence intervals for the predictions are approximately ± 6 cm at younger ages. The more advanced the bone age, the greater the accuracy of the adult height prediction, because a more advanced bone age places a patient closer to his or her final height.

All methods of predicting adult height are based on data from normal children, and none has been documented to be accurate in children with growth abnormalities. For this kind of precision, it would be necessary to develop disease-specific atlases of skeletal maturation (e.g., for achondroplasia or TS). In addition, height predictions will clearly be inaccurate in predicting the final height in the case of a growth-impairing process that is not adequately treated. In addition, height predictions must be used with care in assessing height outcomes during treatment. For example, in patients with precocious puberty treated with GnRH agonists, height prediction is known to overpredict the actual final height.¹²³⁶ It is fair to say that the clinical endocrinologist must not give height predictions a value that is greater than a reasonable estimate.

Tests of the Growth Hormone-IGF1 Axis

In children with growth retardation in whom other causes have been excluded, the possibility of GHD should be considered. However, these tests can have poor specificity, so clinical assessment must always play an important part in the evaluation of abnormalities in the GH-IGF1 axis. For example, a child growing consistently just below the 3rd percentile for height, with a growth rate that is accordingly above the 25th percentile for age, is very unlikely to be GH deficient. Abnormal test results in this situation would most likely represent false-positive results.

Testing of the GH-IGF1 axis begins with “static” testing of GH function, measuring IGF1. It may also be helpful to measure IGFBP3. In some cases—if the clinical presentation is highly suggestive of GHD (see Table 24-8),¹²³⁷ and the IGF1 level (and the IGFBP3 level, if obtained) also indicates a high likelihood of GHD—it is appropriate to proceed directly to the dynamic tests of GH secretion. In most cases, however, unless there is an abnormality identified on the screening tests, it is appropriate to monitor the child's growth for a period of 6 to 12 months to accurately assess the child's growth rate. Then, based on the complete clinical picture, including the growth rate and the IGF1 level, the decision is made to proceed with dynamic testing of GH secretion or to continue monitoring the child's growth.

There is no test that definitively diagnoses GHD. Because there is no “gold standard,” it is impossible to precisely define the sensitivity or specificity of any test for GHD. Some information on specificity can be obtained by comparing the results with those obtained in normal children, although, for the more complicated tests, these data can be difficult to obtain in children. Sensitivity relies on comparing positive results from one test with those of another—for example, comparing low IGF1 concentrations to failed results on provocative GH tests. Poor sensitivity of IGF1 as an indicator of GHD has been based on results

*The column headed "Retarded" is used when bone age is >1 yr below chronologic age; the column headed "Advanced" is used when bone age is >1 yr greater than chronologic age.

Table derived from Richman RA, Kirsch LR. Testosterone treatment in adolescent boys with constitutional delay in growth and development. *N Engl J Med* 1988;319:1563-1567. Based on the data of Bayley and Pinneau.¹²³ Predicted final height is calculated by dividing the current height by the fraction of adult height achieved determined from the table.

from children with normal IGF1 concentrations who have abnormal results on provocative GH tests. However, because of the known limited specificity of these provocative tests (discussed later), one cannot determine whether the discrepant results are due to the poor sensitivity of the IGF1 test or the poor specificity of the provocative GH test. Again, it is critical to interpret all results together and in the context of the clinical data.

Insulin-Like Growth Factor 1. GHD is associated with a low serum concentrations of IGF1 (Fig. 24-40). Unlike GH

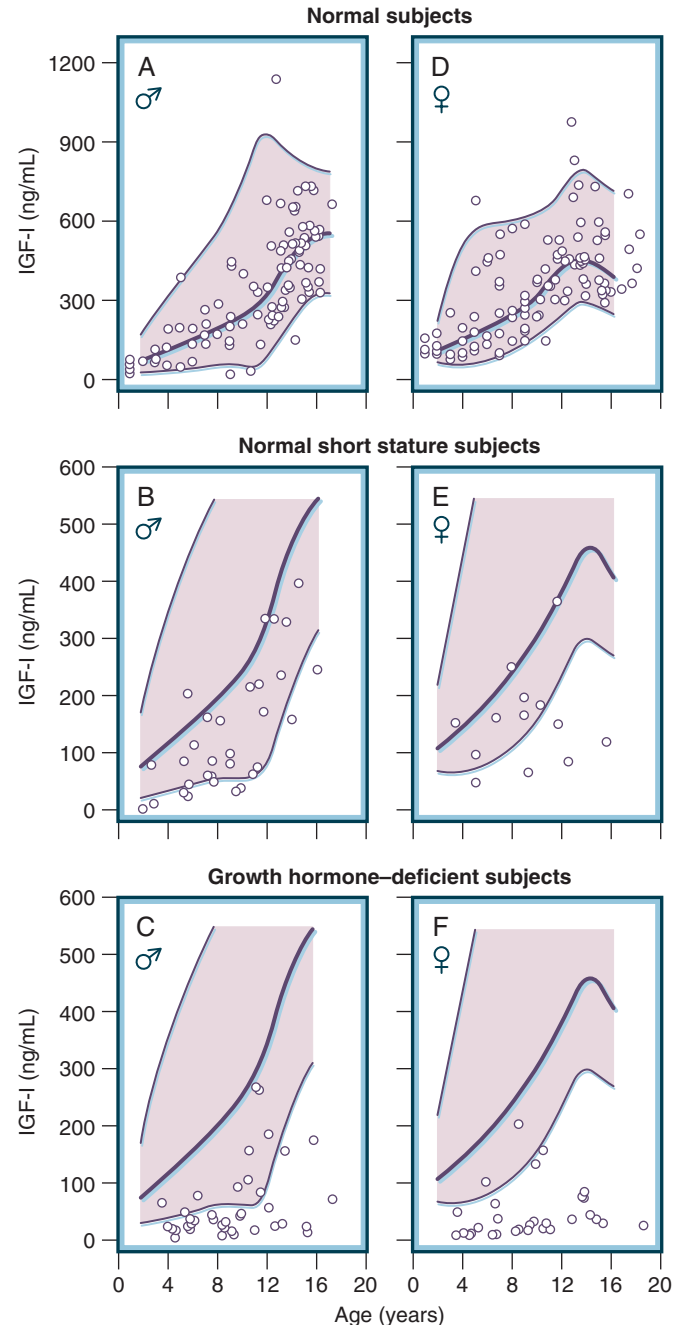

Figure 24-40 Serum levels of insulin-like growth factor I (IGF-I) in normal patients and in patients with growth disorders. Circles represent IGF1 levels in normal subjects (A, D), normal short stature subjects (B, E), and growth hormone deficient subjects (C, F). The lines represent the 5th, 50th, 95th percentiles for log-normalized IGF1 levels in normal subjects. (From Rosenfeld RG, Wilson DM, Lee PD, et al. Insulin-like growth factors I and II in the evaluation of growth retardation. *J Pediatr*. 1986;109:428-433.)

levels, which rise and fall with its pulsatile secretion, the IGF1 level in blood is stable, with minimal diurnal variation. The GH dependency of the IGFs was established in the initial report from Salmon and Daughaday²⁰⁰ and was further clarified with the development of sensitive and specific immunoassays that distinguish between IGF1 and IGF2.¹²³⁸ IGF1 levels are more GH-dependent than IGF2 levels and are more likely to reflect subtle differences in GH secretory patterns. However, serum IGF1 levels are also influenced by age,^{234,235,1239} degree of sexual maturation, and nutritional status. Therefore, IGF1 levels must be compared with age-specific ranges (Fig. 24-41), and with ranges defined by stage of sexual maturation. Some clinicians evaluate IGF1 results against the reference range based on bone age (rather than the chronologic age). This may improve the specificity of this test for GHD, although there are no data to address the validity of this approach.

IGF1 levels in normal children younger than 5 or 6 years of age are low. This leads to poor sensitivity of IGF1 levels for identifying GHD in young children. As few as 40% to 50% of young, short children with evidence of GHD on provocative tests have IGF1 levels below the lower level of the reference range.^{1240,1241} IGF1 levels increase with age, resulting in better separation of IGF1 levels in GH-deficient children from those in normal children and a higher sensitivity of IGF1 levels for GHD. However, although sensitivities of 85% to 100% have been reported in some studies,^{1241,1242} in others it has averaged approximately

70%.^{1225,1242-1245} Again, the lack of a gold standard means that some of the false-negative findings obtained by measurement of IGF1 levels could also represent false-positives on provocative GH testing.

