Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

PREFACE

Welcome to the twelfth edition of *Williams Textbook of Endocrinology*.

Robert Williams inaugurated this enduring textbook more than 50 years ago, and the goals have remained essentially unchanged (i.e., to publish “a condensed and authoritative discussion of the management of clinical endocrinopathies based upon the application of fundamental information obtained from chemical and physiological investigation”). Of course, today we would add results of cellular and genomic investigation, as well as the wealth of clinical trial data, as aids in clinical management. The immense and often overwhelming body of new information from multiple disciplines, in fact, makes this synthetic endeavor more relevant than ever to help guide endocrinologists in the care of their patients. To encourage the goal of both highest quality scientific rigor and knowledge synthesis, we continue to ask the most distinguished authors to synthesize entire areas of clinical endocrine science. The mandate for concise yet authoritative and comprehensive presentations acknowledges both the time pressures on today’s physicians and the desire to make the text affordable and easily navigated.

This edition has involved extensive revisions of the previous text, and 22 new authors have joined our expert

faculty. A uniform style facilitates identification and ready use of clinical algorithms.

We express our deep gratitude to the co-workers in our offices: Anita Nichols, Lynn Moulton, Grace Labrado, Louise Ishibashi, and Sherri Turner, whose energetic efforts have made this work possible. We also thank our colleagues at Elsevier—Joan Ryan, Pamela Hetherington, and Dolores Meloni—who skillfully navigated the dynamic world of medical publishing while assuring achievement of our goals. Their efforts have been essential in ensuring the successful publication of this high-quality textbook, which has become the classic text for all professionals engaged in caring for patients with endocrine disorders.

Finally, we would like to recognize and congratulate Dr. Melvin Grumbach for his outstanding contributions to *Williams Textbook of Endocrinology*, beginning with the fourth edition that was published in 1968.

CHAPTER I

Principles of Endocrinology

HENRY M. KRONENBERG • SHLOMO MELMED • P. REED LARSEN • KENNETH S. POLONSKY

Roughly 100 years ago, Starling coined the term *hormone* to describe secretin, a substance secreted by the small intestine into the bloodstream to stimulate pancreatic secretion. In his Croonian Lectures, Starling considered the endocrine and nervous systems as two distinct mechanisms for coordination and control of organ function. Thus, endocrinology found its first home in the discipline of mammalian physiology.

Work over the next several decades by biochemists, physiologists, and clinical investigators led to the characterization of many hormones secreted into the bloodstream from discrete glands or other organs. Investigations showed that diseases such as hypothyroidism and diabetes could be treated successfully, for the first time, by replacing specific hormones. These initial triumphs formed the foundation of the clinical specialty of endocrinology.

Advances in cell biology, molecular biology, and genetics over the ensuing years began to explain the mechanisms of endocrine diseases and of hormone secretion and action. Even though these advances have embedded endocrinology in the framework of molecular cell biology, they have not changed the essential subject of endocrinology—the signaling mechanisms that coordinate and control the functions of multiple organs and processes. Herein we survey the general themes and principles that underpin the

diverse approaches used by clinicians, physiologists, biochemists, cell biologists, and geneticists to understand the endocrine system.

THE EVOLUTIONARY PERSPECTIVE

Hormones can be defined as chemical signals secreted into the bloodstream that act on distant tissues, usually in a regulatory fashion. Hormonal signaling represents a special case of the more general process of signaling between cells. Even unicellular organisms, such as baker's yeast, *Saccharomyces cerevisiae*, secrete short peptide mating factors that act on receptors of other yeast cells to trigger mating between the two cells. These receptors resemble the ubiquitous family of mammalian seven-transmembrane spanning receptors that respond to ligands as diverse as photons and glycoprotein hormones. Because these yeast receptors trigger activation of heterotrimeric G proteins just as mammalian receptors do, this conserved signaling pathway must have been present in the common ancestor of yeast and humans.

Signals from one cell to adjacent cells—so-called paracrine signals—often trigger cellular responses that use the same molecular pathways used by hormonal signals. For

example, the sevenless receptor controls the differentiation of retinal cells in the *Drosophila* eye by responding to a membrane-anchored signal from an adjacent cell. Sevenless is a membrane-spanning receptor with an intracellular tyrosine kinase domain that signals in a way that closely resembles the signaling by hormone receptors such as the insulin receptor tyrosine kinase.

Because paracrine factors and hormones can share signaling machinery, it is not surprising that hormones can, in some settings, act as paracrine factors. Testosterone, for example, is secreted into the bloodstream but also acts locally in the testes to control spermatogenesis. Insulin-like growth factor 1 (IGF1) is a polypeptide hormone that is secreted into the bloodstream from the liver and other tissues, but it is also a paracrine factor made locally in most tissues to control cell proliferation.

Furthermore, one receptor can mediate actions of a hormone and a paracrine factor, such as parathyroid hormone (PTH) and parathyroid hormone-related protein. In some cases, the paracrine actions of “hormones” have functions quite unrelated to hormonal functions. For example, macrophages synthesize the active form of vitamin D, 1,25-dihydroxyvitamin D₃ or calcitriol, which can then bind to vitamin D receptors in the same cells and stimulate production of antimicrobial peptides.¹ The vitamin D 1 α -hydroxylase responsible for activating 25-hydroxyvitamin D (calcidiol) is synthesized in multiple tissues in which it has functions not apparently related to the calcium homeostatic actions of calcitriol. One can

speculate that the hormonal actions of vitamin D might have evolved well after the paracrine vitamin D apparatus provided the raw materials for the hormonal system.

Target cells respond similarly to signals that reach them from the bloodstream (hormones) or from the cell next door (paracrine factors); the cellular response machinery does not distinguish the sites of origin of signals. The shared final common pathways used by hormonal and paracrine signals should not, however, obscure important differences between hormonal and paracrine signaling systems (Fig. 1-1). Paracrine signals do not travel very far; consequently, the specific site of origin of a paracrine factor determines where it will act and provides specificity to that action. When the paracrine factor bone morphogenic protein 4 (BMP4) is secreted by cells in the developing kidney, BMP4 regulates the differentiation of renal cells; when the same factor is secreted by cells in bone, it regulates bone formation. Thus, the site of origin of BMP4 determines its physiologic role. In contrast, because hormones are secreted into the bloodstream, their sites of origin are often divorced from their functions. There is nothing about thyroid hormone function, for example, that requires that the thyroid gland be in the neck.

Because the specificity of paracrine factor action is so dependent on its precise site of origin, elaborate mechanisms have evolved to regulate and constrain the diffusion of paracrine factors. Paracrine factors of the hedgehog family, for example, are covalently bound to cholesterol to constrain the diffusion of these molecules in the

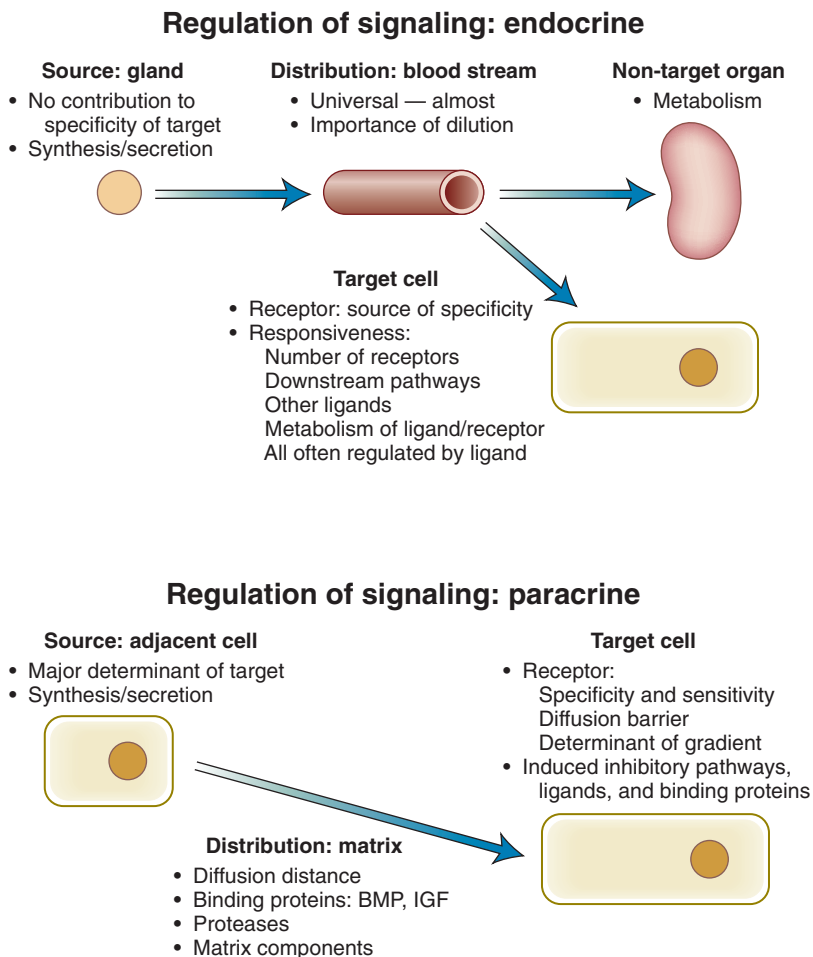

Figure 1-1 Comparison of determinants of endocrine and paracrine signaling.

extracellular milieu. Most paracrine factors interact with binding proteins that block their action and control their diffusion. For example, chordin, noggin, and many other distinct proteins bind to various members of the BMP family to regulate their action. Proteases such as tolloid then destroy the binding proteins at specific sites to liberate BMPs so that they can act on appropriate target cells.

Hormones have rather different constraints. Because they diffuse throughout the body, they must be synthesized in enormous amounts relative to the amounts of paracrine factors needed at specific locations. This synthesis usually occurs in specialized cells designed for that specific purpose. Hormones must then be able to travel in the bloodstream and diffuse in effective concentrations into tissues. Lipophilic hormones, for example, bind to soluble proteins that allow them to travel in the aqueous medium of blood at relatively high concentrations. The ability of hormones to diffuse through the extracellular space means that the local concentration of a hormone at target sites will rapidly decrease when glandular secretion of the hormone stops. Because hormones diffuse throughout extracellular fluid quickly, hormonal metabolism can occur in specialized organs (e.g., liver, kidney) in a manner that determines the effective hormone concentration in other tissues.

In summary, paracrine factors and hormones use several distinct strategies to control their biosynthesis, sites of action, transport, and metabolism. These differing strategies probably explain partly why a hormone such as IGF1, unlike its close relative, insulin, has multiple binding proteins that control its action in tissues. IGF1 exhibits a double life—it is both a hormone and a paracrine factor. Presumably, the local actions of IGF1 mandate an elaborate binding protein apparatus to enable appropriate hormone signaling.

All of the major hormonal signaling programs—G protein-coupled receptors, tyrosine kinase receptors, serine/threonine kinase receptors, ion channels, cytokine receptors, and nuclear receptors—are also used by paracrine factors. In contrast, several paracrine signaling programs appear to be used only by paracrine factors and not by hormones. For example, Notch receptors respond to membrane-based ligands to control cell fate, but no blood-borne ligands are known to use Notch-type signaling. Perhaps the intracellular strategy used by Notch, which involves cleavage of the receptor and subsequent nuclear actions of the receptor's cytoplasmic portion, is too inflexible to serve the purposes of hormones.

The analyses of the complete genomes of multiple bacterial species, the yeast *S. cerevisiae*, the fruit fly *Drosophila melanogaster*, the worm *Caenorhabditis elegans*, the plant *Arabidopsis thaliana*, humans, and many other species have allowed a comprehensive view of the signaling machinery used by various forms of life. As noted earlier, *S. cerevisiae* uses G protein-linked receptors; this organism, however, lacks tyrosine kinase receptors and nuclear receptors that resemble the estrogen/thyroid receptor family. In contrast, the worm and fly share with humans the use of each of these signaling pathways, although with substantial variation in the number of genes committed to each pathway. For example, the *Drosophila* genome encodes 20 nuclear receptors, the *C. elegans* genome 270, and the human genome (tentatively) more than 50. These patterns suggest that ancient multicellular animals must have already established the signaling systems that are the foundation of the endocrine system as we know it in mammals.

Even before the sequencing of the human genome was accomplished, sequence analyses had made clear that many receptor genes are found in mammalian genomes for

which no clear ligand or function is known. The analyses of these “orphan” receptors have succeeded in broadening the current understanding of hormonal signaling. For example, the orphan liver X receptor, LXR, was found during searches for unknown nuclear receptors. Subsequent experiments showed that oxygenated derivatives of cholesterol are the ligands for LXR, which regulates genes involved in cholesterol and fatty acid metabolism.² LXR and many other examples raise the question of what constitutes a hormone.

The classic view of hormones is that they are synthesized in discrete glands and have no function other than activating receptors on cell membranes or in the nucleus. In contrast, cholesterol, which is converted in cells to oxygenated derivatives that activate the LXR receptor, uses a hormonal strategy to regulate its own metabolism. Other orphan nuclear receptors similarly respond to ligands such as bile acids and fatty acids. These “hormones” have important metabolic roles quite separate from their signaling properties, although the hormone-like signaling serves to allow regulation of the metabolic function. The calcium-sensing receptor is an example from the G protein-linked receptor family that responds to a nonclassic ligand, ionic calcium. Calcium is released into the bloodstream from bone, kidney, and intestine and acts on the calcium-sensing receptors on parathyroid cells, renal tubular cells, and other cells to coordinate cellular responses to calcium. Therefore, many important metabolic factors have taken on hormonal properties as part of a regulatory strategy.

ENDOCRINE GLANDS

Hormone formation may occur either in localized collections of specific cells, the endocrine glands, or in cells that have additional roles. Many protein hormones, such as growth hormone (GH), PTH, prolactin, insulin, and glucagon, are produced in dedicated cells by standard protein synthetic mechanisms common to all cells. These secretory cells usually contain specialized secretory granules designed to store large amounts of hormone and to release the hormone in response to specific signals. Formation of small hormone molecules begins with commonly found precursors, usually located in specific glands such as the adrenals, gonads, or thyroid. In the case of the steroid hormones, the precursor is cholesterol, which is modified by various hydroxylations, methylations, and demethylations to form glucocorticoids, androgens, estrogens, and their biologically active derivatives.

However, not all hormones are formed in dedicated and specialized endocrine glands. For example, the protein hormone, leptin, which regulates appetite and energy expenditure, is formed in adipocytes, providing a specific signal that reflects the nutritional state to the central nervous system. The cholesterol derivative, 7-dehydrocholesterol, the precursor of vitamin D, is produced in skin keratinocytes by a photochemical reaction. In the unique enteroendocrine hormonal system, peptide hormones that regulate metabolic and other responses to oral nutrients are produced and secreted by specialized endocrine cells scattered throughout the intestinal epithelium.

Thyroid hormone synthesis occurs by means of a unique pathway. The thyroid cell synthesizes a 660,000-kd homodimer, thyroglobulin, which is then iodinated at specific iodotyrosines. Certain of these “couple” to form the iodothyronine molecule within thyroglobulin, which is then stored in the lumen of the thyroid follicle. For this to occur,

the thyroid cell must concentrate the trace quantities of iodide from the blood and oxidize it via a specific peroxidase. Release of thyroxine (T_4) from the thyroglobulin requires its phagocytosis and cathepsin-catalyzed digestion by the same cells.

Hormones are synthesized in response to biochemical signals generated by various modulating systems. Many of these systems are specific to the effects of the hormone product. For example, PTH synthesis is regulated by the concentration of ionized calcium, and insulin synthesis is regulated by the concentration of glucose. For others, such as gonadal, adrenal, and thyroid hormones, control of hormone synthesis is achieved by the homeostatic function of the hypothalamic-pituitary axis. Cells in the hypothalamus and pituitary monitor the circulating hormone concentration and secrete tropic hormones, which activate specific pathways for hormone synthesis and release. Typical examples are luteinizing hormone (LH), follicle-stimulating hormone (FSH), thyroid-stimulating hormone (TSH), and adrenocorticotropic hormone (ACTH).

These trophic hormones increase rates of hormone synthesis and secretion, and they may induce target cell division, resulting in enlargement of the various target glands. For example, in hypothyroid individuals living in iodine-deficient areas of the world, TSH secretion causes a marked hyperplasia of thyroid cells. In such regions, the thyroid gland may be 20 to 50 times its normal size. Adrenal hyperplasia occurs in patients with genetic deficiencies in cortisol formation. Hypertrophy and hyperplasia of parathyroid cells, in this case initiated by an intrinsic response to the stress of hypocalcemia, occurs in patients with renal insufficiency or calcium malabsorption.

Hormones may be fully active when they are released into the bloodstream (e.g., GH, insulin), or they may require activation in specific cells to produce their biologic effects. These activation steps are often highly regulated. For example, the T_4 released from the thyroid cell is a prohormone that must undergo a specific deiodination to form the active 3,5,3'-triiodothyronine (T_3). This deiodination reaction can occur in target tissues (e.g., in the central nervous system); in the thyrotrophs, where T_3 provides feedback regulation of TSH production; or in hepatic and renal cells, from which it is released into the circulation for uptake by all tissues. A similar postsecretory activation step, catalyzed by a 5α -reductase, causes tissue-specific activation of testosterone to dihydrotestosterone in target tissues including the male urogenital tract and genital skin, as well as in liver. Vitamin D undergoes hydroxylation at the 25 position in the liver and at the 1 position in the kidney. Both hydroxylations must occur to produce the active hormone, calcitriol. The activity of 1α -hydroxylase, but not that of 25-hydroxylase, is stimulated by PTH and reduced plasma phosphate but inhibited by calcium, calcitriol, and fibroblast growth factor 23 (FGF23).

Hormones are synthesized as required on a daily, hourly, or minute-to-minute basis with minimal storage, but there are significant exceptions. One is the thyroid gland, which contains enough stored hormone to last for about 2 months. This permits a constant supply despite significant variations in the availability of iodine. However, if iodine deficiency is prolonged, the normal reservoirs of T_4 can be depleted.

The various feedback signaling systems already described enable the hormonal *homeostasis* that is characteristic of virtually all endocrine systems. Regulation may include the central nervous system or local signal recognition mechanisms in the glandular cells, such as the calcium-sensing receptor of the parathyroid cell. Superimposed, centrally

programmed increases and decreases in hormone secretion or activation also occur through neuroendocrine pathways. Examples include the circadian variation in secretion of ACTH that directs the synthesis and release of cortisol. The monthly menstrual cycle exemplifies a system with much longer periodicity that requires a complex synergism between central and peripheral axes of the endocrine glands. Disruption of hormonal homeostasis due to glandular or central regulatory system dysfunction has both clinical and laboratory consequences. Recognition and correction of these effects are the essence of clinical endocrinology.

TRANSPORT OF HORMONES IN BLOOD

Protein hormones and some small molecules, such as the catecholamines, are water soluble and readily transported via the circulatory system. Others, such as the steroid and thyroid hormones, are almost insoluble in water, and their distribution presents special problems. Such molecules are bound to 50- to 60-kd carrier plasma glycoproteins such as thyroxine-binding globulin (TBG), sex hormone-binding globulin (SHBG), and corticosteroid-binding globulin, as well as to albumin. The ligand-protein complexes serve as reservoirs of these hormones, ensure ubiquitous distribution of their water-insoluble ligands, and protect the small molecules from rapid inactivation or excretion in the urine or bile. Without these proteins, it is unlikely that hydrophobic molecules would be transported much beyond the veins draining the glands in which they are formed.

The protein-bound hormones exist in rapid equilibrium with the often minute quantities of hormone in the aqueous plasma. It is this "free" fraction of the circulating hormone that is taken up by the cell. For example, if tracer thyroid hormone is injected into the portal vein in a protein-free solution, it becomes bound to hepatocytes at the periphery of the hepatic sinusoid. When the same experiment is repeated with a protein-containing solution, there is a uniform distribution of tracer hormone throughout the hepatic lobule.³

Despite the very high affinity of some of the binding proteins for their ligands, a specific protein may not be essential for hormone distribution. For example, in humans with a congenital deficiency of TBG, other proteins, namely transthyretin (TTR) and albumin, subsume its role. Because the affinity of these secondary thyroid hormone transport proteins is several orders of magnitude lower than that of TBG, it is possible for the hypothalamic-pituitary feedback system to maintain free thyroid hormone in the normal range at a much lower total hormone concentration. The fact that the level of "free" hormone concentration is normal in subjects with TBG deficiency indicates that it is this free moiety that is defended by the hypothalamic-pituitary axis and is the active hormone.⁴

The availability of gene targeting techniques has allowed specific tests of the physiologic roles of several hormone-binding proteins. For example, mice with targeted inactivation of the vitamin D-binding protein (DBP) have been generated.⁵ Although the absence of DBP markedly reduces the circulating concentration of vitamin D, the mice are otherwise normal. However, they do show enhanced susceptibility to a vitamin D-deficient diet because of the reduced reservoir of this sterol. In addition, the absence of DBP markedly reduces the half-life of calcitriol by accelerating its hepatic uptake, making the mice less susceptible to vitamin D intoxication.

In rodents, TTR carries retinol-binding protein and is also the principal thyroid hormone-binding protein. This protein is synthesized in the liver and in choroid plexus. It is the major thyroid hormone-binding protein in the cerebrospinal fluid of both rodents and humans and was previously thought to possibly serve an important role in thyroid hormone transport into the central nervous system. This hypothesis was later disproved by the fact that mice without TTR have normal concentrations of T_4 in the brain in addition to free T_4 in the plasma.^{6,7} To be sure, the serum concentrations of vitamin A and total T_4 are decreased, but the knockout mice have no signs of vitamin A deficiency or hypothyroidism. Such studies suggest that these proteins primarily serve distributive and reservoir functions.

Protein hormones and some small ligands (e.g., catecholamines) produce their effects by interacting with cell surface receptors. Others, such as the steroid and thyroid hormones, must enter the cell to bind to cytosolic or nuclear receptors. In the past, it was thought that much of the transmembrane transport of hormones was passive. Evidence has now demonstrated that specific transporters are involved in cellular uptake of thyroid hormone.⁸ This may be found to be the case for other small ligands as well, revealing yet another mechanism for ensuring the distribution of a hormone to its site of action. Studies in mice missing megalin, a large cell surface protein in the low-density lipoprotein (LDL) receptor family, have suggested that estrogen and testosterone uses megalin to enter certain tissues while still bound to SHBG.⁹ In this case, therefore,

it is the hormone bound to SHBG, rather than the “free” hormone, that is the active moiety that enters cells. It is unclear how generally this apparent exception to the “free hormone” hypothesis occurs.

TARGET CELLS AS ACTIVE PARTICIPANTS

Hormones determine cellular target actions by binding with high specificity to receptor proteins. Whether a peripheral cell is hormonally responsive depends to a large extent on the presence and function of specific and selective hormone receptors. Receptor expression determines which cells will respond as well as the nature of the intracellular effector pathways activated by the hormone signal. Receptor proteins may be localized to the cell membrane, cytoplasm, or nucleus. Broadly, polypeptide hormone receptors are associated with cell membranes, whereas steroid hormones selectively bind soluble intracellular proteins (Fig. 1-2). However, exceptions do occur. For example, epidermal growth factor (EGF) may signal directly to receptors located within the nucleus.

Membrane-associated receptor proteins usually consist of extracellular sequences that recognize and bind ligand, transmembrane anchoring hydrophobic sequences, and intracellular sequences that initiate intracellular signaling. Intracellular signaling is mediated by covalent modification and activation of intracellular signaling molecules

Figure 1-2 Hormonal signaling by cell surface and intracellular receptors. The receptors for the water-soluble polypeptide hormones, luteinizing hormone (LH), and insulin-like growth factor I (IGF-I), are integral membrane proteins located at the cell surface. They bind the hormone-utilizing extracellular sequences and transduce a signal through the generation of second messengers: cyclic adenosine monophosphate (cAMP) for the LH receptor and tyrosine-phosphorylated substrates for the IGF-I receptor. Although effects on gene expression are indicated, direct effects on cellular proteins (e.g., ion channels) are also observed. In contrast, the receptor for the lipophilic steroid hormone, progesterone, resides in the cell nucleus. It binds the hormone and becomes activated and capable of directly modulating target gene transcription. AC, Adenylate cyclase; G, heterotrimeric G protein; mRNAs, messenger RNAs; PKA, protein kinase A; R, receptor molecule; TF, transcription factor; Tyr, tyrosine found in protein X; X, unknown protein substrate. (Reproduced from Mayo K. Receptors: molecular mediators of hormone action. In: Conn PM, Melmed S, eds. *Endocrinology: Basic and Clinical Principles*. Totowa, NJ: Humana Press, 1997:11.)

(e.g., STAT proteins) or by generation of small molecule second messengers (e.g., cyclic adenosine monophosphate) through activation of heterotrimeric G proteins. The α -, β -, and γ -subunits of these G proteins activate or suppress effector enzymes and ion channels that generate the second messengers. Some of these receptors may in fact exhibit constitutive activity and have been shown to signal in the absence of added ligand.

Several growth factors and hormone receptors (e.g., for insulin) behave as intrinsic tyrosine kinases or activate intracellular protein tyrosine kinases. Ligand activation may cause receptor dimerization (e.g., GH) or heterodimerization (e.g., interleukin-6), followed by activation of intracellular phosphorylation cascades. These activated proteins ultimately determine specific nuclear gene expression.

Both the number of receptors expressed per cell and their responses are regulated, providing a further level of control for hormone action. Several mechanisms account for altered receptor function. Receptor endocytosis causes internalization of cell surface receptors; the hormone-receptor complex is subsequently dissociated, resulting in abrogation of the hormone signal. Receptor trafficking may then result in recycling back to the cell surface (e.g., as for insulin), or the internalized receptor may undergo lysosomal degradation. Both of these mechanisms, triggered by activation of receptors, effectively lead to impaired hormone signaling by downregulation of these receptors. The hormone signaling pathway may also be downregulated by receptor desensitization (e.g., as for epinephrine); ligand-mediated receptor phosphorylation leads to a reversible deactivation of the receptor. Desensitization mechanisms can be activated by a receptor's ligand (homologous desensitization) or by another signal (heterologous desensitization), which attenuates receptor signaling in the continued presence of ligand. Receptor function may also be limited by the action of specific phosphatases (e.g., SHP) or by intracellular negative regulation of the signaling cascade (e.g., suppressor of cytokine signaling [SOCS] proteins inhibiting JAK-STAT signaling).

Mutational changes in receptor structure can also determine hormone action. Constitutive receptor activation

may be induced by activating mutations (e.g., TSH receptor) leading to endocrine organ hyperfunction, even in the absence of hormone. Conversely, inactivating receptor mutations may lead to endocrine hypofunction (e.g., testosterone receptor, vasopressin receptor). These syndromes are well characterized and are well described in other chapters of this text (Fig. 1-3).

The functional diversity of receptor signaling also results in overlapping or redundant intracellular pathways. For example, both GH and cytokines activate JAK-STAT signaling, whereas the distal effects of these stimuli clearly differ. Therefore, despite common signaling pathways, hormones elicit highly specific cellular effects. Tissue or cell-type genetic programs or receptor-receptor interactions at the cell surface (e.g., dopamine D₂ hetero-oligomerization with somatotropin release-inhibiting factor [SRIF]) may also confer specific cellular response to a hormone and provide an additive cellular effect.¹⁰

CONTROL OF HORMONE SECRETION

Anatomically distinct endocrine glands are composed of highly differentiated cells that synthesize, store, and secrete hormones. Circulating hormone concentrations are a function of glandular secretory patterns and hormone clearance rates. Hormone secretion is tightly regulated to attain circulating levels that are most conducive to eliciting the appropriate target tissue response. For example, longitudinal bone growth is initiated and maintained by exquisitely regulated levels of circulating GH: mild GH hypersecretion results in gigantism, and GH deficiency causes growth retardation. Ambient circulating hormone concentrations are not uniform, and the secretion patterns determine appropriate physiologic function. For example, insulin secretion occurs in short pulses elicited by nutrient intake and other signals; gonadotropin secretion is episodic, determined by a hypothalamic pulse generator; and prolactin secretion appears to be relatively continuous with secretory peaks elicited during suckling.

<i>Diseases caused by mutations in G-protein-coupled receptors</i>			
<i>Condition</i>	<i>Receptor</i>	<i>Inheritance</i>	<i>Δ Function</i>
Retinitis pigmentosa	Rhodopsin	AD/AR	Loss
Nephrogenic diabetes insipidus	Vasopressin V2	X-linked	Loss
Isolated glucocorticoid deficiency	ACTH	AR	Loss
Color blindness	Red/green opsins	X-linked	Loss
Familial precocious puberty	LH	AD (male)	Gain
Familial hypercalcemia	Ca ²⁺ sensing	AD	Loss
Neonatal severe parathyroidism	Ca ²⁺ sensing	AR	Loss
Dominant form hypocalcemia	Ca ²⁺ sensing	AD	Gain
Congenital hyperthyroidism	TSH	AD	Gain
Resistance to thyroid hormone	TSH	AR (comp het)	Loss
Hyperfunctioning thyroid adenoma	TSH	Somatic	Gain
Metaphyseal chondrodysplasia	PTH-PTHrP	Somatic	Gain
Hirschsprung's disease	Endothelin-B	Multigenic	Loss
Coat color alteration (<i>E</i> locus, mice)	MSH	AD/AR	Loss and gain
Dwarfism (<i>little</i> locus, mice)	GHRH	AR	Loss

Figure 1-3 Diseases caused by mutations in G-protein-coupled receptors. All are human conditions with the exception of the final two entries, which refer to the mouse. Loss of function refers to inactivating mutations of the receptor, and gain of function to activating mutations. ACTH, adrenocorticotropic hormone; AD, autosomal dominant; AR, autosomal recessive; LH, luteinizing hormone; TSH, thyroid-stimulating hormone; PTH-PTHrP, parathyroid hormone and parathyroid hormone-related peptide; MSH, melanocyte-stimulating hormone; GHRH, growth hormone-releasing hormone; FSH, follicle-stimulating hormone. (Reproduced from Mayo K. Receptors: molecular mediators of hormone action. In Conn PM, Melmed S, eds. *Endocrinology: Basic and Clinical Principles*. Totowa, NJ: Humana Press, 1997:27.)

Hormone secretion also adheres to rhythmic patterns. Circadian rhythms serve as adaptive responses to environmental signals and are controlled by a circadian timing mechanism.¹¹ Light is the major environmental cue adjusting the endogenous clock. The retinohypothalamic tract entrains circadian pulse generators situated within hypothalamic suprachiasmatic nuclei. These signals subserve timing mechanisms for the sleep-wake cycle and determine patterns of hormone secretion and action. Disturbed circadian timing results in hormonal dysfunction and may also be reflective of entrainment or pulse generator lesions. For example, adult GH deficiency due to a damaged hypothalamus or pituitary is associated with elevations in integrated 24-hour leptin concentrations, decreased leptin pulsatility, and yet preserved circadian rhythm of leptin. GH replacement restores leptin pulsatility, followed by loss of body fat mass.¹² Sleep is also an important cue regulating hormone pulsatility. About 70% of overall GH secretion occurs during slow-wave sleep, and increasing age is

associated with declining slow-wave sleep and concomitant decline in GH and elevation of cortisol secretion.¹³ Most pituitary hormones are secreted in a circadian (day-night) rhythm, best exemplified by the ACTH peaks that occur before 9 a.m., whereas ovarian steroids follow a 28-day menstrual rhythm. Disrupted episodic rhythms are often a hallmark of endocrine dysfunction. For example, loss of circadian ACTH secretion with high midnight cortisol levels is a feature of Cushing's disease.

Hormone secretion is induced by multiple specific biochemical and neural signals. Integration of these stimuli results in net temporal and quantitative secretion of the hormone (Fig. 1-4). For example, signals elicited by hypothalamic hormones (growth hormone-releasing hormone [GHRH], SRIF), peripheral hormones (IGF1, sex steroids, thyroid hormone), nutrients, adrenergic pathways, stress, and other neuropeptides all converge on the somatotroph cell, resulting in the ultimate pattern and quantity of GH secretion. Networks of reciprocal interactions allow for

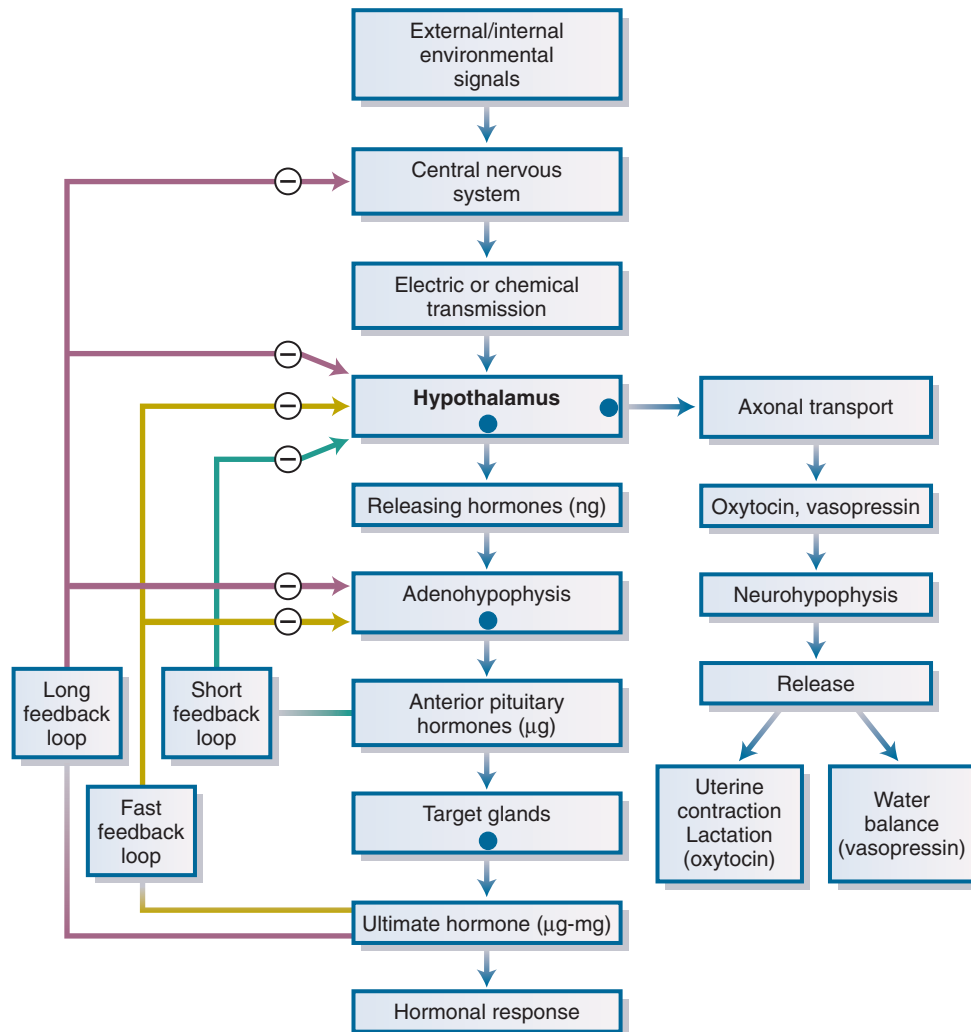

Figure 1-4 Peripheral feedback mechanism and a million-fold amplifying cascade of hormonal signals. Environmental signals are transmitted to the central nervous system, which innervates the hypothalamus, which responds by secreting nanogram amounts of a specific hormone. Releasing hormones are transported down a closed portal system, pass the blood-brain barrier at either end through fenestrations, and bind to specific anterior pituitary cell membrane receptors to elicit secretion of microgram amounts of specific anterior pituitary hormones. These enter the venous circulation through fenestrated local capillaries, bind to specific target gland receptors, trigger release of micrograms to milligrams of daily hormone amounts, and elicit responses by binding to receptors in distal target tissues. Peripheral hormone receptors enable widespread cell signaling by a single initiating environmental signal, thus facilitating intimate homeostatic association with the external environment. Arrows with a black dot at their origin indicate a secretory process. (Reproduced from Normal AV, Litwack G. *Hormones*, ed 2. New York, NY: Academic Press, 1997:14.)

dynamic adaptation and shifts in environmental signals. These regulatory systems embrace the hypothalamic pituitary and target endocrine glands as well as the adipocyte and lymphocyte. Peripheral inflammation and stress elicit cytokine signals that interface with the neuroendocrine system, resulting in activation of the hypothalamic-pituitary axis. The parathyroid and pancreatic secreting cells are less tightly controlled by the hypothalamus, but their functions are tightly regulated by the effects they elicit. For example, PTH secretion is induced when serum calcium levels fall, and the signal for sustained PTH secretion is abrogated by rising calcium levels.

Several tiers of control play a part in the ultimate net glandular secretion. First, central nervous system signals, including stress, afferent stimuli, and neuropeptides, signal the synthesis and secretion of hypothalamic hormones and neuropeptides (Fig. 1-5). Four hypothalamic-releasing hormones—GHRH, corticotropin-releasing hormone, thyrotropin-releasing hormone, and gonadotropin-releasing hormone (GnRH)—traverse the hypothalamic portal vessels and impinge upon their respective transmembrane trophic hormone-secreting cell receptors. These distinct cells express GH, ACTH, TSH, and gonadotropins, respectively. In contrast, hypothalamic somatostatin and dopamine suppress secretion of GH, prolactin, and TSH.

Trophic hormones also maintain the structural and functional integrity of endocrine organs, including the thyroid and adrenal glands and the gonads. Target hormones, in turn, serve as powerful negative feedback regulators of their respective trophic hormones; they often also suppress secretion of hypothalamic-releasing hormones. In certain circumstances (e.g., during puberty), peripheral sex steroids may positively induce the hypothalamic-pituitary-target gland axis. LH induces ovarian estrogen secretion, which feeds back positively to induce further LH release. Pituitary hormones themselves, in a short feedback loop, may also regulate their own respective hypothalamic-controlling hormone. Hypothalamic releasing hormones

are secreted in nanogram amounts and have short half-lives of a few minutes. Anterior pituitary hormones are produced in microgram amounts and have longer half-lives, whereas peripheral hormones can be produced in up to milligram amounts daily, with much longer half-lives.

A further level of secretion control occurs within the gland itself. Intraglandular paracrine or autocrine growth peptides serve to autoregulate pituitary hormone secretion, as exemplified by EGF control of prolactin or IGF1 control of GH secretion. Molecules within the endocrine cell may also subserve an intracellular feedback loop. For example, corticotrope SOCS3 induction by gp130-linked cytokines serves to abrogate the ligand-induced JAK-STAT cascade, blocking transcription of pro-opiomelanocortin and subsequent secretion of ACTH. This rapid on-off regulation of ACTH secretion provides a plastic endocrine response to changes in environmental signaling and serves to maintain homeostatic integrity.¹⁴

In addition to the central-neuroendocrine interface mediated by hypothalamic chemical signal transduction, the central nervous system directly controls several hormonal secretory processes. Posterior pituitary hormone secretion occurs as direct efferent neural extensions. Postganglionic sympathetic nerves also regulate rapid changes in renin, insulin, and glucagon secretion, and preganglionic sympathetic nerves signal to adrenal medullary cells, eliciting adrenaline release.

HORMONE MEASUREMENT

Endocrine function can be assessed by measuring levels of basal circulating hormone, evoked or suppressed hormone, or hormone-binding proteins. Alternatively, peripheral hormone receptor function can be assessed. Meaningful strategies for timing hormonal measurements vary from system to system. In some cases, circulating hormone concentrations can be measured in randomly collected serum samples. This measurement, when standardized for fasting, environmental stress, age, and gender, is reflective of true hormone concentrations only when levels do not fluctuate appreciably. For example, thyroid hormone, prolactin, and IGF1 levels can be accurately assessed in fasting morning serum samples. If hormone secretion is clearly episodic, timed samples may be required over a defined time course to reflect hormone bioavailability. For example, early morning and late evening cortisol measurements are most appropriate. Sampling over 24 hours for GH measurements, with samples collected every 2, 10, or 20 minutes, is expensive and cumbersome, yet may yield valuable diagnostic information. Random sampling may reflect secretion peaks or nadirs, confounding adequate interpretation of results.

In general, confirmation of failed glandular function is made by attempting to evoke hormone secretion by recognized stimuli. For example, testing of pituitary hormone reserve may be accomplished by injecting appropriate hypothalamic releasing hormones. Injection of trophic hormones, including TSH and ACTH, evokes specific target gland hormone secretion. Pharmacologic stimuli (e.g., metoclopramide for induction of prolactin secretion) may also be useful to test hormone reserve. In contrast, hormone hypersecretion can be diagnosed by suppressing glandular function. For example, failure to appropriately suppress GH levels after a standardized glucose load implies inappropriate GH hypersecretion. The failure to suppress insulin

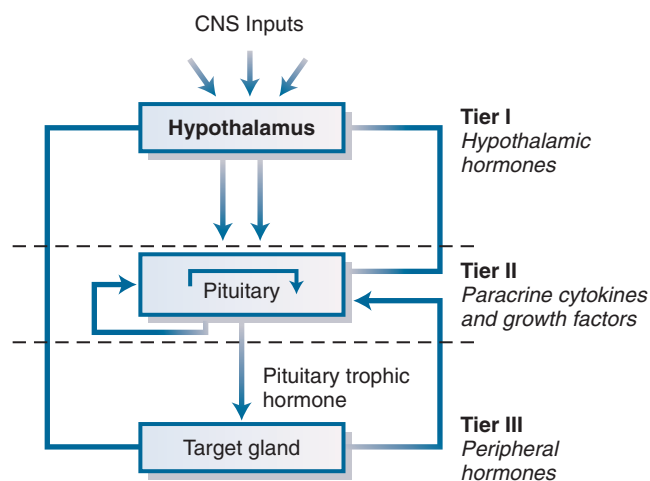

Figure 1-5 Model for regulation of anterior pituitary hormone secretion by three tiers of control. Hypothalamic hormones impinge directly on their respective target cells. Intrapituitary cytokines and growth factors regulate trophic cell function through paracrine (and autocrine) control. Peripheral hormones exert negative feedback inhibition on the synthesis and secretion of their respective pituitary trophic hormones. (Reproduced from Ray D, Melmed S. Pituitary cytokine and growth factor expression and action. *Endocrine Rev.* 1997;18:206-228.)

secretion in response to hypoglycemia indicates inappropriate hypersecretion of insulin and should prompt a search for the cause (e.g., an insulin-secreting tumor).

Radioimmunoassays use highly specific antibodies unique to a hormone, or hormone fragment, to quantify hormone levels. Enzyme-linked immunosorbent assays (ELISAs) employ enzymes instead of radioactive hormone markers, and enzyme activity reflects hormone concentration. This sensitive technique has allowed ultrasensitive measurements of physiologic hormone concentrations. Hormone-specific receptors may be employed in place of the antibody in a radioreceptor assay.

ENDOCRINE DISEASES

Endocrine diseases fall into five broad categories: (1) hormone overproduction, (2) hormone underproduction, (3) altered tissue responses to hormones, (4) tumors of endocrine glands, and a relatively new category exemplified in the thyroid axis, (5) hormone deficiency due to its excessive rate of inactivation caused by overexpression of an endogenous enzyme in a tumor.

Hormone Overproduction

Occasionally, hormones are secreted in increased amounts because of genetic abnormalities that cause abnormal regulation of hormone synthesis or release. For example, in glucocorticoid-remediable hyperaldosteronism, an abnormal chromosomal crossover event puts the aldosterone synthetase gene under the control of the ACTH-regulated 11 β -hydroxylase gene. More often, diseases of hormone overproduction are associated with an increase in the total number of hormone-producing cells. For example, the hyperthyroidism of Graves' disease, in which antibodies mimic TSH and activate the TSH receptors on thyroid cells, is associated with a dramatic increase in thyroid cell proliferation, as well as increased synthesis and release of thyroid hormone from each thyroid cell. The increase in thyroid cell number represents a polyclonal expansion of thyroid cells in which large numbers of thyroid cells proliferate in response to an abnormal stimulus. However, most endocrine tumors are not polyclonal expansions but instead represent monoclonal expansions of one mutated cell. Pituitary and parathyroid tumors, for example, are usually monoclonal expansions in which somatic mutations in multiple tumor suppressor genes and proto-oncogenes occur. These mutations lead to increased proliferation or survival (or both) of the mutant cells. Sometimes, this proliferation is associated with abnormal secretion of hormone from each tumor cell. For example, mutant G_s α -subunit proteins in somatotrophs can lead to both increased cellular proliferation and increased secretion of GH from each tumor cell.

Hormone Underproduction

Underproduction of hormone can result from a wide variety of processes, ranging from surgical removal of parathyroid glands during neck surgery, to tuberculous destruction of adrenal glands, to iron deposition in beta cells of islets in hemochromatosis. A frequent cause of destruction of hormone-producing cells is autoimmunity. Autoimmune destruction of beta cells in type 1 diabetes mellitus or of thyroid cells in Hashimoto's thyroiditis are two of the most common disorders treated by endocrinologists. More

uncommonly, a host of genetic abnormalities can lead to decreased hormone production. These disorders can result from abnormal development of hormone-producing cells (e.g., hypogonadotropic hypogonadism caused by KAL gene mutations), from abnormal synthesis of hormones (e.g., deletion of the GH gene), or from abnormal regulation of hormone secretion (e.g., the hypoparathyroidism associated with activating mutations of the parathyroid cell's calcium-sensing receptor).

Altered Tissue Responses

Resistance to hormones can be caused by a variety of genetic disorders. Examples include mutations in the GH receptor in Laron dwarfism and mutations in the $G_s\alpha$ gene in the hypoparathyroidism of pseudohypoparathyroidism type 1A. The insulin resistance in muscle and liver that is central to the etiology of type 2 diabetes mellitus appears to be polygenic in origin. Type 2 diabetes is also an example of a disease in which end-organ insensitivity is worsened by signals from other organs, in this case by signals originating in fat cells. In other cases, the target organ of hormone action is more directly abnormal, as in the PTH resistance of renal failure.

Increased end-organ function can be caused by mutations in signal reception and propagation. For example, activating mutations in TSH, LH, and PTH receptors can cause increased activity of thyroid cells, Leydig cells, and osteoblasts, even in the absence of ligand. Similarly, activating mutations in the $G_s\alpha$ protein can cause precocious puberty, hyperthyroidism, and acromegaly in McCune-Albright syndrome.

Tumors of Endocrine Glands

Tumors of endocrine glands, as mentioned earlier, often result in hormone overproduction. Some tumors of endocrine glands produce little if any hormone but cause disease through local compressive symptoms or metastatic spread. Examples include so-called nonfunctioning pituitary tumors, which are usually benign but can cause a variety of symptoms due to compression on adjacent structures, and thyroid cancer, which can spread throughout the body without causing hyperthyroidism.

Excessive Hormone Inactivation or Destruction

Although most enzymes important for endocrine systems activate a prohormone or precursor protein, there are also those whose function is to inactivate the hormone in a physiologically regulated fashion. An example is iodothyronine deiodinase type 3 (D3) which inactivates T_3 and T_4 by removing an inner-ring iodine atom from the iodothyronine. The products of these reactions, 3,3'-diiodothyronine and reverse T_3 , respectively, are inactive. Several years ago, an infant was identified with hypothyroidism due to a large hepatic hemangioma expressing high amounts of D3. This condition was termed *consumptive hypothyroidism* because it resulted from inactivation of thyroid hormone at a more rapid rate than it could be produced by the infant's normal thyroid gland.^{15,16} The condition has now been identified in a number of infants and even in adults with D3-expressing tumors. In theory, accelerated destruction of other hormones could occur from similar processes, but there are no examples reported to date.

THERAPEUTIC STRATEGIES

In general, hormones are employed pharmacologically for their replacement or suppressive effects. Hormones may also be used for diagnostic stimulatory purposes (e.g., hypothalamic hormones) to evoke target organ responses or to diagnose endocrine hyperfunction by suppressing hormone hypersecretion (e.g., T_3). Ablation of endocrine gland function from genetic or acquired causes can be restored by hormone replacement therapy. In general, steroid and thyroid hormones are replaced orally, whereas peptide hormones (e.g., insulin, GH) require injection. Gastrointestinal absorption and first-pass kinetics determine oral hormone dosage and availability. Physiologic replacement can achieve both appropriate hormone levels (e.g., thyroid) and approximate hormone secretory patterns (e.g., GnRH delivered intermittently via a pump).

Hormones can also be used to treat diseases associated with glandular hyperfunction. Long-acting depot preparations of somatostatin analogues suppress GH hypersecretion in acromegaly or 5-hydroxyindoleacetic acid (5-HIAA) hypersecretion in carcinoid syndrome. Estrogen receptor antagonists (e.g., tamoxifen) are useful for some patients with breast cancer, and GnRH analogues may downregulate the gonadotropin axis and benefit patients with prostate cancer.

Novel formulations of receptor-specific hormone ligands are now being clinically developed for more selective therapeutic targeting; examples include estrogen agonists/antagonists and somatostatin receptor subtype ligands. Modes of hormone injection (e.g., for PTH) may also determine therapeutic specificity and efficacy. Improved hormone delivery systems, including computerized mini-pumps, intranasal sprays (e.g., for desmopressin [DDAVP]), pulmonary inhalations, and depot intramuscular injections, allow added patient compliance and ease of administration. Insulin delivered by inhalation has already been approved for use, and inhaled forms of GH and other hormones are under investigation. Cell-based therapies employing highly programmed pluripotent stem cells expressing a particular hormone or growth factor are also in development. These approaches require novel administration systems to allow cell-derived endocrine products to reach their intended target.¹⁷ Novel technologies potentially marked prolongation in the half-life of peptide hormones, which would require less frequent administration. For example, a once-weekly preparation of exenatide, a GLP1 analogue used in the treatment of type 2 diabetes as a twice-daily injection, is undergoing clinical trials.

Despite this tremendous progress, some therapies, such as insulin delivery to rigorously control blood sugar, still

require frequent administration by injection and close monitoring by the patient. Novel treatment systems that would link frequent monitoring of glucose levels to appropriate adjustments in the insulin dose promise to substantially reduce the burden of this disease. Hormones are biologically powerful molecules that exert therapeutic benefit and effectively replace pathologic deficits. They should not be prescribed without clearcut indications and should not be administered without careful evaluation by an appropriately qualified medical practitioner.

Clinical Endocrinology: A Personal View

GILBERT H. DANIELS

CLINICAL ENDOCRINOLOGY: A RETROSPECTIVE

I love practicing and teaching clinical endocrinology.

As a young physician in the early 1970s, I was drawn to clinical endocrinology by its strong biochemical basis, elegant physiology, relative diagnostic clarity, and dramatic therapeutic efficacy. I liked the fact that clinical endocrinology made intellectual sense, demanded both clinical and laboratory expertise, and could also make patients feel better.

With respect to biochemistry, I found that knowing the steroid hormone biosynthetic pathways was essential to understanding the adrenogenital syndrome. Knowing how catecholamines were metabolized made it possible to understand the diagnostic tests for pheochromocytomas. In other words, I realized that understanding the biochemical basis of an endocrine disorder could eventually lead to its proper diagnosis and treatment.

Understanding the physiologic basis of an endocrine problem was equally critical. Dr. Fuller Albright was the first to describe hormone resistance and the ectopic

production of hormones. Albright's physiologic insights also led him to develop the popular arrow drawings detailing the feedback loops between trophic hormones and end organs. Many diseases of hormone excess could be categorized using Albright's reasoning. An exception is destructive thyroiditis, in which hyperthyroidism is caused by the uncoordinated release of stored thyroid hormone. This kind of hormonal excess does not occur in other endocrine organs.

Manipulation of physiology allowed us to distinguish deficiency of growth hormone (GH) or cortisol (i.e., failure of levels to rise after insulin-induced hypoglycemia) from a nadir between pulses of these hormones. Conversely, failure to suppress cortisol after administration of the synthetic glucocorticoid dexamethasone (which does not register in the cortisol assay) was recognized to be a sign of "autonomous" cortisol production rather than a cortisol peak. Dr. Daniel Federman taught generations of endocrinologists to apply two simple rules with respect to pulsatile hormones—"If it's low, stimulate it; if it's high, suppress it"—to determine whether low or high hormone concentrations were physiologic or pathologic.

We found that fitting together all the pieces of an endocrine puzzle could lead to remarkably effective therapies. The administration of deficient hormones (GH for GH deficiency, thyroid hormone for hypothyroidism, cortisol for adrenal insufficiency, insulin for “juvenile” diabetes mellitus, pitressin tannate in oil for diabetes insipidus) was life-altering or even life-saving for patients, as well as immensely gratifying for clinicians. Eliminating excess hormone production produced equally beneficial and often dramatic results. Hyperthyroidism could be treated with medication, with targeted therapy using radioactive iodine, or, less commonly, with surgery. Surgery was required to treat the hormone excesses of Cushing’s syndrome, acromegaly, hyperparathyroidism, and pheochromocytoma.

There were also significant limitations to our knowledge of clinical endocrinology in the early 1970s. Our ability to image the thyroid was restricted to radioisotope thyroid scans and the rare ultrasound study. It was almost impossible to image the pituitary or the adrenal glands, because computed tomography (CT scanning) and magnetic resonance imaging (MRI) were not yet available. Thyroid hormone excess was the only type of hormone excess that could be effectively treated nonsurgically. We had a limited knowledge of the spectrum and epidemiology of endocrine diseases (particularly mild functional disease and incidental structural disease) and their diagnostics and therapeutics. There were also endocrine diseases that had yet to be recognized or described, including endocrine disorders precipitated or caused by new therapies for nonendocrine disorders.

Modern Clinical Endocrinology

In the last 40 years, our knowledge of endocrine physiology, pathophysiology, biology, molecular biology, and genetics has dramatically expanded. This new knowledge has changed many of the ways in which we diagnose and treat endocrine disorders. For example, greater understanding of the differential diagnosis and biologic mechanisms of hormone excess has made it possible to distinguish among clinically similar disorders and to identify new disorders.

During the past 40 years, new research has helped explain previously puzzling clinical observations and also opened up entirely new areas of investigation and therapy. Some examples follow.

- The hypokalemia of licorice administration and the hypokalemia of the ectopic adrenocorticotrophic hormone (ACTH) syndrome caused by small cell carcinoma of the lung were understood only after the binding of cortisol to the mineralocorticoid receptor and its inactivation by the enzyme, 11 β -hydroxysteroid dehydrogenase 2 was described. Inhibition of this enzyme by the licorice component, glycyrrhizic acid, was found to prevent inactivation of cortisol at the mineralocorticoid receptor; the dramatic overproduction of cortisol in the ectopic ACTH syndrome presumably overwhelms this enzyme. Cortisol becomes a potent mineralocorticoid receptor agonist in both situations.¹
- Molecular biology was necessary to understand glucocorticoid-remediable hyperaldosteronism, in which a genetic crossover allows the ACTH-driven 11 β -hydroxylase promoter to drive aldosterone synthesis instead of cortisol synthesis—a rare example of a hormone-overproducing syndrome without an increase in the number of cells making the hormone.

- Defining the role of 5 α -reductase in testosterone metabolism led to the understanding of prepubertal “testosterone resistance” in individuals deficient in this enzyme, as well as potential therapies for prostate hypertrophy and androgenic hair loss.
 - Familial hypocalciuric hypercalcemia (FHH) was distinguished from primary hyperparathyroidism by means of an extremely low urine calcium excretion (and clearance). Once the calcium sensor was identified, FHH was proven to be caused by an inactivating mutation of that receptor. More recently, an astute endocrine fellow discovered that antibodies inhibiting the calcium sensor caused intermittent primary hyperparathyroidism in a patient with other autoimmune disorders.² Conversely, mutations and antibodies that activate the calcium sensor cause hypoparathyroidism.
 - New data have emerged about vitamin D. Vitamin D deficiency was identified as a common disorder in adults. The active form of vitamin D (1,25-dihydroxyvitamin D₃, or calcitriol) was characterized as a hormone. It rapidly became an important therapy for hypoparathyroidism and for hereditary syndromes in which it is not produced. Increased production of calcitriol by active granulomas explained the hypercalcemia of sarcoidosis.
 - Recognition of hypophosphatemic syndromes such as tumoral osteomalacia was made possible by elucidation of the fibroblast growth factor (FGF23) pathways.
 - New therapies were developed for osteoporosis. The well-known industrial chemicals, bisphosphonates, were shown to be effective therapy; the well-described but little known anabolic bone effects of parathyroid hormone (PTH) were exploited in treating osteoporosis; and the recognition that different binders to estrogen receptors could sometimes mimic the action of estradiol and sometimes oppose it led to the use of selective estrogen receptor modulators (SERMs) for treatment of osteoporosis.
 - Parathyroid hormone-related protein (PTHrP) was found to be an important cause of the humoral hypercalcemia of malignancy and also to play a major role in bone biology.
 - The use of gonadotropin-releasing hormone analogues for the treatment of precocious puberty and for ovulation induction and as therapy for malignancies demonstrated the rewards of careful physiologic studies.
 - The observation that more insulin is released after oral glucose than after intravenous glucose administration led to the discovery of incretins as well as the clinical application of glucagon-like peptide-1 (GLP1) agonists for the treatment of diabetes mellitus. It is possible that incretins are responsible for the hypoglycemic syndromes that occur after gastric bypass surgery.³ Recently, labeled GLP1 agonists have been used to image insulinomas.⁴
 - Blood sugar control was shown to be important to prevent the complications of diabetes mellitus.
- In addition, the diverse biochemical and physiologic bases of hormone resistance were elucidated, the spectrum of hormone resistance was expanded, and some of this new knowledge led to several important therapies for syndromes of hormone resistance.
- Laron dwarfism is a form of GH resistance caused by a mutation in the GH receptor. Once insulin-like growth factor type 1 (IGF1), the downstream effector

of GH, was identified and synthesized, growth could be induced by bypassing the missing step.

- Pseudo-vitamin D deficiency rickets is caused by a deficient enzyme (25-hydroxyvitamin D₃ 1 α -hydroxylase) and can be treated by administration of calcitriol, the product of that enzyme. However, if the receptor for calcitriol is missing, then true “resistance” is present and cannot be directly overcome.
- Pseudohypoparathyroidism is often caused by mutations in the Gs signaling protein and may be associated with more subtle forms of resistance to hormones other than PTH (e.g., resistance to thyroid-stimulating hormone [TSH]). In pseudohypoparathyroidism type 1A, the renal proximal tubule is resistant to the actions of PTH (because of maternal imprinting in the proximal tubule, where only one allele of the Gs gene is active), but the bones are not resistant. Therefore, resistance may vary among tissues.
- Hormone resistance may be acquired. For example, antibodies to the insulin receptor cause diabetes mellitus with severe insulin resistance requiring thousands of units of insulin daily; obesity worsens the insulin resistance of type 2 diabetes; starvation causes GH resistance; and renal failure causes PTH resistance.
- Hormone resistance at one receptor can result in spill-over to other related receptors. For example, insulin resistance leading to elevated insulin can cause hirsutism by stimulating IGF receptors on the ovary.

We now recognize many autoimmune endocrine disorders and are beginning to understand their physiology.

Changing Spectrum of Endocrine Diseases

Most of the endocrine disorders recognized before 1970 were clinically severe and therefore easily diagnosed. In contrast, many of the endocrine disorders identified after 1970 have been clinically more subtle, easy to overlook, and far more prevalent. As a result, the percentage of severe endocrine disorders has declined over the years, whereas the percentage and prevalence of less severe endocrine disorders have risen sharply (Fig. 2-1).

The following are some examples of less severe endocrine disorders that are now commonly diagnosed.

- “Asymptomatic” hyperparathyroidism is often diagnosed through the routine measurement of serum calcium levels with autoanalyzers.

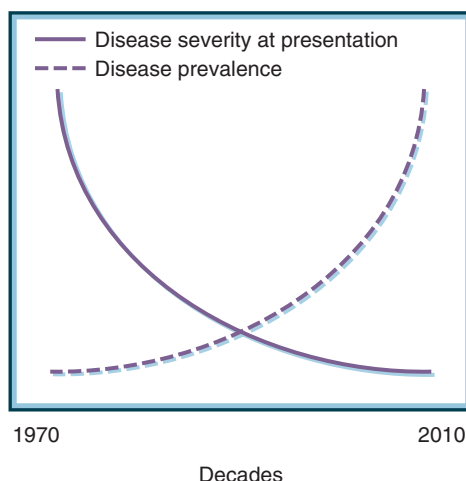

Figure 2-1 Changing pattern of disease severity over time.

- Mild thyroid disease (“subclinical” hyperthyroidism or hypothyroidism) can be detected and studied with the use of readily available sensitive TSH assays.
- “Subclinical” Cushing’s syndrome caused by autonomous adrenal nodules can now be detected by appropriate diagnostic testing after the incidental discovery of an adrenal nodule.
- Type 2 diabetes mellitus is now considered to be the most common cause of diabetic microvascular complications and a leading cause of cardiovascular morbidity and mortality.
- Insulin resistance without diabetes mellitus is now considered to be a condition that poses a significant cardiovascular risk.
- Polycystic ovarian disease, once thought to be a rare disease of obese, hirsute women with infertility, has been shown to be a common cause of irregular menses, hirsutism, and insulin resistance.
- The widespread availability of bone densitometry has led to a greater understanding of the spectrum and population consequences of low bone mass.
- Modern diagnostic algorithms have revealed that 8% to 10% of hypertensive patients have primary hyperaldosteronism. Primary aldosteronism may also be associated with cardiovascular morbidity independent of its effect on blood pressure.⁵

Our ability to diagnose ever-milder stages of endocrine disorders has brought with it a variety of challenging new questions for endocrinologists and epidemiologists:

- What constitutes “normal” levels of hormones and metabolites? Are “normal” and “optimal” levels synonymous? Which of these two levels is more physiologically relevant? Is the optimal physiologic level also optimal for disease prevention?
- Is treatment beneficial for patients with mild endocrine disorders? If intervention is beneficial, when should it be done? Does the treatment of mild endocrine and metabolic abnormalities ultimately benefit society?

It is important to keep in mind that there is not yet a general consensus about what defines “normal,” “optimal,” and “abnormal” levels for any given hormone or metabolite and that these definitions are continuously undergoing revision to reflect the latest research. Some define “normal” in purely statistical terms. Others base their assessment of “optimal” levels on relevant physiologic or pathologic changes. For example, vitamin D deficiency was first recognized as a level of vitamin D so low as to cause rickets and osteomalacia. Investigators then modified the definition of normal to be the level of vitamin D below which PTH levels start to rise. More recently, some have proposed that the optimal level of vitamin D is the one that maximizes bone density in population studies and clinical trials. Diabetologists have used certain glucose concentrations associated with adverse outcomes to define diabetes mellitus, impaired glucose tolerance, and elevated fasting glucose concentrations. The problem is that there is no universally accepted standard for these values.

Radiology and Endocrine Epidemiology

In the 1960s, the great endocrinologist, Dr. George Thorn, reportedly explained in mock exasperation, “Thank goodness we can’t feel the adrenal glands!” He was referring to what at the time seemed like an overwhelming number of thyroidectomies being performed to treat palpable goiters. His fear was that once abnormalities became detectable in

other glands, the inevitable consequence would be an exponential increase in the number of patients requiring evaluation and treatment.

Forty years later, we have come to realize how prescient Thorn was. Advances in radiology now allow us to scrutinize not only the adrenal gland but every other endocrine gland as well. The use of diagnostic ultrasound, CT scans, and MRIs of the head, neck, and abdomen has led to the clinical discovery of thyroid, pituitary, adrenal, and pancreatic tumors that were previously found only at autopsies or during surgery.

The twin epidemics of these incidentalomas and the mild endocrine diseases discussed earlier has created a new dilemma: there are simply too many patients to be cared for by endocrinologists, even with the help of trained endocrine nurses and assistants. The result is precisely what Thorn had foreseen: all this new radiological information has led to the discovery of numerous “incidentalomas,” which in turn has led to a need for diagnostic evaluation and treatment. Part of the endocrinologist’s new job description, therefore, should be to educate primary care physicians and nurses in the optimal care of patients with these endocrine disorders.

“New” Endocrine Disorders

One of the most exciting parts of being a clinical endocrinologist is that new or newly recognized endocrine disorders continue to be discovered, and clinicians are often the ones who find them.

The story of one such discovery was often told by the legendary thyroidologist, Dr. Sydney Ingbar. A clinician called Ingbar to discuss a hyperthyroid patient who had a nil radioactive iodine uptake and a painless thyroid. Ingbar led the clinician through the standard differential diagnosis excluding iodine excess, exogenous thyroid hormone, struma ovarii, and painful (DeQuervain’s) thyroiditis. Ingbar eventually concluded that there was no such disease. In fact, the patient turned out to have what was subsequently named *painless or silent subacute thyroiditis (painless destructive thyroiditis)*. Painless subacute thyroiditis has since been found to occur in 5% to 10% of all women in the postpartum period (postpartum thyroiditis). It had simply been unrecognized. For Ingbar, the story taught an important lesson: when making a diagnosis, the clinician must avoid a rush to judgment and remain open to the possibility of new diseases.

Other endocrine diseases that have been recognized in recent years include the following:

- Endocrine diseases caused by nonendocrine drugs. Many drugs (e.g., amiodarone, lithium, sunitinib) and immune modulators (e.g., denileukin diftitox, interleukin, and interferon in hepatitis C) also cause autoimmune thyroid disorders, and painless subacute thyroiditis in particular. A new B and T lymphocyte-depleting drug for multiple sclerosis (alutuzemab) induces Graves’ disease in 12% of recipients. Etomidate, an anesthetic agent, may produce adrenal insufficiency.
- Somatostatin- and glucagon-secreting tumors of the pancreas
- Maturity-onset diabetes of the young (MODY), which results from a number of different specific biochemical abnormalities
- Lymphocytic hypophysitis, an autoimmune cause of (postpartum) hypopituitarism, possibly related to the postpartum rebound of immune inhibition. This disorder may also be induced during cancer therapy with

antibodies targeting cytotoxic T-lymphocyte antigen 4 (CTLA4)

- Human immunodeficiency virus (HIV) infection, the therapy for HIV, and the consequences of acquired immunodeficiency syndrome (AIDS) cause a spectrum of endocrine disorders, particularly ones involving the adrenal and the thyroid.

Although endocrinology has changed fairly dramatically over the last 40 years, the clinical approach to the patient is based on a series of little-changed principles. The following sections present some insights and approaches that I have learned and taught over many years.

THE CLINICAL APPROACH TO THE PATIENT

An endocrinologist should always view the patient’s condition as a whole rather than exclusively as an endocrine problem. Skillful questioning, personal interaction, careful deliberation, and sound clinical judgment are essential.

The clinical endocrinologist has to fill many roles at once—radiologist, pharmacologist, physiologist, epidemiologist, public health physician, geneticist, oncologist, and educator. But perhaps the most important role is that of internist, because the endocrine system affects every system of the body. For example, caring for a patient with diabetes mellitus involves monitoring and treating not only blood sugar but also cholesterol levels, blood pressure, kidney function, vision, the cardiovascular system, and the nervous system.

The process of clinical care begins with a carefully performed and recorded history and physical examination. During the history and physical examination, the endocrinologist must consider not only all the possible endocrine causes but also all the possible nonendocrine causes for the patient’s symptoms. It is unacceptable to dismiss a patient by saying, “This is not an endocrine problem,” without, if possible, suggesting alternative explanations for the symptoms.

- If a patient has neck tightness and intermittent hoarseness, gastroesophageal reflux disease is a more likely etiology than goiter.
- Severe fatigue (possibly in conjunction with hypogonadism, hypertension, and catecholamine excess) might be related to sleep apnea and may be suspected by asking about lack of restful sleep, the presence of snoring, and collar size (a collar size greater than 17 inches is often indicative of sleep apnea). Sleep apnea is a much more likely cause of fatigue than a minimally elevated serum TSH.
- Depression, iron deficiency, and sleeplessness resulting from menopausal hot flashes should also be considered when a patient complains of fatigue.
- A patient with persistent anxiety after treatment of Graves’ hyperthyroidism needs more than to be told that there is no endocrine basis for his or her anxiety because the thyroid function is now normal. Based on my observations, these symptoms may be a form of “programmed” anxiety resulting from long-standing hyperthyroidism. These patients often benefit from a clear explanation, cognitive behavioral therapy, and/or anxiolytic therapy.
- Always check the neck veins in a hyperthyroid patient with dyspnea to make sure that the dyspnea is caused by the hyperthyroidism per se rather than by congestive heart failure.

- The “uncontrolled” hypertension of a patient with trivial elevation of urine metanephrines may be explained by a history of extensive use of nonsteroidal anti-inflammatory drugs⁶ or by the nonspecific metanephrine elevation of hypertension.
- Weight loss with preserved appetite suggests hyperthyroidism, diabetes mellitus out of control, pheochromocytoma, malabsorption, and possibly anorexia nervosa; weight loss with a poor appetite has other, potentially more serious explanations. However, elderly hyperthyroid individuals may also have anorexia.
- Severe joint pains in a patient with autoimmune thyroid disease may represent rheumatoid arthritis or other nonendocrine autoimmune disorders.
- Vague abdominal pains, unexplained weight loss, or increased requirement for thyroid hormone may be caused by celiac disease, which is more common in patients with autoimmune thyroid disease.

An obvious but often overlooked point is that the patient should be told exactly what the diagnosis means once the clinician makes it. It is important to answer the patient's questions, provide reassurance, and allay any unnecessary fears. For example, many patients with hyperthyroidism and weight loss continue to worry until they hear the key words, “This is *not* cancer.”

History and Physical Examination

What can we learn from the initial clinical examination? A careful history and physical examination are the first steps in establishing a diagnosis. All endocrine fellows learn the classic symptoms and signs of hormone excess and deficiency, but learning the characteristic tempo of each disease is equally important. For example, acute onset of Cushing's symptoms or hirsutism suggests a malignancy, and hyperthyroid symptoms lasting longer than 4 months effectively exclude destructive thyroiditis.

The following are several simple but very useful diagnostic tips to keep in mind during the initial clinical examination:

- Regular menses with molimina is the best sign of a normally functioning hypothalamic-pituitary-ovarian axis and essentially precludes the need for hormonal testing for this axis.
- Erectile dysfunction without loss of libido is rarely a symptom of testosterone deficiency.
- Most patients with Cushing's syndrome complain of difficulty falling asleep.
- When a patient with a neck or thyroid mass complains of difficulty swallowing, the first question should be, “Is it difficult to swallow food or saliva?” and not “Which surgeon would you like to see?” Difficulty swallowing saliva is caused by repetitive swallowing when there is nothing to swallow (globus). If the swallowing difficulty occurs with food, then a barium swallow will help determine whether the dysphagia is related to the neck mass.
- Diabetes insipidus is often characterized by the sudden onset of thirst for ice cold water in particular.
- Severe male hypogonadism may be associated with hot flashes.
- Sudden growth of a neck mass in a patient with a history of Hashimoto's thyroiditis raises the specter of a thyroid lymphoma.
- Severe muscle cramps are often caused by severe hypothyroidism, particularly when the onset is acute.

A careful medication history should include ascertainment of prescription medications, over-the-counter medications, vitamins, and supplements, because both prescription and nonprescription medicines can influence endocrine function. Several targeted chemotherapy agents and immunomodulatory drugs may induce endocrine disorders, particularly hyperthyroidism and hypothyroidism. A history of megestrol acetate (Megace) administration, recent intra-articular glucocorticoid injections, or extensive topical glucocorticoid administration may provide the clue to otherwise unexplained suppression of the hypothalamic-pituitary-adrenal axis. High-dose glucocorticoid therapy may explain the slightly low serum TSH in a patient referred for “subclinical hyperthyroidism.” A host of drugs have been shown to increase the metabolism of thyroid hormone or cortisol, and knowledge of these drugs and their uses may explain otherwise unexplained worsening of treated or untreated hypothyroidism or Addison's disease. Many drugs and supplements inhibit levothyroxine absorption, and it is important to ask the patient whether any of them are being taken. A hyperthyroid patient with a nil radioactive iodine uptake may be ingesting large amounts of (iodine-containing) kelp or over-the-counter thyroid supplements that contain active hormone. Many drugs are associated with hyperprolactinemia, especially atypical antipsychotics such as risperidone. The use of anticoagulants may be associated with adrenal hemorrhage.

Smokers are at increased risk for severe Graves' ophthalmopathy.

A careful family history is necessary to help diagnose those important endocrine disorders that are genetic or familial. An entirely different approach to diagnosis and therapy is necessary when the patient being evaluated for hyperparathyroidism is found to have a parent or sibling with the same diagnosis. A family history of diabetes mellitus may be an important clue when dealing with atypical hypoglycemia. Surreptitious use of insulin or oral hypoglycemics must be excluded. Remember that insulin is also available without a prescription.

Knowledge of the past medical history and concomitant illnesses may provide important clues to current endocrine problems. A history of head and neck irradiation in childhood necessitates a thyroid ultrasound examination and a higher degree of concern when thyroid nodules are discovered. It also places the patient at increased risk for primary hyperparathyroidism. Infants, children, and fetuses who were exposed to radiation during the power plant meltdown near Chernobyl in 1986 are now at risk for thyroid nodules and thyroid cancer. A history of anti-cardiolipin syndrome may be a clue to the presence of Addison's disease caused by adrenal hemorrhage. A recent CT scan with iodinated contrast may explain the sudden onset of hyperthyroidism in a patient with a long-standing nodular thyroid.

Many helpful clues can be obtained from a careful physical examination. Be sure to look at the patient's skin and hair during the physical examination.

- Early gray hair (1 gray hair before age 30) or vitiligo is a marker of autoimmune disease. A hypopigmented thyroidectomy scar suggests that the surgery was for autoimmune thyroid disease (Graves' disease or Hashimoto's thyroiditis).
- ACTH-driven hyperpigmentation (including the buccal mucosa, extensor surfaces, nipples, and recent scars) may be a sign of Addison's disease, Nelson's syndrome (growth of a corticotroph adenoma after adrenalectomy for Cushing's syndrome), or ectopic

Cushing's syndrome resulting from small cell carcinoma of the lungs. Increased sun tanning may occur in hyperthyroidism (because of hypermetabolism of cortisol with resultant ACTH overproduction). Increased melanin also occurs in hemochromatosis, but in this case it is the iron pigment that stimulates melanin production.

- Angiofibromas and collagenomas are characteristic of multiple endocrine neoplasia (MEN) type 1 and may turn a "simple" case of hyperparathyroidism into a search for this familial syndrome.
- Acanthosis nigricans is common with many disorders of insulin resistance.
- Café-au-lait spots may suggest McCune-Albright syndrome or neurofibromatosis type 1.
- Skin tags may be a clue to the diagnosis of acromegaly (and may predict colonic neoplasms). Shaking hands with an acromegalic has often been likened to shaking hands with the Pillsbury doughboy.

Although neck ultrasound has replaced thyroid examination in many offices, the value of the thyroid examination should not be underestimated. I believe that it is easiest to learn to feel the thyroid when facing the patient; the thyroid is palpated with finger pressure toward the trachea as the patient swallows. If a thyroid bruit is present, hyperthyroidism is almost invariably the result of Graves' disease. If the thyroid remains large when hypothyroidism occurs after radioactive iodine treatment of Graves' disease, the hypothyroidism is likely to be transient ("thyroid stunning"). Careful palpation will distinguish the tender thyroid of painful subacute thyroiditis from general neck tenderness or a painful nodule. Although it is often missed on ultrasound, tracheal deviation is an important physical finding of an asymmetric, possibly substernal thyroid mass.

There are several other points to consider during the physical examination:

- The presence of clitoromegaly directs the differential diagnosis of hirsutism toward more aggressive pathologies (hyperthecosis or androgen-secreting tumor).
- Don't forget to examine the testes, because they may provide the only clue to the diagnosis of Klinefelter's syndrome.
- Anosmia (e.g., inability to smell coffee) may help explain the cause of central hypogonadism (Kallmann's syndrome).
- Feel carefully for an abdominal mass, which will allow you to diagnose an adrenocortical carcinoma (ACC) in a patient with Cushing's syndrome.
- Fawn-like wrinkling around the eyes, failure of the hairline to recede, and a chubby habitus provide almost instant recognition of untreated adult male panhypopituitarism.
- The presence of torus palatinus may be a marker for increased bone density caused by activating mutations of low-density lipoprotein receptor-related protein 5 (LRP5), although this finding is not specific.
- Sudden diastolic hypertension may be caused by hypothyroidism, particularly if it occurs acutely after radioactive iodine therapy. Postural hypotension in a hypertensive patient may be found in patients with pheochromocytomas or primary aldosteronism with hypokalemia. Severe postural hypotension, often resulting from autonomic insufficiency, is an important cause of fatigue in the elderly.
- Filling in of the supraclavicular fat pads may be an early sign of Cushing's syndrome.

Laboratory Testing

Endocrinologists are known among their medical colleagues as physicians who order blood and urine tests. Indeed, one of Dr. Fuller Albright's guiding principles was to "measure something." But it is always important to know what you are measuring, why you are measuring it, and what the advantages and pitfalls of the assay are. Testing for the sake of testing is both foolish and expensive.

Be aware that assays can be misleading. In the 1970s, many malignancies were thought to secrete PTH because the assays used at the time were not specific. We now know that many malignancies produce PTHrP, but very few produce PTH. Although almost all patients with pheochromocytomas have elevated urine metanephrines and/or fractionated catecholamines, minimal elevations above normal limits have little specificity for pheochromocytoma. Learn the cutoffs that provide greater specificity. The 24-hour urine free cortisol level is often falsely elevated at high urine volumes (>4 L/day). Serum gastrin and chromogranin A are usually markedly elevated in patients taking proton pump inhibitors.

Take time to learn about the assays that you use. When serum thyroxine (T_4) was the major thyroid test, we had to learn the causes of falsely high and low T_4 concentrations. More recently, we have learned that most modern free T_4 assays give surprisingly low readings during pregnancy, whereas dialyzable free T_4 is normal or high at that time. A total T_4 measurement may be helpful in this situation.

Even though TSH is a near-perfect thyroid function test in outpatients, the clinician must still have a clear understanding of its physiology and potential pitfalls. A normal serum TSH concentration essentially excludes hyperthyroidism and hypothyroidism if the hypothalamus and pituitary are normal. Use of algorithms that measure only TSH if it is normal but add free T_4 if the TSH is high or triiodothyronine (T_3) and free T_4 if the TSH is low reduces the need for further testing and is more efficient and cost-effective than ordering everything at once or reordering after an isolated abnormal TSH measurement. We also use an algorithm for patients taking levothyroxine that adds free T_4 only if the TSH is less than 0.05 IU/L, because we have determined that information from the free T_4 measurement is useful only when a low TSH is in this range. Almost all patients with a normal TSH and a slightly low free T_4 are euthyroid. The low free T_4 level is likely to be a laboratory aberration (and probably should not have been measured in the first place). Although free T_3 measurements have become popular in diagnosing hyperthyroidism, I find that total T_3 concentrations are sufficient.

Many primary care physicians and some endocrinologists do not understand the exponential relationship between thyroid hormone and TSH and therefore cannot explain it to their patients. A 50% decrease in free T_4 causes a 90-fold increase in TSH. Hence, a doubling of TSH from 5 to 10 mIU/L represents at most a decrease of a few percentage points in thyroid hormone concentration and not a 50% decrease. Once patients understand this simple relationship, their concerns about "wild swings" in their hormones can be allayed.

It should be noted that TSH is less useful and can actually be misleading in patients with pituitary or hypothalamic disease and in acutely ill hospitalized patients. We must always interpret the results in the context of the patient's clinical state. A low TSH (and a low free T_4) may signify central hypothyroidism. A slightly high TSH (with

a very low free T_4) occurs in hypothalamic hypothyroidism in which the TSH is biologically inactive. Hyperthyroidism may occur with an elevated TSH (and a high free T_4) if it is caused by a pituitary tumor, but a pituitary tumor also can cause hyperthyroidism with a normal TSH (due to heightened TSH bioactivity). It takes great clinical acumen to suspect hyperthyroidism and order additional thyroid function tests when the TSH is normal. Severe illness ("sick euthyroid") may inhibit TSH release, causing a low serum TSH and, over time, a low serum free T_4 .

TSH measurements can be misleading even with an intact hypothalamic-pituitary-thyroid axis in a healthy individual. I recently saw an elderly woman who had become progressively more hyperthyroid because her elevated TSH could not be brought down to normal with supraphysiologic doses of thyroid hormone prescribed by her personal physician. After a brain MRI to exclude a TSH-secreting pituitary tumor, she was sent for consultation to exclude thyroid hormone resistance despite being clinically hyperthyroid. We eventually discovered that she produced heterophilic antibodies that interfered with the TSH assay, resulting in falsely high TSH readings with some TSH assays. TSH measurements in a different laboratory confirmed an undetectable serum TSH until thyroid hormone was stopped and the TSH returned to normal.

Heterophilic antibodies can interfere with other assays as well. Similar to the example just described, a very high prolactin concentration in a woman with regular menses might suggest macroprolactinemia, a false elevation of the serum prolactin level caused by hormone-binding gamma globulins.

Some valuable insights may be gleaned from basic laboratory tests:

- If the TSH remains low and stable over many years (e.g., 0.2 IU/L), nodular disease (toxic nodular goiter) is the likely cause. The mild hyperthyroidism of Graves' disease often waxes and wanes over time.
- Stable hypercalcemia that dates back years is very likely to be caused by hyperparathyroidism.
- If the serum calcium concentration is consistently at the upper range of "normal," it is likely to be abnormal. Although many laboratories consider serum calcium levels lower than 10.5 mg/dL to be normal, most individuals with consistent calcium measurements in the range of 10.2 to 10.5 mg/dL will prove to have an abnormality of calcium metabolism, usually primary hyperparathyroidism.
- The puzzling rise and fall of serum calcium and PTH in patients with primary hyperparathyroidism is caused by the negative feedback of calcium on the abnormal parathyroid glands: the higher the serum calcium, the lower the PTH concentration. When hyperparathyroid patients take additional calcium, the calcium may rise and the PTH may fall. If calcium intake is decreased or vitamin D deficiency is present, the serum calcium concentration is often lower (or even normal), and the PTH is higher.
- A low serum phosphate level may be a clue to osteomalacia, vitamin D deficiency, hyperparathyroidism, or muscle weakness (phosphate depletion syndrome). However, a low serum phosphate concentration after a meal or during intravenous glucose administration is related to intracellular shifts in phosphate and does not require diagnostic evaluation. After thyroid or parathyroid surgery, a high-normal or elevated serum phosphate concentration suggests hypoparathyroidism. An elevated serum phosphate level may be also found in acromegaly.

- I always check the serum albumin level whenever I check the serum calcium, and I then correct for the albumin concentration. Hemoconcentration (related to use of the tourniquet during phlebotomy) may cause an elevated serum calcium due to an elevated serum albumin level. Hemodilution, often resulting from the administration of intravenous fluids, lowers the serum calcium and albumin concentrations.
- Male hypogonadism is associated with a fall in the hematocrit to the normal female range. Men with appropriate signs and symptoms and a hematocrit in the range of 35% to 40% should be evaluated for hypogonadism.
- An elevated alkaline phosphatase concentration is common in patients with untreated Graves' disease. With treatment, the alkaline phosphatase level usually rises further (as bone heals) and may remain above normal for up to 1 year after the patient is euthyroid.
- A white blood cell count with 1% or 2% eosinophils almost always excludes overt Cushing's syndrome.
- A low neutrophil count may be present in severe Graves' disease before therapy (because of immune destruction of granulocytes by antibodies targeting granulocyte TSH receptors).⁷ This is not a contraindication to anti-thyroid drug therapy.
- Hyponatremia without hyperkalemia may be a consequence of glucocorticoid deficiency from central causes.

Learn the appropriate timing for tests and how to interpret their results:

- A low morning cortisol level (<3 μ g/dL) suggests adrenal insufficiency, and a low midnight salivary cortisol concentration tends to exclude Cushing's syndrome. A high morning cortisol level (>18 μ g/dL) usually excludes adrenal insufficiency.
- Serum prolactin may rise after a meal and therefore should be measured in the fasting state to determine whether minor elevations are abnormal or related to food.
- Although the release of testosterone is pulsatile, testosterone has a diurnal variation, with concentrations being higher in the morning and lower in the evening. As it has been said, only half-jokingly: "If you want to study normal (eugonadal) men, draw a testosterone level in the a.m. If you want to study hypogonadal men, draw a testosterone level in the afternoon." Many patients have been unnecessarily treated with testosterone based on a single afternoon testosterone concentration below the normal range. Be aware that many so-called free testosterone assays report low values even in eugonadal men.
- Once suppressed, the serum TSH may remain undetectable for months, even after the patient is euthyroid. Similarly, the hypothalamic-pituitary-adrenal axis may remain suppressed for 1 year or longer after successful treatment of Cushing's syndrome or weaning from glucocorticoid excess.

Take advantage of clinical serendipity:

- The most useful time to measure serum thyroglobulin in patients with well-differentiated thyroid cancer is when the serum TSH is elevated (after injection of recombinant human TSH or withdrawal of thyroid hormone). If a patient with thyroid cancer is noted to be undertreated with a spontaneously elevated TSH, take advantage of that undertreatment by measuring serum thyroglobulin before increasing the levothyroxine dosage.

- When spontaneous hypoglycemia is reported, try to retrieve the blood sample for an insulin measurement.
- A fully suppressed serum TSH in a patient taking modest doses of levothyroxine suggests thyroid autonomy; a thyroid scan performed when the TSH is low can confirm this suspicion. Note that it is better to perform a “suppression scan” in a patient with a thyroid nodule while the patient is taking thyroid hormone than to stop thyroid hormone before the scan.

Think physiologically:

- A mid-normal or high-normal PTH level in the face of hypercalcemia is inappropriate and hence diagnostic of primary hyperparathyroidism. Similarly, a low PTH level with hypercalcemia excludes hyperparathyroidism. An astute clinical investigator evaluated a critically ill patient with severe hypercalcemia, a low PTH, and a markedly elevated 25-hydroxyvitamin D concentration. Using physiologic reasoning, he concluded that exogenous vitamin D had to be the cause and eventually tracked the source to a miscalculation of the dose of vitamin D added to milk at a specific dairy.⁸
- A “normal” level of follicle-stimulating hormone (FSH) in a postmenopausal woman is inappropriately low and probably indicates a pituitary or hypothalamic problem. Conversely, an elevated postmenopausal FSH is strong (but not conclusive) evidence in favor of normal pituitary function, because loss of gonadotropin function is often an early sign of pituitary failure. Remember that starvation or acute illness can temporarily suppress the serum FSH even when the axis is intact.
- Low levels of plasma cortisol and ACTH in a patient with clinical Cushing’s syndrome suggest the use of a potent glucocorticoid (e.g., dexamethasone) that is not measured in the cortisol assay. An alternative explanation is recent administration and withdrawal of supraphysiologic glucocorticoid.

The ability to use the appropriate minimum number of laboratory tests is a hallmark of a thoughtful clinical endocrinologist. Efficient use of tests to *exclude* endocrine diagnoses is particularly important. A normal serum TSH excludes most cases of hyperthyroidism or hypothyroidism. A normal plasma concentration of metanephrines excludes most cases of pheochromocytoma. A normal midnight salivary cortisol or low-dose overnight dexamethasone suppression test effectively excludes most instances of Cushing’s syndrome. A normal aldosterone-to-renin ratio effectively excludes primary hyperaldosteronism.

An elevated morning urine osmolality argues against diabetes insipidus. A low GH level after glucose administration or a normal basal IGF1 level effectively excludes acromegaly.

Unfortunately, there is a tendency among some endocrinologists to “check off all the boxes” when ordering tests. Remember, Dr. Albright said to “measure something” not to “measure everything.” I see many patients in consultation who have undergone every possible thyroid or adrenal test, sometimes multiple times, even though most of these tests were not needed to make the diagnosis. Take the time to think carefully before ordering laboratory tests and to evaluate the diagnostic value and expense of each test.

- At our institution, the charge for a corticotropin-releasing hormone stimulation test (with eight ACTH measurements) is approximately \$3500. A clinician

should make sure that expensive tests like this one are absolutely necessary before ordering them.

- It is extremely important to measure thyrotropin receptor antibodies (TRAb) in pregnant patients previously treated with radioactive iodine or surgery for Graves’ disease. High-titer TRAb may predict fetal or neonatal Graves’ disease. Institution of appropriate therapy in a timely fashion can be life-saving or life-altering for the newborn. Although many endocrinologists routinely (and often unnecessarily) measure TRAb serially in nonpregnant patients with known Graves’ disease, they often neglect to measure these antibodies in pregnant women previously “cured” of Graves’ disease.
- Although it is relatively inexpensive, a 24-hour urine test for 5-hydroxyindoleacetic acid (5-HIAA) rarely has a true-positive result and is often ordered unnecessarily; most true-positive findings are in patients in whom the diagnosis of carcinoid syndrome can be made clinically.
- Sometimes common sense is superior to standard testing algorithms. If you suspect primary adrenal insufficiency in a hyperpigmented patient, measure the serum cortisol and plasma ACTH. A high ACTH with a low cortisol level is diagnostic of primary adrenal insufficiency. Guidelines are a guide, not gospel.

The role and benefit of screening tests is problematic. Bear in mind that although some screening tests are generally accepted, the value of others remains controversial.

Screening for gestational diabetes is recommended based on data suggesting improved outcomes, but even here the benefits are debated. The value of TSH screening in pregnant women or in the general population is hotly debated. Many European and some North American endocrinologists recommend measurement of serum calcitonin in all patients with thyroid nodules, despite the fact that the relative value of this determination is unknown in terms of benefit (discovery of small medullary thyroid carcinomas) and harm (unnecessary surgery for false-positive calcitonin results or possibly innocent medullary microcarcinomas). In general, the presence of strong feelings on both sides usually indicates that the data suggesting benefit are weak or absent. Although each clinician will decide whether to screen for specific diseases in his or her own practice, major public health decisions about screening need to be supported by compelling data.

Radiology and Interventional Radiology

I was taught to make an endocrine diagnosis before recommending imaging, and adhering to this sequence seems the best way to avoid ordering needless and costly radiologic scans. Imaging of the pituitary in a patient with tests diagnostic of adrenal Cushing’s syndrome is unnecessary. Patients who clearly do not have a pheochromocytoma do not need CT scans, MRIs, or ¹³¹I-*meta*-iodobenzylguanidine (MIBG) nuclear scans. On the other hand, patients referred for incidentalomas do require hormonal evaluation.

Almost all adrenal nodules are benign. Major radiologic advances with CT and MRI imaging have allowed us to characterize most of these tumors as benign adenomas. Patients with benign adrenal tumors generally require endocrine evaluation for Cushing’s syndrome, subclinical Cushing’s syndrome, or pheochromocytoma. If the patient is hypertensive, primary aldosteronism should be excluded. Some of these patients with benign adrenal tumors are appropriately referred to surgeons based solely on tumor size.

There is still uncertainty about the adrenal lesions that are characterized radiologically as “not simple adenomas.” Most of these lesions turn out to be benign, but all of them require careful follow-up, and some may require surgery. There is an unfortunate misconception among many endocrinologists that needle biopsy can distinguish a benign from a malignant adrenal cortical tumor. In fact, a needle biopsy can diagnose metastasis to the adrenals but only rarely distinguishes adrenocortical adenoma from ACCs. Use of a needle biopsy to diagnose ACC is therefore worthless, not to mention potentially harmful. Most adrenal cancers are large and readily diagnosed by CT or MRI.

Given the clinical epidemic of thyroid nodules, many clinical endocrinologists use ultrasonography to interpret and biopsy thyroid nodules that are incidentally discovered during radiologic imaging for other conditions. Ultrasound can provide guidance about which thyroid nodules need to be biopsied. If multiple nodules are present, newer ultrasound algorithms should be used to help determine which nodules are suspicious, thereby avoiding the need to biopsy all the nodules.

At the same time, keep in mind that simply because an ultrasound machine and a biopsy needle are available does not mean that they have to be used. Always consider the value of the diagnostic information that a biopsy could provide, particularly with ever-smaller thyroid nodules. For example, think about whether there really is an advantage to diagnosing a 5-mm papillary thyroid carcinoma. Likewise, common sense and judgment should lead to treating many nodules more conservatively in the aged. Whereas larger nodules in older patients may be aggressive malignancies, it is reasonable to tell octogenarians who present with five or six thyroid nodules of modest size that even if the risk of malignancy is about 10%, the risk of death from such malignancies is quite remote. These older patients can then decide for themselves whether to undergo one or more biopsies. Choosing not to have a biopsy seems particularly appropriate in this age group, especially when other potentially life-threatening illnesses are present.

When consulted for a case of large multinodular thyroids, most endocrinologists check thyroid function and biopsy all concerning nodules. But in focusing on the individual nodules, they sometimes “miss the forest for the trees” and overlook the fact that the goiter is compressing the trachea or the esophagus. An important part of evaluating large goiters is CT imaging (without contrast) or MRI to exclude compression of local structures.

Until recently, it was standard practice to obtain imaging studies of patients with primary hyperparathyroidism only if they were going to have surgery. But now clinicians sometimes image patients with “asymptomatic” primary hyperparathyroidism to help both the patient and the clinician decide whether surgery may be preferable to observation. For example, the ability to localize an abnormal parathyroid gland by ultrasound and/or sestamibi scanning might lead a clinician to recommend minimally invasive surgery for indications (e.g., unexplained fatigue) that do not meet the guideline criteria or to prevent bone loss in the future. Likewise, some patients will elect surgery rather than observation if they know that a minimally invasive procedure is feasible. But remember that parathyroid imaging should never be performed to establish the diagnosis of primary hyperparathyroidism; that task is solely in the domain of the testing laboratory.

Endocrinologists need to be both mindful of physiology when interpreting radiographic images and judicious in their use of radiology. Some examples may be helpful.

- Pituitary macroadenomas with minimal prolactin elevation should be treated as nonfunctioning tumors rather than prolactinomas. Dopamine agonists are usually ineffective in patients with large tumors and minimal prolactin elevations. The minimal prolactin elevation in pituitary macroadenomas is usually caused by either disinhibition of prolactin production or a tumor that produces prolactin but inefficiently.
- A sellar mass in a patient with diabetes insipidus is unlikely to be a simple pituitary adenoma; it is more likely to be a craniopharyngioma or the result of infiltrative disease.
- Diffuse enlargement of the pituitary after pregnancy is most likely caused by lymphocytic hypophysitis.
- Primary hypothyroidism can cause diffuse reversible pituitary enlargement and mild hyperprolactinemia. Serum TSH should therefore be measured in cases of diffuse pituitary enlargement and as part of an evaluation for hyperprolactinemia.
- A 24-hour radioactive iodine uptake of 5% (normal, 10% to 30%) in the face of an undetectable TSH is characteristic of thyroid autonomy rather than destructive thyroiditis (in which the uptake must be nil). A reason should be sought for low radioiodine uptake (e.g., recent iodine exposure).
- Given the growing concern about possible side effects of radiation from CT imaging, careful thought should be given to the use of repeat CT imaging (e.g., for adrenal nodules).

In certain cases, invasive radiologic procedures are necessary before surgery to localize the specific tumor causing the endocrine hyperfunction. Because incidentalomas are common, a pituitary adenoma seen on MRI in a patient with pituitary Cushing's syndrome or an adrenal nodule seen on CT scanning in a patient with primary aldosteronism cannot be assumed to be the site of hormone overproduction. Even in the presence of MRI- or CT-documented pituitary or adrenal adenomas, pituitary corticotroph adenomas often require localization with bilateral inferior petrosal sinus catheterization; aldosteronomas often require localization or exclusion with bilateral adrenal vein catheterization; and some insulinomas require intra-arterial calcium infusion with venous catheterization. All of these invasive radiologic procedures should be performed at specialized centers with extensive experience and well-established expertise.

Genetic Testing and Family Screening

Endocrinologists are increasingly called upon to discuss genetic testing with their patients. Although it may seem like a straightforward matter of checking a box or ordering a blood test, the clinician should keep in mind that genetic testing has the potential to create profound psychological and practical challenges for patients and their families. We therefore recommend genetic counseling before testing, so that patients are prepared for the various problems they may subsequently encounter. For example, before genetic testing that might possibly identify a family member as a gene carrier for a serious condition, a genetic counselor may recommend the purchase of life insurance, because insurance could be extremely difficult to purchase if the patient is found to have the abnormal gene.

Practical application of clinical tumor genetics began before the advent of gene testing with studies of familial medullary thyroid carcinoma (MEN2). The recognition of this dominantly inherited malignancy led to information about the natural history of the disease, rules for family

screening, stimulation tests (pentagastrin and calcium) to diagnose early disease, prophylactic surgery at the first sign of abnormality, and clinical observations that allowed one to predict the risk of developing the disease over time even if the screening test remained normal. The recognition of mutations in the *RET* proto-oncogene made it possible to predict the risk of inheriting MEN2 with greater precision and nuance, and genetic testing replaced endocrine testing as the standard of care for diagnosis of asymptomatic carriers of MEN2. For the first time, individuals in families with known mutations could be excluded as carriers of the disease if their *RET* test was normal. Conversely, carriers of the abnormal gene could be discovered at an early age. As genotype-phenotype correlations improved, recommendations about the appropriate time for testing and prophylactic surgery were modified.

When caring for patients with pheochromocytomas, it is important to realize that a significant minority of these tumors (up to 25%) have a germline mutation that is responsible for the tumor. In fact, the first patient ever diagnosed with pheochromocytoma recently had her pedigree traced to an MEN2 kindred.⁹ Although these tumors may be familial, if the patient presents with a de novo mutation, the family history will not be revealing. When a patient with a pheochromocytoma is young, has bilateral disease, or has an extra-adrenal tumor, genetic testing should be strongly considered. Such genetic testing should look for mutations in the von Hippel-Lindau tumor suppressor gene (*VHL*), the gene encoding succinate dehydrogenase complex subunit B (*SDHB*) and also *SDHD* and *SDHC* (newly recognized abnormalities), *RET*, and, less commonly, neurofibromin 1 (*NF1*). Mutations in *SDHB* may predict malignant behavior.