IGF1 levels also suffer from a lack of specificity in diagnosing GHD. In general, IGF1 levels have higher specificity in younger children, with declining specificity in older children. Juul and colleagues¹²⁴⁵ found that IGF1 levels had a specificity for GHD of 98% in children younger than 10 years of age but a specificity of only 67% in those older than 10 years. Similarly, Cianfarani and colleagues¹²⁴⁰ found a sensitivity of 100% in children younger than 9 years of age that dropped to 76% in older children. The overall specificity of a low IGF1 measurement may only be approximately 70%.^{1225,1242,1243}

In addition to the specific challenges of accurately quantitating IGF1 levels in serum (see later discussion), the nutritional dependence of IGF1 levels significantly affects the accuracy of this test in evaluating for GHD. Even a few days of decreased caloric intake can lower IGF1 levels.^{1225,1246} This probably contributes to the finding that IGF1 levels can vary by as much as 38% from day to day in a given patient.^{1246,1247}

Early quantitation of IGFs used bioassays based on [³⁵S]-sulfate incorporation (hence, "sulfation factor" as an early synonym for IGF/somatomedin C); on stimulation of the synthesis of DNA, RNA, or protein; or on glucose uptake.^{1248,1249} Development of specific antibodies permitted the development of accurate and specific measurement of IGF1 and IGF2.^{1238,1239,1243,1250,1251} However, the presence of IGFBPs results in a significant technical challenge for the accurate quantitation of IGF1 (and IGF2) in serum.^{1225,1248,1252}

Interference is a particular problem in conditions with a relatively high IGFBP/IGF peptide ratio and at the extremes of the assay (i.e., GHD, acromegaly). In uremia, IGFBPs artifactually lower IGF1 levels and increase IGF2 levels in assays that do not eliminate this interference.⁹⁰¹

The most effective way to deal with IGFBPs is to separate them from IGF peptides by chromatography under acidic conditions.¹²⁵³ This labor-intensive procedure has occasionally been replaced by an acid ethanol extraction procedure.¹²⁵⁴ Although the latter method may be reasonably effective for most serum samples, it is problematic in conditions of high IGFBP/IGF peptide ratios, such as conditioned media from cell lines and sera from newborns or from subjects with GHD or uremia. A number of alternative approaches to addressing the interference from the IGFBPs have been developed, including the use of tracers that do not bind to IGFBPs¹²⁵⁵ and "sandwich" assay methods.¹²⁵⁶ Automated IGF1 immunometric (IRMA) or immunochemiluminometric (ICMA) assays typically add an excess of IGF2 to the assay to displace the IGFBPs and use highly specific IGF1 antibodies.^{231,1225,1248} Although current IGF1 assays significantly minimize the interference from IGFBPs, it is important that each assay develop reference ranges that match the clinical samples to be tested, because ethnic variations and nutritional and environmental factors can affect "normal" serum IGF1 concentrations.

A number of assays have been developed that purport to measure "free" or "free dissociable" IGF1 as a means of assessing concentrations of IGF1 peptides that circulate unbound to IGFBPs.¹²⁵⁷ Both the accuracy and the physiologic relevance of these determinations remain open to debate.¹²²⁵

Insulin-Like Growth Factor-Binding Protein 3. Measurement of the serum level of IGFBP3, the major serum carrier of IGF peptides, is a potential additional tool for

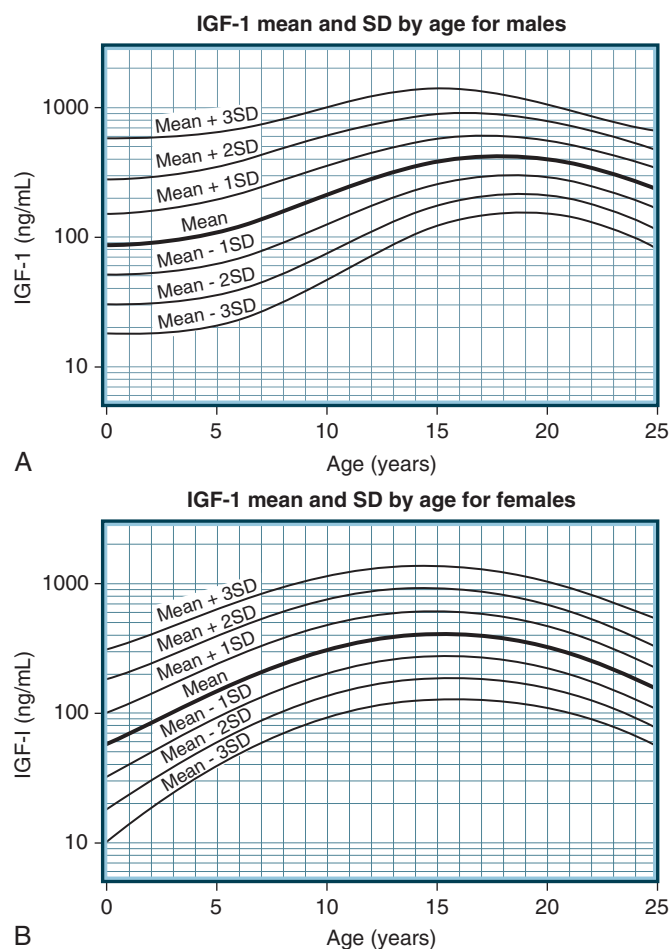

Figure 24-41 Normal serum levels of insulin-like growth factor I (IGF-I) for males (**A**) and females (**B**). SD, standard deviation. (Data courtesy of Diagnostic Systems Laboratories, Inc., Webster, TX.)

evaluating GH function.^{373,1258,1259} The advantages of assaying IGFBP3 concentration include the following:

1. IGFBP-3 levels are GH dependent.
2. IGFBP3 levels are constant throughout the day.
3. The immunoassay of IGFBP3 is technically simple and does not require separation of the binding protein from IGF peptides.
4. Normal serum levels of IGFBP3 are high, typically in the 1 to 5 mg/L range, so that assay sensitivity is not an issue. (The molar concentration of IGFBP3 approximates the sum of the molar concentration of IGF1 and IGF2.)
5. Serum IGFBP3 levels vary with age to a lesser degree than is the case for IGF1 (Fig. 24-42). Even in infants, serum IGFBP3 levels are sufficiently high to allow discrimination of low values from the normal range.
6. Serum IGFBP3 levels are less dependent on nutrition than serum IGF1, reflecting the “stabilizing” effect of IGF2 levels.

Like IGF1 levels, determination of the sensitivity and specificity of IGFBP3 levels for identifying GHD suffers from the lack of a gold standard. With that limitation in mind, Blum and colleagues¹²⁵⁹ initially found that low IGFBP3

levels had both high sensitivity (97%) and high specificity (95%) for GHD. Most subsequent studies confirmed the high specificity, with values generally greater than 80% to 90%.^{1225,1240,1242,1244,1260} However, most studies have found that many children diagnosed with GHD on the basis of provocative GH testing actually have normal IGFBP levels, and the sensitivity of this test is less than 60%. In a study by Cianfarani and colleagues,¹²⁴⁰ only 7% (2/28) of children younger than 14 years of age with GHD had an IGFBP3 level more than 1 SD below the mean. Low IGFBP3 levels may be an indicator of more severe GHD. For example, in one study the sensitivity of the IGFBP3 assay if the peak GH was less than 5 µg/L on provocative testing was 93%, but when the peak GH was 5 to 10 µg/L, the sensitivity was only 43%.¹²⁶¹

Insulin-Like Growth Factor 2. IGF2 levels are higher than those of IGF1. Levels increase rapidly after birth, but thereafter IGF2 levels are less age dependent than those of IGF1. However, although GHD is associated with low IGF2 levels, IGF2 is much less GH dependent than IGF1 (Fig. 24-43). In two studies, IGF2 levels were more than 2 SD below the mean in only 21% and 31% of children defined as GH deficient based on provocative GH testing.^{1240,1262}

Rosenfeld and colleagues¹²⁴³ found low IGF2 levels in 52% of GH-deficient children and in 35% of normal short children. However, only 4% of GH-deficient children and 11% of normal short children had normal plasma levels of both IGF1 and IGF2, showing a similar sensitivity and specificity to combined IGF1/IGFBP3 testing.

Growth Hormone. Assessment of pituitary GH production is difficult because GH secretion is pulsatile, with the most consistent surges occurring at times of slow-wave electroencephalographic rhythms during stage 3 and stage 4 of sleep. Spontaneous GH secretion varies with gender, age, pubertal stage, and nutritional status, all of which must be factored into the evaluation of GH production.