Genetic testing may also be helpful in other circumstances:

- Patients with the cribriform morular variant of papillary thyroid carcinoma often harbor the familial adenomatous polyposis gene (*FAP*). Discovery of this gene may prevent death from colonic cancer when it leads to performance of screening colonoscopies.
- Patients with Cowden's syndrome may have follicular thyroid carcinoma as well as breast cancer. We consider screening younger patients with follicular thyroid carcinoma for Cowden's syndrome, particularly those who have a family history of breast cancer.
- Parathyroid carcinoma is a rare disease that may have a genetic predisposition, particularly when it is associated with jaw tumors and abnormalities of the other parathyroid glands. But a surprisingly high number of patients with apparently sporadic parathyroid cancer harbor familial mutations in *CDC73*, the cell division cycle 73 (parafibromin) gene (formerly called hyperparathyroidism-jaw tumor syndrome 2, or *HRPT2*)—an observation that suggests that genetic testing may be considered for all such patients.
- When patients with hyperparathyroidism are found to have four-gland hyperplasia, we often suggest that other family members be screened for hyperparathyroidism.
- We recommend family screening for individuals with FHH to help family members avoid unnecessary surgery.
- Patients with Zollinger-Ellison syndrome and young patients with hyperparathyroidism or islet cell tumors should be evaluated for possible MEN1. This is also true for patients who have evidence for two possible MEN1 tumors. A careful family history is paramount.

Although gene testing is available for MEN1, mutations may be missed. Even if a mutation is present, careful screening is preferable to prophylactic surgery. With or without genetic testing, both family screening and continued surveillance are important.

Therapeutics

Do all endocrine abnormalities require therapy? According to Sir William Osler, "A desire to take medicine is, perhaps, the great feature which distinguishes man from other animals."¹⁰ To paraphrase Osler, one could say that what distinguishes endocrinologists from other physicians is their desire to replace missing hormones and to take away excess hormones. But as we shall see, logic, a desire to help, and abnormal laboratory tests do not necessarily lead to appropriate therapy.

For many years, estrogen replacement therapy for postmenopausal women seemed to be both therapeutically logical and beneficial: it reduced hot flashes, increased the sense of well-being, and provided a cardiovascular benefit as demonstrated in cross-sectional epidemiologic studies. But appropriately controlled trials not only failed to confirm the cardiovascular benefit but demonstrated that this therapy could actually harm the patient. Additional studies are changing our ideas about postmenopausal hormone replacement therapy still further.

Subclinical hypothyroidism (elevated TSH with a normal free T_4) occurs in up to 20% of the elderly population. It is easily corrected with levothyroxine therapy leading to TSH normalization. But cross-sectional studies of the very elderly (85 years and older) suggest a survival advantage for untreated individuals with subclinical hypothyroidism.¹¹ Furthermore, a significant minority of patients with subclinical hypothyroidism who are treated with levothyroxine develop subclinical hyperthyroidism, with its potential but unquantified consequences.

Although subclinical hypothyroidism has been implicated in adverse pregnancy outcomes, there are still no controlled trials demonstrating improved outcomes with levothyroxine therapy. Despite this lack of evidence, many excellent endocrinologists demand screening for subclinical hypothyroidism, particularly for women contemplating pregnancy. My own feeling is that screening and therapy for subclinical hypothyroidism (or other mild endocrine disorders) may be reasonable for individual patients, but a recommendation that it become national policy is unwarranted in the absence of appropriate therapeutic trials.

The increasing recognition of subclinical Cushing's syndrome is a consequence of the radiologic detection of adrenal incidentalomas. A diagnosis of subclinical Cushing's syndrome in a patient with an adrenal adenoma is most commonly based on the failure to suppress cortisol after overnight administration of dexamethasone, but the actual criteria for diagnosis vary considerably. There is no consensus about which dose of dexamethasone to use, which dexamethasone-suppressed cortisol value is diagnostic, or, more importantly, when surgical removal of the adrenal is advisable. Some patients clearly benefit from surgery, but the vexing issue for the clinician is that there are no definitive guidelines for recommending surgery.

Endocrine Hormone Replacement Therapy

Endocrine replacement therapy has long been considered to be near-perfect therapy. The dramatic response of the patient with myxedema to sautéed sheep thyroid in the 19th century, the life-saving efficacy of insulin for diabetic

ketoacidosis, the use of cortisol for Addison's disease, and HRT for menopausal symptoms are some of the best examples.

But not all endocrine replacement therapy is perfect or even nearly perfect. Indeed, many patients treated with various hormone replacements have decreased quality of life or shortened life expectancy compared with appropriate controls.

- Finger-stick glucose testing, hemoglobin A_{1c} measurements, and a recognition that control of blood sugar is critical have all helped revolutionize diabetes care. Equally important has been the development of "designer" short- and long-acting insulins. But the fact remains that current therapies for type 1 and type 2 diabetes still do not mimic endogenous glucose control. Although excellent glucose control has reduced microvascular complications significantly, only near-perfect glucose control early in the disease appears to prevent macrovascular complications. More rigorous control shows a lack of benefit or even potential harm late in the course of type 2 diabetes or after cardiovascular disease has developed.¹² Hypoglycemia also continues to be a significant problem associated with insulin therapy. Looking ahead, if type 1 diabetes mellitus cannot be prevented, safer and readily available islet cell transplants may be the answer after the immunologic rejection problems are solved. For type 1 and type 2 diabetes mellitus, use of closed-loop glucose monitoring and insulin delivery systems early in the disease, if perfected, may provide near-perfect glucose control. Drugs designed to enhance islet cell regeneration may also turn out to be beneficial.
- Epidemiologic studies suggest that hypothyroid patients receiving replacement therapy do not feel as well as matched controls. Many explanations have been offered. Undertreatment is one possibility, yet the difference remains even when serum TSH is normalized. Whether the lack of well-being reflects inadequate therapy or underlying unrelated symptoms is still unclear. The combination of liothyronine plus levothyroxine was initially hailed as a panacea for symptomatic, treated hypothyroid patients, but it was then rejected. Recent preliminary studies have suggested that only certain individuals (e.g., those with specific type 2 deiodinase polymorphisms) respond favorably to this combination therapy.¹³ This possibility raises the general question of pharmacogenetics, wherein patients have variable responses to treatment and require individualized therapies.
- Therapy for Addison's disease is certainly life-saving, but many studies have documented a less favorable quality of life and a possibly decreased life expectancy among treated individuals. It is still difficult to mimic the early-morning cortisol rise with our current therapeutics, but perhaps the newer, slow-release cortisol preparations given at midnight will prove effective. Most adrenal experts favor therapy with hydrocortisone, but I have found that many patients feel better with intermediate-acting glucocorticoids such as prednisone.
- Unfortunately, there is no simple way to monitor glucocorticoid therapy. To prevent excess glucocorticoid administration, we use relatively crude indices such as blood pressure and presence or absence of pigmentation, normal electrolyte levels, and clinical signs of Cushing's syndrome. Multiple daily measurements of cortisol in patients receiving hydrocortisone are used by some investigators but are quite cumbersome.

- The ability to measure bone density easily and reliably ushered in the modern era of diagnosis and treatment of osteoporosis. We continue to debate the appropriate duration and use of therapeutic agents for this condition, particularly when it is apparently mild. The bisphosphonates and other antiresorptives provide an excellent initial therapy for many patients but are far from being a panacea. PTH is anabolic for bone but has minimal effect on cortical bone mass. We await the development of newer safe agents with potent anabolic properties, particularly for cortical bone.
- Currently available therapy for hypoparathyroidism in children often results in hypercalcemia or hypocalcemia. The inconvenience of administering the possibly more effective parenteral PTH will have to be weighed against the benefits, risks, and ease of current oral therapy with calcium and calcitriol.
- Treatment of the adrenogenital syndrome in children must navigate between the Scylla and Charybdis of adrenal insufficiency and glucocorticoid excess. It is debatable whether endoscopic adrenalectomy plus adrenal replacement therapy is a preferable approach.
- Topical testosterone gels provide serum testosterone concentrations that closely mimic mean endogenous testosterone levels. A goal for the future is to find a simple oral treatment that can mimic this pattern. There are no approved testosterone therapies for sexual dysfunction in women, largely because the efficacy of such therapies continues to be debated.
- The use of GH purified from human pituitaries was abandoned after it was associated with the development of Creutzfeldt-Jakob disease. Recombinant human GH has since become the treatment of choice. Guidelines have been established for the diagnosis and treatment of GH deficiency caused by hypothalamic or pituitary disease in children and in adults. But GH deficiency in adults without structural pituitary or hypothalamic disease poses a challenge for clinicians in that they must weigh the uncertain long-term risks and benefits of GH therapy against the high cost of the drug.

Practical Considerations

Several simple points I have learned over the years can make endocrine replacement therapy significantly easier for the patient:

- Levothyroxine has a 7-day half-life. Patients who miss a pill on one day should be instructed to take two on the next. Up to seven pills once weekly may be prescribed. This flexibility often improves overall compliance with levothyroxine therapy. Be aware that some pharmacy handouts incorrectly inform patients not to make up missed doses. The same logic suggests that occasional missed bisphosphonate doses can be made up with mid-week doses (for drugs administered weekly).
- Do not prescribe two different levothyroxine dosages for the same patient. For example, instead of prescribing 0.2 + 0.025 mg of levothyroxine, prescribe two 0.112-mg pills. Prescribing two different doses confuses the patient and also is more expensive because it requires two separate copayments for patients with insurance coverage.
- To decrease or increase the dosage of levothyroxine by 15%, patients may, respectively, skip their medicine on one day per week or add one extra pill per week (e.g., on Sundays). When you are changing to a

new dosage, old prescriptions rarely need to be discarded.

- Given the many interactions between levothyroxine and foods, vitamins, and supplements, patients should be given the option of taking their levothyroxine at night before bedtime. This will not interfere with sleep and may even provide smoother TSH control.
- The treatment of chronic hypoparathyroidism includes calcium and calcitriol. I prefer to limit the dose of calcium to 500 to 600 mg three or four times daily. I adjust the calcitriol up or down to keep calcium within normal limits and avoid hypercalciuria. Some clinicians add hydrochlorothiazide to prevent hypercalciuria. Chlorthalidone is also effective. Hypokalemia caused by chlorthalidone is a common problem, perhaps because of its long duration of action.
- Acute hypoparathyroidism may require higher initial calcium therapy. Calcium should be administered with meals to lower the high phosphate, which often prolongs the hypocalcemia. It is also advisable to avoid dairy products because of their high phosphate content.
- Patients with Addison's disease have certain special needs: they should always wear a necklace or bracelet informing others about their condition (e.g., Medical Alert); they need to be aware that their glucocorticoid dosage will have to be increased in times of stress or illness; and they or their family members should learn how to administer parenteral hydrocortisone sodium succinate in case of an emergency. Those patients who are taking daily hydrocortisone should consider keeping a supply of prednisone to use for extra doses when sick; this is particularly true for older patients, because they are more likely to be intolerant of fluid retention caused by excess hydrocortisone.

In-Patient Therapeutics

Endocrine therapies in hospitalized patients require special attention.

- After years in which a rather casual approach was taken to glucose control in the hospital, controlled trials in intensive care units (ICUs) showed that intensive glucose control increased survival in some ICUs. However, these conclusions have recently been challenged.
- Nurses often become anxious when a non-ICU patient has an extremely high glucose concentration. However, they are quickly reassured once they learn that the situation can easily be brought under control with an intravenous insulin infusion that decreases the glucose by 80 to 100 mg/dL per hour.
- The parathyroid glands may be damaged or removed, either inadvertently during thyroid or parathyroid surgery or intentionally during en bloc surgery for invasive head and neck cancers. The resulting acute hypocalcemia is often difficult to treat properly. Oral calcitriol takes time to work and cannot be administered to patients who are NPO. A simple temporary regimen to maintain normal serum calcium levels in this setting is the constant infusion of calcium. Four or five ampules of calcium gluconate (400 to 500 mg of elemental calcium) in 1000 mL of fluid is infused at a rate of 40 mL/hour. This regimen avoids the frequent peaks and troughs of bolus calcium administration.
- Endocrinologists are often asked to consult on cases of hyponatremia. Appropriate clinical assessment of salt and water balance in these patients is the key to

appropriate diagnosis and therapy. Parenteral antidiuretic hormone (ADH) antagonists for the treatment of euvolemic hyponatremia are now available, but it remains unclear how and when these agents should be used.

- Critically ill patients often develop abnormalities of thyroid function, including low T_3 , low T_4 and free T_4 , and low TSH. These thyroid changes suggest central hypothyroidism. Because it is unclear whether these changes are adaptive or harmful, it is also unclear whether replacement therapy is appropriate for these patients. In the "euthyroid sick" syndrome, the serum TSH is rarely undetectable unless glucocorticoids or dopamine is administered.
- There are new guidelines for treatment of corticosteroid insufficiency in acutely ill patients, based on responses to the ACTH stimulation test. Although these tests may define a population with glucocorticoid-responsive disease, it is difficult for me to categorize patients with very high serum free cortisol concentrations as adrenally insufficient.¹⁴ Whether they have a form of glucocorticoid resistance or another glucocorticoid-responsive illness is unknown.
- Elderly patients with severe hypercalcemia or hyponatremia may be slow to recover their mental function. Do not be discouraged if the mental state remains abnormal for 2 to 7 days after the metabolic abnormality has been corrected.

Treatment of Hormone Excess

As clinicians trained in internal medicine, endocrinologists would like to be able to treat all hormonal overproduction, including tumor-related hormone excess, with medication rather than surgery. The ideal therapy would be a medication given for a limited period that permanently eliminates the tumor as well as the hormone excess. Although medical therapy rarely approaches this ideal, it is often successful in controlling hormone excess.

Graves' hyperthyroidism is the most common condition of hormone excess treated by endocrinologists. Several important clinical points are worthy of consideration.

In the 1930s and 1940s, surgery for Graves' hyperthyroidism was extremely dangerous, and there was no safe way to prepare patients for surgery. As a result, the operative and perioperative mortality rates were high. After radioactive iodine and antithyroid drugs became available in the late 1940s, they rapidly became the treatment of choice. One problem when treating hyperthyroidism is that no regimen has been able to solve the dilemma of rebound weight gain, often to above baseline.

Radioactive iodine has the advantage of treating hyperthyroidism permanently, but it also has certain disadvantages: it usually causes permanent hypothyroidism; it may cause worsening eye disease; it may cause hyperparathyroidism decades later; and, although there is no conclusive evidence, concern has been raised that the radiation may have additional harmful side effects. In selected patients, the addition of potassium iodide after radioactive iodine therapy for Graves' disease accelerates the return to euthyroidism.

Many young patients currently choose anti-thyroid drugs for the initial treatment of Graves' hyperthyroidism. After years of debate, there is now a consensus that methimazole is the anti-thyroid drug of choice, as opposed to propylthiouracil, because of its higher potency, longer duration of action, and lower toxicity. Propylthiouracil is preferred in cases of thyroid storm because of its ability to

inhibit the conversion of T_4 to T_3 . It is also preferred in early pregnancy and when the patient has a minor allergy to methimazole. Patients must always be informed of the low but significant risk of fatal hepatic necrosis whenever propylthiouracil is prescribed. The 1 in 200 to 1 in 500 risk of agranulocytosis may be somewhat less with lower doses of methimazole.

Hyperthyroid patients who decline both surgery and radioactive iodine therapy are usually given a therapeutic dose of methimazole, which is often tapered over time. There are several other beneficial regimens for treating hyperthyroid patients with methimazole, which endocrinologists should also consider:

- Some patients treated with anti-thyroid drugs develop extremely unpleasant yo-yo swings in thyroid function. They remain hyperthyroid on too little medication, become hypothyroid on too much, and cycle between these two extremes. A block-replace regimen employing a full therapeutic dose of methimazole and the addition of levothyroxine allows stable thyroid function. This approach may also be useful for students going away to school and for patients far removed from laboratories where blood tests can be monitored.
- There are some patients who have repeated relapses after discontinuing anti-thyroid drugs but who continue to decline surgery or radioactive iodine. For many of these patients, therapy with small doses of methimazole (e.g., 5 mg daily) provides long-term stability. Although patients are often told that anti-thyroid drugs can be used for only a limited period, that notion is incorrect, provided that the patient has no long-term toxicity.

Radioactive iodine therapy for a so-called hot nodule (an autonomously producing adenoma) approaches ideal therapy. A single dose of sodium iodide I 131 usually cures the hyperthyroidism. Most patients become euthyroid, and some become hypothyroid. The nodule may persist. It should be noted that some questions have been raised about the potential long-term effects of radiation from radioactive iodine on the remaining normal thyroid gland.

Dopamine agonists are now the therapy of choice for most prolactinomas. In a minority of patients, the tumor disappears and does not recur after the drugs have been withdrawn. The long-acting dopamine agonists (e.g., cabergoline) are easier to administer and have fewer acute side effects than their predecessors. However, some concerns have arisen about cardiac valvular problems with these newer medications.

Primary medical therapy for somatotroph adenomas has become a real possibility with the advent of somatostatin agonists and GH receptor antagonists. The efficacy of these therapies can be monitored by measuring IGF1. Many TSH-secreting pituitary adenomas are also treated successfully with somatostatin analogues. However, GH- and TSH-secreting tumors do not permanently disappear.

Surgery remains the therapy of choice when treatment is needed for primary hyperparathyroidism. Cinacalcet, an activator of the calcium-sensing receptor, is effective in lowering PTH levels in the secondary hyperparathyroidism of renal failure; it also lowers the calcium-phosphate product and is used as part of dialysis treatment. However, although this agent also lowers serum calcium and PTH in primary hyperparathyroidism, it does not improve bone density.

The medical therapy for Cushing's disease is still primitive. Although recurrent Cushing's is often treated with drugs such as ketoconazole, normalization of cortisol is

rarely achieved. Treatment of Cushing's syndrome with a glucocorticoid antagonist such as RU-486 (mifepristone) poses a challenge for endocrinologists. The therapeutic effectiveness of this drug must be monitored clinically because it does not lower serum cortisol concentrations.

Surgery, Invasive Radiologic Therapy, and the Endocrinologist

One of the most important tasks for a clinical endocrinologist is to identify and make use of excellent endocrine surgeons. The basic rule to remember about surgeons is that experience is critical. Experienced pituitary surgeons achieve better results with less morbidity than less experienced pituitary surgeons do. Even though approximately half of the thyroid operations in the United States are performed by surgeons who do fewer than 10 thyroid operations per year, experienced thyroid surgeons typically perform more complete surgeries (particularly for cancer) and with lower incidences of hypoparathyroidism and injury to the recurrent laryngeal nerves. Indeed, first-rate endocrine surgeons can remove the thyroid gland safely in Graves' disease, remove the thyroid and perform a central and lateral neck dissection in thyroid cancer, find and remove abnormal parathyroid glands in hyperparathyroidism, safely remove a pheochromocytoma or functioning adrenal adenoma endoscopically, or locate and remove a small corticotroph adenoma.

The following are several do's and don'ts with respect to endocrine surgery:

- Do discuss the various surgical options with your patients, and, when indicated, do help in the management of these cases both preoperatively and postoperatively. Don't be reluctant to let the surgeon know which operation you prefer. Do help the patient and the surgeon decide between a hemithyroidectomy and a total thyroidectomy for a patient with a thyroid nodule.
- Do pre-treat your hyperthyroid patients with antithyroid drugs before thyroidectomy. Do prescribe preoperative iodine drops (to decrease thyroid vascularity) before surgery for Graves' disease, even if the surgeon does not. Do prescribe and adjust the preoperative β -blocker when a hyperthyroid patient who is allergic to anti-thyroid drugs requires a thyroidectomy. Do take responsibility for prescribing and titrating α -blockade (and sometimes β -blockade) before surgery for pheochromocytoma, if indicated.
- Do discuss the role of adrenal-sparing endoscopic surgery with the surgeon in cases of MEN2 patients with pheochromocytomas. Do diagnose and manage secondary adrenal insufficiency after successful surgery for corticotroph adenomas or cortisol-secreting adrenal adenomas, and do monitor the hypothalamic-pituitary-adrenal axis for recovery.
- Do take responsibility for managing postoperative hypoparathyroidism, because endocrinologists usually have the most experience dealing with this condition.

The following are several situations in which I believe surgery is underutilized:

- When amiodarone causes protracted hyperthyroidism or the hyperthyroidism causes major cardiac problems, an expeditious thyroidectomy can be life-saving. We are still uncertain about whether prolonged prednisone therapy for amiodarone-induced destructive thyroiditis is safer than an expeditious operation, but surgery should always be considered as an option.

- In too many cases, unsuccessful surgery for pituitary Cushing's disease is followed by prolonged unsuccessful medical therapy (usually with ketoconazole). The unfortunate result is that patients are exposed to the deleterious effects of glucocorticoid excess for a prolonged period. Bilateral endoscopic adrenalectomy is almost always definitive therapy for hypercortisolemia and results in surgically induced Addison's disease. When hypercortisolemia from ectopic Cushing's syndrome is life-threatening and the primary tumor cannot be excised, a bilateral endoscopic adrenalectomy can dramatically improve the patient's quality of life. On the other hand, if the prognosis from the primary tumor is poor, this is not a reasonable approach.
- Many endocrinologists either do not understand or do not believe that an "indeterminate" thyroid follicular neoplasm (FNA) is actually a "suspicious" FNA with a malignancy risk of 10% to 40% (usually about 20%). If a hot nodule has been excluded by serum TSH measurement or radioiodine scanning, surgery to remove the nodule is the proper treatment.

Some tumors can be treated with interventional radiologic procedures rather than invasive surgery. These procedures include alcohol ablation; radiofrequency ablation (RFA) or laser ablation of hot thyroid nodules; alcohol or laser ablation of parathyroid adenomas; alcohol or RFA ablation of recurrent nodal disease from papillary thyroid carcinoma; arterial ablation of mediastinal parathyroid adenomas; RFA of metastases to the adrenals and, rarely, for functioning adrenal tumors; and alcohol ablation, thermoablation, RFA, or chemoembolization of hepatic metastases from endocrine tumors. Embolization of bony metastases from thyroid cancer, and of spinal metastases in particular, is often performed before surgical resection. In all situations, the potential morbidity of these procedures and the local expertise must be weighed against the morbidity of surgery. For example, in some patients alcohol ablation of parathyroid tumors causes severe pain and scarring, but this may depend on the expertise and experience of the physician. Laser ablation is not currently available in the United States, and it is still not clear when these nonsurgical procedures should be used.

Turning Negatives into Positives

Observant endocrinologists have noted the negative side effects of some drugs and then taken advantage of them for therapy:

- Lithium inhibits the release of thyroid hormone and can cause hypothyroidism. It has occasionally been used to treat Graves' hyperthyroidism.
- Thiazides impair calcium excretion and can elevate the serum calcium level. They have been used to treat the hypercalciuria of primary hyperparathyroidism. The minimal rise in serum calcium may cause a possibly beneficial fall in PTH concentration. It is also of interest that thiazide diuretics are associated with increased bone density in the general population.
- Demeclocycline and lithium can cause mild diabetes insipidus. These drugs have a beneficial effect on chronic hyponatremia resulting from the syndrome of inappropriate secretion of antidiuretic hormone (SIADH).
- Cholestyramine inhibits the absorption of levothyroxine and can worsen hypothyroidism if administered conjointly with levothyroxine. However, hyperthyroidism improves more quickly when

cholestyramine is added to the anti-thyroid drug regimen, because it inhibits the enterohepatic circulation of thyroid hormone.

- Amiodarone is the most important cause of drug-induced hyperthyroidism. At the same time, amiodarone is also the most potent currently available inhibitor of T_4 -to- T_3 conversion. Because of this property, amiodarone may be added to antithyroid drugs to treat severe hyperthyroidism more quickly.
- The abortifacient RU-486 blocks both the progesterone and the cortisol receptor. It may be useful in the emergency treatment of endogenous Cushing's syndrome or severe glucocorticoid excess.
- Recognition of the downregulation of luteinizing hormone and FSH that occurs after administration of exogenous gonadotropin-releasing hormone (GnRH) has led to the development of GnRH analogues that inhibit gonadotropin release.

THE ENDOCRINOLOGIST AS ONCOLOGIST

Although it is easy to frighten patients, it takes time, patience, and sensitivity to reassure them. For example, the clinician could say to a patient, "Your thyroid (or adrenal) nodule could be a cancer." But for nodules that are obviously not serious malignancies, it would be far better and equally honest to tell the patient, "You have a thyroid nodule. Ninety percent of thyroid nodules are benign, and most thyroid cancers are not life-threatening. We will do a biopsy to help us determine whether surgery is necessary." Although this approach requires a bit of modification for adrenal nodules, it would still be reasonable to say, "The vast majority of adrenal nodules are benign, and adrenal cancers are rare."

With most innocent or nonaggressive thyroid cancers, the rule is to think and act like an endocrinologist. With more aggressive thyroid and other endocrine cancers, a good rule is to think like an oncologist and to refer the patient to one of them if necessary.

In most cases, sensitive tumor markers measured in a simple blood test (thyroglobulin) can tell us whether patients with well-differentiated thyroid cancer are cured. For example, it is relatively common for patients who have undergone total thyroidectomy, with or without nodal dissection for intrathyroidal papillary thyroid carcinoma with nodal metastatic disease, to have persistent, mildly elevated serum thyroglobulin at baseline or after TSH stimulation. But even if these patients are not cured, they should be told that the prognosis is usually excellent. It is important to emphasize to them that an abnormal thyroglobulin concentration is not lethal. Although thyroglobulin persistence is indicative of residual tumor, the remaining tumor is rarely lethal and in many patients never becomes manifest. You might say something like, "We will look for residual disease, and we will remove as much as we can. But even if we do not find anything, you will be fine." Few things cost as little but do as much as a strong dose of reassurance.

Abnormal concentrations of calcitonin and carcinoembryonic antigen after surgery for medullary thyroid carcinoma are of greater concern, because this tumor can have a worse prognosis. Many patients with advanced medullary thyroid carcinoma die of their disease. On the other hand, many patients with persistent modest calcitonin elevations live symptom free for decades despite persistent disease. Although the serum calcitonin concentration roughly

correlates with tumor volume, it is not a good indicator of a patient's prognosis. The doubling time of serum calcitonin is a better prognostic indicator: the shorter the doubling time, the worse the prognosis.

Know Your Cancer

It is very important to understand the course, natural history, and manifestations of endocrine malignancies:

- Younger patients with radioactive iodine–refractory papillary or follicular thyroid cancer metastatic to the lungs may have indolent disease that remains unchanged over decades. If these lesions are negative on fluorodeoxyglucose positron emission tomography (FDG-PET) and the patient is asymptomatic, careful observation is often the most appropriate course of action. Surgery cannot cure diffuse pulmonary disease, and current chemotherapy regimens are not indicated for stable or slow-growing disease. Careful observation may also be the best approach in older, asymptomatic patients with slow-growing PET-positive or -negative pulmonary metastases.
- Papillary and follicular thyroid cancers rarely cause pleural effusions even when they are metastatic to the lung. In a patient with well-differentiated thyroid cancer, extensive pleural effusions in the absence of sizable pulmonary metastases suggest the presence of another malignancy or diagnosis.
- In general, most thyroid cancers (with the important exception of anaplastic thyroid carcinoma) do not kill in a systemic way. Even in advanced thyroid cancer, cachexia is rare until the patient is near death. We therefore recommend aggressive local surgery for important lesions, even when removal is not curative. Such resections include both tumors that invade the trachea or esophagus and a limited number of growing pulmonary lesions that threaten the major bronchi. External irradiation may be appropriate for some of these lesions. Growing and symptomatic hepatic metastases may be treated with chemoembolization, alcohol ablation, or RFA even if these procedures are not curative. When treating well-differentiated thyroid cancer, I recommend avoiding whole-brain irradiation for brain metastases whenever possible. Whole-brain irradiation often causes major brain dysfunction within 1 or 2 years. If the patient is expected to live longer than 2 years, whole-brain irradiation seems inappropriate to me. I recommend surgical resection, if possible, and focused irradiation (including proton irradiation) either in addition or as an alternative.
- In some cancer patients, the major cause of morbidity is hormone excess rather than the cancer itself. Cushing's syndrome due to ACTH production by medullary thyroid carcinoma is often not diagnosed even though it is amenable to treatment. Muscle weakness and hypokalemia are important clues to the diagnosis. Hypercalcemia from metastatic parathyroid carcinoma is often refractory to therapy. The best therapy is to try to resect as much tumor as possible. If surgery is not an option or is unsuccessful, cinacalcet in high doses may provide some benefit.
- Anaplastic thyroid carcinoma is almost invariably fatal. Patients must be informed of the prognosis. Although several controlled trials are under way, successful therapy is probably years away.
- Bony metastases from well-differentiated thyroid cancer are invariably lytic before therapy and may be

extensive with advanced disease. However, hypercalcemia is rare unless the tumors have shown squamous de-differentiation. Conventional bone scans may be falsely negative in patients with lytic metastases, because these scans measure deposition of isotope-tagged bisphosphonate in bone.

- Hypercalcemia in a patient with medullary thyroid carcinoma is more likely to be related to concomitant hyperparathyroidism (MEN2) than to bony metastases.

Endocrinology-Oncology Collaboration

Radioactive iodine is an effective targeted therapy for well-differentiated thyroid cancer with radioiodine-avid metastatic disease. However, the use of radioiodine as a diagnostic or therapeutic tool is often continued long after it has ceased to be effective.

If the serum thyroglobulin concentration is elevated and a high-dose radioactive iodine scan is not informative, then repeated high-dose scans or low-dose scans will also be futile. Patients are frequently referred to me with metastatic thyroid cancer and elevated serum thyroglobulin levels in whom the only localizing tests have been multiple negative ^{131}I scans. Oncologists know, and endocrinologists need to realize, that conventional imaging is necessary to identify structural disease in this situation. An ultrasound study in skilled hands identifies most neck metastases, and a CT or MRI of the neck identifies almost all of the others. A high-resolution CT of the chest identifies almost all pulmonary metastases and significant intrathoracic nodal disease. If inoperable progressive disease is present, the presence and intensity of FDG uptake may help predict both the lack of ^{131}I efficacy and a worse prognosis. In the case of rapidly progressive or symptomatic radioactive iodine–refractory disease, therapeutic trials or available targeted chemotherapy (currently tyrosine kinase inhibitors) should be considered. Targeted chemotherapy for advanced thyroid cancer using tyrosine kinase inhibitors has had notable but temporary success during the past 5 years.¹⁵

Patients with pulmonary or other metastases that are refractory to radioactive iodine may or may not need additional therapy. For FDG-PET–negative lesions that are asymptomatic and stable or growing slowly, observation may be best. If the lesion is growing more quickly or is FDG-PET positive, these difficult questions often require the input of an oncologist: What is the likely life expectancy? Is simple observation the appropriate recommendation? Should targeted chemotherapy be considered? If so, when should it start?

There is a growing need for endocrine oncologists or oncologists with expertise in treating endocrine malignancies. Oncologic expertise is essential in the treatment of thyroid lymphomas, anaplastic thyroid carcinoma, advanced well-differentiated and medullary thyroid carcinoma requiring therapy, metastatic ACC, metastatic pheochromocytoma, islet cell malignancies, and parathyroid carcinoma.

It is important for endocrinologists to collaborate with oncologists in treating these endocrine malignancies, because endocrinologists are more familiar with certain endocrine issues that arise during the course of treatment:

- Endocrinologists know that tyrosine kinase inhibitors increase the requirement for thyroid hormone, thus raising the serum TSH (and potentially causing tumor growth) in patients with well-differentiated thyroid cancer.

- Endocrinologists know that mitotane is a potentially important adjunctive therapy for ACC but that it may temporarily or permanently damage the remaining adrenal gland after unilateral adrenalectomy for ACC, and it may accelerate the metabolism of cortisol, thereby causing an increased glucocorticoid requirement and possibly acute adrenal insufficiency.
- Endocrinologists know that the catecholamine excess of metastatic pheochromocytoma often must be treated with α -blockers or inhibitors of catecholamine biosynthesis, either chronically, before surgery, or before therapies associated with release of catecholamines. The metastases themselves require local therapy if they are symptomatic, and they require systemic targeted therapy when resection, radiation therapy, or ablative therapy is not possible or not successful.
- Endocrinologists are skilled at managing the refractory hypoglycemia of insulinomas that are metastatic and unresectable.
- Endocrinologists are most knowledgeable about treating the hypercalcemia of metastatic parathyroid carcinoma with cinacalcet and other agents.

There are many unresolved therapeutic dilemmas concerning endocrine malignancies, particularly when disease is advanced. However, even initial therapeutic decisions can be problematic and might benefit from collaborative efforts with oncologists.

- Pancreatic neuroendocrine tumors are the leading cause of death in MEN1, yet we lack an effective diagnostic and therapeutic approach to these tumors.
- Patients with parathyroid carcinoma require a wide surgical excision and often have a guarded prognosis. However, there is no consensus as to whether prophylactic postoperative external beam irradiation improves the prognosis.
- It is uncertain whether aggressive therapy (local irradiation and chemotherapy) improves the outcome for patients who have ACC without metastatic disease at presentation.

Advances in molecular biology are likely to have an important impact on the evaluation and treatment of endocrine as well as nonendocrine neoplasms. Current evidence suggests that the presence of mutated oncogenes in "follicular neoplasms" may help direct the surgeon toward a bilateral rather than a unilateral thyroidectomy. The presence of *BRAF* proto-oncogene mutations in papillary thyroid carcinoma may predict a worse prognosis and a lack of response to radioactive iodine. Improved ability to predict tumor behavior and to target therapy based on mutated oncogenes is among the goals for the future.

THE ENDOCRINOLOGIST AS EDUCATOR AND STUDENT

Clinical endocrinology requires lifelong learning. The clinician must keep up-to-date with current research, maintain a continuous dialogue with colleagues, know the literature, and take time to think about complicated cases. Only clinicians who understand the subject can teach it clearly and efficiently to students, fellows, colleagues, and patients. If a description or explanation seems fuzzy, it is probably either incomplete or incorrect. Information contained in textbook chapters or on-line textbooks can be helpful, but secondary sources should always be used in conjunction with original data and original publications.

The Internet has both facilitated and complicated patient education. Some Internet information is excellent, some misleading, some sensationalized, and some completely wrong. Clinical endocrinologists must acquire familiarity with the relevant web sites so that they can advise their patients about which ones are most reliable.

All clinical endocrinologists should provide handouts for their patients containing important information about their disease and its treatment. There are some excellent handouts published by professional endocrine societies, but it is often best to explain the material to your patients in your own words.

FUTURE DIRECTIONS AND CONSIDERATIONS

We have come to realize that the body does not act as a single, homogeneous unit with respect to hormone effects, and it may be possible to target additional hormone receptors and pathways for therapeutic purposes.

- When the peripheral conversion of T_4 to T_3 is inhibited, the pituitary remains euthyroid with unchanged TSH production, but the periphery may become hypothyroid (exposed to a low T_3 concentration).
- SERMs permit differential estrogen effects in certain tissues, thereby leading to important therapies for prevention of osteoporosis and breast cancer while avoiding potential negative estrogen effects. Similarly, thyroid hormone analogues have been developed that have very favorable effects on lipid profiles without causing tachycardia. Thyroid analogues capable of TSH suppression without other thyroid hormone actions may be feasible.
- Appropriate targeting of glucocorticoid nuclear activating pathways may eventually be the basis for a therapy that has anti-inflammatory properties without causing immunosuppression.
- If regional Cushing's syndrome resulting from activation of cortisone to cortisol in the liver by 11β -hydroxysteroid dehydrogenase 1 is found to play a role in central obesity and the metabolic syndrome, it is possible that appropriate therapies might follow.
- In Graves' disease, the thyroid gland is an innocent bystander being stimulated by immunoglobulins (TRAb). A magic bullet for Graves' disease would be a therapy that turns off these specific immunoglobulins selectively and safely.
- Therapy for severe Graves' ophthalmopathy (glucocorticoids, orbital radiation, and/or orbital decompression) has been essentially static for decades. New insights and innovations are sorely needed.
- Genome-wide association studies may yet uncover new, unimagined pathways with important diagnostic, preventive, and therapeutic consequences for clinical endocrinology.

Consider for a moment how far we have come in the practice of endocrinology. Forty years ago, we were still debating whether an elevated blood glucose concentration contributes to diabetic complications. Diabetes was monitored by spot urine glucose determinations. It was almost impossible to diagnose subtle endocrine dysfunction. It was thought that ACTH-dependent Cushing's disease was primarily a hypothalamic disorder. The only way to image the pituitary gland itself was to subject the patient to an extremely painful pneumoencephalogram. Immunoassays were still in their infancy: TSH

measurements were not yet part of the evaluation for hyperthyroidism, and we could not yet detect serum calcitonin when the concentration was less than 1000 pg/mL. The only treatment for osteoporosis was estrogen or, occasionally, androgens. Thyroid nodules were discovered only by palpation. Only a few major centers offered thyroid biopsies, and these were performed by surgeons with large cutting needles. The promise of molecular biology was precisely that, a promise only. Pituitary hormones were extracted from pituitary glands rather than produced as recombinant human hormones. The concept of oncogenes and tumor suppressor genes was unknown. There was no Internet, and there were no guidelines. Much of the excitement and satisfaction I have experienced in being a clinical endocrinologist during the past 40 years has come from seeing all these changes unfold, integrating them into my own practice, learning this new science and technology, thinking about solutions to complicated clinical problems, and finding new clinical conditions. I can't wait to see what the future holds.

CHAPTER

3

Genetic Control of Peptide Hormone Formation

JOEL F. HABENER

Advances in the fields of molecular and cellular biology have provided insights into the mechanistic workings of cells. Recombinant deoxyribonucleic acid (DNA) technology and sequencing (decoding) of the genomes of human, mouse, and several other species make it possible to analyze the precise structure and function of DNA. Discovery of the unique biochemical and structural properties of DNA provided the conceptual framework with which to begin a systematic investigation of the origins, development, and organization of life forms.¹

Sequencing of the human and mouse genomes was accomplished in 2003 and 2004, and annotation of the encoded information is nearing completion. A complete blueprint of the structure and organization of all expressed genes has illuminated the basis of genetically determined diseases. Within the next decade, genotyping of individuals shortly after birth likely will be possible and will provide information about the relative risks of developing these diseases. Therapeutic approaches for the correction of genetic defects by techniques of gene replacement are likely to become a reality.

The polypeptide hormones constitute a critically important and diverse set of regulatory molecules encoded by

the genome; their functions are to convey specific information among cells and organs. This type of molecular communication arose early in the development of life and evolved into a complex system for the control of growth, development, and reproduction and maintenance of metabolic homeostasis. These hormones, including the many chemokines and cytokines primarily involved in regulation of the immune system, consist of more than 400 small proteins, ranging from as few as 3 amino acids (thyrotropin-releasing hormone [TRH]) to 192 amino acids (growth hormone [GH]). These polypeptides function as hormones, whose actions on distant organs are mediated by way of their transport through the bloodstream, and as local cell-to-cell communicators (Fig. 3-1). The latter function of the polypeptide hormones is exemplified by their elaboration and secretion within neurons of the central, autonomic, and peripheral nervous systems, where they act as neurotransmitters, and in leukocytes, where they modulate immune responses. The multiple modes of expression of the polypeptide hormone genes have aroused great interest in the specific functions of these peptides and the mechanisms of their synthesis and release.

Figure 3-1 Modes of polypeptide hormone expression. The peptide hormones are expressed in at least four ways in fulfilling their functions as cellular messenger molecules: (1) endocrine mode, for purposes of communication among organs (e.g., pituitary-thyroid axis); (2) paracrine mode, for communication among adjacent cells, often located within endocrine organs; (3) neuroendocrine mode, for synthesis and release of peptides from specialized peptidergic neurons for action on distant organs through the bloodstream (e.g., neuroendocrine peptides of hypothalamus); and (4) neurotransmitter mode, for action of peptides in concert with classic amino acid–derived aminergic transmitters in the neuronal communication network. Identical polypeptides are often used in the nervous system as both neuroendocrine hormones and neurotransmitters. In some instances, the same gene product is used in all four modes of expression.

This chapter reviews the diverse structures of genes encoding peptide hormones and the mechanisms that govern their expression. The synthesis of nonpeptide hormones (e.g., catecholamines, thyroid hormones, steroid hormones) involves the action of many enzymes and expression of multiple genes, which are discussed in other chapters of this text.

EVOLUTION OF PEPTIDE HORMONES AND THEIR FUNCTIONS

Peptide hormones arose early in the evolution of life. Polypeptides that are structurally similar to mammalian peptides are present in lower vertebrates, insects, yeasts, and bacteria.² An example of the early evolution of regulatory peptides is the α -factor (i.e., mating pheromone) of yeast, which is similar in structure to gonadotropin-releasing hormone (GnRH).³ The oldest member of the cholecystokinin-gastrin family of peptides appeared at least 500 million years ago in the protochordate *Ciona intestinalis* (sea squirt).⁴

The genes encoding polypeptide hormones, particularly those for regulatory peptides, evolved early in the development of life and initially fulfilled the function of cell-to-cell communication to cope with problems concerning nourishment, growth, development, and reproduction. As specialized organs connected by a circulatory system developed during evolution, similar or identical gene products became hormones for purposes of organ-to-organ communication.

STEPS IN EXPRESSION OF A PROTEIN-ENCODING GENE

The steps involved in transfer of information encoded in the polynucleotide language of DNA to the poly-amino-acid language of biologically active proteins involve gene transcription, post-transcriptional processing of ribonucleic acids (RNAs), translation, and post-translational processing of the proteins. The expression of genes and protein synthesis can be considered in terms of several major processes, any one or more of which may serve as specific control points in the regulation of gene expression (Fig. 3-2).

- *Rearrangements and transpositions of DNA segments.* These processes occur over eons in evolution, with the exception of uncommon mechanisms of somatic gene rearrangements such as rearrangements in the immunoglobulin genes occurring during the lifetime of an individual.
- *Transcription.* Synthesis of RNA results in the formation of RNA copies of the two gene alleles and is catalyzed by the basal RNA polymerase II–associated transcription factors.
- *Post-transcriptional processing.* Specific modifications of RNA include the formation of messenger RNA (mRNA) from the precursor RNA by way of excision and rejoining of RNA segments (introns and exons) and the modification of the 3' end of the RNA by polyadenylation and of the 5' end by addition of 7-methylguanine caps.
- *Translation.* Amino acids are assembled by base pairing of the nucleotide triplets (anticodons) of the specific “carrier” amino-acylated transfer RNAs to the corresponding codons of the mRNA bound to polyribosomes and are polymerized into polypeptide chains.
- *Post-translational processing and modification.* Final steps in protein synthesis may involve one or more cleavages of peptide bonds, which result in the conversion of biosynthetic precursors (prohormones) to intermediate or final forms of the protein; derivatization of amino acids (e.g., glycosylation, phosphorylation, acetylation, myristoylation); and folding of the processed polypeptide chain into its native conformation.

Each of the specific steps of gene expression requires the integration of precise enzymatic and other biochemical reactions. These processes have developed to provide high fidelity in reproduction and transmission of the encoded information and to supply control points for genes that direct the expression of the specific phenotype of cells.

Post-translational processing of proteins creates diversity in gene expression through modifications of the protein. Although the functional information contained in a protein is ultimately encoded in the primary amino acid sequence, the specific biologic activities are a consequence of the secondary, tertiary, and quaternary structures of the polypeptide. Given the wide range of possible specific modifications of the amino acids (e.g., glycosylation,

Figure 3-2 Cellular synthesis of polypeptide hormones. Steps that take place within the nucleus include transcription of genetic information into a messenger ribonucleic acid precursor (pre-mRNA) followed by post-transcriptional processing, which includes RNA cleavage, excision of introns, and rejoining of exons, resulting in formation of mRNA. Ends of mRNA are modified by addition of methylguanosine caps at the 5' end and poly(A) tracts at the 3' ends. The cytoplasmic mRNA is assembled with ribosomes. Amino acids, carried by amino-acylated transfer RNAs (tRNAs), are then polymerized into a polypeptide chain. The final processes in protein synthesis take place during growth of the nascent polypeptide chain (cotranslational) and after release of the completed chain (post-translational). They include proteolytic cleavages of the polypeptide chain (conversion of pre-prohormones or prohormones to hormones), derivatizations of amino acids (e.g., glycosylation, phosphorylation), and cross-linking and assembly of the polypeptide chain into its conformed structure. Post-translational synthesis and processing of a typical secreted polypeptide require vectorial or unidirectional transport of the polypeptide chain across the membrane bilayer of the endoplasmic reticulum, resulting in sequestration of the polypeptide in the cisterna of the endoplasmic reticulum, a first step in the export of proteins destined for secretion from the cell (see Fig. 3-6). Most translational processing occurs within the cell (presecretory); in some instances, it occurs outside the cell, when further proteolytic cleavages or modifications of the protein take place (postsecretory). CHO, carbohydrate.

phosphorylation, acetylation, amidation, lipidation, sulfation),⁵ any one of which may affect the conformation or function of the protein, a single gene may ultimately encode a wide variety of specific proteins as a result of post-translational processes.

Polypeptide hormones are synthesized in the form of larger precursors that appear to fulfill several functions in biologic systems (Fig. 3-3), including intracellular trafficking, by which the cell distinguishes among specific classes of proteins and directs them to their sites of action, and the generation of multiple biologic activities from a common genetically encoded protein by regulated or cell-specific variations in the post-translational modifications (Fig. 3-4).

All peptide hormones and regulatory peptides studied contain signal or leader sequences at the amino-terminus. These hydrophobic, helical sequences recognize specific sites on the membranes of the rough endoplasmic reticulum (ER), which results in the transport of nascent polypeptides into the secretory pathway of the cell (see Figs. 3-2 and 3-3).⁶ The consequence of the specialized signal sequences of the precursor proteins is that proteins destined for secretion are selected from a great many other cellular proteins for sequestration and subsequent

packaging into secretory granules and export from the cell. Most smaller hormones and regulatory peptides are produced as a consequence of post-translational cleavages of the precursors within the Golgi complex of secretory cells.

SUBCELLULAR STRUCTURE OF CELLS THAT SECRETE PROTEIN HORMONES

Cells whose principal functions are the synthesis and export of proteins contain highly developed, specialized subcellular organelles for translocating secreted proteins and packaging them into secretory granules. The subcellular pathways used in protein secretion were elucidated largely through the early efforts of Palade (reviewed by Jamieson).^{7,8} Secretory cells contain an abundance of ER, Golgi apparatus, and secretory granules (Fig. 3-5). The proteins that are to be secreted from the cells are transferred during their synthesis into these subcellular organelles, which transport the proteins to the plasma membrane.

Protein secretion begins with translation of the mRNA encoding the precursor of the protein on the rough ER, which consists of polyribosomes attached to elaborate

Figure 3-3 Two configurations of precursors of polypeptide hormones. Diagrams represent the polypeptide backbones of protein sequences encoded in messenger RNA (mRNA). One form of precursor consists of the amino-terminal signal, or presequence, followed by the apoprotein portion of the polypeptide that needs no further proteolytic processing for activity. A second form of precursor is a pre-prohormone that consists of the N-terminal signal sequence followed by a polypeptide, or prohormone, sequence made up of two or more peptide domains linked together that are subsequently liberated by cleavages during post-translational processing of the prohormone. The reason for synthesis of polypeptide hormones in the form of precursors is only partly understood. The N-terminal signal sequences function in the early stages of transport of polypeptide into the secretory pathway. Prohormones, or polypeptides, often provide a source of multiple bioactive peptides (see Fig. 3-4). However, many prohormones contain peptide sequences that are removed by cleavage and have no known biologic activity (*cryptic peptides*). Other peptides may serve as spacer sequences between two bioactive peptides (e.g., the C peptide of proinsulin). When a bioactive peptide is located at the carboxyl-terminus of the prohormone, the N-terminal prohormone sequence may simply facilitate the cotranslational translocation of polypeptide in the endoplasmic reticulum (see Fig. 3-6).

membranous saccules that contain cavities (cisternae). The newly synthesized, nascent proteins are discharged into the cisternae by transport across the lipid bilayer of the membrane. Within the cisternae of the ER, proteins are carried to the Golgi complex by mechanisms that are incompletely understood. The proteins gain access to the Golgi complex by direct transfer from the cisternae, which are in continuity with the membranous channels of the Golgi complex, or by way of shuttling vesicles known as *transition elements* (see Fig. 3-5).

Within the Golgi complex, the proteins are packaged into secretory vesicles or secretory granules that bud from the Golgi stacks in the form of immature granules. Immature granules undergo maturation through condensation of the proteinaceous material and application of a specific coat around the initial Golgi membrane. On receiving the appropriate extracellular stimuli (i.e., regulated pathway of secretion), the granules migrate to the cell surface and fuse to become continuous with the plasma membrane, which results in the release of proteins into the extracellular space, a process known as *exocytosis*.

The second pathway of intracellular transport and secretion involves the transport of proteins contained within secretory vesicles and immature secretory granules (see Fig. 3-5). Although the use of this alternative vesicle-mediated transport pathway remains to be demonstrated conclusively (it is typically considered to be a constitutive, or unregulated, pathway), extracellular stimuli may modulate hormone secretion differently depending on the pathway of secretion. For example, in the parathyroid gland and in the pituitary cell line derived from corticotrophic cells (AtT-20), newly synthesized hormone is released more rapidly than hormone synthesized earlier. This finding suggests that the newly synthesized hormone may be transported by way of a vesicle-mediated pathway without incorporation into mature storage granules.

INTRACELLULAR SEGREGATION AND TRANSPORT OF POLYPEPTIDE HORMONES

Specific amino acid sequences encoded in the proteins serve as directional signals for the sorting of proteins within subcellular organelles.^{6,9,10} A typical eukaryotic cell synthesizes an estimated 5000 different proteins during its life span. Although these proteins are synthesized by a common pool of polyribosomes, each protein is directed to a specific location within the cell, where its biologic function is expressed. For example, specific groups of proteins are transported into mitochondria, into membranes, into the nucleus, or into other subcellular organelles, where they serve as regulatory proteins, enzymes, or structural proteins. A subset of proteins including immunoglobulins, serum albumin, blood coagulation factors, and protein and

Figure 3-4 Primary structures of some prohormones. The shaded areas of prohormones denote regions of sequence that constitute known biologically active peptides after post-translational cleavage from the prohormone. Sequences indicated by hatching denote regions of precursor that alter the biologic specificity of that region of precursor. For example, the precursor contains the sequence of γ -melanocyte-stimulating hormone (γ -MSH), but when the latter is covalently attached to the CLIP peptide, it constitutes adrenocorticotrophic hormone (ACTH). Somatostatin-28 (SS-28) is an amino-terminally extended form of somatostatin-14 (SS-14) that has higher potency than SS-14 on certain receptors. The neurophysin sequence linked to the carboxyl-terminus of vasopressin (ADH) functions as a carrier protein for the ADH hormone during its transport down the axon of neurons in which it is synthesized. The precursor proenkephalin represents a polypeptide that contains multiple similar peptides within the sequence of met-enkephalin (M) or leu-enkephalin (L). Procalcitonin and calcitonin gene-related product (CGRP) share identical N-terminal sequences but differ in their C-terminal regions as a result of alternative splicing during post-transcriptional processing of the RNA precursor. γ -LPH, γ -lipotropin; GLP, glucagon-like peptide; IP, intervening peptide.

Figure 3-5 Subcellular organelles involved in transport and secretion of polypeptide hormones or other secreted proteins within a protein-secreting cell. (1) Synthesis of proteins on polyribosomes attached to rough endoplasmic reticulum (RER) and vectorial discharge of proteins through the membrane into the cisterna. (2) Formation of shuttling vesicles (transition elements) from endoplasmic reticulum followed by their transport to and incorporation by the Golgi complex. (3) Formation of secretory granules in the Golgi complex. (4) Transport of secretory granules to the plasma membrane, fusion with the plasma membrane, and exocytosis resulting in the release of granule contents into the extracellular space. Notice that secretion may occur by transport of secretory vesicles and immature granules or by transport of mature granules. Some granules are taken up and hydrolyzed by lysosomes (crinophagy). Golgi, Golgi complex; SER, smooth endoplasmic reticulum. (From Habener JF. Hormone biosynthesis and secretion. In: Felig P, Baxter JD, Broadus AE, et al, eds. *Endocrinol Metab*. New York, NY: McGraw-Hill, 1981:29-59.)

polypeptide hormones is specifically designed for export from the cell.

This process of directional transport of proteins involves sophisticated informational signals. Because the information for these translocation processes must reside wholly or in part within the primary structure or in the conformational properties of the protein, sequential post-translational modifications may be crucial for determining the specificity of protein function. Continued investigations of protein sorting and trafficking in cells have revealed increased complexities beyond the simple paradigm illustrated in Figure 3-5.¹¹ Sequential sorting of proteins to their final destinations, whether they are exported (secreted) from the cells or targeted to a subcellular compartment or organelle, takes place not only in the Golgi apparatus but before then in the ER, and afterward in endosomes and tubulosacules.¹² Each of the approximately 5000 proteins expressed in a given cell contains a specific targeting signal that is responsible for directing the protein to its final destination. These targeting signals consist of short stretches of amino acids in the proteins that serve as molecular “ZIP codes” to ensure their accurate delivery. Modern approaches using proteomics and bioinformatics can predict localization of proteins in cells based on the characteristics of these targeting signals.¹³

Signal Sequences in Peptide Prohormone Processing and Secretion

The early processes of protein secretion that result in the specific transport of exported proteins into the secretory pathway have become better understood.^{6,10-15} Initial clues to this process came from determinations of the amino acid sequences of the proteins programmed by the cell-free translation of mRNAs encoding secreted polypeptides.¹⁶ Secreted proteins are synthesized as precursors that are

extended at their N-termini by sequences of 15 to 30 amino acids, called *signal* or *leader sequences*. Signal sequence extensions or their functional equivalents are required for targeting the ribosomal or nascent protein to specific membranes and for vectorial transport of the protein across the membrane of the ER.

On emergence of the signal sequence from the large ribosomal subunit, the ribosomal complex specifically makes contact with the membrane; this results in translocation of the nascent polypeptide across the ER membrane into the cisterna as the first step in its secretory pathway. These observations initially left unanswered the question of how specific polyribosomes that translate mRNAs encoding secretory proteins recognize and attach to the ER (Fig. 3-6). Because microsomal membranes *in vitro* reproduce the processing activity of intact cells, it was possible to identify the macromolecules responsible for processing precursors and for translocation activities.¹⁷ The ER and the cytoplasm contain an aggregate of molecules, called a *signal recognition particle complex*, that consists of at least 16 proteins, including three guanosine triphosphatases to generate energy¹⁸ and a 7S RNA.^{6,10,19,20} This complex, or particle, binds to the polyribosomes involved in the translation of mRNAs encoding secretory polypeptides when the N-terminal signal sequence first emerges from the large subunit of the ribosome.

The specific interaction of the signal recognition particle with the nascent signal sequence and the polyribosome arrests further translation of mRNA. The nascent protein remains in a state of arrested translation until it finds a high-affinity binding protein on the ER, the signal recognition particle receptor or docking protein.⁶ On interaction with the specific docking protein, the translational block is released, and protein synthesis resumes. The protein is then transferred across the membrane of the ER through a proteinaceous tunnel called the *translocon*.²⁰

Figure 3-6 Cellular events in the initial stages of synthesis of a polypeptide hormone according to the signal hypothesis. In this schema, a signal recognition particle, consisting of a complex of six proteins and an RNA (7S RNA), interacts with the amino-terminal signal peptide of the nascent polypeptide chain after approximately 70 amino acids are polymerized, arresting further growth of the polypeptide chain. The complex of the signal recognition particle and the polyribosome nascent chain remains in a state of translational arrest until it recognizes and binds to a docking protein, which is a receptor protein located on the cytoplasmic face of the endoplasmic reticular membrane. This interaction of the signal recognition particle complex with the docking protein releases the translational block, and protein synthesis resumes. The nascent polypeptide chain is discharged across the membrane bilayer into the cisterna of the endoplasmic reticulum and is released from the signal peptide by cleavage with a signal peptidase located in the cisternal face of the membrane. In this model, the signal peptide is cleaved from the polypeptide chain by signal peptidase before the chain is completed (i.e., cotranslational cleavage). The configuration of the polypeptide during transport across the membrane and the forces and mechanisms responsible for its translocation are unknown. The loop, or hairpin, configuration of the chain shown here is an arbitrary model; other models are equally possible.

At some point, near the termination of synthesis of the polypeptide chain, the N-terminal signal sequence is cleaved from the polypeptide by a specific signal peptidase located on the cisternal surface of the ER membrane. Removal of the hydrophobic signal sequence frees the protein (prohormone or hormone) so that it may assume its characteristic secondary structure during transport through the ER and the Golgi apparatus. After cleavage from the protein by a signal peptidase, the signal peptide may sometimes be further cleaved in the ER membrane to produce a biologically active peptide. For example, the signal sequence of preprolactin, comprising 30 amino acids, is cleaved by a signal peptide peptidase to yield a charged peptide of 20 amino acids that is released into the cytosol, where it binds to calmodulin and inhibits Ca^{2+} -calmodulin-dependent phosphodiesterase.²¹

This sequence in the directional transport of specific polypeptides ensures optimal cotranslational processing of secretory proteins, even when synthesis commences on free ribosomes. The presence of a cytoplasmic form of the signal recognition particle complex that blocks translation guarantees that the synthesis of the presecretory proteins is not completed in the cytoplasm; the efficient transfer of proteins occurs only after contact has been made with the specific receptor or docking protein on the membrane. Although the presence of signal recognition particles and docking proteins explains the specificity of the binding of ribosomes containing mRNAs encoding the secretory proteins, it does not explain the mode of translocation of the nascent polypeptide chain across the membrane bilayer.

Further dissection and analysis of the membrane have identified other macromolecules that are responsible for the transport process.⁶

Cellular Processing of Prohormones

The signal sequences of prehormones and pre-prohormones are involved in the transport of these molecules, but the function of the intermediate hormone precursors (i.e., prohormones) is not fully understood. Conversion of prohormones to their final products begins in the Golgi apparatus. For example, the time that elapses between the synthesis of pre-parathyroid hormone and the first appearance of parathyroid hormone correlates closely with the time required for radioautographic grains to reach the Golgi apparatus.²² Similarly, conversion of proinsulin to insulin takes place about 1 hour after the synthesis of proinsulin is complete, and processing of proinsulin to insulin and C peptide takes place during the transport within the secretory granule.²³ The conversion of prohormones to hormones can also be blocked by inhibitors of cellular energy production such as antimycin A and dinitrophenol²⁴ and by drugs that interfere with the functions of microtubules (e.g., vinblastine, colchicine).²⁵ Translocation of the prohormone from the rough ER to the Golgi complex depends on metabolic energy and probably involves microtubules.

There is no evidence that sequences specific to the prohormone contribute to or are chemically involved in transport of the newly synthesized protein from the rough ER to the Golgi apparatus, nor that they are involved in the

packaging of the hormone in vesicles or granules. Analyses of the structures of the primary products of translation of mRNAs encoding secretory proteins indicate that many of these are not synthesized in the form of prohormone intermediates (see Fig. 3-3). It remains puzzling that some secretory proteins (e.g., parathyroid hormone, insulin, serum albumin) are formed by way of intermediate precursors, whereas others (e.g., GH, prolactin, albumin) are not.

Size constraints may be placed on the length of a secretory polypeptide. When the bioactivity of peptides resides at the carboxyl-termini of the precursors (e.g., somatostatin, calcitonin, gastrin), N-terminal extensions may be required to provide a sufficient “spacer” sequence to allow the signal sequence on the growing nascent polypeptide chain to emerge from the large ribosome subunit for interaction with the signal recognition particle and to provide adequate polypeptide length to span the large ribosomal subunit and the membrane of the ER during vectorial transport of the nascent polypeptide across the membrane (see Fig. 3-6). If the final hormonal product is 100 amino acids long or longer (e.g., GH, prolactin, the α - and β -subunits of the glycoprotein hormones), there may be no requirement for a prohormone intermediate.

Although the exact functions of prohormones remain unknown, certain details of their cleavages have been established. Unlike the situation with prehormones, in which the amino acids at the cleavage site between the signal sequence and the remainder of the molecule (hormone or prohormone) vary from one hormone to the next, the cleavage sites of the prohormone intermediates consist of the basic amino acid lysine or arginine, or both, usually two to three in tandem. This sequence is preferentially cleaved by endopeptidases with trypsin-like activities.

The family of prohormone-converting (PC) enzymes consists of at least eight specific members.²⁶⁻²⁸ The most studied of the isozymes are PC2 and PC1/3, which are responsible for the cleavages of proinsulin between the A chain/C peptide and the B chain/C peptide, respectively. A rare patient missing PC1 presented with childhood obesity, hypogonadotropic hypogonadism, and hypercortisolism and was found to have elevated proinsulin levels and presumably widespread abnormalities in neuropeptide modification.²⁹ Targeted disruption of the PC2 gene in mice resulted in incomplete processing of proinsulin, leaving the A chain and C peptide intact.³⁰ Proglucagon in the pancreas remained incompletely processed, indicating that PC2 is required for the formation of glucagon. As a consequence of defective PC2 activity and low levels of glucagon, the mice had severe chronic hypoglycemia.

After endopeptidase cleavage, the remaining basic residues are selectively removed by exopeptidases with activity resembling that of carboxypeptidase B. When the C-terminal residue of the peptide hormone is amidated, a process that appears to enhance the stability of a peptide by conferring resistance to carboxypeptidase, specific amidation enzymes (i.e., peptide amidating monooxygenases) in the Golgi complex work in concert with the cleavage enzymes to modify the C-termini of the bioactive peptides.^{31,32}

All proproteins and prohormones are cleaved by PC enzymatic processes within the Golgi complex of cells of diverse origins. The significance of specific cleavages of specific prohormones remains incompletely understood, as does the reason for the existence of prohormone intermediates in some but not all secretory proteins. Precursor peptides removed from the prohormones may have intrinsic biologic activities that are still unrecognized.

PROCESSES OF HORMONE SECRETION

Specific extracellular stimuli control the secretion of polypeptide hormones. These stimuli consist of changes in homeostatic balance; the hormonal products released in response to the stimuli act on the respective target organs to reestablish homeostasis (Fig. 3-7). Endocrine systems typically consist of closed-loop feedback mechanisms; if hormones from organ A stimulate organ B, organ B secretes hormones that inhibit the secretion of hormones from organ A. The concerted actions of positive and negative hormonal influences thereby maintain homeostasis. An example of negative feedback regulation is the control of the secretion of adrenocorticotropic hormone (ACTH) by the anterior pituitary gland. An increased ACTH level stimulates the adrenal cortex to produce and secrete cortisol, which suppresses further pituitary secretion of ACTH. These regulatory processes may include feedback loops in which nonhormonal substances controlled by the target organs regulate hormone secretion. For example, an increase in the concentration of plasma electrolytes as a

Figure 3-7 Regulatory feedback loops of the hypothalamic-pituitary-target organ axis. As combinations of stimulatory and inhibitory factors, hormones often act in concert to maintain homeostatic balance in the presence of physiologic or pathophysiologic perturbations. The concerted actions of hormones typically establish closed feedback loops by stimulatory and inhibitory effects coupled to maintain homeostasis.

consequence of dehydration stimulates the release of arginine vasopressin (antidiuretic hormone) in the neural lobe of the pituitary gland, and vasopressin in turn acts on the kidney to increase reabsorption of water from the renal tubule, thereby readjusting serum electrolyte concentrations toward normal levels.

In many instances, endocrine regulation is complex and involves the responses of several endocrine glands and their respective target organs. After a meal, the release of a dozen or more hormones is triggered as a result of gastric distention, variations in the pH of the contents of the stomach and duodenum, and increased concentrations of glucose, fatty acids, and amino acids in the blood. The rise in plasma glucose and amino acid levels stimulates the release of insulin and the incretin hormones glucagon-like peptide 1 and glucose-dependent insulintropic peptide and suppresses the release of glucagon from the pancreas. Both effects promote the net uptake of glucose by the liver: insulin increases cellular transport and uptake of glucose, and the lower blood levels of glucagon decrease the outflow of glucose because of diminished rates of glycogenolysis and gluconeogenesis.

STRUCTURE OF A GENE ENCODING A POLYPEPTIDE HORMONE

Structural analyses of gene sequences have resulted in at least three major discoveries that are important for understanding the expression of peptide-encoding genes. First, sequences of almost all of the known biologically active hormonal peptides are contained within larger precursors that often encode other peptides, many of which are of unknown biologic activity. Second, the transcribed regions of genes (called *exons*) are interrupted by sequences (called *introns*) that are transcribed but subsequently cleaved from the initial RNA transcripts during their nuclear processing and assembly into specific mRNAs. Third, specific

regulatory sequences reside in the regions of DNA flanking the structural genes and within introns, and these DNA sequences constitute specific targets for the interactions of DNA-binding proteins that determine the level of expression of the gene.

The DNA of higher organisms is wound around proteins, forming tightly and regularly packed chromosomal structures called *nucleosomes*.^{33,34} Nucleosomes are composed of four or five different histone subunits that form a core structure about which approximately 140 base pairs of genomic DNA are wound. The nucleosomes are arranged similarly to beads on a string, and coils of nucleosomes form the fundamental organizational units of the eukaryotic chromosome. The nucleosomal structure serves several purposes. For example, nucleosomes enable the large amount of DNA (approximately 2×10^9 base pairs) included in the genome to be compacted into a small volume. Nucleosomes are involved in the replication of DNA and gene transcription. In addition to histones, other proteins are associated with DNA, and the complex nucleoprotein structure provides specific recognition sites for regulatory proteins and enzymes involved in DNA replication, rearrangements of DNA segments, and gene expression. The processes of acetylation, deacetylation, methylation, and demethylation of histones that are enriched in chromatin are implicated in the regulation of gene transcription (see “Epigenetic Inheritance of Phenotypic Traits”).

The histones of open-configured chromatin (i.e., euchromatin) are heavily acetylated and methylated; this loosens their association with DNA and allows the access of transcription factors to the promoter regions of expressed genes. Conversely, the histones of closed chromatin (i.e., heterochromatin) are underacetylated and undermethylated, adhere tightly to DNA, and prevent access of transcription factors to the promoters of transcriptionally silent genes.

A typical protein-encoding gene consists of two functional units (Fig. 3-8). One is a transcriptional region, and the other is a promoter or regulatory region.

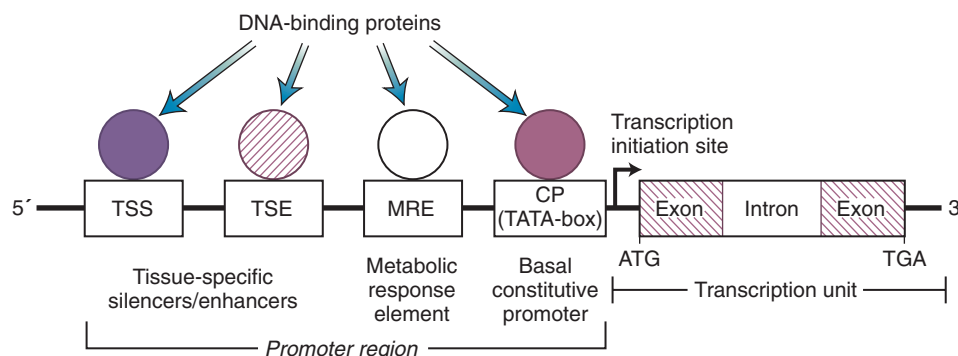

Figure 3-8 Structure of a consensus gene encoding a prototypical polypeptide hormone. A consensus gene typically consists of a promoter region and a transcription unit. The transcription unit is the region of DNA composed of exons and introns that is transcribed into a messenger ribonucleic acid (mRNA) precursor. Transcription begins at the cap site sequence in DNA and extends several hundred bases beyond the poly(A) addition site in the 3' region. During post-transcriptional processing of the RNA precursor, the 5' end of mRNA is capped by the addition of methylguanosine residues. The transcript is then cleaved at the poly(A) addition site approximately 20 bases 3' to the AATAAA signal sequence, and the poly(A) tract is added to the 3' end of the RNA. Introns are cleaved from the RNA precursor, and exons are joined together. Dinucleotides GT and AG are invariably found at the 5' and 3' ends of introns. Translation of mRNA starts with the codon ATG for methionine. Translation is terminated when the polyribosome reaches the stop codon TGA, TAA, or TAG. The promoter region of the gene located 5' to the cap site contains numerous short regulatory DNA sequences that are targets for interactions with specific DNA-binding proteins. These sequences consist of the basal constitutive promoter (TATA box), metabolic response elements that modulate transcription (e.g., in response to cyclic adenosine monophosphate [cAMP], steroid hormone receptors, or thyroid hormone receptors), and tissue-specific enhancers and silencers that respectively permit or prevent transcription of the gene. The enhancer and silencer elements direct expression of specific subsets of genes to cells of a given phenotype. Whether a gene is or is not expressed in a particular cellular phenotype depends on complex interactions of the various DNA-binding proteins among themselves and, most importantly, with the TATA box proteins of the basal constitutive promoter.

Transcriptional Regions

The transcriptional unit is the segment of the gene that is transcribed into an mRNA precursor. The sequences corresponding to the mature mRNA consist of the exon sequences that are spliced from the primary transcript during cotranscriptional and post-transcriptional processing of the precursor RNA. These exons contain the code for the mRNA sequence that is translated into protein and for untranslated sequences at the 5' and 3' flanking regions. The 5' sequence typically begins with a methylated guanine residue known as the *cap site*. The 3' untranslated region contains within it a short sequence, AATAAA, that signals the site of cleavage of the 3' end of the RNA and the addition of a poly(A) tract of 100 to 200 nucleotides located approximately 20 bases from the AATAAA sequence. Although the functions of these modifications of the ends of mRNAs are not completely understood, they appear to provide signals for leaving the nucleus; to enhance stability, perhaps by providing resistance to degradation by exonucleases; and to stimulate initiation of mRNA translation. The protein-coding sequence of the mRNA begins with the codon AUG for methionine and ends with the codon immediately preceding one of the three nonsense, or stop, codons: UGA, UAA, and UAG.

The nature of the enzymatic splicing mechanisms that result in excision of intron-coded sequences and rejoining of exon-coded sequences is incompletely understood. Helpful interpretations of the splicing processes have been provided in recent reviews.^{35,36} Short "consensus" sequences of nucleotides reside at the splice junctions; for example, the bases GT and AG at the 5' and 3' ends of the introns, respectively, are invariant, and a polypyrimidine stretch is found near the AG.³⁷ Splicing involves a series of cleavage and ligation steps that remove the introns as a lariat structure, with its 5' end ligated near the 3' end of the introns, and ligate the two adjacent exons together. The spliceosome, an elaborate mechanism consisting of five *small nuclear RNAs* (snRNAs) and roughly 50 proteins, directs these steps, guided by base pairing between three of the snRNAs and the mRNA precursor.

Regulatory Regions

The molecular mechanisms involved in regulating the expression of genes that encode polypeptides are becoming understood in some detail. Some experiments have deleted certain 5' sequence segments that reside upstream from structural genes and then analyzed the expression of those genes after their introduction into cell lines. These regulatory sequences, called *promoter* and *enhancer* regions, consist of short polynucleotide sequences (see Fig. 3-8). They can be divided into at least four groups with respect to their functions and distance from the transcriptional initiation site.

First, the sequence TATAA (TATA box or Goldberg-Hogness box) is usually present in the more proximal promoter within 25 to 30 nucleotides upstream from the point of transcriptional initiation. The TATA sequence is required to ensure the accuracy of initiation of transcription at a particular site. The TATA box directs the binding of a complex of several proteins, including RNA polymerase II. The proteins, referred to as *TATA box transcription factors*, number six or more basal factors (IIA, IIB, IID, IIE, IIF, IIH); along with RNA polymerase II, they form the general or basal transcriptional machinery required for the initiation of RNA synthesis.³⁸⁻⁴⁰

The other three groups of regulatory sequences are the *tissue-specific silencers* (TSSs), which function by binding

repressor proteins; the *tissue-specific enhancers* (TSEs), which are activated by the binding of transcriptional activator proteins; and the *metabolic response elements* (MREs), which are regulated by the binding of specialized proteins whose transcriptional (repressor or activator) activities are determined by metabolic signaling that often involves changes in their phosphorylation status.

Introns and Exons

Genes encoding proteins and ribosomal RNAs in eukaryotes are interrupted by intervening DNA sequences (i.e., introns) that separate them into coding blocks (i.e., exons).^{35,36,41} In bacterial genes, the nucleotide sequences of the chromosomal genes match precisely the corresponding sequences in the mRNAs. Interruption of the continuity of genetic information appears to be unique to nucleated cells. The reasons for such interruptions are not completely understood, but introns appear to separate exons into functional domains with respect to the proteins that they encode. An example is the gene for proglucagon, a precursor of glucagon in which five introns separate six exons, three of which encode glucagon and the two glucagon-related peptides contained within the precursor (Fig. 3-9).⁴² A second example is the GH gene, which is divided into five exons by four introns that separate the promoter region of the gene from the protein-coding region and divide the latter into three partly homologous repeated segments, two of which code for the growth-promoting activity of the hormone and the third for its carbohydrate metabolic functions.⁴³ As a rule, the genes for the precursors of hormones and regulatory peptides contain introns that are located at or about the region where signal peptides join the apoproteins or prohormones and thus separate the signal sequences from the components of the precursor that are exported from the cell as hormones or peptides.

There are exceptions to the "one exon, one function" theory in mammalian cells. The genes of several precursors of peptide hormones are not interrupted by introns in a manner that corresponds to separation of the functional components of the precursor. For example, the precursor pro-opiomelanocortin (POMC) is cleaved during post-translational processing to produce the peptides ACTH, α -melanocyte-stimulating hormone, and β -endorphin, but the protein-coding region of the *POMC* gene is devoid of introns. Likewise, no introns interrupt the protein-coding region of the gene for the proenkephalin precursor, which contains seven copies of the enkephalin sequences. It is possible that introns separated each of these coding domains in the past and were lost during the course of evolution.

A precedent for the selective loss of introns appears to be exemplified by the rat insulin genes. The rat genome harbors two nonallelic insulin genes, one containing two introns and the other containing a single intron. The most likely explanation is that an ancestral gene containing two introns was transcribed into RNA and spliced, after which that RNA was copied back into DNA by a cellular reverse transcriptase and inserted into the genome at a new site.

REGULATION OF GENE EXPRESSION

Regulation of expression of genes encoding polypeptide hormones can take place at one or more levels in the pathway of hormone biosynthesis^{44,46} (Fig. 3-10): DNA synthesis (cell growth and division), transcription,

Figure 3-9 The pancreatic glucagon gene and its encoded messenger RNA (mRNA): complementary DNA. In the glucagon gene, exons precisely encode separate functional domains. The gene consists of six exons (E1 through E6) and five introns (IA through IE). The mRNA encoding pre-proglucagon, the protein precursor of glucagon, consists of 10 specific regions: from left to right, a 5' untranslated sequence (UN-TX, *open*), a signal sequence (S, *stippled*), an amino-terminal extension sequence (N, *hatched*), glucagon (Gluc, *shaded*), a first intervening peptide (IP-I, *hatched*), a first glucagon-like peptide (GLP-I, *shaded*), a second intervening peptide (IP-II, *hatched*), a second glucagon-like peptide (GLP-II, *shaded*), a dilysyl dipeptide (*hatched*) after the GLP-II sequence, and an untranslated region (UN-TX, *open*). Exons from left to right encode the 5' untranslated region, signal sequence, glucagon, GLP-I, GLP-II, and 3' untranslated sequence. Letters shown above the mRNA denote amino acids located at positions in the pre-proglucagon molecule that are cleaved during cellular processing of the precursor. The amino acid methionine (M) marks the initiation of translation of mRNA into pre-proglucagon. H, histidine; K, lysine; Q, glutamine; R, arginine.

post-transcriptional processing of mRNA, translation, or post-translational processing. In different endocrine cells, one or more levels may serve as specific control points for regulation of the production of a hormone (see “[Biologic Diversification](#)”).

Levels of Gene Control

Newly synthesized prolactin transcripts are formed within minutes after exposure of a prolactin-secreting cell line to TRH.⁴⁷ Cortisol has been demonstrated to stimulate GH synthesis in somatotrophic cell lines and in pituitary slices through increases in rates of gene transcription and enhancement of the stability of mRNA.^{48,49} The time required for cortisol to enhance transcription of the GH gene is 1 to 2 hours, which is considerably longer than the time required for the action of TRH on prolactin gene transcription. Regulation of proinsulin biosynthesis appears to take place primarily at the level of translation.^{50,51} Within minutes after the plasma glucose level is raised, the rate of proinsulin biosynthesis increases 5- to 10-fold. Glucose acts

directly or indirectly to enhance the efficiency of initiation of translation of proinsulin mRNA.⁵²

Rapid metabolic regulation at the level of post-transcriptional processing of mRNA precursors has not been clearly established. However, alternative exon splicing plays a major role in the regulation of the formation of mRNAs during development (see “[Biologic Diversification](#)”). For example, the primary RNA transcripts derived from the calcitonin gene are alternatively spliced to provide two or more tissue-specific mRNAs that encode chimeric protein precursors with both common and different amino acid sequences, indicating that regulation takes place at the level of processing of the calcitonin gene transcripts.

In many instances, the level of gene expression under regulatory control is optimal for meeting the secretory and biosynthetic demands of the endocrine organ. For example, after a meal, there is an immediate requirement for the release of large amounts of insulin. This release depletes insulin stores of the pancreatic beta cells within a few minutes, but mechanisms that increase the translational

Figure 3-10 Potential control points in an endocrine cell for regulation of gene expression during hormone production. Specific effector substances bind to plasma membrane receptors (peptide effectors) or to cytosolic or nuclear receptors (steroids), which leads to initiation of a series of events that couple the effector signal with gene expression. Peptide effector–receptor complex interactions act initially through activation of adenylate cyclase (AC) coupled with a guanosine triphosphate-binding protein (G). Coupling factors and substances such as glucose, cyclic adenosine monophosphate, and cations activate protein kinases, resulting in a series of phosphorylations of macromolecules. Specific effectors for various endocrine cells appear to act at one or more of the indicated five levels of gene expression (see text for details), with the possible exception of post-translational processing of prohormones, for which no definite examples of metabolic regulation have yet been found.

efficiency of preformed proinsulin mRNA rapidly provide additional hormone.

Tissue-Specific Gene Expression

Differentiated cells have a remarkable capacity for selective expression of specific genes. In one cell type, a single gene may account for a large fraction of the total gene expression, and in another cell type, the same gene may be expressed at undetectable levels.

When a gene can be expressed in a particular cell type, the associated chromatin is loosely arranged; when the same gene is never expressed in a particular cell type, the chromatin organization is more compact. DNA within the chromatin of expressed genes is more susceptible to cleavage by deoxyribonuclease than is the DNA in tissues in which the genes are quiescent.⁵³⁻⁵⁵ Chromatin looseness may facilitate access of RNA polymerase to the gene for purposes of transcription. Inactive genes appear to have a higher content of methylated cytosine residues than the same genes in tissues in which they are expressed.^{56,57}

Determinants for the tissue-specific transcriptional expression of genes exist in control sequences that usually reside within 1000 base pairs of the 5'-flanking region of the transcriptional sequence. Enhancer sequences in animal cell genes were first described for immunoglobulin genes, a finding that extended the earlier observations of enhancer control elements in viral genomes.⁵⁸ Historically, the first clear demonstrations of these elements directing transcription to cells of distinct phenotypes came from studies of the comparative expression of two model genes, insulin and chymotrypsin, in the endocrine and exocrine pancreas, respectively.⁵⁹ The restricted expression of genes in a cell-specific manner is determined by the assembly of specific combinations of DNA-binding proteins on a predetermined array of control elements of the promoter regions of genes to create a transcriptionally active complex of proteins that includes the components of the general or basal transcriptional apparatus.

Epigenetic Inheritance of Phenotypic Traits

Darwinian selection is the generally recognized mechanism by which changes in the nucleotide sequences of genes result in patterns of gene expression that allow the resultant phenotype to better survive in a changing environment. These changes in gene sequences that lead to prosurvival phenotypes occur gradually, over hundreds of generations spanning thousands of years of evolution. However, genomic changes in gene expression in response to environmental changes may occur during development within a single generation by epigenetic mechanisms, independently of any nucleotide sequence changes in the DNA.⁶⁰ *Epigenetics* refers to the inheritable phenotypic changes that do not involve alterations in DNA, a nongenetic memory of gene expression functions imparted by environmental cues. Epigenetics defines a nongenetic memory of function that is transmitted from cellular generation to generation.⁶¹ The mechanism of epigenetic memory is beginning to be understood. It involves chromatin modifications—both modifications of cytosines in DNA and post-translational modifications of proteins that collectively define the structure of chromatin.

Broadly speaking, chromatin exists in two configurations that determine whether the involved genes are expressed (active) or are repressed (silent). The two configurations are densely packed *heterochromatin*, in which gene transcription is silent, and *euchromatin*, in which DNA and

proteins are loosely gathered, allowing access of transcription factors to DNA promoters of genes and active transcription. The protein components of chromatin consist of histones and nonhistone proteins.

The key to epigenetic memory, the collective state of expressed or repressed genes in the genome, lies with the methylation of DNA and the post-translational modifications of histones, predominantly by acetylation and methylation. These modifications are interpreted by an elaborate series of protein complexes that change the structure of chromatin and the activity of genes.⁶² The methylation of cytosines in DNA in the configuration of CpG sequences (*CpG islands*), represses gene transcription by impairing productive interactions of transcription factors with DNA promoter sequences. Histones can be grouped into four major classes: H2A, H2B, H3, and H4. Histones carry a strong positive charge because of their large content of the amino acids lysine and arginine. They bind firmly to negatively charged nucleic acids and phosphates of DNA, form heterochromatin, and thereby repress gene expression. The covalently modified histones bind to specific effector proteins that recognize them. Attachment of hydrophobic side chains to the positively charged lysines (and arginines) of histones reduces the positive charge and loosens binding to DNA. Such side chain modifications include acetylation, methylation, ADP-ribosylation, sumoylation, phosphorylation, and ubiquitination. Acetylation and methylation are predominant mechanisms of histone modification. DNA methylation is regulated by a family of cytosine-directed methylases and demethylases. Methylation and acetylation of histones is mediated by methyl and acetyl transferases, demethylases, and deacetylases.

The effects of DNA methylation and histone acetylation and methylation on gene expression are complex. DNA methylation usually is associated with gene silencing, histone acetylation with gene activation, and histone methylation with either silencing or activation. DNA methylation and histone methylation may bidirectionally regulate each other. For example, DNA methylation induces methylation of lysine 8 of histone 3 (H3K9), and, conversely, methylation of H3K9 enhances DNA methylation. Both DNA methylation and H3K9 methylation repress transcription, so they reinforce each other in silencing genes. These changes in chromatin modifications are durable; they can be passed from parent to daughter cells during cell division and, to some extent, can remain during meiosis. In this way, patterns of gene expression imparted by environmental influences are preserved during cell growth and reproduction.

An example of environmentally induced epigenetic modification of gene expression that is reflected in a modified disease phenotype is the remarkable reprogramming of the genome that takes place in utero in rat embryos subjected to nutrient deprivation by partial ligation of the uterine artery during the last 3 days of gestation (days 19 to 22).⁶³ The late prenatal, nutrient-deprived pups go on to progressively develop obesity, insulin resistance, severe diabetes, and premature death. Biochemical studies of the affected nutrient-deprived progeny show that key genes involved in insulin secretion and sensitivity are repressed by the transient nutrient deprivation. For example, mRNA levels for the transcription factor PDX1, which is critical for pancreatic beta cell growth and insulin production, is reduced as early as 24 hours after growth retardation, and histone H3 in the chromatin of the PDX1 promoter is hypomethylated on lysine 4 and hypoacetylated on lysine 9, defining a heterochromatin configuration and gene silencing. The growth and functions of beta cells are

curtailed by the nutrient deprivation to produce less insulin, because less insulin is needed and excessive insulin would be deleterious to the embryo. Likewise, the histones associated with the promoters of the liver genes *PPARGC1A* (formerly called *PGC1A*), which is involved in gluconeogenesis, and *CPT1A*, which is involved in fatty acid oxidation, are hyperacetylated, resulting in activation of these genes and loss of insulin regulation of glucose use and oxidation (i.e., insulin resistance).

The mechanisms by which acetylases, methylases, deacetylases, and demethylases are regulated remain unknown. One possibility is that intermediary metabolites formed in response to nutrient deprivation, such as acetyl coenzyme A, nicotinamide adenine dinucleotide, and S-adenosyl methionine, may modulate the relative activities of these important enzymes.

Transcription Factors in Developmental Organogenesis of Endocrine Systems

Certain families of transcription factors are critical for organogenesis and the development of the body plan. Among these are the homeodomain proteins⁶⁴ and the nuclear receptor proteins.⁶⁵⁻⁶⁷ The family of homeotic selector, or homeodomain, proteins is highly conserved throughout the animal kingdom from flies to humans. The orchestrated spatial and temporal expression of these proteins and the target genes that they activate determine the orderly development of the body plan of specific tissues, limbs, and organs. Similarly, the actions of families of nuclear receptors (e.g., steroid hormones, thyroid hormones, retinoic acid) are critical for normal development. Inactivating mutations in the genes encoding these essential transcription factors predictably result in loss or impairment of the development of the specific target organ.

This section describes three examples of impaired organogenesis attributable to mutations in essential transcription factors: partial anterior pituitary agenesis (*POU1F1*), pancreatic agenesis (*PDX1*), and adrenal and gonadal agenesis (*SF1* and *NROB1/DAX1*).

Partial Pituitary Agenesis

The transcription factor *POU1F1*, formerly called *Pit-1*, is a member of the *POU* family of homeodomain proteins.⁶⁸ *POU1F1* is a key transcriptional activator of the promoters of the genes that encode GH, prolactin, and thyroid-stimulating hormone- β , which are produced in the anterior pituitary somatotrophs, lactotrophs, and thyrotrophs, respectively. *POU1F1* is also the major enhancer activating factor for the promoter of the growth hormone-releasing factor receptor gene.⁶⁹ Mutations in *POU1F1* that impair its DNA-binding and transcriptional activation functions are responsible for the phenotype of the Jackson and Snell dwarf mice.⁶⁸

Mutations in the *POU1F1* gene have been found in patients with combined pituitary hormone deficiency, a condition in which there is no production of GH, prolactin, or thyroid-stimulating hormone, which results in growth impairment and mental deficiency.⁷⁰ In these individuals, hormone production by the other two of the five cell types of the anterior pituitary gland (including production of ACTH and the gonadotropins luteinizing hormone and follicle-stimulating hormone) remains unaffected.⁷⁰ The mutated *POU1F1* can bind to its cognate DNA control elements but is defective in *trans*-activating gene transcription. Furthermore, it acts as a dominant negative inhibitor of the actions of *POU1F1* on the unaffected allele.

Pancreatic Agenesis

The homeodomain protein called *pancreas duodenum homeobox 1* or *PDX1* (previously referred to as *STF1*, *IDX1*, or *IPF1*) appears to be responsible for the development and growth of the pancreas. Targeted disruption of the *Pdx1* gene in mice resulted in a phenotype of pancreatic agenesis.⁷¹ A child born without a pancreas was shown to be homozygous for inactivating mutations in the *PDX1* gene.⁷² Parents and ancestors who are heterozygous for the affected allele have a high incidence of type 2 diabetes mellitus, suggesting that a decrease in gene dosage of *PDX1* may predispose the individual to development of diabetes. The possibility that a mutated *PDX1* allele may be one of several “diabetes genes” is supported by the observation that *PDX1* and the helix-loop-helix transcription factors *E47* (*TCF3*) and $\beta 2$ (*TFB2M*) appear to be key upregulators of the transcription of the insulin gene.⁷³

Agenesis of the Adrenal Gland and Gonads

Two nuclear receptor transcription factors have been identified as critical for the development of the adrenal gland, the gonads, pituitary gonadotrophs, and the ventral medial hypothalamus. These nuclear receptors are *SF1* (steroidogenic factor 1)⁷⁴ and *NROB1* (also called *DAX1*, for dosage-sensitive sex reversal, adrenal hypoplasia congenita, X chromosome).⁷⁵ *SF1* binds to half-sites of estrogen response elements that bind estrogen receptors in the promoters of genes. *DAX1* binds to retinoic acid receptor (*RAR*) binding sites in promoters and inhibits *RAR* actions. Targeted disruption of *SF1* in mice results in a phenotype of adrenal and gonadal agenesis. Pituitary gonadotrophs are absent, and the ventral medial hypothalamus is severely underdeveloped.^{76,77}

Adrenal hypoplasia congenita is an X-linked developmental disorder of the human adrenal gland that is lethal if untreated. The gene responsible for adrenal hypoplasia congenita was identified by positional cloning and found to encode *NROB1/DAX1*, a member of the nuclear receptor proteins related to *RAR*.⁷⁵ Several inactivating mutations identified in the gene result in the syndrome of adrenal hypoplasia congenita and hypogonadotropic hypogonadism. Genetically defined and transmitted defects in the genes encoding the transcription factors *SF1* and *DAX1* result in profound arrest in the development of the target organs regulated by the hypothalamic-pituitary-adrenal axis involved in steroidogenesis: the adrenal gland (e.g., glucocorticoids, mineralocorticoids) and the gonads (e.g., estrogens, androgens).

Coupling of Effector Action to Cellular Response

Another mode of gene control consists of the induction and suppression of genes that are normally expressed in a specific tissue. These processes are at work in the minute-to-minute and day-to-day regulation of rates of production of the specific proteins produced by the cells (e.g., production of polypeptide hormones in response to extracellular stimuli).

At least two classes of signaling pathways—protein phosphorylation and activation of steroid hormone receptors by hormone binding—appear to be involved in the physiologic regulation of hormone gene expression. These two pathways mediate the actions of peptide and steroid hormones, respectively. Peptide ligands bind to receptor complexes on the plasma membrane, which results in enzyme activation, mobilization of calcium,

formation of phosphorylated nucleotide intermediates, activation of protein kinases, and phosphorylation of specific regulatory proteins such as transcription factors (see Chapter 5).^{77,79}

Because of their hydrophobic composition, steroidal compounds readily diffuse through the plasma membrane, bind to specific receptor proteins, and interact with other macromolecules in the nucleus, including specific domains on the chromatin located in and around the gene that is activated (see Chapter 4).⁶⁵⁻⁶⁷ Calcium and phosphorylated nucleotides such as cyclic adenosine monophosphate (cAMP), adenosine triphosphate, and guanosine triphosphate appear to have important functions in secretory processes. In particular, fluxes of calcium from the extracellular fluid into the cell and from intracellular organelles (e.g., ER) into the cytosol are closely coupled to secretion.^{80,81}

The many cellular signaling pathways that involve protein phosphorylations are complex. They typically consist of sequential phosphorylations and dephosphorylations of molecules, referred to as *protein kinase cascades* or *phosphatase cascades*.⁸² These cascades are initiated by hormones, sensor molecules known as *ligands* that bind to and activate receptors located on the surface of cells, resulting in the generation of small second-messenger molecules such as cAMP, diacylglycerol, or calcium ions. These second messengers activate protein kinases that phosphorylate and thereby activate key target proteins (Fig. 3-11). The final step in the signaling pathways is the phosphorylation and activation of important transcription factors resulting in gene expression or repression.

The identities of some phosphoproteins have been elucidated. A specific group of transcription factors, DNA-binding proteins, interacts with cAMP-responsive and phorbol ester-responsive DNA elements to stimulate gene transcription mediated by the cAMP-protein kinase A, diacylglycerol-protein kinase C, and calcium-calmodulin signal transduction pathways (see Fig. 3-11). These proteins are encoded by a complex family of genes and bind to the

DNA elements in the form of heterodimers or homodimers through a coiled-coil helical structure known as a *leucine zipper motif*.⁸³ Phosphorylation of these proteins modulates dimerization, DNA recognition and binding, and transcriptional *trans*-activation activities. Phosphorylation of the protein substrates may change their conformations and activate the proteins, which then interact with coactivator proteins such as the cAMP response element-binding (CREB) protein and the protein components of the basal transcriptional machinery, allowing RNA polymerase to initiate gene transcription.⁸⁴

Second messengers activate serine/threonine kinases, which phosphorylate serine or threonine residues (or both) on proteins, whereas the receptor kinases are tyrosine-specific kinases that phosphorylate tyrosine residues.^{82,85} Examples of receptor tyrosine kinases are growth factor receptors such as those for insulin, insulin-like growth factor (IGF), epidermal growth factor, and platelet-derived growth factor. Receptors in the cytokine receptor family, which include leptin, GH, and prolactin, activate associated tyrosine kinases in a variation on the theme.

The different types of signal transduction pathways are described as more or less distinct pathways for semantic purposes. In reality, there is considerable cross-talk among the different pathways that occur developmentally and in cell type-specific settings. An active area of research in endocrine systems is attempting to understand these complex interactions among different signal transduction pathways. Although the growth factor and cytokine receptors are similar in some respects, they differ in other respects. For example, growth factor receptor tyrosine kinases activate transcription factors through cascades that involve both tyrosine phosphorylation and serine/threonine kinases such as mitogen-activated protein kinases, whereas the Janus kinases (JAKs), activated by cytokine receptors, directly tyrosine phosphorylate the signal transducer and activator of transcription (STAT) factors.^{85,86}

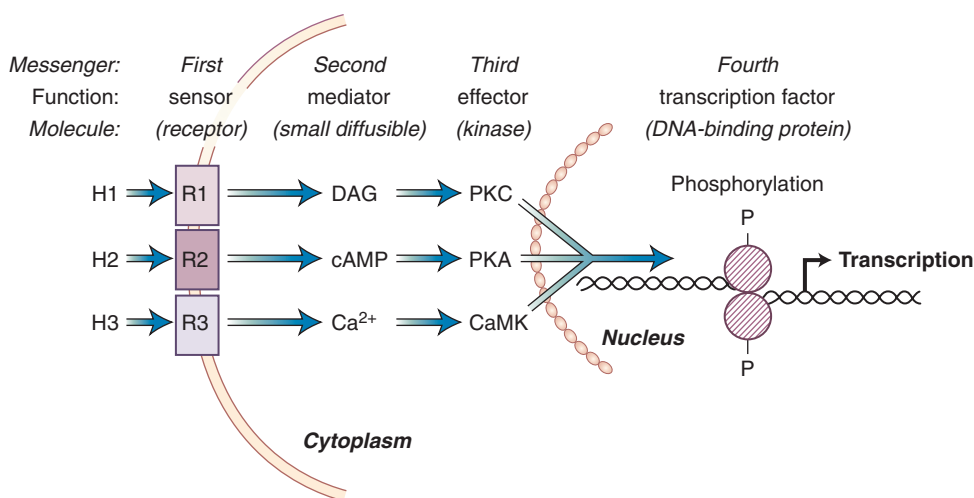

Figure 3-11 Three cell surface receptor-coupled signal transduction pathways involved in the activation of a superfamily of nuclear transcription factors. Peptide hormone molecules (H1, H2, and H3) interact with sensor receptors (R1, R2, and R3) coupled to the diacylglycerol (DAG)-protein kinase C (PKC), cyclic adenosine monophosphate (cAMP)-protein kinase A (PKA), and calcium-calmodulin pathways in which small, diffusible second-messenger molecules are generated (DAG, cAMP, and Ca²⁺, respectively). The third messengers, or effector protein kinases, are generated and phosphorylate transcription factors such as members of the CREB/ATF and JUN/AP-1 families of DNA-binding proteins to modulate DNA-binding affinities or transcriptional activation, or both. The various proteins bind as dimers determined by a poorly understood code that is not promiscuous (i.e., only certain homodimer or heterodimer combinations are permissible). AP-1, activator protein 1; ATF, activating transcription factor; CaMK, calcium/calmodulin-dependent protein kinase; CREB, cAMP response element-binding protein.

BIOLOGIC DIVERSIFICATION

In addition to providing control points for the regulation of gene expression, the various steps involved in transfer of information encoded in the DNA of the gene to the final bioactive protein are a means for diversification of information stored in the gene (Fig. 3-12). Five steps in gene expression can be arbitrarily described: gene duplication and copy number, transcription, post-transcriptional RNA processing, translation, and post-translational processing.

Gene Duplications

At the level of DNA, diversification of genetic information comes about by way of gene duplication and amplification. Many of the polypeptide hormones are derived from families of multiple, structurally related genes. Examples include the growth hormone family (GH, prolactin, and placental lactogen), the glucagon family (glucagon, vasoactive intestinal peptide, secretin, gastric inhibitory peptide, and growth hormone-releasing hormone), and the glycoprotein hormone family (thyrotropin, luteinizing hormone, follicle-stimulating hormone, and chorionic gonadotropin).

A remarkable example of diversification at the level of gene amplifications is the extraordinarily large number of genes encoding the pheromone and odorant receptors.⁸⁷ As many as 1000 of these receptor genes may exist in mouse and rat genomes, each receptive to a particular odorant ligand. Over the course of evolution, an ancestral gene encoding a prototypic polypeptide representative of each of these families was duplicated one or more times, and through mutation and selection, the progeny proteins of the ancestral gene assumed different biologic functions.

The exonic-intronic structural organization of the genomes of higher animals lends itself to gene recombination and RNA copying of genetic sequences with subsequent reintegration of DNA reverse-transcribed sequences back into the genome, resulting in rearrangement of transcriptional units and regulatory sequences.^{88,89}

Transcription

In addition to duplication of genes and their promoters, another way to create diversity in expression is at the level of gene transcription, by providing genes with alternative promoters⁹⁰ and by using a large array of *cis*-regulatory elements in the promoters, governed by complex combinations of transcription factors.

Alternative Promoters

Many of the genes encoding hormones and their receptors use more than one promoter during development or when expressed in different tissue types. Employment of alternative promoters results in the formation of multiple transcripts that are different at their 5' ends (Fig. 3-13). It is presumed that some genes have multiple promoters because they provide flexibility in the control of expression of the genes. For example, in some cases, expression of genes in more than one tissue or developmental stage requires distinct combinations of tissue-specific transcription factors. This flexibility enables genes in different cell types to respond to the same signal transduction pathways or genes in the same cell type to respond to different signal transduction pathways. A single promoter may not be adequate to respond to a complex array of transcription factors and a changing environment of cellular signals.