Between normal pulses of GH secretion, serum GH levels are low (often <0.1 µg/L), below the limits of sensitivity of most conventional assays (typically <0.2 µg/L). Accordingly, measurement of random serum GH concentrations is almost useless in diagnosing GHD but may be useful in the diagnosis of GH insensitivity and GH excess. Measurement of GH “secretory reserve” relies on the use of physiologic or pharmacologic stimuli, and such provocative tests have formed the basis for diagnosis of GHD for more than 30 years.^{1263,1264}

Assay Limitations. One of the biggest confounders in the evaluation of GH secretion is the variability of measured GH levels across different assays. Many studies have demonstrated as much as threefold variability in the measurement of serum GH levels among established laboratories.¹²⁶⁵⁻¹²⁶⁸ This is explained, in part, by the presence of several molecular forms of GH in serum. Circulating GH consists of monomers of the two secreted GH isoforms (with approximately 43% existing as the monomeric 22-kd isoform and 8% as the monomeric 20-kd isoform), along with dimers and higher-order oligomers of the two isoforms, acetylated forms of GH, desamidated GH, and peptide fragments of GH.¹²²⁵ Therefore, much of the variability in results is due to the use of different monoclonal or polyclonal antibodies, including variability in recognition of the different circulating forms of GH by these antibodies. Additionally, variations in the choice of standards, labeling techniques, and assay buffers (matrix) are also contributory.¹²²⁵ Consequently, a child who is determined to have GHD by one assay may be considered

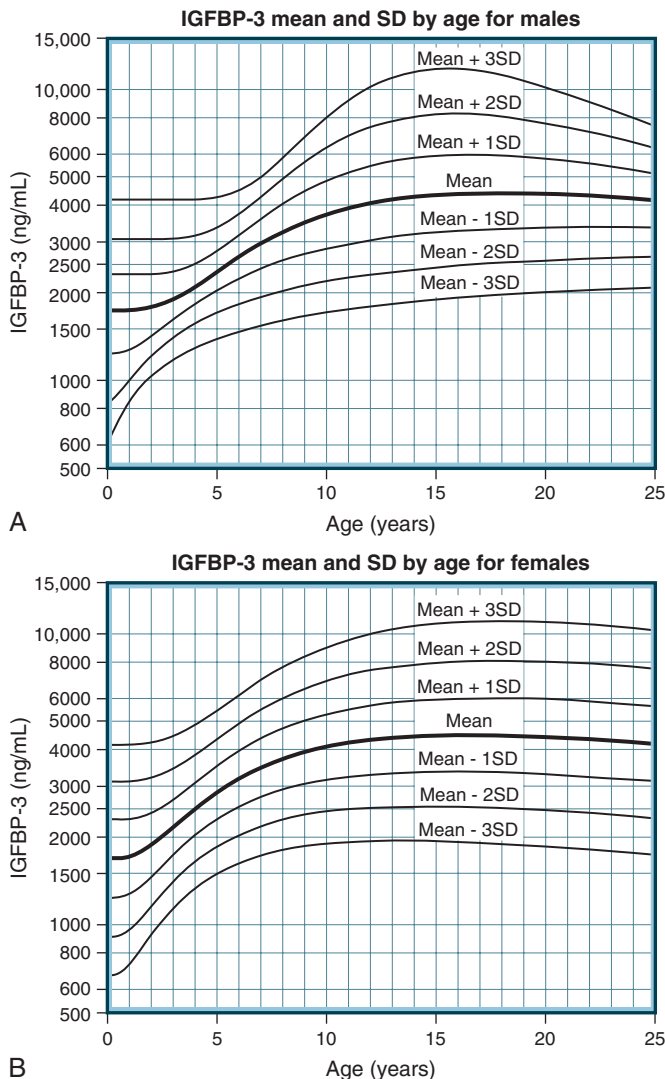

Figure 24-42 Normal serum levels of insulin-like growth factor-binding protein 3 (IGFBP3) for males (A) and females (B). (Data courtesy of Diagnostic Systems Laboratories, Inc., Webster, TX.)

Figure 24-43 Serum insulin-like growth factor 2 (IGF-II) levels in normal patients and in patients with growth disorders. (From Rosenfeld RG, Wilson DM, Lee PD, et al. Insulin-like growth factors I and II in the evaluation of growth retardation. *J Pediatr*. 1986;109:428-433.)

normal by another. This is an unacceptable situation for clinicians, who may be unaware of the type and source of the GH assay being used by a given laboratory.¹²⁶⁹

Provocative Tests. Because random GH levels cannot be used to diagnose GHD, evaluation of GH secretion requires that samples be obtained after an expected stimulation of GH secretion. Physiologic stimuli include fasting, sleep, and exercise, and pharmacologic stimuli include levodopa, clonidine, glucagon, propranolol, arginine, and insulin. Standard provocative GH tests are summarized in Table

24-10. GH levels are measured on multiple specimens obtained after the stimulus. Failure to increase serum GH above a defined cutoff level is believed to indicate GHD.

Although provocative GH testing has been the foundation for diagnosis of GHD since GH assays first became available, they have a number of weaknesses when they are used to identify GHD.^{1263,1269,1270} Most importantly, there is no clear cutoff level that discriminates a normal response from a deficient response, and secondly, these provocative tests have poor specificity.

Determination of the "Subnormal" Response to Provocative Tests. GH secretion has a continuous distribution; there is not a bimodal distribution of either spontaneous GH secretion or peak GH levels after provocative tests that would clearly separate normal from deficient secretion. The initial levels of GH during provocative testing that were used to define GHD were based on the study of patients with profound classic findings or organic destruction of the adenohypophysis.¹²⁷¹ In addition, partly because of the limited supply of GH, one goal was to identify the most severely affected children.

Initially, a cutoff level of 2.5 $\mu\text{g/L}$ was used; this was later increased to 5 $\mu\text{g/L}$ and subsequently to 7 $\mu\text{g/L}$. After the development of recombinant DNA-derived GH eliminated the limits on GH supply, many pediatric endocrinologists considered a peak GH level lower than 10 $\mu\text{g/L}$ to be indicative of GHD. The higher cutoff level can be partially justified by the desire to identify children with GHD that is less complete (i.e., partial GHD). Nonetheless, there have been few data validating the higher cutoff values.^{1270,1272}

Further confounding the determination of an evidence-based cutoff level is the variability in GH levels measured across different assays (discussed earlier). Many new GH assays give results that are 33% to 50% lower than earlier assays, but there has not been a systematic reassessment of the "new normal" GH cutoff levels nor a critical evaluation by many endocrinologists of which assay their center might be using.^{1273,1274} The same cutoff level has been applied without regard to the stimulus used. However, the peak GH levels obtained are only modestly different for many of these agents, with the exception of GHRH, which leads to substantially higher levels of GH,¹²⁷⁵⁻¹²⁷⁷ indicating a need for a higher cutoff value for such tests.

Specificity of Provocative Tests for Growth Hormone Deficiency. The data that are available suggest a low specificity for the provocative tests, with a substantial number of normal children having peak GH levels lower than 7 to 10 $\mu\text{g/L}$.¹²⁶⁹ Ghigo and colleagues¹²⁷⁶ studied 472 healthy, normal children, including 296 with normal stature and 177 with normal short stature. Excluding tests that used GHRH (which has generally not been used in the evaluation of GH function in children), they found that between 10% and 25% of their subjects had peak GH levels lower than 7 $\mu\text{g/L}$ and 23% to 49% had peak levels lower than 10 $\mu\text{g/L}$. Similar results were found in other studies.¹²⁷⁸⁻¹²⁸¹

Because of this poor specificity, failure on two provocative tests should be obtained before GHD is diagnosed on the basis of provocative testing. This approach significantly improves the specificity of provocative testing, although it remains imperfect. In the study of Ghigo and colleagues,¹²⁷⁶ two tests were performed on 78 children, and 10% had peak GH levels lower than 10 $\mu\text{g/L}$ on both tests (2.6% had peak GH levels <7 $\mu\text{g/L}$ on both tests).

The specificity of provocative GH tests can be increased by using a lower cutoff point to define a normal response. However, this is undesirable if it excludes individuals with less severe degrees of GHD. Because of the continuous nature of GH secretion across individuals and the lack of

TABLE 24-10

Tests to Provoke Growth Hormone Secretion

Stimulus	Dosage	Times Samples Are Taken (min)	Comments
Sleep	Obtain sample from indwelling catheter	60-90 min after onset of sleep	
Exercise	Step climbing; exercise cycle for 10 minutes	0, 10, 20	Observe child closely when on the steps
Levodopa	<15 kg: 125 mg 10-30 kg: 250 mg >30 kg: 500 mg	0, 60, 90	Nausea, rarely emesis
Clonidine	0.15 mg/m ²	0, 30, 60, 90	Tiredness, postural hypotension
Arginine HCl (IV)	0.5 g/kg (max 30 g) 10% arginine HCl in 0.9% NaCl over 30 min	0, 15, 30, 45, 60	
Insulin (IV)*	0.05 to 0.1 unit/kg	0, 15, 30, 60, 75, 90, 120	Hypoglycemia, requires close supervision
Glucagon (IM)	0.03 mg/kg (max 1 mg)	0, 30, 60, 90, 120, 150, 180	Nausea, occasional emesis
GHRH (IV) [†]	1 µg/kg	0, 15, 30, 45, 60, 90, 120	Flushing, metallic taste

Patients must be euthyroid at the time of testing. Tests should be performed after an overnight fast. For prepubertal children, pretreating with sex hormones increases the specificity of the tests (see text).

[†]The cutoff used for tests involving GHRH is higher than that for other tests. (Maghnie M et al. *J Clin Endocrinol Metab* 2002; 87:2740-4 and Pandian R et al. *Clin Lab Med* 2004; 24:141-74.)