The organization of alternative promoters in genes manifests in several patterns within exons or introns in the 5'

Figure 3-12 Levels in expression of genetic information at which diversification of information encoded in a gene may take place. The three major levels of genetic diversification are (1) gene duplication, a process that occurs in terms of evolutionary time; (2) variation in the processing of ribonucleic acid (RNA) precursors, which results in formation of two or more messenger RNAs (mRNAs) by way of alternative pathways of splicing of transcript (see Figs. 3-13 and 3-14); and (3) use of alternative patterns in processing of protein biosynthetic precursors (polyproteins or prohormones). These mechanisms provide a means for diversification of gene expression at levels of deoxyribonucleic acid (DNA), RNA, or protein. One or a combination of these processes leads to formation of the final biologically active peptide or hormone. Loops depicted in transcripts denote introns; in protein structures, the *stippled*, *shaded*, and *open* areas denote exons. A, B, and C represent splicing intermediates that lead to two distinct transcripts (1, 2) from one precursor. E1-4 indicate portions of polyproteins cleaved post-translationally as indicated. I, II, and III indicate multiple transcribed genes following gene duplication.

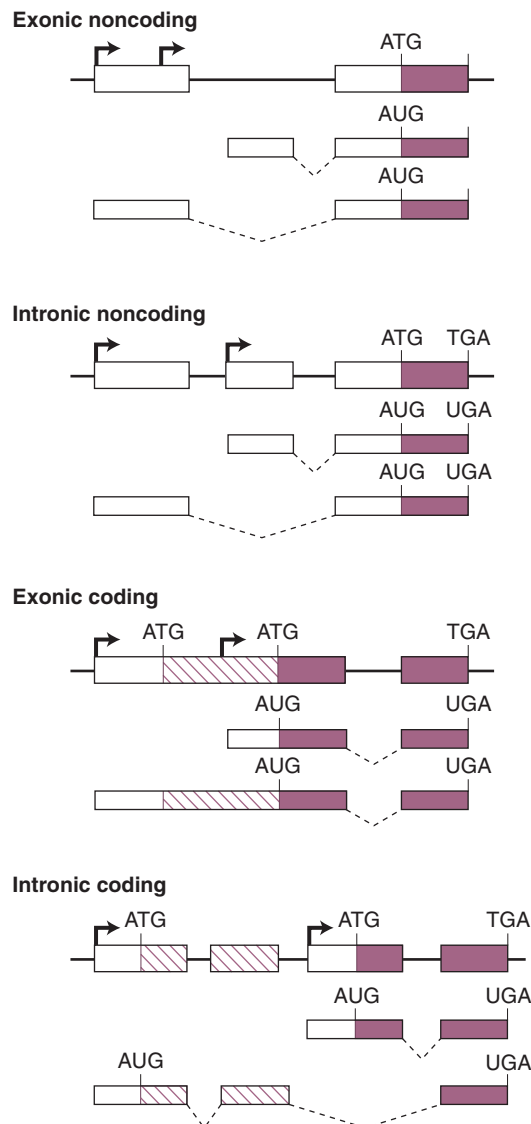

Figure 3-13 Use of alternative promoters in the expression of genes as a means to generate biologic diversification of gene expression. The use of alternative promoters allows a gene to be expressed in a variety of contexts that alter the properties of the messenger ribonucleic acid (mRNA) that is expressed. Alternative promoter use may render the mRNA more or less stable, affect translational efficiencies, or switch the translation of one protein isoform to another. The use of alternative promoters in genes characteristically occurs during development or, after development is completed, to designate tissue-specific patterns of expression of the gene. Exons are shown as boxes whose protein-coding regions are shaded. Introns are designated by horizontal lines. Dashed lines indicate introns that are spliced out. (Adapted from Ayoubi TAY, Van De Ven WJM. Regulation of gene expression by alternative promoters. *FASEB J.* 1996;10:453-460.)

noncoding sequence or the coding sequence (see Fig. 3-13). The most common occurrence of alternative promoters is within the 5' noncoding or leader exons. Use of different promoters in the 5' untranslated region of a gene, often accompanied by alternative exon splicing, results in the formation of mRNAs with different 5' sequences. The alternative use of promoters in 5' leader exons can affect gene expression and generate diversity in several ways, including developmental stage-specific and temporal expression of genes, tissue-type specificity of expression, levels of expression, responsiveness of gene expression to specific

metabolic signals conveyed through signal transduction pathways, stability of the mRNAs, efficiencies of translation, and structures of the N-termini of proteins encoded by the genes.⁹⁰

Examples of genes that use alternative 5' leader promoters during development are those encoding IGF1, IGF2, the RARs, and glucokinase, all of which are regulated by multiple promoters that are active in a variety of embryonic and adult tissues and are subject to developmental and tissue-specific regulation.⁹⁰ During fetal development, promoters P2, P3, and P4 of the *IGF2* gene are active in the liver. These promoters are shut off after birth, at which time the P1 promoter is activated. The P1 and P2 promoters of the *IGF1* gene are differentially responsive to GH; P2 expressed in liver is responsive to GH, whereas P1 expressed in muscle is not.

The RAR exists in alpha, beta, and gamma isoforms (RARA, RARB, and RARG), encoded by separate genes that give rise to at least 17 different mRNAs generated by a combination of multiple promoters and alternative splicing.⁹¹ The RAR isoforms have different specificities for retinoic acid-responsive promoters, different affinities for ligand isoforms, and different *trans*-activating capabilities. The various RAR isoforms are expressed at different times in different tissues during development. It has been proposed that the multiple RAR isoforms provide a means of achieving a diverse set of cellular responses to a single ligand, retinoic acid.⁹¹

Glucokinase is an example of the alternative use of 5' leader promoters that have different levels of metabolic responsiveness.⁹² Expression of glucokinase in pancreatic beta cells and some other neuroendocrine cells uses an upstream promoter (1 β), whereas in liver, a promoter (IL) located 26 kilobases downstream of the 1 β promoter is used exclusively. In beta cells, expression of the glucokinase gene is apparently not responsive to hormones. In liver expression mediated by the IL promoter, it is intensely upregulated by insulin and downregulated by glucagon.

The α -amylase gene provides an example in which two alternative promoters in the 5' noncoding exons expressed in two different tissues have dramatically different strengths of expression.⁹⁰ A strong upstream promoter directs expression within the parotid gland, whereas weak expression is directed by an alternative downstream promoter in liver.

Examples of the use of alternative promoters in the coding regions of genes include the progesterone receptor (PR) and the transcription factor, cAMP response element modulator (CREM). In both of these cases, different protein isoforms are produced that have markedly different functional activities. The genes encoding the chicken and human PRs express two isoforms of the receptor.⁹³ Isoform A initiates translation at a methionine residue located 164 amino acids downstream from the methionine that initiates the translation of the longer form, isoform B. Analyses of the mechanisms responsible for the synthesis of the two isoforms revealed that two promoters exist in the human PR gene, one upstream of the 5' leader exon and the other in the first protein-coding exon. The two isoforms of the human PR differ markedly in their abilities to *trans*-activate transcription from different progesterone-responsive elements (PREs). Both of the human PR isoforms equivalently activate a canonical PRE. Isoform B is much more efficient than A at activating the PRE in the mouse mammary tumor virus promoter, whereas isoform A, but not B, activates transcription from the ovalbumin promoter.⁹³

Use of an alternative intronic promoter within the protein-coding sequence of a gene is exemplified by *CREM*.⁹⁴ The *CREM* gene employs a constitutively active,

unregulated promoter (P1) that encodes predominantly activator forms of CREM and an internal promoter (P2) located in the fourth intron that is regulated by cAMP signaling and encodes a repressor isoform known as *inducible cAMP early response* (ICER). The remarkable complexity of the alternative mechanisms of expression of the CREM and CREB genes is discussed later.

Diversity of Transcription Factors

Diversity at the level of gene transcription can be created by the interplay of multiple transcription factors on multiple *cis*-regulatory sequences. The promoters of typical genes may contain 20 to 30 or more *cis*-acting control elements in the form of enhancers or silencers. These control elements may respond to ubiquitous transcription factors found in all cell types and to cell type-specific factors.

Unique patterns of control of gene expression can be affected by several mechanisms acting in concert. The spacing, relative locations, and juxtapositioning of control elements with respect to each other and to the basal transcriptional machinery influence levels of expression. Transcription factors often act in the form of dimers or higher oligomers among factors of the same or different classes. A given transcription factor may act as either an activator or a repressor, according to the existing circumstances. The ambient concentrations of transcription factors within the nucleus, in conjunction with their relative DNA-binding affinities and *trans*-activation potencies, may determine the levels of expression of genes.

Post-transcriptional Processing: Alternative Exon Splicing

Identification of the mosaic structure of transcriptional units encoding polypeptide hormones and other proteins that consist of exons and introns raised the possibility that the use of alternative pathways in RNA splicing could provide informationally distinct molecules. Different proteins could arise by inclusion or exclusion of specific exonic segments or by use of parts of introns in one mRNA as exons in another mRNA. Differences in the splice sites would result in expression of new translational reading frames. Alternative splicing uses two distinct mechanisms (Fig. 3-14). One is *exon skipping*, or switching in or out of exons. The other, known as *intron slippage*, includes use of part of an intron in an exon, splicing out of part of an exon along with the intron, and use of a “coding” intron.

Both mechanisms can generate diversity in endocrine systems. Included among the genes encoding prohormones in which the pre-mRNAs are alternatively spliced by exon skipping or switching are those for procalcitonin/calcitonin gene-related peptide, prosubstance P/K, and the prokininogens. Alternative processing of the RNA transcribed from the calcitonin gene results in production of an mRNA in neural tissues that is distinct from that formed in the C cells of the thyroid gland.⁹⁵ The thyroid mRNA encodes a precursor to calcitonin, whereas the mRNA in the neural tissues generates the neuropeptide, calcitonin gene-related peptide. Immunocytochemical analyses of the distribution of the peptide in brain and other tissues suggest functions for the peptide in perception of pain, ingestive behavior, and modulation of the autonomic and endocrine systems.

Splicing of the RNA precursor that encodes substance P can take place in at least two ways.⁹⁶ One splicing pattern results in the mRNA that encodes substance P and another peptide called substance K, in a common protein precursor. Other mRNAs are apparently spliced to exclude the coding sequence for substance K. An alternative RNA splicing pattern also occurs in the processing of transcripts arising

Exon skipping/switching

Intron slippage

Figure 3-14 Alternative exon splicing provides a means to generate biologic diversification of gene expression. Mechanisms of exon skipping or switching and intron slippage are frequently used in the alternative processing of precursor-messenger ribonucleic acids (mRNAs) to provide unique mRNAs and encoded proteins during development and in a tissue-specific pattern of expression in fully differentiated tissues or organs. Exons are shown as boxes with protein-coding regions shaded to designate origin of protein isoforms. Introns are depicted as horizontal lines. Dashed lines denote spliced-out introns.

from the gene encoding bradykinin.⁹⁷ The high-molecular-weight and low-molecular-weight kininogens are translated from mRNAs that differ in their alternative use of 3'-end exons encoding the C-termini of the prohormones—a situation similar to that found in the transcription of the calcitonin gene.

Other examples of genetic diversification arise from programmed flexibility in the choice of splice acceptor sites within coding regions (i.e., intron slippage), which allows an array of coding sequences (exons) to be put together in a number of useful combinations. For example, the coding sequences of the GH, lutropin-choriogonadotropin,⁹⁸ and leptin receptors⁹⁹ can be brought together in two different ways, one to include and the other to exclude an exonic coding sequence that specifies the transmembrane-spanning domains of the polypeptide chains that anchor the receptors to the surface of cells. If mRNA splicing excludes the anchor's peptide sequence, a secreted rather than a surface protein is produced.

Translation

The process of translation provides a fourth level for creation of diversity in gene expression. The rate of translational initiation can be regulated, as discussed earlier; this is typified by the proinsulin and prohormone convertase mRNAs, in which translation is augmented by glucose and cAMP. Molecular diversity of translation is generated by the developmentally regulated use of alternative translation initiation (start) codons (i.e., methionine [AUG] codons). The mechanism of translation initiation involves assembly

Figure 3-15 Alternative translational initiation sites are used to change the coding sequences of messenger ribonucleic acids to encode different protein isoforms. The two mechanisms shown involve loose scanning and reinitiation of translation (see text for details).

of the 40S ribosome subunit on the 5' methyl guanosine cap of the mRNA.¹⁰⁰ The ribosome subunit then scans 5' to 3' along the mRNA until it encounters an AUG sequence in a context of surrounding nucleotides favorable for initiation of protein synthesis. On encountering a favorable AUG, the subunit pauses and recruits the 60S subunit and a number of other essential translation initiation factors, allowing the polymerization of amino acids.

The use of an alternative downstream start codon for translation can be achieved by the mechanisms of loose scanning and reinitiation (Fig. 3-15).¹⁰¹ Loose scanning is believed to occur when the most 5' AUG codon is not in a strongly favorable context; it allows the 40S ribosomal subunit to continue scanning until it encounters a more favorable AUG downstream. In the loose scanning mechanism, both translational start codons are used. In contrast, the mechanism of translational reinitiation involves the termination of translation followed by reinitiation of translation at a downstream start codon. Two proteins are encoded from the same mRNA by a start-and-stop mechanism.

The process of translational reinitiation can occur by continued scanning of the 40S ribosomal subunit after termination of translation followed by reinitiation, as in loose scanning, or by complete dissociation of the ribosomal subunits at the time of termination followed by complete reassembly at a downstream start codon, referred to as an *internal ribosomal entry site* (IRES). This use of alternative translation start codons occurs in mRNAs encoding certain classes of transcription factors, as illustrated by the basic leucine zipper (bZIP) proteins CREB, CREM, and the alpha (CEBPA) and beta (CEBPB) isoforms of CCAAT/enhancer binding proteins (CEBPs). In all four of these DNA-binding proteins, the alternative use of internal start codons results in a switch from activators to repressors.

The CREB gene uses translational reinitiation by the somewhat novel mechanism of alternative exon switching that occurs during spermatogenesis.¹⁰² At developmental stages IV and V of the seminiferous tubule of the rat, an exon called *exon W* is spliced into the CREB mRNA. Exon W introduces an in-frame stop codon, thereby terminating translation approximately 40 amino acids upstream of the DNA-binding domain.^{103,104} Translation is then reinitiated at each of two downstream start codons, resulting in the synthesis of two repressor or inhibitor isoforms of CREB, called I-CREBs. The I-CREBs are powerful dominant negative inhibitors of activator forms of CREB and CREM

because they consist of the DNA-binding domain devoid of any *trans*-activation domains.¹⁰²⁻¹⁰⁴ The function of the N-terminal truncated protein consisting of the activation domains devoid of the DNA-binding domain is unknown. It has been postulated that the role of alternative splicing of exon W in the CREB pre-mRNA is to interrupt a forward positive-feedback loop during spermatogenesis.

The CREM, CEBPA, and CEBPB mRNAs use alternative downstream start codons to synthesize repressors during development. Like the I-CREBs, these repressors consist of the DNA-binding domains and lack *trans*-activation domains. The CREM repressor (S-CREM) is expressed during brain development.⁹⁴ The CEBPA-30 and CEBPA -20 isoforms are expressed during differentiation of adipoblasts to adipocytes, and the CEBP repressor, liver inhibitory protein, is expressed during the development of the liver.⁹⁴

Post-translational Processing

A fifth level of gene expression at which diversification of biologic information can take place is post-translational processing. Many precursors of polypeptide hormones, particularly those encoding small peptides, contain multiple peptides that are cleaved during post-translational processing of the prohormones.¹⁰⁵ Certain polypeptide precursors, however, contain several copies of the peptide. Examples of prohormones that contain multiple identical peptides are the precursors encoding TRH¹⁰⁶ and the α -factor of yeast,¹⁰⁷ each of which contains four copies of their respective peptide. Polypeptides that contain several distinct peptides include proenkephalins,¹⁰⁸ POMC,¹⁰⁹ and proglucagon.¹¹⁰

In many instances, biologic diversification at the level of post-translational processing occurs in a tissue-specific manner. The processing of POMC differs markedly in the anterior and intermediate lobes of the pituitary gland. In the anterior pituitary, the primary peptide products are ACTH and β -endorphin, whereas in the intermediate lobe of the pituitary, one of the primary products is α -melanocyte-stimulating hormone. The smaller peptides produced are extensively modified by acetylation and phosphorylation of amino acid residues.

The processing of proglucagon in the pancreatic alpha cells and in the intestinal L cells is different (see Fig. 3-15).⁴² In the pancreatic alpha cells, the predominant bioactive product of the processing of proglucagon is glucagon itself; the two glucagon-like peptides are not processed efficiently from proglucagon in the alpha cells and are biologically inactive by virtue of having N-terminal and C-terminal extensions. In the intestinal L cell, the glucagon immunoreactive product is glicentin, a molecule that consists of the N-terminal extension of the proglucagon plus glucagon and the small C-terminal peptide known as intervening peptide 1. Because glicentin has no glucagon-like biologic activity, the bioactive peptide (or peptides) in the intestinal L cells must be one or both of the glucagon-like peptides. In fact, GLP1(7-37), the 31-amino-acid shortened form of glucagon-like peptide 1, is a potent insulinotropic hormone in its actions of stimulating insulin release from pancreatic beta cells.¹¹¹ This peptide is released from the intestines into the bloodstream in response to oral nutrients and appears to be a potent intestinal incretin factor implicated in the augmented release of insulin in response to oral compared with systemic (intravenous) nutrients. The potential for diversification of biologic information provided by the alternative pathways of gene expression is especially impressive because these pathways can occur in multiple combinations.

Small Regulatory RNAs: MicroRNAs and Small Interfering RNAs

The estimated 25,000 protein-coding genes contained in the human genome comprise only 1.25% of transcribed sequences. More than 98% of the transcriptional output of the genome consists of non-protein-coding, potentially regulatory RNAs.¹¹² The transcription of non-protein-coding RNAs from intronic and intergenic regions of the genome has been recognized for several decades, but it was thought to represent “transcriptional noise,” the production of transcripts without function from so-called selfish DNA (i.e., DNA that replicates itself but has no function). In the past few years, however, important functions in development and disease have been identified for the class of small (21 to 25 nucleotides) transcribed RNAs known as *microRNAs* (miRNAs) and *small interfering RNAs* (siRNAs). These small regulatory RNAs negatively regulate gene expression at the post-transcriptional level by antisense hybridization to mRNAs. This process either destabilizes mRNAs or inhibits the translation of mRNAs into proteins. About 1000 miRNAs and several thousand siRNAs have been identified in mammalian cells. Between 1% and 3% of the genome encodes small regulatory RNAs, and they are thought to be involved in the regulation of up to 30% of the protein-coding genes.¹¹³ One miRNA or siRNA can repress the expression of as many as 100 mRNAs. Although it was initially thought that small regulatory RNAs were ubiquitously expressed in tissues, it is now appreciated that their expression is highly regulated and is cell and tissue specific. These small regulatory RNAs play crucial roles in the regulation of gene expression during embryogenesis and organogenesis and in the control of cell proliferation, apoptosis, differentiation, lineage commitment, and metabolism.

The genes encoding miRNAs and siRNAs are transcribed as hairpin-looped RNA precursors (referred to as *primary miRNAs* or *pri-miRNAs*); these are initially cleaved in the nucleus by Drosha, a ribonuclease that removes a stem loop, thereby producing an intermediate pre-miRNA hairpin of about 70 nucleotides. These duplex pre-miRNA intermediates are exported from the nucleus by the proteins Exportin 5 and RAN-GTP to the cytoplasm, where they are cleaved by the endonuclease Dicer to form the active miRNAs of about 22 nucleotides that become part of the RNA-induced silencing complex (RISC). The duplex miRNAs are bound by the protein argonaute 2 (EIF2C2). One of the strands is eliminated, and the other (antisense) strand is retained as the mature miRNA. MiRNAs function by imperfect base pairing to the 3' untranslated regions of their target mRNAs, resulting in mRNA degradation or inhibition of translation. MiRNAs are expressed in spatiotemporal patterns to regulate biologic processes at distinct stages of development. As a consequence of their highly specific expression patterns, miRNAs have been implicated in several diseases, including cancer, neurologic disorders, asthma, cardiovascular disorders, viral infections, and diabetes.

MiRNAs may be involved in epigenetic programming of the genome. Convincing evidence indicates that miRNAs in plants and worms have a role in transcriptional gene silencing and do so by contributing to the regulation of histone methylation. A role for miRNAs in gene silencing in mammalian cells is controversial. However, studies suggest that argonaute 2 is required for transcriptional silencing in human cells.¹¹⁴

The importance of miRNAs in diseases of endocrine systems has been investigated. Diabetes is a complex endocrine disease involving myriad factors that modulate the

growth, survival, and regeneration of the insulin-producing beta cells of the pancreas and the sensitivities of peripheral tissues to the actions of insulin. One revealing study demonstrated the importance of miRNAs in the development of the endocrine cells of the pancreas through knockout of Dicer.¹¹⁵

Low Numbers of Expressed Genes in Murine and Human Genomes

Sequencing of the human and mouse genomes revealed that each contain approximately 30,000 genes. This number was viewed as remarkably low because the number of genes in the yeast (*Saccharomyces cerevisiae*), worm (*Caenorhabditis elegans*), and fly (*Drosophila melanogaster*) genomes is about 20,000. However, tissue-specific alternative exon splicing and alternative promoter use occur much more frequently in humans and mice than in yeast, worms, and flies. The complexities of the mRNAs expressed in humans and mice are exemplified by the growing database of expressed sequence tags, and it seems reasonable to extrapolate that the human genome may express as many as 100,000 to 200,000 mRNAs that encode proteins with distinct, specific functions. This interpretation is based on the observation that alternative exon splicing and promoter are 5 to 10 times more frequent in higher vertebrate mammals than in yeasts and flies.

Genome-Wide Association Studies for Identification of Complex-Trait Disease Genes

Determination of the nucleic sequence of the human genome and mapping of the locations of expressed genes have created opportunities for the identification of genes responsible for complex-trait diseases,^{116,117} such as diabetes, obesity, hypertension, asthma, schizophrenia, and bipolar disease. The genetic background of complex-trait diseases consists of multiple genes that collectively account for the disease phenotype. Genome-wide association studies (GWAS) enable identification of marker loci that co-segregate with the disease trait loci and association of the marker with risk for the disease. GWAS do not necessarily reveal the cause of disease, but they can identify gene loci that modify risk for the development of disease.

Association studies are based on the assumption that recombination (rearrangements) of DNA sequences in the genome are relatively slow to occur in the population, so that experimentally detectable marker loci consisting of single-nucleotide polymorphisms (SNPs) remain in place with respect to the disease loci. A large population (1000 to 10,000 individuals) with a high prevalence of the disease trait phenotype can be segregated by the presence or absence of the disease trait into cases and controls, respectively. The DNA from cases is screened for the presence of SNPs by high-output DNA array analyses using common SNPs present in the population genome. There are an estimated 10 million random polymorphisms in the genomes of the general human population (approximately 1 SNP per 100 base pairs of DNA).

Currently available high-density SNP libraries contain up to 770,000 SNPs spanning 74% of the genome, making it possible to identify specific SNPs that lie near the disease locus being studied.¹¹⁸ Examination of maps of known genes in the region of the associated SNP or SNPs can help to identify potential candidate genes that may be associated with the disease. The polymorphism may represent mutation in the protein-coding region (exons) of the disease gene

itself, but more often, the SNPs reside in regions of DNA within the gene (i.e., introns) or flanking the gene.

GWAS have identified many genes potentially associated with disease and have provided insights into pathogenesis and possible drug targets. Because of the limitations of the method—the need for very large study populations and the fact that only alleles associated with common SNPs in the population are identified—only a modest fraction of the genetic contribution to common diseases has been delineated.¹¹⁹⁻¹²¹

Type 2 diabetes provides a useful example of what GWAS have accomplished. Screening of large populations in which the prevalence of type 2 diabetes is high (approaching 10%) has uncovered 19 candidate genes to date.¹²² One of these genes, the transcription factor TCF7L2, is strongly associated with the existence and predictive development of insulin-deficient type 2 diabetes in multiple populations. Carriers of the TCF7L2 risk alleles have impaired glucose-stimulated insulin secretion and diminished augmentation of insulin secretion by incretin hormones such as GLP1 and gastric inhibitory polypeptide.¹²³ TCF7L2 is the predominant DNA-binding protein component of beta-catenin/TCF regulators of gene transcription in beta cells, and beta-catenin/TCF7L2 constitutes the downstream effector of the WNT signaling pathway stimulated by the incretin hormone GLP1 and the chemokine CXCL12 (formerly called SDF1).¹²⁴ WNT signaling mediated by GLP1 and CXCL12 is required for beta cell growth and survival, respectively.

ACKNOWLEDGMENTS

I am indebted to the members of the laboratory whose forbearance and helpful discussions of this chapter were invaluable. I thank Apolo Ndyabahika for help in preparation of the manuscript.

CHAPTER

4

Mechanism of Action of Hormones That Act on Nuclear Receptors

MITCHELL A. LAZAR

Hormones can be divided into two groups on the basis of where they function in a target cell. The first group includes hormones that do not enter cells; instead, they signal by means of second messengers generated by interactions with receptors at the cell surface. All polypeptide hormones (e.g., growth hormone), monoamines (e.g., serotonin), and prostaglandins (e.g., prostaglandin E_2), use cell surface receptors (see Chapter 5). The second group, the focus of this chapter, includes hormones that can enter cells. These hormones bind to intracellular receptors that function in the nucleus of the target cell to regulate gene expression. Classic hormones that use intracellular receptors include thyroid and steroid hormones.

Hormones serve as a major form of communication between different organs and tissues. They allow specialized cells in complex organisms to respond in a coordinated manner to changes in the internal and external environments. Classic endocrine hormones are secreted by endocrine glands and are distributed throughout the body through the bloodstream. These hormones were discovered by purifying the biologically active substances from clearly definable glands.

Numerous other signaling molecules share with thyroid and steroid hormones the ability to function in the nucleus to convey intercellular and environmental signals. Not all of these molecules are produced in glandular tissues. Although some signaling molecules, such as classic endocrine hormones, arrive at target tissues through the bloodstream, others have paracrine functions (i.e., acting on adjacent cells) or autocrine functions (i.e., acting on the cell of origin).

In addition to the classic steroid and thyroid hormones, lipophilic signaling molecules that use nuclear receptors include derivatives of vitamins A and D, endogenous metabolites such as oxysterols and bile acids, and non-natural chemicals encountered in the environment (i.e., xenobiotics). These molecules are referred to as *nuclear receptor ligands*. The nuclear receptors for all of these signaling molecules are structurally related and are collectively referred to as the *nuclear receptor superfamily*.¹⁻³ The study of these receptors is a rapidly evolving field, and more detailed information can be obtained by visiting the Nuclear Receptor Signaling Atlas web site (<http://www.nursa.org> [accessed September 2010]).

LIGANDS THAT ACT THROUGH NUCLEAR RECEPTORS

General Features of Nuclear Receptor Ligands

Unlike polypeptide hormones that function through cell surface receptors, no ligands for nuclear receptors are directly encoded in the genome. All nuclear receptor ligands are small (molecular mass <1000 d) and lipophilic, enabling them to enter cells by passive diffusion, although in some cases, a membrane transport protein is involved. For example, several active and specific thyroid hormone transporters have been identified, including monocarboxylate transporter 8 (MCT8), MCT10, and organic anion transporting polypeptide 1C1 (OATP1C1).^{4,5} The lipophilicity of nuclear receptor ligands allows them to be absorbed from the gastrointestinal tract, facilitating their use in replacement or pharmacologic therapies for various disease states.

Another common feature of naturally occurring nuclear receptor ligands is that all are derived from dietary, environmental, or metabolic precursors. In this sense, the function of these ligands and their receptors is to translate cues from the external and internal environments into changes in gene expression. Their critical role in maintaining homeostasis in multicellular organisms is highlighted by the fact that nuclear receptors are found in all vertebrates and insects but not in single-cell organisms such as yeast.⁶

Because nuclear receptor ligands are lipophilic, most are readily absorbed from the gastrointestinal tract. This makes nuclear receptors excellent targets for pharmacological interventions. In addition to natural ligands, many drugs in clinical use target nuclear receptors, ranging from those used to treat specific hormone deficiencies to those used to treat common multigenic conditions such as inflammation, cancer, and type 2 diabetes.

Subclasses of Nuclear Receptor Ligands

One classification of nuclear receptor ligands is outlined in Table 4-1 and is described in the following paragraphs.

Classic Hormones

The classic hormones that use nuclear receptors for signaling are thyroid hormone and steroid hormones. Steroid hormones include cortisol, aldosterone, estradiol, progesterone, and testosterone. In some cases (e.g., thyroid hormone receptor α and β genes [*THRA* and *THRB*], estrogen receptor α and β genes [*ESR1* and *ESR2*]), there are multiple receptor genes that encode multiple receptors. Multiple receptors for the same hormone can also be derived from a single gene by alternative promoter usage or by alternative splicing (e.g., *THRB1* and *THRB2*).

Some receptors can mediate the signals of multiple hormones. For example, the mineralocorticoid receptor, also known as the aldosterone receptor or nuclear receptor 3C2 (NR3C2), has equal affinity for cortisol⁷ and probably functions as a glucocorticoid receptor in some tissues, such as the brain; likewise, the androgen receptor binds and responds to both testosterone and dihydrotestosterone (DHT).⁸

Vitamins

Vitamins are essential constituents of a healthful diet. Two fat-soluble vitamins, A and D, are precursors of important signaling molecules that function as ligands for nuclear receptors.

TABLE 4-1

Nuclear Receptor Ligands and Their Receptors

Ligand	Receptor
Classic Hormones	
Thyroid hormone	Thyroid hormone receptor (TR), subtypes α , β
Estrogen	Estrogen receptor (ER), subtypes α , β
Testosterone	Androgen receptor (AR)
Progesterone	Progesterone receptor (PR)
Aldosterone	Mineralocorticoid receptor (MR)
Cortisol	Glucocorticoid receptor (GR)
Vitamins	
1,25-(OH) ₂ -Vitamin D ₃	Vitamin D receptor (VDR)
All- <i>trans</i> -retinoic acid	Retinoic acid receptor, subtypes α , β , γ
9- <i>cis</i> -Retinoic acid	Retinoid X receptor (RXR), subtypes α , β , γ
Metabolic Intermediates and Products	
Fatty acids	Peroxisome proliferator-activated receptor (PPAR), subtypes α , δ , γ
Oxysterols	Liver X receptor (LXR), subtypes α , β
Bile acids	Bile acid receptor (BAR)
Heme	Rev-Erb subtypes α , β
Xenobiotics	
??	Pregnane X receptor (PXR), constitutive androstane receptor (CAR)

Precursors of vitamin D are synthesized and stored in skin and activated by ultraviolet light; vitamin D can also be derived from dietary sources. Vitamin D is then converted in the liver to 25(OH)D (25-hydroxyvitamin D, calcidiol) and in the kidney to 1,25(OH)₂ D₃ (1,25-dihydroxyvitamin D₃, calcitriol), the most potent natural ligand of the vitamin D receptor (VDR). The 1-hydroxylation of calcidiol is tightly regulated, and calcitriol acts as a circulating hormone.

Vitamin A is stored in the liver and is activated by metabolism to all-*trans*-retinoic acid, which is a high-affinity ligand for retinoic acid receptors (RARs).⁹ Retinoic acid is likely to function as a signaling molecule in paracrine as well as endocrine pathways. Retinoic acid is also converted to its 9-*cis*-isomer, which is a ligand for another nuclear receptor, the retinoid X receptor (RXR).¹⁰ These retinoids and their receptors are essential for normal development of multiple organs and tissues, and they have pharmaceutical utility for conditions ranging from skin diseases to leukemia.¹⁰

Metabolic Intermediates and Products

Certain nuclear receptors respond to naturally occurring endogenous metabolic products. The peroxisome proliferator-activated receptors (PPARs) constitute the best defined subfamily of metabolite-sensing nuclear receptors.¹¹ All three PPAR subtypes are activated by polyunsaturated fatty acids. No single fatty acid has particularly high affinity for any PPAR, and it is possible that these receptors function as integrators of the concentration of a number of fatty acids.

PPAR α is expressed primarily in liver; the natural ligand with highest affinity for PPAR α is an eicosanoid, 8(S)-hydroxyeicosatetraenoic acid,^{12,13} although there is evidence that the natural ligand may be a fatty acid derived from lipolysis of circulating triglyceride-rich lipoproteins.¹⁴ The fibrate class of lipid-lowering pharmaceuticals are

potent ligands for PPAR α , and the very name of this receptor is derived from its ability to induce the proliferation of peroxisomes in the liver.¹⁵ Indeed, stimulation of fatty acid oxidation is an important physiologic role of PPAR α .

The other PPARs (δ and γ) are structurally related but are not activated by peroxisome proliferators. PPAR δ , also known as PPAR β , is ubiquitous, and its ligands—other than fatty acids—are not well characterized. Activation of PPAR δ appears to increase oxidative metabolism in fat and skeletal muscle.¹⁶ PPAR γ is expressed primarily in adipocytes and is necessary for differentiation along the adipocyte lineage.¹⁷ PPAR γ is also expressed in other cell types, including colonocytes, macrophages, and vascular endothelial cells, where it may play physiologic and pathologic roles. The natural ligand for PPAR γ is not known, although prostaglandin J derivatives have been shown to bind and activate the receptor at concentrations in the micromolar range.^{13,18,19} PPAR γ appears to be the target of thiazolidinedione (TZD) antidiabetic drugs that improve insulin sensitivity.^{17,20} These pharmaceutical agents bind to PPAR γ with nanomolar affinities, and non-TZD PPAR γ ligands are also insulin sensitizers, further implicating PPAR γ in this physiologic role.

Another metabolite-responsive nuclear receptor, the liver X receptor (LXR), is activated by oxysterol intermediates in cholesterol biosynthesis. Mice lacking LXR α have a dramatically impaired ability to metabolize cholesterol.²¹ A receptor known as farnesyl X receptor (FXR) binds and is activated by bile acids, and it likely plays a role in regulation of bile synthesis and circulation in normal conditions and in disease states.²²

Xenobiotics

Other nuclear receptors appear to function as integrators of exogenous environmental signals, including natural endobiotics (e.g., medicinal agents and toxins found in plants) and xenobiotics (i.e., compounds that are not naturally occurring). In these cases, the role of the activated nuclear receptor is to induce cytochrome P450 enzymes that facilitate detoxification of potentially dangerous compounds in the liver. Receptors in this class include sterol and xenobiotic receptor (SXR), also known as *pregnane X receptor* (PXR), and constitutive androstane receptor (CAR).²²

Unlike other nuclear receptors that have high affinity for very specific ligands, xenobiotic receptors have low affinity for a large number of ligands, reflecting their function in defense against a varied and challenging environment. Although these xenobiotic compounds are not hormones in the classic sense, the function of these nuclear receptors is consistent with the general theme of helping the organism to cope with environmental challenges.

Orphan Receptors

The nuclear receptor superfamily is one of the largest families of transcription factors. The hormones and vitamins just described account for the functions of only a fraction of the total number of nuclear receptors. The remaining receptors have been designated as *orphan receptors* because their putative ligands are not known.²³

From analyses of mice and humans with mutations in various orphan receptors, it is clear that many of them are required for life or for development of specific organs, ranging from brain nuclei to endocrine glands. Some orphan receptors appear to be active in the absence of any ligand (i.e., constitutively active) and may not respond to a natural ligand. Nevertheless, all of the receptors known

to respond to metabolites and environmental compounds were originally discovered as orphans. Therefore, future research will likely find that additional orphan receptors function as receptors for physiologic, pharmacologic, or environmental ligands. For example, the nuclear receptor NR1D1 (formerly called Rev-Er α), which is a regulator of circadian rhythms,²⁴ has been shown to be a receptor for molecular heme,^{25,26} which is involved in the coordination of circadian rhythms and metabolism.

Variant Receptors

The carboxyl-terminus of the nuclear receptors is responsible for hormone binding. In a few nuclear receptors, including THRA and the glucocorticoid receptor, alternative splicing produces variant receptors with unique C-termini that do not bind ligand.^{27,28} These variant receptors are normally expressed, but their biologic relevance is uncertain. They may modulate the action of the classic receptor to which they are related by inhibiting its function.

Another type of normally occurring variant nuclear receptors lacks a classic DNA-binding domain (discussed later). These include NROB1 (formerly called DAX1), which is mutated in human disease,²⁹ and PTPN6 (formerly called SHP1).³⁰ Their ligands have not been identified, and it is likely that NROB1 and PTPN6 bind to and repress the actions of other receptors.

Rare, naturally occurring mutations of hormone receptors can cause hormone resistance in affected patients.³¹ Inheritance of the hormone resistance phenotype is dominant if the mutant receptor inhibits the action of the normal receptor, as occurs with resistance to thyroid hormone or PPAR γ ligands.³¹ Inheritance is recessive if the mutation results in a complete loss of receptor function, as with the syndrome of hereditary calcitriol-resistant rickets.³² Inheritance can also be X-linked, as with the mutated androgen receptor in androgen insensitivity syndromes, including testicular feminization.³³

Regulation of Ligand Levels

Ligand levels can be regulated in several ways (Table 4-2). A dietary precursor may not be available in required amounts (e.g., in hypothyroidism due to iodine deficiency). Pituitary hormones (e.g., thyroid-stimulating hormone) regulate the synthesis and secretion of classic thyroid and steroid hormones. If the glands that synthesize these hormones fail, hormone deficiency can occur.

Many of the nuclear receptor ligands are enzymatically converted from inactive prohormones to biologically active hormones; examples include the 5' deiodination of thyroxine (T₄) to triiodothyronine (T₃) (see Chapter 11). In other cases, one hormone is a precursor for another, for example, in aromatization of testosterone to estradiol. Biotransformation may occur in a specific tissue that is not the main target of the hormone, as with renal 1-hydroxylation of

TABLE 4-2

Mechanisms Regulating Ligand Levels

Precursor availability

Secretion
Activation (prohormone \rightarrow active hormone)
Deactivation (active hormone \rightarrow inactive hormone)
Elimination (hepatic, renal clearance)

vitamin D (see Chapter 28), or it may occur primarily in target tissues (e.g., 5 α -reduction of testosterone to DHT; see Chapter 19). Deficiency or pharmacologic inhibition of an enzyme can also reduce hormone levels.³⁴

Hormones can be inactivated by standard hepatic or renal clearance mechanisms or by more specific enzymatic processes. In the latter case, reduction in enzyme activity due to gene mutations or pharmacologic agents can result in symptoms of hormone excess, such as renal deactivation of cortisol by 11 β -hydroxysteroid dehydrogenase (11 β -HSD). Because cortisol can activate the mineralocorticoid receptor, insufficient 11 β -HSD activity due to licorice ingestion, gene mutation, or extremely high cortisol levels causes syndromes of apparent mineralocorticoid excess.³⁵

NUCLEAR RECEPTOR SIGNALING MECHANISMS

Nuclear receptors are multifunctional proteins that transduce the signals of their cognate ligands. General features of nuclear receptor signaling are illustrated in Figure 4-1.

For hormone action in the nucleus, the ligand and the nuclear receptor must physically get into the nucleus. The nuclear receptor also must bind its ligand with high affinity. Because a major function of the receptor is to selectively regulate target gene transcription, it must recognize and bind to promoter elements in appropriate target genes. One discriminatory mechanism is dimerization of a receptor with a second copy of itself or with another nuclear receptor. The DNA-bound receptor must work in the context of chromatin to signal the basal transcription machinery to increase or decrease transcription of the target gene. In the regulation of signaling by nuclear receptors, some basic mechanisms are used by many or all members of the nuclear receptor superfamily, whereas other mechanisms impart the specificity that is crucial to the vastly different biologic effects of the many hormones and ligands that use these related receptors.

Figure 4-1 Mechanism of signal transduction by hormones and other ligands that act through nuclear receptors. HRE, hormone response element; mRNA, messenger ribonucleic acid.

Domain Structure of Nuclear Receptors

Nuclear receptors are proteins with molecular masses between 50,000 and 100,000 d. They share a common series of domains, referred to as domains A through F (Fig. 4-2). This linear depiction is useful for describing and comparing receptors, but it does not capture the roles of protein folding and tertiary structure in mediating various receptor functions. Investigations have revealed the structures of

Figure 4-2 Domain structures of nuclear receptors.

individual domains and the first solved structure of a full-length nuclear receptor.

Nuclear Localization

The nuclear receptors, like all cellular proteins, are synthesized on ribosomes that reside outside the nucleus. Import of the nuclear receptors into the nucleus requires the nuclear localization signal (NLS), which is located near the border of the C and D domains (see Fig. 4-2). As a result of their NLSs, most of the nuclear receptors reside in the nucleus, with or without their ligands. A major exception is the glucocorticoid receptor; in the absence of hormone, it is tethered in the cytoplasm to a complex of chaperone molecules, including heat shock proteins (HSPs). Hormone binding to the glucocorticoid receptor induces a conformational change that results in dissociation of the chaperone complex, allowing the hormone-activated glucocorticoid receptor to translocate to the nucleus by means of its NLS.

Hormone Binding

High-affinity binding of a lipophilic ligand is a shared characteristic of many nuclear receptors. This defining function of the receptor is mediated by the C-terminal ligand-binding domain (LBD), domains D and E in Figure 4-2. This region of the receptor has many other functions, including induction of dimerization and transcriptional regulation (see later discussions).

The structure of the LBD has been solved for a number of receptors. All share a similar overall structure consisting of 12 α -helical segments in a highly folded tertiary structure (Fig. 4-3A). The ligand binds within a hydrophobic pocket composed of amino acids in helices 3, 4, and 5 (H3, H4, and H5, respectively). The major structural change induced by ligand binding is an internal folding of the most C-terminal helix (H12), which forms a cap on the ligand-binding pocket (see Fig. 4-3B). Although the overall mechanism of ligand binding is similar for all receptors,

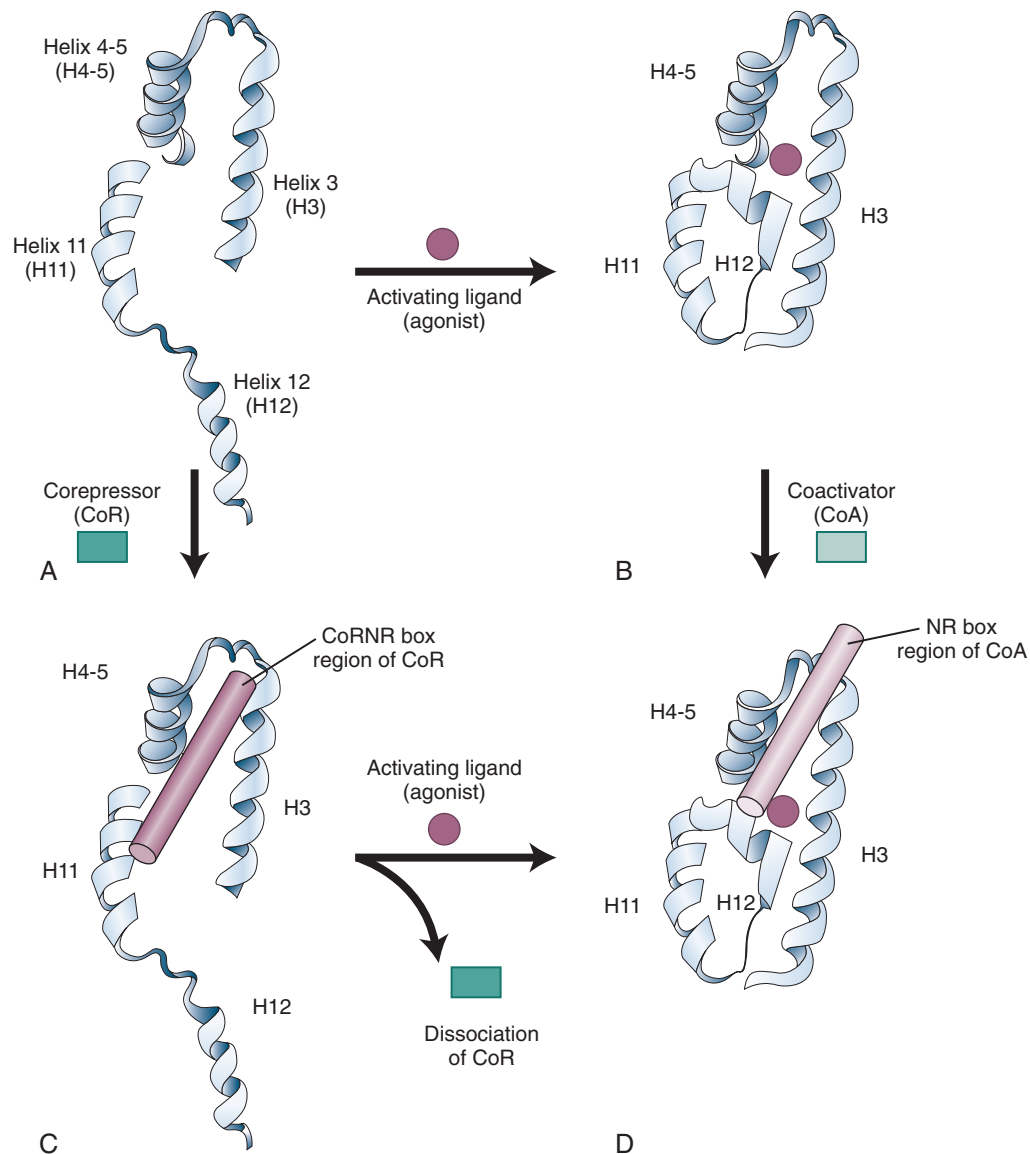

Figure 4-3 Structural basis of nuclear receptor ligand binding and cofactor recruitment. **A** and **B**, Apo-receptor (no ligand bound). **B** and **D**, Ligand-bound receptor. **C** and **D**, Structures showing the positional binding of a corepressor (**C**) or coactivator (**D**). NR, nuclear receptor.

the molecular details are essential for determining ligand specificity.^{36,37} Ligand binding is the most critical determinant of receptor specificity.

Target Gene Recognition by Receptors

Another crucial specificity factor for nuclear receptors is their ability to recognize and bind to the subset of genes that is to be regulated by their cognate ligand. Target genes contain specific DNA sequences that are called *hormone response elements* (HREs). Binding to the HRE is mediated by the central C domain of the nuclear receptors (see Fig. 4-2). This region is typically composed of 66 to 68 amino acids, including two subdomains that are called *zinc fingers* because the structure of each subdomain is maintained by four cysteine residues coordinated with a zinc atom.

The first of these zinc-ordered modules contains basic amino acids that contact DNA; as with the LBD, the overall structure of the DNA-binding domain (DBD) is similar for all members of the nuclear receptor superfamily. The specificity of DNA binding is determined by multiple factors (Table 4-3). All steroid hormone receptors, except for the estrogen receptor, bind to the double-stranded DNA sequence AGAACA (Fig. 4-4).

By convention, the double-stranded sequence is described by the sequence of one of its complementary strands, with the bases ordered from the 5' to the 3' end. Other nuclear receptors recognize the sequence AGGTCA. The primary determinant of this specificity is a group of amino acid residues in the *P box* of the DBD (see Fig. 4-4). These hexamer DNA sequences are referred to as *half-sites*. The only difference between these hexameric half-sites is the central two base pairs (underlined in Fig. 4-4). For some nuclear receptors, the C-terminal extension of the DBD contributes specificity for extended half-sites containing additional, highly specific DNA sequences 5' to the hexamer. Another source of specificity for target genes is the spacing and orientation of these half-sites, which in most cases are bound by receptor dimers.

Receptor Dimerization

The nuclear receptor DBD has affinity for the hexameric half-site or for extended half-sites; however, many HREs are composed of repeats of the half-site sequence, and most nuclear receptors bind these HREs as dimers. Steroid receptors, including estrogen receptors, function primarily as homodimers, which preferentially bind to two half-sites oriented toward each other (i.e., inverted repeats [IRs])

Figure 4-4 Structural basis for nuclear receptor (NR) DNA-binding specificity is shown in the ribbon diagrams of receptor DNA-binding domains (DBDs). **A**, Steroid hormone receptor binding as a homodimer to the inverted repeat (arrows) of the AGAACA half-site. The central base pairs are underlined. **B**, RXR-NR heterodimer binding to the direct repeat of AGGTCA. The position of the P box, the region of the DBD that makes direct contact with DNA, is shown. N, number of base pairs between the two half-sites; RXR, retinoid X receptor.

with three base pairs in between (IR3) (see Fig. 4-4A). The major dimerization domain in steroid receptors is within the C domain, although the LBD contributes. Ligand binding facilitates dimerization and DNA binding of steroid hormone receptors. Most other receptors, including THR, RAR, PPAR, LXR, and VDR, bind to DNA as heterodimers with RXR (see Fig. 4-4B).

Heterodimerization with RXR is mediated by two distinct interactions, one involving LBDs and the other involving DBDs. The receptor LBD mediates the strongest interaction, which occurs even in the absence of DNA. These receptor heterodimers bind to two half-sites arranged as direct repeats (DRs) with variable numbers of base pairs in between.

The spacing of the half-sites is a major determinant of target gene specificity, and it results from the second receptor-receptor interaction, which involves the DBDs and is highly sensitive to the spacing of the half-sites. For example, VDR/RXR heterodimers bind preferentially to DRs separated by three bases (DR3 sites), TR/RXR binds DR4, and RAR/RXR binds DR5 with highest affinity.³⁸

Studies of isolated DBD binding to DNA have shown that these spacing requirements are related to the fact that

TABLE 4-3	
Determinants of Target Gene Specificity of Nuclear Receptors	
Specificity	Region of Receptor
1. Binding to DNA	DBD (C domain)
2. Binding to specific hexamer	P box in C domain (AGGTCA vs AGAACA)
3. Binding to sequences 5' to hexamer	C-terminal extension of DBD
4. Binding to hexamer repeats	Dimerization domain (C domain for steroid receptors; D, E, and F for others)
5. Recognition of hexamer spacing	Heterodimerization with RXR (nonsteroid receptors, C domain)

DBD, DNA-binding domain; RXR, retinoid-X receptor.

the RXR binds to the upstream half-site (i.e., farthest from the start of transcription). As a result of the periodicity of the DNA helix, each base pair separating the half-sites leads to a rotation of about 36 degrees of one half-site relative to the other. Subtle differences in the structure of the receptor DBDs make the interactions more or less favorable at different degrees of rotation.³⁹ Solution of the crystal structure of a nuclear receptor heterodimer (specifically, the PPAR γ -RXR α heterodimer) bound to DNA demonstrated that the heterodimer forms a nonsymmetric complex, allowing the LBD of PPAR γ to cooperate with both DBDs to enhance response element binding.⁴⁰

The discovery of nuclear receptor binding sites has been largely empiric, based on the finding of binding sites in small numbers of known target genes. Unbiased analysis of thousands of nuclear receptor binding locations in living cells has confirmed the canonical binding sequences for several nuclear receptors, including those of the estrogen receptor,^{41,42} the androgen receptor,^{43,44} the glucocorticoid receptor,⁴⁵ and PPAR/RXR heterodimers.^{46,47}

RECEPTOR REGULATION OF GENE TRANSCRIPTION

Nuclear receptors mediate a variety of effects on gene transcription. The most common modes of regulation are ligand-dependent gene activation, ligand-independent repression of transcription, and ligand-dependent negative regulation of transcription (Table 4-4).

Ligand-Dependent Activation

Ligand-dependent activation is the best understood function of nuclear receptors and their ligands. The ligand-bound receptor increases transcription of a target gene to which it is bound. The DBD brings the receptor domains that mediate transcriptional activation to a specific gene. Transcriptional activation itself is mediated primarily by the LBD, which can function in the same way even when it is transferred to a DNA-binding protein that is not related to nuclear receptors. The activation function (AF) of the LBD is referred to as AF-2 (see Fig. 4-2).

Gene transcription is mediated by a large complex of factors that ultimately regulate the activity of ribonucleic acid (RNA) polymerase, the enzyme that uses the chromosomal DNA template to direct the synthesis of messenger RNA. Most mammalian genes are transcribed by RNA polymerase II using a large set of cofactor proteins that include basal transcription factors and associated factors collectively referred to as *general transcription factors* (GTFs). Details about GTFs are of fundamental importance and are available elsewhere.⁴⁸

The ligand-bound nuclear receptor communicates stimulatory signals to GTFs on the gene to which it is bound. Ligands specifically recruit a set of proteins, collectively called *coregulators*, to the nuclear receptor LBD.⁴⁹ Positively acting coregulators, called *coactivators*, specifically recognize the ligand-bound conformation of the LBD and bind to the nuclear receptor on DNA only when an activating (agonist) hormone or ligand is bound.⁵⁰ A number of coactivator proteins that bind to liganded nuclear receptors have been described (Table 4-5).⁵⁰

The most important determinant of coactivator binding is the position of H12, which changes dramatically when activating ligands bind receptors (see Fig. 4-3D). Along with H3, H4, and H5, H12 forms a hydrophobic cleft that is bound by short polypeptide regions of the coactivator molecules.⁵¹⁻⁵³ These polypeptides, called *NR boxes*, have characteristic sequences of LxxLL, in which L is leucine and xx can be any two amino acids.⁵⁴

Coactivators increase the rate of gene transcription. This is accomplished by enzymatic functions, including DNA unwinding in response to histone acetyltransferase (HAT) activity.⁵⁵ HAT activity is critically important for activation because chromosomal DNA is tightly wrapped around nucleosomal units composed of core histone proteins; acetylation of lysine tails on histones opens up this chromatin structure.

The best understood class of coactivator proteins is the p160 family, whose name is based on their protein size (approximately 160 kd). The family contains at least three such molecules, and each has many names (see Table 4-5).⁵⁶ These factors possess HAT activity and recruit other coactivators, such as calcium-binding protein (CBP) and p300, which are also HATs. A third HAT, p300/CBP-associated factor (PCAF, also designated TAF5L or TAF6L), is also recruited by liganded receptors. These HATs, along with a complex of SMARC molecules (SWI/SNF-related, matrix-associated, actin-dependent regulators of chromatin) that direct adenosine triphosphate (ATP)-dependent DNA unwinding, create a chromatin structure that favors transcription (Fig. 4-5).⁵⁷

Recruitment of multiple HATs may reflect different specificities for core histones and, potentially for some nonhistone proteins. Some HATs also interact directly with GTFs and further enhance their activities. The thyroid hormone receptor-associated protein (TRAP) complex and the vitamin D receptor-interacting protein (DRIP) complex link nuclear receptors to GTFs.^{58,59} The HATs and TRAP

factors are recruited to the liganded, target gene–bound receptor in an ordered manner that also involves cycling on and off of receptor gene targets.⁶⁰ Although the mechanism is not understood, the cycling may allow multiple coactivators using similar NR boxes to contribute to gene regulation without binding to a single receptor simultaneously.

Repression of Gene Expression by Unliganded Receptor

Although DNA binding is ligand dependent for steroid hormone receptors, other nuclear receptors are bound to DNA even in the absence of their cognate ligand. The unliganded, DNA-bound receptor is not passively waiting for hormone; instead, it actively represses transcription of the target gene. This repression turns off the target gene and amplifies the magnitude of the subsequent activation by hormone or ligand. For instance, if the level of gene transcription in the repressed state is 10% of the basal level in the absence of a receptor, hormone activation to 10-fold above that basal level represents a 100-fold difference of transcription rate between hormone-deficient (repressed) genes and hormone-activated genes (Fig. 4-6).⁶¹

In many ways, the molecular mechanism of repression is the mirror image of ligand-dependent activation. The unliganded nuclear receptor recruits negatively acting coregulators, called *corepressors*, to the target gene (see Fig. 4-3C). The two major corepressors are large (approximately 270 kD) proteins: nuclear receptor corepressor (NCoR) and silencing mediator for retinoid and thyroid receptors (SMRT).⁶² NCoR and SMRT specifically recognize the unliganded conformation of nuclear receptors and use an amphipathic helical sequence similar to the NR box of coactivators to bind to a hydrophobic pocket in the receptor.

For corepressors, the peptide responsible for receptor binding is called the *CoNR box*, and it contains the sequence (I or L)xx(I or V)I, in which I is isoleucine, L is leucine, V is valine, and xx represents any two amino acids.⁶³ The receptor uses helices 3 to 5 to form the hydrophobic pocket, as in coactivator binding, but H12 does not promote and even hinders corepressor binding. This negative function of H12 highlights the role of the ligand-dependent change in the position of H12 as the switch that

determines repression and activation by nuclear receptors (see Fig. 4-5).⁶⁴

The transcriptional functions of NCoR and SMRT are the opposite of those of the coactivators. The corepressors themselves do not possess enzyme activity but do recruit histone deacetylases (HDACs) to the target gene, thereby reversing the effects of histone acetylation described earlier and leading to a compact, repressed state of chromatin. Although the mammalian genome contains multiple HDACs, several of which may play a role in nuclear receptor function, the main one involved in repression is HDAC3, whose enzyme activity depends on interaction with NCoR or SMRT.⁶⁵ The ability of NCoR to bind and activate HDAC3 is required for normal metabolic and circadian physiology.⁶⁶ The corepressors interact directly with GTFs to inhibit their transcriptional activities, and they also exist in large, multiprotein complexes whose range of functions is not fully understood.

Ligand-Dependent Negative Regulation of Gene Expression: Transrepression

The ligand-dependent switch between repressed and activated receptor conformations explains how hormones activate gene expression. However, many important gene targets of hormones are turned off in the presence of the ligand. This is referred to as *ligand-dependent negative regulation of transcription*, or *transrepression*, to distinguish it from the repression of basal transcription by unliganded receptors.

The mechanism of negative regulation is less well understood than ligand-dependent activation, and there may be several mechanisms.⁶⁷ One mechanism involves nuclear receptor binding to DNA-binding sites that reverse the paradigm of ligand-dependent activation (i.e., negative response elements). For example, when the unliganded thyroid receptor binds to the negative response element of the genes for the β -subunit of thyroid-stimulating hormone or thyroid-stimulating hormone–releasing hormone, transcription is activated.⁶⁸ The role and recruitment of coregulators in this process require further investigation. In other cases, negative regulation may result from ligand binding to nuclear receptors that bind to other transcription factors without binding DNA. This interaction leads to removal of coactivators such as p300 and CBP from the other

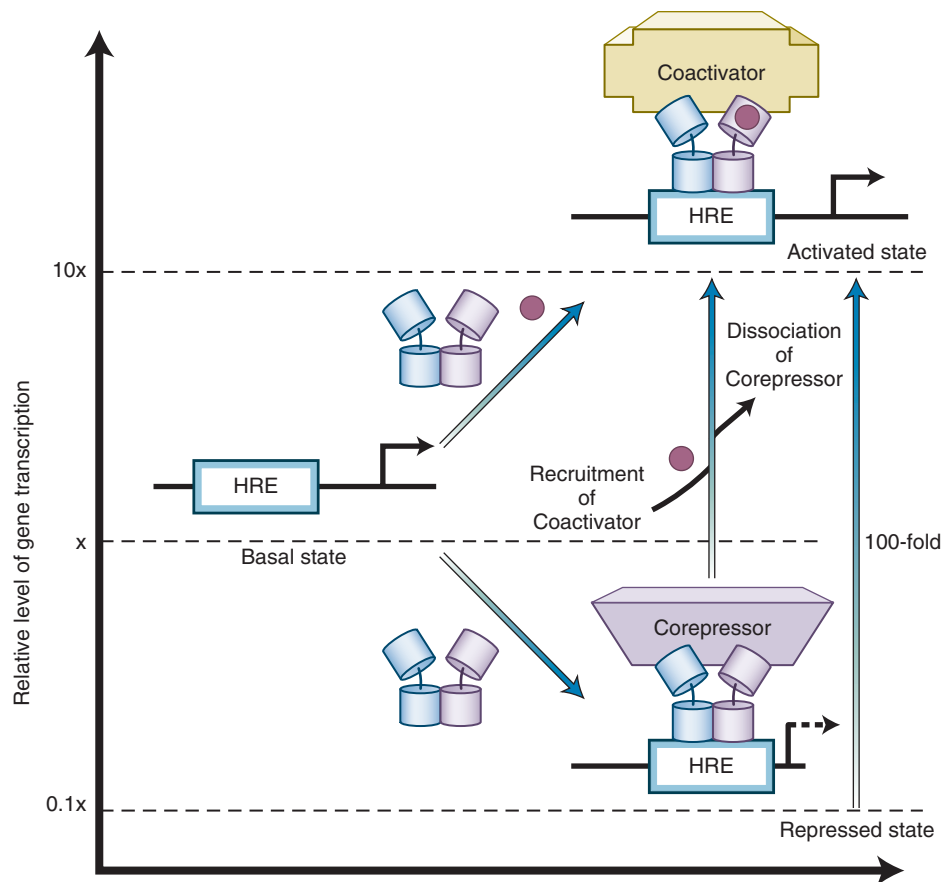

Figure 4-6 Repression and activation functions augment the dynamic range of transcriptional regulation by nuclear receptors. The magnitudes of activation and repression were arbitrarily set at 10-fold for this theoretical example. In cells, these magnitudes vary as a function of coactivator and corepressor concentration and in a target gene-specific manner. HRE, hormone response element.

transcription factors that positively regulate the gene. In this model, inhibition of the activity of the positively acting factors results in the observed negative regulation.

Roles of Other Nuclear Receptor Domains

The amino-terminal A/B domain of the nuclear receptors is the most variable region among all members of the superfamily in terms of length and amino acid sequence. Subtypes of the same receptor often have completely different A/B domains. The function of this domain is the least well defined of any. It is not required for unliganded repression or for ligand-dependent activation. In many receptors, the A/B domain contains positive transcriptional activity, often referred to as activation function 1 (AF-1) (see Fig. 4-2). It is ligand independent but probably interacts with coactivators and may influence the magnitude of activation by agonists or partial agonists. This activation function is tissue specific and tends to be more important for steroid hormone receptors, whose A/B domains are notably longer than those of other members of the superfamily.⁶⁹ The F domain of the nuclear receptors is hypervariable in length and sequence, and its function is not known.

Cross-Talk with Other Signaling Pathways

Hormones and cytokines that signal through cell surface receptors also regulate gene transcription, often by activating protein kinases that phosphorylate transcription factors

such as cAMP-response element-binding protein (CREB). Such signals can also lead to phosphorylation of nuclear receptors. Multiple signal-dependent kinases can phosphorylate nuclear receptors, leading to conformational changes that regulate function.⁷⁰ Phosphorylation can lead to changes in DNA binding, ligand binding, or coactivator binding; these consequences depend on the specific kinase, receptor, and domain of the receptor that is phosphorylated. The properties of coactivators and corepressors are also regulated by phosphorylation.⁷¹

Receptor Antagonists

Certain ligands function as receptor antagonists by competing with agonists for the ligand-binding site. In the case of steroid hormone receptors, the position of H12 in the antagonist-bound receptor is not identical to that in the unliganded receptor or in the agonist-bound receptor. H12, which has a sequence that resembles the NR box, binds to the coactivator-binding pocket of the receptor and thereby prevents coactivator binding.⁷² This antagonist-bound conformation of the receptor also favors corepressor binding to steroid hormone receptors.

Tissue Selectivity of Ligands Interacting with Nuclear Receptors

Many endogenous hormones that act through nuclear receptors do so in a tissue-specific manner. The most

Partial agonist
Antagonist
Concentration and types of coregulators
Coactivators
Corepressors

obvious mechanism is differential expression of the receptors, both in space (e.g., cell-type specificity)⁷³ and in time (e.g., circadian variation).⁷⁴ Ligand levels may be regulated intracellularly (see earlier discussion and Table 4-2), and post-translational modification (e.g., phosphorylation) influences cell-specific receptor function. Although nuclear receptors bind at thousands of sites on genomic DNA, the specific binding sites are regulated in a cell type-specific manner. For example, the estrogen receptor binds to overlapping but clearly different sets of genomic sites in the uterus and in the breast, probably because of the differential actions of so-called pioneer transcription factors, including forkhead box (FOX) proteins.⁷⁵

Some ligands function as antagonists in certain tissues but as full or partial agonists in others. These selective receptor modulators include compounds such as tamoxifen, a selective estrogen receptor modulator (SERM). SERMs are estrogen receptor antagonists with respect to the functions of AF-2, including coregulator binding, and they require the AF-1 for their agonist activity.⁷⁶ This agonism, like AF-1 activity, tends to be tissue specific and therefore has great therapeutic utility.⁷⁷ Table 4-6 summarizes factors contributing to the tissue specificity of receptor activity.

Mechanism of Action of Hormones That Act at the Cell Surface

ALLEN M. SPIEGEL • CHRISTIN CARTER-SU • SIMEON I. TAYLOR • ROHIT N. KULKARNI

Hormones are secreted into the blood and act on target cells at a distance from the secretory gland. To respond to a hormone, a target cell must contain the essential components of a signaling pathway: a receptor to bind the hormone, an effector (e.g., enzymatic activity that is regulated when the hormone binds to its receptor), and appropriate downstream signaling pathways to mediate the physiologic responses to the hormone. This general type of mechanism involving receptors, effectors, and downstream signaling pathways also functions in non-endocrine systems, such as those regulated by neurotransmitters, cytokines, and paracrine and autocrine factors. This chapter reviews several endocrine signaling pathways that begin with activation of receptors located on the surface of target cells and focuses on the molecular mechanisms that function in normal physiology and in pathology.

RECEPTORS

Hormone receptors are defined by their ability to bind hormone and to couple hormone binding to hormone action. Both components of the definition are essential; for

example, many hormones bind to binding proteins that are distinct from receptors because the binding proteins do not trigger the signaling pathways that mediate hormone action.

Many classes of receptors are of interest in endocrinology. Some receptors (e.g., receptors for steroid and thyroid hormones) are located within the cell and function as transcription factors. Other receptors (e.g., low-density lipoprotein receptors) are located on the cell surface and function primarily to transport their ligands into the cell by a process referred to as *receptor-mediated endocytosis*. In this chapter, we focus on cell surface receptors that trigger intracellular signaling pathways. These cell surface receptors can be classified according to the molecular mechanisms by which they accomplish signaling:

1. Ligand-gated ion channels (e.g., nicotinic acetylcholine receptors)
2. Receptor tyrosine kinases (e.g., receptors for insulin and insulin-like growth factor 1)
3. Receptor serine/threonine kinases (e.g., receptors for activins and inhibins)
4. Receptor guanylate cyclase (e.g., atrial natriuretic factor receptor)

5. G protein-coupled receptors (e.g., receptors for adrenergic agents, muscarinic cholinergic agents, glycoprotein hormones, glucagon, and parathyroid hormone)
6. Cytokine receptors (e.g., receptors for growth hormone, prolactin, and leptin)

The receptors belonging to classes 1 through 4 are bifunctional molecules that can bind hormone and serve as effectors by functioning as ion channels or as enzymes. The receptors belonging to classes 5 and 6 can bind the hormone but must recruit a separate molecule to catalyze the effector function. For example, G protein-coupled receptors (GPCRs) use G proteins to regulate downstream effector molecules. Similarly, cytokine receptors recruit cytosolic tyrosine kinases (e.g., Janus family tyrosine kinases [JAKs]) as effectors to trigger downstream signaling pathways.

HORMONE BINDING

As predicted by the fact that hormones circulate in relatively low concentrations in the plasma, the binding interaction between a hormone and its receptor is characterized by high binding affinity. Hormone binding has a high degree of specificity, and the receptor usually binds its cognate hormone more tightly than it binds other hormones. However, some receptors bind structurally related hormones with lower affinity. For example, the insulin receptor binds insulin-like growth factors (IGFs) with approximately 100-fold lower affinity than it binds insulin. Similarly, the thyrotropin receptor binds human chorionic gonadotropin with lower affinity than it binds thyrotropin. This phenomenon has been referred to as *specificity spillover*, and it provides an explanation of several pathologic conditions, such as hypoglycemia caused by tumors secreting IGF2 and hyperthyroidism associated with choriocarcinoma.¹

Binding of a hormone (H) to its receptor (R) can be described mathematically as an equilibrium reaction:

At equilibrium,

$$K_a = (HR)/(H)(R)$$

where K_a is the association constant for the formation of the hormone receptor complex (HR). As was originally shown by Scatchard, it is possible to rearrange this equation in terms of the total concentration of receptor-binding sites, $R_0 = (R) + (HR)$, as follows:

$$K_a = (HP)/\{(R_0 - (HR))(H)\}$$

$$(HR) = K_a[R_0 - (HR)](H)$$

$$(HR)/(H) = K_a R_0 - K_a (HR)$$

A straight line is obtained when $(HR)/(H)$ (i.e., the ratio of bound to free hormone) is plotted as a function of (HR) (the concentration of bound hormone). The slope of the line is $-K_a$, and the line intercepts the horizontal axis at the point where $(HR) = R_0$ = the total number of binding sites. This type of plot, referred to as a *Scatchard plot*, has been used as a graphic method to estimate the affinity with which a receptor binds its hormone. Although the binding properties of some receptors are described more or less accurately by these simple equations, other receptors exhibit more complex properties. This simple algebraic derivation of the Scatchard equation implicitly assumes that there is only one class of receptors and that the binding

sites on the receptors do not interact with one another. If these assumptions do not apply to the interaction of a particular hormone with its receptor, the Scatchard plot may not be linear.

Several molecular mechanisms can contribute to non-linearity of the Scatchard plot. For example, there may be more than one type of receptor that binds the hormone (e.g., a high-affinity, low-capacity site and a low-affinity, high-capacity site). Some receptors (e.g., insulin receptor) have more than one binding site, and there may be cooperative interactions among the binding sites. The interaction between a G protein and a GPCR may affect the affinity with which the receptor binds its ligand; the effect on binding affinity depends on whether guanosine diphosphate (GDP) or guanosine triphosphate (GTP) is bound to the G protein. A detailed discussion of these complexities is beyond the scope of this chapter.

REGULATION OF HORMONE SENSITIVITY

Early in the history of endocrinology, attention was focused on the regulation of hormone secretion as the most important mechanism for regulating physiology. However, it has become apparent that the target cell is not passive. Many influences can alter the sensitivity of the target cell's response to a given concentration of hormone. For example, the number of receptors can be regulated. All things being equal, hormone sensitivity is directly related to the number of hormone receptors expressed on the cell surface. Post-translational modifications of the receptor can modify the affinity of hormone binding or the efficiency of coupling to downstream signaling pathways. All of the downstream components in the hormone action pathway are subject to similar types of regulatory influences, which can have a significant impact on the ability of the target cell to respond to hormone.

Just as hormone sensitivity is subject to normal physiologic regulation, pathologic influences can cause disease by targeting components of the hormone action pathway. Multiple etiologic factors can impair the hormone action pathway, such as genetic influences, autoimmune processes, and exogenous toxins. For example, disease mechanisms can alter the functions of cell surface receptors, effectors such as G proteins, and other components of the downstream signaling pathways. Several examples are provided here to illustrate these principles.

RECEPTOR TYROSINE KINASES

Receptor tyrosine kinases have several structural features in common: an extracellular domain containing the ligand-binding site, a single transmembrane domain, and an intracellular portion that includes the tyrosine kinase catalytic domain (Fig. 5-1). Analysis of the human genome suggests that it contains sequences for approximately 100 receptor tyrosine kinases. The tyrosine kinase domain is the most highly conserved sequence among all of the receptors in this family. In contrast, there is considerable variation among the sequences of the extracellular domains. The family of receptor tyrosine kinases has 16 subfamilies, classified primarily on the basis of differences in the structure of the extracellular domain.² Receptor tyrosine kinases mediate the biologic actions of a wide variety of ligands, including insulin, epidermal growth factor (EGF),

Figure 5-1 Receptor tyrosine kinases. Three of the 16 families of receptor tyrosine kinases are diagrammed.^{2,3} All receptor tyrosine kinases possess an extracellular domain containing the ligand-binding site, a single transmembrane domain, and an intracellular portion containing the tyrosine kinase domain. Several structural motifs (i.e., cysteine-rich domain, immunoglobulin (Ig)-like domain, tyrosine kinase domain) in these receptor tyrosine kinases are indicated on the right side of the figure. Cys, cysteine; EGF, epidermal growth factor; PDGF, platelet-derived growth factor.

platelet-derived growth factor (PDGF), and vascular endothelial growth factor (VEGF). The variation in the sequences of the extracellular domains enables the receptors to bind this structurally diverse collection of ligands.

The EGF receptor was the first cell surface receptor demonstrated to possess tyrosine kinase activity,⁴ and it was the first receptor tyrosine kinase to be cloned.⁵ Like most receptor tyrosine kinases, the EGF receptor exists primarily as a monomer in the absence of ligand. However, binding of ligand induces receptor dimerization. Ligand-induced dimerization is central to the mechanism by which the receptor mediates the biologic activity of EGF. In addition to the ability to form homodimers, the EGF receptor can form heterodimers with other members of the same subfamily of receptor tyrosine kinases. Because a small number of receptors can combine in a large number of pairings, heterodimer formation has the potential to fine-tune the specificity of receptors for ligand binding and downstream signaling.

The insulin receptor is of special interest to endocrinologists because diabetes is among the most common diseases of the endocrine system. The insulin receptor closely resembles the type 1 receptor for IGFs,⁶ which mediates the biologic actions of IGF1 and therefore plays an important role in the physiology of growth hormone (GH) in vivo. Although the kinase domains of receptors for insulin and IGF1 closely resemble other receptor tyrosine kinases, at least two distinctive features set them apart. First, the receptors are synthesized as proreceptors that undergo proteolytic cleavage into two subunits (α and β). The α -subunit contains the ligand-binding site; the β -subunit includes the transmembrane and tyrosine kinase domains. Second, both receptors exist as $\alpha_2\beta_2$ heterotetramers that are stabilized by intersubunit disulfide bonds. In contrast to many other receptor tyrosine kinases, which are thought to dimerize in response to ligand binding, the insulin receptor exists as a dimer of $\alpha\beta$ monomers even in the absence of ligand. The remainder of this section reviews the molecular mechanisms by which receptor tyrosine kinases mediate biologic action, with special emphasis on the insulin receptor as an example.

Receptor Activation: Role of Receptor Dimerization

Dimerization plays a central role in the mechanism by which most receptor tyrosine kinases are activated by their cognate ligands.^{2,7} Although receptor dimerization is a common theme, the detailed molecular mechanisms vary from receptor to receptor. Three examples of the mechanisms of receptor dimerization are provided⁸⁻¹² (Fig. 5-2).

Dimeric Ligand

PDGF and VEGF are examples of dimeric ligands (see Fig. 5-2).^{8,9,13} Because each subunit of ligand can bind one receptor molecule, simultaneous binding of two receptor molecules drives receptor dimerization. Direct support for this type of mechanism is provided by the crystal structure of VEGF when bound to its receptor, FLT1.¹³

Two Receptor-Binding Sites on a Monomeric Ligand

The mechanism of two receptor-binding sites on a single ligand is important for many receptor tyrosine kinases, but it was first rigorously demonstrated for the GH receptor, which is not a member of the receptor tyrosine kinase family (see Fig. 5-2).¹⁰⁻¹² The crystal structure of bound GH shows that one molecule of ligand can bind two molecules of receptor. Two distinct receptor-binding sites exist on each GH molecule, and this enables the ligand to bind to receptor dimers and cause the appropriate conformational change to activate the GH receptor-associated tyrosine kinase, JAK2.

This observation has an important implication for pharmacology. By abolishing one of the two receptor-binding sites, it is possible to design mutant ligands that bind to one of the two sites but lack the ability to bind to both. The mutant ligands therefore cannot trigger hormone action but, by binding to receptors, they inhibit the action of the endogenous hormone. Such mutant GH molecules have been developed as therapeutic agents for use in conditions such as acromegaly.

Figure 5-2 Molecular mechanisms of ligand-induced dimerization of receptors. In the example of platelet-derived growth factor (left), the ligand is dimeric and contains two receptor-binding sites.^{8,9} In the case of growth hormone (right), a single ligand molecule contains two binding sites so that it can bind simultaneously to two receptor molecules.¹⁰⁻¹²

Preexisting Receptor Dimers

The insulin receptor represents a paradox. Like the GH receptor, the insulin receptor exists as a dimer even in the absence of ligand (i.e., it is an $\alpha_2\beta_2$ heterotetramer, which is a dimer of $\alpha\beta$ monomers). If the receptor is already dimerized, why is it not active? Although the molecular details remain to be elucidated, it seems likely that the two halves of the insulin receptor are not oriented in an optimal way to permit receptor activation in the absence of ligand. Perhaps insulin binding triggers a conformational change that mimics the effects of dimerization in other receptor tyrosine kinases. In any case, several studies have demonstrated that receptor dimerization is necessary for insulin to activate its receptor. For example, $\alpha\beta$ monomers retain the ability to bind insulin but are not activated in response to insulin binding.^{14,15} Indirect evidence suggests that a single insulin molecule binds simultaneously to both α -subunits of the insulin receptor,^{16,17} and the ability to bind simultaneously to both halves of the dimeric receptor appears to be essential for insulin to activate its receptor.

Receptor Activation: Conformational Changes in the Kinase Domain

When ligand binds to the extracellular domain, it stimulates the tyrosine kinase activity of the intracellular domain. Although the detailed mechanisms of transmembrane signaling are not completely understood, considerable progress has been made in elucidating the molecular mechanisms of receptor activation. Investigations of the three-dimensional structure of the insulin receptor tyrosine kinase domain help to explain why the receptor is maintained in a low-activity state in the absence of insulin (Fig. 5-3).¹⁸⁻²⁰ In the inactive form of the insulin receptor kinase, Tyr1162 is located in such a position that it blocks protein substrates from binding to the active site. Furthermore, in the inactive state of the tyrosine kinase domain, the active site assumes a conformation that does not accommodate magnesium adenosine triphosphate (ATP). The tyrosine

kinase is inactive because the active site cannot bind either of its substrates.

How does insulin activate the receptor? Insulin binding triggers autophosphorylation of three tyrosine residues (Tyr1158, Tyr1162, and Tyr1163) in the activation loop. When these three tyrosine residues become phosphorylated, an important conformational change occurs. As a result of the movement of the activation loop, the active site acquires the ability to bind both ATP and protein substrates. The conformational change induced by autophosphorylation activates the receptor to phosphorylate other substrates.^{21,22}

It remains unclear how this process is initiated. Because the inactive state of the tyrosine kinase cannot bind ATP, it seems unlikely that phosphorylation of Tyr1162 proceeds by a true autophosphorylation mechanism. Instead, it is likely that Tyr1162 in one β -subunit is transphosphorylated by the second β -subunit in the $\alpha_2\beta_2$ heterotetramer molecule.^{2,23} However, this proposed mechanism poses a chicken-and-egg problem. It requires at least one of the β -subunits to be active before the Tyr residues in the activation loop become phosphorylated. Perhaps the activation loop is somewhat mobile, so that some molecules of unphosphorylated tyrosine kinase can assume an active conformation and initiate a chain reaction of transphosphorylation and receptor activation.

Receptor Tyrosine Kinases Phosphorylate Other Intracellular Proteins

Once activated, tyrosine kinases are capable of phosphorylating other protein substrates. Several factors determine which proteins are phosphorylated under physiologic conditions within the cell.

Amino Acid Sequence Context of Tyr Residue

Tyrosine kinases do not exhibit strict specificity with respect to the amino acid sequence of the phosphorylation site. Nevertheless, most tyrosine phosphorylation sites are located in the vicinity of acidic amino acid residues (i.e., Glu or Asp).²

Figure 5-3 Hypothetical mechanism for ligand-stimulated activation of the insulin receptor tyrosine kinase. Phosphorylation of tyrosine residues in the activation loop leads to activation of the insulin receptor tyrosine kinase. The model is based on the three-dimensional structure of the isolated insulin receptor tyrosine kinase as determined by x-ray crystallography.^{19,20,23} In the inactive insulin receptor kinase (*left*), Tyr1162 blocks the active site so that substrates cannot bind. When the tyrosine residues in the activation loop (including Tyr1162) become phosphorylated (*right*), pTyr1162 moves out of the way; the conformational change allows binding of adenosine triphosphate (ATP) and protein substrate so that the kinase reaction can proceed.

Binding to the Tyrosine Kinase

Some protein substrates bind directly to the intracellular domain of the receptor. The binding interaction brings the substrate close to the kinase, thereby promoting phosphorylation of the substrate. For example, the insulin receptor substrate (IRS) proteins are characterized by a highly conserved phosphotyrosine-binding (PTB) domain that binds to a conserved motif (Asn-Pro-Xaa-pTyr) in the juxtamembrane domain of the insulin receptor.²⁴⁻²⁶ Binding of the PTB domain to the insulin receptor requires phosphorylation of the Tyr residue in the Asn-Pro-Xaa-pTyr motif. This provides another mechanism (in addition to activation of the intrinsic receptor tyrosine kinase) by which autophosphorylation of the receptor enhances phosphorylation of IRS proteins.

Similarly, substrates for some tyrosine kinases contain SRC homology 2 (SH2) domains—highly conserved domains that bind phosphotyrosine residues (see “[Functional Significance of Tyrosine Phosphorylation](#)”). For example, the activated PDGF receptor contains a phosphotyrosine residue near its carboxyl-terminus that binds the SH2 domain of phospholipase C γ . This enables the PDGF receptor to phosphorylate and activate phospholipase C γ .^{2,27}

Subcellular Localization

Because receptor tyrosine kinases are located in the plasma membrane, they are close to other plasma membrane proteins. This co-localization has the potential to promote phosphorylation. For example, the insulin receptor has been reported to phosphorylate pp120/hepatocyte antigen 4 (HA4).^{28,29} Like the insulin receptor, pp120/HA4 is an integral membrane glycoprotein associated with the plasma membrane of hepatocytes. Similarly, FGF receptor substrate 2 (FRS2), a substrate of the fibroblast growth factor receptor, is targeted to the plasma membrane by an amino-terminal myristoylation site.³⁰

Functional Significance of Tyrosine Phosphorylation

Tyrosine phosphorylation regulates protein function by at least two mechanisms. First, tyrosine phosphorylation can induce a conformational change in a protein, altering its

function. For example, phosphorylation of the three Tyr residues in the activation loop of the insulin receptor changes the conformation of the active site, facilitating binding of substrates and activating the receptor tyrosine kinase.¹⁸⁻²⁰ However, most of the effects of tyrosine phosphorylation on protein function are mediated indirectly by regulation of protein-protein interactions. To understand how tyrosine phosphorylation regulates protein-protein interactions, it is useful to review the biochemistry of cellular SRC, the prototype of a nonreceptor tyrosine kinase. When the amino acid sequence of SRC is analyzed, it is apparent that there are three highly conserved domains in the molecule: the kinase catalytic domain and two non-catalytic SRC homology domains that are referred to as SH2 and SH3.

SH2 Domains

SH2 domains consist of conserved sequences (approximately 100 amino acid residues) that are present in many proteins and function in signaling pathways. Functionally, SH2 domains share the ability to bind pTyr residues. However, individual SH2 domains vary with respect to their binding specificity. The binding affinity of an SH2 domain is determined by the three amino acid residues downstream from the pTyr residue. For example, the SH2 domains of phosphatidylinositol 3 kinase (PI3K) exhibit a preference for pTyr-(Met/Xaa)-Xaa-Met, whereas the SH2 domain of growth factor receptor-binding protein 2 (GRB2) prefers to bind pTyr-Xaa-Asn-Xaa. A given SH2 domain binds to a tyrosine-phosphorylated protein if and only if the pTyr residue is located in a context that corresponds to the binding specificity of the SH2 domain.

SH3 Domains

SH3 domains consist of conserved sequences (approximately 50 amino acid residues) that bind to proline-rich sequences. Like SH2 domains, SH3 domains are found in many proteins that function in signaling pathways.

DOWNSTREAM SIGNALING PATHWAYS

Receptor tyrosine kinases mediate the action of many ligands in a wide variety of cell types. The bewildering complexity of the downstream signaling pathways

corresponds to the huge number of physiologic processes that are regulated by receptor tyrosine kinases. Although it is beyond the scope of this chapter to attempt an encyclopedic review of all downstream signaling pathways, we have selected examples to illustrate general principles.

As discussed earlier, the activated insulin receptor phosphorylates multiple substrate proteins, including IRS1, IRS2, IRS3L, IRS4,³¹ and a newly discovered member, growth factor receptor-binding protein 2-associated binder 1 (GAB1).^{32,33} Each of these substrates contains multiple tyrosine phosphorylation sites, many of which correspond to consensus sequences for SH2 domains in important signaling molecules. IRS proteins serve as docking proteins that bind SH2 domain-containing proteins. Among these, two of the most important are PI3K and GRB2. Binding of SH2 domains triggers multiple downstream signaling pathways. It has been suggested that GAB1 serves as a unique intermediate in insulin/IGF1 signaling for induction of early gene expression and stimulation of mitogenesis without direct tyrosine phosphorylation.

Phosphatidylinositol 3 Kinase

The catalytic subunit of PI3K (p110; molecular mass, approximately 110,000 d) is bound to a regulatory subunit. The classic isoforms of the regulatory subunit (p85; molecular mass, approximately 85,000 d) contain two SH2 domains, both of which bind to pTyr in the context of pTyr-(Met/Xaa)-Xaa-Met motifs. Binding of pTyr residues to both SH2 domains of p85 leads to maximal activation of PI3K catalytic activity; submaximal activation can be achieved with occupancy of a single SH2 domain in p85. Because all four IRS molecules (IRS1, IRS2, IRS3L, and IRS4) contain multiple tyrosine phosphorylation sites that conform to the Tyr-(Met/Xaa)-Xaa-Met consensus sequence, insulin-stimulated phosphorylation promotes binding of IRS proteins to the SH2 domains in the regulatory subunit PI3K, thereby increasing the enzymatic activity of the catalytic subunit.³⁴⁻³⁷ Activation of PI3K triggers activation of a cascade of downstream kinases, beginning with phosphoinositide-dependent kinases 1 and 2. These kinases phosphorylate and activate multiple downstream protein kinases, including protein kinase B and atypical isoforms of protein kinase C.³⁸⁻⁴⁴

A large body of evidence demonstrates that the pathways downstream from PI3K mediate the metabolic activities of insulin (e.g., activation of glucose transport into skeletal muscle, activation of glycogen synthesis, inhibition of transcription of the phosphoenolpyruvate carboxykinase gene). Among other lines of evidence, PI3K inhibitors (e.g., LY294002, wortmannin) block the metabolic actions of insulin.⁴⁵ Similarly, overexpression of dominant negative mutants of the p85 regulatory subunit of PI3K also inhibits the metabolic actions of insulin.³⁶ Although it is generally agreed that activation of PI3K is necessary, it is controversial whether it is sufficient to trigger the metabolic actions of insulin. A second parallel pathway may be required, involving tyrosine phosphorylation of CBL, another protein that can be phosphorylated by the insulin receptor in some cell types.⁴⁶⁻⁴⁸

GRB2 and the Activation of RAS

GRB2 is a short adaptor molecule that contains an SH2 domain⁴⁹ capable of binding to pTyr residues in several signaling molecules such as IRS1 and SHC, another PTB domain-containing protein that is phosphorylated by several receptor tyrosine kinases, including the insulin

receptor.^{50,51} The SH2 domain of GRB2 is flanked by two SH3 domains,⁴⁹ which bind to proline-containing sequences in a mammalian homolog of *Drosophila* son-of-sevenless (mSOS, now designated SOS1 or SOS2).⁵² This guanine nucleotide exchange factor can activate RAS, a small G protein that plays an important role in intracellular signaling pathways. The mSOS activates RAS by catalyzing the exchange of GTP for GDP in the guanine nucleotide-binding site of RAS. This, in turn, activates a cascade of serine/threonine-specific protein kinases, including RAF1 kinase, mitogen-activated protein/extracellular signal-regulated kinase (MAP3K), and mitogen-activated protein (MAP) kinase. These pathways downstream from RAS contribute to the ability of tyrosine kinases to promote cell growth and regulate the expression of various genes.

We have focused on the signaling pathways downstream from the insulin receptor because of the importance of insulin and IGF1 in endocrinology (Fig. 5-4). In many ways, the molecular mechanisms closely resemble those downstream from other receptor tyrosine kinases. However, the insulin signaling pathway is atypical in at least one respect: Whereas the insulin receptor phosphorylates docking proteins (e.g., IRS1) that then bind SH2 domain-containing proteins (e.g., PI3K, GRB2), the intracellular domains of most receptor tyrosine kinases contain direct binding sites for SH2 domains. For example, the SH2 domain of GRB2 binds to pTyr716 in the activated PDGF receptor.² Similarly, the PDGF receptor contains two Tyr-(Met/Xaa)-Xaa-Met motifs in the kinase insert domain that bind to the two SH2 domains in the p85 subunit of PI3K.^{2,53} It is not clear why some tyrosine kinases activate PI3K through a direct binding interaction and others use an indirect mechanism involving docking proteins. However, PDGF receptors are associated with the plasma membrane, whereas IRS proteins appear to be associated with the cytoskeleton.⁵⁴ Perhaps this compartmentalization contributes to signaling specificity. Translocation of PI3K to different locations within the cell by two different receptors (e.g., insulin and PDGF receptors) may permit different biologic responses to be elicited by the same signaling molecule (i.e., PI3K).

In addition to being an integral signaling pathway in liver, skeletal muscle, and adipose tissue, most proteins in the insulin/IGF1 signaling pathway are also recognized in pancreatic islet cells⁵⁷⁻⁵⁹ and in the central nervous system⁶⁰⁻⁶² (Fig. 5-5). Exogenous insulin can enhance glucose-stimulated insulin secretion in healthy humans.⁶³ These studies provide insights into the pathogenesis of type 2 diabetes,⁶⁴ neurodegenerative diseases, and aging.

OFF SIGNALS: TERMINATION OF HORMONE ACTION

Just as there are complex biochemical pathways that mediate hormone action, there are mechanisms to terminate the biologic response. The necessity for these mechanisms is illustrated by the following example. After we eat a meal, the concentration of plasma glucose increases. This elicits an increase in insulin secretion, which leads to a decrease in plasma glucose levels. If these processes went on unchecked, the level of glucose in the plasma would eventually fall so low that it would lead to symptomatic hypoglycemia. How is insulin action terminated? The answer is not entirely clear, but several mechanisms contribute to turning off the insulin signaling pathway.

Figure 5-4 Simplified model of signaling pathways downstream from the insulin receptor. Insulin binds to the insulin receptor, activating the receptor tyrosine kinase to phosphorylate tyrosine residues on insulin receptor substrates (IRSs) including IRS1 and IRS2.³¹ The phosphotyrosine residues in the IRS molecules bind to SRC homology 2 (SH2) domains in molecules such as growth factor receptor-binding protein 2 (GRB-2) and the p85 regulatory subunit of phosphatidylinositol (PI) 3-kinase (PI3K). These SH2 domain-containing proteins initiate two distinct branches of the signaling pathway. Activation of PI3K leads to activation of phosphoinositide-dependent kinases (PDKs) 1 and 2, which activate multiple protein kinases, including Akt/protein kinase B, atypical protein kinase C (PKC) isoforms, and serum- and glucocorticoid-induced protein kinases (Sgk).⁵⁵ GRB2 interacts with mSOS, a guanine nucleotide exchange factor that activates Ras.⁵⁶ Activation of Ras triggers a cascade of protein kinases, leading to activation of mitogen-activated protein (MAP) kinase. Shc, SRC homology domain-containing protein.

Receptor-Mediated Endocytosis

Insulin binding to its receptor triggers endocytosis of the receptor. Although most of the internalized receptors are recycled to the plasma membrane, some are transported to lysosomes, where they are degraded.^{65,66} As a result, insulin binding accelerates the rate of receptor degradation, down-regulating the number of receptors on the cell surface. Endosomes contain proton pumps that acidify the lumen; the acidic pH within the endosome promotes dissociation of insulin from its receptor, and the insulin is ultimately

transported to the lysosome for degradation. Receptor-mediated endocytosis is the principal mechanism by which insulin is cleared from the plasma.⁶⁷ Binding of ligands to other receptor tyrosine kinases also triggers receptor-mediated endocytosis by similar mechanisms.

Protein Tyrosine Phosphatases

Protein phosphorylation is a dynamic process. Tyrosine kinases catalyze the phosphorylation of tyrosine residues, but there are also protein tyrosine phosphatases (PTPs) to remove the phosphates.² PTPs antagonize the action of tyrosine kinases. Studies with knockout mice have demonstrated that the absence of PTP1B is associated with increased insulin sensitivity and protects against weight gain.^{68,69} Nevertheless, the human genome encodes a large number of PTPs, and it is an important goal of research to elucidate their physiologic functions. Developing selective inhibitors of the PTPs that oppose the effects of the insulin receptor tyrosine kinase could provide novel therapies for diabetes.

Serine/Threonine Kinases

Most receptor tyrosine kinases, including the insulin receptor, are substrates for phosphorylation by Ser/Thr-specific protein kinases. Ser/Thr phosphorylation appears to inhibit the action of the tyrosine kinase. Other phosphotyrosine-containing proteins are similarly subject to inhibitory influences of Ser/Thr phosphorylation. For example, Ser/Thr phosphorylation of IRS1 may inhibit insulin action, thereby causing insulin resistance.⁷⁰⁻⁷⁴

Figure 5-5

MECHANISMS OF DISEASE

The simplest forms of endocrine disease are caused by a deficiency or an excess of a hormone. Hormone resistance syndromes resulting from defects in the signaling pathways can masquerade as hormone deficiency states, and diseases associated with constitutively activated receptors can mimic states of hormone excess. In some cases, the abnormality in hormone action is genetic in origin, resulting from a mutated gene encoding one of the proteins in the signaling pathway. Similar syndromes also can be caused by other mechanisms; for example, some autoimmune syndromes are caused by autoantibodies directed against cell surface receptors. These clinical syndromes illustrate the principle that understanding the biochemical pathways of hormone action can provide important insights into the pathophysiology of human disease.

Genetic Defects in Receptor Function

At least two major types of genetic defects can cause hormone resistance.⁷⁵ First, mutations can lead to a decrease in the number of receptors. In the case of the insulin receptor, mutations have been identified that decrease receptor number by at least three mechanisms: impairing receptor biosynthesis, inhibiting the transport of receptors to their normal location in the plasma membrane, and accelerating the rate of receptor degradation. Second, mutations can impair the intrinsic activities of the receptor. In the case of the insulin receptor, mutations have been reported that decrease the affinity of insulin binding or inhibit receptor tyrosine kinase activity.

Receptor dimerization plays a central role in the mechanisms by which ligands activate many cell surface receptors. This role has been shown most convincingly in the case of the GH receptor (a member of the family of cytokine receptors) but has also been postulated for receptor tyrosine kinases. The syndromes of multiple endocrine neoplasia types 2A and 2B and familial medullary carcinoma of the thyroid are caused by mutations in the gene encoding the RET tyrosine kinase (a subunit of the receptor for glial cell–derived growth factor).⁷⁶ Ordinarily, cysteine residues in the extracellular domain of RET participate in the formation of intramolecular disulfide bonds. Mutation of one of the cysteine residues leaves an unpaired cysteine residue that promotes dimerization of RET molecules, thereby activating the RET receptor tyrosine kinase (Fig. 5-6). Activation of the RET tyrosine kinase through this germline mutation converts *RET* into an oncogene.

Autoantibodies Directed against Cell Surface Receptors

Inhibitory antireceptor autoantibodies were first identified in patients with myasthenia gravis.⁷⁹ In this neurologic disease, antibodies to the nicotinic acetylcholine receptor impair neuromuscular transmission, apparently by accelerating receptor degradation. Autoantibodies to the insulin receptor were later shown to block insulin action in the syndrome of type B extreme insulin resistance.⁸⁰ Insulin resistance is caused by at least two mechanisms: anti-receptor antibodies inhibit insulin binding to the receptor,⁸¹ and antibodies accelerate receptor degradation.⁸²

Graves' disease provided the first example of stimulatory antireceptor autoantibodies.⁸³ In Graves' disease, autoantibodies are directed against the thyroid-stimulating

Figure 5-6 Mutations leading to constitutive activation of RET. Wild-type Ret protein has intramolecular disulfide bonds formed by two cysteine residues in the same receptor molecule (left). When one of the two cysteine residues is mutated, the unpaired cysteine residue is available to form an intermolecular disulfide bond with a cysteine residue on another receptor molecule. This leads to receptor dimerization (right), which results in constitutive activation of the receptor tyrosine kinase.⁷⁶⁻⁷⁸ This type of mutation has been identified in patients with multiple endocrine neoplasia type 2.

hormone (TSH) receptor. These antireceptor antibodies activate the TSH receptor, stimulating growth of the thyroid gland and hypersecretion of thyroid hormone. This experiment of nature demonstrates that the receptor can be activated by ligands other than the physiologic ligand and that the normal spectrum of biologic actions can be triggered by this unphysiologic ligand (i.e., the anti-receptor antibody). Similarly, antibodies to the insulin receptor have been demonstrated to activate the insulin receptor by mimicking insulin action. Although it is more common for a patient with anti-insulin receptor autoantibodies to present with insulin resistance, patients with these autoantibodies have also been reported to experience fasting hypoglycemia.^{84,85}

RECEPTOR SERINE KINASES

Receptor serine kinases⁸⁶ have several features in common with receptor tyrosine kinases. For example, both classes of receptors possess N-terminal extracellular domains that bind ligand; a single transmembrane domain; and C-terminal intracellular domains that possess protein kinase activity. However, the two classes of receptors have different enzymatic specificities. Whereas receptor tyrosine kinases phosphorylate tyrosine residues, receptor serine kinases phosphorylate serine and threonine residues in their protein substrates. There are two types of receptor serine kinases: type I and type II. The human genome contains 12 genes encoding receptor serine kinases—seven type I and five type II receptors—each of which is approximately 500 amino acids long.

Figure 5-7 Mechanism of action for receptor serine kinases. Binding of dimeric ligand to the type II receptor (RII) subunit triggers assembly of the receptor into the heterotetrameric [(RI)₂(RII)₂] state. RII transphosphorylates the type I receptor (RI), thereby activating phosphorylation of the receptor-regulated SMAD (R-Smad) protein that is bound to the SMAD anchor for receptor activation (SARA) in endosomes. The phosphorylated R-Smad associates with a co-mediator SMAD (Co-Smad). Eventually, the R-Smad is translocated into the nucleus, where it binds to DNA, enabling it to regulate gene transcription. The inhibitory SMAD (I-Smad) also can bind to the activated receptor, promoting ubiquitination and degradation of the receptor. P, phosphorylation; Smurf, SMAD ubiquitination regulatory factor.