*Insulin-induced hypoglycemia is a potential risk of this procedure, which is designed to lower the blood glucose by at least 50%. Documentation of appropriate lowering of blood glucose is recommended. If GHD is suspected, the lower dosage of insulin is usually administered, especially in infants. D₁₀W and glucagon should be available.

(Table derived from Post EM, Richman RA. A condensed table for predicting adult stature. *J Pediatr* 1981; 98:440-442 based on the data of Bayley and Pinneau.¹²³³ Predicted final height is calculated by dividing the current height by the fraction of adult height achieved, determined from the table.)

a gold standard test for GHD, the conflict between specificity and sensitivity cannot be completely resolved. However, two reports have examined multiple clinical and laboratory characteristics of short children who were divided into three groups based on their results on GH stimulation testing: a group whose results were low (<5 or <7 µg/L), fulfilling criteria for GHD; a group whose results were greater than 10 µg and therefore were believed not to have GHD; and a group whose results were intermediate between these high and low cutoff points. In both of these studies, the group with the lowest peak GH levels differed significantly from both the intermediate and the high-GH groups on numerous measures.^{1282,1283} However, the intermediate group was indistinguishable from the group without GHD, rather than having characteristics intermediate between the other two groups, as might be expected if they had a less severe degree of GHD.

Sex Hormone Priming. Serum GH levels rise during puberty, with GH secretion stimulated by the rise in estrogen produced from the ovary or from aromatization of testosterone.^{135,148} This same process results in higher peak GH levels during provocative testing in pubertal children (compared with prepubertal children)^{1279,1284} and in children who have received treatment with estrogen or testosterone.^{1279,1284-1288} In a study by Marin and colleagues,¹²⁷⁹ 61% of normal prepubertal children and 44% of normal children in early puberty (Tanner stage I) had GH levels lower than 7 µg/L on provocative testing; based on these results (but not on their heights), they would have met criteria for a diagnosis of GHD. However, after 2 days of treatment with estrogen, 95% of these children had a peak GH level higher than 7 µg/L. Therefore, the specificity of GH provocative tests can be improved by pretreating ("priming") the pediatric patients with exogenous gonadal steroids.^{1289,1290} In a placebo-controlled comparison, the specificity of GH provocative tests (using 9 µg/L as a cutoff point on a polyclonal GH assay) increased from 80% to 98% after estrogen priming.¹²⁸⁷ In a study of 50 growth-retarded boys who had subnormal results on provocative GH tests without testosterone priming but normal results after priming, final height (without intervention) was

greater than the midparental height, consistent with normal GH function in these children.¹²⁹¹

Another factor to consider when evaluating provocative GH testing is the impact of body weight on GH secretion. In both adults^{121,156,1292,1293} and children,^{152,1294,1295} obese individuals have decreased spontaneous and stimulated GH levels, compared with nonobese individuals. Even within the normal range, the BMI SDS is inversely associated with peak GH level on provocative tests in children.^{1296,1297} Therefore, particular care must be taken when interpreting GH stimulation test results in obese individuals.

Although there are limitations to the information gained from provocative GH tests, they continue to be helpful in evaluating a child for GHD. The tests should be performed after an overnight fast, and the patient needs to be euthyroid at the time of testing. Testing should not be performed if the patient is taking supraphysiologic doses of glucocorticoid (i.e., >15 mg/m² per day of hydrocortisone or the equivalent of a synthetic glucocorticoid), because these drugs can suppress the GH response. The tests are generally safe, although appropriate precautions must be taken. Specifically, tests involving insulin administration carry the risk of hypoglycemia and seizures, and should be performed only by experienced medical personnel and under appropriate patient supervision. Deaths have been reported from insulin-induced hypoglycemia and from its overly vigorous correction with parenteral glucose.¹²⁹⁷ The specificity of the tests can be increased by pretreating the child with estrogen or testosterone (e.g., 5 mg of conjugated estrogens orally on the night before and the morning of the test, or 50 to 100 µg/day of ethinyl estradiol for 3 consecutive days before testing, or 100 mg of depot testosterone 3 days before testing) and by carefully selecting the lower limit for a normal response.

Tests of Spontaneous Growth Hormone Secretion. Another diagnostic approach to evaluate GH secretion involves measurement of spontaneous GH secretion. This can be done either by multiple sampling (every 5 to 30 minutes) over a 12- to 24-hour period or by continuous blood withdrawal over 12 to 24 hours.^{96,1298-1300} The former method allows one to evaluate and characterize GH

pulsatility, whereas the latter only permits determination of the mean GH concentration. Both methods are subject to many of the same limitations as provocative GH testing. The problems of expense and discomfort are obvious, and, although it was thought that this approach might be more reproducible than provocative GH tests, variability remains a problem.¹³⁰¹⁻¹³⁰³ The ability of such tests to discriminate between children with GHD and those with normal short stature is very limited due to significant overlap of each of the parameters measured between normal children and children with GHD. Rose and coworkers¹³⁰⁴ reported that measurement of spontaneous GH secretion identified only 57% of children with GHD as defined by provocative testing. Similarly, Lanes¹³⁰⁵ reported that one fourth of normally growing children have low overnight GH levels, and a longitudinal study of normal boys through puberty demonstrated a wide intersubject variance, including many "low" 24-hour GH production rates in children with fully normal growth.^{135,136} Therefore, measurement of spontaneous GH secretion does not appear to offer advantages over alternative means of evaluating GH function.

Summary. Despite the many problems associated with GH measurement methods, there continues to be value in determining GH secretory capacity in the diagnostic evaluation of a child with growth failure. Documentation of GH levels as being decreased, normal, or increased helps in discriminating among GHD, non-GH/IGF1-related growth failure (including ISS), and GH insensitivity. Results supporting the presence of GHD alert the clinician to the possibility of other pituitary deficiencies. The presence of pituitary dysfunction mandates clinical and radiologic evaluation for evidence of congenital or acquired structural defects of the hypothalamus or pituitary, including the possibility of intracranial tumors. Finally, documentation of GHD, either alone or combined with other pituitary deficiencies, may warrant evaluation for molecular defects of GH production.

Growth Hormone-Binding Protein. Mutation of the GHR can impair GH signaling, resulting in GH insensitivity. The most severe mutations cause profound growth failure (Laron dwarfism). The extracellular portion of the GHR is cleaved from the remaining portion and circulates in the blood as GHBP. GHBP levels can be measured in serum. Low levels, particularly undetectable levels, may be diagnostic of GH insensitivity due to GHR mutations.

GHBP levels are not low in all forms of GH insensitivity. The levels may be normal, or even increased, with mutations in the GHR that do not alter the GHBP portion of the protein (i.e., mutations in the transmembrane or intracellular domains) or with defects that are downstream of the GHR.

IGF1 and IGFBP3 Generation Tests. IGF1 and IGFBP3 generation tests are designed to evaluate for the presence of GH insensitivity.¹³⁰⁶ When patients with GH insensitivity are treated with GH for several days, the levels of IGF1 and IGFBP3 do not increase as they would in normal individuals.¹³⁰⁷⁻¹³¹⁰ Criteria for a response indicating GH insensitivity have included a rise in IGF1 of less than two times the intra-assay variation (approximately 10%)^{755,1311} or a failure to increase IGF1 by at least 15 µg/L.¹³¹² However, Laron dwarfism is extremely rare outside specific communities, so the role of these tests in clinical practice is limited.

The utility of these tests in identifying more subtle forms of GH insensitivity in children with ISS has been explored,^{1307,1313} but at this time additional data are needed to determine the usefulness of this test in such cases. It will also be important to know the limitations of the test in

such instances, including understanding of potential confounders. For example, studies have indicated that the IGF1 response to GH is related to BMI and adiposity^{1284,1314} and to pubertal stage.¹²³⁴

Interpretation of Tests

Neonate. GH levels in the neonate are much higher than levels seen after this period. Levels are highest in cord blood and within the first days of life.¹³¹⁵ Cornblath and colleagues reported in 1965 an average GH concentration in cord blood of 66 µg/L; this fell over the first week to an average of 16 to 20 µg/L in infants 7 to 55 days of age.¹³¹⁵ However, even under the assay conditions used, the range of levels reported included measurements as low as 1 µg/L. Subsequent studies confirmed the high GH levels in neonates, with many documenting cord blood levels in the range of 20 to 40 µg/L,¹³¹⁶⁻¹³¹⁹ although other studies using similar assays found levels of 13 to 18 µg/L. Other studies also confirmed that GH levels fall during the first week of life.^{1316,1320,1321} GH levels in preterm infants have generally been found to be even higher than those in full-term infants.^{1315,1317,1322,1323}

The neonatal period is one period during which random measurement of GH levels may be useful. However, low values can be found in healthy neonates,^{1320,1322,1323} so, although a high value can exclude GHD, a single low value is not diagnostic of GHD. There have been no studies reporting GH levels in GH-deficient infants compared with normal infants. However, after the first week of life, if the clinical findings in a neonate raise concern for GHD (see Table 24-8), multiple random GH levels that are all below the cutoff value used to define normal GH secretion during provocative testing would be supportive of the diagnosis of GHD. GH levels that are obtained during an episode of spontaneous hypoglycemia or during a glucagon stimulation test, should also increase at least above the same cutoff value. An IGFBP3 measurement is of value for the diagnosis of neonatal GHD and should be measured in infants with suspected GHD; IGF1 levels are rarely helpful.¹³²⁴

Growth Hormone Deficiency. Both clinical and laboratory evaluation must be utilized when considering the diagnosis of GHD in a child being evaluated because of short stature or growth failure.^{1237,1325} As discussed earlier, there is no definitive test for the diagnosis for GHD. In addition, the laboratory tests for GHD have poor specificity and should be performed only in children who have a clinical presentation consistent with GHD. Short children who have well-documented normal height velocities usually do not require evaluation of GH function. Therefore, the evaluation starts with identifying those children who may have GHD based on risk factors or growth parameters (see Table 24-8 and Fig. 24-39).

In a child with a history and growth pattern that indicate a risk for GHD and in whom other causes for growth failure (including hypothyroidism) have been excluded, testing for GHD begins with measurement of the IGF1 level and proceeds to GH provocation tests in selected patients (see Fig. 24-39). In some cases, particularly in younger children, it may also be helpful to measure the IGFBP3 level. If IGHD is suspected, two GH provocation tests (given sequentially or on separate days) are required. A patient is diagnosed with classic GHD when the IGF1 (or IGFBP3) level is below the normal range (i.e., >2 SD below the mean for age and pubertal status) and peak GH levels on two provocative tests are below the cutoff value that supports a diagnosis of GHD. The diagnosis is more firmly established if the child is pretreated with estrogen or testosterone before the provocative GH tests. In a patient with defined CNS pathology, a history of irradiation, CPHD, or

a genetic defect, one provocative GH test suffices. In patients who have had cranial irradiation or malformations of the hypothalamic-pituitary unit, GHD may evolve over years, and its diagnosis may require serial testing.

Some patients with auxology suggestive of GHD may have IGF1 and/or IGFBP3 levels below the normal range on repeated tests but GH responses in provocation tests above the cutoff level. Such children do not have classic GHD but may have an abnormality of the GH-IGF1 axis. The child with a history of cranial irradiation, decreased height velocity, and reduced serum levels of IGF1 and IGFBP3 may have GHD (or GH insensitivity) even in the face of normal provocative tests.¹³²⁶ Other children may have GHD that is not supported by the results of nonphysiologic provocative tests (perhaps a more mild degree of GHD than in those who fail the provocative tests), or they may have GH insensitivity (discussed later). Systemic disorders affecting the synthesis or action of IGF1 must again be considered and excluded. Such children that continue to show growth failure (i.e., height below the 3rd percentile and growth velocity below the 25th percentile) could be considered for GH treatment.

A difficult clinical situation to resolve is that of the short child with a persistently subnormal growth velocity whose IGF1 and IGFBP3 levels are normal. One can reasonably exclude consideration of GHD if the IGF1 level is higher than 1 SD below the normal mean. However, because up to 30% of children with GHD identified by GH stimulation testing have had IGF1 levels that were not low,^{1225,1242-1245} it is appropriate to consider provocative GH testing in those children with persistent growth failure who have an IGF1 level between -1 SD and -2 SD for age and puberty status, with abnormal results on two tests indicating a diagnosis of GHD. In this situation in particular, it would be appropriate to pretreat the child with testosterone or estrogen in order to maximize the specificity of the provocative tests.

A cranial MRI scan with particular attention to the hypothalamic-pituitary region should be carried out in any child who is diagnosed as having GHD. In addition,

Figure 24-44 GH assays were performed by RIA (squares) and by immunoradiometric assay (triangles). For GHBP levels, open circles represent females, and closed circles represent males. Mean \pm SEM of GHBP levels in adult Ecuadorian controls are shown. STD, assay standard. (From Rosenfeld RG, Rosenbloom AL, Guevara-Acquiere J. Growth hormone [GH] resistance due to primary GH receptor deficiency. *Endocr Rev*. 1994;15:369-390.)

documentation of abnormal pituitary GH secretion should prompt evaluation for other pituitary hormone deficiencies. Based on the clinical scenario, one may also consider molecular evaluation of GH, GHR, GHRHR and other potential genetic defects.

Growth Hormone Insensitivity. GH insensitivity is characterized by low serum IGF1 concentrations in the presence of normal (or increased) production of GH (Figs. 24-44 and 24-45). As discussed earlier, GH insensitivity can

Figure 24-45 Serum levels of insulin-like growth factors (IGF) and IGF-binding proteins in patients from Ecuador with growth hormone receptor deficiency. Open circles represent females, closed circles represent males. Control values for Ecuadorian adults are shown as mean \pm SD for males and females, except for IGFBP-3, where large circles represent pooled male (closed circle) and female (open circle) control sera. Numbers adjacent to circles represent normal Ecuadorian children of 3, 7, 8, and 13 yr of age. (From Rosenfeld RG, Rosenbloom AL, Guevara-Acquiere J. Growth hormone [GH] resistance due to primary GH receptor deficiency. *Endocr Rev*. 1994;15:369-390.)

be caused by defects of the GHR (Laron syndrome), the GH signaling cascade, IGFBPs, IGF1, or the IGF1 receptor.⁷⁶³ If GH insensitivity is defined more broadly as growth failure in the absence of GHD, then defects in IGFBPs, IGF1, and the type I IGF receptor can also be considered forms of "partial" GH insensitivity (i.e., because non-IGF1-mediated growth is not impaired); IGF1 levels may or may not be low in these disorders.⁷⁶³ GH insensitivity should be considered in a patient with growth failure who has a low IGF1 level but evidence of increased GH secretion based on increased basal or stimulated GH levels (e.g., basal GH levels >5 µg/L or stimulated levels >15 µg/L). This pattern is also seen with malnutrition, a form of physiologic GH insensitivity. If GH insensitivity is suspected, GHBP and ALS can be measured: low values support the diagnosis of GH insensitivity due to mutations in the genes for the GHR or ALS. IGF1/IGFBP3 generation studies may demonstrate GH insensitivity, but they cannot completely discriminate among its various causes. In addition, there is limited normative data or standardization of such tests, so their ability to identify defects other than the severe insensitivity of Laron syndrome is not yet known.

Savage and Rosenfeld^{755,1311} devised a scoring system for use in evaluating short children for the diagnosis of GHR deficiency, based on five parameters: (1) basal serum GH level greater than 10 mU/L (approximately 5 µg/L); (2) serum IGF1 level less than 50 µg/L; (3) height SDS less than -3; (4) serum GHBP less than 10% (based on binding of [¹²⁵I]GH); and (5) a rise in serum IGF1 levels after GH administration of less than two times the intra-assay variation (approximately 10%). Blum and associates¹³¹² proposed that these criteria could be strengthened by (1) evaluating GH secretory profiles rather than isolated basal levels; (2) employing an age-dependent range and the 0.1 percentile as the cutoff level for evaluation of serum IGF1 concentrations; (3) employing highly sensitive IGF1 immunoassays and defining a failed GH response as the inability to increase serum IGF1 levels by at least 15 µg/L; and (4) measuring both basal and GH-stimulated IGFBP3 levels. These criteria fit well with findings in the population of GHR-deficient patients in Ecuador, but that is a homogeneous population with severe GH insensitivity.^{151,1327} The applicability of these criteria elsewhere remains to be evaluated. An important biochemical marker is the response of IGF1 (and possibly, IGFBP3) to GH stimulation.^{1313,1328,1329}

Additional considerations related to GH insensitivity include the following:

1. The presence of IUGR (in addition to postnatal growth failure) suggests IGF1 gene deletions, bioinactive IGF1, or IGF type I receptor abnormalities.
2. Low GHBP suggests a defect in the extracellular domain of the GHR, but normal (or increased) GHBP may be seen in some patients with defects of the GHR or the GH signaling cascade.
3. An elevated IGF1 level (in a child with growth failure) may suggest a defect in the IGF type I receptor.^{1330,1331} markedly elevated levels suggest bioinactive IGF1.³⁴¹
4. IGFBP3 and ALS concentrations may be increased in patients with molecular defects of IGF1.
5. STAT5B defects should be suspected in a child with evidence of GH insensitivity who has evidence of immune deficiency; an elevated PRL level has also been reported in the presence of STAT5B mutation.¹³³²

Constitutional Delay of Growth and Development. The term *CDGD* describes children who have a normal variant of maturational tempo characterized by short stature with

TABLE 24-11

Criteria for Presumptive Diagnosis of Constitutional Delay of Growth and Development