Receptor Activation: Role of Receptor Dimerization

Receptor serine kinases mediate the biologic actions (Fig. 5-7) of a single, large family of ligands, the transforming growth factor- β (TGF- β) family, which is characterized by the presence of six conserved cysteine residues.⁸⁶ The human genome contains 42 genes encoding cytokines in the TGF- β family, which are divided into two classes: the activin/TGF- β family and the müllerian inhibitory substance (MIS)/bone morphogenic protein (BMP) family. Activin, the related inhibin, and MIS are of particular interest within the field of reproductive endocrinology (see Chapters 8 and 16).

Ligand binding to the receptor serine kinases promotes a physical interaction between the type I receptor (RI) and the type II receptor (RII) (see Fig. 5-7). As a consequence, the RII receptor activates the RI receptor by phosphorylating one or more serine residues in the GS domain (i.e., TTSGSGSG sequence) of the RI receptor.⁸⁶ How does the ligand trigger receptor activation? In the case of the MIS/BMP family of cytokines, the ligand binds to the isolated RI receptor with high affinity and to the RII receptor with relatively low affinity. The ligand can bind simultaneously to RI and RII, providing an explanation for its ability to promote a physical interaction between RI and RII. The mechanism is different in the case of the activin/TGF- β family of cytokines. For example, TGF- β binds with high affinity to RII but does not interact directly with RI. However, TGF- β binding appears to induce a conformational change in RII, promoting a direct binding interaction between the intracellular domains of RII and RI. Cytokines such as TGF- β exist as dimers; this permits them to bind simultaneously to two RII molecules, so the

activated receptor complex probably exists as a heterotetramer: (RI)₂(RII)₂.

An additional level of complexity contributes to the regulation of receptor serine kinases.⁸⁶ The biology related to activin provides several examples. Follistatin is a “ligand trap,” a soluble protein that binds activin, thereby blocking access to RI and RII. Inhibin is a peptide that inhibits activin signaling by binding to the receptor without activating the phosphorylation of RI. Betaglycan is a membrane-anchored protein that functions as a coreceptor for inhibin by promoting inhibin binding to the activin receptor. Betaglycan itself does not bind activin.

Receptor Serine Kinases Phosphorylate Other Intracellular Proteins

Once activated, receptor serine kinases are capable of phosphorylating other protein substrates. Receptor-regulated SMAD proteins (R-SMADs) function as the immediate downstream effectors of receptor serine kinases (see Fig. 5-7).⁸⁶ SMAD proteins are the mammalian homologs of the proteins encoded by the *Drosophila mad* (mothers against decapentaplegic) gene and the *Caenorhabditis elegans Sma* genes. There are five human R-SMAD proteins. SMAD2 and SMAD3 mediate the actions of the activin/TGF- β family of cytokines. SMAD1, SMAD5, and SMAD8 mediate the actions of the MIS/BMP family of cytokines.

The mechanism of action of TGF- β has been studied in considerable detail⁸¹ and provides a prototype for the receptor serine kinases.⁸⁶ When RI becomes phosphorylated in its GS domain in response to TGF- β , the binding affinity for R-SMAD proteins such as SMAD2 is increased (see Fig. 5-7). This leads to phosphorylation of the two serine residues in the SSXS sequence at the C-terminus of

SMAD2. Receptor-mediated phosphorylation of SMAD2 takes place when SMAD2 is bound to the SMAD anchor for receptor activation (SARA), which is located in early endosomes. Phosphorylation promotes dissociation of SMAD2 from SARA and binding of SMAD2 to the co-mediator (Co-SMAD), SMAD4. Thus, phosphorylation of the R-SMAD promotes the assembly of heteromeric complexes of R-SMAD molecules with the Co-SMAD. SMADs also contain sites for phosphorylation by other protein kinases, providing an opportunity for regulatory cross-talk with other cellular signaling systems.

SMAD7 is an inhibitory SMAD (I-SMAD). It binds to activated receptors in competition with R-SMADs. Binding of SMAD7 promotes receptor ubiquitination and degradation mediated by E3 ubiquitin ligases and SMAD ubiquitination regulatory factors (SMURFs). These processes represent a negative feedback system that contributes to the termination of TGF- β signaling (see Fig. 5-7).

SMAD Proteins Regulate Gene Expression

Some R-SMADs contain lysine-rich nuclear localization signals (KKLKK) that bind to importin, mediating translocation into the nucleus.⁸⁶ Direct binding to components of the nuclear pore complex also may contribute to the mechanism by which SMADs are translocated into the nucleus. Most R-SMADs (with the exception of SMAD2) bind to DNA in a sequence-specific fashion. The minimum SMAD binding element is a 4-base-pair sequence, 5'-AGAC-3'. This sequence is quite short and is not expected to provide a high degree of specificity. Therefore, it seems likely that other factors contribute to the specificity of gene regulation.

RECEPTORS THAT SIGNAL THROUGH ASSOCIATED TYROSINE KINASES

Members of the cytokine family of receptors resemble receptor tyrosine kinases in their mechanism of action, with one important difference. Instead of having a tyrosine kinase that is intrinsic to the receptor, enzymatic activity

resides in a protein that associates with the cytokine receptor. As with receptor tyrosine kinases, ligand binding to the cytokine receptor activates the associated kinase. The more than 40 ligands that bind to members of the cytokine receptor family have diverse functions. Three of the ligands are hormones: GH, which is vital for normal body height; prolactin, which is required for reproduction and lactation; and leptin, which suppresses appetite, stimulates energy expenditure, and promotes glucose homeostasis through a variety of mechanisms.⁸⁷⁻⁸⁹ Other ligands of cytokine receptors, such as erythropoietin, most interleukins, and interferons- α , - β , and - γ , regulate hematopoiesis or the immune response. A number of genetic diseases can be traced to defects in cytokine receptors. For example, Laron dwarfism is caused by autosomal recessive mutations of the GH receptor,⁹⁰ and autosomal recessive mutations of the leptin receptor can cause morbid obesity.⁹¹ A gain-of-function mutation of the prolactin receptor has been identified in women with benign breast tumors.⁹²

Cytokine Receptors with Multiple Subunits

Members of the cytokine family of receptors share homology in the extracellular and cytoplasmic domains. Some cytokine receptors, including the receptors for GH, prolactin, and leptin, are thought to be composed of dimers of a single receptor subunit (Fig. 5-8). One ligand is thought to bind to both receptor subunits, as discussed earlier for the GH receptor.

Most cytokine receptors are composed of two or more different subunits, with as many as six subunits constituting a single receptor.^{93,94} Some of these receptors are thought to bind ligand dimers. One or more receptor subunits are shared by receptors for other cytokines. This phenomenon of mixing and matching receptor subunits is an efficient way for the cell to fine-tune its cellular responses and increase the number of ligands that can be bound by a particular group of receptor subunits. For example, a receptor composed of the gp130 subunit and the leukemia inhibitory factor receptor β -subunit binds leukemia inhibitory factor, a pleiotropic cytokine with multiple functions that appears to serve as a molecular interface between the

Figure 5-8 Cytokine receptors are composed of multiple subunits and bind to one or more members of the Janus kinase (JAK) family of tyrosine kinases. **A**, Growth hormone (GH), like prolactin and leptin, binds to growth hormone receptor (GHR) homodimers and activates JAK2. **B**, Interferon- γ (IFN γ) homodimers bind to their ligand-binding γ R1 subunits. The γ R2 subunits are then recruited, leading to activation of JAK1, which binds to the γ R1 subunit, and JAK2, which binds to the γ R2 subunit. Both subunits and both JAKs are necessary for responses to IFN γ . **C**, Interleukin 2 (IL-2) binds to receptors composed of three subunits: a γ C subunit shared with receptors for IL-4, -7, -9, -15, and -21; an IL-2R β subunit shared with the IL-15 receptor; and a noncytokine receptor subunit, IL-2R α . IL-2 activates JAK3, bound to the γ C subunit, and JAK1, bound to IL-2R β . Extracellular regions of homology are indicated by the black lines and colored patterns. Intracellular regions of homology are indicated by the small white boxes. Identical subunits are indicated by identical colors.

neuroimmune and endocrine systems.⁹⁵ The same receptor subunits, when combined with a ciliary neurotrophic factor receptor subunit, show a preference for ciliary neurotrophic factor, a trophic factor for motor neurons in the ciliary ganglia and spinal cord that is also a potent appetite suppressor.⁹⁶ And if two gp130 subunits are combined with an interleukin 6 (IL-6) receptor subunit, the new receptor shows a preference for IL-6, an inducer of the acute phase response with additional anti-inflammatory properties.⁹⁷

Cytokine Receptors Activate Members of the Janus Family of Tyrosine Kinases

Members of the cytokine family of receptors do not themselves exhibit enzymatic activity. Rather, they bind members of the Janus family of tyrosine kinases (JAKs) in a proline-rich region (see Fig. 5-8). There are four known JAKs, designated JAK1, JAK2, JAK3, and TYK2. Like the cytokine receptors themselves, the JAKs mix and match their subunits. Some cytokine receptors show a strong preference for a single JAK, some require two different JAKs, and others appear to activate multiple JAK family members. GH, prolactin, and leptin preferentially activate JAK2; interferon- γ activates JAK1 and JAK2; and IL-2 activates JAK1 and JAK3.^{93,98}

Binding of ligand to a cytokine receptor activates the appropriate JAK family member or members. In some cases (e.g., prolactin), the JAKs appear to be constitutively associated with the cytokine receptor, and ligand binding increases their activity.⁹⁹ In other cases (e.g., GH receptor), ligand binding appears to increase both the affinity of JAKs for the cytokine receptor and the activity of the associated JAKs.¹⁰⁰ Activation of JAKs requires receptor oligomerization, presumably to bring two or more JAKs sufficiently close to transphosphorylate each other on the activating tyrosine in the kinase domain (see earlier discussion of receptor tyrosine kinases). Both receptor dimerization and ligand-induced changes in receptor conformation appear

to be required for receptor activation.¹⁰¹ Transphosphorylation is thought to cause a conformational change that exposes the ATP-binding or substrate-binding site, or both, and activation is thought to release an autoinhibitory domain.¹⁰² After the JAKs are activated, they phosphorylate themselves and their associated receptor subunits on multiple tyrosines.

JAKs appear to be vital for normal human function. Mutations in the *JAK3* gene have been linked to an autosomal recessive form of severe combined immunodeficiency disease.¹⁰³ Targeted disruption of the *JAK2* gene in mice embryos is lethal.¹⁰⁴

Signaling Pathways Initiated by Cytokine Receptor-JAK Complexes

Phosphorylated tyrosines within the cytokine receptor subunits and their associated JAKs form binding sites for various signaling proteins containing phosphotyrosine-binding domains, such as the SH2 and PTB domains. Each cytokine receptor-JAK complex is expected to have some tyrosine-containing motifs shared with many other cytokine receptor-JAK complexes (e.g., tyrosines within JAKs) and some ligand-specific tyrosine-containing motifs (e.g., tyrosines within a specific combination of receptor subunits). Ligand binding to cytokine receptors is expected to initiate some signaling pathways that are shared by many cytokines and some that are more specialized to a particular cytokine receptor.

The signaling proteins recruited to subsets of cytokine receptor-JAK complexes are generally the same as those recruited to receptor tyrosine kinases. Examples include the IRS proteins, the adaptor proteins SHC and GRB2 that lead to activation of the RAS/MAP kinase pathway, phospholipase C γ , and PI3K. However, one family of signaling proteins appears to be particularly important for the function of cytokines: the signal transducers and activators of transcription (STATs) (Fig. 5-9).

Figure 5-9 Cytokines activate signal transducers and activators of transcription (STATs). STAT proteins are latent cytoplasmic transcription factors. STATs bind through SRC homology 2 (SH2) domains to one or more phosphorylated tyrosines (P) in activated receptor-Janus kinase (JAK) complexes. Once bound, STATs themselves are tyrosyl phosphorylated, presumably by the receptor-associated JAKs. STATs then dissociate from the receptor-JAK complex, homodimerize or heterodimerize with other STAT proteins, move to the nucleus, and bind to gamma-activated sequence-like elements (GLEs) in the promoters of cytokine-responsive genes. P, phosphorylation. (Adapted from J. Herrington, with permission.)

STAT proteins are latent cytoplasmic transcription factors that cycle between the cytoplasm and the nucleus. After ligand activation, inactive STATs in the cytoplasm bind through their SH2 domains to one or more phosphorylated tyrosines in the activated receptor-JAK complexes. Once bound, they are tyrosyl phosphorylated, presumably by the receptor-associated JAKs. STATs then dissociate from the receptor-JAK complexes, homodimerize or heterodimerize with other STAT proteins, move to the nucleus, and bind to gamma-activated sequence-like elements in the promoters of cytokine-responsive genes.^{104,105}

The transcriptional response depends on how many STAT binding sites exist in the receptor-JAK complex, with which of the seven known STATs a particular STAT heterodimerizes, to what other proteins a particular STAT binds, other post-translational modifications in the degree of serine or threonine phosphorylation of the STAT, and what other transcription factors are activated. For example, the receptor for leukemia inhibitory factor contains seven STAT3 binding motifs (YxxQ, in which Y is tyrosine, Q is glutamine, and x can be any amino acid [i.e., Tyr-Xaa-Xaa-Gln]), and leukemia inhibitory factor is a particularly potent activator of STAT3.¹⁰⁶ The transcriptional activity of STAT5 is enhanced when it forms a complex with the glucocorticoid, mineralocorticoid, and progesterone receptors but diminished when it forms a complex with the estrogen receptor.¹⁰⁷ The importance of STAT5B for GH signaling is illustrated by the finding that severe growth failure in humans is associated with point mutations in the *STAT5B* gene that result in a defective SH2 domain or an unstable, truncated form of STAT5B.^{108,109}

Precise Regulation of Cytokine Receptors Required for Normal Function

Ligand binding to cytokine receptors normally activates JAKs rapidly and transiently. Conversely, constitutively activated JAKs and STATs are associated with cellular transformation. For example, a single acquired activating point mutation in *JAK2* is present in most patients with a myeloproliferative disorder.¹¹⁰ Constitutively active JAKs and STATs are also a common characteristic of leukemias,¹¹¹ and *JAK2* and *STAT5B* have been identified as fusion partners in translocations in leukemias. The TEL-*JAK2* fusion protein is constitutively active, leading to constitutively active STAT proteins. Understanding what turns off cytokine receptor signaling is of utmost importance in understanding normal signaling through cytokine receptors.

As with the receptor tyrosine kinases, multiple steps have been hypothesized to serve as points of signal termination for cytokine signaling. They include receptor internalization and degradation (e.g., through a ubiquitination/proteasome and/or lysosomal pathway) and dephosphorylation of tyrosines within the JAK or the receptor (e.g., by a tyrosine phosphatase that binds to receptor-JAK complexes).

The suppressors of cytokine-signaling (SOCS) proteins are thought to be particularly important players in the termination or suppression of cytokine signaling pathways. SOCS proteins are an excellent example of an effective negative feedback loop. They usually are synthesized in response to activation of STAT proteins. The newly synthesized SOCS proteins bind through the SH2 domain to phosphorylated tyrosines within the cytokine receptor-JAK complex and inhibit further cytokine signaling. In some cases (e.g., SOCS1), SOCS proteins are thought to bind to phosphotyrosines in the kinase domain of JAK and inhibit kinase activity.¹¹² In other cases (e.g., SOCS3), SOCS

proteins bind to phosphorylated tyrosines in the receptor and inhibit JAK activity.¹¹³ In some cases (e.g., cytokine-inducible SH2 protein [CIS]), SOCS proteins bind to phosphorylated tyrosines in the receptor and block STAT binding and activation.¹¹⁴

SOCS proteins are ubiquitin ligases,¹¹⁵ and in some cases, they are thought to alternatively or additionally promote receptor-JAK internalization or degradation.¹¹⁶ SOCS proteins can be synthesized in response to noncytokine receptors, suggesting a mechanism whereby prior exposure to one ligand suppresses subsequent responses to another. For example, SOCS proteins have been implicated in the well-known ability of endotoxin to cause resistance to GH.¹¹⁷

Summary of Regulatory Mechanisms

Hormones, growth factors, and cytokines that bind to members of the cytokine family of receptors activate JAK family tyrosine kinases. The activated kinases phosphorylate tyrosines in themselves and in associated receptors. The phosphorylated tyrosines form binding sites for other signaling proteins, including STAT proteins and a variety of other phosphotyrosine-binding proteins. STAT proteins promote the regulation of cytokine-sensitive genes. SOCS proteins that serve a negative feedback function of terminating ligand activation of JAKs or STATs, or both.

This picture of regulation is continuously becoming much more complex. For example, there are reports that members of the SRC family of tyrosine kinases can also be activated by some cytokine receptors (e.g., prolactin receptor),¹¹⁸ that some JAK-binding proteins (e.g., SH2-B1) are potent activators of specific JAKs,¹¹⁹ and that other proteins contribute to the downregulation of cytokine-signaling pathways. This last group includes the protein inhibitors of activated STAT (PIAS), proteins that bind to specific STATs and inhibit their transcriptional activity.^{120,121} Cytokine receptors, JAKs, STATs, and SOCS proteins also interact with or are components of signaling downstream of some receptor tyrosine kinases (e.g., receptors for insulin, IGF1, EGF) and several GPCRs (e.g., receptors for angiotensin II, serotonin, α -thrombin, luteinizing hormone). In contrast to their essential role in signaling by cytokine receptors, JAKs do not appear to be the primary signaling mediator for either the receptor tyrosine kinases or the GPCRs.

G PROTEIN-COUPLED RECEPTORS

GPCRs are an evolutionarily conserved gene superfamily with members in all eukaryotes from yeast to mammals. They transduce a wide variety of extracellular signals, including photons of light; chemical odorants; divalent cations; monoamine, amino acid, and nucleoside neurotransmitters; lipids; and peptide and protein hormones.¹²² All members of the GPCR superfamily share a common structural feature—seven membrane-spanning helices—but various subfamilies diverge in their primary amino acid sequence and in the domains that serve in ligand binding, G protein coupling, and interaction with other effector proteins (Fig. 5-10).

All GPCRs act as guanine nucleotide exchange factors. In their activated (agonist-bound) conformation, they catalyze the exchange of GDP tightly bound to the α -subunit of heterotrimeric G proteins for GTP (Fig. 5-11). This leads to activation of the α -subunit and its dissociation from the G protein $\beta\gamma$ dimer. Both G protein subunits are capable of regulating effector activity.¹²³ Identified G protein-regulated

Figure 5-10 The G protein-coupled receptor (GPCR) superfamily: diversity in ligand binding and structure. Each panel depicts members of the GPCR superfamily. The seven-membrane-spanning α -helices are shown as cylinders, with the extracellular amino-terminus and three extracellular loops above them and the intracellular carboxyl-terminus and three intracellular loops below. The superfamily can be divided into three subfamilies on the basis of amino acid sequence conservation within the transmembrane helices. Family 1 includes the opsins, **A**, in which light (arrow) causes isomerization of retinal covalently bound within the pocket created by the transmembrane helices (bar); monoamine receptors, **B**, in which agonists (arrow) bind noncovalently within the pocket created by the transmembrane helices (bar); receptors for peptides such as vasopressin, **C**, in which agonist binding (arrow) may involve parts of the extracellular N-terminus and loops and the transmembrane helices (bar); and glycoprotein hormone receptors, **D**, in which agonists (oval) bind to the large extracellular N-terminus, activating the receptor through undefined interactions with the extracellular loops or transmembrane helices (arrow). Family 2, **E**, includes receptors for peptide hormones such as parathyroid hormone and secretin. Agonists (arrow) may bind to residues in the extracellular N-terminus and loops and to transmembrane helices (bar). Family 3, **F**, includes the extracellular Ca^{2+} -sensing receptor and metabotropic glutamate receptors. Agonists (circle) bind in a cleft of the Venus flytrap-like domain in the large extracellular N-terminus, activating the receptor through undefined interactions with the extracellular loops or transmembrane helices (arrow).

is considerable diversity in G protein subunits, with multiple genes encoding all three subunits and alternative gene splicing resulting in additional polypeptide products. There are at least 16 distinct α -subunit genes in mammals. These vary widely in range of expression. Some, such as G_α , which couples many GPCRs to stimulation of adenylyl cyclase, are ubiquitous; others, such as $\text{G}_{\text{H}\alpha}$, which couples the GPCR rhodopsin to cyclic guanosine monophosphate phosphodiesterase in retinal rod photoreceptor cells, are highly localized.

Because multiple GPCRs, G proteins, and effectors are expressed within a cell, the degree and basis for specificity in G protein coupling to GPCRs and to effectors are major subjects of investigation, with implications for understanding drug actions and disease mechanisms.¹² Since the pioneering work of Rodbell¹²⁵ in discovering G proteins and showing that G protein-mediated signal transduction involves three separable components (i.e., receptor, G protein, and effector), additional complexity has emerged.

A large gene family whose members are regulators of G protein signaling (RGS) has been identified. RGS proteins bind to a transition state of the GTP-activated G protein α -subunit and accelerate its GTPase activity, helping to deactivate the α -subunit. RGS domains have also been found in modular proteins with additional functions, in certain cases linking heterotrimeric G protein signaling with the function of low-molecular-weight GTP-binding proteins in the RAS superfamily.¹²⁴ Lefkowitz¹²⁵ has shown that a family of GPCR kinases and arrestin proteins is involved in GPCR desensitization after agonist binding. GPCRs interact directly with a number of other proteins in addition to G proteins. GPCRs are important targets for treatment of many diseases, and mutations in genes encoding GPCRs have been identified as the cause of several endocrine and non-endocrine disorders.

G Protein-Coupled Receptor Structure and Function

Structure

Hydropathy analysis of the primary sequence of all GPCRs predicts seven membrane-spanning α -helices connected by

effectors include enzymes of second-messenger metabolism such as adenylyl cyclase and phospholipase $\text{C}\beta$ and a variety of ion channels. Agonist binding to GPCRs alters intracellular second-messenger and ion concentrations, with resultant rapid effects on hormone secretion, muscle contraction, and a variety of other physiologic functions. Long-term changes in gene expression result from second messenger-stimulated phosphorylation of transcription factors.

The G protein subunits are encoded by three distinct genes. The α -subunit binds guanine nucleotides with high affinity and specificity and has intrinsic guanosine triphosphatase (GTPase) activity. The β and γ polypeptides are tightly but noncovalently associated in a functional dimer subunit. The three-dimensional structures of the individual and associated subunits have been determined.^{123,124} There

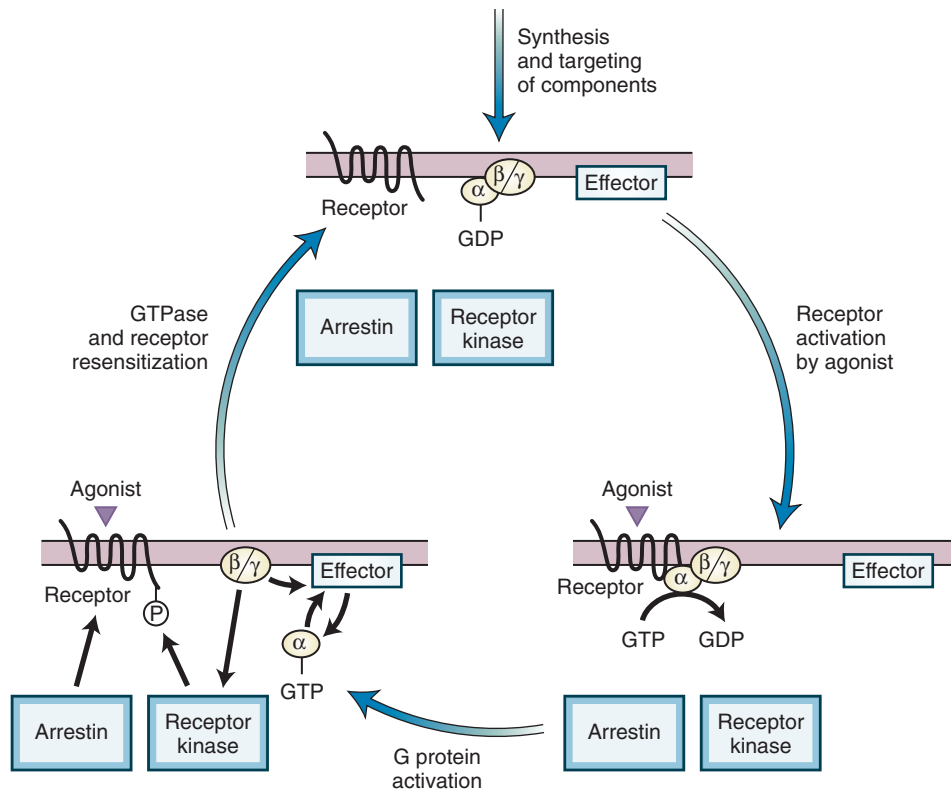

Figure 5-11 The G protein guanosine triphosphatase (GTPase) and G protein–coupled receptor (GPCR) desensitization-resensitization cycle. In each panel, the shaded area denotes the plasma membrane, with the extracellular region above and the intracellular region below. In the basal state, the G protein is a heterotrimer with guanosine diphosphate (GDP) tightly bound to the α -subunit. The agonist-activated GPCR catalyzes release of GDP, which permits guanosine triphosphate (GTP) to bind. The GTP-bound α -subunit dissociates from the $\beta\gamma$ dimer. Arrows from the α -subunit to the effector and from the $\beta\gamma$ dimer to the effector indicate regulation of effector activity by the respective subunits. The arrow from effector to the α -subunit indicates regulation of its GTPase activity by effector interaction. Under physiologic conditions, effector regulation by G protein subunits is transient and is terminated by the GTPase activity of the α -subunit. The latter converts bound GTP to GDP, thereby returning the α -subunit to its inactivated state with high affinity for the $\beta\gamma$ dimer, which reassociates to form the heterotrimer in the basal state. In the basal state, the receptor kinase and arrestin are shown as cytosolic proteins. Dissociation of the GTP-bound α -subunit from the $\beta\gamma$ dimer permits the dimer to facilitate binding of receptor kinase to the plasma membrane (arrow from $\beta\gamma$ dimer to receptor kinase). Plasma membrane binding permits the receptor kinase to phosphorylate the agonist-bound GPCR (P, depicted here as occurring on the carboxyl-terminal tail of the GPCR, although sites on intracellular loops are also possible). GPCR phosphorylation facilitates arrestin binding to the GPCR, resulting in desensitization. Endocytic trafficking of arrestin-bound GPCR and recycling to the plasma membrane during resensitization are not shown.

three intracellular loops and three extracellular loops with an extracellular N-terminus and an intracellular C-terminus (see Fig. 5-10). This basic structure has been verified by x-ray crystallography for rhodopsin, β_1 - and β_2 -adrenergic, and adenosine A_{2a} receptors.¹²⁷ Although there was evidence that visual transduction in the retina and hormone activation of adenylyl cyclase shared common features, the discovery that the β -adrenergic receptor has the same topographic structure as rhodopsin came as a surprise.¹²⁶ Cloning of the complementary deoxyribonucleic acids (cDNAs) for a vast number of GPCRs followed elucidation of the primary sequence of the β -adrenergic receptor, and in every case, the same core structure was predicted by hydropathy analysis.

In addition to the predicted core structure, other common features (with exceptions in some subsets of the GPCR superfamily) have been identified¹²²:

- A disulfide bridge connecting the first and second extracellular loops
- One or more N-linked glycosylation sites, usually in the N-terminus but occasionally in extracellular loops
- Palmitoylation of one or more cysteines in the C-terminus, which effectively creates a fourth intracellular loop

- Potential phosphorylation sites in the C-terminus and occasionally in the third intracellular loop

Glycosylation appears to be important for proper folding and trafficking to the plasma membrane rather than for ligand binding. The disulfide bridge may help in proper arrangement of the transmembrane helices.

Superimposed on the basic structure of GPCRs are a number of variations relevant to differences in ligand binding, G protein coupling, and interaction with other proteins.¹²² There are major differences in amino acid sequence among members of the GPCR superfamily. Sequence alignment, especially of the transmembrane helices, allows division of the superfamily into subfamilies (see Fig. 5-10).

Family 1, the largest group, can itself be subdivided. The largest subset includes opsins, odorant receptors, and monoamine, purinergic, and opiate receptors. These are characterized by a short N-terminus. The second subset includes chemokine, protease-activated, and certain peptide hormone receptors characterized by a slightly longer N-terminus. The third subset comprises receptors for the large glycoprotein hormones, TSH, luteinizing hormone, and follicle-stimulating hormone. They have an approximately 400-residue extracellular N-terminus.

Family 2 shows essentially no sequence homology to family 1, even within the transmembrane helices, and it is characterized by an approximately 100-residue N-terminus. Members include receptors for several peptide hormones such as parathyroid hormone (PTH), calcitonin, vasoactive intestinal peptide, and corticotropin-releasing hormone.

Family 3, in addition to having a unique primary sequence, has other distinctive features such as an approximately 200-residue C-terminus and an approximately 600-residue N-terminus. The latter consists of a putative Venus flytrap-like domain and a cysteine-rich domain. Members include the metabotropic glutamate receptors, an extracellular Ca^{2+} -sensing receptor, and putative taste and pheromone receptors.¹²⁸ Determination of the three-dimensional crystal structure of part of the extracellular N-terminus of the metabotropic glutamate receptors has verified a two Venus flytrap-like structure linked to the cysteine-rich region by a disulfide bridge.¹²⁸

Ligand Binding

Given the diversity of ligands (>1000) that bind to GPCRs, it is not surprising that considerable diversity is evident in the sequence and structure of presumptive GPCR ligand-binding domains. The opsins are unique among GPCRs in that the ligand, retinal, is covalently bound to a lysine in the seventh transmembrane helix.¹²⁷ Ligand binding for other members of family 1 with a short extracellular N-terminus, such as adrenergic and other monoamine receptors, involves a pocket within the transmembrane helices, as has been demonstrated for rhodopsin (see Fig. 5-10). Rhodopsin's N-terminus and extracellular loops form a well-structured domain that occludes the retinal binding site. The hormone receptors have a more open extracellular structure that facilitates ligand entry into the transmembrane domain.¹²⁷

For other family 1 GPCRs, the extracellular N-terminus, perhaps together with extracellular loops and portions of the transmembrane helices, is involved in ligand binding. In the case of the glycoprotein hormone receptors, the large, curved, extracellular N-terminus plays the principal role in hormone binding.¹²⁹

In a model for peptide binding to family 2 receptors, the extracellular N-terminus is responsible for initial binding to the peptide C-terminus, followed by peptide N-terminus binding to the seven-transmembrane domain.¹³⁰ For family 3 GPCRs, the three-dimensional structure of the metabotropic glutamate receptor shows that agonist binding occurs within a cleft between the lobes of the Venus flytrap.¹²⁸

G Protein Coupling

Because the number of potential G proteins to which GPCRs couple is much more limited than the number of ligands that bind GPCRs, more conservation of the domains involved in G protein coupling is expected. Although GPCRs can be broadly divided into those that couple to G_s , those that couple to the G_q subfamily, and those that couple to the G_i - G_o subfamily, the situation is probably more complicated.¹²⁴ Specificity of coupling to the most recently identified G proteins, G_{12} and G_{13} , is still uncertain. Also, some GPCRs evidently can couple to both G_s and G_q .

Many studies have been performed to define the sites of ligand binding and G protein coupling of GPCRs.^{124,131} Considerable evidence points to the third intracellular loop (particularly its membrane-proximal portions) and to the membrane-proximal portion of the C-terminus as key determinants of G protein-coupling specificity. For example, exchanging only the third intracellular loop

between different GPCRs confers the G protein-coupling specificity of the exchanged loop on the recipient GPCR.¹³² In contrast, the second intracellular loop, although important for G protein coupling, appears to play a role in the activation mechanism rather than in determining specificity of coupling.¹³² A tripeptide "DRY" motif (D/E, R, Y/W) at the juncture between the third transmembrane helix and the start of the second intracellular loop that is highly conserved in family 1 GPCRs is critical for G protein activation.¹³¹ The three-dimensional structure of a complex between activated rhodopsin and a C-terminal peptide of the retinal G protein α -subunit shows direct binding of the latter to the arginine of the receptor's DRY motif.¹²⁷

Mechanism of Activation

The precise mechanism of activation after agonist binding has not been defined for most GPCRs, but x-ray crystallographic studies of rhodopsin, β -adrenergic, and adenosine receptors provide the clearest picture available. In the ground state, retinal covalently bound to the seventh transmembrane helix in rhodopsin holds the transmembrane helices in an inactive conformation, at least in part through so-called ion lock created by electrostatic interaction between the arginine at the end of the third transmembrane domain and a glutamate at the end of the sixth transmembrane domain.¹²⁷ Isomerization of retinal on absorption of light of the appropriate wavelength converts an antagonist ligand into an agonist. The rhodopsin crystal structure identifies the residues in the transmembrane helices that interact with retinal and suggests a mechanism for movement of the helices, particularly the third and sixth transmembrane domains, on photoactivation of retinal.¹²⁷ Movement of the transmembrane helices leads to changes in conformation of cytoplasmic loops that promote G protein activation.

For family 1 receptors related to rhodopsin, determination of their three-dimensional structures validates the idea that a change in conformation of transmembrane helices is the direct result of agonist or antagonist binding to residues within the helices.¹²⁷ Molecular modeling by computer on the basis of the rhodopsin structure and experimental testing offers a useful approach to defining critical structural regions of other GPCRs.¹³³ The availability of three-dimensional structures for β -adrenergic and adenosine receptors also permits *in silico* studies of ligand binding to these receptors.¹²⁷

For other GPCRs whose presumptive site of agonist binding does not solely involve direct contact with transmembrane helices (i.e., families 2 and 3 and the glycoprotein hormone receptors in family 1), much remains to be learned about how agonist binding to the extracellular domain of these GPCRs leads to presumptive changes in conformation of transmembrane helices and receptor activation. Determination of the structure of the extracellular domain of the FSH receptor bound to FSH illustrates the general mechanism of glycoprotein hormone binding to cognate GPCRs and resultant interactions with the seven-transmembrane domain receptor leading to activation.

A hypothesis of GPCR activation postulates that GPCRs are in equilibrium between an activated state and inactive state. These states presumably differ in the disposition of the transmembrane helices and the cytoplasmic domains that determine G protein coupling. According to this ternary complex model, agonists are viewed as stabilizing the activated state. Antagonists may be neutral; that is, they may simply compete with agonists for receptor binding, with their binding having no influence on the equilibrium. Alternatively, they may be inverse agonists,

with their binding stabilizing the inactive state of the receptor.¹³⁴ Multiple conformational states may exist between the so-called active and inactive conformations, with different ligands capable of promoting a particular conformation. This possibility has important implications for the downstream signaling consequences of a given ligand, a concept called *ligand-directed signaling*¹²⁴ or *ligand-biased efficacy*.

Dimerization

Members of the tyrosine kinase receptor family require dimerization as part of their activation mechanism, and many GPCRs form homodimers and heterodimers.^{122,124} Residues within transmembrane helix 6 may foster dimerization of small, family 1 GPCRs,¹³⁶ and intermolecular disulfide bonds in the extracellular N-terminal domain are involved in homodimerization of most family 3 GPCRs.^{128,137,138} A coiled-coil interaction in the C-terminus of γ -aminobutyric acid B receptor subtypes is responsible for heterodimerization, and this is critical for proper receptor function.¹³⁹ Modifications of ligand binding, signaling, and receptor sequestration have been demonstrated on heterodimerization of angiotensin with bradykinin receptors, of κ with δ opioid receptors, and of opioid with β -adrenergic receptors, and a role for ligand-independent action of heterodimerized orphan GPCRs (discussed later) has been proposed.¹⁴⁰ Additional studies are needed to elucidate the physiologic relevance of GPCR homodimerization and heterodimerization.

G Protein–Coupled Receptor Desensitization

Pharmacologists have long appreciated that continued exposure to agonist leads to a diminished response, or *desensitization*. This phenomenon has been extensively studied in GPCRs. Two forms are defined: heterologous desensitization, in which binding of agonist to one GPCR leads to a diminished response of a different GPCR to its agonist, and homologous desensitization, in which desensitization occurs only for the GPCR to which agonist is bound. Both forms involve GPCR phosphorylation but by different kinases and at different sites. Stimulation of cyclic adenosine monophosphate formation by agonist binding to a G_s -coupled GPCR leads to activation of protein kinase A, which in turn can phosphorylate and desensitize the GPCR. Phosphorylation may also alter G protein-coupling specificity.¹²² Similarly, protein kinase C activation resulting from GPCR coupling to G_q family members may cause protein kinase C-catalyzed phosphorylation of GPCRs with desensitization.

In retinal photoreceptors, a specific rhodopsin kinase and the arrestin protein have been implicated in attenuation of the light response. Just as there are parallels between rhodopsin and GPCR structure, parallels have also been identified in desensitization mechanisms. Rhodopsin kinase is only one member of a family of GPCR kinases and arrestin only one of a family of related proteins that function in desensitization of many members of the GPCR superfamily.¹²⁶ GPCR kinases preferentially phosphorylate the agonist-bound form of a GPCR, ensuring homologous desensitization. On GPCR phosphorylation by GPCR kinase, arrestins bind to the third intracellular loop and C-terminal tail of the GPCR, thereby blocking G protein binding (see Fig. 5-11). GPCR kinases and arrestins not only desensitize GPCRs but also mediate other functions, including receptor internalization and interaction with other effectors.

G PROTEIN-COUPLED RECEPTOR INTERACTIONS WITH OTHER PROTEINS

The initial paradigm of GPCR function postulated that G protein activation is the sole outcome of agonist binding to GPCRs. With the identification of GPCR interactions with GPCR kinases and arrestins, this concept was modified to include the proteins involved in GPCR desensitization. Later evidence suggested that GPCR interaction with arrestins may also permit recruitment of other proteins to the GPCR. For example, the SRC tyrosine kinase may interact with the β -adrenergic receptor, with β -arrestin serving as an adaptor.¹⁴¹ Arrestins may also recruit proteins involved in endocytosis, and GPCR kinases may recruit additional signaling proteins to the GPCR.¹⁴¹

Other classes of proteins may interact with specific GPCRs without recruitment by GPCR kinases and arrestins. They include SH2 domain-containing proteins, small GTP-binding proteins, and postsynaptic density protein-95/discs large/zona occludens 1 (PDZ) domain-containing proteins. An example of the latter is binding of the Na^+/H^+ exchanger regulatory factor to the C-terminus of the β -adrenergic receptor.¹⁴¹ The long C-terminus of family 3 GPCRs (e.g., metabotropic glutamate receptors) contains polyproline motifs involved in binding members of the Homer family of PDZ proteins, which can facilitate functional interactions with other proteins such as the inositol triphosphate receptor.¹⁴² Receptor activity-modifying proteins (RAMPs), a family of single-transmembrane-domain proteins, appear to heterodimerize with certain GPCRs, assisting them in proper folding and membrane trafficking.¹⁴³ This rapidly evolving aspect of GPCR function promises many interesting developments.

G PROTEIN-COUPLED RECEPTORS IN DISEASE PATHOGENESIS AND TREATMENT

Because of their diverse and critical roles in normal physiology, their accessibility on the cell surface, and their ability to synthesize selective agonists and antagonists, GPCRs have been a major target for drug development. One estimate is that about 65% of prescription drugs target GPCRs. Drugs targeting GPCRs may act as agonists, antagonists, or allosteric modulators. For example, calcimimetic drugs inhibit PTH release by binding to the seven-transmembrane domain and acting as positive allosteric modulators of the Ca^{2+} -sensing receptor.¹³⁸ With the cloning of GPCR cDNAs, much greater diversity of receptor subclasses became evident than had been anticipated on the basis of pharmacologic studies. For example, five muscarinic receptor subtypes and an even greater number of serotonergic GPCRs were identified.¹³⁰ This information has enabled development of highly specific subtype-selective drugs that have fewer side effects than those produced by previously available agents.

Another result of the cloning of GPCR cDNAs by homology screening and polymerase chain reaction-based approaches is the identification of orphan GPCRs, receptors that have the canonical, predicted seven-transmembrane-domain structure of GPCRs but have no identified physiologic agonists. There have been substantial efforts to identify the relevant ligands for these orphan

receptors.¹⁴⁰ For example, the Krebs cycle intermediates, succinate and α -ketoglutarate, were shown to be the physiologically relevant activators of the orphan GPCRs, GPR91, and GPR99, respectively; through binding, they regulate renin release and blood pressure.¹⁴⁴ In addition to revealing novel physiologic and pathophysiologic mechanisms, GPCR “deorphanization” provides novel targets for drug development.

Beyond drug development, defects in GPCRs are an important cause of a variety of human diseases.¹⁴⁵ GPCR mutations can cause loss of function by impairing any of several steps in the normal GPCR-GTPase cycle (see Fig. 5-11), including failure to synthesize the GPCR protein altogether, failure of synthesized GPCR to reach the plasma membrane, failure of GPCR to bind or be activated by agonist, and failure of GPCR to couple to or activate G protein. Because in most cases clinically significant impairment of signal transduction requires loss of both alleles of a GPCR gene, most of these diseases are inherited in autosomal recessive fashion (Table 5-1).

Most diseases manifest as resistance to the action of the normal agonist and mimic deficiency of the agonist. For example, TSH receptor loss-of-function mutations cause a form of hypothyroidism that mimics TSH deficiency, but the serum TSH level is elevated in such cases, reflecting resistance to the hormone's action caused by defective receptor function. Hypogonadotropic hypogonadism may be caused by loss-of-function mutations of the GnRH receptor, the orphan GPR54, or the prokineticin receptor 2 (PROKR2). In the first case, there is resistance to the action of GnRH. In the latter two cases, hypogonadotropic hypogonadism may reflect failure to release GnRH, but the precise mechanism has not been defined.^{146,147} Nephrogenic diabetes insipidus (i.e., renal vasopressin resistance) is caused by loss-of-function mutations in the arginine vasopressin receptor 2 gene (*AVPR2*) located on the X chromosome. Males with a single copy of the gene develop the disease when they inherit a mutant gene; most females do

TABLE 5-1

Diseases Caused by G Protein–Coupled Receptor Loss-of-Function Mutations

Receptor	Disease	Inheritance
V2 vasopressin	Nephrogenic diabetes insipidus	X-linked
ACTH	Familial ACTH resistance	AR
GHRH	Familial GH deficiency	AR
GnRH	Hypogonadotropic hypogonadism	AR
GPR54	Hypogonadotropic hypogonadism	AR
Prokineticin receptor 2	Hypogonadotropic hypogonadism	AD*
FSH	Hypergonadotropic ovarian dysgenesis	AR
LH	Male pseudohermaphroditism	AR
TSH	Familial hypothyroidism	AR
Ca ²⁺ sensing	Familial hypocalciuric hypercalcemia	AD
	Neonatal severe primary hyperparathyroidism	AR
Melanocortin 4	Obesity	AR
PTH/PTHrP	Blomstrand chondrodysplasia	AR

*With incomplete penetrance.

ACTH, adrenocorticotrophic hormone; AD, autosomal dominant; AR, autosomal recessive; FSH, follicle-stimulating hormone; GH, growth hormone; GHRH, growth hormone–releasing hormone; GnRH, gonadotropin-releasing hormone; GPR54, orphan G protein–coupled receptor 54; LH, luteinizing hormone; PTH, parathyroid hormone; PTHrP, parathyroid hormone–related protein; TSH, thyroid-stimulating hormone.

TABLE 5-2

Diseases Caused by G Protein–Coupled Receptor Gain-of-Function Mutations

Receptor	Disease	Inheritance
LH	Familial male precocious puberty	AD
TSH	Sporadic hyperfunctional thyroid nodules	Noninherited (somatic)
	Familial nonautoimmune hyperthyroidism	AD
Ca ²⁺ sensing	Familial hypocalcemic hypercalciuria	AD
PTH/PTHrP	Jansen's metaphyseal chondrodysplasia	AD
V2 vasopressin	Nephrogenic inappropriate antidiuresis	AD

AD, autosomal dominant; LH, luteinizing hormone; PTH, parathyroid hormone; PTHrP, parathyroid hormone–related protein; TSH, thyroid-stimulating hormone.

not show overt disease because random X inactivation leaves them with an average of 50% of normal gene function. Most *AVPR2* mutations associated with nephrogenic diabetes insipidus cause loss of function by impairing normal synthesis or folding of the receptor, or both. A novel mechanism for receptor loss of function elucidated for an *AVPR2* missense mutation associated with nephrogenic diabetes insipidus involves constitutive arrestin-mediated desensitization.¹⁴⁸

The extracellular Ca²⁺-sensing receptor appears to be an interesting exception to the association between GPCR loss-of-function mutations and hormone resistance. Loss-of-function mutations of this receptor mimic a hormone hypersecretion state, primary hyperparathyroidism. Such mutations do cause hormone resistance, but extracellular Ca²⁺ is the hormonal agonist that acts through this receptor to inhibit PTH secretion. A loss-of-function mutation of one copy of the receptor gene typically causes mild resistance to extracellular Ca²⁺, which manifests as familial hypocalciuric hypercalcemia. If two defective copies are inherited, extreme Ca²⁺ resistance causing neonatal severe primary hyperparathyroidism results (see Table 5-1). In some cases, a heterozygous receptor loss-of-function mutation is associated with neonatal severe primary hyperparathyroidism, perhaps reflecting a dominant negative effect caused by dimerization of wild-type and mutant receptors.¹⁴⁹

GPCR gain-of-function mutations are an important cause of disease (Table 5-2).¹⁴⁵ Given the dominant nature of activating mutations, most of these diseases are inherited in an autosomal dominant manner. Activating TSH receptor mutations may be inherited in autosomal dominant fashion and cause diffuse thyroid enlargement in familial nonautoimmune hyperthyroidism, or they may occur as somatic mutations causing focal, sporadic, hyperfunctional thyroid nodules.¹⁵⁰ Activating germline LH receptor mutations cause familial male precocious puberty due to LH-independent Leydig cell hyperfunction, and somatic LH receptor mutations may cause focal Leydig cell tumors.¹⁵⁰

Unlike loss-of-function mutations, which may be missense, nonsense, or frameshift mutations that truncate the normal receptor protein, GPCR gain-of-function mutations are almost always missense mutations. The location and nature of naturally occurring, disease-causing mutations offer important insights into GPCR structure and function. The basis for defective receptor function is clear with mutations that truncate receptor synthesis prematurely. More

subtle missense mutations may impair function if they involve highly conserved residues in transmembrane helices critical for normal protein folding. Activating missense mutations often involve residues within or bordering transmembrane helices and are thought to disrupt normal inhibitory constraints that maintain the receptor in its inactive conformation.^{127,151} Mutations disrupting these constraints mimic the effects of agonist binding and shift the equilibrium toward the activated state of the receptor. A striking example is the activating missense mutations in *AVPR2* of arginine 137, part of the DRY motif at the intracellular border of transmembrane helix 3 that is conserved in most family 1 GPCRs, which lead to the syndrome of nephrogenic inappropriate antidiuresis.¹⁵²

Diseases caused by activating GPCR mutations clinically mimic states of agonist excess, but direct measurement shows that agonist concentrations are low, reflecting normal negative feedback mechanisms. The Ca^{2+} -sensing receptor is an apparent exception, with activating mutations causing functional hypoparathyroidism. Although in most GPCRs, disease-associated gain-of-function mutations cause constitutive, agonist-independent activation, such mutations in the Ca^{2+} -sensing receptor, with rare exceptions, cause increased sensitivity to extracellular Ca^{2+} rather than to Ca^{2+} -independent activation.¹⁴⁹

Naturally occurring animal models of human disease have revealed additional examples of etiologic GPCR mutations. For example, a loss-of-function mutation in the hypocretin (orexin) type 2 receptor gene was identified in canine narcolepsy.¹⁵³ Dozens of mouse GPCR gene knockout models have been created, and many have revealed interesting and unexpected phenotypes. Characterization of the phenotype resulting from disruption of a mouse GPCR gene may accurately predict the clinical picture resulting from the corresponding mutation in humans; examples include disruption of the melanocortin 4 receptor gene, which results in obesity¹⁵⁴ and disruption of the PTH/PTH-related protein receptor gene, which impairs normal bone growth and development in mice¹⁵⁵ and in the human disease known as *Blomstrand chondrodysplasia*.¹⁵⁶ Knockouts of orphan GPCR genes can help reveal their physiologic functions. For example, knockout of the mouse gene encoding an orphan GPCR (GPR48) demonstrated its role in regulation of bone formation and remodeling.¹⁵⁷ Studies of a constitutively active GPR3 in the mouse and in *Xenopus* revealed a role in maintaining meiotic arrest in oocytes.¹⁵⁸

Availability of mouse knockout models of human diseases should facilitate testing of novel therapies, including gene transfer. For example, aminoglycosides, which suppress premature termination codons, were shown to rescue expression and function in mice with nephrogenic diabetes insipidus caused by a nonsense mutant in *AVPR2*.¹⁵⁹ Many disease-causing loss-of-function mutations in GPCRs lead to defective protein folding or protein routing. Novel therapeutic approaches such as use of molecular chaperones and modulation of a cell's quality-control mechanisms have shown promise in *in vitro* studies.¹⁶⁰

Screening of GPCR genes for mutations as the potential cause of human disorders may continue to identify more examples, but it is also becoming clear that variations in GPCR gene sequence can have profound consequences beyond causing resistance to or activation independent of the cognate hormone agonist. For example, familial spontaneous ovarian hyperstimulation syndrome occurring in early pregnancy was shown to be caused by missense mutations in the transmembrane helix domain of the FSH receptor.¹⁶¹ These mutations increase receptor basal activity and

permit low-affinity binding of human chorionic gonadotropin to the ectodomain to activate the FSH receptor. Studies are needed to determine whether variable susceptibility to iatrogenic ovarian hyperstimulation occurring in the context of *in vitro* fertilization may be caused by such variations in FSH receptor sequence.¹⁶¹

As more polymorphisms are discovered in the human genome, many examples of variations in the GPCR gene sequence will be found, and the challenge will be to elucidate their possible functional significance.¹⁶² *In vitro* studies may reveal functional differences but further studies are required to determine whether such differences are important in individual responses to various drugs (i.e., pharmacogenomics) or whether they create other subtle physiologic differences that could confer susceptibility to disease (i.e., complex disease genes). Evidence for an important role of adrenergic receptor polymorphisms in the development and treatment of heart failure supports the need for comparable studies of other GPCR family members.¹⁶³ A large proportion of the human genome is devoted to GPCR genes, and studies of this gene superfamily will play a prominent role in the future.

CHAPTER 6

Laboratory Techniques for Recognition of Endocrine Disorders

GEORGE G. KLEE

Endocrinology is a practice of medicine that is highly dependent on accurate laboratory measurements because small changes in hormone levels often may be more specific and more sensitive for early disease than the classic physical signs and symptoms. Most endocrinologists currently do not have facilities to develop and validate laboratory assays; therefore they rely on commercial analytic assays or send a patient's specimen to specialized laboratories. Even most hospital and commercial laboratories have minimal expertise for developing analytic assays. This critical dependence on quality laboratory measurements, combined with minimal information about the performance of these tests, places endocrinologists in a potentially vulnerable position.

This chapter provides an overview of the strengths and weaknesses of the analytic techniques typically used for endocrine measurements in blood and urine. Concentrations of most hormones are much lower than those of general chemistry analytes, and specialized techniques are necessary to measure these low concentrations.

Two major types of assays for measuring hormones are described: immunoassays (both competitive and sandwich) and chromatographic assays with various detection systems including mass spectrometry. Also, a brief overview is provided for selected nucleic acid-based assays for evaluation of genetic alterations.

The analytic performance validation required by the U.S. government for laboratories testing specimens of Medicare patients is outlined, along with explanations of these performance parameters. This information should help endocrinologists better assess the performance of the analytic systems that they are using. Techniques to investigate discordant laboratory test values also are presented to help clinicians work with their specific laboratories to reconcile test values that do not match clinical presentations.

Hormone concentrations are reported in molar units, mass units, or standardized units, such as World Health Organization (WHO) International Units (IU). When these measurements are expressed in molar units, most

Figure 6-1 Six-logarithm range of normal plasma concentrations in endocrine tests. DHEA, dehydroepiandrosterone; FSH, follicle-stimulating hormone; FT₄, free thyroxine; FT₃, free triiodothyronine; LH, luteinizing hormone; T₃, triiodothyronine; T₄, thyroxine; TSH, thyrotropin.

hormones in blood and urine are present in concentrations of 10^{-6} to 10^{-12} mol/L (Fig. 6-1). The terms used to describe these concentrations are micromolar (10^{-6} mol/L), nanomolar (10^{-9} mol/L), and picomolar (10^{-12} mol/L). The range—from the lowest to the highest concentrations—is more than a million-fold difference. Therefore, laboratory techniques must be targeted to the levels of each given hormone.

The major techniques for measuring the lower picomolar concentrations are immunoassay and mass spectrometry, whereas the higher nanomolar and micromolar concentrations can be measured by these methods or by optical density chromatography and chemical detection systems. Some hormones, such as thyrotropin (thyroid stimulating hormone, or TSH), have very low concentrations, in the femtomolar (10^{-15} mol/L) range, in patients with diseases such as thyrotoxicosis. Exquisitely sensitive immunometric assays are usually used to measure these very low concentrations.^{1,2}

TYPES OF ASSAYS

The major techniques used for steroid and protein measurements are (1) antibody-based immunologic assays, of which there are two subcategories—competitive immunoassays and immunometric (sandwich) assays, and (2) chromatographic assays with various detectors including mass spectrometers.

Competitive Immunoassays

The term *competitive radioimmunoassay* refers to a measurement method in which an antigen (e.g., a hormone) in a specimen competes with radiolabeled reagent antigen for a limited number of binding sites on a reagent antibody. The three basic components of a competitive immunoassay are (1) antiserum specific for a unique epitope on a hormone or antigen, (2) labeled antigen that binds to this antiserum, (3) unlabeled antigen in the specimen or standard that is to be measured.^{3,4}

The antiserum is diluted to a concentration at which the number of binding sites available on the antibodies is fewer than the number of antigen molecules (labeled and unlabeled) in the reaction mixture. The labeled and unlabeled antigens compete for this limited number of binding sites on the antiserum. The competition is not always equal because the labeled antigen (*tracer*) and the native antigen may react differently with the antibody. This disparity in reactivity may be caused by alteration of the antigen due to the chemical attachment of the label or by differences in the endogenous antigen compared with the form of the antigen used in the reagents. As long as the reactions are reproducible, these differences in reactivity are not important because the reaction can be *calibrated* with standard reference materials having known concentrations.

Figure 6-2 illustrates the concepts of a competitive immunoassay. In the schematic diagram, 8 units of antibody react with 16 units of labeled antigen and 4 units of

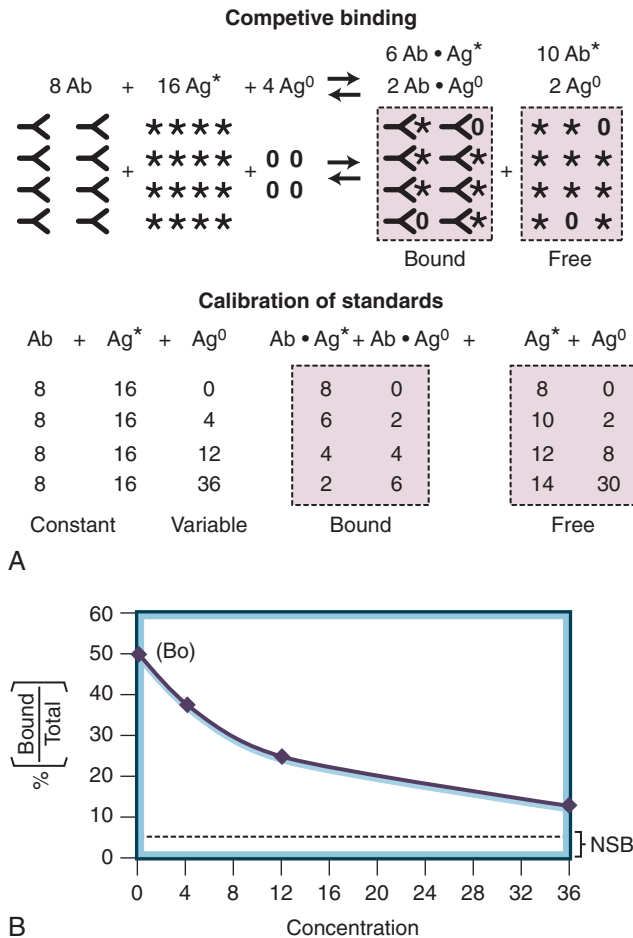

Figure 6-2 A, Principles of competitive binding assays. Ab, antibody; Ag*, labeled antigen; Ag⁰, native antigen. See text for details. **B**, Typical dose-response curve. The point on the curve labeled (B₀) represents the percentage binding of the radiolabeled antigen when zero native antigen is present. The nonspecific binding (NSB) level is the minimal binding level of radiolabeled antigen at high concentrations of native antigen.

native antigen. At equilibrium (assuming equal reactivity), 6 units of label and 2 units of native antigen are bound to the limited supply of antibody. The antigen bound to the antibody is separated from the liquid antigen by any of several methods, and the amount of labeled antigen in the bound portion is quantitated (see Fig. 6-2A). The assay is calibrated by measuring standards with known concentrations and cross-plotting the signal (i.e., counts of the gamma rays emitted from the radioactive label) versus the concentration of the standard to generate a dose-response curve. As the concentration increases, the signal decreases exponentially.

Generally, the antiserum used in a competitive assay is diluted to a titer that binds between 40% and 50% of the labeled antigen when no unlabeled antigen is present. Further dilution of the antiserum increases the analytic sensitivity but decreases both the signal and the range of the assay.

The precision of competitive immunoassays is related to the rate of change of the signal compared with the rate of change of concentration (i.e., the slope of the dose-response curve).⁵ In Figure 6-2B, the slope is much lower at higher concentrations, causing the assay precision to be less at higher concentrations. Most competitive immunoassays also have a relatively flat dose-response curve at very low

concentrations, causing poor precision at the low end of the assay. Consequently, the precision profile for most immunoassays is U-shaped, having the best coefficients of variation in the center of the dose-response curve.

As shown in Figure 6-2, the higher the concentration of unlabeled antigen, the lower the amount of radiolabeled antigen that binds to the limited amount of antiserum. The signal decreases exponentially, from approximately 50% of total counts at zero concentration to a minimum value at high concentrations. This minimal binding, or *nonspecific binding* (NSB), is a valuable control parameter. Elevations in NSB usually signify impurities in the label that bind to the sides of the tubes and are not competitively displaced. Most assays add surfactants and proteins to minimize the NSB. Monitoring of changes in the NSB provides an early warning of potential assay problems.

Statistical data processing techniques are needed to translate the assay signals into concentrations. As illustrated, these dose-response curves typically are not linear, and numerous curve-fitting algorithms have been developed. Before the introduction of microprocessors, tedious, error-prone, manual calculations were required to mathematically transform the data into linear models. A commonly used model was to cross-plot the logit of the normalized signal versus the logarithm of the concentration and to use linear regression lines to establish the dose-response curve.⁵ Today, curve fitting usually is accomplished electronically with the use of programs that automatically test the robustness of fit of multiparameter curves after statistically eliminating discordant data points.^{6,7} However, users of these systems must understand their limitations and should pay attention to any warnings presented by the programs during processing of the data.

In radioimmunoassays, radioactive iodine (¹²⁵I) is usually used to label the antigen. The immune complexes are separated from the unbound molecules by precipitation with centrifugation after reaction with secondary antisera and precipitating reagents (e.g., polyethylene glycol).⁸ These radioimmunoassays are labor intensive and may require special handling and licensure to ensure safety of the radioisotopes. Because of the statistical counting errors associated with the relatively low radioactive counts and the poor reproducibility associated with the multiple manual steps, most laboratories perform the measurements in duplicate.⁹ Even when the averages of duplicate measurements are used, many manual radioimmunoassays have coefficients of variation between 10% and 15%.

It is important that key quality control parameters for radioimmunoassays be carefully monitored. In addition to NSB, another key quality control parameter is the percentage binding of the radiolabeled when zero native antigen (B₀) is present (i.e., when B represents the signal from tracer bound in the sample). As the label deteriorates, because of aging, the binding often decreases, resulting in a less reliable assay.

Another important quality control parameter is the slope of the dose-response curve. This parameter can be tracked by monitoring the concentration corresponding to half-maximum binding (50% of B/B₀). If this concentration increases significantly, the slope of the response curve decreases and the assay may not be capable of reliably measuring patient specimens at clinically important concentrations.

Many commercial kits and automated immunoassays use nonisotopic signal systems to measure hormone concentrations. These assays often use colorimetric, fluorometric, or chemiluminescent signals rather than radioactivity to quantitate the response. The advantages of these signals

are biosafety, longer reagent shelf life, and ease of automation. On the other hand, they are more subject to matrix interferences than radioactive iodine.

Radioactivity is not affected by changes in protein concentration, hemolysis, color, or drugs (except for other radioactive compounds), whereas many of the current signal systems can yield spurious results when such interferences are present. In addition, many automated immunoassays are read kinetically before the reactions reach equilibrium. This early reading accentuates the effects of any matrix differences between the reference standards and patient specimens. Later in this chapter, potential troubleshooting steps are outlined to help clinicians evaluate the integrity of test measurements when spurious results are suspected.

Solid-phase reactions often are used in current immunoassays to facilitate the separation of the bound antibody-antigen complexes from the free reactants.¹⁰ Three frequently used solid-phase materials are microtiter plates, polystyrene beads, and paramagnetic particles.¹¹ Typically, the antibody is attached to the solid phase, and the separation of the immune complexes from the unbound moieties is accomplished by plate washers, bead washers, or magnetic wash stations, eliminating the need for centrifugation. Another novel way of accomplishing this separation is to attach high-affinity linkers to antiserum, which then can be coupled to a complementary linker on the solid phase.

An excellent pair of linkers is biotin and streptavidin. These compounds bind with affinity constants of approximately 10^{15} L/M.¹² Biotin is a relatively small molecule that can be easily covalently attached to antiserum and used with streptavidin (a 70-kd tetrameric, nonglycosylated protein) conjugated to microtiter plates, beads, or paramagnetic particles to facilitate separation. This technique allows the antibody-antigen reaction to proceed faster with less steric hindrance than when the antibody is directly coupled to the solid phase.

The antiserum used in these assays is a crucial component. Earlier immunoassays used *polyclonal* antiserum produced in animals. The process of generating these antisera is a combination of art, science, and luck. In general, a relatively pure form of the antigen is conjugated to a carrier protein (especially if the antigen is less than 10 kd), mixed with adjuvant (e.g., Freud's complete adjuvant), and injected intradermally into the host animal. After several boosts with conjugated protein plus Freud's incomplete adjuvant, the host animal recognizes the material as foreign and develops immune responses. The antiserum then is harvested from the animal's blood. Under optimal conditions, moderate quantities of high-affinity antisera that react only with the specific target antigen are developed. The analytic sensitivity of a competitive immunoassay is approximately inversely related to the affinity of the antiserum, such that an antiserum with an affinity constant of 10^9 L/M can be used to measure analytes in the nanomolar concentration range.

The polyclonal antiserum developed by immunizing animals represents a composite of many immunologic clones, with each clone having a different affinity and different immunologic specificity. Most clones have affinities in the 10^7 to 10^8 L/M range, with only rare clones having affinities greater than 10^{12} L/M. Various techniques are used to develop a specific antiserum, including (1) altering the form of the antigen by blocking cross-reacting epitopes and (2) purifying the antiserum by using affinity chromatography to select antibodies directed toward the epitope of interest. Affinity-column purification also can be used

for immunoextraction of higher-affinity antisera by selectively eluting antiserum from the column by means of a series of buffers with increasing acidity.¹³

The major disadvantage of a polyclonal antiserum is the limited quantity produced. The large quantities needed by commercial suppliers of immunoassay reagents often require them to use multiple sources of antisera. These changes in antisera can cause significant changes in assay performance. In many instances, laboratories and clinicians are not informed about these changes, a situation that may cause problems in medical decisions.

Monoclonal antisera are used in many current immunoassays. These antisera are made by immunizing animals (usually mice) using techniques similar to those used for polyclonal antisera; instead of harvesting the antisera from the blood, the animal is euthanized and the spleen is removed.¹⁴ The lymphocytes in the spleen are fused with myeloma cells to make cells that will grow in culture and produce antisera. These fused cells are separated into clones by means of serial plating techniques similar to those used in subculturing bacteria. The supernatant of these monoclonal cell lines (or ascites fluid if the cells are transplanted into carrier mice) contains monoclonal antisera. The selection processes used to separate the initial clones can be targeted to identify specific clones, producing antisera with high affinities and low cross-reactivity to related compounds.

The high specificity of monoclonal antisera can cause problems for some endocrine assays. Many hormones circulate in the blood as heterogeneous mixtures of multiple forms. Some of these forms are caused by genetic differences in patients, and others are related to metabolic precursors and degradation products of the hormone. Genetic differences cause some patients to produce variant forms of a hormone such as luteinizing hormone (LH). These genetic differences can cause marked variations in measurements made using assays with specific monoclonal antisera, compared with more uniform measurements made using assays with polyclonal antisera that cross-react with the multiple forms.¹⁵ Well-characterized monoclonal antisera can be mixed together to make an "engineered polyclonal antiserum" with improved sensitivity and specificity.¹⁶ Cross-reactivity with precursor forms of the analytes and with metabolic degradation products can cause major differences in assays. For example, cross-reactivity with six molecular forms of human chorionic gonadotropin (hCG) causes differences in hCG assays, and cross-reactivity with metabolic fragments causes differences in parathyroid hormone (PTH) assays.^{17,18} Cortisol is another analyte for which major cross-reactivity with other steroids, such as corticosterone, 11-deoxycortisol, cortisone, and numerous synthetic steroids, causes significant immunoassay interferences.¹⁹ Matrix effects with albumin also can cause major differences in cortisol immunoassays²⁰ (see "[Mass Spectrometry](#)" for a more robust method for measuring steroids).

Extraction of hormones from serum and urine specimens before measurement is a technique that can enhance both the sensitivity and the specificity of immunoassays. Numerous extraction systems have been developed, including organic-aqueous partitioning to remove water-soluble interferences seen with steroids, solid-phase extraction with absorption and selective elution from resins such as silica gels, and immunoaffinity chromatography.^{21,22} However, extraction and purification before immunoassay are seldom used in clinical assays; these techniques are difficult to automate and require skills and equipment not available in many clinical laboratories. Although

Figure 6-3 Comparison of an immunologic technique for measuring hormone concentration versus a receptor technique for measuring hormone activity. ATP, Adenosine triphosphate; cAMP, cyclic adenosine monophosphate.

commercial assays generally use reagents having adequate sensitivity and specificity to measure *most* patient specimens, some patient specimens may give spurious results, and some disease states may require more analytic sensitivity to ensure sound clinical decisions. In these cases, extraction of specimens before measurement may provide more reliable information.

Immunoassays measure concentrations rather than biologic activity. For most hormones, there is a strong correlation between the concentration of the protein or steroid being measured and the biologic activity, but this is not universally true. The reactive site for most antibodies is relatively small, about 5 to 10 amino acids for linear peptides. Some antiserum reactions are specific for the tertiary structure that corresponds to unique molecular configurations, but immunoassays seldom react with the exact antigenic structure that confers biologic activity.

Figure 6-3 presents a schematic illustration of the difference between the immunologic binding site and the biologic receptor binding site on a hormone. Indirect immunoassays have been developed using cultured cells that synthesize second messengers such as cyclic adenosine monophosphate (cAMP) at rates related to the concentration of hormone in the specimen. An example of this technique is the immunoassay measurement of cAMP produced by osteosarcoma cells to quantitate PTH bioactivity in serum.²³ Unfortunately, these assays are tedious and generally are not reproducible. Techniques using recombinant receptors as immunoassay binders may provide improved specificity with good reliability.²⁴⁻²⁶

Immunometric (Sandwich) Assays

A second immunologic technique used to measure hormones is the immunometric (sandwich) assay. The three basic components of a sandwich assay are (1) an antigen large enough to allow two antibodies to bind concurrently on different binding sites, (2) a *capture* antiserum directed to one of the antigenic sites on the antigen (this antiserum is attached to a solid phase to permit immunologic extraction of the immune complexes), and (3) a *signal* antiserum directed to a second antigenic site on the antigen (this antiserum is attached to an assay signal system).

In contrast to competitive immunoassays, these assays use a large excess of antiserum-binding sites compared with the concentration of antigen. The capture antibody immunoextracts the antigen from the sample, and the signal antibody binds to the capture antibody-antigen complex

to form a tertiary complex. As the antigen concentration increases, the signal increases progressively.

Figure 6-4 schematically illustrates these concepts. The capture antiserum (ATB1) is attached to biotin (represented by solid circles). The signal antiserum (ATB2) is labeled with a detection system (asterisks). The ATB1-antigen-ATB2 complexes are immunologically extracted using a streptavidin solid phase (represented by the horizontal cups). After the complex is bound to the solid phase, most of the unbound signal antibody is washed away.

As shown in Figure 6-4B, the signal increases progressively with the concentration. For lower concentrations, the signal increases proportionally to the assay concentrations (after the offset caused by the NSB). At higher concentrations of native antigen, the signal is generally less than proportional, so nonlinear curve-fitting techniques are used to generate the dose-response curves. Again, the relative imprecision, expressed as a coefficient of variation, depends on the slope of the dose-response curve; consequently, the relative precision is less at higher concentrations.

In immunometric assays, the background level of signal is associated with very low concentrations. This background signal is caused by the NSB. The analytic sensitivity of immunometric assays is related to the ratio of the true signal to the NSB signal. Therefore, assays can be made more sensitive by increasing the response signal or by decreasing NSB. Inadvertent increases in NSB caused by

A

B

Figure 6-4 A, Principles of immunometric assays. Ag, antigen; ATB1, capture antiserum; ATB2, signal antiserum; ATBs, antibodies. See text for details. B, Typical dose-response curve. NSB, nonspecific binding level.

Figure 6-5 Immunometric high-dose hook effect. The response signal reaches a maximum and then decreases when the antigen concentration exceeds the limit of the assay.

specimen interference or reagent deterioration can significantly alter assay performance.

In immunometric assays, it is also important that a large excess of capture antibody be used. As the antigen concentration approaches the effective binding capacity of the capture antibody system, the signal no longer increases. If the antigen concentration exceeds the binding capacity of the capture antibody, the signal may actually decrease.

Figure 6-5 illustrates this *high-dose hook effect* for immunometric assays caused by insufficient amounts of capture or signal antiserum.²⁷ The signal increases progressively until the hormone concentration exceeds the binding capacity; the signal then decreases, probably as a result of removal of some of the more weakly binding antigen-antibody complexes during the wash cycle on the assay.²⁸⁻³⁰ This is a potentially dangerous phenomenon, because the same values might be measured with very high and lower concentrations. If this artifact is suspected, the specimen may be diluted and reanalyzed. If the measured value for the diluted specimen is higher than the original result, a high-dose hook effect probably is present.

Most manufacturers are aware of this potential problem and configure assays with relatively large amounts of capture antibody; however, some patients produce high concentrations of hormones or antigens that may exceed assay limits. Laboratories can detect this phenomenon by analyzing specimens at two dilutions, but this practice generally is not cost-effective. Therefore, feedback to the laboratory about results that are inconsistent with clinical findings is essential.

Another potential problem for immunometric assays is the presence of endogenous heterophile antibodies that cross-react with reagent antiserum.³¹ Normally, the signal antibody does not form a “sandwich” with the capture antibody unless the specific antigen is present; however, divalent heterophile antibodies may mimic the antigen by simultaneously binding to the signal and capture reagent antibodies, thereby causing falsely elevated results.^{32,33}

Figure 6-6 schematically illustrates this situation. The problem is most common with monoclonal antibodies but may also occur with polyclonal antibodies. Immunoglobulins contain both a *constant* (Fc) region and a *variable* (Fab) region. As implied in the name, the Fc region is constant, or similar, for all immunoglobulins from that species. Therefore, if a patient receives immunotherapy or imaging reagents containing mouse immunoglobulin, he or she is likely to develop human antimouse antibodies (HAMAs) directed to the Fc fragment.³⁴ Some patients develop heterophile antibodies after exposure to foreign proteins from

domestic pets or food contaminants. If these endogenous antibodies are present in a patient's specimen, they may bridge across the reagent antibodies used in immunometric assays and cause falsely high values. These antibodies also may bind to sites on the reagent antibodies, sterically blocking the binding of the specific antigen and leading to falsely low test values. Most manufacturers include nonimmune immunoglobulin in the assays to help block these interferences; as with the high-dose hook effect, however, the amounts added are not always adequate, and some patients with high-titer antibodies may still show in vitro assay interference.³⁵

The combined specificity of the two antibodies used in an immunometric assay can produce exquisitely sensitive and specific immunoassays. In the past, a common problem with early competitive immunoassays was cross-reactivity among the structurally similar gonadotropins: LH, follicle-stimulating hormone (FSH), TSH, and hCG. The α -subunits of each of these hormones are almost identical, and the β -subunits have considerable structural homology. Many individual antisera (especially polyclonal antisera) used for measuring one of these hormones may have cross-reactivity for the other gonadotropins. The cross-reactivity of a pair of antibodies is less than the cross-reactivity of each of the individual antibodies because any cross-reacting substance must contain both of the binding epitopes in order to simultaneously bind to both antibodies.

For example, consider two antibodies for LH, each having 1% cross-reactivity with hCG. The cross-reactivity of the pair is less than the product of the two cross-reactivities or, in this case, less than 0.01%. Most current immunoassays for LH have a cross-reactivity of less than 0.01%. This low cross-reactivity is important, because pregnant patients and patients with choriocarcinoma can have very high hCG concentrations that could interfere with measurements of the other gonadotropin hormones.

Most hormones circulate in the blood in multiple forms. Some hormones (e.g., prolactin, growth hormone) circulate with macro forms, which can cause difficulty in their analysis if specimens are not pretreated.⁸ For hormones composed of subunits (e.g., the gonadotropins), both the intact and the free subunits circulate in blood. Immunometric assays can be made specific for intact molecules by pairing an antibody specific for the α - β bridge site of the subunits with a second antibody specific for the β -subunit. Assays using these antibody pairs retain the two-antibody, low cross-reactivity needed for measuring gonadotropins and do not react with the free subunit forms of the hormones.

Figure 6-6 Assay interferences caused by heterophile antibodies, which result in either falsely high or falsely low values. Ag, antigen; ATB, antibody; ATB1, capture antiserum; ATB2, signal antiserum.

TABLE 6-1

Effect of Immunoassay Specificity on Calibration of Human Chorionic Gonadotropin (hCG) Assay

	Assay 1	Assay 2	Assay 3
Specificity for intact hCG standard (%)	100	100	100
Cross-reactivity with free β -hCG (%)	0	100	200
Measured values (IU/L)			
Specimen with 0% free β -hCG	10.0	10.0	10.0
Specimen with 10% free β -hCG	9.0	10.0	11.0
Specimen with 50% free β -hCG	5.0	10.0	15.0

The heterogeneous forms of circulating hormones and differences in specificity characteristics of immunoassays for these forms make calibration and harmonization difficult. Two immunoassays calibrated with the same reference preparation can give widely varying measurements on patient specimens. Consider the example of hCG in Table 6-1. The three assays are calibrated with a pure preparation of intact hCG, such as the WHO Third International Reference Preparation.³⁵ The three assays differ in their cross-reactivity with free β -hCG (0%, 100%, and 200%, respectively). These assays give identical measurements for a specimen containing only intact hCG but progressively disparate values as the percentage of free β -hCG in the specimen increases. In reality, the standardization issue is much more complex, because multiple forms of hormones (i.e., intact hormone, free subunits, nicked forms, glycosylated forms, degradation products) circulate in patients, and each assay has different cross-reactivities for these forms.^{17,36}

Free (Unbound) Hormone Assays

Many hormones are tightly bound to specific plasma-binding proteins and loosely bound to albumin. Usually, only the unbound (free) forms and some of the loosely bound forms are biologically active.

Many methods are available to measure these free, unbound forms of a hormone. Theoretically, the best procedure is direct measurement of the free hormone concentration after physical separation of the free hormone from the bound hormone by equilibrium dialysis, ultrafiltration, or gel filtration. However, this method is difficult to perform and therefore is not readily available, and it is subject to technical errors.

The two major clinical applications for free hormone measurements are for thyroid hormones (i.e., thyroxine [T_4] and triiodothyronine [T_3]) and for steroids (testosterone and estradiol). Four techniques are commonly used to estimate free thyroid hormone concentrations: indirect index methods, two-step labeled hormone methods, one-step labeled hormone analogue methods, and labeled antibody methods.

Indirect Index Methods

The *indirect indices* involve two measurements: one for total hormone concentration and another for the thyroxine-binding globulin (TBG), followed by calculation of the ratio or of a normalized free thyroid hormone index (FT₄I or FT₃I). The availability of test results for total T_4 and T_4 binding capacity has the advantage of assessing these two different quantities but the disadvantage that ratios and indices are subject to the combined error of both

measurements. These methods correct for routine changes in TBG such as those associated with estrogen levels, but they may produce inappropriately abnormal values in patients with extreme variations in TBG levels, such as those with congenital disorders of the TBG gene, familial dysalbuminemic hyperthyroxinemia, thyroid hormone autoantibodies, or certain nonthyroidal illnesses. Because of the necessity for two measurements and the sensitivity of these methods to interference with drugs, these indirect methods are being used less frequently.

Two-Step Labeled Hormone Methods

The two-step labeled hormone methods immunologically bind the free and loosely bound thyroid hormone to a solid phase. The other serum components are washed away, and the residual binding sites are back-titrated with labeled hormone. When calibrated with appropriate serum standards, these methods are thought to pose fewer problems related to binding protein abnormalities.

One-Step Labeled Hormone Analogue Methods

The one-step labeled hormone analogue methods use synthetic analogues of T_4 and T_3 that bind to the measurement antibody but do not bind to normal TBG. These methods are seldom used because performance has been poor in patients with abnormal albumin concentrations, abnormal free fatty acid concentrations, and all conditions that interfere with the indirect indices.³⁷

Labeled Antibody Methods

The labeled antibody methods use kinetic reactions of antibodies with selected affinities that bind preferentially with the free form of the hormone. These methods work best for automated testing instruments and have become popular.

Complexities in Testing

Each of the methods described here works well for correcting for minor changes in TBG levels, but each has problems with some patient sera, especially sera containing interfering substances such as inhibitors and heterophilic antibodies. Most manufacturers have not fully validated their methods in patients with these abnormalities.³⁸

Multiple methods are also available for measuring both the free and the biologically active forms of steroid hormones. The preferred method for measurement of free hormones consists of direct physical separation and high-sensitivity assays, similar to those methods recommended for the thyroid hormones. One-step labeled hormone analogue methods also have been developed, but they are associated with interference problems similar to the problems associated with free thyroid hormone assays. The measurement of free testosterone has been problematic. Most immunoassays are unreliable at low concentrations, and the concentration of free testosterone is much lower than that of total testosterone.

Another complexity in regard to steroid hormones is that, in addition to the free hormones, testosterone and estrogen bound to albumin also are biologically active. The concentration of the biologically active forms can be estimated with the use of indirect indices calculated from measurements of the total hormones and sex hormone-binding globulin (SHBG) or by measurement of the residual free and albumin-bound steroids after separation of the SHBG-bound forms after differential precipitation with ammonium sulfate. Recent work with tandem mass spectrometry shows promise as a more reliable test method (see later discussions).

Chromatographic Assays

The second major method of measuring hormone concentrations involves chromatographic separation of the various biochemical forms and quantitation of specific characteristics of the molecules. High-performance liquid chromatography (HPLC) systems use multiple forms of detection, including light absorption, fluorescence, and electrochemical properties.^{39,40} Chromatography also is frequently combined with mass spectrometry.

There are two major advantages of these techniques: they can be used to simultaneously measure multiple forms of an analyte, and they are not dependent on unique immunologic reagents. Therefore, harmonization of measurements made with different assays is more feasible. The major disadvantages of these methods are their complexity and their limited availability.

Many chemical separation techniques are based on chromatography, but the two most commonly used for liquid chromatography are *normal-phase* HPLC and *reverse-phase* HPLC.²⁹ In both systems, a bonded solid-phase column is made that interacts with the analytes as they flow past in a liquid solvent. In normal-phase HPLC, the functional groups of the stationary phase are polar (e.g., amino or nitrile ions) relative to the nonpolar stationary phase (e.g., hexane); in reverse-phase HPLC, a nonpolar stationary phase (e.g., C18 octadecylsilane molecules bonded to silica) is used.

More recently, polymeric packings made of mixed copolymers have been made with C4, C8, and C18 functional groups directly incorporated so that they are more stable over a wide pH range. The mobile and stationary phases are selected to optimize adherence of the analytes to the stationary phase. The adhered molecules can be eluted differentially from the solid phase, after washing to separate specific forms of the analyte from interfering substances. If the composition of the mobile phase remains constant throughout the run, the process is called an *isocratic elution*. If the mobile-phase composition is abruptly changed, a *step elution* occurs. If the composition is gradually changed throughout the run, a *gradient elution* occurs.

The efficiency of separation in a chromatography system is a function of the flow rates of the different substances.⁴¹ The resolution of the system is a measure of the separation of the two solute bands in terms of their relative retention volumes (V_r) and their bandwidths (ω). Resolution (R_s) of solutes A and B is shown as

$$R_s = \frac{2[V_r(B) - V_r(A)]}{\omega(A) + \omega(B)}$$

Values of R_s lower than 0.8 result in inadequate separation, and values greater than 1.25 correspond to baseline separation. The resolution of a chromatography column is a function of flow rates and thermodynamic factors.

Simultaneous measurement of the three catecholamines (epinephrine, norepinephrine, and dopamine) can be performed with reverse-phase HPLC with a C18 column and an electrochemical detection system⁴² or fluorometric detection.⁴³ Prior extraction by absorption on activated alumina and acid elution helps improve specificity. Dihydroxybenzylamine, a molecule similar to endogenous catecholamines, can be used as an internal standard.

Mass Spectrometry

The technique of mass spectrometry involves fragmentation of target molecules, followed by separation and measurement of the mass-to-charge ratio of the components.⁴¹

Quadrupole Mass Spectrometer

Figure 6-7 Basic components of quadrupole mass spectrometer.

When coupled with liquid chromatography, a mass spectrometer can function as a unique detector to provide structural information about the composition of individual solutes.⁴⁴ Inclusion in the specimens of internal standards, which are molecularly similar to the measured compounds, allows precise quantitation of the concentration of the eluting analytes. The measurement of specific mass fragments makes possible the quantitation of multiple specific analytes in complex mixtures.

The basic components of a quadrupole mass spectrometer are an ionizer, an ion analyzer, and a detector (Fig. 6-7). The initial step in mass spectrometry is fragmentation of the target compound into charged ions. Many techniques are used to generate these charged ions, including *chemical ionization* and *electron-impact ionization*.

Chemical ionization uses reagent gas molecules such as methane, ammonia, water, and isobutane to transfer protons. This process produces less fragmentation than other techniques because the process is not highly excited.

The electron impact method bombards gas molecules from the sample with electrons emitted from a heated filament. The process occurs in a vacuum to prevent the filament from burning out. *Electron-spray ionization* is a process in which a solution containing the analyte is introduced into a gas phase and is sprayed across an ionizing potential.⁴⁵ The charged droplets are desolvated and analyzed in a mass spectrometer.

The ion analyzer uses four charged rods to systematically set up a charged field that selects only certain ions with particular mass-to-charge ratios and facilitates their movement along a path to the detector. Regular calibration is necessary to ensure accuracy of the instrument.

A *mass spectrum* is a bar graph in which the heights of the bars correspond to the relative abundance of a particular ion plotted as a function of the mass-to-charge ratio. Modern mass spectrometers can measure molecular masses so accurately and precisely that the elemental composition of a compound can be predicted by comparison with stored spectral libraries. When these systems are used to measure only a few selected compounds with known spectrums, the mass spectrometer can be programmed to focus only on these selected ions.

Stable isotopes of the compounds of interest can be used as internal standards through a technique called *isotope dilution mass spectrometry*. Stable isotopes typically perform the same as the native compounds in terms of extraction, chromatography, and mass spectrometry and therefore are ideal internal standards. However, there must be a sufficient number of isotopic atoms to ensure that their mass is different from that of naturally occurring substances that may be in the specimen.

Figure 6-8 Liquid chromatography–tandem mass spectroscopy profiles of nine steroids.⁴⁹ DHEAS, Dehydroepiandrosterone 3-sulfate; DHEA, dehydroepiandrosterone. (From Guo T, Chan M, Soldin SJ. Steroid profiles using liquid chromatography–tandem mass spectrometry with atmospheric pressure photoionization source. *Arch Pathol Lab Med*. 2004;128:469–475. Reproduced with permission from Archives of Pathology of Laboratory Medicine.)

Tandem mass spectrometry (MS/MS) is a powerful tool consisting of two mass analyzers separated by an ion-activation device.^{46,47} The first analyzer is used to isolate and dissociate the ion of interest by activation, and the second mass analyzer to analyze its dissociation products. This technique can be used to provide rapid, definitive measurements of multiple endocrine analytes.⁴⁴ For example, liquid chromatography and tandem mass spectrometry can be used to simultaneously quantitate multiple steroid compounds.^{48–52} In Figure 6-8, the chromatograph shows well-separated peaks for nine steroids in a standard solution.⁴⁸

Standardization and harmonization of hormone assays have become priorities for quality health care. The National Institute of Standards and Technology (NIST) has developed mass spectrometry reference methods for measuring cortisol, progesterone, estradiol-17 β , T₄, and T₃.^{51,53–58} The International Federation of Clinical Chemistry (IFCC) has proposed reference measurement procedures for free T₄.^{59,60} MS methods also have been developed for insulin, PTH, 17-hydroxyprogesterone, and free T₃, although these are not considered reference methods at this time. Efforts are under way to try to harmonize clinical measurements using these reference methods; however, that will be a difficult task because of the difference inherent in the antibody specificity of the immunoassays used for most measurements.

Nucleic Acid–Based Assays

The decoding of the human genome has set the stage for a large potential increase in nucleic acid–based gene assays. The basic principles of nucleic acid–based assays have been known for several decades, but the identification of specific

genes and the mapping of gene defects to clinical disease states have now made these measurements clinically useful.⁶¹ However, as this field has evolved, it has been found that genetic heterogeneity is very common and clinical testing usually is based on strategies to find mutations as efficiently as possible.⁶² Four concepts important for nucleic acid measurements are hybridization, amplification, restriction fragment length polymorphisms (RFLPs), and electrophoretic separation.⁶³ Newer techniques such as comparative genomic hybridization (CGH) and next-generation sequencing offer potential advances for genomic testing.^{64–66}

Hybridization

Nucleic acid molecules have a unique ability to fuse with complementary base-pair sequences. When a fragment of a known sequence (probe) is mixed under specific conditions with a specimen containing a complementary sequence, hybridization occurs. This feature is analogous to the antibody–antigen binding used in immunoassays. Many of the formats used for immunoassay have been adopted to nucleic acid assays, including some of the same signal systems (e.g., radioactivity, fluorescence, chemiluminescence) and the same solid-phase capture systems (e.g., magnetic beads, biotin–streptavidin binding). In situ hybridization, which involves the binding of probes to intact tissue and cells, provides information about morphologic localization analogous to that provided by immunohistochemistry.

Amplification

Nucleic acid assays have an advantage in that low concentrations can be amplified in vitro before quantitation. The best-known amplification procedure is the polymerase

chain reaction (PCR), first reported by Mullis and Faloona.⁶⁷ The three steps in the process (denaturation, annealing, and elongation) occur rapidly at different temperatures. Each cycle of amplification can occur in less than 90 seconds by cycling the temperature. The target double-stranded DNA is denatured at high temperature to make two single-stranded DNA fragments. Oligonucleotide primers, which are specific for the target region, are annealed to the DNA when the temperature is lowered. Addition of DNA polymerase allows the primer DNA to extend across the amplification region, thus doubling the number of DNA copies.

At 85% to 90% efficiency, this process can amplify the DNA by about 250,000-fold in 20 cycles. This huge amplification is subject to major problems with contamination if special precautions are not taken. In one control technique, a psoralen derivative is used to prevent subsequent copying by polymerase during exposure to ultraviolet light.

Restriction Fragment Length Polymorphisms

Some diseases (e.g., sickle cell anemia) are associated with a specific gene mutation; usually, however, a series of deletions and additions of DNA are involved with a particular disease. A number of restriction enzymes that cleave DNA at specific locations have been identified. Changes in the sequence of DNA result in different fragment lengths. The RFLP technique is particularly helpful in family studies for disorders that have a unique *genetic fingerprint*.

Electrophoretic Separation

E. M. Southern invented an electrophoretic separation technique known as *Southern blotting*.⁶⁸ Restriction enzymes are used to digest a sample of DNA into fragments, and the product is subjected to electrophoresis. The separated bands of DNA are then transferred to a solid support and hybridized. *Northern blotting* is a similar technique in which RNA is used as the starting material. *Western blotting* refers to electrophoresis and transfer of proteins.

Newer Nucleic Acid Measurement Technologies

Comparative Genome Hybridization

CGH is a molecular-cytogenetic method for analyzing the gains and losses of a given subject's DNA.⁶⁴ This technique detects only unbalanced chromosome changes; balanced reciprocal translocations or inversions may not be detected. Currently, this procedure is an adjunct to standard karyotype analysis, but it may provide higher resolution.

Next-Generation Sequencing

Next-generation sequencing uses large numbers of parallel processors to sequence clonally amplified DNA molecules separated in a flow cell.⁶⁶ This provides advantages of speed, lower cost, and better accuracy. On the other hand, this technique can rapidly generate large amounts of sequence data, posing challenges to bioinformatic analysis. The interpretation of these data requires linkage with large databases and a good understanding of genomic variations in the targeted regions.

ANALYTIC VALIDATION

Clinicians usually assume that laboratory methods have been validated and that they function correctly. Although this assumption is generally true, it is helpful to

understand the level of assay validation performed and the appropriateness of the validation criteria for each clinical application of a test.^{69,70}

In the United States, the federal government regulates all laboratories performing complex tests for patients receiving Medicare.^{71,72} These regulations, published in the *Federal Register*, outline the validation requirements for Food and Drug Administration (FDA)-approved instruments, kits, and test systems as well as methods developed in house. Laboratories must document analytic accuracy, precision, reportable ranges, and reference ranges for all procedures. The regulations for in-house procedures and modifications of approved commercial procedures are more extensive and require laboratories to further document the analytic sensitivity; analytic specificity, including interfering substances; and other performance characteristics required for testing patient specimens.

Although the details of method validation may be unique to a specific procedure, the following analytic validation studies have proved valuable for most procedures: method comparison, precision, linearity, recovery, detection limit, reportable range, analytic interference, carry-over, reference interval, specimen stability, and specimen type. Similar recommendations for validating nucleic acid tests were recently published by the College of American Pathologists.⁷³ Laboratories should have documentation for each of these performance characteristics, either from the diagnostics manufacturer or from direct studies.

Method Comparison

Ideally, the system should be compared with an established reference method; however, many endocrine tests do not have reference methods, and many laboratories do not have the facilities to perform reference methods when they exist. At a minimum, the assay should be compared with an analytic system that has been clinically validated with specimens from healthy subjects and specimens from patients with the diseases being investigated.⁷⁴ The system should be traceable to established reference standards, such as those from the WHO or the NIST.⁷⁵⁻⁷⁷ Between 100 and 200 different specimens distributed over the assay range are recommended for method comparisons.⁷⁸

A cross-plot portraying the new method on the vertical axis and the established method on the horizontal axis, along with the identity line, reference value lines, and regression statistics, is a useful way of displaying these comparisons. An alternative display method is the Bland-Altman difference plot, in which the difference between the test method and the reference method is plotted against the reference method values.

Although acceptable performance criteria for method comparisons are not well established, some important characteristics to examine are

- Any grossly discordant test values
- The degree of scatter about the regression curve
- The size of the regression offset on the vertical axis
- The number of points crossing between the low, normal, and high reference intervals for the two methods

The European Union has enacted an In Vitro Diagnostics Directive that requires manufacturers marketing in the European Union to establish that their products are "traceable to reference standards and reference procedures of a higher order" when such references exist. Hopefully, medically relevant performance characteristics that define the allowable ranges for differences between a specific assay's test values and the traceable standards will be linked with

this traceability requirement.⁷⁹ This combination of traceability and allowable error requirements could serve to harmonize many test methods worldwide, because most diagnostic companies market internationally.⁸⁰

Precision

Precision is a measure of the replication of repeated measurements of the same specimen; it is a function of the time between repeats and the concentration of the analyte. Both short-term precision (within a run or within a day) and long-term precision (across calibrations and across batches of reagents) should be documented at clinically appropriate concentration levels.⁸¹

In general, normal-range, abnormally low-range, and abnormally high-range targets are chosen for precision studies; however, targets focused on critical medical decision limits may be more appropriate for some analytes. Twenty measurements are recommended at each level for both short-term and long-term precision validations. Precision usually is expressed as the coefficient of variation, calculated as 100 times the standard deviation (SD) divided by the average of the replicate measurements.⁸²

There is no universal agreement on the performance criteria for analytic precision, although numerous recommendations have been put forth. Two major approaches to defining these criteria have been (1) comparison with biologic variation and (2) expert opinion of clinicians based on their perceived impact of laboratory variation on clinical decisions.

The total variation clinically observed in test measurements is a combination of the analytic and biologic variations. For instance, if the analytic SD is less than one fourth of the biologic SD, the analytic component increases the SD of the total error by less than 3%. If the analytic precision is less than one half of the biologic SD, the total error increases by only 12%. These observations have led to recommendations for maintaining precision of less than one fourth or one half of the biologic variation.

The expert opinion precision recommendations are based on estimates of the magnitude of change of a test value that would cause clinicians to alter their clinical decisions. Table 6-2 lists some precision recommendations for selected endocrine tests.⁸³⁻⁸⁵

Linearity

Patient specimens commonly contain several different forms of the hormones to be measured, whereas pure forms are contained in the reference standards and calibrators used to establish the assay dose-response curve.⁸⁶ When a patient specimen is diluted, the measured value for these dilutions should parallel the dose-response curve and give results proportional to the dilution. Linearity can be evaluated by measuring serial dilutions of patient specimens, with high concentrations diluted in the appropriate assay diluents.^{87,88} The product of the measured value multiplied by the dilution factor should be approximately constant. There are no performance standards for linearity, but a reasonable expectation for most hormones is that dilutions are comparable within 10% of the undiluted value.

Recovery

Two methods of assessing the recovery of assays are (1) measuring the increase in test values after the reference analyte is added and (2) measuring the proportional changes caused by mixing high-concentration and

TABLE 6-2

Recommended Analytic Performance Limits*

Analyte	Biologic CVi (%)	Precision (%)	Accuracy (%)
Calcium	1.8	0.9 [†]	0.7
Glucose	4.4	2.2 [†]	1.9
Thyroxine	7.6	3.4 [†]	4.1
Potassium	4.4	2.4 [†]	1.6
Triiodothyronine	8.7 [†]	4.0 [†]	5.5 [‡]

CVi, intraindividual variation.

Data from Stockl D, Baadenhuijsen H, Fraser CG, et al. Desirable routine analytical goals for quantities assayed in serum. Discussion paper from the members of the External Quality Assessment (EQA) Working Group A on analytical goals in laboratory medicine. *Eur J Clin Chem Clin Biochem.* 1995;33:157-169.

low-concentration specimens. Some analytes circulate in the blood in multiple forms, and some of these forms may be bound to carrier proteins. The recovery rate of pure substances added to a specimen may be low if the assay does not measure some of the bound forms. Mixtures of patient specimens may not be measured correctly if one of the specimens contains cross-reacting substances such as autoantibodies. A thorough understanding of the chemical forms of the analyte and their cross-reactivities in the assay is important during assessment of recovery data.

Detection Limit

The minimal analytic detection limit is the smallest concentration that can be statistically differentiated from zero. This concentration is mathematically determined as the upper 95% limit of replicate measurements of the *zero standard*, calculated from the average signal plus 2.0 SD. This minimal detection limit is valid only for the average of multiple replicate measurements. When individual determinations are performed on a specimen having a true concentration exactly at the minimal detection limit, the probability that the measurement is above the noise level of the assay is only about 50%.

A second parameter for the lowest level of reliable measurement for an assay is the *functional detection limit*, or the *limit of quantitation*. For this value to be measured, multiple pools with low concentrations are made and analyzed in the replicate. A cross-plot of the coefficient of variation of the measurements versus concentration allows one to generate a precise profile. The concentration corresponding to a coefficient of variation of 20% is the functional detection limit.¹ This term typically applies to across-assay variation, but it also can be calculated for within-assay variation if

one uses the tests to evaluate results measured within one run (e.g., provocative and suppression tests).

Reportable Range

The reportable range of an assay usually spans from the functional detection limit to the concentration of the highest standard. Values above the highest standard may be reported if they are diluted and the measured value is multiplied by the dilution factor. The validity of the analytic range is documented by the linearity and recovery studies. Some laboratories erroneously report the exact values displayed by the test systems even if they are outside the analytic range. It is important for clinicians to understand the limitations of valid measurements and not to inappropriately use meaningless numbers that may be reported.

Another potential source of error is failure of the technologist to multiply the measured value of diluted specimens by the dilution factor to correct for the dilution. In addition, care should be taken to define the number of significant figures used for reporting test values and to establish an appropriate algorithm for rounding test values to the significant number of digits.