1. No history of systemic illness
2. Normal nutrition
3. Normal physical examination, including body proportions
4. Normal thyroid and growth hormone levels
5. Normal complete blood count, sedimentation rate, electrolytes, blood urea nitrogen
6. Height ≤3rd percentile but with annual growth rate >5th percentile for age
7. Delayed puberty: in males, failure to achieve Tanner G2 stage by age 13.8 yr or P2 by 15.6 yr; in females, failure to achieve Tanner B2 stage by age 13.3 yr
8. Delayed bone age
9. Normal predicted adult height: in males, >163 cm (64"); in females, >150 cm (59")

relatively normal growth rates during childhood, delayed puberty with a late and attenuated pubertal growth spurt, and attainment of a normal adult height that is also within the target height range based on parental heights (Table 24-11).^{38,1333} In childhood, such patients have heights that are lower than expected based on parental heights. CDGD aggregates in families.¹³³⁴ The diagnosis of CDGD may be suspected in a child with short stature if one or both parents have a history of a late timing of puberty. Bone age is usually delayed, so the predicted final height is in the normal range and is within the child's target height range, although the correlation between predicted and final height is imperfect and must be viewed with caution.^{43,1335,1336} The predicted final height, especially when the skeletal age is extremely delayed, is greater than that usually achieved but is difficult to reliably anticipate.^{43,1336,1338} Although the findings described can lead to a presumptive diagnosis of CDGD, the diagnosis can only be made retrospectively, once the child demonstrates a late timing for puberty and completes his or her growth in the normal range and at a height consistent with the parents' heights.

Because of the estrogen stimulation associated with GH secretion that occurs during puberty, children with CDGD can be expected to have decreased GH secretion and lower IGF1 levels compared with their pubertal, age-matched peers. However, IGF1 levels should be normal for pubertal stage, and GH levels on provocative tests should be normal after pretreatment with gonadal steroids.^{122,1289,1338,1339} Overnight GH secretion is usually normal in these children when control groups are carefully matched.¹³⁴⁰

It is often difficult to differentiate CDGD from GHD. Both groups of patients have height SDS below their target height SDS range, and both have delayed bone ages. As the child with CDGD enters the usual age for puberty, his or her growth rate can be too low to exclude GHD on that basis. (The growth rate normally declines throughout childhood until it increases at the time of the pubertal growth spurt; a child with CDGD and delayed pubertal growth spurt may have an additional 2 or more years of declining growth velocity, which can result in growth velocities <4 cm/year.) If there is a clear family history of CDGD, the likelihood is high that the child also has CDGD, and careful continued observation may be all that is needed. An increase in growth velocity after treatment with a short course of sex hormone can be taken as evidence against the presence of GHD.¹³⁴¹ In some cases, however, a laboratory investigation to exclude GHD is necessary. In such children, levels of IGF1 and IGFBP3 that are

low for pubertal stage or skeletal age and a poor GH response to provocative testing after priming with gonadal steroids would raise concern for GHD and would mandate the appropriate investigation for underlying pathology (e.g., intracranial tumor).

Genetic (Familial) Short Stature. The control of growth in childhood and the final height attained are polygenic in nature. Familial height affects the growth of an individual, and evaluation of a specific growth pattern must be placed in the context of familial growth and stature. As discussed at the beginning of this chapter, calculations can be made to determine whether a child's growth pattern is appropriate based on his or her parents' heights. As a general rule, a child who is growing at a rate that is inconsistent with that of siblings or parents warrants further evaluation.

Genetic short stature (GSS), also called familial short stature, is a normal growth pattern that describes the growth of healthy individuals who fall at the lower extreme of the distribution of height (i.e., below the 3rd percentile). Their height is appropriate for their genetic potential based on the parents' heights; that is, their height SDS is within the target height SDS range. Particularly when the midparental height is significantly above or below the mean, it is important to include adjustment for regression toward the mean when calculating this target height range.

Although the differentiation may not be complete, children with GSS are generally distinguished from children with CDGD: those with GSS will have a final height that is below the 3rd percentile, whereas children with CDGD will achieve a final height in the normal range. The midparental height of children with GSS is lower than that of children with CDGD; often, height in both parents is below the 10th percentile. Growth in children with GSS is at or below the 3rd percentile, but the velocity is usually normal. The onset and progression of puberty are normal, so the skeletal age is concordant with chronologic age. Final heights in these individuals are in the target height range for the family.⁴² By definition, the GH/IGF1 system is normal (as are all other systems).

Many diseases characterized by growth retardation are genetically transmitted, including GH insensitivity due to mutations of the *GHR* gene; *GH* gene deletions; mutations of the *PROPI*, *POUFI*, or *SHOX* genes; pseudohypoparathyroidism; and some forms of hypothyroidism. Inherited nonendocrine diseases characterized by short stature include osteochondrodysplasias and dysmorphic syndromes associated with IUGR (both described earlier), inborn errors of metabolism, renal disease, and thalassemia. Identifying a patient's short stature as inherited does not, by itself, relieve the clinician of responsibility for determining the underlying cause of growth failure. Moreover, a parent's short stature may be the result of an uncharacterized genetic difference that has been transmitted to the child and is causing the child's short stature. Because height is normally distributed in the population, it can be arbitrary whether one characterizes such genetic differences as mutations or as allelic variants. However, the further the parents' and the child's heights are from the mean, the more reasonable it is to consider such genetic alterations as abnormal.

Idiopathic Short Stature. ISS is defined as "a condition in which the height of the individual is more than 2 SD below the corresponding mean height for a given age, sex and population group, and in whom no identifiable disorder is present."¹³³² This definition includes children with CDGD,

those with GSS, and short children who will not have delayed puberty and whose height is not consistent with parental heights. Therefore, this definition includes both normal, healthy children (those with GSS and CDGD) and children who are presumed to have an unidentified disorder impairing their growth. It is not always a simple matter to distinguish among these possibilities: CDGD can be definitively diagnosed only at the completion of growth, and GSS does not exclude inherited disorders of growth.

Children with ISS may have undiagnosed disorders outside the GH-IGF1 axis (e.g., an uncharacterized chondrodysplasia), or they may have more subtle disorders of the hypothalamic-pituitary-IGF axis than those that are identified by the currently available diagnostics tests.^{763,775} Because of the lack of a gold standard for the diagnosis of GHD, the distinction between isolated partial GHD and ISS is somewhat arbitrary, relying heavily on the results of the nonphysiologic provocative stimulation tests. The activity of different GH promoter haplotypes can differ as much as sixfold.^{728,1342} Some children with ISS may have GH neurosecretory dysfunction that cannot be detected with current diagnostic tests.^{1298,1299} Similarly, although the severe GH insensitivity of Laron syndrome can be identified by laboratory testing, partial GH insensitivity may be an unrecognized cause of ISS.¹³⁴³

Heterozygous mutations in the *GHR* have been found in significant numbers of children with ISS.^{774,777,1344} In heterozygotes, protein from the mutant allele may disrupt the normal dimerization and rotation that is needed for normal *GHR* activation, leading to diminished GH action and growth impairment.¹³⁴⁵ In addition, *GHBP* expression may be decreased in patients with ISS, 20% of whom have serum levels of *GHBP* below the normal range.^{1343,1346,1347} Other potential causes for partial GH insensitivity in ISS include heterozygous mutations in other components of the growth system, a relatively greater preponderance of blockers of the GH-signaling cascade (e.g., enhanced intracellular phosphatase activity, production of such signaling factors as *SOC2* and *CIS*), gene-mediated alterations in patterns of GH or IGF production, or other possibilities yet to be discovered.¹³⁴⁸

Treatment of Growth Retardation

When growth failure is the result of a chronic underlying disease, such as renal failure, CF, or malabsorption, therapy must first be directed at treatment of the underlying condition. Although growth acceleration may occur in such children with GH or IGF1 therapy, complete catch-up requires correction of the primary medical problem. If treatment of the underlying condition involves glucocorticoids, growth failure may be profound and is unlikely to be correctable until steroids are reduced or discontinued.

Correction of growth failure associated with chronic hypothyroidism requires appropriate thyroid replacement. As discussed earlier, thyroid therapy causes dramatic catch-up growth but also markedly accelerates skeletal maturation, potentially limiting adult height.

Treatment of Constitutional Delay

CDGD is a normal growth variant with delayed pubertal maturation and a normal adult height. Most subjects can be managed by careful evaluation to rule out other causes of abnormal growth or delayed puberty combined with appropriate explanation and counseling. A family history of CDGD is frequently a source of reassurance. The skeletal age and Bayley-Pinneau table are often helpful in explaining the potential for normal growth to the patient and

parents. The predicted final height is usually greater than that achieved, especially when the skeletal age is extremely delayed, but this is difficult to reliably anticipate.^{43,1335,1337}

On occasion, the stigmata of short stature and delayed maturation are psychologically disabling for a preadolescent or teenage patient. Some adolescents with delayed puberty have poor self-image and limited social involvement.¹³⁴⁹ In such patients and in some in whom pubertal delay is predicted based on the overall clinical picture, there may be a role for judicious short-term treatment with androgen.