Analytic Interference

The cross-reactivity and potential interference of other analytes that may react in a test system should be documented.⁸⁴ The choice of potential interfering substances that must be evaluated requires an understanding of the analytic system and the pathophysiology of the analyte being evaluated. In immunoassays, for example, compounds with similar structures, as well as precursor forms and degradation products, should be tested.⁸⁹⁻⁹² Drugs commonly prescribed for the diseases under evaluation should be assessed for interference, both by addition of the drug to a specimen and by analysis of specimens from patients before and after receiving the drug.^{93,94} Most assays also are evaluated for the effects of hemolysis, lipemia, and icterus.

Carryover Studies

Many diagnostic systems use automated sample-handling devices. If a specimen to be tested is preceded by a specimen with a very high concentration, a trace amount remaining from the first specimen may significantly increase the reported concentration in the second specimen. The choice of the concentration that should be tested for carryover depends on the pathophysiology of the disease, but high values may need to be tested because some endocrine disorders can produce high values. A prudent procedure would be to retest all specimens after a specimen with an extraordinarily high value. One also should document that carryover from the sampling probe has not inadvertently contaminated subsequent specimen vials, thereby invalidating subsequently repeated measurements.

Reference Intervals

The development and validation of reference intervals for endocrine tests can be very complex tasks.^{95,96} The normal reference interval for most laboratory tests is based on estimates of the central 95-percentile limits of measurements in healthy subjects.⁹⁷ A minimum of 120 subjects is needed to reliably define the 2.5 and 97.5 percentiles. The reference intervals for many endocrine tests depend on

gender, age, developmental status, and other test values. Formal statistical consultation is recommended to determine the appropriate number of subjects to test and to develop statistical models for defining multivariate reference ranges.

Full evaluation of the adrenal, gonadal, and thyroid axes requires simultaneous measurement of the trophic and target hormones. Bivariate displays of these hormone concentrations along with their multivariate reference intervals facilitate the interpretation.⁹⁸ Preanalytic conditions should be well defined and controlled during evaluation of both healthy reference subjects and patients.

Specimen Stability

Analyte stability is a function of storage conditions and specimen type.⁹⁹ Although most hormones are relatively stable in serum or urine if they are rapidly frozen and stored in hermetically sealed vials at -70°C , multiple freeze/thaw cycles can damage analytes, and storage in frost-free freezers that repeatedly cycle through thawing temperatures can adversely affect stability. Blood specimens collected in edetate (EDTA) often are more stable than serum or heparinized specimens because edetate chelates calcium and magnesium ions that function as coenzymes for some proteases. The addition of protease inhibitors (e.g., aprotinin) to blood specimens may also improve specimen stability.¹⁰⁰

Types of Specimens

Most hormones are measured in blood or urine, but alternative testing sources, such as saliva and transdermal membrane monitors, are also used.

Urine Specimens

The 24-hour urine specimen is used for many endocrine tests. Such urine specimens represent a time average that integrates over the multiple pulsatile spikes of hormone secretion occurring throughout the day. The 24-hour urine specimen also has the advantage of better analytic sensitivity for some hormones.^{101,102} Urine often contains not only the original hormone but also key metabolites that may or may not have biologic activity.

Drawbacks include the inconvenience of collecting the 24-hour specimen and delays in collection. Another limitation of urine specimens is uncertainty regarding the completeness of the collection. Measurement of urinary creatinine concentrations helps in monitoring collection completeness, especially when this value is compared with the patient's muscle mass. Many urinary hormones are conjugated to carrier proteins before excretion. Therefore, both hepatic function and, to a lesser degree, renal function may alter urinary hormone values.

Blood Specimens

Blood specimens have both the advantage and the limitation of time dependency. The ability to detect rapid changes to a provocative stimulus is a strong advantage, whereas the unsuspected changes resulting from pulsatile secretions may be a major limitation. Most hormones undergo significant biologic variations, including ultradian, diurnal, menstrual, and seasonal changes.¹⁰³⁻¹⁰⁵ Many hormones have short half-lives and are rapidly cleared from the blood. The half-life is particularly important when one is attempting to measure the response to a provocative drug, such as the effect of gonadotropin-releasing hormone.¹⁰⁶ The development of rapid intraoperative methods for

measuring PTH and growth hormone has highlighted the importance of plasma specimens, which do not require extra waiting time for the blood to clot to make serum.^{107,108}

Saliva Specimens

Saliva is becoming an alternative specimen for measuring non-protein-bound hormones and small molecules.¹⁰⁹⁻¹¹³ Small analytes in blood pass into oral fluid by crossing capillary walls and basement membranes and by passing through lipophilic membranes of epithelial cells.¹¹¹ This transport involves passive diffusion, ultrafiltration, active transport, or some combination of these processes. The concentration in saliva depends on the concentration of the non-protein-bound analyte in blood, the salivary pH, the acid dissociation constant (pKa) of the analyte, and the size of the analyte. Analytes entering saliva by passive diffusion usually are less than 500 d in size, non-protein bound, and nonionized. Saliva measurements correlate with blood measurements for some hormones such as cortisol, progesterone, estradiol, and testosterone, but they do not correlate well for others (e.g., thyroid and pituitary hormones).¹¹⁴⁻¹¹⁶

Multiple preanalytic variables can affect the salivary measurement. Stimulation of oral fluid production by chewing or by the use of candy or drops that contain stimulants such as citric acid can increase oral fluid volume and stabilize pH but may alter some analyte concentrations. Several commercial devices are available for collection of oral fluid; however, these devices need to be validated for each analyte and each assay system to ensure they adequately recover each of the analytes.

Blood Drops

Blood drops collected on filter paper from punctures of a finger or heel are a convenient system for collecting, transporting, and measuring hormones.^{117,118} If standardized collection conditions and extraction techniques are used, these measurements correlate well with serum measurements. Integration of immunochemistry with computer chip technology has also led to immunochips that can measure multiple analytes using a single drop of blood.¹¹⁹

Noninvasive Measurements

Noninvasive transcutaneous measurements also have been developed for some endocrine tests.¹²⁰ Transcutaneous glucose measurements using near-infrared spectroscopy correlate well with blood measurements.¹²¹ Glycemic control in subjects with diabetes requiring insulin has been shown to improve with continuous real-time transcutaneous glucose monitoring.¹²²

QUALITY ASSURANCE

Quality Control Systems

Laboratory quality control programs are intended to ensure that the test procedures are being performed within defined limits. A critical component of control systems is the definition of acceptable performance criteria.^{123,124} Such criteria often are not well defined, and many laboratories use floating criteria that change when assays change.¹²⁵ Control limits are often set at the mean \pm 2 or 3 SDs, where the mean and the SD are arbitrarily assigned based on measurements made in that laboratory. When reagents or equipment changes, new limits are assigned. These types of control systems provide some assurance that the laboratory is functioning at a level of performance similar to that of

the recent past, but they provide little assurance that measurements are adequate for clinical decisions.

Statistically, there are two major forms of analytic errors: random and systematic. *Random error* relates to reproducibility; *systematic error* relates to the offset or bias of the test values from the target or reference value. Performance criteria can be defined for each of these parameters, and quality control systems can be programmed to monitor compliance with these criteria. Control systems must have low false-positive rates as well as high statistical power to detect assay deviations. The multirule algorithms developed by Westgard and colleagues¹²⁶ use combinations of control rules—such as two consecutive controls outside of *warning limits*, one control outside of *action limits*, or moving average trend analyzers outside of limits—to achieve good statistical error detection characteristics.¹²⁷

Traditionally, quality control programs have focused primarily on precision; however, analytic bias also can cause major clinical problems. If fixed decision levels are used to trigger clinical actions (e.g., therapy, additional investigations), changes in the analytic set point of an assay can cause major changes in the number of follow-up cases.¹²⁷ This concept is illustrated in Figure 6-9 for TSH measurements.

Under stable laboratory testing conditions, approximately 122 per 1000 patients tested have TSH values greater than 5.0 mIU/L. If the test shifts upward by 20%, the number of patients with TSH values greater than 5.0 mIU/L increases to 189, which is an increase of more than 50% in the number of patients flagged as abnormal (see Fig. 6-9). These changes in test value distributions often can be sensed by clinicians who encounter multiple patients with unexpectedly elevated test values, causing them to call the laboratory and inquire whether the “test is running high today.” Some modern quality control systems use moving averages of patient test values to help monitor changes in analytic bias.¹²⁸

Some medical facilities have linked together into networks to provide more integrated patient care. This cross-over of both physicians and patients is increasing the importance of *harmonized* testing systems. For endocrine tests, harmonization is best achieved when all the laboratories in the network use the same test systems. Differences in analytic specificity may cause across-method differences in patient test distributions even when the methods use the same reference standards. Full harmonization of testing requires not only standardization of equipment but also standardization of reagents (including use of the same lot numbers) and standardization of laboratory protocols.

Figure 6-9 Effect of analytic bias, or shift, on the number of patients with elevated levels of thyrotropin (TSH).

Real-time quality control monitors with peer group comparisons across the laboratories in the health care network are necessary to ensure uniformity of testing.

Investigation of Discordant Test Values

The practice of modern endocrinology depends extensively on reliable and accurate test values; even in the best laboratories, however, erroneous results sometimes are reported. Careful correlation of pathophysiology with test values can help to identify values that are “discordant.”⁹⁸ Some of these discordant test values may be analytically correct, but others may be erroneous. Clinicians can help investigate these suspicious test values by requesting laboratories to perform a few simple validation procedures.

Repeated testing of the same specimen is a valuable first step. If the specimen has been stored under stable conditions, the absolute value of the difference between the initial and the repeated measurements should be less than 3 analytic SDs 95% of the time. Normally, the 95% confidence range is associated with the mean \pm 2 SDs; with repeated laboratory tests, however, errors are associated with the first as well as the second measurement. The confidence interval for the uncertainty of the difference between two measurements can be calculated using the statistical rules for propagation of errors.

To better understand this propagation of error, consider

$$D = X_1 - X_2$$

where X_1 is the first measurement, X_2 is the repeated measurement, and D is the difference.

$$\text{Variance}(D) = \text{Variance}(X_1) + \text{Variance}(X_2)$$

$$\text{Variance}(D) = 2 \text{ Variance}(X)$$

$$\text{SD}(D) = \sqrt{2 \text{ Variance}(X)}$$

$$\text{SD}(D) = \sqrt{2} \text{SD}(X)$$

The variance of D is the sum of the variance of X_1 and the variance of X_2 . The SD of D is the square root of the variance of D , or the square root of twice the variance of X_1 . The SD of D equates to the square root of 2 multiplied by $\text{SD}(X)$. Therefore, 95% of the absolute values for D should be within square root of 2 times 2 $\text{SD}(X)$, or approximately 3 $\text{SD}(X)$. If a repeat measurement exceeds this 3 $\text{SD}(X)$ limit, the initial (or reagent) measurement is probably in error.

Linearity and recovery are valuable techniques for evaluating test validity. If the initial test value is elevated, serial dilution of the specimen in the assay diluent and reassay should be considered. If the specimen dilutes nonproportionately, no meaningful value can be reported with that assay. In the example in Figure 6-10, the undiluted specimen reads 22, the twofold dilution multiplies back to 34 (2×17), and the fourfold dilution multiplies back to 60 (4×15). Therefore, the result depends on the dilution factor, so that no reliable answer can be reported.

If the initial value is low, one may consider adding known quantities of the analyte to part of the specimen. Analyzing these spiked or diluted specimens with the original specimen allows one to evaluate both reproducibility and recovery. It may be helpful to analyze the linearity or recovery of the assay standards at the same time, to provide internal controls of the dilution or spiking procedures and the appropriateness of the diluent and spiking material.

If the replication, dilution, or recovery experiment appears successful, further analytic troubleshooting will

Figure 6-10 Nonproportional dilutions. Discordant values are produced when samples do not dilute linearly. Nt, undiluted (neat).

vary according to the method used. Immunoassays may be affected by interference caused by heterophile antibodies. Addition of nonimmune mouse serum or heterophile antibody-blocking solutions may neutralize these effects.^{129,130} Chromatographic assays are usually more robust than immunoassays. Specimens with suspected interference on one type of assay can be reanalyzed by means of an alternative methodology.

Water-soluble interferences have been reported for some direct assays for steroid measurements.^{21,22,131} Extraction of the hormones into organic solvents, followed by drying down and reconstitution in the assay zero standard, removes these interferences. Similarly, interferences with cross-reacting drugs and metabolic products can be minimized with selective extraction.

The analytic methods of assessing endocrine problems in patients are continually expanding. The newer systems are often based on analytic techniques similar to those outlined in this chapter, but the configurations are generally more user-friendly. These advances make the systems more convenient, but they also become more of a “black box” that conceals most of the details of the system. The performance validation steps outlined in this chapter become important procedures for ensuring that these systems continue to provide the reliable measurements needed for quality medical care.

CHAPTER

7

Neuroendocrinology

MALCOLM J. LOW

HISTORICAL PERSPECTIVE

The field of neuroendocrinology has expanded from its original focus on the control of pituitary hormone secretion by the hypothalamus to encompass multiple reciprocal interactions between the central nervous system (CNS) and endocrine systems in the control of homeostasis and physiologic responses to environmental stimuli. Although many of these concepts are relatively recent, the intimate interaction of the hypothalamus and the pituitary gland was recognized more than a century ago. For example, at the end of the 19th century, clinicians including Alfred Fröhlich described an obesity and infertility condition referred to as *adiposogenital dystrophy* in patients with sellar tumors.¹ This condition subsequently became known as *Fröhlich's syndrome* and was most often associated with the accumulation of excessive subcutaneous fat, hypogonadotropic hypogonadism (HH), and growth retardation.

Whether this syndrome was a result of injury to the pituitary gland itself or to the overlying hypothalamus was extremely controversial. Several leaders in the field of endocrinology, including Cushing and his colleagues, argued that the syndrome was caused by disruption of the pituitary gland.² However, experimental evidence began to accumulate that the hypothalamus was somehow involved

in the control of the pituitary gland. For example, Aschner demonstrated in dogs that precise removal of the pituitary gland without damage to the overlying hypothalamus did not result in obesity.³ Later, seminal studies by Hetherington and Ranson demonstrated that stereotaxic destruction of the medial basal hypothalamus with electrolytic lesions, sparing the pituitary gland, resulted in morbid obesity and neuroendocrine derangements similar to those of the patients described by Fröhlich.⁴ This and subsequent studies clearly established that an intact hypothalamus is required for normal endocrine function. However, the mechanisms by which the hypothalamus was involved in endocrine regulation remained unsettled for years. It is now thought that the phenotypes of Fröhlich's syndrome and of the ventromedial hypothalamic lesion syndrome are caused by dysfunction or destruction of key hypothalamic neurons that regulate pituitary hormone secretion and energy homeostasis.

The field of neuroendocrinology took a major step forward when several groups, especially that of Ernst and Berta Scharrer, recognized that neurons in the hypothalamus are the source of the axons that constitute the neural lobe (see "[Neurosecretion](#)"). The hypothalamic control of the anterior pituitary gland remained unclear, however. Popa and Fielding identified the pituitary portal vessels linking the median eminence of the hypothalamus and the

anterior pituitary gland.⁵ Although they appreciated the fact that this vasculature provided a link between the hypothalamus and the pituitary gland, they initially hypothesized that blood flowed from the pituitary up to the brain. Anatomic studies by Wislocki and King supported the concept that blood flow was from the hypothalamus to the pituitary.⁶ Later studies, including the seminal work of Geoffrey Harris, established the flow of blood from the hypothalamus at the median eminence to the anterior pituitary gland.⁷ This supported the concept that the hypothalamus controls anterior pituitary gland function indirectly and led to the now accepted hypophyseal-portal chemotransmitter hypothesis.

Subsequently, several important studies, especially those from Schally and colleagues and from the Guillemin group, established that the anterior pituitary is tightly controlled by the hypothalamus.^{8,9} Both groups identified several putative peptide hormone-releasing factors (see later sections). These fundamental studies resulted in the awarding of the Nobel Prize in Medicine in 1977 to Andrew Schally and Roger Guillemin.^{10,11} We now know that these releasing factors are the fundamental link between the CNS and the control of endocrine function. Furthermore, these neuropeptides are highly conserved across species and are essential for reproduction, growth, and metabolism. The anatomy, physiology, and genetics of these releasing factors constitute a major portion of this chapter.

Over the past 2 decades, work in the field of neuroendocrinology has continued to advance across several fronts. Cloning and characterization of the specific G protein-coupled receptors used by the hypothalamic releasing factors have helped define their signaling mechanisms. Characterization of the distribution of these receptors has universally demonstrated receptor expression in the brain and in peripheral tissues other than the pituitary, arguing for multiple physiologic roles for the neuropeptide-releasing factors. Finally, the last 2 decades have also seen tremendous advances in understanding of regulatory neuronal and humoral inputs to the hypophyseotropic neurons.

The adipostatic hormone leptin, discovered in 1994,¹² is an example of a humoral factor that has profound effects on multiple neuroendocrine circuits. Reduction in circulating leptin is responsible for suppression of the thyroid and reproductive axes during the starvation response. The subsequent discovery of ghrelin,¹³ a stomach peptide that regulates appetite and also acts on multiple neuroendocrine axes, demonstrated that much remains to be learned regarding the regulation of the hypothalamic releasing hormones. Traditionally, it has been extremely difficult to study releasing-factor gene expression or the specific regulation of the releasing factor neurons because of their small numbers and, in some cases, diffuse distribution. Transgenic experiments have produced mice in which expression of fluorescent marker proteins is specifically targeted to gonadotropin-releasing hormone (GnRH) neurons¹⁴ and arcuate pro-opiomelanocortin (POMC) neurons,¹⁵ among others. This technology allows detailed study of the electrophysiologic properties of hypothalamic neurons in the more native context of slice preparations or organotypic cultures.

Although much of the field of neuroendocrinology has focused on hypothalamic releasing factors and their influence on reproduction, growth, development, fluid balance, and the stress response through control of pituitary hormone production, the term *neuroendocrinology* has come to mean the study of the interactions of the endocrine and nervous systems in the regulation of homeostasis. The field of neuroendocrinology has been further

expanded by input from diverse areas of basic research that has often been fundamental to understanding of the neuroendocrine system. These areas include studies of neuropeptide structure, function, and mechanism of action; neural secretion; hypothalamic neuroanatomy; G protein-coupled receptor structure, function, and signaling; transport of substances into the brain; and the action of hormones on the brain. Moreover, homeostatic systems often involve integrated endocrine, autonomic, and behavioral responses. In many of these systems (e.g., energy homeostasis, immune function), the classic neuroendocrine axes are important but not autonomous pathways, and these subjects are also often studied in the context of neuroendocrinology.

In this chapter, the concepts of neural secretion, the neuroanatomy of the hypothalamic-pituitary unit, and the CNS structures most relevant to control of the neurohypophysis and adenohypophysis are presented. Then, each classic hypothalamic-pituitary axis is described, including a consideration of the immune system and its integration with neuroendocrine function. Finally, the pathophysiology of disorders of neural regulation of endocrine function are reviewed. The neuroendocrinology of energy homeostasis is fully considered in Chapter 35.

NEURAL CONTROL OF ENDOCRINE SECRETION

A fundamental principle of neuroendocrinology encompasses the regulated secretion of hormones, neurotransmitters, or neuromodulators by specialized cells.¹⁶ Endocrine cells and neurons are prototypical secretory cells. Both have electrically excitable plasma membranes and specific ion conductances that regulate exocytosis of their signaling molecules from storage vesicles. Secretory cells are broadly classified by their topographic mechanisms of secretion. For example, *endocrine* cells secrete their contents directly into the bloodstream, allowing these substances to act globally as hormones. Cells classified as *paracrine* secrete their contents into the extracellular space and predominantly affect the function of closely neighboring cells. *Autocrine* secretory cells affect their own function by the local actions of their secretions. In contrast, secretory cells within *exocrine* glands secrete proteinaceous substances, including enzymes, and lipids into the lumen of ductal systems.

Neurosecretion

Neurons are secretory cells that send their axons throughout the nervous system to release their neurotransmitters and neuromodulators predominantly at specialized chemical synapses. Neurohumoral or neurosecretory cells constitute a unique subset of neurons whose axon terminals are not associated with synapses. Two examples of neurosecretory cells are neurohypophyseal and hypophyseotropic cells. The prototypical neurohypophyseal cells are the magnicellular neurons of the paraventricular (PVH) and supraoptic (SON) nuclei in the hypothalamus. Hypophyseotropic cells are neurons that secrete their products into the pituitary portal vessels at the median eminence (Fig. 7-1).

In the most basic sense, neurosecretory cells are neurons that secrete substances directly into the bloodstream to act as hormones. The theory of neurosecretion evolved from the seminal work of Scharrer and Scharrer,^{16,17} who used morphologic techniques to identify stained secretory

Figure 7-1 Three types of hypothalamic neurosecretory cells. *Left*, A magnicellular neuron that secretes arginine vasopressin (AVP) or oxytocin (OXY). The cell body, which is located in the supraoptic (SON) or paraventricular hypothalamic (PVH) nucleus, projects its neuronal process into the neural lobe, and neurohormone is released from nerve endings. *Center*, Similar peptidergic neurons are located in the medial basal hypothalamus in nuclear groups including the periventricular hypothalamic nucleus (PeVH), the PVH, and the infundibular or arcuate nucleus of the hypothalamus (Arc). The neuropeptides in this case are released into the specialized blood supply to the pituitary to regulate its secretion. *Right*, A third category of hypothalamic peptidergic neurons terminates at chemical synapses on other neurons. These projection neurons are found in sites including the PVH, Arc, and lateral hypothalamic area (LHA) that innervate multiple central nervous system nuclei, including autonomic preganglionic neurons in the brain stem and spinal cord. Such substances act as neurotransmitters or neuromodulators. ACTH, corticotropin; AgRP, agouti-related peptide; CRH, corticotropin-releasing hormone; FSH, follicle-stimulating hormone; GH, growth hormone; GHRH, growth hormone-releasing hormone; GnRH, gonadotropin-releasing hormone; LH, luteinizing hormone; MCH, melanin-concentrating hormone; ORX, orexin/hypocretin; POMC, pro-opiomelanocortin; TRH, thyrotropin-releasing hormone; TSH, thyrotropin.

granules in the SON and PVH neurons. They found that cutting the pituitary stalk led to an accumulation of these granules in the hypothalamus, which led them to hypothesize that hypothalamic neurons were the source of substances secreted by the neural lobe (posterior pituitary). Although this concept initially raised great skepticism among contemporary researchers, it is now known that the axon terminals in the neural lobe arise from the SON and PVH magnicellular neurons that contain oxytocin and the antidiuretic hormone, arginine vasopressin (AVP).

The modern definition of neurosecretion has evolved to include the release of any secretory product from a neuron. Indeed, a fundamental tenet of neuroscience is that all neurons in the CNS, including neurons that secrete AVP and oxytocin in the neural lobe, receive multiple synaptic inputs largely onto their dendrites and cell bodies. In addition, neurons have the basic ability to detect and integrate input from multiple neurons through specific receptors. They in turn fire action potentials that result in the release of neurotransmitters and neuromodulators into synapses formed with postsynaptic neurons. Most communications between neurons are accomplished by the classic fast-acting neurotransmitters (e.g., glutamate, γ -aminobutyric acid [GABA], acetylcholine) and neuromodulators (e.g.,

neuropeptides) acting at chemical synapses.^{11,18} Neurosecretion represents a fundamental concept in understanding the mechanisms used by the nervous system to control behavior and maintain homeostasis.

In the era of the elucidation of the human genome, the importance of these early observations is often not fully appreciated. However, accounts of these early studies are illuminating, and it is not an overstatement that confirmation of the neurosecretion hypothesis represented one of the major advances in the fields of neuroscience and neuroendocrinology. Indeed, these and other early experiments, including the pioneering work of Geoffrey Harris,^{7,19} led to the fundamental concept that the hypothalamus releases hormones directly into the bloodstream (neurohypophyseal cells). These observations provided the principles on which the modern discipline of neuroendocrinology is built.

Contribution of the Autonomic Nervous System to Endocrine Control

Another major precept of neuroendocrinology is that the nervous system controls or modifies the function of both endocrine and exocrine glands. The exquisite control of

the anterior pituitary gland is accomplished by the action of releasing factor hormones (see “**Hypophyseotropic Hormones and Neuroendocrine Axes**”). Other endocrine and exocrine organs (e.g., pancreas, adrenal, pineal, salivary glands) are also regulated through direct innervation from the cholinergic and noradrenergic inputs from the autonomic nervous system. Although it is beyond the scope of this chapter, an appreciation of the functional anatomy and pharmacology of the parasympathetic and sympathetic nervous systems is fundamental to understanding of the neural control of endocrine function.

The efferent arms of the autonomic nervous system comprise the sympathetic and parasympathetic systems. These have similar wiring diagrams characterized by a preganglionic neuron that innervates a postganglionic neuron that in turn targets an end organ.²⁰ Preganglionic and postganglionic parasympathetic neurons are cholinergic. In contrast, preganglionic sympathetic neurons are cholinergic and postganglionic neurons are noradrenergic (except for those innervating sweat glands, which are cholinergic). Another basic concept is that autonomic neurons coexpress several neuropeptides. This coexpression is a common feature of neurons in the central and peripheral nervous systems.^{11,18,21} For example, postganglionic noradrenergic neurons coexpress somatostatin and neuropeptide Y (NPY). Postganglionic cholinergic neurons coexpress neuropeptides including vasoactive intestinal polypeptide (VIP) and calcitonin gene-related peptide (CGRP).

Most sympathetic preganglionic neurons lie in the intermediolateral cell column in the thoracolumbar regions of the spinal cord.²⁰ Most postganglionic sympathetic neurons are located in sympathetic ganglia lying near the vertebral column (e.g., sympathetic chain, superior cervical ganglia). Postganglionic fibers innervate target organs. As a rule, the sympathetic preganglionic fibers are relatively short, and the postganglionic fibers are long. In contrast, the parasympathetic preganglionic neurons lie in the mid-brain (perioculomotor area, long misidentified as the Edinger-Westphal nucleus²²), the medulla oblongata (e.g., dorsal motor nucleus of the vagus, nucleus ambiguus), and the sacral spinal cord. Postganglionic neurons that innervate the eye and salivary glands arise from the ciliary, pterygopalatine, submandibular, and otic ganglia. Postganglionic parasympathetic neurons in the thorax and abdomen typically lie within the target organs, including the gut wall and pancreas.²⁰ Consequently, the parasympathetic preganglionic fibers are relatively long, and the postganglionic fibers are short.

A dual autonomic innervation of the pancreas illustrates the importance of coordinated neural control of endocrine organs. The endocrine pancreas receives both sympathetic (noradrenergic) and parasympathetic (cholinergic) innervation.^{20,23} The latter activity is provided by the vagus nerve (dorsal motor nucleus of the vagus) and is an excellent example of neural modulation, because the cholinergic tone of the beta cells affects their secretion of insulin. For example, vagal input is thought to modulate insulin secretion before (cephalic phase), during, and after ingestion of food.²⁴ In addition, noradrenergic stimulation of the endocrine pancreas can alter the secretion of glucagon and inhibits insulin release.²³ Of course, a major regulator of insulin secretion is the extracellular concentration of glucose,²⁵ and glucose can induce insulin secretion in the absence of neural input. However, the exquisite control by the nervous system is illustrated by the fact that populations of neurons in the brain stem and hypothalamus have the ability, like the beta cell, to sense glucose levels in the bloodstream.²⁶ This information is integrated by the

hypothalamus and ultimately results in alterations in the activity of the autonomic nervous system innervating the pancreas. Therefore, neural control of the endocrine pancreas probably contributes to the physiologic control of insulin secretion and may contribute to the pathophysiology of disorders such as diabetes mellitus. Certainly, an increased understanding of this complex interplay between the CNS and endocrine function is necessary to diagnose and clinically manage endocrine disorders.

HYPOTHALAMIC-PITUITARY UNIT

The hypothalamus is one of the most evolutionarily conserved and essential regions of the mammalian brain. Indeed, the hypothalamus is the ultimate brain structure that allows mammals to maintain homeostasis, and destruction of the hypothalamus is not compatible with life. Hypothalamic control of homeostasis stems from the ability of this collection of neurons to orchestrate coordinated endocrine, autonomic, and behavioral responses. A key principle is that the hypothalamus receives sensory inputs from the external environment (e.g., light, nociception, temperature, odorants) and information regarding the internal environment (e.g., blood pressure, blood osmolality, blood glucose levels). Of particular relevance to neuroendocrine control, hormones (e.g., glucocorticoids, estrogen, testosterone, thyroid hormone) exert both negative and positive feedback directly on the hypothalamus.

The hypothalamus integrates diverse sensory and hormonal inputs and provides coordinated responses through motor outputs to key regulatory sites. These include the anterior pituitary gland, posterior pituitary gland, cerebral cortex, premotor and motor neurons in the brain stem and spinal cord, and parasympathetic and sympathetic preganglionic neurons. The patterned hypothalamic outputs to these effector sites ultimately result in coordinated endocrine, behavioral, and autonomic responses that maintain homeostasis. The hypothalamic control of the pituitary gland is an elegant system that underlies the ability of mammals to coordinate endocrine functions that are necessary for survival.

Development and Differentiation of Hypothalamic Nuclei

Tremendous advances in knowledge of the molecular and genetic basis for embryonic development of the hypothalamic-pituitary unit have occurred in the past 2 decades as a result of the genome sequencing projects and use of transgenic model systems.²⁷ Pituitary development is discussed in detail in Chapter 8, and only a few key points most relevant to the physiology and pathophysiology of the neuroendocrine hypothalamus are presented here.

There has been considerable debate concerning the extent to which developmental studies in the rodent hypothalamic-pituitary system are applicable to the human. However, accumulating data suggest that the similarities outweigh the differences. Ontogenic analyses of the organization of the human hypothalamus using a battery of neurochemical markers have reinforced its homologies to the better-studied rat brain.²⁸ The cytoarchitectonic boundaries of hypothalamic nuclei are much more easily discerned in fetal human brain than in the adult brain and for the most part correspond to homologous structures in the rat hypothalamus. This finding has important implications for the validity of interspecies comparative analyses.

Two examples further illustrate this point. First, the ventromedial nucleus of the hypothalamic core (ventromedial hypothalamus, or VMH), which plays a role in energy balance and in female sexual behavior, differentiates from neuroblasts in both humans and rodents at a time point that is intermediate between the earlier differentiation of lateral hypothalamic nuclei and later differentiation of the midline nuclei, including the suprachiasmatic nucleus (SCN), the arcuate nucleus, and the PVH.^{28,29} Expression of the transcription factor SF1 has been shown to be restricted both temporally and spatially to cells in the VMH, and knockout of the SF1 gene in mice alters VMH development by influencing the migration of cells and their ultimate location.²⁹ A second example of interspecies homologies in hypothalamic development is the migration of GnRH-secreting neurons from their origins in rostral neuroepithelium to the anterior hypothalamus.³⁰ As discussed later, spontaneous and inherited mutations in genes that affect the migration of these neurons are an important cause of Kallmann's syndrome or HH associated with anosmia.

In addition to SF1 and the genes associated with Kallmann's syndrome, a growing list of genes primarily encoding transcription factors have been implicated in human neuroendocrine disorders and characterized experimentally in rodent models.³¹ This list includes the homeobox transcription factor OTX and the heterodimeric complex formed by the basic helix-loop-helix (bHLH) factors SIM1 and ARNT2. These factors are required for the proper development of the PVH and the SON and for expression of many key hypophyseotropic neuropeptide genes. The physiologic importance of SIM1 is illustrated by the development of an obesity phenotype in both mice and humans with a haploinsufficiency of SIM1 expression.³¹ MASH1 and its downstream target GSH1 are both critical for neuron specification and expression of growth hormone-releasing hormone (GHRH).³²

Two key concepts involved in CNS development, which also apply to the hypothalamus, are the balance between neurogenesis and cell death in the establishment of nuclei and the role of circulating hormones in providing organizational signals that regulate cell number and synaptic remodeling. The most thoroughly characterized examples are the effects of sex steroid hormones on the developing brain, which result in key sexual dimorphisms of functional importance in later reproductive behaviors.³³ This principle has been extended to include organizational effects of other classes of hormones. For example, leptin plays an important role in the development of medial-basal hypothalamic circuits that are important for energy homeostasis by mediating axonal projections between hypothalamic nuclei.³⁴

Anatomy of the Hypothalamic-Pituitary Unit

The pituitary gland is regulated by three interacting elements: hypothalamic inputs (releasing factors or hypophyseotropic hormones), feedback effects of circulating hormones, and paracrine and autocrine secretions of the pituitary itself. In humans, the pituitary gland (hypophysis) can be divided into two major parts, the adenohypophysis and the neurohypophysis, which are easily distinguishable on T1-weighted magnetic resonance imaging (MRI) (Fig. 7-2).³⁵ The adenohypophysis can be subdivided into three distinct lobes: the pars distalis (anterior lobe), pars intermedia (intermediate lobe), and pars tuberalis. Whereas a well-developed intermediate lobe is found in most mammals, only rudimentary vestiges of the

intermediate lobe are detectable in adult humans, with the bulk of intermediate lobe cells being dispersed in the anterior and posterior lobes.

The neurohypophysis is composed of the pars nervosa (also known as the neural or posterior lobe), the infundibular stalk, and the median eminence. The infundibular stalk is surrounded by the pars tuberalis, and together they constitute the *hypophyseal stalk*. The pituitary gland lies in the sella turcica ("Turkish saddle") of the sphenoid bone and underlies the base of the hypothalamus. This anatomic location explains the hypothalamic damage described by Fröhlich.¹ In humans, the base of the hypothalamus forms a mound called the *tuber cinereum*, the central region of which gives rise to the median eminence (see Fig. 7-2).³⁶

The anterior and intermediate lobes of the pituitary derive from a dorsal invagination of the pharyngeal epithelium, called *Rathke's pouch*, in response to inductive signals from the overlying neuroepithelium of the ventral diencephalon. During development, precursor cells within the pouch undergo steps of organ determination, cell fate commitment to a pituitary phenotype, proliferation, and migration.²⁷ The intermediate lobe is in direct contact with the neural lobe and is the least prominent of the three lobes. With age, the human intermediate lobe decreases in size to leave a small, residual collection of POMC cells. In nonprimate species, these cells are responsible for secreting the POMC-derived product α -melanocyte-stimulating hormone (α -MSH).³⁷

The major component of the neural lobe is a collection of axon terminals arising from magnicellular secretory neurons located in the PVH and SON nuclei of the hypothalamus (Fig. 7-3; see Fig. 7-1). These axon terminals are in close association with a capillary plexus, and they secrete substances including AVP and oxytocin into the hypophyseal veins and thence into the general circulation (Table 7-1). The blood supply to the neurohypophysis arises from the inferior hypophyseal artery (a branch of the internal carotid artery). Glial-like cells called *pituicytes* are scattered among the nerve terminals. As the source of AVP to the general circulation, the PVH and SON nuclei and their axon terminals in the neural lobe are the effector arms for the central regulation of blood osmolality, fluid balance, and blood pressure (see Chapter 10).

The secretion of oxytocin by magnicellular neurons is critical at parturition, resulting in uterine myometrial contraction. In addition, the secretion of oxytocin is regulated by the classic milk let-down reflex.³⁸ Although the exact neuroanatomic substrate underlying this response is unclear, apparently mechanosensory information from the nipple reaches the magnicellular neurons, directly or indirectly, from the dorsal horn of the spinal cord, resulting in release of oxytocin into the general circulation.³⁹ Oxytocin acts on receptors on myoepithelial cells in the mammary gland acini, leading to release of milk into the ductal system of the mammary gland.

The Median Eminence and Hypophyseotropic Neuronal System

The median eminence is the functional link between the hypothalamus and the anterior pituitary gland. It lies in the center of the tuber cinereum and is composed of an extensive array of blood vessels and nerve endings (Fig. 7-4; see Fig. 7-2).^{17,36,40} Its extremely rich blood supply arises from the superior hypophyseal artery (a branch of the internal carotid artery), which sends off many small branches that form capillary loops. The small capillary loops extend into the internal and external zones of the

Figure 7-2 Normal anatomy of the human hypothalamic-pituitary unit in sagittal (**A**) and coronal (**B**) planes. Structures that are visible in the T1-weighted magnetic resonance images (left panels) are identified in the corresponding diagrams (right panels). The hypothalamus is bounded anteriorly by the optic chiasm, laterally by the sulci formed with the temporal lobes, and posteriorly by the mammillary bodies (in which the mammillary nuclei are located). Dorsally, the hypothalamus is delineated from the thalamus by the hypothalamic sulcus. The smooth, rounded base of the hypothalamus is the tuber cinereum; the pituitary stalk descends from its central region, which is termed the *median eminence*. The median eminence stands out from the rest of the tuber cinereum because of its dense vascularity, which is formed by the primary plexus of the hypophyseal-portal system. The long portal veins run along the ventral surface of the pituitary stalk. Notice the location of the pituitary stalk, the hyperintense signal (white) from the posterior pituitary (PP) (panel **A**, left), and the anatomic relationships of the pituitary gland to the optic chiasm (oc) and the sphenoidal and cavernous sinuses. ac, anterior commissure; AP, anterior pituitary; cc, corpus callosum; MB, mammillary body; pc, posterior commissure. (Magnetic resonance images courtesy of Dr. D.M. Cook.)

median eminence, form anastomoses, and drain into sinusoids that become the pituitary portal veins that enter the vascular pool of the pituitary gland.⁴⁰⁻⁴² The flow of blood in these short loops is thought to be predominantly (if not exclusively) in a hypothalamic-to-pituitary direction.⁴² This well-developed plexus results in a tremendous increase in the vascular surface area. In addition, the vessels are fenestrated, allowing diffusion of the peptide-releasing factors to their site of action in the anterior pituitary gland. Because this vascular complex in the base of the hypothalamus and its “arteriolized” venous drainage to the pituitary compose a circulatory system analogous to the portal vein system of the liver, it has been termed the *hypophyseal-portal circulation*.

Three distinct compartments of the median eminence are recognized: the innermost ependymal layer, the internal zone, and the external zone (see Fig. 7-4).⁴⁰ Ependymal cells form the floor of the third ventricle and are unique in that they have microvilli rather than cilia. Tight junctions at the ventricular pole of the ependymal cells prevent the diffusion of large-molecular-weight substances between

the cerebrospinal fluid (CSF) and the extracellular space within the median eminence. The ependymal layer also contains specialized cells, called *tanycytes*, that send processes into the other layers of the median eminence.⁴³ Tight junctions between tanycytes at the lateral edges of the median eminence likely prevent the diffusion of releasing factors back into the medial basal hypothalamus.

The internal zone of the median eminence is composed of axons of the SON and PVH magnicellular neurons passing en route to the posterior pituitary (see Fig. 7-4C) and axons of the hypophyseotropic neurons destined for the external layer of the median eminence (see Fig. 7-4A and B). In addition, supportive cells populate this layer.

Finally, the external zone of the median eminence represents the exchange point of the hypothalamic releasing factors and the pituitary portal vessels.⁴⁰ Two general types of tuberohypophyseal neurons project to the external zone: peptide-secreting (peptidergic) neurons including thyrotropin-releasing hormone (TRH), corticotropin-releasing hormone (CRH), and GnRH (see Fig. 7-1) and neurons containing monoamines (e.g., dopamine,

Figure 7-3 The tuberoinfundibular system is revealed by retrograde transport of cholera toxin subunit B (CtB). The location of hypothalamic cell bodies of neurons projecting to the median eminence (ME) and the posterior pituitary are identified by microinjection of a small volume of the retrograde tracer CtB into the median eminence of the rat. **A**, Retrogradely labeled cells can be seen in the paraventricular (PVH) and supraoptic (SON) nuclei of the hypothalamus. **B**, Magnicellular neurons are observed in the SON. **C**, Labeled neurons are found in the posterior magnicellular group (pm) and in the medial parvicellular subdivision (mp). The labeled cells in the PVH include those that contain corticotropin-releasing hormone and thyrotropin-releasing hormone. **D**, Retrogradely labeled cells are also found in the arcuate nucleus of the hypothalamus (Arc). These include neurons that secrete growth hormone–releasing hormone and dopamine. 3v, third ventricle; ot, optic tract. (Photomicrographs courtesy of Dr. R. M. Lechan.)

serotonin). Although the secretion of these substances into the portal circulation is an important control mechanism, some peptides and neurotransmitters in nerve endings are not released into the hypophyseal-portal circulation but instead function to regulate the secretion of other nerve terminals.⁴⁴ The anatomic relationships of nerve endings, basement membranes, interstitial spaces, fenestrated (windowed) capillary endothelia, and glia in the median eminence are similar to those in the neural lobe. As in the case of neurohormone secretion from the neurohypophysis, depolarization of hypothalamic cells leads to the release of neuropeptides and monoamines at the median eminence.

Non-neuronal supporting cells in the hypothalamus also play a dynamic role in hypophyseotropic regulation. For example, nerve terminals in the neurohypophysis are enveloped by pituicytes; they surround the nerve endings when the gland is inactive but retract to expose the terminals when AVP secretion is enhanced, as in states of dehydration. Within the median eminence, GnRH nerve endings are enveloped by the tanycytes, which also cover or uncover neurons with changes in functional status.^{43,45} Thus, supporting elements, with their own sets of receptors, can change the neuroregulatory milieu within the hypothalamus, median eminence, and pituitary.

The site of production, the genetics, and the regulation of synthesis and release of individual peptide-releasing factors are discussed in detail in later sections. Briefly, there are several cell groups in the medial hypothalamus that contain releasing factors that are secreted into the pituitary

portal circulation (Table 7-2).^{36,46} These cell groups include the infundibular nucleus (called the *arcuate nucleus* in rodents) (see Fig. 7-3D), the PVH (see Fig. 7-3A and C), and a group of cells in the medial preoptic area near the organum vasculosum of the lamina terminalis (OVLT) (Fig. 7-5). As discussed earlier, magnicellular neurons in the SON and PVH send axons that predominantly traverse the median eminence to terminate in the neural lobe of the pituitary. In addition, a smaller number of magnicellular axons project directly to the external zone of the median eminence, but their functional significance is unknown.

The third structure often grouped as a component of the median eminence is a subdivision of the adenohypophysis called the *pars tuberalis*. It is a thin sheet of glandular tissue that lies around the infundibulum and pituitary stalk. In some animals, the epithelial component makes up as much as 10% of the total glandular tissue of the anterior pituitary. The *pars tuberalis* contains cells that make pituitary tropic hormones including luteinizing hormone (LH) and thyrotropin (thyroid-stimulating hormone, or TSH). A definitive physiologic function of the *pars tuberalis* is not established, but melatonin receptors are expressed in the *pars tuberalis*.

CIRCUMVENTRICULAR ORGANS

A guiding principle of neurophysiology and neuropharmacology is that the brain, including the hypothalamus, resides in an environment that is protected from humoral

TABLE 7-1

Neurotransmitters and Neuromodulators in the Paraventricular Nucleus and the Arcuate Nucleus of the Hypothalamus

Paraventricular Nucleus	Arcuate Nucleus
Magnicellular Division	Acetylcholine
Angiotensin II	γ -Aminobutyric acid (GABA)
Cholecystokinin (CCK)	Agouti-related peptide (AgRP)
Dynorphins	Cocaine- and amphetamine-regulated transcript (CART)
Nitric oxide (NO)	Dopamine
Oxytocin	Dynorphin
Vasopressin (AVP)	Endocannabinoids
Parvicellular Divisions	Enkephalins
γ -Aminobutyric acid (GABA)	Galanin
Angiotensin II	Galanin-like peptide (GALP)
Atrial natriuretic factor (ANF)	Glutamate
Bombesin-like peptides	Gonadotropin-releasing hormone (GnRH)
Cholecystokinin (CCK)	Growth hormone-releasing hormone (GHRH)
Corticotropin-releasing hormone (CRH)	Kisspeptins
Dopamine	Melanocortins (ACTH, α -MSH, β -MSH, γ -MSH)
Endocannabinoids	Neurokinin B (NKB)
Enkephalins	Neuromedin U
Galanin	Neuropeptide Y (NPY)
Glutamate	Neurotensin
Interleukin-1 (IL-1)	Nociceptin/orphanin FQ (OFQ)
Neuropeptide Y (NPY)	Opioids (β -endorphin) peptides
Neurotensin	Pancreatic polypeptide
Nitric oxide (NO)	Prolactin
Rfamide-related peptides (RFRP)	Pro-opiomelanocortin
Somatostatin	Pyro-glutamyl-Rfamide peptide (QRFP)
Thyrotropin-releasing hormone (TRH)	Somatostatin
Vasopressin (AVP)	Substance P
Vasoactive intestinal peptide (VIP)	

signals.^{43,47,48} The exclusion of macromolecules is achieved by the structural vascular specializations that make up the blood-brain barrier. These specializations include tight junctions of brain vascular endothelial cells that preclude the free passage of polarized macromolecules including peptides and hormones. In addition, astrocytic foot processes and perivascular microglial cells contribute to the integrity of the blood-brain barrier.⁴⁸ However, to exert homeostatic control, the brain must assess key sensory information from the bloodstream, including levels of hormones, metabolites, and potential toxins. To monitor key signals, the brain has “windows on the circulation” or circumventricular organs (CVOs) that serve as a conduit of peripheral cues into key neuronal cell groups that maintain homeostasis.^{47,48}

As the name implies, CVOs are specialized structures that lie on the midline of the brain along the third and fourth ventricles. These structures include the OVLT, subfornical organ (SFO), median eminence, neurohypophysis (posterior pituitary), subcommissural organ (SCO), and area postrema (see Fig. 7-5). Unlike the vasculature in the rest of the brain, the blood vessels in CVOs have fenestrated capillaries that allow relatively free passage of molecules such as proteins and peptide hormones. Thus, neurons and glial cells that reside within the CVOs have

access to these macromolecules. In addition to the distinct nature of the vessels themselves, the CVOs have an unusually rich blood supply, which allows them to act as integrators at the interface of the blood-brain barrier. Several of the CVOs have major projections to hypothalamic nuclear

groups that regulate homeostasis (see later discussion). Therefore, the CVOs serve as a critical link between peripheral metabolic cues, hormones, and potential toxins and cell groups within the brain that regulate coordinated endocrine, autonomic, and behavioral responses. Detailed discussion of the physiologic roles of individual CVOs is beyond the scope of this chapter, but several in-depth reviews have assessed the function of each.⁴⁷⁻⁵⁰

Median Eminence

The median eminence and neurohypophysis contain the neurosecretory axons that control pituitary function. The role of the median eminence as a link between the hypothalamus and the pituitary gland is detailed in other sections of this chapter (see “Hypothalamic-Pituitary Unit” and Figs. 7-2 and 7-4). The anatomic location of the median eminence places it in a position to serve as an afferent sensory organ as well. Specifically, the median eminence is located adjacent to several neuroendocrine and autonomic regulatory nuclei at the tuberal level of the hypothalamus (see Fig. 7-3). These nuclear groups include the infundibular or arcuate, ventromedial, dorsomedial, and paraventricular nuclei.³⁶

A role of the hypothalamic nuclei surrounding the median eminence as afferent sensory centers is supported by several observations. For example, toxins such as monosodium glutamate and gold thioglucose damage neurons in cell groups overlying the median eminence, resulting in obesity and hyperphagia. Experimental evidence suggests that the median eminence is a portal of entry for hormones such as leptin. Indeed, administration of radiolabeled peptides or hormones, such as α -MSH or leptin, led to their

Figure 7-5 Median sagittal section through the human brain shows the circumventricular organs (dark brown). New York, NY: Oxford University Press, 1973:3-32.)

accumulation around the median eminence.^{51,52} Moreover, leptin receptor messenger ribonucleic acid (mRNA) and leptin-induced gene expression are densely localized in the arcuate, ventromedial, dorsomedial, and ventral premammillary hypothalamic nuclei.⁵³ Leptin is an established mediator of body weight and neuroendocrine function that acts on several cell groups in the hypothalamus, including POMC neurons that reside in the arcuate nucleus.^{15,53,54} Because POMC neurons are also found embedded within the median eminence, it is likely that the median eminence is involved in conveying information from humoral factors such as leptin to key hypothalamic regulatory neurons in the medial basal hypothalamus.⁴³

Organum Vasculosum of the Lamina Terminalis and the Subfornical Organ

The OVLT and the SFO are located at the front wall of the third ventricle, the lamina terminalis. The OVLT and SFO lie, respectively, at the ventral and dorsal boundaries of the third ventricle (see Fig. 7-5).⁴⁷ Because it lies at the rostral and ventral tip of the third ventricle, the OVLT is surrounded by cell groups of the preoptic region of the hypothalamus. Like other CVOs, the OVLT is composed of neurons, glial cells, and tanycytes. Axon terminals containing several neuropeptides and neurotransmitters including GnRH, somatostatin, angiotensin, dopamine, norepinephrine, serotonin, acetylcholine, oxytocin, AVP, and TRH innervate the OVLT. In the rodent, neurons that contain GnRH surround the OVLT. In addition, the OVLT in the rat brain contains estrogen receptors, and the application of estrogen or electric stimulation at this site is capable of stimulating ovulation through GnRH-containing neurons that project to the median eminence, suggesting that the region regulates sexual behavior in the rat.⁴⁵

The region of the hypothalamus that immediately surrounds the OVLT regulates a diverse array of autonomic processes. However, because the OVLT is potentially involved in the maintenance of so many processes, definitive studies ascribing specific functions to the OVLT are inherently difficult. For example, lesions of the OVLT and surrounding preoptic area led to altered febrile responses after immunologic stimulation and to disruptions in fluid and electrolyte balance, blood pressure, reproduction, and thermoregulation. Large lesions of the OVLT attenuated lipopolysaccharide-induced fever.⁵⁵ Consistent with this finding, it was demonstrated that receptors for prostaglandin E₂ are located within and immediately surrounding the OVLT.⁵⁶ Because prostaglandin E₂ is thought to be an obligate endogenous pyrogen, the OVLT may be a critical regulator of febrile responses.

The OVLT is also likely to be involved in sensing serum osmolality, because lesions of the OVLT attenuate AVP and oxytocin secretion in response to osmotic stimuli. In addition, hypertonic saline administration in rats induced c-Fos (a marker of neuronal activation) in OVLT neurons.⁵⁷ The efferent projections of the OVLT are not well defined because of the fundamental difficulty of injecting this small structure with specific neuroanatomic tracers without contaminating surrounding preoptic nuclei. However, the neurons in the OVLT apparently have a remarkably restricted range of projections that include the PVH and SON nuclei, the dorsomedial hypothalamic nucleus, and the lateral hypothalamic area (J.K. Elmquist, J.E. Sherin, and C.B. Saper, unpublished observations).

The SFO is located in the roof of the third ventricle below the fornix. This CVO critically regulates fluid homeostasis and contributes to blood pressure regulation.⁴⁷

Consistent with these functions, the SFO has receptors for angiotensin II and atrial natriuretic peptide.^{49,58} In addition to expressing these key receptors, the SFO is thought to regulate fluid homeostasis because of its specific and massive projections to key hypothalamic regulatory sites. Notable among these are the inputs to oxytocin and AVP magnicellular neurons in the SON and PVH. Parvicellular neurons in the PVH concerned with neuroendocrine and autonomic control also receive innervation from the SFO. In addition, the SFO densely innervates the paramedian preoptic region of the hypothalamus (often known as the anteroventral third ventricular region) and other hypothalamic sites including the perifornical area of the lateral hypothalamus. A major cell group within the anteroventral third ventricular region is the median preoptic nucleus, which receives dense innervation from the SFO.⁵⁹ Several neuroanatomic studies have demonstrated that the median preoptic nucleus is a major source of afferents to the magnicellular neuroendocrine neurons in the PVH and SON.

In addition to the preceding neuroanatomic findings, physiologic evidence suggests that the SFO is critical in maintaining fluid balance. Simpson and Routtenberg reported that substances such as angiotensin II elicited drinking behavior when microinjected at low doses directly into the SFO.⁶⁰ Later studies demonstrated that SFO neurons have electrophysiologic responses to angiotensin II.⁴⁹ In addition, stimulation of the SFO elicited AVP secretion. Like the OVLT, the SFO expressed Fos after stimulation by hypertonic saline administration.⁵⁷ Therefore, the SFO provides dense direct and indirect innervation to the magnicellular neuroendocrine neurons in the PVH and SON that are critical in the maintenance of fluid balance and blood pressure.

Area Postrema

The area postrema lies at the caudal end of the fourth ventricle, adjacent to the nucleus of the solitary tract (see Fig. 7-5). In experimental animals such as the rat and mouse, it is a midline structure lying above the nucleus of the solitary tract.^{48,61} However, in humans, the area postrema is a bilateral structure. Because the area postrema overlies the nucleus of the solitary tract, it also receives direct visceral afferent input from the glossopharyngeal nerve (including the carotid sinus nerve) and the vagus nerve. In addition, the area postrema receives direct input from several hypothalamic nuclei. The efferent projections of the area postrema include projections to the nucleus of the solitary tract, the ventral lateral medulla, and the parabrachial nucleus. Consistent with its role as a sensory organ, the area postrema is enriched with receptors for several neuropeptides, including glucagon-like peptide 1 and cholecystokinin.^{62,63} It also contains chemosensory neurons including osmoreceptors.⁴⁷ The area postrema is thought to be critical in the detection of potential toxins and can induce vomiting in response to foreign substances. In fact, the area postrema is often referred to as the *chemoreceptor trigger zone*.⁶¹

The best-described physiologic role of the area postrema is the coordinated control of blood pressure.^{47,48} The area postrema contains binding sites for angiotensin II, AVP, and atrial natriuretic peptide. Lesions of the area postrema in rats blunt the rise in blood pressure induced by angiotensin II.⁶⁴ Administration of angiotensin II induces the expression of Fos in neurons of the area postrema. This area has also been hypothesized to play a role in responding to inflammatory cytokines during the acute febrile response.

Subcommissural Organ

The SCO is located near the junction of the third ventricle and the cerebral aqueduct, below the posterior commissure and the pineal gland (see Fig. 7-5).⁴⁷ It is composed of specialized ependymal cells that secrete a highly glycosylated protein of unknown function. The secretion of this protein leads to aggregation and formation of the so-called Reissner's fibers.⁵⁰ The glycoproteins are extruded through the aqueduct, the fourth ventricle, and the spinal cord lumen to terminate in the caudal spinal canal. In humans, intracellular secretory granules are identifiable in the SCO, but Reissner's fibers are absent. The SCO secretion in humans is therefore presumed to be more soluble and to be absorbed directly from the CSF. Compared with other CVOs, the physiologic role of the SCO is largely unknown. Hypothesized roles for the SCO include clearance of substances from the CSF.⁵⁰

PINEAL GLAND

Descartes called the pineal gland the "seat of the soul." A more contemporary, although less colorful, viewpoint is that the pineal integrates information encoded by light into coordinated secretions that underlie biologic rhythmicity.^{65,66} The pineal gland is both an endocrine organ and a CVO; it is derived from cells located in the roof of the third ventricle and lies above the posterior commissure near the level of the habenular complex and the sylvian aqueduct. The gland is composed of two cell types, pinealocytes and interstitial (glial-like) cells. Histologic studies suggest that the pineal gland cells are secretory in nature, and indeed the pineal is the principal source of melatonin in mammals.

The pineal is an epithalamic structure and consists of primordial photoreceptive cells. The gland retains its light sensitivity in lower vertebrates such as fish and amphibians but lacks direct photosensitivity in mammals and has evolved as a strictly secretory organ in higher vertebrates. However, neuroanatomic studies have established that

light-encoded information is relayed to the pineal by a polysynaptic pathway. This series of synapses ultimately results in innervation of the gland by noradrenergic sympathetic nerve terminals that are critical regulators of melatonin production and release. Specifically, retinal ganglion cells directly innervate the SCN of the hypothalamus through the retinohypothalamic tract.⁶⁷ The SCN in turn provides input to the dorsal parvocellular PVH, a key cell group in neuroendocrine and autonomic control. This pathway consists of direct and indirect intrahypothalamic projections.^{68,69} The PVH in turn provides direct innervation to sympathetic preganglionic neurons in the intermediolateral cell column of the thoracic regions of the spinal cord.⁷⁰ Sympathetic preganglionic neurons innervate postganglionic neurons in the superior cervical ganglion⁷¹ that ultimately supply the noradrenergic innervation to the pineal (see "Hypothalamic-Pituitary Unit"). This rather circuitous pathway represents the anatomic substrate for light to regulate the secretion of melatonin. In the absence of light input, the pineal gland rhythms persist but are not entrained to the external light-dark cycle.

The Pineal Is the Source of Melatonin

The predominant hormone secreted by the pineal gland is melatonin. However, the pineal contains other biogenic amines, peptides, and GABA. Pineal-derived melatonin is synthesized from tryptophan, through serotonin, with the rate-limiting step catalyzed by the enzyme arylalkylamine *N*-acetyltransferase (AANAT) (Fig. 7-6).^{72,73} Hydroxyindole-*O*-methyltransferase (HIOMT) catalyzes the final step of melatonin synthesis. These enzymes are expressed in a pineal-specific manner; however, HIOMT is also expressed in the retina and in red blood cells. Melatonin plays a key role in regulating a myriad of circadian rhythms, and a fundamental principle of circadian biology is that the synthesis of melatonin is exquisitely controlled.⁶⁵ AANAT mRNA levels, AANAT activity, and melatonin synthesis and release are regulated in a circadian fashion and are entrained by the light-dark cycle, with darkness thought to be the most important signal.^{66,72,73} Melatonin and AANAT levels

Figure 7-6 Biosynthesis of melatonin from tryptophan in the pineal gland. Step 1 is catalyzed by tryptophan hydroxylase, step 2 by aromatic-L-amino acid decarboxylase, step 3 by arylalkylamine *N*-acetyltransferase, and step 4 by hydroxyindole-*O*-methyltransferase. (From Wurtman RJ, Axelrod J, Kelly DE. Biochemistry of the pineal gland. In: Wurtman RJ, Axelrod J, Kelly DE, eds. *The Pineal*. New York, NY: Academic Press, 1968:47-75.)

are highest during the dark and decrease sharply with the onset of light. Melatonin is not stored to any significant degree; it is released into blood or CSF directly after its biosynthesis in proportion to AANAT activity.

CNS control of melatonin secretion during the dark is mediated by the neuroanatomic pathway just outlined. Lack of light ultimately results in the release of norepinephrine from postganglionic sympathetic nerve terminals that act on β -adrenergic receptors in pinealocytes, resulting in an increase in adenylyl cyclase activity and synthesis of cyclic adenosine monophosphate (cAMP) from adenosine triphosphate.⁷² Increased levels of intracellular cAMP activate downstream signal transduction cascades, including the catalytic subunits of protein kinase A and phosphorylation of cAMP response element (CRE) binding protein. CREs have been identified in the promoter of AANAT.^{72,74} Therefore, light (or lack of it) acting through the sympathetic nervous system induces an increase in cAMP, representing a fundamental regulator of AANAT transcription and melatonin synthesis that ultimately results in a dramatic change of melatonin levels across the day.

Physiologic Roles of Melatonin

One of the best-characterized roles of melatonin is regulation of the reproductive axis, including gonadotropin secretion⁷⁵ and the timing and onset of puberty (see “Gonadotropin-Releasing Hormone and Control of the Reproductive Axis”). The potent regulation of the reproductive axis by melatonin is established in rodents and domestic animals such as the sheep. It was observed experimentally with the demonstration that removal of the pineal leads to precocious puberty. In addition, male rats exposed to constant darkness or blinded by enucleation display testicular atrophy and decreased levels of testosterone. These profound effects of gonadal involution are normalized by removal of the pineal gland.⁷⁶ The physiologic significance of melatonin is probably most important in species referred to as seasonal breeders. Indeed, the role of melatonin in regulating reproductive capacity in species such as the sheep and the horse is now established. This type of reproductive strategy probably evolved to synchronize the length of day with the gestational period of the species, to ensure that the offspring are born at favorable times of the year and to maximize the viability of the young. Interestingly, although there is a strong and consistent correlation between altered melatonin secretion, day length, and seasonal breeding in diverse species, the valence of the signal can be either positive or negative, depending on the ecologic niche of each species.

Despite the potent effects of day length on reproduction in these species, the exact mechanisms of melatonin regulation of GnRH release are unsettled. However, melatonin inhibits LH release from the rat pars tuberalis.⁷⁵ The role of the pineal in human reproduction is even less understood.⁷⁷ Earlier onset of menarche in blind women has been reported. In addition, a decline in melatonin at puberty has been described in some but not all studies.

Interspecies comparative studies of melatonin's physiologic function must be tempered by knowledge of key differences between rodent and human melatonin regulation. Significantly more light, as much as 4 log units, is required in humans to produce an equivalent nocturnal suppression of melatonin,⁷⁸ and the control of AANAT is largely post-transcriptional in humans, rather than transcriptional.⁷³

Melatonin Receptors

Melatonin mediates its effects by acting on a family of G protein-coupled receptors that have been characterized by pharmacologic, neuroanatomic, and molecular approaches.^{65,66,73} The first member of the family, MT1 (also called Mel_{1a} or melatonin receptor type 1A [MTNR1A]), is a high-affinity receptor that was isolated originally from *Xenopus* melanophores. The second, MT2 (Mel_{1b} or MTNR1B), has approximately 60% homology with MT1. A third receptor in mammals, MT3, is not a G protein-coupled receptor but instead a high-affinity binding site on the cytosolic enzyme quinone reductase 2 that is involved in cellular detoxification; this might explain some of melatonin's effects as an antioxidant.^{66,73}

The mechanisms for melatonin's effects on regulating and entraining circadian rhythms are becoming increasingly understood. For example, melatonin inhibits the activity of neurons in the SCN of the hypothalamus, the master circadian pacemaker in the mammalian brain.^{65,79,80}

Melatonin can entrain several mammalian circadian rhythms, probably by inhibition of neurons in the SCN. Neuroanatomic evidence suggests that many of the effects of melatonin on circadian rhythms involve actions on MT1 receptors, in that the distribution of MT1 mRNA overlaps with radiolabeled melatonin-binding sites in the relevant brain regions. These sites include the SCN, the retina, and the pars tuberalis of the adenohypophysis. The MT2 receptor is also expressed in retina and brain, particularly in the SCN, but evidently at much lower levels.^{65,73,79}

Genetic studies in mice have also helped to illuminate the relative roles of each melatonin receptor in mediating the effects of this hormone. Targeted deletion (knockout) of the MT1 but not the MT2 receptor abolished the ability of melatonin to inhibit the activity of SCN neurons.^{80,81} Several studies have suggested that inhibition of SCN neurons by melatonin is of great physiologic significance. For example, Reppert and colleagues proposed that elevations of melatonin at night decrease the responsiveness of the SCN to activity-related stimuli that could result in phase shifts.⁸⁰ As noted, light potently inhibits melatonin synthesis and release. Therefore, melatonin may underlie the mechanism by which light induces phase shifts. However, it should be noted that lack of the MT1 gene does not block the ability of melatonin to induce phase shifts. These unexpected and somewhat confusing results have resulted in the hypothesis that MT2 is involved in melatonin-induced phase shifts, because this receptor is expressed in the SCN in human brain.⁷³

Melatonin Therapy in Humans

Melatonin is purported to exert multiple beneficial functions that include slowing or reversing the progression of aging, protecting against ischemic damage after vascular reperfusion, and enhancing immune function.^{66,73} However, the most studied and established role of melatonin in humans is that of phase shifting and resetting circadian rhythms. In this context, melatonin has been used to treat jet lag and may be effective in treating circadian-based sleep disorders.⁸² In addition, melatonin administration has been shown to regulate sleep in humans. Specifically, melatonin has a hypnotic effect at relatively low doses. Melatonin therapy has also been suggested as a way to treat seasonal affective disorders. However, two recent meta-analyses of the published reports on melatonin for treatment of either primary or secondary sleep disorders concluded that there is limited evidence for significant

clinical efficacy, although melatonin is safe with short-term use (≤ 3 months).^{83,84} Because melatonin is now available over the counter and without a prescription throughout the United States, it is important that further controlled clinical studies be conducted to assess fully the therapeutic potential and safety of long-term melatonin use in humans.

HYPOPHYSEOTROPIC HORMONES AND NEUROENDOCRINE AXES

With the demonstration by the first half of the 1900s that pituitary secretion is controlled by hypothalamic hormones released into the portal circulation, the race was on to identify the hypothalamic releasing factors. The search for hypothalamic neurohormones with anterior pituitary-regulating properties focused on extracts of stalk median eminence, neural lobe, and hypothalamus from sheep and pigs. To give some idea of the herculean nature of this effort, approximately 250,000 hypothalamic fragments were required to purify and characterize the first such factor, TRH.⁹ Such hypophyseotropic substances were initially called *releasing factors* but are now more commonly called *releasing hormones*.

All of the principal hypothalamic-pituitary regulating hormones are peptides, with the notable exception of dopamine, which is a biogenic amine and the major prolactin-inhibiting factor (PIF; see later discussion and Table 7-2). All are available for clinical investigations or diagnostic tests, and therapeutic analogues for dopamine, GnRH, and somatostatin are widely prescribed.

In addition to regulating hormone release, some hypophyseotropic factors control pituitary cell differentiation and proliferation and hormone synthesis. Some act on more than one pituitary hormone. For example, TRH is a potent releaser of prolactin (PRL) and of TSH, and under some circumstances it releases corticotropin (ACTH) and growth hormone (GH). GnRH releases both LH and follicle-stimulating hormone (FSH). Somatostatin inhibits the secretion of GH, TSH, and a wide variety of nonpituitary hormones. The principal inhibitor of PRL secretion, dopamine, also inhibits secretion of TSH, gonadotropin, and, under certain conditions, GH. Dual control is exerted by the interaction of inhibitory and stimulatory hypothalamic hormones. For example, somatostatin interacts with GHRH and TRH to control secretion of GH and TSH, respectively, and dopamine interacts with prolactin-releasing factors (PRFs) to regulate PRL secretion. Some hypothalamic hormones act synergistically; for example, CRH and AVP cooperatively regulate the release of pituitary ACTH.

Secretion of the releasing hormones in turn is regulated by neurotransmitters and neuropeptides released by a complex array of neurons synapsing with hypophyseotropic neurons. Control of secretion is also exerted through feedback control by hormones such as glucocorticoids, gonadal steroids, thyroid hormone, anterior pituitary hormones (short-loop feedback control), and hypophyseotropic factors themselves (ultrashort-loop feedback control).

The distribution of the hypophyseotropic hormones is not limited to the hypothalamus. Most are produced in nonhypophyseotropic hypothalamic neurons, in extrahypothalamic regions of the brain, and in peripheral organs where they mediate functions unrelated to pituitary regulation (e.g., effects on behavior or homeostasis). Most of the peptides, hormones, and neurotransmitters involved in the regulation of hypothalamic-pituitary control transduce

their signals through members of the extensive G protein-coupled receptor family (Table 7-3).

Feedback Concepts in Neuroendocrinology

To understand the regulation of each hypothalamic-pituitary-target organ axis, it is important to understand some basic concepts of homeostatic systems. A simplified account of feedback control in relation to neuroendocrine regulation is presented here.⁸⁵⁻⁸⁷ Hormonal systems form part of a feedback loop in which the controlled variable (usually the blood hormone level or some biochemical surrogate of the hormone) determines the rate of secretion of the hormone. In negative feedback systems, the controlled variable inhibits hormone output, and in positive feedback control systems it increases hormone secretion. Both negative and positive endocrine feedback control systems can be part of a closed loop, in which regulation is entirely restricted to the interacting regulatory glands, or an open loop, in which the nervous system influences the feedback loop. All pituitary feedback systems have nervous system inputs that either alter the set point of the feedback control system or introduce open-loop elements that can influence or override the closed-loop control elements.

In engineering formulations of feedback, three types of controlled variables can be identified: a sensing element that detects the concentration of the controlled variable, a reference input that defines the proper control levels, and an error signal that determines the output of the system. The reference input is the set point of the system.

Hormonal feedback control systems resemble engineering systems in that the concentration of the hormone in the blood (or some function of the hormone) regulates the output of the controlling gland. However, hormonal feedback differs from engineering systems in that the sensor element and the reference input element are not readily distinguishable. The set point of the controlled variable is determined by a complex cascade beginning with the kinetics of binding to a receptor and the activities of successive intermediate messengers. Sophisticated models incorporating control elements, compartmental analysis, and hormone production and clearance rates exist for many systems. This sort of modeling, which is applied to developmental programming, intracellular signaling cascades, and neural circuits in addition to endocrine feedback systems, is commonly referred to as *systems biology*.⁸⁸

Endocrine Rhythms

Virtually all functions of living animals (regardless of their position on the evolutionary scale) are subject to periodic or cyclic changes, many of which are influenced primarily by the nervous system (Table 7-4).⁸⁹⁻⁹² Most periodic changes are free-running; that is, they are intrinsic to the organism, independent of the environment, and driven by a biologic "clock."

Most free-running rhythms are coordinated (entrained) by external signals (cues), such as light-dark changes, meal patterns, cycles of the lunar periods, or the ratio of day-length to night-length. External signals of this type (*zeitgeber*, or "time givers") do not bring about the rhythm but provide the synchronizing time cue. Many endogenous rhythms have a period of approximately 24 hours. Circadian changes follow an intrinsic program that is about 24 hours long, whereas diurnal rhythms can be either circadian or dependent on shifts in light and dark. Rhythms that occur more frequently than once a day are ultradian. Infradian rhythms have a period longer than 1 day, as in

TABLE 7-3

Receptors for Neurotransmitters and Neuropeptides Involved in Hypothalamic-Pituitary Control and Neuroendocrine Homeostasis

Group and Ligand	Receptor Family	Receptor Protein*	Receptor Gene	Mode of Action†		
Classic Neurotransmitters						
Catecholamines (norepinephrine, epinephrine)	α_1 -Adrenoreceptors	ADA1A (α 1A)	ADRA1A	7-TM, G _{q/11}

TABLE 7-3

Receptors for Neurotransmitters and Neuropeptides Involved in Hypothalamic-Pituitary Control and Neuroendocrine Homeostasis (Continued)

Group and Ligand	Receptor Family	Receptor Protein*	Receptor Gene	Mode of Action†
Glucagon-like peptide (GLP)	GLP receptor	GLP1R	GLP1R	7-TM, G _s
Cholecystokinin (CCK)/Gastrin	CCK receptors	CCKAR (CCK1-R)	CCKAR	7-TM, G _{q/11}
		GASR (CCK2-R)	CCKBR	7-TM, G _{q/11}
Neuropeptide Y (NPY)	NPY/PYY/PP receptors	NPY1R (NPY-Y1)	NPY1R	7-TM, G _{i/o}
Peptide YY (PYY ³⁻³²)		NPY2R (NPY-Y2)	NPY2R	7-TM, G _{i/o}
Pancreatic polypeptide (PP)		NPY4R (PPI)	PPYR1	7-TM, G _{i/o}
Neuropeptide Y		NPY5R (NPY-Y5)	NPY5R	7-TM, G _{i/o}
Other				
Cannabinoid	Cannabinoid receptor	CNR1 (CB1)	CNR1	7-TM, G _{i/o}

*Receptors cited are human. Swiss-Prot identifiers and alternative names (in parentheses) are provided for each receptor and were obtained with the use of the GPCRDB information system (available at <http://www.gpcr.org/7tm/>) described in Horn F, Bettler E, Oliveira L, et al. GPCRDB information system for G protein-coupled receptors. *Nucleic Acids Res.* 2003;31:294-297.

†The mode of action designation is oversimplified. It is common for 7-TM GPCRs to interact with multiple different G-protein complexes depending on the specific cell. G_{i/o}, GPCR coupled to the G_{i/o} family, inhibits adenylyl cyclase and decreases intracellular cAMP; opens K⁺ channels and closes Ca²⁺ channels; G_{q/11}, GPCR coupled to the G_{q/11} family, stimulates the phosphoinositol cascade; G_s, GPCR coupled to the G_s family, stimulates adenylyl cyclase and increases intracellular cAMP; PLC-β, GPCR coupled to G protein that activates phospholipase Cβ (PLC-β); cGMP, guanylate cyclase activity intrinsic to these I transmembrane pass receptors.

AMPA, α-amino-3-hydroxy-5-methyl-4-isoxazdepropionic acid; cAMP, cyclic adenosine monophosphate; CART, cocaine- and amphetamine-responsive transcript; GALP, galanin-like peptide; (GPCR) G protein-coupled receptor; GHS, growth hormone secretagogue; NMDA, N-methyl-D-aspartate; OFQ, orphanin FQ; PACAP, pituitary adenylyl cyclase activating peptide; TM, transmembrane.

the approximately 27-day human menstrual cycle and the yearly breeding patterns of some animals.

Most endocrine rhythms are circadian (Fig. 7-7). The secretion of GH and PRL in humans is maximal shortly after the onset of sleep, and that of cortisol is maximal between 2 a.m. and 4 a.m. TSH secretion is lowest in the morning, between 9 a.m. and 12 noon, and maximal between 8 p.m. and midnight. Gonadotropin secretion in adolescents is increased at night. Superimposed on the circadian cycle are ultradian bursts of hormone secretion. LH secretion during adolescence is characterized by rapid, high-amplitude pulsations at night, whereas in sexually

mature individuals secretory episodes are lower in amplitude and occur throughout the 24 hours. GH, ACTH, and PRL are also secreted in brief, fairly regular pulses. The short-term fluctuations in hormonal secretion have important functional significance. In the case of LH, the normal endogenous rhythm of pituitary secretion reflects the pulsatile release of GnRH. The period of approximately 90 minutes between LH peaks corresponds to the optimal timing of GnRH pulses to induce maximal pituitary stimulation. Episodic secretion of GH also enhances its biopotency, but for many rhythms, the function is not clear. Most homeostatic activities are rhythmic, including body temperature, water balance, blood volume, sleep, and activity.^{93,94}

Assessment of endocrine function must take into account the variability of hormone levels in the blood. Appropriately obtained samples at different times of day or night may provide useful dynamic indicators of hypothalamic-pituitary function. For example, the loss of diurnal rhythm of GH and ACTH secretion may be an early sign of hypothalamic dysfunction. The optimal timing for administration of glucocorticoids to suppress ACTH secretion (e.g., in therapy for congenital adrenal hyperplasia) must take into account the varying suppressibility of the axis at different times of day.

The best understood neural structures responsible for circadian rhythms are the SCN, paired structures in the anterior hypothalamus above the optic chiasm.^{90,94} In addition to the retinohypothalamic projection from the retina described earlier, the SCN receives neuronal input from many nuclei. Individual cells of the SCN have an intrinsic capacity to oscillate in a circadian pattern,⁹⁵ and the nucleus is organized to permit many reciprocal neuron-neuron interactions through direct synaptic contacts. It is especially rich in neuropeptides, including somatostatin, VIP, NPY, and neurotensin. Microinjections of pancreatic polypeptide into the SCN reset the timing cycle of some circadian rhythms in hamsters. The SCN also responds to the pineal hormone melatonin through melatonin receptors.^{66,73} Studies have indicated that intrinsic pacemaker

TABLE 7-4

Terms Used to Describe Cyclic Endocrine Phenomena

Period	Length of the cycle
Circadian	About a day (24 hr)
Diurnal	Exactly a day
Ultradian	Less than a day (i.e., minutes or hours)
Infradian	Longer than a day (i.e., month or year)
Mean	Arithmetic mean of all values within a cycle
Range	Difference between the highest and lowest values
Nadir	Minimal level (inferred from mathematical curve fitting calculations)
Acrophase	Time of maximal levels (inferred from curve fitting)
Zeitgeber	"Time-giver" (German); the external cue, usually the light-dark cycle that synchronizes endogenous rhythms
Entrainment	The process by which an endogenous rhythm is regulated by a zeitgeber
Phase shift	Induced change in an endogenous rhythm
Intrinsic clock	Neural structures that possess intrinsic capacity for spontaneous rhythms; for circadian rhythms, these are located in the suprachiasmatic nucleus

(Adapted from Van Cauter E, Turek FW. Endocrine and other biological rhythms. In: DeGroot LJ, ed. *Endocrinology*, 3rd ed. Philadelphia, PA: Saunders, 1995:2497-2548).

The temporal relationship between gonadotropin releasing hormone [GnRH] and luteinizing hormone [LH] secretion in ovariectomized ewes. *Endocrinology.* 1982;111:1737-1739, Fig. 2A.)

function is not unique to neurons of the SCN; circadian oscillators are also found in many peripheral tissues.⁹⁴

Metabolic changes in the SCN, such as increased uptake of 2-deoxyglucose and an increased level of VIP, accompany circadian rhythms. This nucleus projects to the pineal gland indirectly via the PVH and the autonomic nervous system (see earlier discussion) and regulates its activity.⁹⁰ However, the bulk of SCN outflow occurs in a trunk that courses dorsolaterally through the ventral subparaventricular zone and terminates in the dorsal medial hypothalamic nucleus. Polysynaptic pathways involving these latter structures are responsible for the actions of the SCN in producing the circadian rhythms in thermoregulation, glucocorticoid secretion, sleep, arousal, and feeding.⁹⁰

Circadian rhythms during fetal life are regulated by maternal circadian rhythms.⁹⁶ Circadian changes can be

detected 2 to 3 days before birth, and SCN from fetuses of this age display spontaneous rhythmicity in vitro. Maternal regulation of fetal circadian rhythms may be mediated by circulating melatonin or by cyclic changes in the food intake of the mother. The timing of the circadian pacemaker can be shifted in humans by administration of triazolam (a short-acting benzodiazepine) or melatonin (described earlier) or by altered patterns of intense illumination.⁷⁸

Thyrotropin-Releasing Hormone

Chemistry and Evolution

TRH, the smallest known peptide hypophyseotropic hormone, is the tripeptide pyroGlu-His-Pro-NH₂. Six copies

Figure 7-8 Structure of the human thyrotropin-releasing hormone (TRH) gene, complementary DNA, and prohormone, showing six repeats of the TRH peptide sequence encoded within exon 3. CPE, carboxypeptidase E; CRE, cyclic adenosine monophosphate (cAMP) response element; GRE, glucocorticoid response element; PAM, peptidylglycine α -amidating monooxygenase; PC1/PC2, prohormone convertases 1 and 2; Sp1, specificity protein 1 binding sequence; Stat, signal transducer and activator of transcription binding sequence; TATA, Goldstein-Hogness box involved in binding RNA polymerase; TRE, thyroid hormone response element; UTR, untranslated. (Adapted from data in Yamada M, Radovick S, Wondisford FE, et al. Cloning and structure of human genomic DNA and hypothalamic cDNA encoding human preprothyrotropin-releasing hormone. *Mol Endocrinol*. 1990;4:551-556.)

of the TRH peptide sequence are encoded within the human TRH pre-prohormone gene (Fig. 7-8).⁹⁷ The rat pro-TRH precursor contains five TRH peptide repeats flanked by dibasic residues (Lys-Arg or Arg-Arg), along with seven or more non-TRH peptides.⁹⁸ Two prohormone convertases, PC1 and PC2, cleave the TRH tripeptides at the dibasic residues as the prohormone molecule transits the regulated secretory pathway. Carboxypeptidase E then removes the dibasic residues, leaving the sequence

Gln-His-Pro-Gly. This peptide is then amidated at the carboxy terminus by peptidylglycine α -amidating monooxygenase (PAM), with Gly acting as the amide donor. The amino-terminal pyro-glutamate (pyroGlu) residue results from cyclization of the Gln.

TRH is a phylogenetically ancient peptide that has been isolated from primitive vertebrates such as the lamprey and even from invertebrates such as the snail. TRH is widely expressed in both the CNS and periphery in amphibians, reptiles, and fishes but does not stimulate TSH release in these poikilothermic vertebrates. Therefore, TRH has multiple peripheral and central activities and was co-opted as a hypophyseotropic factor midway during the evolution of vertebrates, perhaps specifically as a factor needed for coordinated regulation of temperature homeostasis.

Although the TRH tripeptide is the only established hormone encoded within its large prohormone, rat pro-TRH yields seven additional peptides that have unique tissue distributions.⁹⁹ Several biologic activities of these peptides have been observed. The fragment pro-TRH(160-169) may be a hypophyseotropic factor because it is released from hypothalamic slices and potentiates the TSH-releasing effects of TRH. The pro-TRH(178-199) is also released from the median eminence and appears to inhibit ACTH release.

Effects on the Pituitary Gland and Mechanism of Action

After intravenous injection of TRH in humans, serum TSH levels rise within a few minutes,¹⁰⁰ followed by a rise in serum triiodothyronine (T₃) levels. There is an increase in thyroxine (T₄) release as well, but a change in blood levels of T₄ is usually not demonstrable because the pool of circulating T₄ (most of which is bound to carrier proteins) is so large. The clinical applications of TRH testing are covered later in this chapter and in Chapter 11. TRH action on the pituitary is blocked by previous treatment with thyroid hormone, which is a crucial element in the feedback control of pituitary TSH secretion.

TRH is also a potent PRF.¹⁰⁰ The time course of response of blood PRL levels to TRH, the dose-response characteristics, and the suppression by thyroid hormone pretreatment (all of which parallel changes in TSH secretion) suggest that TRH may be involved in the regulation of PRL secretion. Moreover, TRH is present in the hypophyseal-portal blood of lactating rats. However, it is unlikely to be a physiologic regulator of PRL secretion, because the PRL response to nursing in humans is unaccompanied by changes in plasma TSH levels,¹⁰¹ and mice lacking TRH have normal lactotrophs and normal basal PRL secretion.¹⁰² Nevertheless, TRH may occasionally cause hyperprolactinemia (with or without galactorrhea) in patients with hypothyroidism.

In normal individuals, TRH has no influence on the secretion of pituitary hormones other than TSH and PRL, but it enhances the release of GH in patients with acromegaly and of ACTH in some patients with Cushing's disease. Furthermore, prolonged stimulation of the normal pituitary with GHRH can sensitize it to the GH-releasing effects of TRH. TRH also causes the release of GH in some patients with uremia, hepatic disease, anorexia nervosa, or psychotic depression and in children with hypothyroidism.¹⁰⁰ TRH inhibits sleep-induced GH release through its actions in the CNS (see later discussion).

Stimulatory effects of TRH are initiated by binding of the peptide to specific receptors on the plasma membrane of the thyrotroph.¹⁰³ Thyroid hormone and somatostatin antagonize the effects of TRH but do not interfere with its binding. TRH action is mediated mainly through hydrolysis

of phosphatidylinositol, with phosphorylation of key protein kinases and an increase in intracellular free calcium (Ca^{2+}) as the crucial steps in postreceptor activation (see Chapter 5).¹⁰⁴ TRH effects can be mimicked by exposure to a Ca^{2+} ionophore and are partially abolished by a Ca^{2+} -free medium. TRH stimulates the formation of mRNAs coding for TSH and PRL, in addition to regulating their secretion and stimulates the mitogenesis of thyrotrophs.

TRH is degraded to acid TRH and to the dipeptide histidylprolineamide, which cyclizes nonenzymatically to histidylproline diketopiperazine (cyclic His-Pro). Acid TRH has some behavioral effects in rats that are similar to those of TRH but no other proven actions. Cyclic His-Pro is reported to act as a PRF and to have other neural effects, including reversal of ethanol-induced sleep (TRH is also effective in this system), elevation of brain cyclic guanosine monophosphate levels, an increase in stereotypical behavior, modification of body temperature, and inhibition of eating behavior. Some of the effects of TRH may be mediated through cyclic His-Pro, but the fact that cyclic His-Pro is abundant in some areas and is not proportional to the amount of TRH suggests that the peptide may not be derived solely from TRH. This latter assertion appears to be confirmed by the detection of substantial amounts of the dipeptide in brains of TRH knockout mice.¹⁰²

Extrapituitary Function

TRH is present in virtually all parts of the brain: cerebral cortex, CVOs, neurohypophysis, pineal gland, and spinal cord.¹⁰⁵ TRH is also found in pancreatic islet cells and in the gastrointestinal tract. Although it exists in low concentration, the total amount in extrahypothalamic tissues exceeds the amount in the hypothalamus.

The extensive extrahypothalamic distribution of TRH, its localization in nerve endings, and the presence of TRH receptors in brain tissue suggest that TRH serves as a neurotransmitter or neuromodulator outside the hypothalamus.¹⁰⁶ TRH is a general stimulant and induces hyperthermia on intracerebroventricular injection, suggesting a role in central thermoregulation.¹⁰⁵ Studies in TRH knockout mice may further clarify the nonhypophyseotropic actions of TRH.¹⁰²

Clinical Applications

The use of TRH for the diagnosis of hyperthyroidism has become less common since the development of ultrasensitive assays for TSH¹⁰⁰ (see Chapter 11). Use of TRH to discriminate between hypothalamic and pituitary causes of TSH deficiency has also declined because of the test's poor specificity,¹⁰⁰ but the application of ultrasensitive assays in conjunction with the TRH test has not been fully evaluated. TRH testing is also not of value in the differential diagnosis of causes of hyperprolactinemia, but it is useful for the demonstration of residual abnormal somatotropin-secreting cells in acromegalic patients who release GH in response to TRH before treatment.

Studies of the effect of TRH on depression have shown inconsistent results, possibly because of poor blood-brain barrier penetration.¹⁰⁵ Intrathecal administration of TRH may improve responses in depressed patients, but its clinical utility is unknown.¹⁰⁷ Although a role for TRH in depression is not established, many depressed patients have a blunted TSH response to TRH, and changes in TRH responsiveness correlate with the clinical course. The mechanism by which blunting occurs is unknown.

TRH has been evaluated for the treatment of diverse neurobiologic disorders (for review, see Gary and colleagues¹⁰⁵) including spinal muscle atrophy and

amyotrophic lateral sclerosis; transient improvement in strength was reported in both disorders, but the combined experience at many centers using a variety of treatment protocols including long-term intrathecal administration failed to confirm efficacy. TRH administration reduces the severity of experimentally induced spinal and ischemic shock; preliminary studies in humans suggest that TRH treatment may improve recovery after spinal cord injury and head trauma. TRH has been used to treat children with neurologic disorders including West's syndrome, Lennox-Gastaut syndrome, early infantile epileptic encephalopathy, and intractable epilepsy.¹⁰⁸ TRH has been proposed to be an analeptic agent. Sleeping or drug-sedated animals were awakened by the administration of TRH, TRH reportedly reversed sedative effects of ethanol in humans, and TRH is said to have awakened a patient with a profound sleep disorder caused by a hypothalamic and midbrain eosinophilic granuloma.¹⁰⁵

Regulation of Thyrotropin Release

The secretion of TSH is regulated by two interacting elements: negative feedback by thyroid hormone and open-loop neural control by hypothalamic hypophyseotropic factors (Fig. 7-9). TSH secretion is also modified by other hormones, including estrogens, glucocorticoids, and possibly GH, and it is inhibited by cytokines in the pituitary and hypothalamus.^{100,109} Aspects of the pituitary-thyroid axis are considered further in Chapter 11.

Feedback Control: Pituitary-Thyroid Axis

In the context of a feedback system, the level of thyroid hormone or of its unbound fraction in blood is the controlled variable, and the set point is the normal resting level of plasma thyroid hormone. Secretion of TSH is inversely regulated by the level of thyroid hormone so that deviations from the set point lead to appropriate changes in the rate of TSH secretion (Fig. 7-10). Factors that determine the rate of TSH secretion required to maintain a given level of thyroid hormone include the rate at which TSH and thyroid hormone disappear from the blood (turnover rate) and the rate at which T_4 is converted to its more active form, T_3 .

Thyroid hormones act on both the pituitary and the hypothalamus. Feedback control of the pituitary by thyroid hormone is remarkably precise.^{109a,109b} Administration of small doses of T_3 and T_4 inhibited the TSH response to TRH, and barely detectable decreases in plasma thyroid hormone levels were sufficient to sensitize the pituitary to TRH. TRH stimulates TSH secretion within a few minutes through its action on a membrane receptor, whereas thyroid hormone actions, mediated by intranuclear receptors, require several hours to take effect (see Chapter 11).

The secretion of hypothalamic TRH is also regulated by thyroid hormone feedback. Systemic injections of T_3 or implantations of tiny T_3 pellets in the PVH of hypothyroid rats¹¹⁰ (Fig. 7-11A and B) reduced the concentration of TRH mRNA and TRH prohormone in TRH-secreting cells. Thyroid hormone also suppressed TRH secretion into hypophyseal-portal blood in sheep.

T_4 in the blood gains access to TRH-secreting neurons in the hypothalamus by way of the CSF. The hormone is taken up by epithelial cells of the choroid plexus of the lateral ventricle of the brain, bound within the cell to locally produced transthyretin (T_4 -binding prealbumin), and then secreted across the blood-brain barrier.¹¹¹ Within the brain, T_4 is converted to T_3 by type II deiodinase, and T_3 interacts with subtypes of the thyroid hormone receptor ($\text{TR}\alpha_1$, $\text{TR}\beta_1$, and $\text{TR}\beta_2$) in the PVH and other brain cells

Figure 7-9 Regulation of the hypothalamic-pituitary-thyroid axis. (see Chapter 11). In this way, the set point of the pituitary-thyroid axis is determined by thyroid hormone levels within the brain.¹¹² T₃ in the circulation is not transported into brain in the same manner but presumably gains access to the paraventricular TRH neurons across the blood-brain barrier. The brain T₄ transport and deiodinase system accounts for the fact that higher blood levels of T₃ are required to suppress pituitary-thyroid function after administration of T₃ than after administration of T₄.^{112,113}

Transthyretin is present in the brain of early reptiles and in addition is synthesized by the liver in warm-blooded animals.¹¹¹ During embryogenesis in mammals, transthyretin is first detected when the blood-brain barrier appears, ensuring thyroid hormone access to the developing nervous system.

Neural Control

The hypothalamus determines the set point of feedback control around which the usual feedback regulatory

responses are elicited. Lesions of the thyrotropic area lower basal thyroid hormone levels and make the pituitary more sensitive to inhibition by thyroid hormone, and high doses of TRH raise the levels of TSH and thyroid hormone. Synthesis of TRH in the PVH is regulated by feedback actions of thyroid hormones.¹¹² The hypothalamus can override normal feedback control through an open-loop mechanism involving neuronal inputs to the hypophyseotropic TRH neurons (see Fig. 7-9). For example, cold exposure causes a sharp increase in TSH release in animals and in human newborns. Circadian changes in TSH secretion are another example of brain-directed changes in the set point of feedback control, but if thyroid hormone levels are sufficiently elevated, as in hyperthyroidism, TRH cannot override the inhibition.

Hypothalamic regulation of TSH secretion is also influenced by two inhibitory factors, somatostatin and dopamine. Anti-somatostatin antibodies increase basal TSH levels and potentiate the response to stimuli that normally

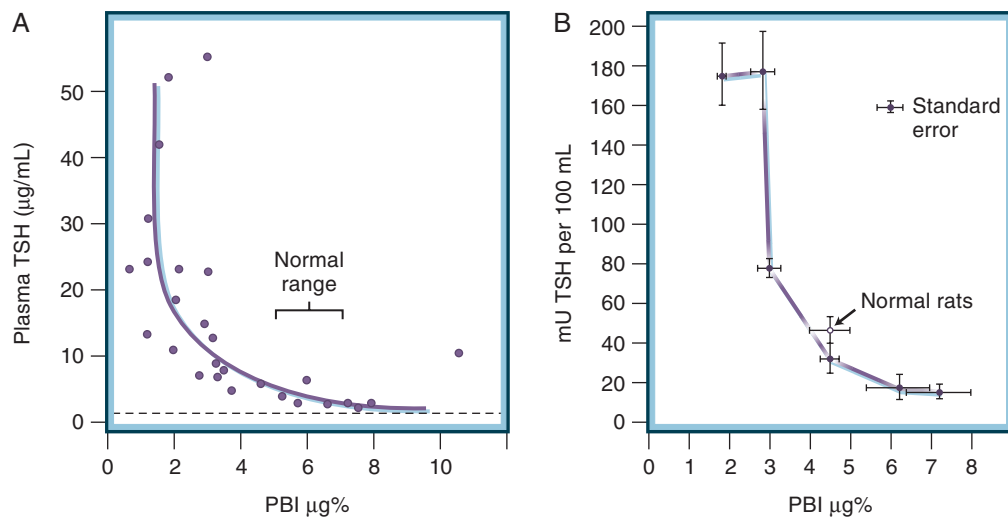

Figure 7-10 Relationship between plasma thyrotropin (TSH) levels and thyroid hormone as determined by measurements of plasma protein-bound iodine (PBI) in humans and rats. These curves illustrate that plasma TSH levels are a curvilinear function of the plasma thyroid hormone level. **A**, Human studies were carried out by giving myxedematous patients successive increments of thyroxine (T_4) at approximately 10-day intervals. Each point represents simultaneous measurements of plasma PBI and plasma TSH at various times in the six patients studied. **B**, The rat studies were performed by treating thyroidectomized animals with various doses of T_4 for 2 weeks before assay of plasma TSH and plasma PBI. These curves illustrate that the secretion of TSH is regulated over the entire range of thyroid hormone levels. At the normal set point for T_4 , small changes above and below the control level are followed by appropriate increases or decreases in plasma TSH. (**A** from Reichlin S, Utiger RD. Regulation of the pituitary thyroid axis in man: relationship of TSH concentration to concentration of free and total thyroxine in plasma. *J Clin Endocrinol Metab.* 1967;27:251-255, copyright by The Endocrine Society. **B** from Reichlin S, Martin JB, Boshans RL, et al. Measurement of TSH in plasma and pituitary of the rat by a radioimmunoassay utilizing bovine TSH: effect of thyroidectomy or thyroxine administration on plasma TSH levels. *Endocrinology.* 1970;87:1022-1031, copyright by The Endocrine Society.)

induce TSH release in the rat, such as cold exposure or TRH administration.¹¹⁴ Thyroid hormone in turn inhibits the release of somatostatin, implying coordinated, reciprocal regulation of TRH and somatostatin by thyroid hormone. GH stimulates hypothalamic somatostatin synthesis and can inhibit TSH secretion. However, the physiologic role of somatostatin in the regulation of TSH secretion in humans is uncertain.

Dopamine has modest effects on TSH secretion, and blockade of dopamine receptors (in the human) stimulates TSH secretion slightly. Changes in the metabolism of thyroid hormone also influence T_3 homeostasis within the brain. In states of thyroid hormone deficiency, brain T_3 levels are maintained by an increase in the deiodinase that converts T_4 to T_3 .⁴³

The pineal gland has been reported to inhibit thyroid function in some but not all studies. The pineal gland contains TRH, and in the frog its content changes with the season and with light and dark cycles independently of hypothalamic TRH.

Circadian Rhythm

Plasma TSH in humans is characterized by a circadian periodicity, with a maximum between 9 p.m. and 5 a.m. and a minimum between 4 p.m. and 7 p.m. (see Fig. 7-7E).¹¹⁵ Smaller ultradian TSH peaks occur every 90 to 180 minutes, probably because of bursts of TRH released from the hypothalamus, and are physiologically important in controlling the synthesis and glycosylation of TSH. Glycosylation is a determinant of TSH potency.¹¹⁶

Temperature

External cold exposure activates and high ambient temperature inhibits the pituitary-thyroid axis in animals, and analogous changes occur in humans under certain conditions.¹¹⁷ Exposure of infants to cold at the time of delivery causes an increase in blood TSH levels, possibly because of

alterations in the turnover and degradation of the thyroid hormones. Blood thyroid hormone levels are higher in winter than in summer among people living in cold climates but not in other climates. However, it is difficult to show that changes in environmental or body temperature in adults influence TSH secretion. For example, exposure to cold ambient temperature or central hypothalamic cooling does not modify TSH levels in young men. Behavioral changes, activation of the sympathetic nervous system, and shivering appear to be more important than the thyroid response for temperature regulation in adults.

The autonomic nervous system and the thyroid axis work together to maintain temperature homeostasis in mammals, and TRH plays a role in both pathways.¹¹⁷ Hypothalamic TRH release is rapidly increased (30 to 45 minutes) in rats exposed to cold. Rapid inhibition of somatostatin release in the median eminence has also been documented, and both changes appear to play important roles in the rise in plasma TSH induced by cold exposure. TRH mRNA is elevated within 1 hour of cold exposure (see Fig. 7-11C and D). The regulation of hypophyseotropic TRH release and expression by cold is largely mediated by catecholamines. Noradrenergic and adrenergic fibers, originating in the brain stem, are found in close proximity to TRH nerve endings in the median eminence, and a rapid rise in TRH release was seen after norepinephrine treatment of hypothalamic fragments containing mainly median eminence.¹¹⁷ Brain stem adrenergic and noradrenergic fibers also make synaptic contacts with TRH neurons in the PVH (see Fig. 7-9),¹¹⁸ so catecholamines are likely to be involved in the regulation of TRH gene expression by cold. TRH neurons in the PVH are densely innervated by NPY terminals,¹¹⁹ and a portion of the NPY terminals arising from the C1, C2, C3, and A1 cell groups of the brain stem and projecting to the PVH are known to be catecholaminergic. Somatostatin, dopamine, and serotonin also play a variety of roles in the regulation of TRH.

Figure 7-11 Direct effects of triiodothyronine (T_3) on thyrotropin-releasing hormone (TRH) synthesis in the rat hypothalamic paraventricular nucleus (parvicellular division) were shown by immunohistochemical detection of pre-proTRH(25-50) after implantation of a pellet of either inactive diiodotyrosine (T_2) as a control (panel **A**) or T_3 (panel **B**). The T_2 pellet had no effect on the concentration of pre-proTRH, whereas the TRH prohormone concentration was markedly reduced by T_3 (black arrow indicates the unilateral pellet implantation). These studies demonstrated that thyroid hormone regulates the hypothalamic component of the pituitary-thyroid axis as well as the pituitary thyrotrope itself. **C** and **D**, Effects on TRH messenger ribonucleic acid (mRNA) levels detected by in situ hybridization before (panel **C**) and after (panel **D**) 1-hour exposure of a rat to 4°C cold. **E** to **G**, Effects on TRH mRNA levels of starvation (panel **F**) and leptin replacement during starvation (panel **G**) compared to control levels (panel **E**). Joseph-Bravo.)

Stress

Stress is another determinant of TSH secretion.¹⁰⁹ In humans, physical stress inhibits TSH release, as indicated by the finding that low levels of T_3 and T_4 in patients with the euthyroid sick syndrome do not cause compensatory increases in TSH secretion as would occur in normal individuals.¹²⁰

A number of observations demonstrate interactions between the thyroid and adrenal axes. Physiologically, the bulk of evidence suggests that glucocorticoids in humans and rodents act to blunt the thyroid axis through actions in the CNS.¹²¹ Some actions may be direct, because the TRH gene (see Fig. 7-8) contains a glucocorticoid response element consensus half-site⁹⁸ and hypophyseotropic TRH neurons appear to contain glucocorticoid receptors.¹²² The diurnal rhythm of cortisol is opposite that of TSH (see Fig. 7-7), and acute administration of glucocorticoids can block the nocturnal rise in TSH; however, disruption of cortisol synthesis with metyrapone only modestly affects the TSH circadian rhythm.

Nevertheless, several lines of evidence identify conditions in which elevated glucocorticoids are associated with stimulation of the thyroid axis. Human depression is often associated with hypercortisolism and hyperthyroxinemia, and TRH mRNA levels are elevated by glucocorticoids in a number of cell lines as well as in cultured fetal hypothalamic TRH neurons from the rat. Therefore, although glucocorticoids probably stimulate TRH production in TRH neurons, their overall inhibitory effect on the thyroid axis results from indirect glucocorticoid negative feedback on structures such as the hippocampus. Disruption of hippocampal suppression of the hypothalamic-pituitary-adrenal (HPA) axis is proposed to be involved in the hypercortisolemia commonly seen in affective illness, and disruption of hippocampal inputs to the hypothalamus has been shown to produce a rise in hypophyseotropic TRH in the rat.¹²³

Starvation

The thyroid axis is depressed during starvation, presumably to help conserve energy by depressing metabolism (Fig. 7-11E to G). In humans, T_3 , T_4 , and TSH are reduced during starvation or fasting.¹²⁴ There are also changes in the thyroid axis in anorexia nervosa, including low blood levels of T_3 and low-normal levels of T_4 (see Chapter 11). Inappropriately low levels of TSH are found, suggesting defective activation of TRH production by low thyroid hormone levels. During starvation in rodents, reduced TRH release into hypophyseal portal blood and reduced pro-TRH mRNA levels are seen, despite lowered thyroid hormone levels.¹²⁵ Reduced basal TSH levels are also usually present.

The hypothyroidism seen in fasting or in the leptin-deficient *ob/ob* mouse can be reversed by administration of leptin,¹²⁶ and evidence suggests that the mechanism involves leptin's ability to upregulate TRH gene expression in the PVH (see Fig. 7-11E to G).¹²⁷ Leptin appears to act both directly through leptin receptors on hypophyseotropic TRH neurons and indirectly through its actions on other hypothalamic cell groups, such as arcuate nucleus POMC and NPY/agouti-related peptide (AgRP) neurons.^{128,129} TRH neurons in the PVH receive dense NPY/AgRP and POMC projections from the arcuate and express NPY and melanocortin-4 receptors (MC4R),¹³⁰ and α -MSH administration partially prevents the fasting-induced drop in thyroid hormone levels.^{128,129} Indeed, the TRH promoter contains a signal transducer and activator of transcription (STAT) response element and a CRE that have been

demonstrated to mediate induction of TRH gene expression by leptin and α -MSH, respectively, in a heterologous cell system (see Fig. 7-8).¹³⁰ The regulation of TRH by metabolic state is likely to be under redundant control, because leptin-deficient children, unlike rodents, are euthyroid,¹³¹ whereas both rodents and humans with MC4R deficiency are euthyroid.¹³²

Infection and Inflammation

The molecular basis of infection- or inflammation-induced TSH suppression is partially established. TSH secretion is inhibited by sterile abscesses; by the injection of interleukin-1 β (IL-1 β), an endogenous pyrogen and secretory peptide of activated lymphocytes¹³³; or by tumor necrosis factor- α (TNF- α). IL-1 β stimulates the secretion of somatostatin.¹³⁴ TNF- α inhibits TSH secretion directly and induces functional changes in the rat characteristic of the "sick euthyroid" state.¹³⁵ It is likely that the TSH inhibition in animal models of the sick euthyroid syndrome results from cytokine-induced changes in hypothalamic and pituitary function.¹³⁶ IL-6, IL-1, and TNF- α contribute to the suppression of TSH in the sick euthyroid syndrome.¹³⁷

Corticotropin-Releasing Hormone

Chemistry and Evolution

The HPA axis is the humoral component of an integrated neural and endocrine system that functions to respond to internal and external challenges to homeostasis (stressors). The system comprises the neuronal pathways linked to release of catecholamines from the adrenal medulla (fight-or-flight response) and the hypothalamic-pituitary control of ACTH release through control of glucocorticoid production by the adrenal cortex. Pituitary ACTH release is stimulated primarily by CRH and to a lesser extent by AVP (see Chapter 8). The hypophyseotropic CRH neurons are located in the parvocellular division of the PVH and project to the median eminence (see Figs. 7-3 and 7-4).

In a broader context, the CRH system in the CNS is also vitally important in the behavioral response to stress. This complex system includes not only nonhypophyseotropic CRH neurons but also three CRH-like peptides (urocortin, urocortin 2 or stresscopin-related peptide, and urocortin 3 or stresscopin), at least two cognate receptors (CRH-R1 and CRH-R2), and a high-affinity CRH-binding protein, each with distinct and complex distributions in the CNS.

The Schally and Guillemin laboratories demonstrated in 1955 that extracts from the hypothalamus stimulated ACTH release from the pituitary. The primary active principle, CRH, was purified and characterized from sheep in 1981 by Vale and colleagues.^{137a} Human CRH is an amidated 41-amino-acid peptide that is cleaved from the C-terminus of a 196-amino-acid pre-prohormone precursor by PC1 and PC2 (Fig. 7-12).¹³⁸ CRH is highly conserved phylogenetically; the human peptide is identical in sequence to the mouse and rat peptides but differs at seven residues from the ovine sequence. Mammalian CRH, the three urocortin peptides, fish urotensin, anuran sauvagine, and the insect diuretic peptides are members of an ancient family of peptides that evolved from an ancestral precursor early in the evolution of metazoans, approximately 500 million years ago.¹³⁹ Comparison of peptide sequences in vertebrates suggests a grouping of the peptides into two subfamilies, CRH-urotensin-urocortin-sauvagine and urocortin 2-urocortin 3 (Fig. 7-13).¹⁴⁰ Urocortin and sauvagine appear to represent tetrapod orthologues of fish urotensin. Sauvagine, isolated originally from *Phyllomedusa sauvagei*, is an osmoregulatory

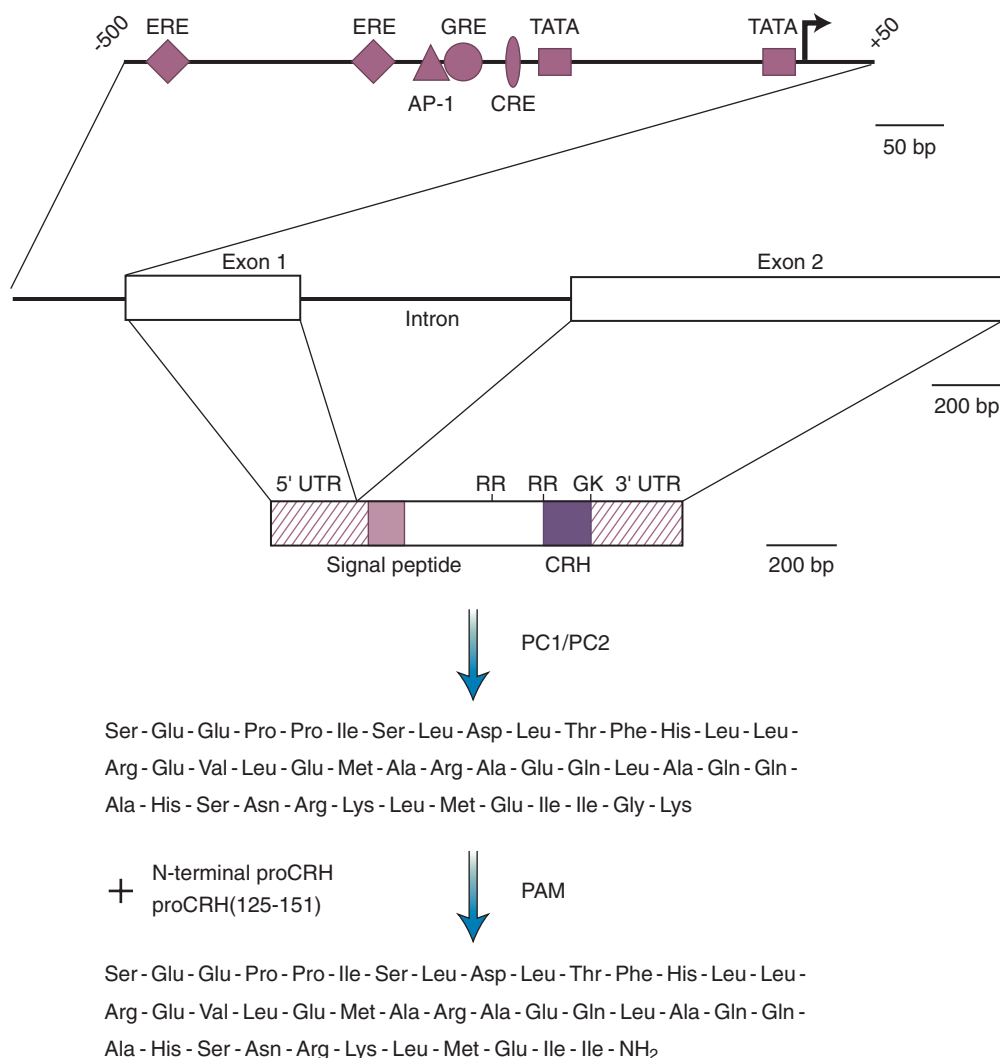

Figure 7-12 Structure of the human corticotropin-releasing hormone (CRH) gene, complementary DNA, and peptide. The sequence encoding CRH occurs at the carboxy-terminus of the prohormone. peptide produced in the skin of certain frogs; urotensin is an osmoregulatory peptide produced in the caudal neurosecretory system of the fish. Whereas isolation of CRH required 250,000 ovine hypothalami, the "virtual" cloning of urocortin 2 and 3 was accomplished by computer search of the human genome database.¹⁴⁰

The CRH peptides signal by binding to CRH-R1^{141,142} and CRH-R2¹⁴³ receptors that couple to the stimulatory G protein (G_s) and activate adenylyl cyclase. Two splice

variants of the CRH-R2 receptor that differ in their extracellular N-terminal domain, termed CRH-R2 α and CRH-R2 β , have been found in both rodents and humans,¹⁴⁴ and a third N-terminal splice variant, CRH-R2 γ , has been reported in the human.¹⁴⁵

CRH, urotensin, and sauvagine are potent agonists of CRH-R1; urocortin is a potent agonist of both receptors; and urocortins 2 and 3 are specific agonists of CRH-R2. CRH-activation of the HPA axis is mediated exclusively

through CRH-R1 expressed in the corticotroph. CRH neurons projecting to the median eminence are found mostly in the PVH, although most hypothalamic nuclei contain some of these neurons (Fig. 7-14A). Some CRH fibers in the PVH also project to the brain stem, and non-hypophyseotropic CRH neurons are abundant elsewhere, primarily in limbic structures involved in processing sensory information and in regulating the autonomic nervous system. Sites include the prefrontal, insular, and cingulate cortices; amygdala; substantia nigra; periaqueductal gray; locus ceruleus; nucleus of the solitary tract; and parabrachial nucleus. In the periphery, CRH is found in human placenta, where it is upregulated 6- to 40-fold during the third trimester, in lymphocytes, in autonomic nerves, and in the gastrointestinal tract. Urocortin is expressed at highest levels in the non-preganglionic Edinger-Westphal nucleus, the lateral superior olive, and the SON nucleus of the rodent brain, with additional sites including the substantia nigra, ventral tegmental area, and dorsal raphe (see Fig. 7-14B). In the human, urocortin is widely distributed, with highest levels in the frontal cortex, temporal cortex, and hypothalamus,¹⁴⁶ and has also been reported in the non-preganglionic Edinger-Westphal nucleus.²² In the periphery, urocortin is seen in placenta, mucosal inflammatory cells of the gastrointestinal tract, lymphocytes, and cardiomyocytes. Urocortin 2 is expressed in hypothalamic neuroendocrine and stress-related cell groups in the mouse, including the locus ceruleus, whereas urocortin 3 is expressed in hypothalamus and amygdala, and particularly in pancreatic islet beta cells.^{147,148}

In addition to its expression in pituitary corticotrophs, CRH-R1 is found in the neocortex and cerebellar cortex, subcortical limbic structures, and amygdala, with little to no expression in the hypothalamus (see Fig. 7-14C). CRH-R1 is also found in a variety of peripheral sites in humans, including ovary, endometrium, and skin. CRH-R2 α is found mainly in the brain in rodents, with high levels of expression in the VMH and lateral septum (see Fig. 7-14C)¹⁴⁹; CRH-R2 β is found centrally in cerebral arterioles and peripherally in gastrointestinal tract, heart, and muscle.^{143,150} In humans, CRH-R2 α is expressed in brain and periphery, whereas the β and γ subtypes are primarily central.^{144,145} Little CRH-R2 message is seen in pituitary. Although CRH-R1 appears to be exclusively involved in regulation of pituitary ACTH synthesis and release, both receptors are expressed in the rodent adrenal cortex. Data suggest that this intra-adrenal CRH-ACTH system may be involved in fine-tuning of adrenocortical corticosterone release.

The CRH system is also regulated in both brain and periphery by a 37-kd high-affinity CRH-binding protein.¹⁵¹⁻¹⁵³ This factor was initially postulated from the observation that CRH levels rise dramatically during the second and third trimesters of pregnancy without activating the pituitary-adrenal axis. Among hypophyseotropic factors, CRH is the only one for which a specific binding protein (in addition to the receptor) exists in tissue or blood. The placenta is the principal source of pregnancy-related CRH-binding protein. Human and rat CRH-binding proteins are homologous (85% amino acid identity), but in the rat the protein is expressed only in brain. The binding protein is species specific; bovine CRH, which is almost identical in sequence to rat and human CRH, has a lower affinity of binding to the human binding protein.

The functional significance of the CRH-binding protein is not fully understood. CRH-binding protein does not bind to the CRH receptor but does inhibit CRH action. For this reason, CRH-binding protein probably acts to

modulate CRH actions at the cellular level. Corticotroph cells in the anterior pituitary have membrane CRH receptors and intracellular CRH-binding protein; conceivably, the binding protein acts to sequester or terminate the action of membrane-bound CRH. CRH-binding protein is present in many regions of the CNS, including cells that synthesize CRH and cells that receive innervation from CRH-containing neurons. The anatomic distribution of the protein, the variability of its location in relation to the presence of CRH, and its relative sparseness in the CRH tuberohypophyseal neuronal system suggest a control system that is as yet poorly understood. Transgenic mouse models with both overexpression and gene deletion of the CRH-binding protein have been produced with little effect on basal or stress activation of the HPA axis (reviewed by Bale and Vale¹⁵⁴).

Structure-activity relationship studies have demonstrated that both C-terminal amidation and an α -helical secondary structure are important for biologic activity of CRH. The first CRH antagonist described was termed α -helical CRH(9-41).¹⁵⁵ A second, more potent antagonist, termed *astressin*, has the structure cyclo(30-33)(D-Phe¹², Nle, ¹² Glu, ¹² Lys¹²)hCRH(12-41).¹⁵⁶ Both peptides are somewhat nonspecific, antagonizing both CRH-R1 and CRH-R2. Because of the anxiogenic activity of CRH and urocortin, a number of pharmaceutical companies have developed small-molecule CRH antagonists; several of these are currently in clinical trials for anxiety and depression (see later discussion). Thus far, this structurally diverse group of small-molecule compounds, including antalarmin, CP-154,526, and NBI27914, are potent antagonists of CRH-R1, with little activity at CRH-R2. The efficacy of these compounds across the entire behavioral, neuroendocrine, and autonomic repertoire of response to stress has been demonstrated in a number of laboratory animal studies. For example, oral administration of antalarmin in a social stress model in the primate (introduction of strange males) reduced behavioral measures of anxiety such as lack of exploratory behavior, decreased plasma ACTH and cortisol, and reduced plasma epinephrine and norepinephrine.¹⁵⁷ Other preclinical studies in rhesus monkeys have compared the pharmacologic profiles of *astressin* B and antalarmin.¹⁵⁸ A peptide antagonist with 100-fold selectivity for the CRH-R2 β receptor, (D-Phe¹¹, His¹²)sauvagine 11-40 or anti-sauvagine-30, has also been described.¹⁵⁹

Effects on the Pituitary and Mechanism of Action

Administration of CRH to humans causes prompt release of ACTH into the blood, followed by secretion of cortisol (Fig. 7-15) and other adrenal steroids including aldosterone. Most studies have used ovine CRH, which is more potent and longer acting than human CRH, but human and porcine CRHs appear to have equal diagnostic value. The effect of CRH is specific to ACTH release and is inhibited by glucocorticoids.

As mentioned earlier, CRH acts on the pituitary corticotroph primarily by binding to CRH-R1 and activating adenyl cyclase. The concentration of cAMP in the tissue is increased in parallel with the biologic effects and is reduced by glucocorticoids. The rate of transcription of the mRNA that encodes the ACTH prohormone POMC is also enhanced by CRH.

Extrapituitary Functions

CRH and the urocortin peptides have a wide range of biologic activities in addition to the hypophyseotropic role of CRH in regulating ACTH synthesis and release. Centrally, these peptides have behavioral activities in anxiety, mood,

arousal, locomotion, reward, and feeding^{160,161} and increase sympathetic activation. Many of the nonhypophyseotropic behavioral and autonomic functions of these peptides can be viewed as complementary to activation of the HPA axis in the maintenance of homeostasis under exposure to stress. In the periphery, activities have been reported in immunity, cardiac function, gastrointestinal function, and reproduction.¹⁶²

The CRH and urocortin peptides have a repertoire of behavioral and autonomic actions after central administration that suggests a role for these pathways in mediating the behavioral-autonomic components of the stress response. Hyperactivity of the HPA axis is a common neuroendocrine finding in affective disorders (see Fig. 7-15).^{160,163} Normalization of HPA regulation is highly predictive of successful treatment. Defective dexamethasone

suppression of CRH release, implying defective corticosteroid receptor signaling, is seen not only in depressed patients but also in healthy subjects with a family history of depression.¹⁶⁴ Depressed patients also show elevated levels of CRH in the CSF.¹⁶⁵ Extensive behavioral testing in a variety of mutant mouse models with genetically altered expression of the CRH ligands or receptors has generally supported the hypothesis that activation of central CRH pathways is a critical neurobiologic substrate of anxiety and depressive states.^{154,161}

Central administration of CRH or urocortin activates neuronal cell groups involved in cardiovascular control and increases blood pressure, heart rate, and cardiac output.¹⁶⁶ However, urocortin is expressed in cardiac myocytes, and intravenous administration of CRH or urocortin decreases blood pressure and increases heart rate in most species, including humans.¹⁶⁶ This hypotensive effect is probably mediated peripherally, because ganglion blockade did not disrupt the hypotensive effects of intravenous urocortin. Furthermore, high levels of CRH-R2 β have been seen in the cardiac atria and ventricles,^{143,150} and knockout of the CRH-R2 gene in the mouse eliminated the hypotensive effects of intravenous urocortin administration.^{167,168}

Cytokines have an important role in extinguishing inflammatory responses through activation of CRH and AVP neurons in the PVH and subsequent elevation of anti-inflammatory glucocorticoids. Interestingly, CRH is generally proinflammatory in the periphery, where it is found in sympathetic efferents, in sensory afferent nerves, in leukocytes, and in macrophages in some species.^{162,169} CRH also functions as a paracrine factor in the endometrium, where it may play a role in decidualization and implantation and may act as a uterine vasodilator.¹⁶²

The relative contributions of each of the CRH-urocortin peptides and receptors to the various biologic functions reported has been the topic of considerable analysis, given the receptor-specific antagonists already described and the availability of CRH, CRH-R1, and CRH-R2 knockout mice for study (reviewed by Bale and Vale¹⁵⁴ and Keck and colleagues¹⁶¹). Examination of three potent stressors—restraint, ether, and fasting—demonstrated that other ACTH secretagogues, such as AVP, oxytocin, and catecholamines, could not replace CRH in its role in mounting the stress response. In contrast, augmentation of glucocorticoid secretion by a stressor after prolonged stress was not defective in CRH knockout mice, implicating CRH-independent mechanisms.

Although CRH is a potent anxiogenic peptide, CRH knockout mice exhibit normal anxiety behaviors in, for example, conditioned fear paradigms. The nonpeptide CRH-R1-specific antagonist CP-154,526 was anxiolytic in a shock-induced freezing paradigm in both wild-type and CRH knockout mice, suggesting that the anxiogenic activity is a CRH-like peptide acting at the CRH-R1 receptor (see review¹⁵⁴).

CRH and urocortin peptides also have potent anorexic activity, implicating the CRH system in stress-induced inhibition of feeding. However, in CRH knockout mice, stress-induced inhibition of feeding and suppression of the proestrous LH surge by restraint remained intact. Both CRH-R1 and CRH-R2 knockout strains had normal weight and feeding behaviors but were distinctly different from wild-type mice in the anorexic response to centrally administered urocortin or CRH. The CRH-R1-deficient mice lacked the acute anorexic response (0 to 1.5 hours) to urocortin seen in wild-type mice. Wild-type and CRH-R1 knockout mice exhibited comparable reductions in feeding 3 to 11 hours after administration. In contrast,

the late phase of urocortin responsiveness appeared to depend on the presence of CRH-R2. Therefore, signaling through CRH-R1 and CRH-R2 plays a complex role in the acute effects of stress on feeding behavior (see review¹⁵⁴).

Additional gene knockout studies have suggested that urocortin 2 plays a physiologic role in female mice to dampen basal daily rhythms of the HPA axis and reduce behavioral coping mechanisms in response to chronic stress.¹⁴⁷ Urocortin 3 may have a primary action to augment insulin secretion in response to the metabolic stress of excessive calorie intake.¹⁴⁸

Clinical Applications

No approved therapeutic application of CRH or CRH-like peptides exists, although the peptide has been demonstrated to have a number of activities in human and primate studies. Intravenous administration was found to stimulate energy expenditure, but CRH is an unlikely pharmaceutical target for inducing weight loss. The development of small-molecule, orally available, CRH-R1 antagonists has produced considerable interest in their potential for treatment of anxiety and depression.^{165,170} In particular, the compound R121919 was studied in phase 1 and 2a clinical trials before its discontinuance. These studies of 20 patients demonstrated significant reductions in anxiety and depression scores, using ratings determined by patient or clinician, and also demonstrated the compound's safety and favorable side-effect profile, including a lack of effect on endocrine function or body weight gain.¹⁷¹

Feedback Control

The administration of glucocorticoids inhibits ACTH secretion, and, conversely, removal of the adrenals (or administration of drugs that impair secretion of glucocorticoids) leads to increased ACTH release. The set point of pituitary feedback is determined by the hypothalamus acting through hypothalamic releasing hormones CRH and AVP (see Chapter 8).¹⁷²⁻¹⁷⁵ Glucocorticoids act on both the pituitary corticotrophs and the hypothalamic neurons that secrete CRH and AVP. These regulatory actions are analogous to the control of the pituitary-thyroid axis. However, whereas TSH becomes completely unresponsive to TRH when thyroid hormone levels are sufficiently high, severe neurogenic stress and large amounts of CRH can break through the feedback inhibition due to glucocorticoids. A still higher level of feedback control is exerted by glucocorticoid-responsive neurons in the hippocampus that project to the hypothalamus; these neurons affect the activity of CRH hypophyseotropic neurons and determine the set point of pituitary responsiveness to glucocorticoids.¹⁷⁵ A comprehensive review of glucocorticoid effects on CRH and AVP and regulation of the HPA axis emphasized the complexity of this control beyond that of a simple closed-loop feedback.¹⁷⁶

Glucocorticoids are lipid soluble and freely enter the brain through the blood-brain barrier.¹⁷⁴ In brain and pituitary, they can bind to two receptors. Type 1 (encoded by *NR3C2*) is called the *mineralocorticoid receptor* because it binds aldosterone and glucocorticoids with high affinity). Type 2 (*NR3C1*), the glucocorticoid receptor, has low affinity for mineralocorticoids.¹⁷³⁻¹⁷⁵ Classic glucocorticoid action involves binding of the steroid-receptor complex to regulator sequences in the genome. MR are saturated by basal levels of glucocorticoids, whereas GR are not saturated under basal conditions but approach saturation during peak phases of the circadian rhythm and during stress. These differences and differences in regional

distribution within the brain suggest that MR determine basal activity of the hypothalamic-pituitary axis and GR mediate stress responses.

In the pituitary, glucocorticoids inhibit secretion of ACTH and the synthesis of POMC mRNA; in the hypothalamus, they inhibit the secretion of CRH and AVP and the synthesis of their respective mRNAs, although with distinct temporal patterns.¹⁷⁴⁻¹⁷⁶ Neuron membrane excitability and ion transport properties are suppressed by changes in glucocorticoid-directed synthesis of intracellular protein. Glucocorticoids can exert additional rapid signaling events in neurons, including an endocannabinoid-mediated suppression of synaptic excitation.¹⁷⁷ These rapid events involve membrane-associated complexes and are independent of changes in gene transcription or acute protein translation, but the exact mechanisms and nature of the receptors are still under investigation.¹⁷⁸

Glucocorticoids block stress-induced ACTH release. The latency of the inhibitory effect is so short (<30 minutes) that it is likely that gene regulation is not the sole basis of the response.¹⁷⁸ Long-term suppression (>1 hour) clearly acts through genomic mechanisms.

Glucocorticoid receptors are also found outside the hypothalamus, in the septum and in the amygdala,^{174,175} and these structures are involved in the psychobehavioral changes of hypercortisolism and hypocortisolism. In all of these areas, apart from the CRH neurons of the PVH, glucocorticoids have either a stimulatory or a neutral effect on CRH gene expression.¹⁷⁶ Hippocampal neurons are reduced in number by prolonged elevation of glucocorticoids during chronic stress.¹⁷⁵

Neural Control

Significant physiologic or psychological stressors evoke an adaptive response that commonly includes activation of both the HPA axis and the sympathoadrenal axis. The end products of these pathways then help to mobilize resources to cope with the physiologic demands in emergency situations, acutely through the fight-or-flight response and over the long term through systemic effects of glucocorticoids on functions such as gluconeogenesis and energy mobilization (see Chapter 15). The HPA axis also has unique stress-specific homeostatic roles, the best example being the role of glucocorticoids in downregulating immune responses after infection and other events that stimulate cytokine production by the immune system.

The PVH is the primary hypothalamic nucleus responsible for providing the integrated whole-animal response to stress.^{176,179,180} This nucleus contains within it three major types of effector neurons that are spatially distinct from one another: (1) magnicellular oxytocin and AVP neurons that project to the posterior pituitary and participate in the regulation of blood pressure, fluid homeostasis, lactation, and parturition; (2) neurons projecting to the brain stem and spinal cord that regulate a variety of autonomic responses, including sympathoadrenal activation; and (3) parvicellular CRH neurons that project to the median eminence and regulate ACTH synthesis and release. Many CRH neurons coexpress AVP, which acts as an auxiliary ACTH secretagogue, synergistic with CRH. AVP is regulated quite differently, in parvicellular versus magnicellular neurons, but also somewhat differently from CRH by stressors in parvicellular cells that express both peptides.¹⁷⁶ Different stressors result in different patterns of activation of the three major visceromotor cell groups within the PVH, as measured by the general neuronal activation marker Fos (Fig. 7-16). For example, salt loading

downregulates CRH mRNA in parvicellular CRH cells, upregulates CRH in a small number of magnicellular CRH cells, but activates only magnicellular cells. Hemorrhage activates every division of the PVH, whereas cytokine administration primarily activates parvicellular CRH cells, with some minor activation of magnicellular and autonomic divisions.

The synthesis and release of AVP, which regulates renal water absorption and vascular smooth muscle, are controlled mainly by the volume and tonicity of the blood. This information is relayed to the magnicellular AVP cell

through the nucleus of the solitary tract and A1 noradrenergic cell group of the ventrolateral medulla and through projections from a triad of CVOs lining the third ventricle: the SFO, the medial preoptic nucleus (MePO), and the OVLT. Oxytocin is primarily involved in reproductive functions, such as parturition, lactation, and milk ejection, although it is cosecreted with AVP in response to osmotic and volume challenges, and oxytocin cells receive direct projections from the nucleus of the solitary tract as well as from the SFO, MePO, and OVLT. In contrast to the neurosecretory neurons functionally defined by the three

peptides CRH, oxytocin, and AVP, PVH neurons projecting to brain stem and spinal cord include neurons expressing each of these peptides.

In the rodent, a wide variety of stressors have been determined to activate parvicellular CRH neurons, including cytokine injection, salt loading, hemorrhage, adrenalectomy, restraint, foot shock, hypoglycemia, fasting, and ether exposure. In contrast to the simplicity of inputs to magnicellular cells (Fig. 7-17A), it is not surprising that parvicellular CRH neurons receive a diverse and complex assortment of inputs (Fig. 7-18; see Fig. 7-17B). These inputs are divided into three major categories: brain stem, limbic forebrain, and hypothalamus. Because the PVH is not known to receive any direct projections from the cerebral cortex or thalamus, stressors relating to emotional or cognitive processing must involve indirect relay to the PVH.

Visceral sensory input to the PVH involves primarily two pathways. The nucleus of the solitary tract, the primary recipient of sensory information from the thoracic and abdominal viscera, sends dense catecholaminergic projections to the PVH, both directly and through relays in the ventrolateral medulla. These brain stem projections account for about half of the NPY fibers present in the PVH. A second major input responsible for transducing signals from bloodborne substances derives from three CVOs adjacent to the third ventricle: the SFO, the OVLT, and the

MePO. These pathways account for activation of CRH neurons by what are referred to as *systemic* or *physiologic stressors*.¹⁸⁰

By contrast, what are termed *neurogenic*, *emotional*, or *psychological stressors* involve, in addition, nociceptive or somatosensory pathways as well as cognitive and affective brain centers. Using elevation of Fos as an indicator of neuronal activation, detailed studies have compared PVH-projecting neurons activated by IL-1 treatment (systemic stressor) versus foot shock (neurogenic stressor).¹⁸⁰ Only catecholaminergic solitary tract nucleus and ventrolateral medulla neurons were activated by moderate doses of IL-1. In contrast, foot shock activated neurons of the solitary tract nucleus and ventrolateral medulla but also cell groups in the limbic forebrain and hypothalamus. Notably, pharmacologic or mechanical disruption of the ascending catecholaminergic fibers blocked IL-1-mediated activation but not foot shock-mediated activation of the HPA axis. Data suggest that pathways activated by other neurogenic and systemic stressors may overlap significantly with those activated by foot shock and IL-1 treatment, respectively.^{179,180}

Except for the catecholaminergic neurons of the nucleus of the solitary tract and ventrolateral medulla, parts of the bed nucleus of the stria terminalis, and the dorsomedial nucleus of the hypothalamus, many inputs to the PVH, such as those deriving from the prefrontal cortex and

lateral septum, are thought to act indirectly through local hypothalamic glutamatergic¹⁸¹ and GABAergic neurons¹⁸² with direct synapses to the CRH neurons. The bed nucleus of the stria terminalis is the only limbic region with prominent direct projections to the PVH. With substantial projections from the amygdala, hippocampus, and septal nuclei, this region may serve as a key integrative center for transmission of limbic information to the PVH.¹⁷⁹

Inflammation and Cytokines

Stimulation of the immune system by foreign pathogens leads to a stereotyped set of responses orchestrated by the CNS. This constellation of stereotyped responses result from the complex interaction of the immune system and the CNS. They are mediated in large part by the hypothalamus and include coordinated autonomic, endocrine, and

behavioral components with adaptive consequences to restore homeostasis. It is now clear that cytokines produced by peripheral circulating cells of the immune system and central glial cells mediate the CNS responses. Early evidence supporting this hypothesis was provided by the seminal observations that cytokines such as IL-1 β can activate the HPA axis.¹⁸³⁻¹⁸⁵ Neuroimmunology, the discipline arising from the study of reciprocal interactions between the neuroendocrine and immune systems, and particularly the role of cytokines in mediating cachexia, is covered fully in Chapter 35.

This section focuses on cytokines and activation of the HPA axis. The resultant glucocorticoid secretion acts as a classic negative feedback to the immune system to dampen its response. In general, glucocorticoids inhibit most limbs of the immune response, including lymphocyte proliferation, production of immunoglobulins, cytokines, and cytotoxicity. These inhibitory reactions form the basis of the anti-inflammatory actions of glucocorticoids.

Glucocorticoid feedback on immune responses is regulatory and beneficial because loss of this function makes animals with adrenal insufficiency vulnerable to inflammation. However, this feedback response can have pathophysiologic consequences, because chronic activation of the HPA axis can certainly be detrimental.^{186,187} Indeed, it is well established that chronic stress can lead to immunosuppression. The fact that products of inflammation such as IL-1 β can activate the HPA axis suggests the operation of a negative feedback control loop to regulate the intensity of inflammation. The role of the hypothalamus in regulating pituitary-adrenal function is an excellent example of neuroimmunomodulation. Proposed models to explain how immune system signals might act on the CNS to modulate homeostatic circuits through integration of vagal input, peripheral cytokine interactions with receptors in the CVOs and cerebral blood vessels, and local production of cytokines within the CNS are explored in Chapter 35.

Other Factors Influencing Secretion of Corticotropin

Circadian Rhythms. Levels of ACTH and cortisol peak in the early morning, fall during the day to reach a nadir at about midnight, and begin to rise between 1 a.m. and 4 a.m. (see Fig. 7-7). Within the circadian cycle, approximately 15 to 18 pulses of ACTH can be discerned, their heights varying with the time of day.¹⁸⁸ The set point of feedback control by glucocorticoids also varies in a circadian pattern. Pituitary-adrenal rhythms are entrained to the light-dark cycle and can be changed over several days by exposure to an altered light schedule. It has long been assumed that the rhythm of ACTH secretion is driven by CRH rhythms, and CRH knockout mice were found to exhibit no circadian rhythm in corticosterone production. Remarkably, however, a diurnal rhythm in corticosterone was restored by a constant infusion of CRH to CRH knockout mice,¹⁸⁹ suggesting that CRH is necessary to permit pituitary or adrenal responsiveness to another diurnal rhythm generator.

Corticotropin Release-Inhibiting Factor. Disconnection of the pituitary from the hypothalamus in several species leads to increased basal levels of ACTH, and certain responses to physical stress (in contrast to psychological stress) are retained in such animals. These observations led several investigators to postulate the existence of an ACTH inhibitory factor, analogous to dopamine in the control of PRL secretion and to somatostatin in the control of GH

secretion. Candidate hypothalamic peptides to inhibit ACTH release at the level of the pituitary include somatostatin, atrial natriuretic peptide, activins and inhibins, and peptide sequence 178 to 199 of the TRH prohormone.¹⁹⁰ There is not yet a consensus on the existence or identity of a physiologically relevant ACTH release-inhibiting factor.

Growth Hormone-Releasing Hormone

Chemistry and Evolution

Evidence for neural control of GH secretion came from studies of its regulation in animals with lesions of the hypothalamus¹⁹¹ and from the demonstration that hypothalamic extracts stimulate the release of GH from the pituitary. After it was shown that GH is released episodically, follows a circadian rhythm, responds rapidly to stress, and is blocked by pituitary stalk section, the concept of neural control of GH secretion became a certainty. However, it was only with the discovery of the paraneoplastic syndrome of ectopic GHRH secretion by pancreatic adenomas in humans that sufficient starting material became available for peptide sequencing and subsequent cloning of a complementary deoxyribonucleic acid (cDNA).¹⁹²⁻¹⁹⁵

Two principal molecular forms of GHRH occur in the human hypothalamus: GHRH(1-44)-NH₂ and GHRH(1-40) (Fig. 7-19).¹⁹⁶ As with other neuropeptides, the various forms of GHRH arise from post-translational modification of a larger prohormone.^{192,197} The N-terminal tyrosine of GHRH (or histidine in rodent GHRH) is essential for bioactivity, but a C-terminal NH₂ group is not. Fragments as short as (1-29)-NH₂ are active, but GHRH(1-27)-NH₂ is inactive. A circulating type IV dipeptidylpeptidase potentially inactivates GHRH to its principal and more stable metabolite, GHRH(3-44)-NH₂,¹⁹⁸ which accounts for most of the immunoreactive peptide detected in plasma. As in the case of GnRH, there are GHRH differences among species; the peptides from seven species range in sequence homology with the human peptide from 93% in the pig to 67% in the rat.¹⁹⁶ The C-terminal end of GHRH exhibits the most sequence diversity among species, consistent with the exon arrangement of the gene and dispensability of these residues for GHRH receptor binding.

Despite its importance for elucidation of GHRH structure, ectopic secretion of the peptide is a rare cause of acromegaly. Fewer than 1% of acromegalic patients have elevated plasma levels of GHRH (see Chapter 9).¹⁹⁹ Approximately 20% of pancreatic adenomas and 5% of carcinoid tumors contain immunoreactive GHRH, but most are clinically silent.²⁰⁰

In addition to expression in the hypothalamus, the GHRH gene is expressed eutopically in human ovary, uterus, and placenta,²⁰¹ although its function in these tissues is not known. Studies in rat placenta indicate that an alternative transcriptional start site 10 kilobases upstream from the hypothalamic promoter is used, together with an alternatively spliced exon 1a.²⁰²

Growth Hormone-Releasing Hormone Receptor

The GHRH receptor is a member of a subfamily of G protein-coupled receptors that includes receptors for VIP, pituitary adenyl cyclase-activating peptide, secretin, glucagon, glucagon-like peptide 1, calcitonin, parathyroid hormone or parathyroid hormone-related peptide, and gastric inhibitory polypeptide.^{203,204} GHRH elevates intracellular cAMP by its receptor coupling to a stimulatory G protein (G_s), which activates adenylyl cyclase, increases

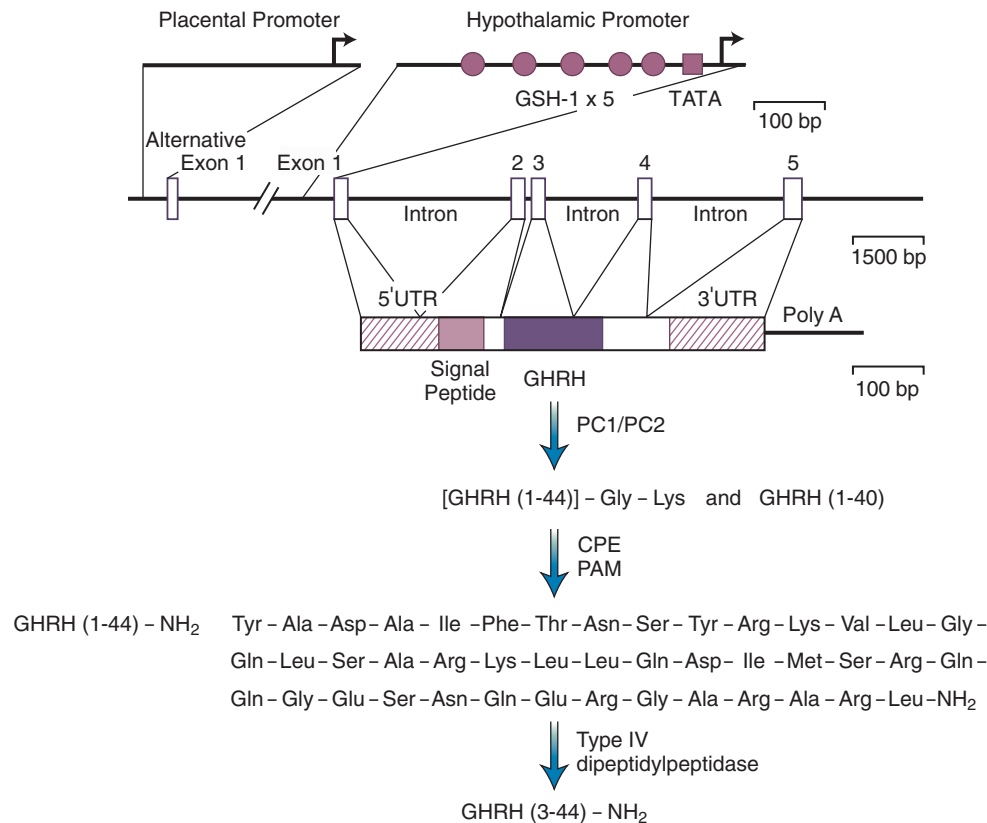

Figure 7-19 Diagram illustrating the genomic organization, messenger RNA structure, and post-translational processing of the human growth hormone-releasing hormone (GHRH) prohormone. The five GSH-I homeodomain transcription factor binding sites in the proximal promoter have been characterized in the rat gene. All of the amino acid residues required for bioactive GHRH peptides are encoded by exon 3. An amino-terminal exopeptidase that cleaves the Tyr-Ala dipeptide is primarily responsible for inactivation of GHRH peptides in extracellular compartments. Expression of the rat growth hormone-releasing hormone gene in placenta is directed by an alternative promoter. *Proc Natl Acad Sci U S A*. 1991;88:8749-8753; and Mutsuga N, Iwasaki Y, Morishita M, et al. Homeobox protein Gsh-1-dependent regulation of the rat GHRH gene promoter. *Mol Endocrinol*. 2001;15:2149-2156.)

intracellular free Ca^{2+} , releases preformed GH, and stimulates GH mRNA transcription and new GH synthesis (see Chapter 8).²⁰⁵ GHRH also increases pituitary phosphatidylinositol turnover. Nonsense mutations in the human GHRH receptor gene are the cause of rare familial forms of GH deficiency^{206,207} and indicate that no other gene product can fully compensate for the specific receptor in pituitary.

Effects on the Pituitary and Mechanism of Action

Intravenous administration of GHRH to individuals with normal pituitaries causes a prompt, dose-related increase in serum GH that peaks after 15 and 45 minutes, followed by a return to basal levels by 90 to 120 minutes (Fig. 7-20).²⁰⁸ A maximally stimulating dose of GHRH is approximately 1 $\mu\text{g}/\text{kg}$, but the response differs considerably among individuals and within the same individual tested on different occasions, presumably because of endogenous cosecretagogue and somatostatin tone that exists at the time of GHRH injection. Repeated bolus administration or sustained infusions of GHRH over several hours cause a modest decrease in the subsequent GH secretory response to acute GHRH administration. However, unlike the marked desensitization of the GnRH receptor and decline in

circulating gonadotropins that occur in response to continuous GnRH exposure, pulsatile GH secretion and insulin-like growth factor type 1 (IGF1) production are maintained by constant GHRH in the human.²⁰⁸ This response suggests the involvement of additional factors that mediate the intrinsic diurnal rhythm of GH, and these factors are addressed in the following sections.

The pituitary effects of a single injection of GHRH are almost completely specific for GH secretion, and there is minimal evidence for any interaction between GHRH and the other classic hypophyseotropic releasing hormones.²⁰⁸ GHRH has no effect on gut peptide hormone secretion. The GH secretory response to GHRH is enhanced by estrogen administration, glucocorticoids, and starvation. Major factors known to blunt the response to GHRH in humans are somatostatin, obesity, and advancing age.

In addition to its role as a GH secretagogue, GHRH is a physiologically relevant growth factor for somatotrophs. Transgenic mice expressing a GHRH cDNA coupled to a suitable promoter developed diffuse somatotroph hyperplasia and eventually pituitary macroadenomas.^{209,210} The intracellular signal transduction pathways mediating the mitogenic action of GHRH are not known with certainty but probably involve an elevation of adenylyl cyclase

Figure 7-20 Response of normal men to growth hormone–releasing hormone GHRH(1-29) (1 μg/kg), ghrelin (1 μg/kg), or the combination of GHRH(1-29) and ghrelin administered by intravenous injection. Note the prompt release of growth hormone (GH), followed by a rather prolonged fall in hormone level in response to the administered secretagogues. Ghrelin alone was more efficacious than GHRH(1-29), and there was an additive effect when the two peptides were administered simultaneously. (From Arvat E, Macario M, Di Vito L, et al. Endocrine activities of ghrelin, a natural growth hormone secretagogue (GHS), in humans: comparison and interactions with hexarelin, a nonnatural peptidyl GHS, and GH-releasing hormone. *J Clin Endocrinol Metab*. 2001;86:1169-1174.)

activity. Several lines of evidence support this conclusion, including the association of activating mutations of the G_{α} polypeptide in many human somatotroph adenomas.²¹¹

Extrapituitary Functions

GHRH has few known extrapituitary functions. The most important may be its activity as a sleep regulator. The administration of nocturnal GHRH boluses to normal men significantly increased the density of slow-wave sleep, and this has also been shown in other species.²¹² Furthermore, there is a striking correlation between the age-related declines in slow-wave sleep and daily integrated GH secretion in healthy men.²¹³ These and other data suggest that central GHRH secretion is under circadian entrainment, and nocturnal elevations in GHRH pulse amplitude or frequency directly mediate sleep stage and sleep-induced increases in GH secretion.

GHRH has been reported to stimulate food intake in rats and sheep, but the effect is dependent on route of administration, time of administration, and macronutrient composition of the diet.²⁰³ The neuropeptide's physiologic relevance to feeding in humans is unknown, although a study indicated that GHRH stimulated food intake in patients with anorexia nervosa but reduced it in patients with bulimia and in normal female control subjects.²¹⁴

Growth Hormone–Releasing Peptides

In studies of the opioid control of GH secretion, several peptide analogues of met-enkephalin were found to be potent GH secretagogues. These include the GH-releasing peptide GHRP-6 (Fig. 7-21), hexarelin (His-D2MeTrp-Ala-Trp-DPhe-Lys-NH₂), and other more potent analogues including cyclic peptides and modified pentapeptides.^{203,215}

GHRP-6: His-DTrp-Ala-Trp-DPhe-Lys-NH₂

Figure 7-21 Structure of a synthetic peptidyl growth hormone (GH) secretagogue (GH-releasing peptide 6, or GHRP-6) and nonpeptidyl GH secretagogue (MK-0677 and L-163,540) and a natural ligand (ghrelin), all of which bind and activate the growth hormone secretagogue (GHS) receptor. Ghrelin is an acylated 28-amino-acid peptide. The O-n-octanoylation at Ser3 is essential for biologic activity and is a unique post-translational modification among all known proteins. (Adapted from Smith RG, Feighner S, Prendergast K, et al. A new orphan receptor involved in pulsatile growth hormone release. *Trends Endocrinol Metab*. 1999;10:128-135; Kojima M, Hosoda H, Date Y, et al. Ghrelin is a growth hormone-releasing acylated peptide from stomach. *Nature*. 1999;402:656-660.)

Subsequently, a series of nonpeptidyl GHRP mimetics were synthesized with greater oral bioavailability, including the spiropiperidine MK-0677 and the shorter-acting benzylpiperidine L-163,540 (see Fig. 7-21). Common to all of these compounds, and the basis of their differentiation from GHRH analogues in pharmacologic activity screens, is their activation of phospholipase C and inositol 1,4,5-triphosphate. This property was exploited in a cloning strategy that led to the identification of a G protein-coupled receptor, GHS-R, that is highly selective for the GH secretagogue class of ligands.²¹⁶ The GHS-R is unrelated to the GHRH receptor and is highly expressed in the anterior pituitary gland and multiple brain areas, including the medial basal hypothalamus, the hippocampus, and the mesencephalic nuclei that are centers of dopamine and serotonin production.

Peptidyl and nonpeptidyl GHSs are active when administered by intranasal and oral routes, are more potent on a weight basis than GHRH itself, are more effective *in vivo* than *in vitro*, synergize with coadministered GHRH and are almost ineffective in the absence of GHRH, and do not suppress somatostatin secretion.^{203,208} Prolonged infusions of GHRP amplify pulsatile GH secretion in normal men. GHRP administration, like that of GHRH, facilitates slow-wave sleep. Patients with hypothalamic disease leading to GHRH deficiency have low or no response to hexarelin; similarly, pediatric patients with complete absence of the pituitary stalk have no GH secretory response to hexarelin.²¹⁷

The potent biologic effects of GHRPs and the identification of the GHS-R suggested the existence of a natural ligand for the receptor that is involved in the physiologic regulation of GH secretion. A probable candidate for this ligand is the acylated peptide ghrelin, which is produced and secreted into the circulation from the stomach (Fig. 7-22).¹³ The effects of ghrelin on GH secretion in humans are identical to or more potent than those of the non-natural GHRPs (see Fig. 7-20).²¹⁸ In addition, ghrelin acutely increases circulating PRL, ACTH, cortisol, and aldosterone levels.²¹⁸ There is debate concerning the extent and localization of ghrelin expression in the brain that must be resolved before the implications of gastric-derived ghrelin in the regulation of pituitary hormone secretion are fully understood. A proposed role for ghrelin in appetite and the regulation of food intake is discussed in Chapter 35.

Clinical Applications

GHRH stimulates growth in children with intact pituitaries, but the optimal dosage, route, and frequency of administration, as well as possible usefulness by the nasal route, have not been determined. The availability of recombinant human GH (which requires less frequent injections than GHRH) and the development of the more potent GHSs with improved oral bioavailability have reduced enthusiasm for the clinical use of GHRH or its analogues. GHRH is not useful for the differential diagnosis of hypothalamic and pituitary causes of GH deficiency in children. However, in adults a combined GHRH-GHRP challenge test may be ideal for the diagnosis of GH reserve. GH release in response to the combined secretagogues is not influenced by age, sex, or body mass index, and the test has a wider margin of safety than an insulin tolerance test.^{219,220}

The potential clinical applications of GHSs including MK-0677 are still being explored.^{203,215} An area of intense interest is the normal decline in GH secretion with age. GH administration in healthy older individuals has been associated with increased lean body mass, increased muscle strength, and decreased fat mass, although there is a high

incidence of adverse side effects. The physiologic GH profile induced by MK-0677 may be better tolerated than GH injections. However, in contrast to treatment with GHRH, chronic administration of GHSs leads to significant desensitization of the GHS-R and attenuation of the GH response. The release of pituitary hormones other than GH may also limit the applicability of GHS therapy. Finally, apart from actions on GH secretion, both GHRH and GHSs are being investigated for the treatment of sleep disorders commonly associated with aging.

Neuroendocrine Regulation of Growth Hormone Secretion

GH secretion is regulated by hypothalamic GHRH and somatostatin interacting with circulating hormones and additional modulatory peptides at the level of both the pituitary and the hypothalamus (see Fig. 7-22).^{203,208,221} Additional background on somatostatin and its functions other than control of GH secretion are presented in a later section (see "Somatostatin").

Feedback Control

Negative feedback control of GH release is mediated by GH itself and by IGF1, which is synthesized in the liver and other tissues under control of GH. Direct GH effects on the hypothalamus are produced by short-loop feedback, whereas those involving IGF1 and other circulating factors influenced by GH, including free fatty acids and glucose, are long-loop systems analogous to the pituitary-thyroid and pituitary-adrenal axes. Control of GH secretion therefore includes two closed-loop systems (GH and IGF1) and one open-loop regulatory system (neural).

Although most of the evidence for a direct role of GH in its own negative feedback has been derived from animals, an elegant study in normal men demonstrated that GH pretreatment blocks the subsequent GH secretory response to GHRH by a mechanism that is dependent on somatostatin.²²² The mechanism responsible for GH feedback through the hypothalamus has been largely elucidated in rodent models. GH receptors are selectively expressed on somatostatin neurons in the PVH nucleus and on NPY neurons in the arcuate nucleus. Fos gene expression is acutely elevated in both populations of GH receptor-positive neurons by GH administration, indicating an activation of hypothalamic circuitry that includes these neurons. Similarly, GHRH neurons in the arcuate nucleus are acutely activated by MK-0677 because of their selective expression of the GHS-R. Zheng and colleagues²²³ showed in the latter group of neurons that Fos induction after MK-0677 administration was blocked by pretreatment of mice with GH (Fig. 7-23). The effect must be indirect, because there are no GH receptors on GHRH neurons. However, type 2 somatostatin receptors are expressed on GHRH neurons, and the somatostatin analogue octreotide also significantly blocked Fos activation in the arcuate nucleus by MK-0677. The inhibitory effects of either GH or octreotide pretreatment were abolished in knockout mice lacking the specific somatostatin receptor (see Fig. 7-23). Together with data from many other experiments, these results strongly support a model of GH-negative feedback regulation that involves the primary activation of periventricular somatostatin neurons by GH. These tuberoinfundibular neurons then inhibit GH secretion directly by release of somatostatin in the median eminence, but they also indirectly inhibit GH secretion by way of collateral axonal projections to the arcuate nucleus that synapse on and inhibit GHRH neurons (see Fig. 7-22). It is probable from evidence in rodents that NPY and

Figure 7-22 Regulation of the hypothalamic-pituitary-growth hormone axis. Growth hormone (GH) secretion by the pituitary is stimulated by growth hormone-releasing hormone (GHRH) and inhibited by somatostatin (SRIF). Negative feedback control of GH secretion is exerted at the pituitary level by insulin-like growth factor type I (IGF-I) and by free fatty acids (FFA). GH itself exerts a short-loop negative feedback through activation of SRIF neurons in the hypothalamic periventricular nucleus. These SRIF neurons directly synapse on arcuate GHRH neurons and project axon collaterals to the median eminence. Neuropeptide Y (NPY) neurons in the arcuate nucleus also indirectly modulate GH secretion by integrating peripheral GH, leptin, and ghrelin signals and projecting to periventricular SRIF neurons. Ghrelin is secreted from the stomach and is a putative natural ligand for the growth hormone secretagogue (GHS) receptor that stimulates GH secretion at both the hypothalamic and pituitary levels. On the basis of indirect pharmacologic data, release of GHRH is stimulated by galanin, γ -aminobutyric acid (GABA), α_2 -adrenergic, and dopaminergic inputs and inhibited by somatostatin. Secretion of somatostatin is inhibited by muscarinic acetylcholine (ACh) and 5-HT-1D receptor ligands and increased by β_2 -adrenergic stimuli and corticotropin-releasing hormone (CRH). CNS, central nervous system; DA, dopamine; 5-HT, serotonin.

galanin also play a part in the short-loop feedback of GH secretion, but a definitive mechanism in humans is not yet established.

IGF1 has a major inhibitory action on GH secretion at the level of the pituitary gland.²⁰³ IGF1 receptors are expressed on human somatotroph adenoma cells and inhibit both spontaneous and GHRH-stimulated GH

release. In addition, gene expression of both GH and the pituitary-specific transcription factor PIT1 is inhibited by IGF1. Conflicting data among species suggest that circulating IGF1 may also regulate GH secretion by actions within the brain. The feedback effects of IGF1 account for the fact that serum GH levels are elevated in conditions in which circulating levels of IGF1 are low, such as anorexia nervosa,

Figure 7-23 Somatostatin and the somatostatin receptor 2 subtype are involved in the short-loop inhibitory feedback of growth hormone (GH) on arcuate neurons. Activation of neurons in the arcuate nucleus was determined by the quantification of immunoreactive Fos-positive cells after administration of the growth hormone secretagogue MK-0677 (MK). Preliminary treatment of wild-type mice (*Sstr2*^{+/+}) with either GH or the somatostatin analogue octreotide (Octreo) significantly attenuated the neuronal activation by MK-0677. In contrast, GH and octreotide had no effect on MK-0677 neuronal activation in somatostatin receptor 2-deficient mice (*Sstr2*^{-/-}). (Adapted from Zheng H, Bailey A, Jian M-H, et al. Somatostatin receptor subtype 2 knockout mice are refractory to growth hormone-negative feedback on arcuate neurons. *Mol Endocrinol.* 1997;11:1709-1717.)

protein-calorie starvation,²²⁴ and Laron dwarfism (the result of a defect in the GH receptor).

Neural Control

The predominant hypothalamic influence on GH release is stimulatory, and section of the pituitary stalk or lesions of the basal hypothalamus cause reduction of basal and induced GH release.²⁰³ When the somatostatinergic component is inactivated (e.g., by anti-somatostatin antibody injection in rats), basal GH levels and GH responses to the usual provocative stimuli are enhanced.

GHRH-containing nerve fibers that terminate adjacent to portal vessels in the external zone of the median eminence arise principally from within, above, and lateral to the infundibular nucleus in human hypothalamus, corresponding to rodent arcuate and ventromedial nuclei.²²⁵ Perikarya of the tuberoinfundibular somatostatin neurons are located almost completely in the medial periventricular nucleus and the parvocellular component of the anterior PVH. Neuroanatomic and functional evidence suggests a bidirectional synaptic interaction between the two peptidergic systems.²⁰³

Multiple extrahypothalamic brain regions provide efferent connections to the hypothalamus and regulate GHRH and somatostatin neuronal activity (Fig. 7-24; see Fig. 7-22). Somatosensory and affective information is integrated and filtered through the amygdaloid complex. The basolateral amygdala provides an excitatory input to the hypothalamus, and the central extended amygdala, which includes the central and medial nuclei of the amygdala together with the bed nucleus of the stria terminalis, provides a GABAergic inhibitory input. Many intrinsic neurons

of the hypothalamus also release GABA, often with a peptide cotransmitter. Excitatory cholinergic fibers arise to a small extent from forebrain projection nuclei but mostly from hypothalamic cholinergic interneurons, which densely innervate the external zone of the median eminence. Similarly, the origin of dopaminergic and histaminergic neurons is local, with their cell bodies located in the hypothalamic arcuate and tuberomammillary bodies, respectively. Two important ascending pathways to the medial basal hypothalamus regulate GH secretion and originate from serotonergic neurons in the raphe nuclei and adrenergic neurons in the nucleus of the tractus solitarius and ventral lateral nucleus of the medulla.

Both GHRH and somatostatin neurons express presynaptic and postsynaptic receptors for multiple neurotransmitters and peptides (Table 7-5). The α_2 -adrenoreceptor agonist clonidine reliably stimulates GH release, and for this reason a clonidine test was a standard diagnostic tool in pediatric endocrinology. The stimulatory effect is blocked by the specific α_2 -antagonist yohimbine and appears to involve a dual mechanism of action—inhibition of somatostatin neurons and activation of GHRH neurons. In addition, partial attenuation of the effects of clonidine by mixed serotonin 5-HT₁ and 5-HT₂ antagonists suggests that some of the relevant α_2 -receptors are located presynaptically on serotonergic nerve terminals and increase serotonin release. Both norepinephrine and epinephrine play physiologic roles in the adrenergic stimulation of GH secretion. The α_1 -agonists have no effect on GH secretion in humans, but β_2 -agonists such as the bronchodilator salbutamol inhibit GH secretion by stimulating the release of somatostatin from nerve terminals in the median

Figure 7-24 Neural pathways involved in growth hormone (GH) regulation. This diagram illustrates the varied pathways by which impulses from the limbic system and brain stem ultimately impinge on the hypothalamic periventricular and arcuate nuclei to stimulate GH release through the mediation of somatostatin (SRIF) and growth hormone–releasing hormone (GHRH). Psychological stress modulates hypothalamic function indirectly through the bed nucleus of the stria terminalis (BNST) and the amygdalar complex (Amyg). Circadian rhythms are entrained in part by projections from the suprachiasmatic nucleus (SCN). Complex reciprocal interactions between sleep stage and GHRH release involve cortex and subcortical nuclei, but the detailed mechanisms are not known. Dopaminergic and histaminergic input are from neurons located in the arcuate and mammillary nuclei, respectively, of the hypothalamus (HYP). Ascending catecholaminergic projections arise in both the nucleus of the tractus solitarius (NTS) and the ventral lateral medulla (VLM). Serotonergic (5-HT) afferents are from the raphe nuclei. In addition to these neural pathways, a variety of peripheral hormonal and metabolic signals and cytokines influence GH secretion by actions within the medial basal hypothalamus and pituitary gland.

eminence. These effects are blocked by propranolol, a non-specific β -antagonist. Dopamine generally has a net effect of stimulation of GH secretion, but the mechanism is not clear because of multiple dopamine receptor subtypes and the apparent activation of both GHRH and somatostatin neurons.

Serotonin's effect on GH release in humans was difficult to decipher because of the large number of receptor subtypes. However, clinical studies with the receptor-selective agonist sumatriptan clearly implicated the 5-HT_{1D} receptor subtype in the stimulation of basal GH levels.²²⁶ The drug also potentiates the effect of a maximal dose of GHRH, suggesting the recurring theme of GH disinhibition by inhibition of hypothalamic somatostatin neurons in its mechanism of action. Histaminergic pathways acting through H₁ receptors play only a minor, conditional stimulatory role in GH secretion in humans.

Acetylcholine appears to be an important physiologic regulator of GH secretion.²²⁷ Blockade of muscarinic acetylcholine receptors reduces or abolishes GH secretory responses to GHRH, glucagon and arginine, morphine, and exercise. In contrast, drugs that potentiate cholinergic transmission increase basal GH levels and enhance the GH response to GHRH in normal individuals and in subjects with obesity or Cushing's disease. In vitro acetylcholine inhibits somatostatin release from hypothalamic fragments, and acetylcholine can act directly on the pituitary to inhibit GH release. There may even be a paracrine cholinergic control system within the pituitary. However, the sum of evidence suggests that the primary mechanism of action of muscarinic M1 agonists is inhibition of somatostatin neuronal activity or release of peptide from somatostatinergic terminals. Short-term cholinergic blockade with the M1 muscarinic receptor antagonist pirenzepine reduced the GH excess in patients with poorly controlled diabetes mellitus.²²⁸ However, in the long term, cholinergic blockade did not prevent complications associated with the hypersomatotropic state.

Many neuropeptides in addition to GHRH and somatostatin are involved in the modulation of GH secretion in

humans (see Table 7-5).^{203,208} Among these, the evidence is most compelling for a stimulatory role of galanin acting in the human hypothalamus by a GHRH-dependent mechanism.²²⁹ Many GHRH neurons are immunopositive for galanin as well as neurotensin and tyrosine hydroxylase. Galanin's actions may be explained, in part, by presynaptic facilitation of catecholamine release from nerve terminals and subsequent direct adrenergic stimulation of GHRH release.²³⁰ Opioid peptides also stimulate GH release, probably by disinhibition of GHRH neurons, but under normal circumstances, endogenous opioid tone in the hypothalamus is presumed to be low because opioid antagonists have little acute effect on GH secretion.

A larger number of neuropeptides are known or suspected to inhibit GH secretion in humans, at least under certain circumstances.²⁰⁸ The list includes NPY, CRH, calcitonin, oxytocin, neurotensin, VIP, and TRH. Inhibitory actions of NPY are well established in the rat. The effect on GH secretion is secondary to stimulation of somatostatin neurons and is of particular interest because of the presumed role in GH autocrine feedback (discussed earlier) and the integration of GH secretion with regulation of energy intake and expenditure (see "External and Metabolic Signals"). Finally, TRH has the well-established paradoxical effect of increasing GH secretion in patients with acromegaly, type 1 diabetes mellitus, hypothyroidism, or hepatic or renal failure.

Other Factors Influencing Secretion of Growth Hormone

Human Growth Hormone Rhythms. The deciphering of rhythmic GH secretion has relied on a combination of technical innovations in sampling and GH assay and sophisticated mathematical modeling, including deconvolution analysis and the calculation of approximate entropy as a measure of orderliness or regularity in minute-to-minute secretory patterns.²⁰⁸ At least three distinct categories of GH rhythms, which differ markedly in their time scales, can be considered here.

TABLE 7-5

Factors That Change Growth Hormone (GH) Secretion in Humans

Physiologic	Hormones and Neurotransmitters	Pathologic
Stimulatory Factors		
Episodic, spontaneous release	Insulin hypoglycemia 2-Deoxyglucose Amino acid infusions	Acromegaly TRH GnRH
Exercise	Arginine, lysine	Glucose
Stress	Neuropeptides	Arginine
Physical	GHRH	Interleukins 1, 2, 6
Psychological	Ghrelin	Protein depletion
Slow-wave sleep	Galanin	Starvation
Postprandial glucose decline	Opioids (μ -receptors)	Anorexia nervosa
Fasting	Melatonin	Renal failure
	Classic neurotransmitters	Liver cirrhosis
	α_2 -Adrenergic agonists	Type 1 diabetes mellitus
	β -Adrenergic antagonists	
	M1 cholinergic agonists	
	5-HT1D-serotonin agonists	
	H1-histamine agonists	
	GABA (basal levels)	
	Dopamine (? D2 receptor)	
	Estrogen	
	Testosterone	
	Glucocorticoids (acute)	
Inhibitory Factors*		
Postprandial hyperglycemia	Glucose infusion	Acromegaly
Elevated free fatty acids	Neuropeptides	L-Dopa
Elevated GH levels	Somatostatin	D2R DA agonists
Elevated IGF I (pituitary)	Calcitonin	Phentolamine
REM sleep	Neuropeptide Y (NPY) [†]	Galanin
Senescence, aging	CRH [†]	Obesity
	Classic neurotransmitters	Hypothyroidism
	$\alpha_{1/2}$ -Adrenergic antagonists	Hyperthyroidism
	β_2 -Adrenergic agonists	
	H1 histamine antagonists	
	Serotonin antagonist	
	Nicotinic cholinergic agonists	
	Glucocorticoids (chronic)	

*In many instances, the inhibition can be demonstrated only as a suppression of GH release induced by a pharmacologic stimulus.

[†]The inhibitory actions of NPY and CRH on GH secretion are firmly established in the rodent and are secondary to increased somatostatin tone. Contradictory evidence exists in the human for both peptides, and further studies are required.

CRH, Corticotropin-releasing hormone; DA, dopamine; GHRH, growth hormone-releasing hormone; GnRH, gonadotropin-releasing hormone; IGF I, insulin-like growth factor type I; REM, rapid eye movement; TRH, thyrotropin-releasing hormone.

The daily GH secretion rate varies over 2 orders of magnitude, from a maximum of almost 2.0 mg/day in late puberty to a minimum of 20 μ g/day in older or obese adults. The neonatal period is characterized by markedly amplified GH secretory bursts followed by a prepubertal decade of stable, moderate GH secretion of 200 to 600 μ g/day. There is a marked increase in daily GH secretion during puberty that is accompanied by a commensurate

rise in plasma IGF1 to levels that constitute a state of physiologic hypersomatotropism. This pubertal increase in GH secretion is the result of increased GH mass per secretory burst rather than increased pulse frequency. Although the changes are clearly related to the increases in gonadal steroid hormones and can be mimicked by administration of estrogen or testosterone to hypogonadal children, the underlying neuroendocrine mechanisms are not fully understood. One hypothesis is that decreased sensitivity of the hypothalamic-pituitary axis to negative feedback from GH and IGF1 leads to increased GHRH release and action. Young adults have a return of daily GH secretion to prepubertal levels despite continued gonadal steroid elevation. The so-called somatopause is defined by an exponential decline in GH secretory rate with a half-life of 7 years starting in the third decade of life.

GH secretion in young adults exhibits a true circadian rhythm over a 24-hour period, characterized by a greater nocturnal secretory mass that is independent of sleep onset.²³¹ However, as discussed earlier, GH release is further facilitated when slow-wave sleep coincides with the normal circadian peak. Under basal conditions, GH levels are low most of the time, with an ultradian rhythm of about 10 secretory pulses per 24 hours in men (20 in women), as calculated by deconvolution analysis.²³² Both sexes have an increased pulse frequency during the nighttime hours, but the fraction of total daily GH secretion associated with nocturnal pulses is much greater in men. Overall, women have more continuous GH secretion and more frequent GH pulses that are of more uniform size than in men.²³² A complementary study using approximate entropy analysis concluded that the nonpulsatile regularity of GH secretion is also significantly different in men and women.²³³ These sexually dimorphic patterns in the human are actually quite similar to those in the rat, although the sex differences are not as extreme in humans.^{208,233}

The neuroendocrine basis for sex differences in the ultradian rhythm of GH secretion is not fully understood. Gonadal sex steroids play both an organizational role during development of the hypothalamus and an activational role in the adult, regulating expression of the genes for many of the peptides and receptors central to GH regulation.^{203,208} In the human, unlike the rat, the hypothalamic actions of testosterone appear to result predominantly from its aromatization to 17 β -estradiol and interaction with estrogen receptors. Hypothalamic somatostatin appears to play a more prominent role in men than in women in the regulation of pulsatile GH secretion, and this difference is postulated to be a key factor in producing the sexual dimorphism.^{232,234,235}

External and Metabolic Signals. The various peripheral signals that modulate GH secretion in humans are summarized in Table 7-5 (also see Figs. 7-22 and 7-24). Of particular importance are factors related to energy intake and metabolism, because they provide a common signal between the peripheral tissues and hypothalamic centers regulating nonendocrine homeostatic pathways in addition to the classic hypophyseotropic neurons. It is also in this complex arena that species-specific regulatory responses are particularly prominent, making extrapolations between rodent experimental models and human GH regulation less reliable.^{203,208}

Important triggers of GH release include the normal decrease in blood glucose concentration after intake of a carbohydrate-rich meal, absolute hypoglycemia, exercise, physical and emotional stress, and high intake of protein

(mediated by amino acids). Some of the pathologic causes of elevated GH represent extremes of these physiologic signals and include protein-calorie starvation, anorexia nervosa, liver failure, and type 1 diabetes mellitus. A critical concept is that many of these GH triggers work through the same final common mechanism of somatostatin withdrawal and consequent disinhibition of GH secretion. In contrast, postprandial hyperglycemia, glucose infusion, elevated plasma free fatty acids, type 2 diabetes mellitus (with obesity and insulin resistance), and obesity are all associated with inhibition of GH secretion. The role of leptin in mediating increases or decreases in GH release is complicated by its multiple sites of action and coexistent secretory environment. Similarly, other members of the cytokine family including IL-1, IL-2, IL-6, and endotoxin have been inconsistently shown to stimulate GH in humans.

The actions of steroid hormones on GH secretion are complex because of their multiple loci of action within the proximal hypothalamic-pituitary components in addition to secondary effects on other neural and endocrine systems. Glucocorticoids in particular produce opposite responses that are dependent on the chronicity of administration. Moreover, glucocorticoid effects follow an inverted U-shaped dose-response curve. Both low and high glucocorticoid levels reduce GH secretion, the former because of decreased GH gene expression and somatotroph responsiveness to GHRH and the latter because of increased hypothalamic somatostatin tone and decreased GHRH. Similarly, physiologic levels of thyroid hormones are necessary to maintain GH secretion and promote GH gene expression. Excessive thyroid hormone is also inhibitory to the GH axis, and the mechanism is speculated to be a combination of increased hypothalamic somatostatin tone, GHRH deficiency, and suppressed pituitary GH production.

Somatostatin

Chemistry and Evolution

A factor that potently inhibits GH release from pituitary in vitro was unexpectedly identified during early efforts to isolate GHRH from hypothalamic extracts.²³⁶ Somatostatin, the peptide responsible for this inhibition of GH secretion and the inhibition of insulin secretion by a pancreatic islet extract, was eventually isolated from hypothalamus and sequenced by Brazeau and colleagues in 1973.²³⁷ The term *somatostatin* was originally applied to a cyclic peptide containing 14 amino acids, called somatostatin-14 (SST-14) (Fig. 7-25). Subsequently, a second form, known as N-terminal extended somatostatin-28 (SST-28), was identified as a secretory product. Both forms of somatostatin are derived through independent cleavage of a common prohormone by prohormone convertases.²³⁸ In addition, the isolation of SST-28(1-12) in some tissues suggests that SST-14 can be secondarily processed from SST-28. SST-14 is the predominant form in the brain (including the hypothalamus), whereas SST-28 is the major form in the gastrointestinal tract, especially the duodenum and jejunum.

The name *somatostatin* is descriptively inadequate because the molecule also inhibits TSH secretion from the pituitary and has nonpituitary roles including activity as a neurotransmitter or neuromodulator in the central and peripheral nervous systems and as a regulatory peptide in gut and pancreas. As a pituitary regulator, somatostatin is

a true neurohormone—that is, a neuronal secretory product that enters the blood (hypophyseal-portal circulation) to affect cell function at remote sites. In the gut, somatostatin is present in the myenteric plexus, where it acts as a neurotransmitter, and in epithelial cells, where it influences the function of adjacent cells as a paracrine secretion. Somatostatin can influence its own secretion from delta cells (an autocrine function) in addition to acting as a paracrine factor in pancreatic islets. Gut exocrine secretion can be modulated by intraluminal action, so it is also a lumone. Because of its wide distribution, broad spectrum of regulatory effects, and evolutionary history, this peptide can be regarded as an archetypical pansystem modulator.

The genes that encode somatostatin in humans²³⁹ (see Fig. 7-25) and a number of other species exhibit striking sequence homology, even in primitive fish such as the anglerfish. Furthermore, the amino acid sequence of SST-14 is identical in all vertebrates. Formerly, it was accepted that all tetrapods have a single gene encoding both SST-14 and SST-28 and that teleost fish have two nonallelic pre-prosomatostatin genes (*PPSI* and *PPSII*), each of which encodes only one form of the mature somatostatin peptides. This situation implied that a common ancestral gene underwent a duplication event after the split of teleosts from the descendants of tetrapods.

However, both lampreys and amphibians, which predate and postdate the teleost evolutionary divergence, respectively, have now been shown to have at least two PPS genes.²⁴⁰ A more distantly related gene has been identified in mammals that encodes cortistatin, a somatostatin-like peptide that is highly expressed in cortex and hippocampus.^{241,242} Cortistatin-14 differs from SST-14 by three amino acid residues but has high affinity for all known subtypes of somatostatin receptors (see later discussion). The human gene sequence predicts a tripeptide-extended cortistatin-17 and a further N-terminal extended cortistatin-29.²⁴³ A revised evolutionary concept of the somatostatin gene family is that a primordial gene underwent duplication at or before the advent of chordates, and the two resulting genes underwent mutation at different rates to produce the distinct pre-prosomatostatin and pre-procortistatin genes in mammals.²⁴⁰ A second gene duplication probably occurred in teleosts to generate *PPSI* and *PPSII* from the ancestral somatostatin gene.

Apart from its expression in neurons of the PVH and the arcuate hypothalamic nucleus and its involvement in GH secretion (discussed earlier), somatostatin is highly expressed in the cortex, lateral septum, extended amygdala, reticular nucleus of the thalamus, hippocampus, and many brain stem nuclei. Cortistatin is present in the brain, at a small fraction of the level of somatostatin and in a more limited distribution, primarily confined to cortex and hippocampus. The molecular mechanisms underlying the developmental and hormonal regulation of somatostatin gene transcription have been most extensively studied in pancreatic islet cells.²⁴⁴⁻²⁴⁶ Less is known concerning the regulation of somatostatin gene expression in neurons, except that activation is strongly controlled by binding of the phosphorylated transcription factor CRE-binding protein to its cognate CRE contained in the promoter sequence.^{247,248} Enhancer elements in the somatostatin gene promoter that bind complexes of homeodomain-containing transcription factors (PAX6, PBX, PREP1) and upregulate gene expression in pancreatic islets may actually represent gene silencer elements in neurons (see Fig. 7-25, promoter elements TSE_{II} and UE-A).²⁴⁶ Conversely,

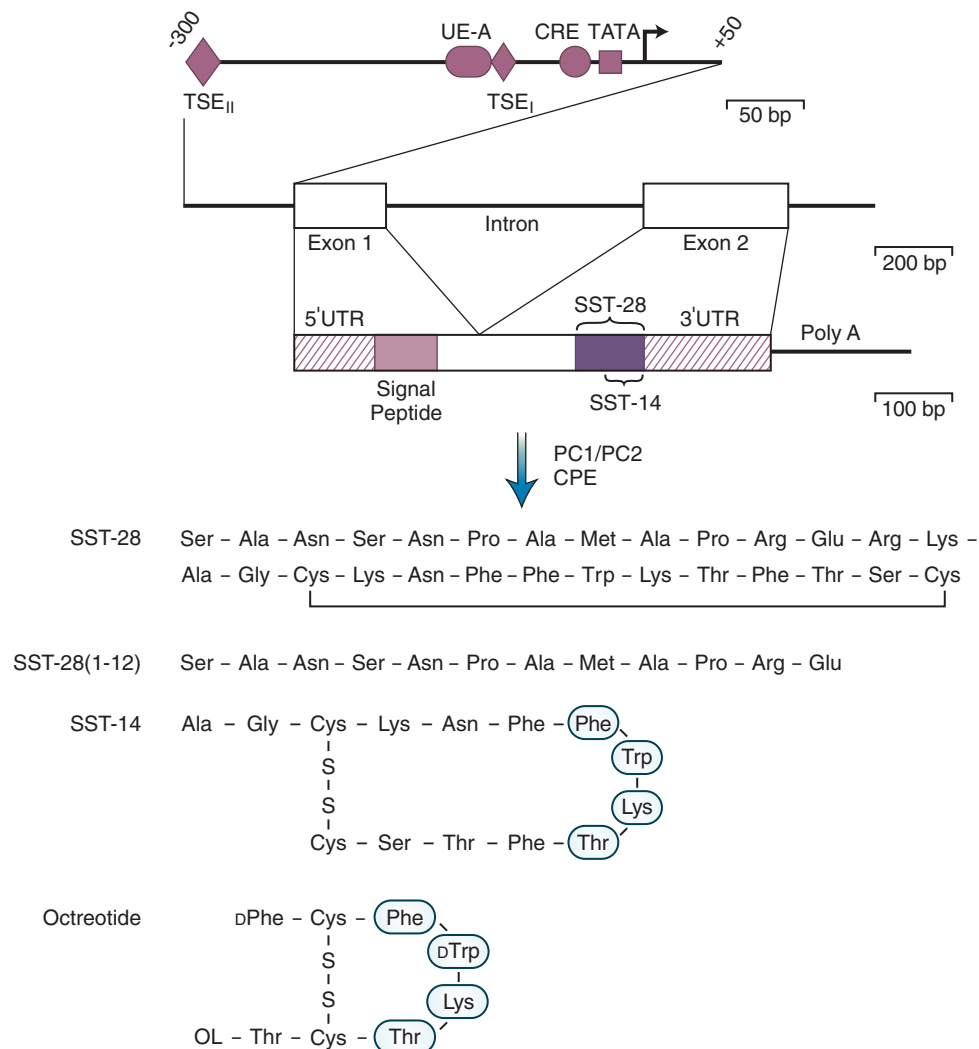

Figure 7-25 Diagram illustrating the genomic organization, messenger RNA structure, and post-translational processing of the human somatostatin prohormone. Transcriptional regulation of the somatostatin gene has been studied extensively in pancreatic islet cell lines. Binding sites for specific factors, including tissue-specific elements (TSE), upstream elements (UE), and the cyclic adenosine monophosphate (cAMP) response element (CRE), have been identified. It is not known whether all or some of these factors are also involved in the neural-specific expression of somatostatin. SST-28 and SST-14 are cyclic peptides that contain a single covalent disulfide bond between a pair of Cys residues. A β -turn containing the tetrapeptide Phe-Trp-Lys-Thr is stabilized by hydrogen bonds to produce the core receptor binding epitope. This minimal structure has been the model for conformationally restrained analogues of somatostatin including octreotide. CPE, carboxypeptidase E; PC1/PC2, prohormone convertases 1 and 2; SST, somatostatin; TATA, Goldstein-Hogness box involved in binding RNA polymerase; UTR, untranslated region. another related *cis* element in the somatostatin gene (see Fig. 7-25, promoter element TSE_I) apparently binds a homeodomain transcription factor PDX1 (also called *STF1*, *IDX1*, or *IPF1*) that is common to developing brain, pancreas, and foregut and regulates gene expression in both the CNS and the gut.²⁴⁹

The function of somatostatin in GH and TSH regulation was considered earlier in this chapter. Its actions in the extrahypothalamic brain and diagnostic and therapeutic roles are considered in the remainder of this section and in Chapter 8. An additional function of somatostatin in pancreatic islet cell regulation is described in Chapter 34, and the manifestations of somatostatin excess (as in somatostatinoma) are described in Chapter 39.

Somatostatin Receptors

Five somatostatin receptor subtypes (SSTR1 to SSTR5) have been identified by gene cloning techniques, and one of these (SSTR2) is expressed in two alternatively spliced forms.²⁵⁰ These subtypes are encoded by separate genes located on different chromosomes; they are expressed in unique or partially overlapping distributions in multiple target organs; and they differ in their coupling to second-messenger signaling molecules and therefore in their range and mechanism of intracellular actions.^{250,251} The subtypes also differ in their binding affinity to specific somatostatin analogues. Certain of these differences have important implications for the use of somatostatin analogues in therapy and in diagnostic imaging.

TABLE 7-6

Biologic Actions of Somatostatin Outside the Central Nervous System

Hormone Secretion Inhibited (by Gland)	Other Gastrointestinal and Extragastrointestinal Actions Inhibited
Pituitary gland	Gastric acid secretion
GH, thyrotropin, ACTH, prolactin	Gastric and jejunal fluid secretion
Gastrointestinal tract	Gastric emptying
Gastrin	Pancreatic bicarbonate secretion
Secretin	Pancreatic enzyme secretion
Gastrointestinal polypeptide	Stimulates intestinal absorption of water and electrolytes
Motilin	Gastrointestinal blood flow
Glicentin (enteroglucagon)	AVP-stimulated water transport
Vasoactive intestinal peptide	Bile flow
Pancreas	
Insulin	Extragastrintestinal Actions
Glucagon	Inhibits the function of activated immune cells
Somatostatin	Inhibition of tumor growth
Genitourinary tract	
Renin	

ACTH, adrenocorticotrophic hormone; AVP, arginine vasopressin; GH, growth hormone.

All SSTR subtypes are coupled to pertussis toxin-sensitive G proteins and bind SST-14 and SST-28 with high affinity in the low nanomolar range, although SST-28 has a uniquely high affinity for SSTR5. SSTR1 and SSTR2 are the two most abundant subtypes in brain; they probably function as presynaptic autoreceptors in the hypothalamus and limbic forebrain, respectively, in addition to their postsynaptic actions. SSTR4 is most prominent in hippocampus. All the subtypes are expressed in pituitary, but SSTR2 and SSTR5 are the most abundant subtypes on somatotrophs. They are also the most physiologically important subtypes in pancreatic islets, with SSTR5 responsible for inhibition of insulin secretion from beta cells and SSTR2 responsible for inhibition of glucagon from alpha cells.²⁵²

Binding of somatostatin to its receptor leads to activation of one or more plasma membrane-bound inhibitory G proteins ($G_{i/o}$), which in turn inhibit adenyl cyclase activity and lower intracellular cAMP. Other G protein-mediated actions common to all SSTRs are activation of a vanadate-sensitive phosphotyrosine phosphatase and modulation of mitogen-activated protein kinase (MAPK). Different subsets of SSTRs are also coupled to inwardly rectifying K^+ channels, voltage-dependent Ca^{2+} channels, an Na^+/H^+ exchanger, α -amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA)-kainate glutamate receptors, phospholipase C, and phospholipase A_2 .²⁵⁰ The lowering of intracellular cAMP and Ca^{2+} is the most important mechanism for inhibition of hormone secretion, and actions on phosphotyrosine phosphatase and MAPK are postulated to play a role in somatostatin's antiproliferative effect on tumor cells.

Effects on Target Tissues and Mechanisms of Action

In the pituitary, somatostatin inhibits secretion of GH, TSH, and, under certain conditions, PRL and ACTH. It exerts inhibitory effects on virtually all endocrine and exocrine secretions of the pancreas, gut, and gallbladder (Table 7-6). Somatostatin inhibits secretion by the salivary glands and, under some conditions, secretion of parathyroid

hormone and calcitonin. Somatostatin blocks hormone release in many endocrine-secreting tumors, including insulinomas, glucagonomas, VIPomas, carcinoid tumors, and some gastrinomas.

The physiologic actions of somatostatin in extrahypothalamic brain remain the subject of investigation.²⁵³ In the striatum, somatostatin increases the release of dopamine from nerve terminals by a glutamate-dependent mechanism. It is widely expressed in GABAergic interneurons of limbic cortex and hippocampus, where it modulates the excitability of pyramidal neurons. Temporal lobe epilepsy is associated with a marked reduction in somatostatin-expressing neurons in the hippocampus, consistent with a putative inhibitory action on seizures.²⁵⁴ A wealth of correlative data has linked reduced forebrain and CSF concentrations of somatostatin with Alzheimer's disease, major depression, and other neuropsychiatric disorders, raising speculation about the role of somatostatin in modulating neural circuits underlying cognitive and affective behaviors. A study using both genetic and pharmacologic methods to induce somatostatin deficiency in mice bolstered the hypothesis that the neuropeptide plays a physiologic role in the acquisition of contextual fear memory, possibly by altering long-term potentiation in hippocampal circuits.²⁵⁵

Clinical Applications of Somatostatin Analogues

An extensive pharmaceutical discovery program has produced somatostatin analogues with receptor subtype selectivity and improved pharmacokinetics and oral bioavailability compared with the native peptide. Initial efforts focused on the rational design of constrained cyclic peptides incorporating D-amino acid residues and including the Trp^8 - Lys^9 dipeptide of somatostatin, which was shown by structure-function studies to be necessary for high-affinity binding to the somatostatin receptor (see Fig. 7-25). Many such analogues have been studied in clinical trials, including octreotide, lanreotide, vapreotide, and the hexapeptide MK-678. These compounds are agonists with similar high-affinity binding to SSTR2 and SSTR5, moderate binding to SSTR3, and no (or low) binding to SSTR1 and SSTR4. A combinatorial chemistry approach has now led to a new generation of nonpeptidyl somatostatin agonists that bind selectively and with subnanomolar affinity to each of the five SSTR subtypes.^{256,257} In contrast to the marked success in development of potent and selective somatostatin agonists, there is a relative paucity of useful antagonists.²⁵⁰

The actions of octreotide (SMS 201-995 or Sandostatin) illustrate the general therapeutic potential of somatostatin analogues.^{258,259} Octreotide controls excess secretion of GH in acromegaly in most patients and shrinks tumor size in about one third. It is also indicated for the treatment of recurrent TSH-secreting adenomas after surgery. It is used to treat other functioning metastatic neuroendocrine tumors, including carcinoid, VIPoma, glucagonoma, and insulinoma, but is seldom of use for the treatment of gastrinoma. Octreotide is also useful in the management of many forms of diarrhea (acting on salt and water excretion mechanisms in the gut) and in reducing external secretions in pancreatic fistulas (thus permitting healing). A decrease in blood flow to the gastrointestinal tract is the basis for its use in bleeding esophageal varices, but it is not effective in the treatment of bleeding from a peptic ulcer.

The only major undesirable side effect of octreotide is reduction of bile production and of gallbladder contractility, which leads to "sludging" of bile and an increased incidence of gallstones. Other common adverse effects,

Figure 7-26 The use of ^{111}In -labeled diethylenetriaminepentaacetic acid (DTPA)-octreotide (radioactive somatostatin analogue) and external imaging techniques to localize a carcinoid tumor expressing somatostatin receptors. Scans were obtained 24 hours after administration of labeled tracer. **A**, Anterior view of the abdomen showing nodular metastases in an enlarged liver and the primary carcinoid tumor (arrow) in the wall of the jejunum of a patient with severe flushing and diarrhea. **B**, Posterior view of the chest and neck showing a metastasis in a lymph node on the left side of the neck (arrow) and multiple metastases in the ribs and pleura. (Reprinted with modifications from Lamberts SWJ, Krenning EP, Reubi J-C. The role of somatostatin and its analogs in the diagnosis and treatment of tumors. *Endocrine Rev.* 1991;12:450-482. Copyright 1991, The Endocrine Society.)

including nausea, abdominal cramps, diarrhea secondary to malabsorption of fat, and flatulence, usually subside spontaneously within 2 weeks of continued treatment. Impaired glucose tolerance is not associated with long-term octreotide therapy, despite an inhibitory effect on insulin secretion, because of compensating reductions in carbohydrate absorption and GH and glucagon secretion that are caused by the drug.

Somatostatin analogues labeled with a radioactive tracer have been used as external imaging agents for a wide range of disorders.^{258,259} An indium 111 (^{111}In)-labeled analogue of octreotide (OctreoScan) has been approved for clinical use in the United States and several other countries (Fig. 7-26). The majority of neuroendocrine tumors and many pituitary tumors that express somatostatin receptors are visualized by external imaging techniques after administration of this agent; a variety of nonendocrine tumors and inflammatory lesions are also visualized, all of which have in common the expression of somatostatin receptors. Such tumors include non-small cell cancer of the lung (100%), meningioma (100%), breast cancer (74%), and astrocytomas (67%). Because activated T cells of the immune system display somatostatin receptors, inflammatory lesions that take up the tracer include sarcoidosis, Wegener's granulomatosis, tuberculosis, and many cases of Hodgkin's disease and non-Hodgkin's lymphoma. Although the tracer lacks specificity in differential diagnosis, its ability to identify the presence of abnormality and the extent of the lesion provides important information for management, including tumor staging. The use of a small, hand-held radiation detector in the operating room makes it possible to ensure the completeness of removal of medullary thyroid carcinoma metastases.²⁶⁰ New developments in the synthesis of tracers chelated to octreotide for positron emission tomography have allowed the sensitive detection of meningiomas only 7 mm in diameter and located beneath osseous structures at the base of the skull.²⁶¹

The ability of somatostatin to inhibit the growth of normal and some neoplastic cell lines and to reduce the growth of experimentally induced tumors in animal models has stimulated interest in somatostatin analogues for the treatment of cancer. Somatostatin's tumorigenic effects may be a combination of direct actions on tumor cells related to inhibition of growth factor receptor expression, inhibition of MAPK, and stimulation of phosphotyrosine phosphatase. SSTR1, SSTR2, SSTR4, and SSTR5 can all promote cell cycle arrest associated with induction of the tumor suppressor retinoblastoma (Rb) and p21 (CDKN1A),

and SSTR3 can trigger apoptosis accompanied by induction of the tumor suppressor TP53 and the proapoptotic protein Bax.²⁵⁰ In addition, somatostatin has indirect effects on tumor growth through inhibition of circulating, paracrine, and autocrine tumor growth-promoting factors, and it can modulate the activity of immune cells and influence tumor blood supply. Despite this promise, the therapeutic utility of octreotide as an antineoplastic agent remains controversial.

Two new treatment approaches in preclinical trials may yet effectively utilize somatostatin receptors in the arrest of cancer cells.²⁵⁸ The first is receptor-targeted radionuclide therapy using octreotide chelated to a variety of β - or γ -emitting radioisotopes. Theoretical calculations and empiric data suggest that radiolabeled somatostatin analogues can deliver a tumoricidal radiotherapeutic dose to some tumors after receptor-mediated endocytosis. A variation on this theme is the chelation of a cytotoxic chemotherapeutic agent, such as doxorubicin, to a somatostatin analogue. A second approach involves somatic cell gene therapy to transfect SSTR-negative pancreatic cancer cells with an SSTR gene.²⁶² Therapeutic results can be obtained with the creation of autocrine or paracrine inhibitory growth effects or the addition of targeted radionuclide treatments.

Prolactin-Regulating Factors

Dopamine

It is well known that PRL secretion, unlike the secretion of other pituitary hormones, is primarily under tonic inhibitory control by the hypothalamus (Fig. 7-27).²⁶³ Destruction of the stalk median eminence or transplantation of the pituitary gland to ectopic sites causes a marked constitutive increase in PRL secretion, in contrast to a decrease in the release of GH, TSH, ACTH, and the gonadotropins. Many lines of evidence indicate that dopamine is the principal physiologic PIF released from the hypothalamus.²⁶⁴ Dopamine is present in hypophyseal-portal vessel blood in sufficient concentration to inhibit PRL release²⁶⁵; dopamine inhibits PRL secretion from lactotrophs both in vivo and in vitro²⁶⁶; and dopamine D_2 receptors are expressed on the plasma membrane of lactotrophs.^{267,268} Mutant mice with a targeted disruption of the D_2 receptor gene (*Drd2*) uniformly developed lactotroph hyperplasia, hyperprolactinemia, and eventually lactotroph adenomas, further emphasizing the importance of dopamine in the

Figure 7-27 Regulation of the hypothalamic-pituitary-prolactin (PRL) axis. The predominant effect of the hypothalamus is inhibitory, an effect mediated principally by the tuberohypophyseal dopaminergic neuron system and dopamine D₂ receptors on lactotrophs. The dopamine neurons are stimulated by acetylcholine (ACh) and glutamate and inhibited by histamine and opioid peptides. One or more prolactin-releasing factors (PRFs) probably mediate acute release of PRL (e.g., in suckling, during stress). There are several candidate PRFs, including thyrotropin-releasing hormone (TRH), vasoactive intestinal polypeptide (VIP), and oxytocin. PRF neurons are activated by serotonin (5-HT). Estrogen sensitizes the pituitary to release PRL, which feeds back on the pituitary to regulate its own secretion (ultrashort-loop feedback) and also influences gonadotropin secretion by suppressing the release of luteinizing hormone-releasing hormone (LHRH). Short-loop feedback is also mediated indirectly by PRL receptor regulation of hypothalamic dopamine synthesis, secretion, and turnover. CNS, central nervous system; GABA, γ -aminobutyric acid.

physiologic regulation of lactotroph proliferation in addition to hormone secretion.²⁶⁹

The intrinsic dopamine neurons of the medial-basal hypothalamus constitute a dopaminergic population with regulatory properties that are distinct from those in other areas of the brain. Notably, they lack D₂ autoreceptors but express PRL receptors, which are essential for positive feedback control (discussed in detail later). In the rat, these

neurons are subdivided by location into the A12 group within the arcuate nucleus and the A14 group in the anterior PVH. The caudal A12 dopamine neurons are further described as tuberoinfundibular (TIDA) because of their axonal projections to the external zone of the median eminence. Tuberohypophyseal (THDA) neuronal soma are located more rostrally in the arcuate nucleus and project to both the neural lobe and the intermediate lobe through

axon collaterals that are found in the internal zone of the median eminence. Finally, the A14 periventricular hypothyseal (PHDA) neurons send their axons only to the intermediate lobe of the pituitary gland.

Although the TIDA neurons are considered to be the major source of dopamine to the anterior lobe through the long portal vessels originating in the median eminence, dopamine can also reach the anterior lobe from the neural and intermediate lobes by the interconnecting short portal veins.²⁷⁰ Consistent with this pathway for dopamine access to the anterior lobe, surgical removal of the neurointermediate lobe in rats caused a significant increase in basal PRL levels.²⁷¹ In addition to direct actions of dopamine on lactotrophs, central dopamine can indirectly affect PRL secretion by altering the activity of inhibitory interneurons that synapse on the TIDA neurons. These effects are complicated by opposing intracellular signaling pathways linked to D₁ and D₂ receptors located on different populations of interneurons.²⁷²

The binding of dopamine or selective agonists such as bromocriptine to the D₂ receptor has multiple effects on lactotroph function. D₂ receptors are coupled to pertussis toxin-sensitive G proteins and inhibit adenylyl cyclase and decrease intracellular cAMP levels. Other effects include activation of an inwardly rectifying K⁺ channel, increase of voltage-activated K⁺ currents, decrease of voltage-activated Ca²⁺ currents, and inhibition of inositol phosphate production. Together, this spectrum of intracellular signaling events decreases free Ca²⁺ concentrations and inhibits exocytosis of PRL secretory granules.²⁷³ Dopamine also has a modest effect on thyrotrophs to inhibit the secretion of TSH.

There is continuing debate concerning the mechanism by which D₂ receptor activation inhibits transcription of the PRL gene. Likely pathways involve inhibition of MAPK or protein kinase C, with a resultant reduction in the phosphorylation of Ets family transcription factors. Ets factors are important for the stimulatory responses of TRH, insulin, and epidermal growth factor on PRL expression,²⁷⁴⁻²⁷⁶ and they interact cooperatively with the pituitary-specific protein PIT1 (a member of the POU domain family of transcription factors), which is essential for cAMP-mediated PRL gene expression.²⁷⁷

The second-messenger pathways used by the D₂ receptor to inhibit lactotroph cell division are also unsettled. A study using primary pituitary cultures from rats demonstrated that forskolin treatment, which activates protein kinase A and elevates intracellular cAMP, or insulin treatment, which activates a potent receptor tyrosine kinase, were both effective mitogenic stimuli for lactotrophs. Bromocriptine competitively antagonized the proliferative response caused by elevated cAMP. Furthermore, inhibition of MAPK signaling by PD98059 markedly suppressed the mitogenic action of both insulin and forskolin, suggesting an interaction of MAPK and protein kinase A signaling.²⁷⁸

Another line of study has implicated the stimulation of phospholipase D activity by a Rho A-dependent, pertussis toxin-insensitive pathway in the antiproliferative effects of D₂ receptor activation in both GH4C1 pituitary cells and NCI-H69 small cell lung cancer cells.²⁷⁹ Therefore, it is clear that dopamine actions on lactotrophs involve multiple different intracellular signaling pathways linked to activation of the D₂ receptor, but different combinations of these pathways are relevant for the inhibitory effects on PRL secretion, PRL gene transcription, and lactotroph proliferation.

The other major action of dopamine in the pituitary is inhibition of hormone secretion from the POMC-expressing

cells of the intermediate lobe—although, as noted earlier, the adult human differs from most other mammals in the rudimentary nature of this lobe. THDA and PHDA axon terminals provide a dense plexus of synaptic-like contacts on melanotrophs. Dopamine release from these terminals is inversely correlated with serum MSH levels²⁸⁰ and also regulates POMC gene expression and melanotroph proliferation.²⁸¹

Other hypothalamic factors probably play a role secondary to that of dopamine as additional PIFs.²⁶³ The primary reason to conjecture the existence of these PIFs is the frequent inconsistency between portal dopamine levels and circulating PRL in different rat models. GABA is the strongest candidate and most likely acts through GABA_A ionotropic receptors in the anterior pituitary. Melanotrophs, like lactotrophs, are inhibited by both dopamine and GABA but with the principal involvement of G protein-coupled, metabotropic GABA_B receptors.²⁸² Because basal dopamine tone is high, the measurable inhibitory effects of GABA on PRL release are generally small under normal circumstances. Other putative PIFs include somatostatin and calcitonin.