Androgen (Oxandrolone and Testosterone). Two aspects of CDGD in boys are addressed by androgen treatment: short stature, especially in boys 10 to 14 years of age, and delayed puberty after age 14. In the younger group, in whom CDGD is the presumed cause of short stature, the orally administered synthetic androgen oxandrolone has been used extensively to accelerate growth so that height increases into (or closer to) the normal range sooner than it would without treatment.¹³⁵⁰ In several controlled studies,¹³⁵¹⁻¹³⁵⁶ oxandrolone therapy for 3 months to 4 years increased linear growth velocity by 3 to 5 cm/year without adverse effects and without decreasing either actual¹³⁵⁶⁻¹³⁵⁸ or predicted^{1353,1357,1359} final height. (This treatment does not increase the final height of these boys.) The growth-promoting effects of oxandrolone appear to be related to its androgenic and anabolic effects rather than to augmentation of the GH-IGF1 axis.^{1360,1361} The lack of a measurable effect on the GH-IGF1 axis probably reflects the fact that oxandrolone cannot be aromatized to estrogen. Currently recommended treatment is 0.05 to 0.1 mg/kg orally per day.

Oxandrolone is a relatively weak androgen, and its use stimulates only minimal pubertal masculinization. In older boys in whom the delayed pubertal maturation is highly stressful and anxiety-provoking, testosterone enanthate has been administered intramuscularly with success.^{1350,1351,1362} Criteria for treatment in such adolescents should include (1) a minimum age of 14 years; (2) height below the 3rd percentile; (3) prepubertal or early Tanner G2 stage with an early-morning serum testosterone level of less than 3.5 nmol/L (<1 ng/mL); and (4) a poor self-image that does not respond to reassurance alone. Therapy consists of intramuscular testosterone enanthate, 50 to 100 mg every 3 to 4 weeks for a total of four to six injections.^{1349-1359,1360-1363} Patients typically show early secondary sex characteristics by the fourth injection and grow an average of 10 cm in the ensuing year. Testosterone enhances growth velocity by direct actions, increases GH production, and may have a direct effect on IGF1 secretion.^{122,148,149,154,1360,1364} Brief testosterone regimens do not cause overly rapid skeletal maturation, compromise adult height, or suppress pubertal maturation.¹³⁶⁵ It is important to emphasize to the patient that he is normal, that therapy is short-term and is designed to provide some pubertal development earlier than he would on his own, and that treatment will not increase his final adult height. In such situations, the combination of short-term androgen therapy, reassurance, and counseling can help boys with CDGD to cope with a difficult adolescence.

The availability of several new forms of testosterone, which are approved for adults with hypogonadism, provides adolescents with an opportunity for a choice among different androgen replacement therapies. Testosterone gel is painless and easy to apply and has proved popular since its release.¹³⁶⁶ However, there are concerns about environmental contamination, including reports of precocious puberty in children caused by topical testosterone use by

an adult in the household.¹³⁶⁷⁻¹³⁶⁹ If topical testosterone is prescribed, careful instruction must be given to avoid such inadvertent exposure of others. Testosterone patches also avoid the need for injections, but they are often poorly tolerated because of local skin reactions. Another disadvantage of topical testosterone and the transdermal patches is the need for daily application. The dosing of these alternative forms of therapy in children and adolescents has not been established, and care must be taken to avoid treating with too high a dose, which risks compromising final height.

Patients must be reevaluated to ensure that they enter "true" puberty. One year after testosterone treatment, boys should have testicular enlargement and a serum testosterone level in the pubertal range. If this is not the case, a diagnosis of hypothalamic-pituitary insufficiency or hypogonadotropic hypogonadism should be considered. Although the diagnosis of constitutional growth delay remains most likely in such patients, some eventually prove to be gonadotropin deficient, especially if they are still prepubertal late in adolescence.

Referrals for CDGD are more common in boys than girls. When CDGD is a problem in girls, short-term estrogen therapy may be employed, but the acceleration of skeletal maturation is a greater hazard at doses that enhance growth velocity and sexual maturation.

Growth Hormone. The final height of a child with CDGD will be in the normal range and appropriate for the child's genetic potential. No treatment is needed for these children to achieve a normal height. However, as discussed earlier, the diagnosis of CDGD cannot be confirmed until a late puberty and normal height are achieved. Therefore, it can be difficult in some cases to distinguish these children from children with ISS or GHD. In such cases, there may be uncertainty about whether the final height will be in the normal range, and treatment to try to increase final height may be considered. If laboratory studies support a diagnosis of GHD, then GH treatment would be appropriate. If there is no evidence of GHD, the consideration regarding treatment with GH would be the same as that regarding the use of GH to treat ISS (discussed later).

The FDA indication for GH treatment includes in its definition of ISS the criterion that the child has "growth rate[s] unlikely to permit attainment of normal adult height." A child with CDGD, who is expected to achieve a normal adult height, would not fit within this definition. Nonetheless, partly because of the uncertainty of the diagnosis and the inability to perfectly predict final height, the database on outcomes of children treated with GH for ISS includes within it data on the treatment of children with CDGD. ISS GH treatment trials may include children with significant bone age delay,^{1370,1371} at least some of whom have CDGD. For this reason, the outcome data for GH treatment of ISS (see later) can be taken as an indication of the expected outcome of GH treatment of CDGD. Moreover, because estimated final height gain with GH treatment of ISS is proportional to the bone age delay at the time of initiation of treatment,¹³⁷² height gain with GH treatment of CDGD may be greater than that for treatment of ISS. However, a retrospective study specifically reporting the outcome of GH treatment in CDGD found no difference in adult height between those treated with GH and those receiving either no treatment or testosterone treatment.¹³⁷³

Aromatase Inhibitor. In view of the important role of estrogen in the process of skeletal maturation, aromatase

inhibitors could be used in conjunction with androgen therapy to prevent an acceleration of bone age and further enhance final adult height.^{1374,1375} The one report of combined use of an aromatase inhibitor (letrozole) and testosterone did not provide a clear answer as to whether the addition of aromatase inhibitor increased final height in boys with CDGD. Whereas the near-final height in the boys treated with letrozole plus testosterone was higher than that of boys treated with testosterone alone, the letrozole-treated boys were a year older at the time of these height measurements and had higher pretreatment and midparental heights.¹³⁷⁵ In addition, the boys treated with testosterone alone achieved a near-final height within the normal range (consistent with the diagnosis of CDGD). Given the lack of long-term safety data on the use of aromatase inhibitors in pubertal boys, there are insufficient data to suggest a role for aromatase inhibitors in CDGD.

Treatment of Growth Hormone Deficiency

Nomenclature and Potency Estimation. The nomenclature for the various biosynthetic GH preparations reflects the source and the chemical composition of the product. *Somatropin* refers to GH of the same amino acid sequence as that in naturally occurring human GH. Somatropin from human pituitary glands is abbreviated *GH* or *pit-GH*; somatropin of recombinant origin is termed *recombinant GH* or *rGH*. *Somatrem* refers to the methionine derivative of recombinant GH and is abbreviated *met-rGH*. Although the latter is a more antigenic preparation, that propensity is not clinically relevant; despite the presence of anti-GH antibodies, growth responses to met-rGH were similar to those in patients treated with rGH.^{1376,1377} This derivative of GH is no longer available for use. In this discussion, we refer to the biosynthetic preparations as GH.

The biopotency of commercially available biosynthetic GH preparations, expressed as international units per milligram of the new World Health Organization (WHO) recombinant GH reference reagent for somatropin 88/624, is 3 IU/mg.¹³⁷⁸ It was necessary to standardize the early GH preparations by bioassay because of variable production techniques (e.g., extraction, column purification). The most common bioassays have been the hypophysectomized rat weight-gain assay, the tibial width assay, and the more sensitive Nb2 rat lymphoma proliferation assay.¹³⁷⁸⁻¹³⁸¹ With the availability of purified and essentially equivalent recombinant GH products, the requirement for bioassays has become an FDA requisite to substantiate biologic activity rather than to assess potential differences between preparations. The bioassays are likely to be replaced by in vitro binding assays using GHRs or GHBP derived from molecular techniques.¹³⁷⁸

Historical Perspective. Because untreated patients with GHD have profound short stature (averaging almost -5 SDS,¹³⁸²⁻¹³⁸⁵), the clinical urgency to use GH therapy as soon as it became available is understandable.¹²⁷² The action of GH is highly species-specific, and humans do not respond to animal-derived GH (except that from other primates).¹³⁸⁶ Human cadaver pituitary glands were for many years the only practical source of primate GH for treatment of GHD, and more than 27,000 children with GHD worldwide were treated with pit-GH.¹³⁸⁷ The limited supplies of pit-GH, the low doses used, and interrupted treatment regimens resulted in incomplete growth increments; usually, therapy was discontinued in boys who reached a height of 5 feet 5 inches and in girls who reached 5 feet. Nonetheless, this treatment did increase linear growth and in many patients enhanced final adult height. The dose-response

relationship and the relation of age to GH response were recognized during this period.¹³⁸⁸