Prolactin-Releasing Factors

Although tonic suppression of PRL release by dopamine is the dominant effect of the hypothalamus on PRL secretion, a number of stimuli promote PRL release, not merely by disinhibition of PIF effects but by causing release of one or more neurohormonal PRFs (see Fig. 7-27). The most important of the putative PRFs are TRH, oxytocin, and VIP, but AVP, angiotensin II, NPY, galanin, substance P, bombesin-like peptides, and neurotensin can also trigger PRL release under different physiologic circumstances.²⁶³ TRH has already been discussed. In humans, there is an imperfect correlation between pulsatile PRL and TSH release, suggesting that TRH cannot be the sole physiologic PRF under basal conditions.²⁸³

Like TRH, oxytocin, AVP, and VIP fulfill all the basic criteria for a PRF. They are produced in PVH neurons that project to the median eminence. Concentrations of the hormones in portal blood are much higher than in the peripheral circulation and are sufficient to stimulate PRL secretion *in vitro*. Moreover, there are functional receptors for each of the neurohormones in the anterior pituitary gland, and either pharmacologic antagonism or passive immunization against each hormone can decrease PRL secretion, at least under certain circumstances.²⁸⁴⁻²⁸⁸

AVP is released during stress and hypovolemic shock, as is PRL, suggesting a specific role for AVP as a PRF in these contexts. Similarly, another candidate PRF, peptide histidine isoleucine, may be specifically involved in the secretion of PRL in response to stress. Peptide histidine isoleucine and the human homologue PHM are structurally related to VIP and are synthesized from the same prohormone precursor in their respective species.²⁸⁹ Both peptides are coexpressed with CRH in parvocellular PVH neurons, and presumably they are released by the same stimuli that cause release of CRH into the hypophyseal-portal vessels.²⁹⁰

There is evidence suggesting that dopamine itself may also act as a PRF, in contrast to its predominant function as a PIF.²⁶³ At concentrations 3 orders of magnitude lower than that associated with maximal inhibition of PRL secretion, dopamine was shown to be capable of stimulating secretion from primary cultures of rat pituitary cells.²⁹¹ These studies were extended to an *in vivo* model by Arey and colleagues,²⁹² who demonstrated that low-dose dopamine infusion in cannulated rats caused a further increase in circulating PRL above the already elevated baseline

produced by pharmacologic blockade of endogenous dopamine biosynthesis. The physiologic relevance of these findings to humans has yet to be established.

Finally, reports of newly recognized PRFs continue to be published. Much excitement was generated by the isolation of a mammalian RFamide peptide from bovine hypothalamus named *prolactin-releasing peptide* (PrRP).^{293,294} PrRP binds with high affinity to its G protein-coupled receptor GPR10, expressed in human pituitary; it selectively stimulates PRL release from rat pituitary cells with a potency lower than that of TRH by itself, but synergistically in combination with TRH. However, PrRP is expressed predominantly in a subpopulation of noradrenergic neurons in the medulla and a small population of non-neurosecretory neurons of the VMH, raising the serious question about whether PrRP reaches the anterior pituitary and actually causes PRL secretion. Subsequent studies found no direct evidence for release of PrRP in the arcuate nucleus or median eminence, further suggesting that the peptide is not a hypophyseotropic neurohormone. PrRP probably does function as a neuromodulator within the CNS at sites expressing its receptor and probably is involved in the neural circuitry mediating stress responses and satiety.^{294,295}

Intrapituitary Regulation of Prolactin Secretion

Probably more than that of any other pituitary hormone, the secretion of PRL is regulated by autocrine-paracrine factors within the anterior lobe and by neurointermediate lobe factors that gain access to venous sinusoids of the anterior lobe by way of the short portal vessels. The wealth of local regulatory mechanisms within the anterior lobe has been reviewed extensively^{263,296} and is also discussed in Chapter 8. Galanin, VIP, endothelin-like peptides, angiotensin II, epidermal growth factor, basic fibroblast growth factor, GnRH, and the cytokine IL-6 are among the most potent local stimulators of PRL secretion. Locally produced inhibitors include PRL itself, acetylcholine, transforming growth factor- β , and calcitonin. Although none of these stimulatory or inhibitory factors plays a dominant role in the regulation of lactotroph function and much of the research in this area has not been directly confirmed in human pituitary, it seems apparent that the local milieu of autocrine and paracrine factors plays an essential modulatory role in determining the responsiveness of lactotrophs to hypothalamic factors in different physiologic states.

As noted earlier, a proportion of the inhibitory dopamine tone affecting the anterior lobe lactotrophs is derived from the neurointermediate lobe. It was therefore unanticipated that surgical removal of this structure in rats would block suckling-induced PRL release over the moderate basal increase attributed to partial dopamine disinhibition.²⁹⁷ Further studies showed that exposure of the anterior pituitary to intermediate-lobe extracts (devoid of VIP, AVP, and other known PRFs) stimulated PRL secretion. At least two kinds of PRF activity have been isolated from intermediate-lobe tumors of the mouse, but the specific molecules involved have yet to be identified.²⁹⁸ Other researchers have suggested a more passive role for the neurointermediate lobe in the regulation of PRL secretion. Melanotroph-derived *N*-acetylated MSH appears to act as a lactotroph responsiveness factor by recruiting nonsecretory cells to an active state and sensitizing secreting lactotrophs to the actions of other direct PRFs.²⁹⁹ However, the relevance of the neurointermediate lobe for PRL regulation in primates (including humans) is not clear because of its attenuated structure in these species.

Neuroendocrine Regulation of Prolactin Secretion

Secretion of PRL, like that of other anterior pituitary hormones, is regulated by hormonal feedback and neural influences from the hypothalamus.^{263,264,300} Feedback is exerted by PRL itself at the level of the hypothalamus. PRL secretion is regulated by many physiologic states including the estrous and menstrual cycles, pregnancy, and lactation. PRL is stimulated by several exteroceptive stimuli including light, ultrasonic vocalization of pups (in rodents), olfactory cues, and various modalities of stress. Expression and secretion of PRL are also influenced strongly by estrogens at the level of both the lactotrophs and the TIDA neurons³⁰¹ (see Fig. 7-27) and by paracrine regulators within the pituitary such as galanin and VIP.

Feedback Control

Negative feedback control of PRL secretion is mediated by a unique short-loop mechanism within the hypothalamus.³⁰² PRL activates PRL receptors, which are expressed on all three subpopulations of A12 and A14 dopamine neurons, leading to increased tyrosine hydroxylase expression and increased dopamine synthesis and release.^{301,303} Ames dwarf mice that secrete virtually no PRL, GH, or TSH have decreased numbers of arcuate dopamine neurons, and this hypoplasia can be reversed by neonatal administration of PRL, suggesting a trophic action on the neurons.³⁰⁴ However, another mouse model of isolated PRL deficiency generated by gene targeting appears to have normal numbers of hypofunctioning dopamine neurons secondary to the loss of PRL feedback.³⁰⁵

Neural Control

Lactotrophs have spontaneously high secretory activity, and therefore the predominant effect of the hypothalamus on PRL secretion is tonic suppression, which is mediated by regulatory hormones synthesized by tuberohypophyseal neurons. Secretory bursts of PRL are caused by the acute withdrawal of dopamine inhibition, stimulation by PRFs, or combinations of both events. At any given moment, locally produced autocrine and paracrine regulators further modulate the responsiveness of individual lactotrophs to neurohormonal PIFs and PRFs.

Multiple neurotransmitter systems impinge on the hypothalamic dopamine and PRF neurons to regulate their neurosecretion (see Fig. 7-27).²⁶³ Nicotinic cholinergic and glutamatergic afferents activate TIDA neurons, whereas histamine, acting predominantly through H₂ receptors, inhibits these neurons. An inhibitory peptidergic input to TIDA neurons of major physiologic significance is that associated with the endogenous opioid peptides enkephalin and dynorphin and their cognate μ - and κ -receptor subtypes.³⁰⁶ Opioid inhibition of dopamine release has been associated with increased PRL secretion under virtually all physiologic conditions, including the basal state, different phases of the estrous cycle, lactation, and stress.

Ascending serotonergic inputs from the dorsal raphe nucleus are the major activator of PRF neurons in the PVH.³⁰⁷ There is still debate concerning the identity of the specific 5-HT receptors involved in this activation.

The PRL regulatory system and its monoaminergic control have been scrutinized in detail because of the frequent occurrence of syndromes of PRL hypersecretion (see Chapter 8). Both the pituitary and the hypothalamus have dopamine receptors, and the response to dopamine receptor stimulation and blockade does not distinguish between central and peripheral actions of the drug. Many commonly used neuroleptic drugs influence PRL secretion. Reserpine

(a catecholamine depletor) and phenothiazines such as chlorpromazine and haloperidol enhance PRL release by disinhibition of dopamine action on the pituitary, and the PRL response is an excellent predictor of the antipsychotic effects of phenothiazines because of its correlation with D₂ receptor binding and activation.³⁰⁸ The major antipsychotic neuroleptic agents act on brain dopamine receptors in the mesolimbic system and in the pituitary-regulating tuberoinfundibular system. Consequently, treatment of such patients with dopamine agonists such as bromocriptine can reverse the psychiatric benefits of these drugs. A report of three patients with psychosis and concomitant prolactinomas recommended the combination of clozapine and quina-golide as the treatment of choice to manage both diseases simultaneously.³⁰⁹

Factors Influencing Secretion

Circadian Rhythm. PRL is detectable in plasma at all times during the day but is secreted in discrete pulses superimposed on basal secretion, exhibiting a diurnal rhythm with peak values in the early morning hours.³¹⁰ In humans, this is a true circadian rhythm, because it is maintained in a constant environment independently of the sleep rhythm.³¹¹ The combined body of data examining TIDA neuronal activity, dopamine concentrations in the median eminence, and manipulations of the SCN suggests that endogenous diurnal alterations in dopamine tone that are entrained by light constitute the major neuroendocrine mechanism underlying the circadian rhythm of PRL secretion.

External Stimuli. The suckling stimulus is the most important physiologic regulator of PRL secretion. PRL levels rise within 1 to 3 minutes after nipple stimulation, and they remain elevated for 10 to 20 minutes.³¹² This reflex is distinct from the milk let-down, which involves oxytocin release from the neurohypophysis and contraction of mammary alveolar myoepithelial cells. These reflexes provide a mechanism by which the infant regulates both the production and the delivery of milk. The nocturnal rise in PRL secretion in nursing and non-nursing women may have evolved as a mechanism of milk maintenance during prolonged nonsuckling periods at night.

Pathways involved in the suckling reflex arise in the nerves innervating the nipple, enter the spinal cord by way of spinal afferent neurons, ascend the spinal cord through spinothalamic tracts to the midbrain, and enter the hypothalamus by way of the median forebrain bundle (see Fig. 7-27). Neurons regulating the oxytocin-dependent milk let-down response accompany those involved in PRL regulation throughout most of this pathway and then separate at the level of the PVH nuclei. The suckling reflex brings about an inhibition of PIF activity and a release of PRFs, although an undisputed suckling-induced PRF has not been identified.

Although their significance for PRL regulation in humans is not certain, environmental stimuli arising from seasonal changes in light duration and auditory and olfactory cues are clearly of great importance to many mammalian species.²⁶³ Seasonal breeders, such as sheep, exhibit a reduction in PRL secretion in response to shortened days. The specific ultrasound vocalization of rodent pups is among the most potent stimuli for PRL secretion in lactating and virgin female rats. Olfactory stimuli from pheromones also have potent actions in rodents. A prime example is the Bruce effect, or spontaneous abortion induced by exposure of a pregnant female rat to an unfamiliar male. It is mediated by a well-studied neural circuitry involving the

vomeroneural nerves, the corticomedial amygdala, and the medial preoptic area of the hypothalamus, which results in activation of TIDA neurons and a reduction in circulating PRL that is essential for maintenance of luteal function in the first half of pregnancy.

Stress in many forms dramatically affects PRL secretion, although the teleologic significance is uncertain. It may be related to actions of PRL on cells of the immune system or some other aspect of homeostasis. Different stressors are associated with either a reduction or an increase in PRL secretion, depending on the local regulatory environment at the time of the stress. However, whereas well-documented changes in PRL are associated with relatively severe forms of stress in laboratory animal models, a study of academic stress in college students failed to show any significant correlation of diurnal PRL levels with the time periods before, during, or after final examinations.³¹³

Gonadotropin-Releasing Hormone and Control of the Reproductive Axis

Chemistry and Evolution

GnRH is the 10-amino-acid hypothalamic neuropeptide that controls the function of the reproductive axis. It is synthesized as part of a larger precursor molecule that is enzymatically cleaved to remove a signal peptide from the N-terminus and GnRH-associated peptide (GAP) from the C-terminus (Fig. 7-28).³¹⁴ All forms of the decapeptide have a pyroGlu at the N-terminus and Gly-amide at the C-terminus, indicating the functional importance of the terminal residues throughout evolution.

Two genes encoding GnRH have been identified within mammals.^{315,316} The first, *GNRH1*, encodes a 92-amino-acid precursor protein. This is the form of GnRH that is found in hypothalamic neurons and serves as a releasing factor to regulate pituitary gonadotroph function.³¹⁷ The second GnRH gene, *GNRH2*, encodes a decapeptide that differs from the first by three amino acids.³¹⁸ This form of GnRH is found in the midbrain region and serves as a neurotransmitter rather than as a pituitary releasing factor. Both GnRH-I and GnRH-II are found in phylogenetically diverse species, from fish to mammals, suggesting that these multiple forms of GnRH diverged from one another early in vertebrate evolution.³¹⁷ A third form of GnRH, GnRH-III, has been identified in neurons of the telencephalon in teleost fish. GnRH is also found in cells outside the brain. The roles of GnRH peptides produced outside the brain are not well understood but are an area of current investigation.

All GnRH genes have the same basic structure, with the pre-prohormone mRNA encoded in four exons. Exon 1 contains the 5' untranslated region of the gene; exon 2 contains the signal peptide, GnRH, and the N-terminus of GAP; exon 3 contains the central portion of GAP; and exon 4 contains the C-terminus of GAP and the 3' untranslated region (see Fig. 7-28).³¹⁷ Among species, the nucleotide sequences encoding the GnRH decapeptide are highly homologous. This chapter focuses on the hypothalamic GnRH that is derived from *GNRH1* mRNA and plays an important role in the regulation of the hypothalamic-pituitary-gonadal axis.

Two transcriptional start sites have been identified in the rat *Gnrh1* gene, at the +1 and -579 positions, with the +1 promoter being active in hypothalamic neurons and the other promoter active in placenta. The first 173 base pairs of the promoter are highly conserved among species. In the rat, this promoter region has been shown to contain

Figure 7-28 Schematic diagram of the human gene for gonadotropin-releasing hormone I (*GNRHI*), the hypothalamic complementary DNA (cDNA), and post-translational processing of the GnRH peptide. A cluster of binding sites for the homeodomain transcription factor BRN2 is present in both the proximal promoter and a distal enhancer region and is important for neuron-specific expression of the gene. Phylogenetically conserved homologous regions have been identified in the rat GnRH-I gene, but in that species the OCT1 transcription factor has been implicated in neuron-specific expression. The cDNA for GnRH-I isolated from human placenta has a longer 5' untranslated region (UTR) because of differential splicing of the heterogeneous nuclear RNA (hnRNA) and inclusion of intron A sequences. GAP, GnRH-associated peptide; PAM, peptidylglycine α -amidating monooxygenase; TATA, Goldstein-Hogness box involved in binding RNA polymerase. (Compiled from data of Cheng CK, Leung PCK. Molecular biology of gonadotropin-releasing hormone (GnRH)-I, GnRH-II, and their receptors in humans. *Endocr Rev.* 2005;26:283-306; Wolfe A, Kim HH, Tobet S, et al. Identification of a discrete promoter region of the human GnRH gene that is sufficient for directing neuron-specific expression: a role for POU homeodomain transcription factors. *Mol Endocrinol.* 2002;16:435-449.)

two Oct1 binding sites; three regions that bind the POU domain family of transcription factors (Scip, Oct6, and Tst1); and three regions that can bind the progesterone receptor.³¹⁹ In addition, a variety of hormones and second messengers have been shown to regulate GnRH gene expression, and the majority of the *cis*-acting elements that have been characterized for hormonal control of GnRH transcription are located in the proximal promoter region.^{320,321} The 5' flanking region of the rodent and human GnRH-I genes also contain a distal 300-base-pair enhancer region that is 1.8 or 0.9 kb, respectively, upstream of the transcription start site.^{321,322} Studies have implicated the homeodomain transcription factors OCT1, MSX, and DLX in the specification of neuron expression and developmental activation.^{322,323}

Anatomic Distribution

GnRH neurons are small, diffusely located cells that are not concentrated in a discrete nucleus. They are generally bipolar and fusiform in shape, with slender axons projecting predominantly to the median eminence and infundibular stalk. The location of hypothalamic GnRH neurons is species dependent. In the rat, hypothalamic GnRH neurons are concentrated in rostral areas, including the medial preoptic area, the diagonal band of Broca, the septal areas, and the anterior hypothalamus. In humans and non-human primates, the majority of hypothalamic GnRH neurons are located more dorsally in the medial basal

hypothalamus, the infundibulum, and the periventricular region. Throughout the hypothalamus, neurohypophyseal GnRH neurons are interspersed with non-neuroendocrine GnRH neurons that extend their axons to other regions of the brain including other hypothalamic regions and various regions of the cortex. GnRH secreted from non-neuroendocrine neurons has been implicated in the control of sexual behavior in rodents but not in higher primates.³²⁴

Embryonic Development

GnRH neuroendocrine neurons are an unusual neuronal population in that they originate outside the CNS, from the epithelial tissue of the nasal placode.³²⁵ During embryonic development, GnRH neurons migrate across the surface of the brain and into the hypothalamus, with the final hypothalamic location differing somewhat among species. Migration is dependent on a scaffolding of neurons and glial cells along which the GnRH neurons move, with neural cell adhesion molecules playing a critical role in guiding the migration process. In contrast to this widely accepted view of GnRH development, more recent data have suggested an alternative embryonic origin of GnRH neurons from the anterior pituitary placode and cranial neural crest.³⁰

Failure of GnRH neurons to migrate properly leads to a clinical condition, Kallmann's syndrome, in which GnRH neuroendocrine neurons do not reach their final

destination and therefore do not stimulate pituitary gonadotropin secretion.³²⁶ Patients with Kallmann's syndrome do not enter puberty spontaneously. The X-linked form of Kallmann's syndrome results from a deficiency of the *KAL1* gene, which encodes the extracellular glycoprotein termed *anosmin-1*. Loss-of-function mutations in the fibroblast growth factor receptor type 1 gene (*FGFR1*) produce an autosomal dominant form of Kallmann's syndrome. This, together with other known genetic mutations in *FGF8*, prokinectin receptor 2 (*PROKR2*), and prokinectin 2 (*PROK2*), still account for only 30% of cases, and other lesions are yet to be characterized.³²⁷ Administration of exogenous GnRH effectively treats this form of hypothalamic hypogonadism. Patients with Kallmann's syndrome often have other congenital midline defects, including anosmia, which results from hypoplasia of the olfactory bulb and tracts.

Action at the Pituitary

Receptors. GnRH binds to a membrane receptor on pituitary gonadotrophs and stimulates synthesis and secretion of both LH and FSH. The GnRH receptor is a seven-transmembrane-domain G protein-coupled receptor, but it lacks a typical intracellular C-terminal cytoplasmic domain.³²¹ Under physiologic conditions, GnRH receptor number varies and is usually directly correlated with the gonadotropin secretory capacity of pituitary gonadotrophs. For example, across the rat estrous cycle, a rise in GnRH receptors is seen just before the surge of gonadotropins that occurs on the afternoon of proestrus. GnRH receptor message levels are regulated by a variety of hormones and second messengers, including steroid hormones (estradiol can both suppress and stimulate; progesterone suppresses), gonadotropins (which suppress), and calcium and protein kinase C (which stimulate).³²¹

G_{q/11} is the primary guanosine triphosphate-binding protein mediating GnRH responses; however, there is evidence that GnRH receptors can couple to other G proteins, including G_s and G_i.³²¹ With activation, the GnRH receptor couples to a phosphoinositide-specific phospholipase C, which leads to increases in calcium transport into gonadotrophs and calcium release from internal stores through a diacylglycerol-protein kinase C pathway. Increased calcium entry is a critical step in GnRH-stimulated release of gonadotropin secretion. However, GnRH also stimulates the MAPK cascade.

When there is a decline in GnRH stimulation to the pituitary, as occurs in a variety of physiologic conditions including states of lactation, undernutrition, or seasonal periods of reproductive quiescence, the number of GnRH receptors on pituitary gonadotrophs declines dramatically. Subsequent exposure of the pituitary to pulses of GnRH restores receptor number by a Ca²⁺-dependent mechanism that requires protein synthesis.³²⁸ The effect of GnRH to induce its own receptor is termed *upregulation* or *self-priming*. Only certain physiologic frequencies of pulsatile GnRH can augment GnRH receptor production, and these frequencies appear to differ among species.³²⁹ Upregulation of GnRH receptors after a period of low GnRH stimulation to the pituitary can take hours to days of exposure to pulsatile GnRH, depending on the duration and extent of the prior decrease in GnRH. The self-priming effect of GnRH to upregulate its own receptors also plays a crucial role in the production of the gonadotropin surge that occurs at midcycle in females of spontaneously ovulating species and triggers ovulation. Just before the gonadotropin surge, two factors—the increased frequency of pulsatile GnRH release and a sensitization of the pituitary gonadotrophs

by rising levels of estradiol—make the pituitary exquisitely sensitive to GnRH and allow an output of LH that is an order of magnitude greater than the release seen during the rest of the female reproductive cycle. This surge of LH triggers the ovulatory process at the ovary.

In contrast to upregulation of GnRH receptors by pulsatile regimens of GnRH, continuous exposure to GnRH leads to downregulation of GnRH receptors and an accompanying decrease in LH and FSH synthesis and secretion, termed *desensitization*.³³⁰ Downregulation does not require calcium mobilization or gonadotropin secretion. It involves a rapid uncoupling of receptor from G proteins and sequestration of the receptors from the plasma membrane, followed by internalization and proteolytic degradation of the receptors.

The concept of downregulation has a number of clinical applications. For example, the most common current therapy for precocious puberty of hypothalamic origin (i.e., precocious GnRH secretion) is to treat it with a long-acting GnRH “superagonist” that downregulates pituitary GnRH receptors and effectively turns off the reproductive axis.^{329,331} Children with precocious puberty can be maintained with long-acting GnRH agonists for years to suppress the premature activation of the reproductive axis, and at the normal age of puberty agonist treatment can be withdrawn, allowing reactivation of pituitary gonadotrophs and a downstream increase in gonadal steroid hormone production (also see Chapter 25). Long-acting GnRH agonists are also used in the treatment of forms of breast cancer that are estrogen dependent and of other gonadal steroid-dependent cancers.³²⁹ Long-acting antagonists of GnRH have been developed that can also be used for these therapies.³³² Antagonists have the advantage of not having a flare effect; that is, an acute stimulation of gonadotropin secretion that is seen during the initial treatment of individuals with superagonists.

Pulsatile Gonadotropin-Releasing Hormone Stimulation. Because a single pulse of GnRH stimulates the release of both LH and FSH and chronic exposure of the pituitary to pulsatile GnRH supports the synthesis of both LH and FSH, it is generally believed that there is only one releasing factor regulating the synthesis and secretion of LH and FSH. However, because there are divergent patterns of LH and FSH secretion in a number of physiologic conditions, a second FSH-releasing peptide has been proposed, but such a peptide has not been isolated to date. Other mechanisms, discussed in more detail later, are likely to account for the differential regulation of LH and FSH release.

The ensemble of GnRH neurons in the hypothalamus that send axons to the portal blood system in the median eminence fire in a coordinated, repetitive, episodic manner, producing distinct pulses of GnRH in the portal bloodstream.³³³ The pulsatile nature of GnRH stimulation of the pituitary leads to the release of distinct pulses of LH into the peripheral circulation. In experimental animals, in which it is possible to collect blood samples simultaneously from the portal and peripheral blood, GnRH and LH pulses have been found to correspond in an approximately 1:1 ratio at most physiologic rates of secretion.³³⁴ Because the portal blood stream is generally inaccessible in humans, the collection of frequent peripheral venous blood samples is used to define the pulsatile nature of LH secretion (i.e., frequency and amplitude of LH pulses), and pulsatile LH is used as an indirect measure of the activity of the GnRH secretory system. Indirect assessment of GnRH secretion by monitoring the rate of pulsatile LH secretion is also used in many animal studies examining the factors that govern

the regulation of the pulsatile activity of the reproductive neuroendocrine axis. Unlike LH secretion, FSH secretion is not always pulsatile, and even when it is pulsatile, there is only partial concordance between LH and FSH pulses.

It is possible to place multiple-unit recording electrodes in the medial basal hypothalamus of monkeys and other species and find spikes of electrical activity that are concordant with the pulsatile secretion of LH secretion.³³⁵ However, it is unknown whether these bursts of electrical activity reflect the activity of GnRH neurons themselves or the activity of neurons that impinge on GnRH neurons and govern their firing. With the development of mice in which the gene for green fluorescent protein has been put under the regulation of the GnRH promoter, it has been possible to identify GnRH neurons in hypothalamic tissue slices using fluorescence microscopy and to record from them intracellularly.¹⁴ These studies have shown that many, but not all, GnRH neurons show a bursting pattern of electrical activity. A central, unsolved question in the field of reproductive neuroendocrinology is what causes GnRH neurons to pulse in a coordinated manner. Studies using a line of clonal GnRH neurons have shown that these neurons grown in culture can release GnRH in a pulsatile pattern, suggesting that the pulse-generating capacity of GnRH neurons is intrinsic.³³⁶ The term *GnRH pulse generator* is often used to acknowledge the fact that GnRH secretion occurs in pulses and to refer to the central mechanisms responsible for pulsatile GnRH release.

A critical factor governing LH and FSH secretion is the rate of pulsatile GnRH stimulation of the gonadotrophs. Experimental studies in which the hypothalamus was lesioned and GnRH was replaced by pulsatile administration of exogenous GnRH showed that different frequencies of GnRH can lead to different ratios of LH to FSH secretion from the pituitary. Figure 7-29 shows that in a monkey with a hypothalamic lesion, replacement of one pulse of GnRH per hour led to a relatively low ratio of FSH to LH secretion. Subsequent institution of a slower pulse frequency (one pulse of GnRH every 3 hours) led to a decrease in LH secretion but an increase in FSH secretion, so that the ratio of FSH to LH secretion was greatly elevated. It is likely that this effect of pulse frequency on the ratio of FSH to LH secretion accounts, at least in part, for the clinical finding that at times when the GnRH pulse generator is just turning on, such as at the onset of puberty and during

recovery from chronic undernutrition, the ratio of FSH to LH is higher than when it is measured in adults experiencing regular reproductive function. As discussed later, steroid hormones act at both the hypothalamus and the pituitary to influence strongly the rate of pulsatile GnRH release and the amount of LH and FSH secreted from the pituitary.

GnRH pulse frequency not only influences the rate of pulsatile gonadotropin release and the ratio of FSH to LH secretion but also plays an important role in modulating the structural makeup of the gonadotropins. LH and FSH are structurally similar glycoprotein hormones. Each of these hormones is made up of an α and a β subunit. LH, FSH, and TSH share a common α -subunit, and each has a unique β subunit that conveys receptor specificity to the intact hormone. Before secretion of gonadotropins, terminal sugars are attached to each gonadotropin molecule.¹¹⁶ The sugars include sialic acid, galactose, *N*-acetylglucosamine, and mannose, but the most important is sialic acid. The extent of glycosylation of LH and FSH is important for the physiologic function of these hormones.¹¹⁶ Forms of gonadotropin with more sialic acid have a longer half-life because they are protected from degradation by the liver. Forms of gonadotropin with less sialic acid can have more potent effects at their biologic receptors. Both the rate of GnRH stimulation and ovarian hormone feedback at the level of the pituitary regulate the degree of LH and FSH glycosylation. For example, slow frequencies of GnRH release, seen during follicular development, are associated with greater degrees of FSH glycosylation, which would provide sustained FSH support to growing follicles. In contrast, faster frequencies of GnRH release, seen just before the midcycle gonadotropin surge, are associated with lesser degrees of FSH glycosylation, providing a more potent but shorter-lasting form of FSH at the time of ovulation.³³⁷

Regulatory Systems

Many neurotransmitter systems from the brain stem, limbic system, and other areas of the hypothalamus convey information to GnRH neurons (Fig. 7-30). These afferent systems include neurons that contain norepinephrine, dopamine, serotonin, GABA, glutamate, endogenous opiate peptides, NPY, galanin, and a number of other peptide neurotransmitters. Glutamate and norepinephrine play important roles in providing stimulatory drive to the

Figure 7-29 The influence of gonadotropin-releasing hormone (GnRH) pulse frequency on luteinizing hormone (LH) and follicle-stimulating hormone (FSH) secretion in a female rhesus monkey with an arcuate nucleus lesion ablating endogenous GnRH support of the pituitary. Decreasing the GnRH pulse frequency from 1 pulse every hour to 1 pulse every 3 hours led to a decrease in plasma LH concentrations but an increase in plasma FSH concentrations. (Redrawn from Wildt L, Haulser A, Marshall G, et al. Frequency and amplitude of gonadotropin-releasing hormone stimulation and gonadotropin secretion in the rhesus monkey. *Endocrinology*. 1981;109:376-385.)

Figure 7-30 Regulation of the hypothalamic-pituitary-gonadal axis. Schematic diagram of the hypothalamic-pituitary-gonadal neural systems that regulate gonadotropin-releasing hormone (GnRH) secretion and feedback of gonadal steroid hormones at the level of the hypothalamus and pituitary. reproductive axis, whereas GABA and endogenous opioid peptides provide a substantial portion of the inhibitory drive to GnRH neurons. Influences of specific neurotransmitter systems are discussed where appropriate in the following sections, which cover the physiologic regulation of GnRH neurons.

GnRH neurons are surrounded by glial processes, and only a small percentage of their surface area is available to receive dendritic contacts from afferent neurons. Changes in the steroid hormone milieu influence the degree of glial sheathing and may play important roles in regulating afferent input to GnRH neurons by this mechanism.^{43,45} Some glial cells also secrete substances including transforming growth factor-α and prostaglandin E₂ that can modulate the activity of GnRH neurons.

Feedback Regulation

Steroid hormone receptors are abundant in the hypothalamus and in many neural systems that impinge on GnRH neurons, including noradrenergic, serotonergic, β-endorphin-containing, and NPY neurons. Early studies identifying regions of the brain that bind labeled estrogens showed that in rodents the preoptic area and the VMH had the highest concentrations of estrogen receptors in the brain. Further localization studies, identifying estrogen receptors by immunocytochemistry or in situ hybridization, confirmed the strong presence of estrogen receptors in the hypothalamus and in brain areas with abundant connections to the hypothalamus, including the amygdala, septal nuclei, bed nucleus of the stria terminalis,

medial part of the nucleus of the solitary tract, and lateral portion of the parabrachial nucleus.³³⁸ In 1986, a new member of the steroid hormone receptor superfamily with high sequence homology to the classic estrogen receptor (now referred to as *estrogen receptor- α*) was isolated from rat prostate and named *estrogen receptor- β* . This novel estrogen receptor was shown to bind estradiol and to activate transcription by binding to estrogen response elements.³³⁹

In situ hybridization studies examining the localization of estrogen receptor- β mRNA have shown that these receptors are present throughout the rostral-caudal extent of the brain, with a high level of expression in the preoptic area, bed nucleus of the stria terminalis, PVH and SON nuclei, amygdala, and laminae II to VI of the cerebral cortex.³⁴⁰ Specific receptors for progesterone are induced by estrogen in hypothalamic regions of the brain, including the preoptic area, the ventromedial and ventrolateral nuclei, and the infundibular-arcuate nucleus, although there is also evidence for constitutive expression of progesterone receptors in some regions.³⁴¹ Androgen receptor mapping studies have shown considerable overlap in the distribution of androgen and estrogen receptors throughout the brain. The highest density of androgen receptors was found in hypothalamic nuclei known to participate in the control of reproduction and sexual behaviors, including the arcuate nucleus, PVH, medial preoptic nucleus, ventromedial nucleus, and brain regions with strong connections to the hypothalamus including the amygdala, nuclei of the septal region, bed nucleus of the stria terminalis, nucleus of the solitary tract, and lateral division of the parabrachial nucleus.³³⁸ The anterior pituitary also contains receptors for all of the gonadal steroid hormones.

Steroid hormones can dramatically alter the pattern of pulsatile release of GnRH and of the gonadotropins through actions at both the hypothalamus and the pituitary. At the hypothalamus, estradiol, progesterone, and testosterone can all act to slow the frequency of GnRH release into the portal bloodstream as part of a closed negative feedback loop.³⁴² Because GnRH neurons have generally been shown to lack steroid hormone receptors, it is likely that the effects of steroid hormones on the firing rate of GnRH neurons are mediated by steroid hormone actions on other neural systems that provide afferent input to GnRH neurons. For example, progesterone-mediated negative feedback on GnRH secretion in primates appears to be regulated by β -endorphin-containing neurons in the hypothalamus, acting primarily through μ -opioid receptors. If a μ -receptor antagonist, such as naloxone, is administered along with progesterone, the negative feedback action of progesterone on GnRH secretion can be blocked.

Negative feedback of steroid hormones can also occur directly at the level of the pituitary. For example, estradiol has been shown to be capable of binding to the pituitary, decreasing LH and FSH synthesis and release, and decreasing the sensitivity of pituitary gonadotrophs to the actions of GnRH so that less LH and FSH are released when a pulse of GnRH stimulates the pituitary. Evidence for such a direct pituitary action of estradiol came from studies with rhesus monkeys that had been rendered deficient in endogenous GnRH by a lesion in the arcuate nucleus and showed a decline in endogenous gonadotropin secretion. When these monkeys received a pulsatile regimen of GnRH gonadotropin secretion, subsequent estradiol infusions dramatically suppressed the responsiveness of the pituitary to GnRH and suppressed the gonadotropin secretion that was being driven by the pulsatile administration of GnRH.³⁴³ Similarly, in a compound mutant mouse model on a GnRH-deficient (*hpg*) genetic background, expression

of a human FSH- β transgene was inhibited by testosterone directly at the pituitary level.³⁴⁴ In primate species including humans, there is considerable feedback of estradiol at the pituitary, but most of the progesterone- and testosterone-negative feedback occurs at the level of the hypothalamus.³⁴²

Most of the time, the hypothalamic-pituitary axis is under the negative feedback influence of gonadal steroid hormones. If the gonads are removed surgically or their normal secretion of steroid hormones is suppressed pharmacologically, there is a dramatic increase (10-fold to 20-fold) in circulating levels of LH and FSH secretion.³⁴² This type of "castration response" occurs normally at menopause in women, when ovarian follicular development and, therefore, ovarian production of large quantities of estradiol and progesterone decrease and eventually cease.

In addition to negative feedback, estradiol can have a positive feedback action at the level of the hypothalamus and pituitary leading to a massive release of LH and FSH from the pituitary. This massive release of gonadotropins occurs once each menstrual cycle and is referred to as the *LH-FSH surge*. The positive feedback action of estradiol occurs as a response to the rising tide of estradiol that is produced during the process of dominant follicle development in the late follicular phase of the menstrual cycle. In women, elevated estradiol levels are typically maintained at about 300 to 500 pg/mL for approximately 36 hours before the stimulation of the gonadotropin surge.

Experiments have shown that both a critical concentration and a critical duration of elevated estradiol are necessary to achieve positive feedback and a resulting gonadotropin surge. If supraphysiologic doses of estradiol are administered, the surge can occur as early as 18 hours after their administration. Because the ovary is responsible for the production of estradiol and the time course and magnitude of estradiol release control the rate of positive feedback, the ovary has been referred to as the *zeitgeber* of the menstrual cycle. The dependence of the positive feedback system on the magnitude of estradiol production helps explain the fact that the portion of the menstrual cycle that varies most in length is the follicular phase. Production of higher levels of estradiol by a dominant follicle in one cycle leads to a more rapid positive feedback action, with earlier ovulation and therefore a shorter follicular phase, compared with a cycle in which the dominant follicle produced lower levels of estradiol.

As with negative feedback in response to estradiol, the positive feedback actions of estradiol occur both at the hypothalamus, to increase GnRH secretion, and at the pituitary, to greatly enhance pituitary responsiveness to GnRH. Estradiol increases pituitary sensitivity to GnRH by increasing the synthesis of new GnRH receptors and by enhancing the responsiveness to GnRH at a postreceptor site of action. At the level of the hypothalamus in rodent species, estradiol appears to act at a "surge center" to induce the ovulatory surge of GnRH. Lesions in areas adjacent to the medial preoptic area, near the anterior commissure and septal complex, block the ability of estradiol to induce a surge in these species without blocking negative feedback effects of estradiol.³⁴⁵ In primate species, there does not appear to be a separate surge center mediating the positive feedback actions of estradiol.

Cellular mechanisms that mediate the switch from negative to positive feedback of estrogen are not fully understood, but there is support for the concept that estrogen induction of various transcription factors and receptors (notably progesterone receptors) may play an important

role in mediating this switch.³⁴⁶ The recent isolation of a novel mammalian RFamide peptide, named *kisspeptin* or *metastin*, that is the natural ligand for the former orphan G protein-coupled receptor GPR54 has shed considerable light on this area.²⁹⁴ Loss-of-function mutations in GPR54 (now termed *KISSR*) cause HH. Kisspeptin is expressed in subpopulations of arcuate and anteroventral periventricular (AVPV) neurons that project to GnRH neurons. Kisspeptin expression is regulated by estradiol and testosterone and is upregulated at the time of puberty, and intracerebroventricular administration of kisspeptin causes the secretion of GnRH and gonadotropins.^{347,348} Furthermore, kisspeptin expression in the AVPV, but not in the arcuate nucleus, is sexually diergic, with a much greater number of kisspeptin neurons in the female. This particular subpopulation of kisspeptin neurons is activated in an estrogen-dependent manner immediately preceding the GnRH surge, as detected by Fos expression, and is postulated to play a key role in the positive feedback effects of estradiol on GnRH release.³⁴⁹

Regulation of the Ovarian Cycle

Cyclic activity in the ovary is controlled by an interplay between steroid hormones produced by the ovary and the hypothalamic-pituitary neuroendocrine components of the reproductive axis. The duration of each phase of the ovarian cycle is species dependent, but the general mechanisms controlling the cycle are similar in all species that

have spontaneous ovarian cycles. In the human menstrual cycle, day 1 is designated as the first day of menstrual bleeding. At this time, small and medium-sized follicles are present in the ovaries and only small amounts of estradiol are being produced by the follicular cells. As a result, there is a low level of negative feedback to the hypothalamic-pituitary axis, LH pulse frequency is relatively fast (one pulse about every 60 minutes), and FSH concentrations are slightly elevated compared with much of the rest of the cycle (Fig. 7-31). FSH acts at the level of the ovarian follicles to stimulate development and causes an increase in follicular estradiol production, which in turn provides increased negative feedback to the hypothalamic-pituitary unit.

A result of the increased negative feedback is a slowing of pulsatile LH secretion over the course of the follicular phase, to a rate of about one pulse every 90 minutes. However, as the growing follicle (or follicles, depending on the species) secretes more estradiol, a positive feedback action of estradiol is triggered and leads to an increase in GnRH release and a surge release of LH and FSH. The surge of gonadotropins acts at the fully developed follicle to stimulate dissolution of the follicular wall, leading to ovulation of the matured ovum into the nearby fallopian tube, where fertilization takes place if sperm are present. Ovulation results in a reorganization of the cells of the follicular wall, which undergo hypertrophy and hyperplasia and start to secrete large amounts of progesterone and some

Figure 7-31 Diagrammatic representation of changes in plasma levels of estradiol, progesterone, luteinizing hormone (LH), and follicle-stimulating hormone (FSH) and in portal levels of gonadotropin-releasing hormone (GnRH) over the human menstrual cycle.

estradiol. Progesterone and estradiol have a negative feedback effect at the level of the hypothalamus and pituitary, so the LH pulse frequency becomes very slow during the luteal phase of the menstrual cycle. The corpus luteum has a fixed life span, and without additional stimulation in the form of chorionic gonadotropin from a developing embryo, the corpus luteum regresses spontaneously after about 14 days and secretion of progesterone and estradiol diminishes. This reduces the negative feedback signals to the hypothalamus and pituitary and allows an increase in FSH and LH secretion. The fall in progesterone is also a withdrawal of steroid hormone support to the endometrial lining of the uterus; as a result, the endometrium is shed as menses, and a new cycle begins.

In other species, the interplay between the neuroendocrine and ovarian hormones is similar but the timing of events is different and other factors, such as circadian and seasonal regulatory factors, play a role in regulating the cycle. The rat has a 4- or 5-day ovarian cycle with no menses (the endometrial lining is absorbed rather than shed). The rat also shows strong circadian rhythmicity in the timing of the LH-FSH surge, with the surge always occurring in the afternoon of the day of proestrus. The sheep is an example of a species that has a strongly seasonal pattern of ovarian cyclicity. During the breeding season, sheep have 15-day cycles, with a very short follicular phase and an extended luteal phase; during the non-breeding season, signals relaying information about day length through the visual system, pineal, and SCN cause a dramatic suppression of GnRH neuronal activity, and cyclic ovarian function is prevented by a decrease in trophic hormonal support from the pituitary.

Early Development and Puberty

Neuroendocrine stimulation of the reproductive axis is initiated during fetal development, and in primates in mid-gestation circulating levels of LH and FSH reach values similar to those in castrated adults.³⁵⁰ Later in gestational development, gonadotropin levels decline, restrained by rising levels of circulating gonadal steroids. The steroids that have this effect are probably placental in origin, because after parturition there is a rise in circulating gonadotropin levels that is apparent for a variable period in the first year of life, depending on the species.³⁵¹ The decline in reproductive hormone secretion in the postnatal period appears to be caused by a decrease in GnRH stimulation of the reproductive axis because it occurs even in the castrate state and because gonadotropin and gonadal steroid secretion can be supported by administration of pulses of GnRH.³⁵²

Pubertal reawakening of the reproductive axis occurs in late childhood and is marked initially by nighttime elevations in gonadotropin and gonadal steroid hormone levels.^{352,353} The mechanisms controlling the pubertal reawakening of the GnRH pulse generator have been an area of intense investigation for more than 2 decades.³⁵² Although the mechanisms are not fully understood, significant progress has been made in identifying central changes in the hypothalamus that appear to play a role in this process. At puberty, there is both a decrease in transsynaptic inhibition to the GnRH neuronal system and an increase in stimulatory input to GnRH neurons.³⁵² One of the major inhibitory inputs to the GnRH system is provided by GABAergic neurons. Studies in rhesus monkeys have shown that hypothalamic levels of GABA decrease during early puberty and that blocking the GABAergic input before puberty, by intrahypothalamic administration of antisense oligodeoxynucleotides against the enzymes responsible for

GABA synthesis, results in premature activation of the GnRH neuronal system.

It has been suggested, on the basis of findings that a subset of glutamate receptors (i.e., kainate receptors) increase in the hypothalamus at puberty, that the pubertal decrease in GABA tone may be caused by an increase in glutamatergic transmission. Further evidence pointing to a role for glutamate comes from studies showing that administration of *N*-methyl-D-aspartic acid (NMDA) to prepubertal rhesus monkeys can drive the reawakening of the reproductive axis.³⁵⁴ Increased stimulatory drive to the GnRH neuronal system also appears to come from increases in norepinephrine and NPY at the time of puberty.³⁵² Furthermore, as discussed earlier, there is evidence that growth factors act through release of prostaglandin from glial cells at puberty to play a role in stimulating GnRH neurons.³⁵⁵

Despite an increased understanding of the neural changes occurring at puberty, the question of what signals trigger the pubertal awakening of the reproductive axis is unanswered at this time.³⁵⁶ However, the kisspeptin neuron system (described earlier) has become a prime integrative candidate for this function.³⁴⁹ Also relevant to pubertal onset was the discovery of galanin-like peptide (GALP), which is expressed specifically in the arcuate nucleus and binds with high affinity to galanin receptors. GALP is a potent central stimulator of gonadotropin release and sexual behavior in the rat and can reverse the decreased reproductive function associated with diabetes mellitus and hypoinsulinemia.³⁵⁷ Both kisspeptin and GALP neurons are targets of leptin and are hypothesized to be involved in the well-known modulation of puberty and reproductive function by food availability and nutritional status (described in the next section).

Reproductive Function and Stress

Many forms of physical stresses, such as energy restriction, exercise, temperature stress, infection, pain, and injury, as well as psychological stresses, such as being subordinate in a dominance hierarchy or being acutely psychologically stressed, can suppress the activity of the reproductive axis.³⁵⁸ If the stress exposure is brief, there may be acute suppression of circulating gonadotropins and gonadal steroid hormones; in females, normal menstrual cyclicity may be disrupted, but fertility is unlikely to be impaired.³⁵⁸ In contrast, prolonged periods of significant stress exposure can lead to complete impairment of reproductive function, also characterized by low circulating levels of gonadotropins and gonadal steroids. Stress appears to decrease the activity of the reproductive axis by decreasing GnRH drive to the pituitary, because in all cases in which it has been examined, administration of exogenous GnRH can reverse the effects of the stress-induced decline in reproductive hormone secretion. Although the neural circuits through which many forms of stress suppress GnRH neuronal activity are not known, some forms of stress-induced suppression of reproductive function are better understood.

In the case of foot-shock stress in rats³⁵⁹ or immune stress (i.e., injection of IL-1 α) in primates,³⁶⁰ the suppression of gonadotropin secretion that occurs was shown to be reversible by administration of a CRH antagonist, implying that endogenous CRH secretion mediates the effects of these stresses on GnRH neurons. In other studies, naloxone, a μ -opioid receptor antagonist, was shown to be capable of reversing restraint stress-induced suppression of gonadotropin secretion in monkeys; however, naloxone was ineffective in reversing the suppression of gonadotropin secretion that occurs during insulin-induced hypoglycemia.^{361,362} In the case of metabolic stresses, multiple

regulators appear to mediate changes in the neural drive to the reproductive axis.

Various metabolic fuels including glucose and fatty acids can regulate the function of the reproductive axis, and blocking cellular utilization of these fuels can lead to suppression of gonadotropin secretion and decreased gonadal activity. Leptin, a hormone produced by fat cells, can also modulate the activity of the reproductive axis. Mutant *ob/ob* mice that are deficient in leptin or leptin receptors are infertile, and fertility can be restored by administration of leptin.³⁶³ Moreover, leptin administration has been shown to reverse the suppressive effects of undernutrition on the reproductive axis in some situations.³⁶⁴ Leptin receptors are found in several cell populations that are known to have a strong influence on the reproductive axis, particularly NPY and kisspeptin neurons.³⁴⁹

In summary, it appears that a number of neural circuits can mediate effects of stress on the GnRH neuronal system

and that the neural systems involved are at least somewhat specific to the type of stress that is experienced.

NEUROENDOCRINE DISEASE

Disease of the hypothalamus can cause pituitary dysfunction, neuropsychiatric and behavioral disorders, and disturbances of autonomic and metabolic regulation. In the diagnosis and treatment of suspected hypothalamic or pituitary disease, four issues must be considered: the extent of the lesion, the physiologic impact, the specific cause, and the psychosocial setting. The etiology of hypothalamic neuroendocrine disorders categorized by age and syndrome is summarized in Tables 7-7 and 7-8.

Manifestations of pituitary insufficiency secondary to hypothalamic or pituitary stalk damage are not identical to those of primary pituitary insufficiency. Hypothalamic injury causes decreased secretion of most pituitary

TABLE 7-7

Etiology of Hypothalamic Disease by Age

Premature Infants and Neonates	10 to 25 yr
Intraventricular hemorrhage Meningitis: bacterial Tumors: glioma, hemangioma Trauma Hydrocephalus, kernicterus	Tumors Craniopharyngioma Glioma, hamartoma, dysgerminoma Histiocytosis X, leukemia Dermoid, lipoma, neuroblastoma Trauma Vascular Subarachnoid hemorrhage Aneurysm Arteriovenous malformation Inflammatory disease Meningitis Encephalitis Sarcoidosis Tuberculosis Structural brain defect Chronic hydrocephalus Increased intracranial pressure
1 mo to 2 yr	25 to 50 yr
Tumors Glioma, especially optic glioma Histiocytosis X Hemangioma Hydrocephalus Meningitis Familial disorders Laurence-Moon-Biedl syndrome Prader-Willi syndrome	Nutritional: Wernicke's disease Tumors Glioma, lymphoma, meningioma Craniopharyngioma, pituitary tumors Angioma, plasmacytoma, colloid cysts Ependymoma, sarcoma, histiocytosis X Inflammatory disease Sarcoidosis Tuberculosis, viral encephalitis Vascular Aneurysm, subarachnoid hemorrhage Arteriovenous malformation Damage from pituitary radiation therapy
2 to 10 yr	50 yr and Older
Neoplasms Craniopharyngioma Glioma, dysgerminoma, hamartoma Histiocytosis X, leukemia Ganglioneuroma, ependymoma Medulloblastoma Meningitis Bacterial meningitis Tuberculous meningitis Encephalitis Viral Exanthematous demyelinating Familial Diabetes insipidus Radiation therapy Diabetic ketoacidosis Moyamoya disease, circle of Willis	Nutritional: Wernicke's disease Tumors: pituitary tumors, sarcoma, glioblastoma, ependymoma, meningioma, colloid cysts, lymphoma Vascular disease Infarct, subarachnoid hemorrhage Pituitary apoplexy Inflammatory disease: encephalitis, sarcoidosis, meningitis Damage from radiation therapy for ear-nose-throat carcinoma, pituitary tumors

TABLE 7-8

Etiology of Endocrine Syndromes of Hypothalamic Origin**Hypophyseotropic Hormone Deficiency**

Surgical pituitary stalk section
 Inflammatory disease: basilar meningitis and granuloma, sarcoidosis, tuberculosis, sphenoid osteomyelitis, eosinophilic granuloma
 Craniopharyngioma
 Hypothalamic tumor: infundibuloma; teratoma (ectopic pinealoma); neuroglial tumor; particularly astrocytoma
 Maternal deprivation syndrome, psychosocial dwarfism
 Isolated GHRH deficiency
 Hypothalamic hypothyroidism
 Panhypophyseotropic failure

Disorders of Regulation of GnRH Secretion**Female**

Precocious puberty: GnRH-secreting hamartoma, hCG-secreting germinoma
 Delayed puberty
 Neurogenic amenorrhea
 Pseudocyesis
 Anorexia nervosa
 "Functional" amenorrhea and oligomenorrhea
 Drug-induced amenorrhea

Male

Precocious puberty
 Fröhlich's syndrome
 Olfactory-genital dysplasia (Kallmann's syndrome)

Disorders of Regulation of Prolactin-Regulating Factors

Tumor
 Sarcoidosis
 Drug-induced
 Reflex
 Herpes zoster of chest wall
 Post-thoracotomy
 Nipple manipulation
 Spinal cord tumor
 "Psychogenic"
 Hypothyroidism
 Carbon dioxide narcosis

Disorders of Regulation of CRH

Paroxysmal corticotropin discharge (Wolff's syndrome)
 Loss of circadian variation
 Depression
 CRH-secreting gangliocytoma

CRH, corticotropin-releasing hormone; hCG, human chorionic gonadotropin; GHRH, growth hormone-releasing hormone; GnRH, gonadotropin-releasing hormone.

hormones but can cause hypersecretion of hormones that are normally under inhibitory control by the hypothalamus, as in hypersecretion of PRL after damage to the pituitary stalk and precocious puberty caused by loss of the normal restraint over gonadotropin maturation. Impairment of inhibitory control of the neurohypophysis can lead to the syndrome of inappropriate vasopressin secretion (SIADH) (see Chapter 10). More subtle abnormalities in secretion can result from impairment of the control system. For example, loss of the normal circadian rhythm of ACTH secretion may occur before loss of pituitary-adrenal secretory reserve, and responses to physiologic stimuli may be paradoxical. Because hypophyseotropic hormone levels cannot be measured directly and pituitary hormone secretion is regulated by complex, multilayered controls, assay of pituitary hormones in blood does not necessarily give a

meaningful picture of events at hypothalamic and higher levels. Rarely, tumors secrete excessive amounts of releasing peptides and cause hypersecretion of hormones from the pituitary.

Disorders of the hypothalamic-pituitary unit can result from lesions at several levels. Defects can arise from destruction of the pituitary (as by tumor, infarct, inflammation, or autoimmune disease) or from a hereditary deficiency of a particular hormone (as in rare cases of isolated FSH, GH, or POMC deficiency). Selective loss of thyroid hormone receptors in the pituitary can give rise to increased TSH secretion and thyrotoxicosis. Furthermore, disorders can arise through disruption of the contact zone of the stalk and median eminence, the stalk itself, or the nerve terminals of the tuberohypophyseal system; such disruption occurs after surgical stalk section, with tumors involving the stalk, and in some inflammatory diseases. At a higher level, tonic inhibitory and excitatory inputs can be lost; this is manifested by absence of circadian rhythms or by the development of precocious puberty. Physical stress, cytokine products of inflammatory cells, toxins, and reflex inputs from peripheral homeostatic monitors also impinge on the tuberoinfundibular system. At the highest level of control, emotional stress and psychological disorders can activate the pituitary-adrenal stress response and suppress gonadotropin secretion (e.g., psychogenic amenorrhea) or inhibit GH secretion (e.g., psychosocial dwarfism) (see Chapter 17). Intrinsic disease of the anterior pituitary is reviewed in Chapter 8, and disturbances in neurohypophyseal function are discussed in Chapter 10. This chapter considers primarily diseases of the hypothalamic-pituitary unit.

Pituitary Isolation Syndrome

Destructive lesions of the pituitary stalk, such as may occur with head injury, surgical transection, tumor, or granuloma, produce a characteristic pattern of pituitary dysfunction.³⁶⁵⁻³⁶⁷ Central diabetes insipidus (DI) develops in a large percentage of patients, depending on the level at which the stalk has been sectioned. If the cut is close to the hypothalamus, DI is almost always produced, but if the section is low on the stalk, the incidence is lower. The extent to which nerve terminals in the upper stalk are preserved determines the clinical course. The classic triphasic syndrome of initial polyuria followed by normal water control and then by AVP deficiency over a period of 1 week to 10 days occurs in fewer than half of the patients. The sequence is attributed to an initial loss of neurogenic control of the neural lobe, followed by autolysis of the neural lobe with release of AVP into the circulation and finally by complete loss of AVP. However, full expression of polyuria requires adequate cortisol levels; if cortisol is deficient, AVP deficiency may be present with only minimal polyuria. DI can also develop after stalk injury without an overt transitional phase. When DI occurs after head injury or operative trauma, varying degrees of recovery can be seen even after months or years. Sprouting of nerve terminals in the stump of the pituitary stalk may give rise to sufficient functioning tissue to maintain water balance. In contrast to the effects of stalk section, nondestructive injury to the neurohypophysis or stalk, such as during surgical resection of optic chiasmatic astrocytomas, can sometimes give rise to transient SIADH.³⁶⁸

Although head injury, granulomas, and tumors are the most common causes of acquired DI, other cases develop in the absence of a clearcut cause.³⁶⁹ Autoimmune disease of the hypothalamus may be the cause in some instances, as was suggested by the finding of autoantibodies to

neurohypophyseal cells in one third of patients with “idiopathic” DI in one series.³⁷⁰ However, autoantibodies were also frequently found in association with histiocytosis X. Later reports suggested the importance of continued vigilance in cases of idiopathic DI. A definite cause is frequently uncovered in time, including a high proportion of occult germinomas, whose detection by MRI may be preceded by elevated levels of human chorionic gonadotropin (hCG) in CSF.^{371,372} Congenital DI can be part of a hereditary disease. DI in the Brattleboro rat is caused by an autosomal recessive genetic defect that impairs production of AVP but not of oxytocin. In contrast, inherited forms of DI in humans have been attributed to mutations in the vasopressin V₂ receptor gene or, less frequently, in the aquaporin or the AVP gene.³⁷³⁻³⁷⁶

Menstrual cycles cease after stalk section, although gonadotropins may still be detectable, unlike the situation after hypophysectomy. Plasma glucocorticoid levels and urinary excretion of cortisol and 17-hydroxycorticoids decline after hypophysectomy and stalk section, but the change is slower after stalk section. A transient increase in cortisol secretion after stalk section is believed to result from the release of ACTH from preformed stores. The ACTH response to the lowering of blood cortisol is markedly reduced, but ACTH release after stress may be normal, possibly because of CRH-independent mechanisms. Reduction in thyroid function after stalk section is similar to that seen with hypophysectomy. The fall in GH secretion is said to be the most sensitive indication of damage to the stalk; however, the insidious nature of this endocrinologic change in adults who have suffered traumatic brain injury may cause it to be overlooked and therefore contribute to delayed rehabilitation.³⁷⁷

Humans with stalk sections or tumors of the stalk region have widely varying levels of hyperprolactinemia and may have galactorrhea.³⁷⁸ PRL responses to hypoglycemia and to TRH are blunted, in part because of loss of neural connections with the hypothalamus. PRL responses to dopamine agonists and antagonists in patients with pituitary isolation syndrome are similar to those in patients with prolactinomas. Interestingly, PRL secretion continues to show a diurnal variation in patients with either hypothalamopituitary disconnection or microprolactinoma.³¹⁰ Both forms of hyperprolactinemia are characterized by a similarly increased frequency of PRL pulses and a marked rise in nonpulsatile or basal PRL secretion, although the disruption is greater in the tumoral hyperprolactinemia.

An incomplete pituitary isolation syndrome may occur with the empty sella syndrome, intrasellar cysts, or pituitary adenomas.³⁷⁹⁻³⁸¹ Anterior pituitary failure after stalk section is in part due to loss of specific neural and vascular links to the hypothalamus and in part to pituitary infarction.

Hypophyseotropic Hormone Deficiency

Selective pituitary failure can be caused by a deficiency of specific pituitary cell types or a deficiency of one or more hypothalamic hormones. Isolated GnRH deficiency is the most common hypophyseotropic hormone deficiency. In Kallmann's syndrome (gonadotropin deficiency commonly associated with hyposmia),³²⁶ hereditary agenesis of the olfactory lobe may be demonstrable by MRI.³⁸² Abnormal development of the GnRH system is a result of defective migration of the GnRH-containing neurons from the olfactory nasal epithelium in early embryologic life (see earlier discussion). Other malformations of the cranial midline structures, such as absence of the septum pellucidum in

septo-optic dysplasia (De Morsier's syndrome), can cause HH or, less commonly, precocious puberty. A surprisingly large percentage of children with septo-optic dysplasia who otherwise have multiple hypothalamic-pituitary abnormalities actually retain normal gonadotropin function and enter puberty spontaneously.³⁸³ The genetic basis of HH, including Kallmann's syndrome, has now been established in approximately 15% of patients.^{327,384} Mutations in *KAL1*, the Kallmann's syndrome gene, and in *NROB1* (formerly *AHC* or *DAX1*), the gene that causes adrenal hypoplasia congenita with hypogonadotropic hypogonadism, produce X-linked recessive disease. Autosomal recessive HH has been associated with mutations in the genes encoding the GnRH receptor, *KISS1* (metastin) receptor, leptin, leptin receptor, FSH, LH, *PROP1* (combined pituitary deficiency), and *HESX1* (septo-optic dysplasia), and deficient *FGFR1* function causes an autosomal dominant form of HH. Mutations in *PROK2* and *PROKR2*, which encode prokineticin 2 and its receptor, have been associated with heterozygous, homozygous, compound heterozygous, and oligogenic patterns of genetic penetrance.

The GnRH response test is of little value in the differential diagnosis of HH. Most patients with GnRH deficiency show little or no response to an initial test dose but normal responses after repeated injection. This slow response has been attributed to downregulation of GnRH receptors in response to prolonged GnRH deficiency. In patients with intrinsic pituitary disease, the response to GnRH may be absent or normal. Consequently, it is not possible to distinguish between hypothalamic and pituitary disease with a single injection of GnRH. Prolonged infusions or repeated administration of GnRH agonists after hormone replacement therapy priming may aid in the diagnosis or provide therapeutic options for women with Kallmann's syndrome who wish to become pregnant.^{385,386}

Deficiency of TRH secretion gives rise to hypothalamic hypothyroidism, also called *tertiary hypothyroidism*, which can occur in hypothalamic disease or, more rarely, as an isolated defect.³⁸⁷ Molecular genetic analyses have revealed infrequent autosomal recessive mutations in the TRH and TRH receptor genes in the etiology of central hypothyroidism.³⁸⁸ Hypothalamic and pituitary causes of TSH deficiency are most readily distinguished by imaging methods. Although it is theoretically reasonable to use the TRH stimulation test for the differentiation of hypothalamic disease from pituitary disease, it is of limited value. The typical pituitary response to TRH administration in patients with TRH deficiency is an enhanced and somewhat delayed peak, whereas the response with pituitary failure is subnormal or absent. The hypothalamic type of response has been attributed to an associated GH deficiency that sensitizes the pituitary to TRH (possibly through suppression of somatostatin secretion), but GH also affects T₄ metabolism and may alter pituitary responses as well.³⁸⁹ In practice, the responses to TRH in hypothalamic and pituitary disease overlap so much that this test cannot be used reliably for a differential diagnosis. Persistent failure to demonstrate responses to TRH is good evidence for the presence of intrinsic pituitary disease, but the presence of a response does not mean that the pituitary is normal. Deficient TRH secretion leads to altered TSH biosynthesis by the pituitary, including impaired glycosylation. Poorly glycosylated TSH has low biologic activity, and dissociation of bioactive and immunoreactive TSH can lead to the paradox of normal or elevated levels of TSH in hypothalamic hypothyroidism.^{387,390}

GHRH deficiency appears to be the principal cause of hGH deficiency in children with idiopathic dwarfism.³⁹¹

This condition is frequently associated with abnormal electroencephalograms, a history of birth trauma, and breech delivery, although a cause-and-effect relationship has not been established. MRI scans show that most children with isolated, idiopathic hGH deficiency have a normal sized or only slightly reduced anterior pituitary; less common findings are ectopic posterior pituitary, anterior pituitary hypoplasia, or empty sella.³⁹² In contrast, children with idiopathic combined pituitary hormone deficiency are significantly more likely to have evidence of moderate to severe anterior pituitary hypoplasia, ectopic posterior pituitary, complete agenesis of the pituitary stalk (both nervous and vascular components), and a variety of associated midline cerebral malformations.³⁹² Human GH is the most vulnerable of the anterior pituitary hormones when the pituitary stalk is damaged. It can be difficult to differentiate between primary pituitary disease and GHRH deficiency by standard tests of GH reserve. However, a substantial GH secretory response to a single administration of hexarelin occurs only in the presence of at least a partially intact vascular stalk (Fig. 7-32).²¹⁷

In many children with dwarfism, the anatomic abnormalities of the intrasellar contents and pituitary stalk, together with the frequent occurrence of other midline defects, such as those observed in septo-optic dysplasia, are consistent with the alternative hypothesis of a developmental defect occurring in embryogenesis.³⁹² There has been a remarkable advance in understanding of the molecular ontogeny of the hypothalamic-pituitary unit, much of it based on mutant mouse models.²⁷ Parallel genetic analyses have been conducted in children with isolated GH deficiency or combined pituitary hormone deficiencies. These studies have identified autosomal recessive mutations in structural and regulatory genes including the genes encoding the GHRH receptor, PIT1, PROP1, HESX1, LHX3, and LHX4 that are responsible for a sizable proportion of congenital hypothalamic-pituitary disorders once considered idiopathic.^{206,207,391,392}

Adrenal insufficiency is another manifestation of hypothalamic disease and rarely is caused by CRH deficiency.³⁹³ Isolated ACTH deficiency is uncommon, but there is suggestive evidence in at least one family of genetic linkage to the *CRH* gene locus.³⁹⁴ More recent investigations have revealed mutations in *TBX19*, the gene encoding TPIT, a T-box transcription factor expressed only in pituitary corticotrophs and melanotrophs, which is associated with the majority of cases of isolated ACTH deficiency in neonates.³⁹⁵ The CRH stimulation test does not reliably distinguish hypothalamic from pituitary failure as a cause of ACTH deficiency.³⁹⁶

Apart from intrinsic diseases of the hypothalamus such as tumors and granulomas, two environmental causes of central hypophyseotropic deficiencies are of increasing clinical importance: trauma to the brain,^{366,367,377} particularly from motor vehicle accidents, and the sequelae of chemotherapy and radiation therapy for intracranial lesions in children and adults.^{390,397,398} Improved short-term survival from head injuries associated with coma and CNS malignancies has greatly increased the prevalence of long-term neuroendocrine consequences.

Craniopharyngioma

Craniopharyngioma is the most common pediatric tumor occurring in the sellar and parasellar area (see Table 7-7). Because of their location, these benign neoplasms frequently cause significant neuroendocrine dysfunction. The more common adamantinomatous tumors in children

Figure 7-32 Effect of hypothalamic-pituitary disconnection on the growth hormone (GH) secretory responses to growth hormone–releasing hormone (GHRH) (1 μg/kg) and hexarelin (2 μg/kg) administered intravenously to children with GH deficiency. *Top*, Mean responses in a group of 24 prepubertal children with short stature secondary to familial short stature or constitutional growth delay are shown. *Middle*, Children with GH deficiency and an intact vascular pituitary stalk as visualized by dynamic magnetic resonance imaging exhibited a clear, but blunted, GH response to both secretagogues. *Bottom*, In contrast, children with pituitary stalk agenesis (both vascular and neural components) had no response or a markedly attenuated response to both peptides. (From Maghnie M, Spica-Russotto V, Cappa M, et al. The growth hormone response to hexarelin in patients with different hypothalamic-pituitary abnormalities. *J Clin Endocrinol Metab.* 1998;83: 3886-3889.)

usually contain both a cystic component filled with a turbid, cholesterol-rich fluid and a solid component characterized by organized epithelial cells.³⁹⁹ Roughly 25% of craniopharyngiomas are diagnosed in patients after the age of 25 years, and this subset of tumors is more typically papillary in nature, solid, and less likely to be calcified or cystic.³⁹⁹ Both forms of craniopharyngioma probably result from metaplastic changes in vestigial epithelial cell rests

that originate in Rathke's pouch and the craniopharyngeal duct during fetal development.

Common presenting symptoms are those resulting from a mass intracranial lesion and increased intracranial pressure. Visual field defects, papilledema, and optic atrophy can occur from compression of the optic chiasm or nerves. Between 80% and 90% of affected children have signs and symptoms of endocrine dysfunction, although these are not usually the chief complaint. The most frequent hormone deficiencies are GH and gonadotropins. The latter is almost universal in adolescents and adults and probably is also present, but undetected, in prepubertal children with craniopharyngioma. TSH and ACTH deficiencies are also common. Even if not present at initial diagnosis, endocrine dysfunction often occurs subsequent to treatment and necessitates long-term follow-up and retesting.⁴⁰⁰

MRI is the imaging modality of choice in cases of suspected craniopharyngioma.⁴⁰¹ A recommended examination includes T1-weighted thin sagittal and coronal sections, obtained before and after contrast administration, through the sella and suprasellar regions. T2-weighted and fluid attenuation inversion recovery (FLAIR) images are useful to further delineate cysts and are hyperintense. Computed tomography scans can be useful to determine the presence of calcification.

Hypophyseotropic Hormone Hypersecretion

Pituitary hypersecretion is occasionally caused by tumors of the hypothalamus. GnRH-secreting hamartomas can cause precocious puberty.⁴⁰² CRH-secreting gangliocytomas can cause Cushing's syndrome,⁴⁰³ and GHRH-secreting gangliocytomas of the hypothalamus can cause acromegaly.⁴⁰⁴ Although they do not arise from the hypothalamus, paraneoplastic syndromes can also cause pituitary hypersecretion, as with CRH-secreting tumors and GHRH-secreting tumors of the bronchi and pancreas. Bronchial carcinoids and pituitary islet cell tumors are the usual causes of this phenomenon.

Neuroendocrine Disorders of Gonadotropin Regulation

Precocious Puberty

The term *precocious puberty* is used when physiologically normal pituitary-gonadal function appears at an early age (see also Chapter 25).⁴⁰⁵ By convention, it is defined as the onset of androgen secretion and spermatogenesis before the age of 9 or 10 years in boys or the onset of estrogen secretion and cyclic ovarian activity before age 7 or 8 in girls.^{406,407} Central precocious puberty is caused by disturbed CNS function, which may or may not have an identifiable structural basis. The term *pseudoprecocious puberty* refers to premature sexual development resulting from excessive secretion of androgens, estrogens, or hCG; it is caused by tumors (both gonadal and extragonadal), administration of exogenous gonadal steroids, or genetically determined activation of gonadotropin receptors (see Chapter 25). Central precocious puberty with neurogenic causes and pineal gland disease are discussed in this chapter.

Idiopathic Sexual Precocity. Familial occurrence of idiopathic sexual precocity is uncommon, but there is a hereditary form that is largely confined to boys. Abnormal

electroencephalograms and behavioral disturbances, suggesting the presence of brain damage, have been reported occasionally in girls with idiopathic precocious puberty. The pathogenesis may be related to the rate of hypothalamic development or other, undetermined nutritional, environmental, or psychosocial factors. Many cases previously thought to be idiopathic are caused by small hypothalamic hamartomas (see later discussion). It has been argued that localized activation of discrete cellular subsets connected to GnRH neurons may be sufficient to initiate puberty.⁴⁰⁸

Neurogenic Precocious Puberty. Approximately two thirds of hypothalamic lesions that influence the timing of human puberty are located in the posterior hypothalamus, but in the subset of patients who come to autopsy, damage is extensive. Specific lesions known to cause precocity include craniopharyngioma (although delayed puberty is far more common with these lesions), astrocytoma, pineal tumors, subarachnoid cysts, encephalitis, miliary tuberculosis, tuberous sclerosis or neurofibromatosis type 1, the Sturge-Weber syndrome, porencephaly, craniostenosis, microcephaly, hydrocephalus, empty sella syndrome, and Tay-Sachs disease.^{409,410}

Hamartoma of the hypothalamus is an exception to the generalization that tumors of the brain cause precocious puberty by impairment of gonadotropin secretion (although hamartomas on occasion cause hypothalamic damage). A hamartoma is a tumor-like collection of normal-appearing nerve tissue lodged in an abnormal location. The parahypothalamic type consists of an encapsulated nodule of nerve tissue attached to the floor of the third ventricle or suspended from the floor by a peduncle; it is typically less than 1 cm in diameter. The intrahypothalamic or sessile type is enveloped by the posterior hypothalamus and can distort the third ventricle. These hamartomas tend to be larger than the pedunculated variety; they grow in the interpeduncular cistern and are frequently accompanied by seizures, mental retardation, and developmental delays. They result in precocious puberty with about half the incidence observed with the parahypothalamic lesions.^{411,412} Before the development of high-resolution scanning techniques, this tumor was considered rare, but small ones can now be visualized. Miniature hamartomas of the tuber cinereum are commonly discovered at autopsy. Precocious puberty occurs when the hamartoma makes connections with the median eminence and thus serves as an accessory hypothalamus. Peptidergic nerve terminals containing GnRH have been found in these tumors.⁴⁰² Early pubertal development is presumably caused by unrestrained GnRH secretion, although the hamartomas almost certainly have an intrinsic pulse generator of GnRH secretion, because pulsatility is required for stimulation of gonadotropin secretion (see earlier discussion).

Manifestations of premature puberty in patients with hamartomas are similar to those associated with other central causes of precocity. Hamartomas occur in both sexes and may be present as early as age 3 months. In the past, most cases were thought to be fatal by age 20 years, but many hamartomas cause no brain damage and need not be excised.⁴¹¹ The interpeduncular fossa of the brain is difficult to approach, and surgical experience is somewhat limited. Early in the course of illness, epilepsy manifested as "brief, repetitive, stereotyped attacks of laughter"⁴¹³ may provide a clue to the disease. Late in the course, hypothalamic damage can cause severe neurologic defects and intractable seizures.

Hypothyroidism. Hypothyroidism can cause precocious puberty in girls that is reversible with thyroid therapy. Hyperprolactinemia and galactorrhea may be present. One possibility is that elevated TSH levels (in children with thyroid failure) cross-react with the FSH receptor.⁴¹⁴ Alternatively, low levels of thyroid hormone might simultaneously activate release of LH, FSH, and TSH. A third possibility is that hypothyroidism causes hypothalamic encephalopathy that impairs the normal tonic suppression of gonadotropin release by the hypothalamus. The high PRL levels that sometimes accompany this disorder may result from a deficiency in PIF secretion, increased secretion of TRH, or increased sensitivity of the lactotrophs to TRH secretion.

Tumors of the Pineal Gland. Pineal gland tumors account for only a small percentage of intracranial neoplasms. They occur as a central midline mass with an enhancing lesion on MRI frequently accompanied by hydrocephalus. Pinealomas cause a variety of neurologic abnormalities. Parinaud's syndrome, which consists of paralysis of upward gaze, pupillary areflexia (to light), paralysis of convergence, and a wide-based gait, occurs with about half of patients with pinealomas. Gait disturbances can also occur because of brain stem or cerebellar compression. Additional neurologic signs occurring with moderate frequency include spasticity, ataxia, nystagmus, syncope, vertigo, cranial nerve palsies other than VI and VIII, intention tremor, scotoma, and tinnitus.

Several discrete cytopathologic entities account for mass lesions in the pineal region (Table 7-9).⁴¹⁵ The most common non-neoplastic conditions are degenerative pineal cysts, arachnoid cysts, and cavernous hemangioma. Pinealocytes give rise to primitive neuroectodermal tumors, the so-called *small blue-cell tumors* that are immunopositive for the neuronal marker synaptophysin and negative for the lymphocyte marker CD45. True pinealomas can be relatively well differentiated pineocytomas, intermediate mixed forms, or the less differentiated pineoblastomas,^{415,416} the latter of which are essentially identical to medulloblastomas, neuroblastomas, and oat cell carcinomas of the lung.

The most common tumors of the pineal gland are actually germinomas (a form of teratoma), so designated because of their presumed origin in germ cells. Germinomas may also occur in the anterior hypothalamus or the floor of the third ventricle, where they are often associated with the clinical triad of DI, pituitary insufficiency, and visual abnormalities.⁴¹⁰ Identical tumors can be found in the testis and anterior mediastinum. Intracranial germinomas have a tendency to spread locally, infiltrate the hypothalamus, and metastasize to the spinal cord and CSF. Extracranial metastases (to skin, lung, or liver) are rare. Teratomas derived from two or more germ cell layers also occur in the pineal region. Chorionic tissue in teratomas and germinomas may secrete hCG in sufficient amounts to cause gonadal maturation, and some of these tumors have histologic and functional characteristics of choriocarcinomas. Diagnosis is confirmed by the combination of a mass lesion, cytologic analysis of CSF, and radioimmunoassay detection of hCG in the CSF.

Precocious puberty is a relatively unusual manifestation of pineal gland disease. When it occurs, neuroanatomic studies suggest that the cause is secondary to pressure or destructive effects of the pineal tumor on the function of the adjacent hypothalamus, or to the secretion of hCG. Most patients have other evidence of hypothalamic involvement, such as DI, polyphagia, somnolence, obesity, or behavioral disturbance. Choriocarcinoma of the pineal gland is associated with high plasma levels of hCG. The

TABLE 7-9

Classification of Tumors of the Pineal Region

A. Germ Cell Tumors

1. Germinoma
 - a. Posterior third ventricle and pineal lesions
 - b. Anterior third ventricle, suprasellar, or intrasellar lesions
 - c. Combined lesions in anterior and posterior third ventricle, apparently noncontiguous, with or without foci of cystic or solid teratoma
2. Teratoma
 - a. Evidencing growth along two or three germ lines in varying degrees of differentiation
 - b. Dermoid and epidermoid cysts with or without solid foci of teratoma
 - c. Histologically malignant forms with or without differentiated foci of benign, solid, or cystic teratoma-teratocarcinoma, chorioepithelioma, embryonal carcinoma (endodermal-sinus tumor or yolk-sac carcinoma); combinations of these with or without foci of germinoma, chemodectoma

B. Pineal Parenchymal Tumors

1. Pinealocytes
 - a. Pineocytoma
 - b. Pineoblastoma
 - c. Ganglioglioma and chemodectoma
 - d. Mixed forms exhibiting transitions between these
2. Glia
 - a. Astrocytoma
 - b. Ependymoma
 - c. Mixed forms and other less frequent gliomas (e.g., glioblastoma, oligodendroglioma)

C. Tumors of Supporting or Adjacent Structures

1. Meningioma
2. Hemangiopericytoma

D. Nonneoplastic Conditions of Neurosurgical Importance

1. "Degenerative" cysts of pineal gland lined by fibrillary astrocytes
2. Arachnoid cysts
3. Cavernous hemangioma

From DeGirolami U. Pathology of tumors of the pineal region. In: Schmidek HH, ed. *Pineal Tumors*. New York, NY: Masson; 1977:1-19.

hCG can stimulate testosterone secretion from the testis but not estrogen secretion by the ovary; it therefore causes premature puberty almost exclusively in boys. The prevalence of elevated hCG levels in children with premature puberty related to tumors in the pineal region is unknown, but the fact that this phenomenon occurs further challenges the theory that nonparenchymal tumors cause precocious puberty by damaging the normal pineal gland. Rarely, pinealomas cause delayed puberty, raising speculation about a role of melatonin in inhibiting gonadotropin secretion in these cases.

Management of tumors in the pineal region is not straightforward.^{415,417} Operative mortality rates can be high, but the rationale for an aggressive approach is based on the need to make a histologic diagnosis, the variety of lesions found in this region, the possibility of cure of an encapsulated lesion, and the effectiveness of chemotherapeutic agents for germinomas and choriocarcinoma. Stereotaxic biopsy of the pineal region provided diagnosis in 33 of 34 cases in one series, suggesting that this is a useful alternative to open surgical exploration for diagnostic purposes.⁴¹⁸ Long-term palliation or cure of many pineal region tumors is possible through combinations of surgery, radiation, gamma knife, or chemotherapy, depending on the nature of the lesion.⁴¹⁹

Approach to the Patient with Precocious Puberty. Several groups have reviewed the diagnostic approach to suspected

central precocious puberty (see Chapter 25).^{420,421} Although guidelines differ, the index of suspicion is clearly inversely proportional to the age of the patient. A GnRH stimulation test to assess gonadotropin release and thereby differentiate between primed and inactive gonadotrophs is probably the single most important endocrinologic measure. If LH and FSH levels are not stimulated and there is no evidence of gonadal germ cell maturation, the cause of precocious puberty lies outside the hypothalamic-pituitary axis, and the diagnostic process should focus on the adrenal glands and gonads (see Chapters 15 and 25). MRI studies are central to the workup for exclusion or characterization of organic lesions in the areas of the sella, optic chiasm, suprasellar hypothalamus, and interpeduncular cistern.⁴²²

Management of Sexual Precocity. Structural lesions of the hypothalamus are treated by surgery, radiation, chemotherapy, or combinations of these treatments, as indicated by the pathologic diagnosis and extent of disease. Endocrinologic manifestations of precocious puberty are best treated by GnRH agonists with the therapeutic goals of delaying sexual maturation to a more appropriate age and achieving optimal linear growth and bone mass, possibly with the combined use of GH treatment.^{423,424} Other approaches include the use of cyproterone acetate, testosterone, or spironolactone to antagonize or inhibit gonadal steroid biosynthesis.^{425,426} Precocious puberty is stressful to both the child and the parents, and it is essential that psychological support be provided.

Psychogenic Amenorrhea

Menstrual cycles can cease in young nonpregnant women with no demonstrable abnormalities of the brain, pituitary, or ovary in several situations,^{427,428} including pseudocyesis (false pregnancy), anorexia nervosa, excessive exercise, psychogenic disorders, and hyperprolactinemic states (see Chapter 17). Psychogenic amenorrhea, the most common cause of secondary amenorrhea except for pregnancy, can occur with major psychopathology or minor psychic stress and is often temporary. Psychogenic amenorrhea is probably mediated by excessive endogenous opioid activity, because naloxone or naltrexone (both opiate receptor blockers) can induce ovulation in some patients with this disorder.⁴²⁸

Exercise-induced amenorrhea may be a variant of psychogenic amenorrhea, or it may result from loss of body fat.^{427,429} The syndrome is associated with intense and prolonged physical exertion such as running, swimming, or ballet dancing. Affected women are always at less than ideal body weight and have low stores of fat. If the activity is begun before puberty, normal sexual maturation can be delayed for many years. Fat mass may be a regulator of gonadotropin secretion, with adipocyte-derived leptin as the principal mediator between peripheral energy stores and hypothalamic regulatory centers.⁴³⁰ Studies in nonhuman primates showed a direct role of caloric intake in the pathogenesis of amenorrhea associated with long-distance running.⁴³¹ Exercise and psychogenic amenorrhea can have adverse effects because of the associated estrogen deficiency and accompanying osteopenia (also see Chapter 28).⁴³²

Neurogenic Hypogonadism in Males

A discussion of neurogenic hypogonadism in males should begin with an account of Fröhlich's syndrome (adiposogenital dystrophy), which was originally characterized as delayed puberty, hypogonadism, and obesity associated with a tumor that impinges on the hypothalamus.¹ It was

later recognized that either hypothalamic or pituitary dysfunction can induce hypogonadism, and the presence of obesity indicates that the appetite-regulating regions of the hypothalamus have been damaged. Several organic lesions of the hypothalamus can cause this syndrome, including tumors, encephalitis, microcephaly, Friedreich's ataxia, and demyelinating diseases. Other important causes of HH are Kallmann's syndrome, a disorder caused by failure of GnRH-containing neurons to migrate normally (see earlier discussions of GnRH and hypophyseotropic hormone deficiency), and a subset of the Prader-Willi syndrome.⁴³³

However, most males with delayed sexual development do not have serious neurologic conditions. Furthermore, most obese boys with delayed sexual development have no structural damage to the hypothalamus but have constitutional delayed puberty, which is commonly associated with obesity. It is not known whether there is a functional disorder of the hypothalamus in this condition. It is thought that psychosexual development of brain maturation depends on the presence of androgens within a critical developmental window corresponding to puberty; therefore, hypogonadism in boys (regardless of cause) should be treated by the middle teen years (15 years of age at the latest).

In adult men, hypogonadism (including reduced spermatogenesis) can be induced by emotional stress or severe exercise,⁴³⁴ but this abnormality is seldom diagnosed because the symptoms are more subtle than menstrual cycle changes in similarly stressed women. Prolonged physical stress and sleep and energy deficiencies can also decrease testosterone and gonadotropin levels.⁴³⁵ Chronic intrathecal administration of opiates for the control of intractable pain syndromes is strongly associated with HH, and to a lesser extent with hypocorticism and GH deficiency, in both men and women.⁴³⁶ Finally, critical illness with multiple causes is well known to be associated with hypogonadism and ineffectual altered pulsation of GnRH.⁴³⁷

Neurogenic Disorders of Prolactin Regulation

Neurogenic causes of hyperprolactinemia include irritative lesions of the chest wall (e.g., herpes zoster, thoracotomy), excessive tactile stimulation of the nipple, and lesions within the spinal cord (e.g., ependymoma).⁴³⁸ Prolonged mechanical stimulation of the nipples by suckling or the use of a breast pump can initiate lactation in some women who are not pregnant, and neurologic lesions that interrupt the hypothalamic-pituitary connection can cause hyperprolactinemia, as discussed earlier. Hyperprolactinemia also occurs after certain forms of epileptic seizures. In one series, six of eight patients with temporal lobe seizures had a marked increase in PRL, whereas only one of eight patients with frontal lobe seizures led to hyperprolactinemia.⁴³⁹ Agents that block D₂-like dopamine receptors (e.g., phenothiazines, later-generation atypical antipsychotics) or prevent dopamine release (e.g., reserpine, methyldopa) must be excluded in all cases.

Because the nervous system exerts such profound effects on PRL secretion, patients with hyperprolactinemia (including those with adenomas) may have a deficit of PIF or an excess of PRF activity. In studies of PRL secretion in patients apparently cured of hyperprolactinemia by removal of a pituitary microadenoma, regulatory abnormalities persisted in some but not all patients. Regulatory abnormalities may persist because of incomplete removal of tumor, abnormal function of the remaining part of the gland, or underlying hypothalamic abnormalities.⁴⁴⁰

Neurogenic Disorders of Growth Hormone Secretion

Hypothalamic Growth Failure

Loss of the normal nocturnal increase in GH secretion and loss of GH secretory responses to provocative stimuli occur early in the course of hypothalamic disease and may be the most sensitive endocrine indicator of hypothalamic dysfunction. As described earlier, anatomic malformations of midline cerebral structures are associated with abnormal GH secretion, presumably related to failure of the development of normal GH regulatory mechanisms. Such disorders include optic nerve dysplasia and midline prosencephalic malformations (absence of the septum pellucidum, abnormal third ventricle, and abnormal lamina terminalis). Certain complex genetic disorders including Prader-Willi syndrome also commonly involve reduced GH secretory capacity.⁴⁴¹ Idiopathic hypopituitarism with GH deficiency was considered earlier.

Maternal Deprivation Syndrome and Psychosocial Dwarfism

Infant neglect or abuse can impair growth and cause failure to thrive (the maternal deprivation syndrome). Malnutrition interacts with psychological factors to cause growth failure in these children, and each case should be carefully evaluated from this point of view. Older children with growth failure in a setting of abuse or severe emotional disturbance (termed *psychosocial dwarfism*) may also have abnormal circadian rhythms and deficient hGH release after insulin-induced hypoglycemia or arginine infusion (see Chapter 24).⁴⁴² Deficient release of ACTH and gonadotropins may also be present. A new variant, termed *hyperphagic short stature*, has been identified.⁴⁴³ These disorders can be reversed by placing the child in a supportive milieu; growth and neuroendocrine hGH responses rapidly return to normal.⁴⁴⁴ The pathogenesis of altered GH secretion in children in response to deprivation is unknown. Furthermore, in the adult human, physical or emotional stress usually causes an increase in hGH secretion (see earlier discussion).

Neuroregulatory Growth Hormone Deficiency

The availability of biosynthetic hGH for treatment of short stature has brought into focus a group of patients who grow at low rates (<3rd percentile) and have low levels of serum IGF1 but a normal hGH secretory reserve. Studies of 24-hour hGH secretion profiles indicate that many of these children do not have normal spontaneous hGH secretion (i.e., abnormal ultradian and circadian rhythms or decreased number or amplitude of secretory bursts, or both). These children with idiopathic short stature may have a functional regulatory disturbance of the hypothalamus and appear to grow normally when given exogenous hGH.⁴⁴⁵

There is considerable uncertainty about the criteria for diagnosis of neuroregulatory hGH deficiency. Many normally growing children have profiles of hGH secretion that are indistinguishable from those of children with the postulated syndrome.⁴⁴⁶ Patterns of hGH secretion do not predict which child will benefit from therapy, and there is a poor correlation between hGH secretion and growth. Furthermore, the results of repeated tests in children show considerable variability. It has been suggested that specific genetic defects may underlie the pathogenesis of a subset of children with this heterogeneous syndrome of growth failure.⁴⁴⁷ The prevalence of an hGH

neuroregulatory deficiency syndrome is therefore unclear, and the decision to treat short children with hGH should be made cautiously.^{448,449}

Neurogenic Hypersecretion of Growth Hormone

Diencephalic Syndrome. Children and infants with tumors in and around the third ventricle frequently become cachectic, which is often associated with elevated hGH levels and paradoxical GH secretory responses to glucose and insulin.⁴⁵⁰ GH hypersecretion may be caused by a hypothalamic abnormality or by malnutrition. Deficits of pituitary-adrenal regulation are less common. A striking feature is an alert appearance and seeming euphoria despite the profound emaciation. A variety of associated neurologic abnormalities may be present, including nystagmus, irritability, hydrocephalus, optic atrophy, tremor, and excessive sweating. CSF abnormalities include increased protein and the presence of abnormal cells. Most cases are caused by chiasmatic-hypothalamic gliomas, with the majority classified as astrocytomas.⁴⁵⁰ Treatment options include surgical resection, radiation therapy, and chemotherapy.⁴⁵¹

Growth Hormone Hypersecretion Associated with Metabolic Disturbances. Apparently inappropriate hGH hypersecretion occurs with uncontrolled diabetes mellitus, hepatic failure, uremia, anorexia nervosa, and protein-calorie malnutrition. Nutritional factors are probably important in this response, because in normal persons obesity inhibits and fasting stimulates episodic GH hypersecretion.⁴⁵² In diabetes mellitus, cholinergic blockers reverse the abnormality,²²⁸ possibly by inhibiting hypothalamic somatostatin secretion (see earlier discussion). Loss of inhibition of GH secretion by IGF1 may also play a role, because most disorders in which this syndrome occurs are associated with low IGF1 levels.

Neurogenic Disorders of Corticotropin Regulation

Hypothalamic CRH hypersecretion is the likely cause of sustained pituitary-adrenal hyperfunction in at least two situations: Cushing's syndrome caused by rare CRH-secreting gangliocytomas of the hypothalamus⁴⁵³ and severe depression. Severe depression is associated with pituitary-adrenal abnormalities, including inappropriately elevated ACTH levels, abnormal cortisol circadian rhythms, and resistance to dexamethasone suppression.^{160,164,165,454} The dexamethasone suppression test has, in fact, been used as an aid to the diagnosis of depressive illness. Another possible example of disordered neurogenic control of CRH associated with stress is the dysmetabolic syndrome.^{455,456} This syndrome is characterized by mild hypercortisolism, blunted dexamethasone suppression of the HPA axis, visceral obesity, and hypertension and is strongly associated with greater risks for cardiovascular disease and stroke.

A unique syndrome of ACTH hypersecretion, termed *periodic hypothalamic discharge* (Wolff's syndrome), has been described in one young man. The patient had a recurring cyclic disorder characterized by high fever, paroxysms of glucocorticoid hypersecretion, and electroencephalographic abnormalities.⁴⁵⁷

Nonendocrine Manifestations of Hypothalamic Disease

The hypothalamus is involved in the regulation of diverse functions and behaviors (Table 7-10). Psychological

TABLE 7-10

Neurologic Manifestations of Nonendocrine Hypothalamic Disease**Disorders of Temperature Regulation**

Hyperthermia
Hypothermia
Poikilothermia

Disorders of Food Intake

Hyperphagia (bulimia)
Anorexia nervosa, aphagia
Cachexia

Disorders of Water Intake

Compulsive water drinking
Adipsia
Essential hyponatremia

Disorders of Sleep and Consciousness

Narcolepsy/cataplexy
Somnolence
Sleep rhythm reversal
Akinetic mutism
Coma
Delirium

Periodic Disease of Hypothalamic Origin

Diencephalic epilepsy
Kleine-Levin syndrome
Periodic discharge syndrome of Wolff

Disorders of Psychic Function

Rage behavior
Hallucinations
Hypersexuality

Disorders of the Autonomic Nervous System

Pulmonary edema
Cardiac arrhythmias
Sphincter disturbance

Congenital Hypothalamic Disease

Prader-Willi syndrome
Laurence-Moon-Biedl syndrome

Miscellaneous

Diencephalic syndrome of infancy
Cerebral gigantism

abnormalities in hypothalamic disease include antisocial behavior; attacks of rage, laughing, or crying; disturbed sleep patterns; excessive sexuality; and hallucinations. Both somnolence (with posterior lesions) and pathologic wakefulness (with anterior lesions) occur, as do bulimia and profound anorexia. The abnormal eating patterns are analogous to the syndromes of hyperphagia produced in rats by destruction of the VMH or connections to the PVH. Lateral hypothalamic damage causes profound anorexia. A more complete discussion of imbalance in energy homeostasis (obesity and cachexia) associated with hypothalamic dysfunction and neuropeptides is presented in Chapter 35.

Patients with hypothalamic damage may experience hyperthermia, hypothermia, unexplained fluctuations in body temperature, and poikilothermy. Disturbances of sweating, acrocyanosis, loss of sphincter control, and diencephalic epilepsy are occasional manifestations. Hypothalamic damage also causes loss of recent memory, believed to result from damage of the mammillothalamic pathways.

Severe memory loss, obesity, and personality changes (apathy, loss of ability to concentrate, aggressive antisocial behavior, severe food craving, inability to work or attend school) may occur with suprasellar extension of pituitary tumors, hypothalamic irradiation, or damage incurred from surgical removal of parasellar tumors. Hypothalamic tumors grow slowly and may reach a large size while producing minimal disturbance of behavior or visceral homeostasis, whereas surgery of limited extent can produce striking functional abnormalities. Presumably, this is because slowly growing lesions permit compensatory responses to develop. These potential consequences should be weighed carefully with the neurosurgeon, patient, and patient's family in planning the therapeutic approach. Adverse effects of treatment have led to more conservative surgical guidelines for the treatment of craniopharyngioma. A recent review from the University of Pittsburgh summarizes their individualized treatment program, which includes microsurgical tumor resection, intracavitary ^{32}P radiotherapy, and gamma knife stereotactic radiosurgery to produce maximal benefit with minimal morbidity.⁴⁵⁸

Narcolepsy

A convergence of functional genomics from two animal species, the dog and mouse, has dramatically refocused attention on neuropeptide circuits of the hypothalamus in the control of sleep and wakefulness. Positional cloning was used to identify mutations in the hypocretin-orexin receptor 2 as a cause of canine narcolepsy.⁴⁵⁹ Subsequently knockout of the gene encoding the hypocretin-orexin peptide precursor produced an equivalent narcoleptic syndrome in mice,⁴⁶⁰ further establishing this neuropeptide system as a major component of sleep-modulating neural circuits. The additional role of hypocretin-orexin in coordinating arousal states and feeding behavior is discussed in Chapter 35. These new discoveries add to the list of other hypothalamic neuropeptides, including GHRH, somatostatin, cortistatin, CRH, galanin, ghrelin, and NPY, that have established functions in modulation of the sleep cycle.

Histaminergic neurons of the tuberomammillary nucleus express both forms of the orexin receptor and make reciprocal synaptic connections with orexin neurons in the lateral hypothalamus. Furthermore, orexin is an excitatory transmitter for the histamine neurons, suggesting that the two populations cooperate in the regulation of rapid eye movement sleep.⁴⁶¹ A recent study suggested that the two populations of neurons also play complementary but distinct roles in the maintenance of wakefulness.⁴⁶²

Targeted ablation of orexin neurons in the lateral hypothalamus of rats by means of a hypocretin receptor 2-saporin conjugate produced narcoleptic-like sleep behavior,⁴⁶³ closely paralleling the clinical findings and profound reduction in numbers of hypocretin-orexin neurons in the lateral hypothalamus of humans with narcolepsy.⁴⁶⁴

In summary, most cases of spontaneous narcolepsy with cataplexy result from a degenerative hypothalamic disorder, most likely autoimmune in pathogenesis, that produces a selective destruction of neuropeptidergic neurons. The absence of immunoreactive hypocretin-orexin in CSF is a sensitive diagnostic test for the disease. Future development of bioavailable, hypocretin-orexin receptor-selective compounds may provide a specific treatment alternative or adjunct to the stimulant and antidepressant drugs currently used for the management of symptoms. More generally, these discoveries suggest the possibility that other cryptic hypothalamic disorders could be caused by selective disturbances in other neuropeptidergic circuits.

ACKNOWLEDGMENTS

The author is highly indebted to Dr. Seymour Reichlin not only for material he shared from the ninth edition of this text but also for the inspiration and mentorship he provided to the current generation of neuroendocrinologists.

CHAPTER

8

Pituitary Physiology and Diagnostic Evaluation

SHLOMO MELMED • DAVID KLEINBERG • KEN HO

INTRODUCTION

The pituitary gland, situated within the sella turcica, derives its name from the Greek *ptuo* and Latin *pituita*, “phlegm,” reflecting its nasopharyngeal origin. Galen hypothesized that nasal phlegm originated from the brain and drained via the pituitary gland. It is now clear that the pituitary, together with the hypothalamus, orchestrates the structural integrity and function of endocrine glands including the thyroid, adrenal, and gonads, as well as target tissues including cartilage and breast. The pituitary stalk serves as an anatomic and functional connection to the hypothalamus. Preservation of the hypothalamo-pituitary unit is critical for integration of anterior pituitary control of sexual function and fertility, linear and organ growth, lactation, stress responses, energy, appetite, and temperature regulation, and it is secondarily important for carbohydrate and mineral metabolism.

Integration of vital body functions by the brain was first proposed by Descartes in the 17th century. In 1733, Morgagni recorded the absence of adrenal glands in an

anencephalic neonate, providing early evidence for a developmental and functional connection between the brain and the adrenal glands. In 1849, Claude Bernard set the stage for later advances in neuroendocrinology by demonstrating that central lesions to the area of the fourth ventricle resulted in polyuria.¹ Subsequent studies resulted in the identification and chemical isolation of pituitary hormones, and astute clinical observations led to the realization that pituitary tumors were associated with functional hypersecretory syndromes, including acromegaly and Cushing’s disease.^{2–4} In 1948, Geoffrey Harris, the father of modern neuroendocrinology, reviewed the control of anterior pituitary gland hormones and proposed that they were regulated by the hypothalamus, predicting the discovery of specific hypothalamic regulating hormones.⁵

Pituitary Anatomy

The pituitary gland comprises the predominant anterior lobe, the posterior lobe, and a vestigial intermediate lobe (Fig. 8-1). The gland is situated within the bony sella

Figure 8-1 Schematic representation of the blood supply of the hypothalamus and pituitary. (Reproduced from Scheithauer BW. The hypothalamus and neurohypophysis. In: Kovacs K, Asa SL, eds. *Functional Endocrine Pathology*. Oxford, UK: Blackwell Scientific; 1991.)

turcica and is overlain by the dural diaphragma sellae, through which the stalk connects to the median eminence of the hypothalamus. The adult pituitary weighs approximately 600 mg (range, 400 to 900 mg) and measures approximately 13 mm in the longest transverse diameter, 6 to 9 mm in vertical height, and about 9 mm anteroposteriorly. Structural variation may occur in multiparous women, and gland volume also changes with the menstrual cycle. During pregnancy, size may be increased in any dimension, and pituitary weight increases up to 1 g. Pituitary hypertrophy without evidence for the presence of an adenoma was described in 7 eugonadal women with pituitary height greater than 9 mm and a convex upper gland boundary observed on magnetic resonance imaging (MRI).⁶

The sella turcica, located at the base of the skull, forms the thin, bony roof of the sphenoid sinus. The lateral walls are made up of bony and dural tissue and surround the cavernous sinuses, which are traversed by the third, fourth, and sixth cranial nerves and the internal carotid arteries. The cavernous sinus contents are vulnerable to intrasellar expansion. The dural roofing protects the gland from compression by fluctuant cerebrospinal fluid pressure. The optic chiasm, located anterior to the pituitary stalk, is directly above the diaphragma sellae. The optic tracts and central structures are vulnerable to pressure effects from an expanding pituitary mass, which is likely to follow the path of least tissue resistance by lifting the diaphragma sellae. The intimate relationship between the pituitary and the chiasm is borne out in optic chiasmic hypoplasia

associated with developmental pituitary dysfunction, seen in patients with septo-optic dysplasia.