Distribution of pit-GH was halted in the United States and most of Europe in 1985 because of concern about a causal relationship with Creutzfeldt-Jakob disease (CJD), a rare and fatal spongiform encephalopathy that had been previously reported to be capable of iatrogenic transmission through human tissue.^{1389,1390} In North America and Europe, this disorder has an incidence of approximately 1 case per 1 million in the general population, and it is exceedingly rare before the age of 50 years. To date, more than 200 young adults who had received human cadaver pituitary products have been diagnosed with CJD, with the sad likelihood that all affected patients will die of the disease.¹³⁹¹⁻¹³⁹³ In the United States, the onset of CJD occurred 14 to 33 years after starting treatment, whereas in the large cohort of French patients the median incubation period was approximately 5 years shorter.¹³⁹³ No cases of CJD have been identified in Americans who began treatment after new methods of purifying the hormone came into use in the United States in 1977. Although the incubation period is now more than 33 years, vigilant surveillance for this dreadful complication continues; information is available on the website www.niddk.nih.gov/health/endo/pubs/creutz/updatecomp.htm (accessed October 2010).^{1394,1395}

By the time the risks of pituitary-derived GH were discovered, biosynthetic GH was being tested for safety and efficacy.^{1376,1396,1397} The original recombinant GH mimicked pit-GH in regard to both anabolic and metabolic actions and was scrupulously scrutinized for monoisomerism, antigenic bacterial products, and toxins of any sort. GH has universally replaced pit-GH as the accepted treatment for children with GHD.

Treatment Regimens. The recommended therapeutic starting dose of GH in children with GHD is 0.18 to 0.35 mg/kg body weight per week, administered in seven daily doses, with the mean American dose being 0.3 mg/kg per week.¹³⁹⁸ Alternative regimens include a 6 day/week and a 3 day/week schedule, with the same weekly dosage, but they are not as successful. In general, the growth response to GH is a function of the log-dose given, so increasing dosages further enhance growth velocities,^{1387,1388,1399} but daily dosing may be the most important treatment parameter.¹⁴⁰⁰ Subcutaneous and intramuscular administration have equivalent growth-promoting activity¹⁴⁰¹; the former is now used exclusively. At this time, all of the commercially available GH preparations yield comparable growth outcomes.

Growth responses to exogenous GH vary, depending on the frequency of administration, dosage, age (greater absolute gain in a younger child, although not necessarily greater growth velocity SDS), weight, GHR type and amount (as assessed by serum GHBP levels), and, perhaps, seasonality.^{783,1402-1405} Nevertheless, the general regimen of daily GH at the recommended doses typically accelerates growth in a GH-deficient child from a pretreatment rate of 3 to 4 cm/year to 10 to 12 cm/year in year 1 of therapy to 7 to 9 cm/year in years 2 and 3. Progressive waning of GH efficacy occurs and is poorly understood. The importance of dosage frequency is illustrated (Figs. 24-46 and 24-47) by data from a carefully done assessment of growth responses in prepubertal naïve GH-deficient children randomly assigned to receive thrice-weekly or daily GH at the same total weekly dose (0.30 mg/kg per week).¹⁴⁰⁰ The mean total height gain during this period was 9.7 cm greater in the patients treated daily (38.4 versus 28.7 cm, $P < .0002$), with similar increments in skeletal maturation and no acceleration of the

Figure 24-46 Annual growth velocity (mean \pm standard deviation) for prepubertal patients with growth hormone (GH) deficiency before and during 4 years of GH treatment, contrasting results from daily (QD) versus thrice-weekly (TIW) injections. The mean annual growth velocity in the QD group was significantly greater than that in the TIW group during each year, although significance diminished from year 1 to year 4. (From MacGillivray MH, Baptista J, Johanson A, et al. Outcome of a four-year randomized study of daily versus three times weekly somatotropin treatment in prepubertal naive growth hormone deficient children. *J Clin Endocrinol Metab.* 1996;81:1806-1809. Reproduced by permission of M.H. MacGillivray.)

onset of puberty. Mean height SDS at the end of 4 years was +0.2, or at the midpoint of normal for age. Studies using varying dosing of GH based on gender, growth responsivity, and growth factor concentrations have suggested the need for greater sophistication and individualization of the current treatment regimens.¹⁴⁰⁶⁻¹⁴⁰⁷

Sophisticated mathematical models^{1399,1408} have examined many laboratory and auxologic parameters that influence response to GH therapy. Because age at onset of treatment is inversely correlated with growth responses, and because the smaller, lighter child requires less GH (with marked economic benefit), it is important to assess growth data in children treated early. In short-term studies of 134 patients¹⁴⁰⁹⁻¹⁴¹¹ treated before age 3 years, marked early catch-up growth occurred, with a mean height gain of about 3 SDS by 4 years of therapy, allowing most children to reach their normal height range by middle childhood. Mean height in one study¹⁴⁰⁹ reached -0.4 SDS after 8 years of treatment. Near-adult height in 13 patients treated before 5 years of age¹⁴¹² did not differ significantly from the midparental target height (-0.9 versus -0.7 SDS). In a group of 25 children treated before 12 months of age,¹⁴¹³ adult height also matched the target height despite low dosage and less frequent administration. In an analysis of postmarketing data for development of a growth prediction model, a greater height gain per GH amount occurred in the very young children, but a seemingly lowered sensitivity to endogenous GH in early infancy adds complexity to interpretation of these data.¹⁴¹⁴ If long-term outcome studies continue to show excellent growth responses with achievement of genetic target height and adherence to

treatment regimens in very young children, recommendations for early treatment would be appropriate.¹⁴¹⁵

Adult Height Outcomes. Much information on growth has been reported about children treated with pit-GH, usually administered intramuscularly on a thrice-weekly regimen. Five-year data are available from Bundak and colleagues¹⁴¹⁶ from a study of 58 prepubertal and 20 pubertal children with GHD. The younger group increased its height from -3.6 SDS to -2 SDS, and the pubertal children grew to -2.3 SDS. However, the height SDS for bone age did not increase. Therefore, further loss of adult height was prevented, but there was no increase in the adult height prediction. The importance of early initiation of treatment is emphasized by such data. Libber and coworkers¹⁴¹⁷ similarly found that GH therapy increased mean height from about -4.2 SDS to -2.3 SDS. Bierich¹⁴¹⁸ reviewed nine trials of pit-GH to determine effect on final height. Overall, there was a dose-response relationship between doses of 0.11 versus 0.25 mg/kg per week. The greatest SDS increment (2.7) occurred with the highest dosage of pit-GH. The pretreatment heights ranged from -5.6 to -3.6 SDS, with adult heights achieving -3.6 to -1.6 SDS. Final height data from the same large U.S. center permit a comparison of pit-GH and recombinant GH therapeutic results. The mean final height was -2.0 SDS in the group treated with pit-GH, who received only 0.1 mg/kg per week, and -1.5 SDS in the group treated with recombinant GH 0.3 mg/kg per week.¹⁴¹⁹

Figure 24-47 Height standard deviation score (SDS) for prepubertal patients with growth hormone (GH) deficiency before and during 4 years of GH treatment, contrasting results (mean \pm standard deviation) with daily (QD) versus thrice-weekly (TIW) injections. The mean SDS in the QD group was significantly greater throughout the treatment period. Younger patients had the greatest increase in height SDS, and the effect of age was more marked in the QD group. (From MacGillivray MH, Baptista J, Johanson A, et al. Outcome of a four-year randomized study of daily versus three times weekly somatotropin treatment in prepubertal naive growth hormone deficient children. *J Clin Endocrinol Metab.* 1996;81:1806-1809. *Data from Reiter EO, Price DA, Wilton P, et al. Effect of growth hormone (GH) treatment on the near-final height of 1258 patients with idiopathic GH deficiency: analysis of a large international database. *J Clin Endocrinol Metab*. 2006;91:2047-2054.

[†]Data from Westphal O, Lindberg A, Swedish KIGS National Board. Final height in Swedish children with idiopathic growth hormone deficiency enrolled in KIGS treated optimally with growth hormone. *Acta Paediatr*. 2008 ;97:1698-1706.

[‡]Data from August GP, Julius JR, Blethen SL. Adult height in children with growth hormone deficiency who are treated with biosynthetic growth hormone: The National Cooperative Growth Study experience. *Pediatrics*. 1998;102(2 Pt 3):512-516; updated NCGS data from Dana K, Baptista J, Blethen SL (personal communication, 2001).

Patients treated largely with biosynthetic GH^{1272,1412,1419-1428} have improved actual or near-final adult height SDS, with average final height in more than 1400 patients approximating -1.3 SD. Data from the two largest databases,^{1420,1422,1427-1429} representing the North American and European experiences as reported by pediatric endocrinologists, are shown in Table 24-12.