The posterior pituitary gland, in contrast to the anterior pituitary, is directly innervated by supraopticohypophyseal and tuberohypophyseal nerve tracts of the posterior stalk. Hypothalamic neuronal lesions, stalk disruption, or direct systemically derived metastases are often associated with attenuated secretion of vasopressin (diabetes insipidus) or oxytocin or both.

The hypothalamus contains nerve cell bodies that synthesize hypophysiotropic releasing and inhibiting hormones as well as the neurohypophyseal hormones of the posterior pituitary (vasopressin and oxytocin). Five distinct hormone-secreting cell types are present in the mature anterior pituitary gland:

- Corticotroph cells express pro-opiomelanocortin (POMC) peptides including adrenocorticotrophic hormone (ACTH, also called *corticotropin*).
- Somatotroph cells express growth hormone (GH, also called *somatotropin*).
- Thyrotroph cells express the common glycoprotein α -subunit (α GSU) and the specific β -subunit of thyroid-stimulating hormone (TSH, also called *thyrotropin*).
- Gonadotrophs express the α - and β -subunits for both follicle-stimulating hormone (FSH) and luteinizing hormone (LH).
- Lactotrophs express prolactin (PRL).

Each cell type is under highly specific signal controls that regulate its differentiated gene expression.

Pituitary Blood Supply

The pituitary gland enjoys an abundant blood supply derived from several sources (see Fig. 8-1). The superior hypophyseal arteries branch from the internal carotid arteries to supply the hypothalamus, where they form a capillary network in the median eminence, external to the blood-brain barrier. The long and short hypophyseal portal vessels originate, respectively, from infundibular plexuses and from the pituitary stalk. These vessels form the hypophyseal-portal circulation, the predominant blood supply to the anterior pituitary gland. They deliver hypothalamic releasing and inhibiting hormones to the trophic hormone-producing cells of the adenohypophysis without significant systemic dilution, allowing the pituitary cells to be sensitively regulated by timed hypothalamic hormone secretion. Vascular transport of hypothalamic hormones is also locally regulated by a contractile internal capillary plexus (*gomitoli*) derived from stalk branches of the superior hypophyseal arteries.⁷

Retrograde blood flow toward the median eminence also occurs, facilitating bidirectional functional hypothalamic-pituitary interactions.⁸ Systemic arterial blood supply is maintained by inferior hypophyseal arterial branches that predominantly supply the posterior pituitary. Disruption of stalk integrity may lead to compromised pituitary portal blood flow, depriving the anterior pituitary cells of hypothalamic hormone access.

Pituitary Development

The pituitary gland arises from within the rostral neural plate. Rathke's pouch, a primitive ectodermal invagination anterior to the roof of the oral cavity, is formed by the 4th or 5th week of gestation⁹ and gives rise to the anterior pituitary gland (Fig. 8-2).^{10,11} The pouch is directly connected to the stalk and hypothalamic infundibulum and ultimately becomes distinct from the oral cavity and nasopharynx. Rathke's pouch proliferates toward the third ventricle, where it fuses with the diverticulum and subsequently obliterates its lumen, which may persist as Rathke's cleft. The anterior lobe is formed from Rathke's pouch, whereas the diverticulum gives rise to the adjacent posterior lobe. Remnants of pituitary tissue may persist in the nasopharyngeal midline and may rarely give rise to functional ectopic hormone-secreting tumors in the nasopharynx. The neurohypophysis arises from neural ectoderm associated with third ventricle development.¹²

Functional development of the anterior pituitary cell types involves complex spatiotemporal regulation of cell lineage-specific transcription factors expressed in pluripotential pituitary stem cells and dynamic gradients of locally acting soluble factors.¹³⁻¹⁶ Critical neuroectodermal signals for organizing the dorsal gradient of pituitary morphogenesis include infundibular bone morphogenetic protein 4 (BMP4), which is required for initial pouch invagination¹¹; fibroblast growth factor 8 (FGF8), Wnt5, and Wnt4. Subsequent ventral developmental patterning and transcription factor expression are determined by spatial and graded expression of factors including BMP2 and sonic hedgehog protein (Shh), which appears to be critical for directing early patterns of cell proliferation.¹⁷

The human fetal Rathke's pouch is evident at 3 weeks of gestation, and the pituitary grows rapidly in utero. By 7 weeks, the anterior pituitary vasculature begins to develop, and by 20 weeks, the entire hypophyseal portal system is already established. The anterior pituitary undergoes major cellular differentiation during the first 12 weeks, by which

time all of the major secretory cell compartments are structurally and functionally intact, except for lactotrophs. Totipotential pituitary stem cells give rise to acidophilic (somatotroph, and lactotroph) and basophilic (corticotroph, thyrotroph, and gonadotroph) differentiated pituitary cell types, which appear at clearly demarcated developmental stages.

At 6 weeks, corticotroph cells are morphologically identifiable, and immunoreactive ACTH is detectable by 7 weeks. At 8 weeks, somatotroph cells are evident with abundant immunoreactive cytoplasmic GH expression. Glycoprotein hormone-secreting cells express α GSU, and at 12 weeks, differentiated thyrotrophs and gonadotrophs express immunoreactive β -subunits for TSH and for LH and FSH, respectively. In females, LH- and FSH-expressing gonadotrophs are equally distributed, whereas in the male fetus, LH-expressing gonadotrophs predominate.¹⁸ Fully differentiated PRL-expressing lactotrophs become evident late in gestation (after 24 weeks). Before that time, immunoreactive PRL is detectable only in mixed mammosomatotrophs, which also express GH, reflecting the common genetic origin of these two hormones.¹⁹

Pituitary Transcription Factors

Determination of anterior pituitary cell type lineages results from a temporally regulated cascade of homeodomain transcription factors.¹³ Although most pituitary developmental information has been acquired from murine models,²⁰ histologic and pathogenetic observations in human subjects largely corroborate these developmental mechanisms (see Fig. 8-2). Early cell differentiation requires intracellular Rpx (*HESX1*) and Ptx (*PITX*) expression. Rathke's pouch expresses several transcription factors of the LIM homeodomain family, including Lhx3, Lhx4, and Isl-1,²⁰ which are early determinants of functional pituitary development and are required for progenitor cell survival and proliferation. Ptx1 is expressed in the oral ectoderm, and subsequently in all pituitary cell types, particularly those arising ventrally.²¹ Rieger's syndrome, which is characterized by defective eye, tooth, umbilical cord, and pituitary development, is caused by mutations in Ptx2.²²

Ptx behaves as a universal pituitary regulator and activates transcription of α GSU, POMC, LH β (Ptx1), and GH (Ptx2). Lhx3 determines GH-, PRL-, and TSH-cell differentiation. PROP1 behaves as a prerequisite for POU1F1, which activates GH, PRL, TSH, and growth hormone-releasing hormone (GHRH) receptor transcription. TSH and gonadotropin-expressing cells share α GSU expression under developmental control of *GATA2*.²³ *FOXL2*, a forkhead transcription factor, regulates differentiation of cell types expressing the α GSU, including gonadotrophs and thyrotrophs.²⁴ In contrast, activated *Notch2* acts to delay murine gonadotroph differentiation,²⁵ underscoring the role of Notch signaling pathways, including *Hesx1* in the developmental cascade. Diversity of pituitary cell type determination is mediated by binary Wnt/ β -catenin signaling that leads to induction of PROP1 and suppression of *Hesx1*.²⁶ These specific anterior pituitary transcription factors participate in a highly orchestrated cascade that results in commitment of the five differentiated cell types (see Fig. 8-4). The major proximal determinant of pituitary cell lineage is PROP1 expression, which determines subsequent development of POU1F1-dependent and gonadotroph cell lineages.^{27,28}

POU1F1 encodes a POU-homeodomain transcription factor (also called Pit-1) that determines development and appropriate temporal and spatial expression of cells

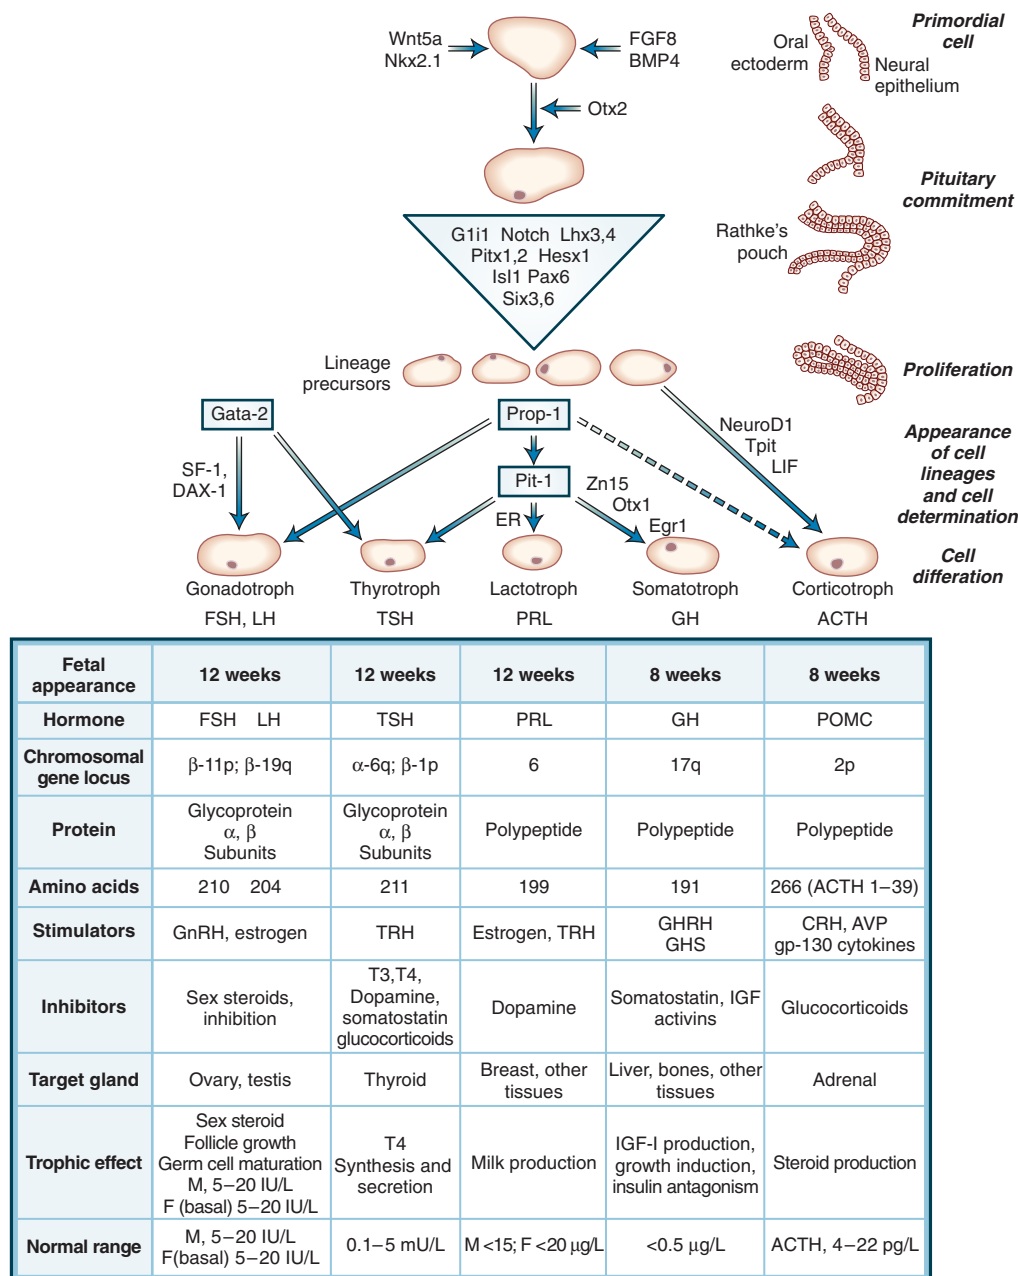

Figure 8-2 Model for development of the human anterior pituitary gland and cell lineage determination by a cascade of transcription factors. Trophic cells are depicted with transcription factors known to determine cell-specific human or murine gene expression. ACTH, corticotropin; AVP, arginine vasopressin; CRH, corticotropin-releasing hormone; ER, estrogen receptor; F, female; FSH, follicle-stimulating hormone; GH, growth hormone; GHRH, growth hormone-releasing hormone; GHS, growth hormone secretagogue; GnRH, gonadotropin-releasing hormone; IGF, insulin-like growth factor; LH, luteinizing hormone; M, male; POMC, pro-opiomelanocortin; PRL, prolactin; T₃, triiodothyronine; T₄, thyroxine; TRH, thyrotropin-releasing hormone; TSH, thyrotropin. (Adapted from Shimon I, Melmed S. Anterior Pituitary Hormones. In: Conn P, Melmed S, eds. *Scientific Basis of Endocrinology*. Totowa, NJ: Humana Press, 1996; and Amselem S. Perspectives on the molecular basis of developmental defects in the human pituitary region. In Rappaport R, Amselem S, eds. *Hypothalamic-Pituitary Development*. Basel, Switzerland: Karger; 2001; and Dasen JS, O'Connell SM, Flynn SE, et al. Reciprocal interactions of Pit1 and GATA2 mediate signaling gradient-induced determination of pituitary cell types. *Cell*. 1999;97:587-598.)

committed to GH, PRL, TSH, and GHRH receptor expression. POU1F1 binds to specific DNA motifs to activate and regulate somatotroph, lactotroph, and thyrotroph development and mature secretory function. Signal-dependent coactivating factors also cooperate with POU1F1 to determine specific hormone expression. For example, in POU1F1-containing cells, high estrogen receptor levels induce a commitment to express PRL, whereas thyrotroph embryonic factor (TEF) favors TSH expression. Selective

pituitary cell-type specificity is also perpetuated by binding of POU1F1 to its own DNA regulatory elements as well as those contained within the GH, PRL, and TSH genes. Steroidogenic factor (SF1) and DAX1 (encoded by *NROB1*) determine subsequent gonadotroph development.^{29,30} Corticotroph cell commitment occurs earliest during fetal development but is independent of POU1F1-determined lineages. TPIT protein (encoded by *TBX19*) is a prerequisite for POMC expression.³¹ Hereditary mutations arising

within these transcription factors may result in isolated or combined pituitary hormone failure syndromes (discussed later).³²

Pituitary Stem Cells

The adult pituitary gland exhibits plastic and regenerative trophic properties that allow maintenance of homeostatic functions.³³ This characteristic is exemplified by pituitary lactotroph expansion during pregnancy and by pituitary trophic hormone cell hyperplasia occurring after target organ ablation. Mechanisms underlying adult pituitary cell renewal and expansion are as yet unclear and may include intrinsic pituitary transdifferentiation, differentiation of previously uncommitted “null” cells, or expansion of already differentiated cells.

Several lines of evidence support the existence of cells with stem or progenitor characteristics in the adult pituitary gland.³⁴⁻³⁶ Pituitary progenitor cells exhibit several characteristics of a stem cell phenotype, including an undifferentiated gene profile, clonality, and expression of known stem cell markers such as *Scal* and *CD133*. Other markers, including *Notch*, *Wnt*, and *Shh*, are essential transcription factors for cell-type determination and expansion of pituitary cell lineages. *SOX2*-expressing pituitary progenitor cells exhibit properties for multipotent pituitary cell differentiation, and a population of nestin-expressing murine pituitary cells was found to fulfill criteria consistent with organ-specific multipotent stem cells.³⁶ These cells form differentiated pituitary-expressing progeny and contribute to a distinct adult pituitary stem cell population distinct from embryonic precursor cells. Factors regulating expansion of these putative adult pituitary stem cells remain to be determined.

Pituitary Control

Three levels of control regulate anterior pituitary hormone secretion (Fig. 8-3). Hypothalamic control is mediated by adenohypophysectomy hormones secreted into the portal

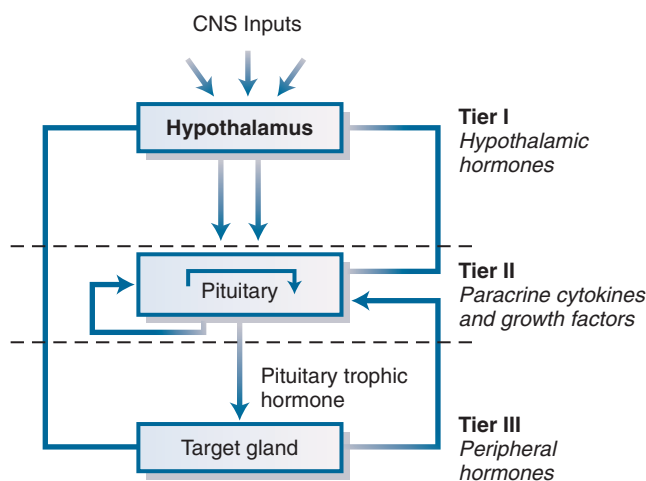

Figure 8-3 Model for regulation of anterior pituitary hormone secretion by three tiers of control. Hypothalamic hormones traverse the portal system and impinge directly on their respective target cells. Intrapituitary cytokines and growth factors regulate tropic cell function by paracrine (and autocrine) control. Peripheral hormones exert negative feedback inhibition of respective pituitary trophic hormone synthesis and secretion. CNS, central nervous system. (Reproduced from Ray D, Melmed S. Pituitary cytokine and growth factor expression and action. *Endocr Rev*. 1997;18:206-228.)

system that impinge directly on anterior pituitary cell surface receptors. G protein-linked cell surface membrane binding sites are highly selective and specific for each of the hypothalamic hormones; they elicit positive or negative signals that mediate pituitary hormone gene transcription and secretion. Peripheral hormones also participate in mediation of pituitary cell function, predominantly through negative feedback regulation of trophic hormones by their respective target hormones. Intrapituitary paracrine and autocrine soluble growth factors and cytokines act to locally regulate neighboring cell development and function.

The net result of these three tiers of complex intracellular signals is the controlled pulsatile secretion of the six pituitary trophic hormones (i.e., ACTH, GH, PRL, TSH, FSH, and LH) through the cavernous sinus, the petrosal veins, and, ultimately, the systemic circulation via the superior vena cava (Fig. 8-4). Temporal and quantitative control of pituitary hormone secretion is critical for physiologic integration of peripheral hormonal systems such as the menstrual cycle, which relies on complex and precisely regulated pulse control.

PHYSIOLOGY AND DISORDERS OF PITUITARY HORMONE AXES

Prolactin

Physiology

Until 1970, the identification of PRL in humans was elusive because human GH is highly lactogenic and active in bioassays used to isolate and measure PRL³⁷ and because GH is present in human pituitary glands in much higher concentrations (5 to 10 mg) than PRL (approximately 100 µg).³⁸ To distinguish human PRL from GH, lactogenic activity was neutralized with GH antiserum; sera from postpartum women and patients with galactorrhea had high lactogenic activity in the presence of GH antibodies.^{39,40} Human PRL, bioassayed by stimulation of pregnant mouse mammary milk production,⁴¹ was elevated in patients with nonpuerperal galactorrhea due to pituitary tumors, exposure to phenothiazines, or withdrawal from oral contraceptives. Purification and isolation of PRL by Friesen and development of a specific radioimmunoassay (RIA) underscored the utility of PRL measurements in understanding human disease.^{42,43}

Lactotroph Cells. Lactotroph cells comprise 15% to 25% of functioning anterior pituitary cells (Fig. 8-5). Their absolute number does not change with age, but lactotroph hyperplasia occurs during pregnancy and lactation⁴⁴ and resolves within several months after delivery (Fig. 8-6). Most PRL-expressing cells appear to arise from GH-producing cells. Ablation of somatotrophs by expression of GH-diphtheria toxin and GH-thymidine kinase fusion genes inserted into the germline of transgenic mice eliminates most lactotrophs, suggesting that the majority of PRL-producing cells arise from postmitotic somatotrophs.⁴⁵ Two cell forms expressing the PRL gene are the large, polyhedral cells found throughout the gland and the smaller, angulated or elongated cells clustered mainly in the lateral wings and median wedge. Large PRL secretory granules (250 to 800 nm) are present in the evenly distributed cells, whereas the laterally localized cells are sparsely populated by smaller granules (200 to 350 nm) (Fig. 8-7). Occasional mammosomatotroph cells may also cosecrete both PRL and GH, often storing both hormones within the same

Figure 8-4 Control of hypothalamic-pituitary target organ axes. ACTH, adrenocorticotrophic hormone; CRH, corticotropin-releasing hormone; FSH, follicle-stimulating hormone; GH, growth hormone; GHRH, growth hormone-releasing hormone; GnRH, gonadotropin-releasing hormone; IGF, insulin-like growth factor; LH, luteinizing hormone; PRL, prolactin; T_3 , triiodothyronine; T_4 , thyroxine; TRH, thyrotropin-releasing hormone; TSH, thyroid-stimulating hormone. (Adapted from Melmed S. Mechanisms for pituitary tumorigenesis: the plastic pituitary. *J Clin Invest*. 2003;112:1603-1618.)

granule (Fig. 8-8). In animal models, lactotroph cell function is heterogeneous. For example, responsiveness of dopamine or thyrotropin-releasing hormone (TRH) and shifting proportions of PRL- versus GH-secreting cells may depend on cell location within the pituitary and on the surrounding hormonal milieu, especially that of estrogen.⁴⁶

Prolactin Structure. The human PRL gene, located on chromosome 6,⁴⁷ apparently arose from a single common ancestral gene giving rise to the relatively homologous PRL, GH, and placental lactogen-related proteins.⁴⁸ Several factors influence PRL gene expression, including estrogen, dopamine, TRH, and thyroid hormones.⁴⁹ PRL is

Figure 8-5 Lactotroph cell. Normal prolactin-secreting cells express strong positivity for prolactin within the cytoplasm of polyhedral cells with elongated cell processes. Some processes surround adjacent immunonegative cells that correspond to gonadotrophs. (From Asa SL. Tumors of the pituitary gland. In: Rosai J, ed. *Atlas of Tumor Pathology*, Series III, Fascicle 22. Washington, DC: Armed Forces Institute of Pathology, 1997:15.)

Figure 8-6 Prolactin cell hyperplasia. In the third trimester of pregnancy, hyperplasia of prolactin cells occurs. Cells containing immunoreactive prolactin comprise almost 50% of the cell population of the gland. (From Asa SL. Tumors of the pituitary gland. In: Rosai J, ed. *Atlas of Tumor Pathology*, Series III, Fascicle 22. Washington, DC: Armed Forces Institute of Pathology, 1997:15.)

Figure 8-7 Electron micrograph of a normal lactotroph shows a well-developed rough endoplasmic reticulum that forms concentric whorls. A prominent Golgi complex is seen in a juxtannuclear location and harbors forming pleomorphic secretory granules. The cytoplasm is otherwise sparsely granulated. (From Asa SL. Tumors of the pituitary gland. In: Rosai J, ed. *Atlas of Tumor Pathology*, Series III, Fascicle 22. Washington, DC: Armed Forces Institute of Pathology, 1997:16.)

a 199-amino-acid polypeptide containing three intramolecular disulfide bonds. It circulates in blood in various sizes, including the 23-kd monomeric PRL ("little prolactin"), 48- to 56-kd dimeric PRL ("big prolactin"), and polymeric forms larger than 100 kd ("big, big prolactin").⁵⁰⁻⁵² The monomeric form is the most bioactive PRL. In response to TRH, the proportion of the more active monomeric form increases.

Figure 8-8 Normal mammosomatotroph. Occasional cells resembling densely granulated somatotrophs exhibit atypical features consistent with prolactin secretion: the secretory granules are highly pleomorphic, and there is misplaced exocytosis (i.e., extrusion of secretory material along the lateral cell border), as indicated by the arrow. (From Asa SL. Tumors of the Pituitary Gland. In: Rosai J, ed. *Atlas of Tumor Pathology*, Series III, Fascicle 22. Washington, DC: Armed Forces Institute of Pathology, 1997:17.)

A glycosylated form of PRL identified in pituitary extracts is less biologically active than "little prolactin."⁵³ Monomeric PRL is cleaved into 8- and 16-kd forms,⁵⁴ and the 16-kd variant is antiangiogenic.^{55,56} A circulating PRL-binding protein corresponds to the extracellular domain of the PRL receptor.⁵⁷

Regulation

PRL secretion is under the inhibitory control of dopamine, which is largely produced by the tuberoinfundibular cells and the hypothalamic tuberohypophyseal dopaminergic system.^{58,59} Dopamine reaches the lactotrophs via the hypothalamic pituitary portal system and inhibits PRL secretion by binding to the type 2 dopamine (D₂) receptors on pituitary lactotrophs.⁶⁰ PRL participates in negative feedback to control its release by increasing tyrosine hydroxylase activity in the tuberoinfundibular neurons.⁵⁹ In PRL-deficient animals, dopamine is decreased in the median eminence.⁶¹ Mice lacking the D₂ receptor develop hyperprolactinemia and lactotroph proliferation.⁶⁰ Factors other than dopamine inhibit PRL secretion, including endothelin-1 and transforming growth factor- β 1, which act as paracrine PRL inhibitors,^{62,63} and calcitonin, which may be derived from the hypothalamus.⁶⁴

Several substances act as PRL-releasing factors. Basic FGF and epidermal growth factor induce PRL synthesis and secretion. Vasoactive intestinal polypeptide (VIP) stimulates PRL synthesis via cyclic adenosine monophosphate (cAMP).⁶⁵ A hypothalamic prolactin-releasing peptide (PrRP) acts through a specific receptor⁶⁶ in normal pituitary glands and in a subset of PRL-secreting tumors.⁶⁷ Oxytocin and pituitary adenylate cyclase-activating protein also release PRL.⁵⁹ TRH stimulates PRL⁶⁸ but probably does not play an important role in PRL secretion. Estrogen stimulates PRL gene transcription and secretion,⁶⁹ explaining why women have higher PRL pulse frequency than do postmenopausal women and men.⁷⁰ Galanin is synthesized in both the pituitary and the hypothalamus and may act as a PRL-releasing factor.⁷¹ The physiologic roles of γ -aminobutyric acid (GABA), neurotensin, substance P, bombesin, and cholecystokinin in regulating human PRL secretion are unresolved.⁵⁹

Serotonin may be additive with VIP in releasing PRL, and infusion of 5-hydroxytryptophan (5-HTP), a serotonin precursor, elicits PRL release. Nocturnal PRL secretion is attenuated by cyproheptadine. Serotonin may mediate nocturnal PRL secretion and may also participate with VIP in the suckling reflex. Opiates acutely induce PRL release, although naloxone does not consistently suppress PRL levels. GHRH, when administered at high doses, moderately induces PRL secretion, and patients harboring ectopic GHRH-producing tumors have mild to moderate hyperprolactinemia. GnRH also stimulates PRL in women, especially during the periovulatory menstrual phase. Although posterior pituitary hormones have been shown to regulate rat PRL secretion,⁷² the roles of vasopressin, oxytocin, and other neurohypophyseal molecules in regulating human PRL remain unresolved. Histamine may act on the hypothalamus to regulate PRL, and H₂ blockers induce PRL secretion.

A short-loop feedback of PRL has been proposed, and transgenic mice with deleted PRL have decreased hypothalamic dopamine content.⁷³ In humans, the existence of this regulatory loop has been difficult to prove.

Prolactin Secretion

The calculated production rate of PRL ranges from 200 to 536 μ g/day per square meter of body surface area, and the

metabolic clearance rate ranges from 40 to 71 mL/min per m².⁷⁴ PRL is cleared rapidly, with a calculated disappearance half-life ranging from 26 to 47 minutes. PRL secretion occurs episodically; between 4 and 14 secretory pulses occur over 24 hours, each lasting between 67 and 76 minutes.^{75,76} PRL is secreted episodically during the day, with highest levels achieved during sleep and lowest occurring between 10 a.m. and noon.⁷⁷ The nocturnal elevation is sleep entrained; a temporal relationship exists between rapid-eye-movement (REM) and non-REM sleep cycles,⁷⁸ and PRL may cause periods of REM. PRL levels fall with age in both men and women. In older men, less PRL is produced with each secretory burst than in younger men.⁷⁹ Likewise, postmenopausal women have lower mean serum PRL levels and lower PRL pulse frequency than do premenopausal women or men, suggesting a stimulatory effect of estrogen on both parameters.⁷⁰

Prolactin Action

The prolactin receptor gene (*PRLR*) is a member of the cytokine receptor superfamily,⁸⁰ localizes to chromosome 5p13, and comprises 10 exons. The receptor gene has two 5' promoters that direct transcription of a 598-amino-acid peptide⁸¹ comprising an extracellular domain, a hydrophobic transmembrane domain, and an intracytoplasmic region homologous to the GH receptor (Fig. 8-9).⁸² PRLR dimerization occurs with or without ligand binding and results ultimately in phosphorylation of intracellular JAK/STAT molecules. Two binding sites, encompassing helices 1 and 4 and helices 1 and 3 on the PRL molecule, are critical for formation of the trimeric ligand-receptor complex and subsequent signaling.⁸³⁻⁸⁵ PRLR induces protein tyrosine phosphorylation and activation of JAK2 kinase and signal transducing activators of transcription proteins

(STATs) 1 through 5.^{86,87} STAT5 phosphorylation mediates transcriptional activation of the β -casein gene.⁸⁸

PRLRs are expressed in breast, pituitary, liver, adrenal cortex, kidneys, prostate, ovary, testes, intestine, epidermis, pancreatic islets, lung, myocardium, brain and lymphocytes. Estrogen also induces liver PRLR expression.⁸³ Regulation of milk production occurs via a cascade of intracellular events, and homozygous mice in which the PRLR has been inactivated are infertile.⁸³ A gain-of-function mutation conferring constitutive activity of the PRLR is present in a subset of patients with multiple breast fibroadenomas.⁸⁹ PRLR receptor antagonists have been developed for targeting the receptor in PRL-sensitive disturbances, including resistant prolactinomas and breast and prostate tumors.^{85,90}

Function of Prolactin. PRL is essential for human species survival, because it is required for milk production during pregnancy and lactation. Additional biologic functions ascribed to PRL include reproductive and metabolic effects, mammary development, pigeon crop sac activity, freshwater survival, melanin synthesis, water-seeking behavior of newts, molting, and parental behavior.⁹¹ Although PRL and its receptor are clearly crucial in lower animals,⁹² the impact of PRL on maternal behavior in humans has not been fully delineated.

Mammary Gland Development and Lactation

Puberty. PRL is not essential for pubertal mammary development, which appears to require GH, the action of which is mediated by insulin-like growth factor 1 (IGF1).⁹³⁻⁹⁵ At birth, the rodent mammary gland consists of a fat pad with small areas of ductal anlagen that differentiate into pubertal mammary glandular elements under the influence of estrogen, GH, and IGF1. At puberty, a surge of

Figure 8-9 Ligand-dependent and -independent dimerization of the prolactin (PRL) receptor (PRLr). **A**, Ligand-dependent dimerization model. PRLr is in monomeric form at the cell membrane. One molecule of PRL first binds to one PRLr monomer via binding site 1, and this 1:1 complex then recruits the second PRLr via binding site 2. Dimerization of the two PRLRs leads to activating changes in the intracellular domain, resulting in PRL signal transduction, such as phosphorylation (P) of the Jak2 kinase, phosphorylation of the PRLr, and recruitment and phosphorylation of Stat5a. **B**, Ligand-independent model. PRLr exists in dimeric form at the cell membrane in the absence of ligand. The receptors are held in an inactive form until binding of PRL to this preformed complex induces activating changes in the intracellular domain, leading to phosphorylation of the Jak2 kinase, phosphorylation of the PRLr, and recruitment and phosphorylation of Stat5a. (From Clevenger C, Gadd SL, Zheng J. New mechanisms for PRLr action in breast cancer. *Trends Endocrinol Metab.* 2009;20:223.)

estrogen begins the process. Terminal end buds form and lead the process of mammary development by branching and extending into the substance of the mammary fat pad, leaving in their wake a network of ducts that virtually fill the mouse mammary fat pad.^{96,97} GH acts on the mammary stromal compartment to produce IGF1, which, in turn, stimulates formation of the terminal end buds and ducts in synergy with estrogen.^{95,98} Parathyroid hormone–related protein is essential for fetal mammary development,⁹⁹ and epidermal growth factor is essential for pubertal mammary development.¹⁰⁰ Progesterone, possibly in association with GH and PRL, causes formation of lobular “decorations” along ducts, which are precursors to true glands; progestins have similar effects.¹⁰¹ Pubertal mammary development begins in girls between the ages of 8 and 13 (see Chapter 23). Once fully developed, the pubertal mammary gland remains quiescent until pregnancy, although cyclic changes do occur during the menstrual cycle.

In pregnancy, alveolar elements proliferate and begin to produce milk proteins and colostrum. At 3 to 4 weeks of gestation, terminal ductal sprouting occurs, followed by lobular-alveolar formation, and true alveoli form at the end of the first trimester. Glandular elements proliferate further, and secretory products appear in the alveolar lumina. During the third trimester, fat droplets are seen within alveolar cells, and the glands fill with colostrum.¹⁰² A combination of estrogen, PRL, progesterone, and possibly IGF1 and placental hormones are largely responsible for this phase of mammary development.¹⁰³ In the absence of PRL, formation of alveolar structures is impaired, as was demonstrated in mice with targeted disruption of the PRL gene.⁶⁰ Likewise, women with isolated PRL deficiency are unable to lactate.¹⁰⁴

Alveolar formation and milk production also require progesterone, and lobular-alveolar formation does not occur in mice lacking the progesterone receptor.¹⁰⁵ Only a minority of women have expressible milk during pregnancy, most likely due to inhibitory effects of estradiol¹⁰⁶ and progesterone¹⁰⁷ on PRL-induced milk production. Hormone perturbations during pregnancy also act on the fetal mammary gland, causing prominent neonatal nipples and secretion of “witch’s milk.”

Lactation. Mechanisms of milk production are similar in all mammals, but milk composition differs.¹⁰⁸ Active lactation is due in part to attenuation of estrogen and progesterone levels and elevation of PRL levels after delivery. Suckling increases milk production after parturition, and suckling is essential for continued lactation because of its distal effect on pituitary hormone production and because it empties the mammary gland of milk.¹⁰⁹ Milk accumulation further inhibits milk synthesis, explaining why a certain level of nursing activity is necessary for successful breast-feeding. In the absence of suckling, PRL concentrations, which rise throughout gestation, return to normal by 7 days after delivery.¹¹⁰ Whereas PRL is essential for milk production, the milk yield does not closely correlate with serum PRL levels.¹¹¹

Suckling also stimulates release of oxytocin from the posterior pituitary. In contrast to PRL, oxytocin responses to suckling do not decline as nursing continues for up to 6 months. Mothers who breast-fed exclusively had mean stimulated oxytocin levels significantly higher during late versus early lactation.¹¹² Oxytocin induces myoepithelial cell contraction, thereby causing milk ejection.¹¹³ Oxytocin also has important effects on alveolar proliferation.¹¹⁴ Mice that are deficient in oxytocin are unable to nurse their young, and oxytocin replacement permits these dams to nurse.

Lactational Amenorrhea. Lactational amenorrhea results in secondary infertility, and this natural form of contraception depends on the frequency and duration of breast-feeding. Infants of Kung hunter-gatherer women are suckled approximately four times per hour and at will during the night; these women bear a mean of 4.7 children during their reproductive years.¹¹⁵ In contrast, the Hutterites of North America bear a mean of 10.6 children during their lifetimes, presumably because they nurse according to a rigid schedule, use supplemental feedings, and wean at 1 year. In Edinburgh, resumption of anovulatory menses occurs within 28 weeks after delivery, and the first ovulation occurs at a mean of 34 weeks due to persistently abnormal LH pulsatile secretion.¹¹⁶

Immune Function. Previously, evidence had indicated that PRL stimulates immune responsiveness,¹¹⁷ and PRL was shown to stimulate immune cell functions in immunosuppressed mice.¹¹⁸ However, more recent evidence¹¹⁹ indicates that PRL may not be important for immune function, because innate immunity is not altered in mice that lack either the PRLR ($PRLR^{-/-}$) or the PRL gene ($PRL^{-/-}$).^{60,120,121}

Reproductive Function. In mice with disrupted PRLR expression, both ovulation and the number of primary follicles are reduced.⁸³ These findings underscore the luteotrophic function of PRL but do not explain the suppressed gonadal function observed in patients with hyperprolactinemia,¹²² which include short luteal phase, reduced central FSH and LH levels, decreased granulosa cells, decreased estradiol levels, and, ultimately, amenorrhea (Fig. 8-10). Clearly, attenuated gonadotropin secretion is

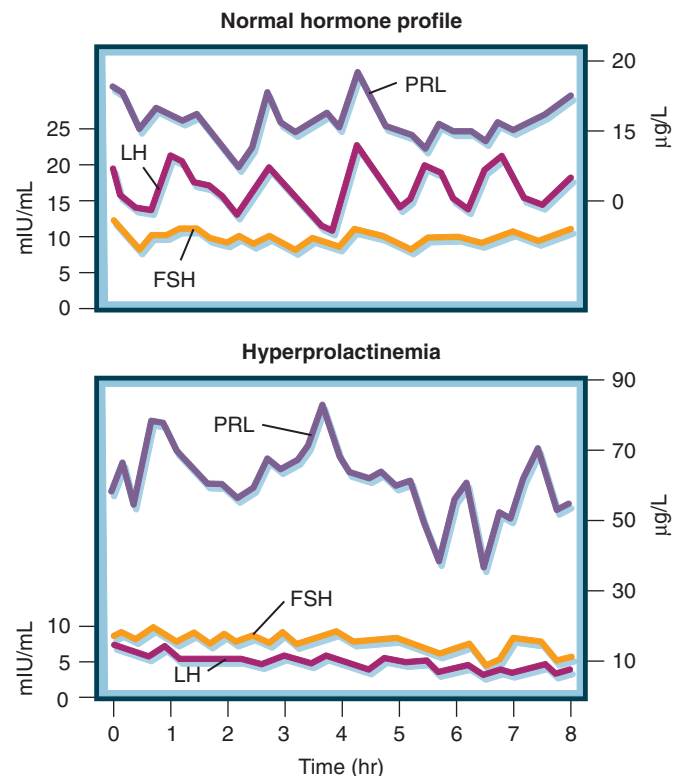

Figure 8-10 Effect of hyperprolactinemia on FSH and LH secretory patterns leading to hypogonadotropism in a female patient. FSH, follicle-stimulating hormone; LH, luteinizing hormone; PRL, prolactin. (Adapted from Tolis G. Prolactin: physiology and pathology. *Hosp Pract.* 1980;15:85-95.)

also a major determinant of ovarian dysfunction in these patients.

Male mice with disrupted PRLRs are fertile with low gonadotropin and normal testosterone levels. In human male subjects with hyperprolactinemia, LH and FSH pulsatility is attenuated, testosterone levels are suppressed, and sperm counts and motility are low.

Prolactin Assays

The PRL RIA is highly specific and clearly distinguishes PRL from GH. PRL measurements are standardized; reference preparations are provided by the National Institute for Biological Standards and Control in London and by the National Hormone and Pituitary Program in the United States. Improved assay efficiency and turnaround time, reproducibility, and sensitivity have been achieved by immunoradiometric (IRMA) and chemiluminescent (ICMA) PRL assays. Because these samples are usually assayed at a single dilution, extremely high PRL concentrations may saturate the ability of these assays to detect the correct level, resulting in a falsely low value being reported.¹²³ This "hook effect" may result in misdiagnosis of PRL-secreting macroadenomas as clinically nonfunctioning adenomas, with "normal" PRL levels reported in about 5% of the patients. Therefore, for patients harboring macroadenomas with clearcut clinical features of hyperprolactinemia, serum samples should be subjected to dilution of at least 1:100 before assay.

Hyperprolactinemia

The causes of hyperprolactinemia may be physiologic, pathologic, or drug induced (Table 8-1).^{124,125}

Physiologic Causes

Pregnancy. During pregnancy, the normal pituitary gland may increase in size by twofold or more⁴⁴; this is the result of a marked increase in the number of PRL-producing cells and a relative decrease in other hormone-secreting cells. Serum PRL concentrations rise to a mean of 207 $\mu\text{g/L}$ during pregnancy,¹¹⁰ and amniotic fluid PRL concentrations are 100 times those of maternal or fetal blood.¹¹⁰

Suckling increases serum PRL levels approximately 8.5-fold in actively nursing mothers,^{126,127} and the milk let-down phenomenon is not associated with increased PRL. As nursing continues, PRL concentrations fall, but each suckling episode continues to cause a subsequent episodic rise in serum PRL. Mean serum concentrations were 162 $\mu\text{g/L}$ at 2 to 4 weeks postpartum, 130 $\mu\text{g/L}$ at 5 to 14 weeks, and 77 $\mu\text{g/L}$ at 15 to 24 weeks.¹¹² It is unclear why active milk production continues despite progressively lower PRL levels after parturition.

Idiopathic Hyperprolactinemia. An elevated circulating PRL level in patients in whom no cause is identified is considered idiopathic, and these cases are relatively resistant to dopamine therapy. Mean serum PRL levels in patients with idiopathic hyperprolactinemia is usually less than 100 $\mu\text{g/L}$.¹²⁸

Macroprolactinemia. PRL is a 23-kd, single-chain polypeptide, but it may also circulate in higher-molecular-weight forms (50 and 150 kd). High-molecular-weight PRL variants (see earlier discussion) may represent 85% or more of total PRL, but under usual circumstances the 22-kd variety predominates. Macroprolactinemia reflects these larger circulating PRL molecules (particularly the 150-kd variety), which exhibit markedly reduced bioactivity. Few of the expected clinical abnormalities usually associated with hyperprolactinemia (sexual dysfunction, galactorrhea, osteoporosis) occur in patients with macroprolactinemia.¹²⁹

Screening for macroprolactinemia can be accomplished by polyethylene glycol precipitation of serum samples. In one survey, macroprolactinemia was detected in 22% of 2089 hyperprolactinemia samples.¹³⁰

Pathologic Causes. Pathologic causes include prolactinomas and pituitary or sellar tumors that inhibit dopamine because of pressure on the pituitary stalk or interruption of the vascular connections between the pituitary and hypothalamus. In a large series of histologically confirmed cases, a serum PRL level greater than 2000 mU/L (approximately 100 $\mu\text{g/L}$) was almost never encountered as a result of stalk dysfunction.¹³¹ However, prolactinomas can manifest with any level of PRL elevation.

Breast stimulation has only a minimal effect on serum PRL levels. In 18 normal women, serum PRL levels rose from a mean of 10 $\mu\text{g/L}$ to 15 $\mu\text{g/L}$ during breast pump stimulation.¹²⁶ Up to 20% of patients with hypothyroidism have elevated PRL levels.¹³² Treatment of hypothyroidism with thyroid hormone normalizes serum PRL if the hyperprolactinemia is caused by thyroid hormone deprivation.

PRL is moderately elevated (mean, 28 $\mu\text{g/L}$) in patients with chronic renal failure and in those being treated with dialysis.¹³³ The increase is largely a result of an increase in "little prolactin," due in part to decreased glomerular filtration rate. Sexual dysfunction is common in men on dialysis. Reducing PRL with dopamine agonists improves sexual function in patients on chronic hemodialysis¹³⁴ but does not normalize menses.¹³⁵ Side effects of dopamine agonists in patients with renal failure may be exacerbated because of fluid shifts and multiple medication interactions.

PRL levels rise in response to stress, correlate with the degree of stress, and typically return to normal as stress abates. The mean peak serum PRL level in 19 women undergoing general anesthesia was 39 $\mu\text{g/L}$ immediately before surgery and 173 $\mu\text{g/L}$ at surgery; PRL was still elevated 24 hours after surgery (mean, 47 $\mu\text{g/L}$).¹³⁶

Severe head trauma also results in hyperprolactinemia, often accompanied by diabetes insipidus or the syndrome of inappropriate antidiuretic hormone secretion (SIADH) and other anterior pituitary hormone deficiencies. Fifty percent of patients develop moderate hyperprolactinemia after cranial and hypothalamic radiation.¹³⁷

Pharmacologic Causes. A variety of medications cause minimal or moderate PRL elevations and may cause galactorrhea, amenorrhea, or reduced male sexual function. Neuroleptic drugs elevate PRL because of their dopamine antagonist properties. Chlorpromazine stimulates PRL, as do neuroleptics, which act by antagonizing both serotonin and dopamine receptors. Risperidone is a potent PRL stimulator.¹³⁸

Unless patients exhibit sexual dysfunction, related osteoporosis, or troublesome galactorrhea, no treatment of drug-induced hyperprolactinemia may be advised.¹³⁹ It should not always be assumed that hyperprolactinemia in patients who are taking drugs known to elevate PRL is, in fact, caused by those medications. Prolactinoma, other sellar lesions,¹⁴⁰ hypothyroidism, or renal failure should be considered as causes of hyperprolactinemia requiring active management.

In patients taking neuroleptic medications, if the clinical situation permits, temporary drug withdrawal may be considered to determine whether PRL levels will normalize. If PRL levels do not normalize, a pituitary MRI should be performed. If neuroleptics are elevating PRL levels, switching to olanzapine may be attempted, because it does not

TABLE 8-1

Causes of Hyperprolactinemia	
PHYSIOLOGIC	PHARMACOLOGIC (cont'd)
Pregnancy Lactation Stress Sleep Coitus Exercise	Cholinergic Agonist
	Physostigmine
	Antihypertensives
PATHOLOGIC	Labetalol Reserpine Verapamil
	H2 Antihistamines

Dopamine Synthesis Inhibitors α -Methyldopa	
Catecholamine Depletors Reserpine	

elevate PRL levels. In determining whether to discontinue a drug or whether to use an alternative medication,¹⁴¹ the benefits should be weighed against the risks of drug replacement or cessation. Although combined use of dopamine antagonists and dopamine agonists is not usually advised because of increased risk of side effects (e.g., postural hypotension) and exacerbation of underlying psychosis, some advocate the use of both formulations simultaneously.¹⁴²

Clinical Features of Hyperprolactinemia. Galactorrhea and reproductive dysfunction are the hallmarks of non-physiologic hyperprolactinemia. Women present with galactorrhea associated with a range of menstrual

disturbances including oligomenorrhea and amenorrhea, whereas men present with symptoms of hypogonadism and tumor mass effects, although galactorrhea also occurs infrequently in men.

Galactorrhea and amenorrhea were reported in the 19th century by Chiari and Frommel.¹⁴³ The Chiari-Frommel syndrome comprises postpartum galactorrhea, amenorrhea, and "utero-ovarian atrophy" in patients not nursing. This disorder is usually self-limited, and fertility eventually returns spontaneously, sometimes without an intervening menstrual period. Patients with postpartum amenorrhea, hyperprolactinemia, and galactorrhea have also been found to harbor prolactinomas. In the 1950s, Argonz¹⁴⁴ and

Forbes¹⁴⁵ and their colleagues associated galactorrhea and amenorrhea with pituitary tumors. In a report of 18 such patients, galactorrhea and amenorrhea were present for up to 11 years after parturition, and the patients had a mean PRL level of 45 $\mu\text{g/L}$.¹³²

Galactorrhea. Inappropriate nipple secretion of milk-like substances¹⁴⁶ may persist after childbirth or discontinuation of nursing for as long as 6 months. After that time, continued milk production is considered abnormal, and other causes for galactorrhea should be investigated. Galactorrhea can occur in women or men; it can be unilateral or bilateral, profuse or sparse, and it can vary in color and thickness. If blood is present in the galactorrhea fluid, it could be the harbinger of an underlying pathologic process (such as a ductal papilloma or carcinoma), and mammography or sonography is indicated.

Twenty-nine of 48 patients with pituitary tumors and galactorrhea had PRL concentrations lower than 200 $\mu\text{g/L}$, most likely on the basis of stalk compression, suggesting that they harbored pituitary tumors other than prolactinomas.¹³² It is likely that most patients with so-called idiopathic galactorrhea with amenorrhea harbor microprolactinomas. Fifty percent of patients with acromegaly also have hyperprolactinemia, because human GH is a potent lactogen and can cause galactorrhea when elevated.¹⁴⁷

Normoprolactinemic galactorrhea with regular menses represents the largest single cause of galactorrhea. In two thirds of patients, postpartum galactorrhea persists despite the resumption of menses, and this probably does not represent a pathologic entity. Normal PRL levels may still permit milk production, and treatment of such patients with dopamine agonists alleviates galactorrhea. Galactorrhea may also develop transiently after surgical procedures to the chest wall, including mastoplasty. The secretion may be copious and may arise from neural reflex intercostal nerve stimulation.¹⁴⁸

The management of galactorrhea should be determined by identifying and treating the underlying cause. Regardless of the etiology, galactorrhea associated with hyperprolactinemia responds to correction of the hyperprolactinemia.

Growth Hormone

Physiology

Somatotroph Cells. Mammosomatotroph cells expressing both PRL and GH arise from the acidophilic stem cell and immunostain mainly for PRL. Somatotrophs are located predominantly in the lateral wings of the anterior pituitary gland and comprise between 35% and 45% of pituitary cells (Fig. 8-11). These ovoid cells contain prominent secretory granules up to 700 μm in diameter. Juxtanuclear Golgi structures are particularly prominent, with secretory granules in formation. The gland contains a total of 5 to 15 mg of GH.¹⁴⁹

Biosynthesis. The human GH locus spans approximately 66 kilobases (kb) on the long arm of chromosome 17q22-24.¹⁵⁰ It contains a cluster of five highly conserved genes, each consisting of five exons separated by four introns,¹⁵¹ that encode the various forms of human growth hormone (hGH) and human chorionic somatomammotropin (hCS):

- hGH-N is encoded by *GH1* (growth hormone 1)
- hCS-L is encoded by *CSHL1* (chorionic somatomammotropin-like 1)

Figure 8-11 Normal somatotroph. A somatotroph in the nontumorous pituitary is large and round to ovoid. It contains numerous electron-dense secretory granules that range from 250 to 700 μm in diameter. Short profiles of rough endoplasmic reticulum are scattered throughout the cytoplasm. The juxtanuclear Golgi complex is prominent and harbors forming secretory granules. (From Asa SL. Tumors of the pituitary gland. In: Rosai J, ed. *Atlas of Tumor Pathology*, Series III, Fascicle 22. Washington, DC: Armed Forces Institute of Pathology, 1997:14.)

- hCS-A is encoded by *CSH1* (chorionic somatomammotropin hormone 1)
- hGH-V is encoded by *GH2* (growth hormone 2)
- hCS-B is encoded by *CSH2* (chorionic somatomammotropin hormone 2)

The hGH-N gene codes for a 22-kd (191-amino-acid) protein and is selectively transcribed in pituitary somatotrophs¹⁵² (see later discussion). Other genes of the hGH/hCS cluster are expressed in the placenta. The hCS-A and hCS-B genes are expressed in placental trophoblasts.¹⁵³ hCS-L is found in placental villi but has been considered a pseudogene. hGH-V, expressed in placental syncytiotrophoblasts, encodes a 22-kd protein that can be detected in maternal circulation from midgestation, as well as a minor form called hGH-V2. Elevated maternal hGH-V serum concentrations are accompanied by a decline in hGH-N, suggesting feedback regulation of the maternal hypothalamic pituitary axis. After delivery, circulating hGH-V levels drop rapidly and are undetectable after 1 hour.¹⁵⁴

The GH1 *hGH* promoter region contains *cis*-elements that mediate both pituitary-specific and hormone-specific signaling. The transcription factor POU1F1 confers tissue-specific GH expression, and a second, ubiquitous factor binds to a distal POU1F1 site containing a consensus sequence for the Sp1 transcription factor. POU1F1 and Sp1 both contribute to GH promoter activation, because mutation of the Sp1 binding site leads to attenuation of promoter activity.¹⁵⁵ Deoxyribonuclease-hypersensitive sites of a locus control region (LCR) of the hGH gene determine somatotroph and lactotroph GH expression, and the LCR is involved in regulation of a chromatin domain in these pituitary cells.¹⁵⁰ GH synthesis and release are under the control of a variety of hormonal agents, including GHRH, somatostatin, ghrelin, IGF1, thyroid hormone, and glucocorticoids. GHRH stimulates GH synthesis and release, mediated by cAMP. cAMP response element (CREB)-binding protein, known as CREBBP or CBP, is phosphorylated by protein kinase A and is a cofactor for POU1F1-dependent human GH activation. IGF1 attenuates basal and stimulated GH gene expression.

The GH1 molecule, a single-chain polypeptide hormone consisting of 191 amino acids, is synthesized, stored, and secreted by somatotroph cells. The crystal structure of human GH reveals four α -helices.¹⁵⁶ Circulating GH

molecules comprise several heterogeneous forms: 22- and 20-kd monomers, an acetylated 22-kd form, and two des-amino GH molecules. The 22-kd peptide is the major physiologic GH component, accounting for 75% of pituitary GH secretion. Amino acids 32 through 46 are deleted by alternative splicing of the GH gene to yield 20-kd GH, which accounts for about 10% of pituitary GH. The 20-kd GH has a slower metabolic clearance time,¹⁵⁷ accounting for the fact that plasma ratio of the 20- and 22-kd forms is higher than in the pituitary gland.

Regulation

Neuropeptides, neurotransmitters, and opiates impinge on the hypothalamus and modulate release of GHRH and somatostatin (somatotropin release-inhibiting factor, or SRIF). Integrated effects of these complex neurogenic influences determine the final secretory pattern of GH. Apomorphine, a central dopamine receptor agonist, stimulates GH secretion,¹⁵⁸ as does levodopa (L-dopa). Oral L-dopa administration evokes a brisk serum GH response within 1 hour in healthy young subjects. Norepinephrine increases GH secretion via α -adrenergic pathways and inhibits GH release via β -adrenergic pathways. Insulin-induced hypoglycemia, clonidine, arginine administration, exercise, and L-dopa facilitate GH secretion by α -adrenergic effects.¹⁵⁹ β -Adrenergic blockade increases GHRH-induced GH release, possibly by a direct pituitary action or by decreasing hypothalamic somatostatin release. Endorphins and enkephalins stimulate GH and may account for GH release during severe physical stress and extreme exercise.¹⁵⁹ Galanin, a 29-amino-acid neuropeptide, induces GH release and responds to GHRH. Cholinergic and serotonergic neurons and several neuropeptides stimulate GH, including neurotensin, VIP, motilin, cholecystokinin, and glucagon.

Interaction of GHRH and SRIF. The somatotroph cell expresses specific receptors for GHRH,¹⁶⁰ growth hormone secretagogues (GHS), and SRIF receptor subtypes 2 and 5, which mediate GH secretion.^{161,162} GHRH selectively induces GH gene transcription and hormone release.¹⁶³ GHRH administered to normal adults elicits a prompt rise in serum GH levels, with higher levels occurring in female subjects.¹⁶⁴ SRIF suppresses both basal and GHRH-stimulated GH pulse amplitude and frequency but does not affect GH biosynthesis.

Hypothalamic SRIF and GHRH are secreted in independent waves and interact together with additional GH secretagogues to generate pulsatile GH release. The rat hypothalamus releases GHRH and SRIF 180 degrees out of phase every 3 to 4 hours, resulting in pulsatile GH levels. SRIF antibody administration elevates GH levels, but the intervening GH pulses remain intact,¹⁶⁵ implying that hypothalamic SRIF secretion generates GH troughs. GHRH antibodies eliminate spontaneous GH surges. In humans, GH pulsatility persists when GHRH is tonically elevated, as in ectopic tumor GHRH production or during GHRH infusion,¹⁶⁶ suggesting that hypothalamic SRIF is largely responsible for GH pulsatility. Preexposure to SRIF enhances somatotroph sensitivity to GHRH stimulation. Therefore, during a normal GH trough period, the high SRIF level probably primes the somatotroph to respond maximally to a subsequent GHRH pulse, thus optimizing GH release. SRIF also inhibits central GHRH release via direct synaptic connections with hypothalamic SRIF-containing neurons.

Chronic GHRH stimulation, by continuous infusion or repeated bolus administration, eventually desensitizes GH release in vitro and in vivo, possibly due to depletion of a

GHRH-sensitive pool of GH. GHRH pretreatment also decreases somatotroph GHRH binding sites.¹⁶⁷ GH stimulates hypothalamic SRIF, GHRH and SRIF autoregulate their own respective secretion, and GHRH also stimulates SRIF release.^{168,169} GH secretion is further regulated by its target growth factor, IGF1, which participates in a hypothalamic-pituitary peripheral regulatory feedback system.^{170,171} IGF1 stimulates hypothalamic SRIF release and inhibits pituitary GH gene transcription and secretion.

Growth Hormone Secretagogues and Ghrelin. The isolation of ghrelin implicated an additional control system for regulation of GH secretion (see Chapter 7). Ghrelin is a 28-amino-acid peptide that binds the GHS receptor¹⁷² to induce hypothalamic GHRH and pituitary GH.¹⁷³ A unique *n*-octanoylated serine 3 residue confers GH-releasing activity to the molecule. Ghrelin is synthesized in peripheral tissues, especially in gastric mucosal neuroendocrine cells, as well as centrally in the hypothalamus. Ghrelin administration dose-dependently evokes GH release and also induces food intake (Fig. 8-12). Hypothalamic ghrelin

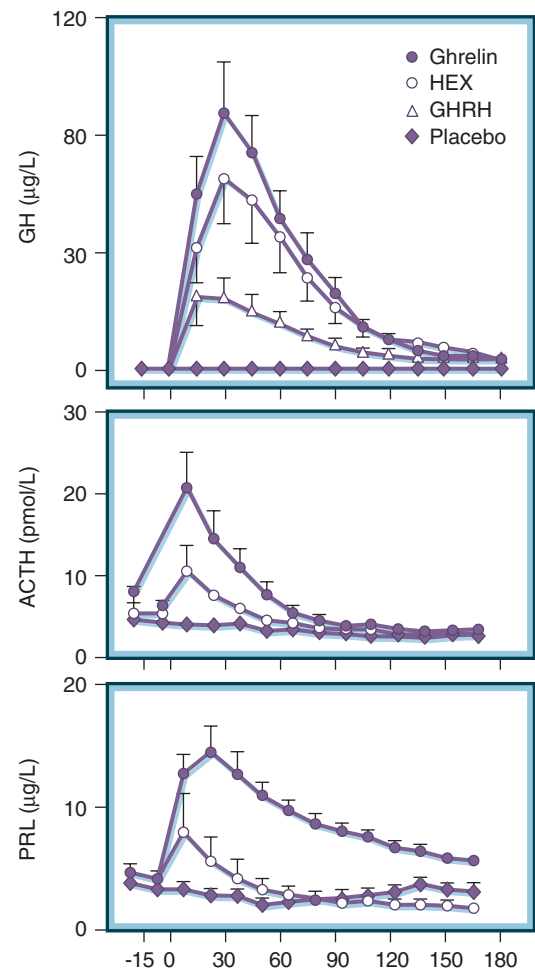

Figure 8-12 Effect of growth hormone (GH) secretagogues on secretion of GH, corticotropin (ACTH), and prolactin (PRL) in healthy subjects. Mean (\pm standard error of the mean [SEM]) curve responses after administration of ghrelin (1.0 μ g/kg), hexarelin (HEX, 1.0 μ g/kg), growth hormone-releasing hormone (GHRH, 1.0 μ g/kg), or placebo. (Adapted from Arvat E, Maccario M, Di Vito L, et al. Endocrine activities of ghrelin, a natural growth hormone secretagogue [GHS], in humans: comparison and interactions with hexarelin, a nonnatural peptidyl GHS, and GH-releasing hormone. *J Clin Endocrinol Metab*. 2001;86:1169-1174.)

likely controls GH secretion, whereas peripheral sources exhibit additional complex nutritional effects (see Chapter 7). Plasma ghrelin levels are suppressed after gastric bypass surgery,¹⁷⁴ and mice with disrupted ghrelin or GHS receptors are resistant to diet-induced obesity.¹⁷⁵ Accumulating evidence indicates that ghrelin subserves both GH secretion and control of appetite.¹⁷⁶ Control of GH secretion requires hypothalamic GHRH and SRIF as well as ghrelin.¹⁷⁷

Synthetic hexapeptides (artificial GHSs) recognize the GHS (ghrelin) receptor, induce potent and reproducible GH release, and are useful for the diagnosis of GH deficiency (GHD).¹⁷⁸ GHSs stimulate GH secretion, and GHRH and GHS act through distinct receptors and via different intracellular signaling pathways on somatotroph subpopulations.¹⁷⁹ However, GHRH also acts as an allosteric coagonist for the ghrelin receptor.¹⁸⁰ Ghrelin agonists require the presence of a functional hypothalamus to evoke GH release, as evidenced in patients with intact pituitary but disordered hypothalamic function, in whom GHS does not induce GH.¹⁸¹ GHS agonists also potentiate GH release in response to a maximal stimulating dose of exogenous GHRH.¹⁸² After a saturating dose of GHRH, subsequent GHRH administration is ineffective, whereas GHS agonists remain effective.¹⁸³

GHSs are now used as pharmacologic tools in the diagnosis of adult GHD. An advantage of GHS testing relates to their lack of side effects, unlike the insulin tolerance test. Modest PRL and ACTH/cortisol increases have been reported with some GHSs, leading to the development of novel GHSs with more selective somatotroph actions.¹⁷⁶

Secretion. GH secretion is normally episodic and exhibits a diurnal rhythm with approximately two thirds of the total daily GH secretion produced at night, triggered by the onset of slow-wave sleep. Major GH secretory pulses accounting for up to 70% of daily GH secretion occur with the first episode of slow-wave sleep.¹⁸⁴ Normal GH secretion is characterized by secretory episodes separated by troughs of minimal basal secretion during which GH is undetectable.

GH concentration is high in the fetal circulation, peaking at approximately 150 µg/L during midgestation. Neonatal levels are lower (approximately 30 µg/L), possibly reflecting negative feedback control by rising levels of circulating IGF. GH output falls to a stable level during childhood, then rises at the onset of puberty to peak at a twofold to threefold higher level at late puberty. GH output declines exponentially in both sexes at the young adulthood transition, declining to one quarter of the values achieved in late puberty.¹⁵⁹ The decline in GH status occurs by a change in pulse amplitude rather than frequency. On average, the daily production of GH in the prepubertal state is 200 to 600 µg, rising to 1000 to 1800 µg at the pubertal peak.¹⁵⁹ In adulthood, production rates range from approximately 200 to 600 µg/day, with higher rates in women than in men.^{159,185} Adiposity that accompanies the aging process accounts for a significant component of declining GH output with increasing age (Table 8-2).¹⁸⁶

The ultradian rhythm of GH secretion is generated by coordinated interaction of many factors (Fig. 8-13). “Jet lag” increases GH peak amplitude, resulting in a transient increase of 24-hour GH secretion. Exercise and physical stress, including trauma with hypovolemic shock and sepsis, increase GH levels.¹⁸⁷ Emotional deprivation is associated with suppressed GH secretion, and attenuated GH responses to provocative stimuli occur in endogenous depression.¹⁸⁸

TABLE 8-2

Secretion of Growth Hormone in Adults*

Interval	Young Adult	Fasting	Obesity	Middle Age
24-hr Secretion (µg/24 hr)	540 ± 44	2171 ± 333	77 ± 20	196 ± 65
Secretory bursts (no. in 24 hr)	12 ± 1	32 ± 2	3 ± 0.5	10 ± 1
GH burst (µg)	45 ± 4	64 ± 9	24 ± 5	10 ± 6

*Deconvolution analysis of growth hormone (GH) secretion in adult males. From Thoner MO, Vance ML, Horvath E, et al. The anterior pituitary. In: Wilson JD, Foster D, eds. *Williams Textbook of Endocrinology*, 8th ed. Philadelphia, PA: Saunders; 1992:221-310.^{508,509}

Nutrition plays a major role in GH regulation. Chronic malnutrition and prolonged fasting increase GH pulse frequency and amplitude (Fig. 8-14).¹⁸⁹ Obesity decreases basal and stimulated GH secretion, insulin-induced hypoglycemia stimulates GH, and hyperglycemia inhibits GH secretion. However, chronic hyperglycemia is not associated with low GH levels, and, in fact, poorly controlled diabetes is associated with increased basal and

Figure 8-13 The growth hormone (GH) axis. Simplified diagram of the GH-insulin-like growth factor I (IGF-I) axis involving hypophysiotropic hormones controlling pituitary GH release, circulating GH-binding protein (GHBP) and its GH receptor (GHR) source, IGF-I and its largely GH-dependent binding proteins (IGFBP), and cellular responsiveness to GH and IGF-I interacting with their specific receptors. GHRH, growth hormone-releasing hormone; IGFR, IGF-I receptor; FFA, free fatty acids; SRIF, somatostatin. Figure 8-14 Effect of fasting on growth hormone (GH) secretion patterns in a healthy male subject. (Reproduced from Hartman ML, Veldhuis JD, Johnson ML, et al. Augmented growth hormone [GH] secretory burst frequency and amplitude mediate enhanced GH secretion during a two-day fast in normal men. *J Clin Endocrinol Metab.* 1992;74:757-765.)

exercise-induced GH levels.¹⁹⁰ Central glucoreceptors appear to sense glucose fluctuations, rather than absolute levels. High-protein meals and intravenous administration of single amino acids (including arginine and leucine) stimulate GH secretion. Increased serum free fatty acids blunt the effects of arginine infusion, sleep, L-dopa, and exercise on GHRH-stimulated GH release.¹⁹¹ Leptin plays a key role in regulation of body fat mass,¹⁹² regulating food intake and energy expenditure, and may act as a metabolic signal to regulate GH secretion. Leptin- and neuropeptide Y-producing hypothalamic neurons synapse with somatostatin neurons, and antisera to neuropeptide Y and somatostatin reverse starvation-induced GH release.¹⁹³ In GH-deficient hypopituitary adults, leptin concentrations are higher than would be expected from their body fat mass.¹⁹⁴

Interaction with Other Hormone Axes. There are complex and sometimes opposing interactions between GH and other pituitary hormone axes. Acute glucocorticoid administration stimulates GH secretion, whereas chronic steroid treatment inhibits GH. GH levels rise 3 hours after acute glucocorticoid administration, and they remain elevated for 2 hours.¹⁹⁵ However, supraphysiologic glucocorticoid exposure retards growth, and Cushing's disease is also associated with growth retardation, decreased serum GH, and decreased pituitary GH content surrounding the adenoma.¹⁹⁶ Glucocorticoids administered to normal subjects dose-dependently inhibit GHRH-stimulated GH secretion, similar to what is seen in Cushing's syndrome.¹⁹⁵

There are also complex interactions with the thyroid system. In hyperthyroid patients, GH levels are decreased, but levels normalize when patients are rendered euthyroid. However, thyroid hormones are necessary to evoke normal GH responses to stimulation testing and to achieve optimal responsiveness.¹⁹⁷

Gonadal steroids regulate GH secretion and GH action by different mechanisms. Testosterone stimulates GH secretion centrally, an effect that is dependent on prior aromatization to estrogen.¹⁹⁸ Estrogen stimulates GH secretion, but this is evident only with oral, not parenteral administration, because of first-pass hepatic inhibition of IGF1 production with oral administration.¹⁹⁹ Therefore, the stimulatory effect on GH secretion by estrogen is indirect and is facilitated by reduction in IGF1 feedback inhibition. Whether estrogen stimulates GH secretion centrally in women is unresolved.¹⁹⁹

Growth Hormone-Binding Proteins. Circulating growth hormone-binding proteins (GHBP) include a 20-kd low-affinity GHBP and a 60-kd high-affinity GHBP. The latter corresponds to the extracellular domain of the hepatic GH receptor and binds half of the circulating 22-kd form of GH.^{200,201} The high-affinity GHBP in humans is generated by proteolytic cleavage through the action of tumor necrosis factor- α (TNF- α)-converting enzyme, a metalloprotease.²⁰² The 20-kd GH binds preferentially to the low-affinity BP, which is unrelated to the GH receptor.

The GHBP's function to dampen acute oscillations in serum GH levels associated with pulsatile pituitary GH secretion, and plasma GH half-life is prolonged by decreased renal GH clearance of bound GH. The high-affinity BP also competes with GH for binding to surface GH receptors and, as such, alters GH pharmacokinetics and distribution.

GHBP concentrations are normal in hypopituitarism and acromegaly.²⁰³ Some patients with Laron dwarfism have absent or reduced levels of GHBP, reflecting mutations that result in translation of the GH receptor or the extracellular domain.²⁰⁴ Serum concentrations of GHBP are low in some children with idiopathic short stature²⁰⁵ and in African pygmies, suggesting abnormalities in the gene for the GH receptor.²⁰⁶ GHBP levels are increased in obesity, in pregnancy, and in subjects undergoing refeeding²⁰⁶ and reduced in individuals with malnutrition, cirrhosis, or hypothyroidism. GHBP levels are reduced by glucocorticoids and androgens²⁰⁷ and increased by oral estrogen administration.²⁰⁸

Action

GH acts to mediate growth and metabolic functions (Fig. 8-15).

Signaling. GH elicits intracellular signaling through a peripheral receptor and initiates a phosphorylation cascade involving the JAK/STAT pathway.²⁰⁹ The liver contains abundant GH receptors, and several peripheral tissues also express modest amounts of receptor, including muscle and fat (Fig. 8-16).²¹⁰ The GH receptor is a 620-amino-acid, 70-kd protein of the class I cytokine/hematopoietin receptor superfamily that consists of an extracellular ligand-binding domain, a single membrane-spanning domain, and a cytoplasmic signaling component.²¹¹ The GH receptor superfamily is homologous with receptors for PRL, interleukin 2 (IL-2) through IL-7, erythropoietin, interferon, and colony-stimulating factor.

GH complexes with two predimerized GH receptor components to induce a conformational rotation that triggers signaling (see Fig. 8-16).^{210,212} This is characterized by rapid JAK2 tyrosine kinase activation leading to phosphorylation of intracellular signaling molecules including STAT1, STAT3, and STAT5, critical signaling components for GH action.²¹³ Phosphorylated STAT proteins are directly translocated to the cell nucleus, where they elicit GH-specific target gene expression by binding to nuclear DNA. STAT1 and STAT5 may also interact directly with the GH receptor molecule.²¹³ GH also induces c-fos (FOS) induction, insulin receptor substrate 1 (IRS1) phosphorylation, and insulin synthesis. Additional intracellular signaling pathways induced by GH include mitogen-activated protein kinase (MAP kinase), protein kinase C, SH2- β , SHP2 (now called PTPN11), signal regulatory protein- α (SIRPA), SHC, FAK (PTK2), Crk-II, and SRC. How these seemingly overlapping pathways converge to integrate the net cellular effects of GH is at present unclear.

Intracellular GH signaling is abrogated by suppressor of cytokine signaling (SOCS) proteins, which disrupt the JAK/

Figure 8-15 Integrated model of the GH-IGF axis in the growth process. Three mechanisms are proposed. In the first hypothesis, growth hormone (GH) stimulates production of insulin-like growth factor I (IGF-I); circulating IGF-I (endocrine IGF-I) then acts at the growth plate. In the second hypothesis, GH regulates hepatic production of IGF-binding protein 3 (IGFBP-3) and the acid-labile subunit (ALS) of the IGFBP complex; IGF-I binds to IGFBP-3 and with ALS, forming the 150-kD ternary complex. Proteases then cleave this complex into fragments that release IGFBP-3 and IGF-I in the intravascular space and at the growth plate. In the third hypothesis, GH induces differentiation and local IGF-I production, and IGF-I acts via autocrine and paracrine mechanisms to stimulate cell division. T₃, triiodothyronine. (From Spagnol A, Rosenfeld RG. The mechanism by which GH brings about growth: the relative contributions of GH and insulin-like growth factors. *Endocrinol Metab Clin North Am.* 1996;25:615-631; and Clemmons DR, Van Wyk JJ, Ridgway EC, et al. Evaluation of acromegaly by radioimmunoassay of somatomedin-C. *N Engl J Med.* 1979;301:1138-1142.)

STAT pathway and thus disrupt GH action.²¹⁴ In transgenic mice with deletion of SOCS2, gigantism develops, presumably due to unrestrained GH action. Because SOCS proteins are also induced by pro-inflammatory cytokines, critically ill patients and those with renal failure may develop GH resistance due to cytokine-induced SOCS.²¹⁵ Unraveling of the STAT/SOCS regulation in syndromes associated with disordered GH signaling will likely yield mechanistic insights for dysregulated GH action.

The pattern of GH secretion determines tissue responses to GH in addition to the absolute amount of circulating hormone. Gender-specific patterns of GH secretion profiles determine sex-specific expression of cytochrome P450 enzymes. In turn, circulating steroids regulate neuroendocrine release of GH. SRIF, by suppressing interpulse GH levels, serves to masculinize the ultradian GH rhythm. In mice harboring a disrupted SRIF gene, plasma GH secretory patterns are elevated and liver enzyme induction loses its

gender-specific dimorphism, but these animals retain sexually dimorphic growth patterns.²¹⁶ Linear growth patterns and liver enzyme induction are phenotypically gender-specific due to higher GH pulse frequency rates and also show gender-specific STAT5B activity.²¹⁷ Sexually dimorphic patterns of GH secretion and tissue targeting appear to be determined by STAT5B, which is sensitive to repeated pulses of injected GH,²¹⁸ unlike other GH-induced responses, which are desensitized by repeated GH administration. Disruption of STAT5B in transgenic mice causes impaired male-pattern body growth²¹⁹ associated with female-pattern levels of IGF1 and testosterone. Appropriate GH pulsatility is also required to determine body growth mediated by STAT5B^{220,221} but not for metabolic effects of GH on carbohydrate metabolism. A STAT mutation has been described as a cause of short stature.²²²

IGF1 mediates growth-promoting activities of GH¹⁷⁰ in an endocrine or paracrine manner.²²³ In mice, paracrine IGF1 produced in extrahepatic tissues appears to be critical for growth, which persists even when hepatic IGF1 is deleted.²²⁴ GH receptor mutations are associated with partial or complete GH insensitivity and growth failure. These syndromes are associated with normal or high circulating GH levels, decreased circulating GHBP levels, and low levels of circulating IGF1. Multiple homozygous or heterozygous exonic and intronic GH receptor mutations have been described. These occur mostly in the extracellular ligand-binding receptor domain (see Chapter 24).

Metabolic Action. GH functions as a major metabolic hormone in the adult by optimizing body composition and physical function and regulating energy and substrate metabolism. Metabolic actions of GH also closely interact with those of insulin in the control of fat, glucose, and protein metabolism during fasted and fed states.

GH promotes fat metabolism by enhancing lipolysis and fatty acid oxidation. This function is particularly important during the fasted state, when GH secretion is enhanced, resulting in the partitioning of fuel utilization toward fat and the sparing of protein. Stimulation of lipolysis occurs indirectly through potentiation of the activity of hormone-sensitive lipase by β -adrenergic stimulation. GH also regulates lipoprotein metabolism by enhancing clearance of low-density lipoprotein (LDL) through activating expression of hepatic LDL receptors.^{225,226} The atherogenic profile of lipoproteins is increased in GHD and reduced by GH therapy.²²⁷

GH exerts profound effects on glucose metabolism both directly and by antagonizing insulin action. GH enhances glucose uptake and utilization in cells; this is referred to as its *insulin-like* effects.²²⁸ At the whole-body level, GH suppresses glucose oxidation and utilization while enhancing hepatic glucose production,²²⁹ potentially for increased use of glucose that is nonoxidative in nature. The target tissues and the biochemical fate of this glucose surplus are unclear. Because GH is an important counterregulatory hormone, it is conceivable that this function protects against hypoglycemia.

Protein anabolism is a signature property of GH that reduces urea synthesis, blood urea concentration, and urinary urea excretion. The conventional view is that GH-induced protein anabolism is mediated by IGF1. However, GH also acutely stimulates amino acid uptake and incorporation into protein *in vitro*.²³⁰ Arteriovenous measurements in the forearm showed an acute increase in protein synthesis over a few hours after GH infusion, suggesting a direct effect.²³¹ Whole-body studies in humans using isotopes have consistently shown that GH reduces

Figure 8-16 Action of growth hormone (GH). GH binds to the growth hormone receptor (GHR) dimer, which undergoes internal rotation, resulting in Jak2 phosphorylation (P) and subsequent signal transduction. Ligand binding to a preformed GHR dimer results in internal rotation and subsequent phosphorylation cascades. GH signaling is mediated by Jak2 phosphorylation of depicted signaling including Src/ERK pathways. STAT, SHC, and IRS cascades. GH targets include insulin-like growth factor I (IGF1), c-fos, cell proliferation genes, glucose metabolism, and cytoskeletal proteins. GHR internalization and translocation (dotted lines) induce nuclear pro-proliferation genes via importin α/β (Imp α /Imp β) coactivator (CoAA) signaling. IGF1 may also block GHR internalization, acting in a feedback loop. ERK, extracellular signal-related kinase; IRS, insulin receptor substrate; JAK 2, Janus kinase 2; MEK, dual specifying mitogen-activated kinase 2. (From Lupu F, Terwilliger JD, Lee K, et al. Roles of growth hormone and insulin-like growth factor I in mouse postnatal growth. *Dev Biol.* 2001;229:141; and Melmed S. Acromegaly pathogenesis and treatment. *J Clin Invest.* 2009;119:3189-3202.)

protein oxidation and stimulates protein synthesis.¹³⁰ The protein-sparing effect of GH is coupled to the availability and increased parallel utilization of free fatty acids, whereas pharmacologic reduction of free fatty acids during fasting augments the rate of protein breakdown.²²⁹

Growth Hormone Deficiency

GH is the most abundant hormone in the adult pituitary gland, and it plays an important role in maintaining the metabolic process and the integrity of many tissues. GHD in adults is recognized as a distinct entity (Table 8-3).²³²⁻²³⁴ GHD has negative effects on body composition, cardiovascular risk, quality of life, and physical functioning.^{233,235,236} Life expectancy is reduced in hypopituitary patients with GHD,²³⁷⁻²³⁹ largely as a consequence of cardiovascular and cerebrovascular events, especially in female subjects.²⁴⁰ Neither estrogen nor thyroid deficiency accounts for this increased risk and reduced survival, and it is not yet rigorously confirmed that the observed increased mortality and morbidity occur solely as a result of GHD.

Pathophysiology. Adult GHD may be acquired or congenital. Of the acquired causes, 50% arise from pituitary tumors, 20% from extrapituitary tumors, and 5% from inflammatory or infiltrative lesions, with up to 15% of cases being idiopathic.²⁴¹ Surgical or radiation treatment of pituitary and parasellar tumors is the most common cause of GHD, accounting for almost two thirds of cases.

The frequency of causes is different in childhood-onset versus adult-onset GHD.^{241,242} Idiopathic causes are most common in childhood-onset GHD and likely represent a heterogeneous collection of congenital developmental abnormalities, including mutations of *PROPI* and *POU1F1* genes, that cause GHD and other pituitary hormone deficiencies.²⁴³ Isolated GHD may be complete or partial, and

up to 67% of children initially diagnosed with idiopathic GHD had normal GH responses when subsequently retested as adults for GHD after cessation of GH treatment.²⁴⁴ Therefore, children with GHD should be retested before GH treatment is continued into adulthood unless they have clearly documented panhypopituitarism or a defined genetic or developmental abnormality that causes complete and irreversible GHD.

Mutations in the GH²⁴⁵ and GHRH receptor genes²⁴⁶ and GH insensitivity as a result of primary GH receptor dysfunction²⁴⁷ result in GHD.

Presentation. Symptoms of GHD are nonspecific and include fatigue, lack of energy, social isolation, low mood, poor concentration, and reduced physical capacity.²³² The signs are also nonspecific and include general and central adiposity, reduced lean tissue, and bone mineral density along with unfavorable biochemical changes such as hyperlipidemia^{248,249} and glucose intolerance.²³² Some patients have established evidence of macrovascular disease, such as increased carotid intimal thickness.^{250,251} GHD may also be associated with heart abnormalities including reduced left ventricular mass.²⁵²⁻²⁵⁵ Cardiovascular risk abnormalities are often less pronounced in adults with childhood-onset GHD than in those with GHD acquired during adulthood, who have more pronounced disorders of quality of life, lipids, and body composition.^{252,256,257}

Although the features of GHD are recognizable, they are not particularly distinct, and they mimic body compositional and biochemical changes of the aging process. Therefore, clinical suspicion must be confirmed by accurate biochemical diagnosis to ensure that GH-deficient patients are accurately identified and treated.

Evaluation. GHD is diagnosed biochemically within an appropriate clinical context. Biochemical testing for GHD should be considered in patients with a high probability of hypothalamic-pituitary disease manifesting the clinical features of the syndrome.^{233,234} These include patients with a history of organic hypothalamic-pituitary dysfunction, cranial irradiation, known childhood-onset GHD, or traumatic brain injury.

Provocative Testing. The diagnosis of adult GHD is established by provocative testing of GH secretion (Table 8-4). Patients should receive adequate replacement for other pituitary hormonal deficits before testing. Provocative tests include the insulin tolerance test (ITT), arginine, glucagon, clonidine, growth hormone-releasing peptide

(GHRP), (GURP), and GHRH, alone or in combination with arginine or pyridostigmine. GHRPs are synthetic analogs of ghrelin. Because provocative tests vary in their ability to evoke GH release, a single value cannot be applied as a diagnostic threshold across different tests (Fig. 8-17).²⁵⁸ ITT is a more potent stimulator of GH release than arginine, clonidine, or L-dopa, and combinations such as arginine plus GHRH, or GHRP plus GHRH are more potent than ITT alone.^{178,259,260}

The ITT is the gold standard test for GHD. Normal subjects respond to insulin-induced hypoglycemia with peak GH concentrations of more than 5 µg/L (Fig. 8-18).²⁶¹ Severe GHD is defined by a peak GH response to hypoglycemia of less than 3 µg/L.²³⁵ These cutoff values have been defined with the use of GH assays employing polyclonal competitive RIAs.²³⁵ The test is contraindicated in patients with a history or electrocardiographic evidence of ischemic heart disease and in patients with seizure disorders.

Alternative tests that have been validated for the diagnosis of GHD are GHRH plus arginine,²⁶⁰ GHRH plus GHRP,^{178,262} and glucagon.²⁶³ The diagnostic thresholds for these tests are shown in Table 8-4. The ITT evaluates the integrity of the hypothalamic-pituitary axis and has the added advantage of stimulating ACTH secretion. Diagnostic tests employing GHRH or GHRP, both of which directly stimulate GH release from the pituitary gland, may not effectively diagnose GHD caused by hypothalamic disease.²⁶⁴ This is exemplified by studies in patients treated with cranial irradiation, for whom the ITT showed the greatest sensitivity and specificity within the first 5 years after irradiation.²⁶⁵ If peak GH levels are normal during a GHRH plus arginine test in a patient who has received radiation therapy, then an ITT should also be performed. In irradiated patients and in those with inflammatory/infiltrative parasellar lesions, GHD may develop many years after the initial insult. This group of patients should undergo long-term monitoring, with repeat testing as clinically indicated. Obesity is a potential confounder in the diagnostic testing of GHD because it is associated with blunted peak GH responses.²⁶⁶ Reference ranges adjusted for body mass index are available for validating results of the combined arginine-GHRH test.²⁶⁷

Growth Hormone-Responsive Markers. Growth hormone-responsive markers include IGF1, IGF binding protein 3 (IGFBP3), and the acid-labile subunit of the IGFBP complex. Serum IGF1 concentrations are useful for diagnosis only when age-adjusted normal ranges are used. Although IGF1 levels are reduced in adult GHD, a normal concentration does not exclude the diagnosis.²⁶¹ A subnormal IGF1 level in an adult patient with coexisting pituitary hormone deficits is strongly suggestive of GHD, particularly in the absence of conditions known to reduce IGF1 levels, such as malnutrition, liver disease, poorly controlled diabetes mellitus, and hypothyroidism. The separation of IGF1 values between GH-deficient and normal subjects is greatest in the young. As IGF1 levels decline with aging in normal subjects, IGF1 measurements become less reliable as a biochemical marker of GHD, and in patients older than 50 years, the values merge with those of normal age-matched subjects.²⁶⁸ Measurement of IGFBP3 or the acid-labile subunit does not offer any advantage over that of IGF1.^{233,234}

In patients with organic hypothalamic-pituitary disease, the prevalence of GHD is strongly linked to the number of pituitary hormone deficits, ranging from approximately 25% to 40% in those with no other deficit to 95% to 100% when more than three pituitary hormone deficiencies are present.²⁶⁹ Patients with three or more pituitary hormone

deficiencies and an IGF1 level lower than the reference range have a greater than 97% chance of being GH deficient (see Fig. 8-17)²⁷⁰ and therefore do not require GH stimulation testing.^{233,234}

Spontaneous Secretion of Growth Hormone. Because pituitary GH secretion occurs episodically, accurate quantification of integrated GH secretion requires continuous measurement of secretion over 24 hours. This procedure requires insertion of a continuous withdrawal pump or a patent indwelling catheter for frequent sampling with unrestricted food intake and physical activity. Although it

is cumbersome and expensive, this method eliminates the error of isolated peak or trough measurements that might otherwise be obtained by single or multiple random GH samplings. Continuous 24-hour GH measurement in the diagnosis of GHD is not superior to provocative testing (see Fig. 8-18).²⁶¹

Urinary Growth Hormone Measurement. Immunoassay methods for urinary GH measurement do not reliably reflect pharmacologic GH testing and do not adequately discriminate between normal and abnormal GH secretion.²⁷¹

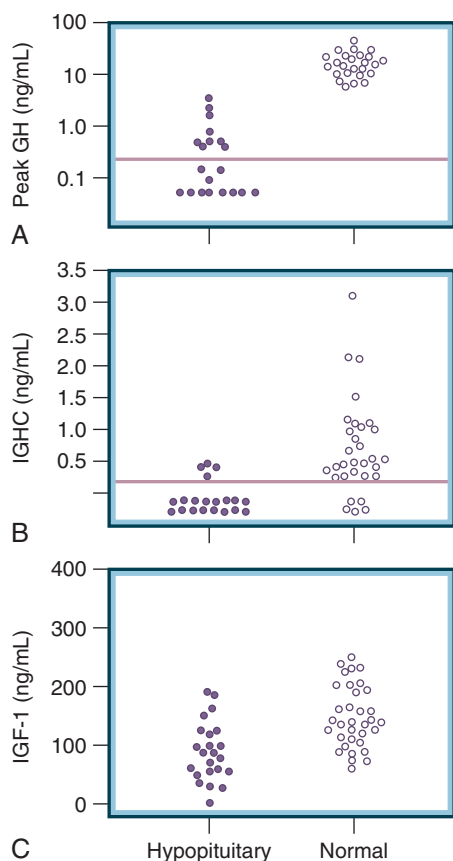

Figure 8-18 **A**, Comparison of peak growth hormone (GH) concentration obtained during an insulin tolerance test, **B**, integrated GH concentration (IGHC) obtained from blood samples withdrawn every 20 minutes over 24 hours, and, **C**, insulin-like growth factor I (IGF-I) concentrations in patients with organic hypopituitarism and sex-matched normal subjects. The horizontal lines represent the limit of reading. (Modified from Hoffman DM, O'Sullivan AJ, Baxter RC, et al. Diagnosis of growth hormone deficiency in adults. *Lancet*. 1994;343:1064-1068.)

Growth Hormone Assays. Plasma GH is measured by RIA (polyclonal or monoclonal) or by IRMA (dual monoclonal), but comparative GH measurements obtained using 11 commercial immunoassays varied by a factor of 3.²⁷² Measured GH concentrations are antibody dependent, and different antibodies bind to a heterogeneous spectrum of GH isoforms.²⁷³ Furthermore, GH isoform patterns vary among individuals, and all circulating GH forms are not routinely detectable in GH assays, adding further difficulty to comparison of results from different GH immunoassays. Monomeric 22-kd GH1, the most abundant circulating form, is the only GH standard of sufficient purity and quantity, and it is used as the basis for GH measurement; however, it accounts for only about 25% of circulating immunoreactivity.²⁷⁴ Other GH forms are recognized to varying to largely unknown degrees. Polyclonal antibodies, used in earlier RIAs, recognized several molecular forms of GH; newer immunometric assays employ highly specific monoclonal antibodies.²⁷⁵

GH standards also affect comparison of GH values. In 1994, the first World Health Organization (WHO) International Standard for Somatotropin (IRP 88/624)²⁷⁶ used recombinant technology, in contrast to previous standards prepared from pituitary extracts. GHBP may also interfere because approximately 50% of GH is complexed to GHBP. Noncompetitive immunometric assays may lead to low estimates of GH. In competitive assays employing

antibodies directed against GH molecular epitopes that bind GHBP, spuriously high GH values may be reported.²⁷⁷ The heterogeneity of GH immunoassay results poses a challenge in the definition of accepted standards for diagnosis of GHD. However, the RIA is now infrequently used, and clinicians should be aware of the nature of the GH assay employed and how values compare to those previously obtained by polyclonal RIA. New GH assays based on measurement of GH bioactivity have been developed, including the eluted stain assay (ESTA) and the immunofunctional assay (IFA). The growth hormone exclusion assay (GHEA) also measures circulating GH isoforms.²⁷⁵

Growth Hormone Replacement Therapy. The effects of GH replacement were first reported in 1989; since then, studies lasting up to 10 years have reported sustained benefits on substrate metabolism, body composition, and physical function.^{278,279}

GH replacement induces profound effects on protein, fat, and energy metabolism, resulting in increased lean body mass and decreased fat mass without a significant change in body weight (Figs. 8-19 through 8-23).²⁸⁰ The greatest reduction of body fat occurs in abdominal and

Figure 8-21 Mean concentrations of insulin-like growth factor I (IGF-I) before and during incremental doses of growth hormone (GH)—0.5, 1.0, and 2.0 IU/day, equivalent to approximately 0.25 to 1.0 mg daily—during oral and transdermal estrogen therapy in eight GH-deficient women. (From Volthers T, Hoffman DM, Nugent AG, et al. Oral estrogen therapy impairs the metabolic effects of growth hormone (GH) in GH deficient women. *Am J Physiol.* 2001;281:E1191-E1196.)

visceral adipose tissue.²⁸¹ Significant increases in extracellular water also occur as a consequence of the dose-dependent antinatriuretic properties of GH.²⁸² GH replacement increases bone density,²⁸³ which is accompanied by activation of both bone formation and bone

resorption.²⁸⁴ Initial studies reporting changes in bone mineral density (BMD) during 6 to 12 months of treatment yielded conflicting results. However, studies reporting long-term results have shown a progressive increase in BMD beyond 12 to 18 months of treatment,²⁸³ reaching a plateau after 3 years. GH-induced reduction in abdominal and visceral fat is accompanied by a significant shift of lipoprotein metabolism to a less atherogenic profile. Most studies report an improvement in cholesterol levels and in HDL-cholesterol ratio with little or no change in triglycerides.²²⁷ The favorable effects of improving the lipoprotein profile are more evident after treatment for more than a year. GH treatment reduces intimal media thickness of the carotid arteries.²⁵⁰ Pro-inflammatory factors such as C-reactive protein and IL-6, strongly implicated in the pathogenesis of vascular disease, fall significantly with GH treatment.²⁴⁸

GH replacement improves exercise capacity and performance in parallel with an increase in maximal oxygen uptake^{285,286} and in cardiac output and diastolic function.^{287,288} Several but not all studies have reported improved muscle strength. Quadriceps or hip muscle strength improves significantly after 6 months of treatment,²⁸⁵ but muscle strength normalized after 2 years, without further significant change at 5 years.²⁸⁹

The effects on quality of life are less clear. Some²⁹⁰ but not all studies have reported improved energy, mood, and quality of life. Discrepant results may relate to the varying study tools used, including generic health questionnaires on perceived health status and subjective well-being and those developed specifically for patients with GHD. Disease-specific tools have reported unequivocal improvement in measures of life satisfaction after GH treatment.²⁹⁰ A large survey in 304 patients showed improved quality of life and also significant reduction in the numbers of sick leave and doctor visits during 12 months of GH therapy.²⁹¹ A latency period up to 3 months is required before patients recognize benefits of hGH replacement, and these benefits are most obvious in those patients with the most profound symptoms and signs of GHD.²⁹²

Growth Hormone Administration

GH secretion is greater in the young, and greater in women than in men. It is recommended that the starting dose of GH should be 0.2 mg/day in young men, 0.3 mg/day in young women, and 0.1 mg/day in older individuals²³⁴; these doses are then titrated according to serum IGF1 concentrations and at a rate that minimizes side effects (see Fig. 8-23).²⁹³ If side effects occur, the dose should be reduced, and if no side effects are reported, the therapeutic goal is to maintain IGF1 levels in the normal age- and gender-matched range while avoiding levels in the upper quintile or above. Dose determination based on body weight is not recommended due to large interindividual variation in absorption, insensitivity to GH, and lack of evidence that a larger replacement is required for heavier adults.²³³ GH is administered by nightly subcutaneous injection to mimic the greater secretion of GH at night. Side effects of GH in children are considerably fewer than those observed in adults.

Women with GHD require higher doses of hGH if they are also receiving oral (rather than transdermal) estrogen²⁹⁴⁻²⁹⁶ because of the first-pass hepatic effect. Fifty percent more GH was required during oral estrogen treatment to maintain an IGF1 level equivalent to that achieved during transdermal estrogen administration (see Fig.

Figure 8-22 Ten-year growth hormone (GH) therapy in 87 GH-deficient adults.²⁷⁹ CI, confidence interval; HbA1c, hemoglobin A_{1c}; HDL-C, high-density lipoprotein-cholesterol; LDL-C, low-density lipoprotein-cholesterol; TC, total cholesterol. (Modified from Melmed S. Update in pituitary disease. *J Clin Endocrinol Metab.* 2008;93:331-338.)

8-21).²⁹⁴ In contrast, androgens enhance metabolic effects of GH.¹³⁰ The divergent effects of estrogens and androgens on GH action are a likely explanation for the observation that women are less responsive than men to GH.²⁹⁷

Precautions and Caveats of Treating with Human Growth Hormone

The most common side effects of hGH replacement include edema, arthralgias, and myalgias (Table 8-5). However, these symptoms are mild and dose related, and they resolve in most patients spontaneously or with dosage reduction.²⁹³ Although GH antagonizes insulin action, the risk of developing hyperglycemia is very low (see Fig. 8-22). None of 166 patients developed diabetes in an Australian study,²⁹⁸ and insulin sensitivity did not change after 7 years of GH treatment.²⁹⁹ A meta-analysis of 13 placebo-controlled trials involving 511 patients found a mean elevation in fasting blood glucose of 0.22 mmol/L compared with placebo levels.²²⁷ Nevertheless, glucose should be monitored, especially in patients who are also being treated for diabetes.

Patients with active malignancies should not be treated with GH. The possibility that hGH might initiate new cancers or stimulate growth of preexisting benign tumors is an important theoretical issue. An epidemiologic association between higher, albeit normal, IGF1 levels and later risk of developing prostate cancer in men,³⁰⁰ breast cancer in premenopausal women,³⁰¹ and colon and lung cancer³⁰² has been reported. In contrast, patients with acromegaly, who have very high serum levels of IGF1, do not have an increased incidence of breast or prostate cancer or of cancer in general. In fact, the overall risk for cancer in acromegaly is lower than expected. However, these patients have a significantly increased mortality from colon cancer.³⁰³⁻³⁰⁵

Analysis of the extensive pediatric experience shows no convincing evidence for a causal link between GH treatment and tumor recurrence or the development of neoplasms including leukemia.^{306,307} When comparing the relative risk of brain tumor recurrence in 180 children

treated with hGH versus 891 who did not receive hGH, the risk of recurrence after a mean of 6.4 years was lower in the treated group than in those not receiving hGH.³⁰⁸ GH treatment does, however, increase the risk of radiation-induced second tumor, especially meningiomas.³⁰⁹ Nevertheless, long-term surveillance with adequate control groups and avoidance of high IGF1 levels in adults being treated for adult GHD are required to ensure that adult GH replacement does not increase the incidence of new cancers or growth of existing benign tumors.

Investigational Uses of Growth Hormone

Catabolic States. The well-recognized anabolic actions of GH have prompted its use in catabolic states including surgery, trauma, burns, parenteral nutrition, and organ failure. These potential indications for GH are not approved in the United States. The negative nitrogen balance in critically ill patients is partly attributable to GH resistance and decreased IGF1 production and action.³¹⁰ GH administered to postsurgical patients and to normal subjects receiving hypocaloric intravenous alimentation resulted in reversion to positive nitrogen balance.

Beneficial effects of GH have been reported in patients with extensive burns, in those receiving chronic high-dose glucocorticoid treatment, in those with chronic obstructive pulmonary disease, in cancer patients, and in patients with cardiac failure. Nevertheless, published end points for these studies have not been definitive. When GH was administered to elderly malnourished patients, it was found to be an effective adjuvant for dietary augmentation.³¹¹ A study in which critically ill patients received very high doses of GH (up to 7 mg/day) was prematurely terminated due to enhanced unexplained mortality.³¹² It has been suggested that GH may have had an adverse effect on acute phase protein synthesis in these patients.³¹³ Caution is advised for nonapproved uses of GH in adults.³¹⁴

Osteoporosis. GH has been administered to otherwise healthy subjects with idiopathic osteoporosis in an attempt to decrease bone loss. A 2-year study in osteoporotic women

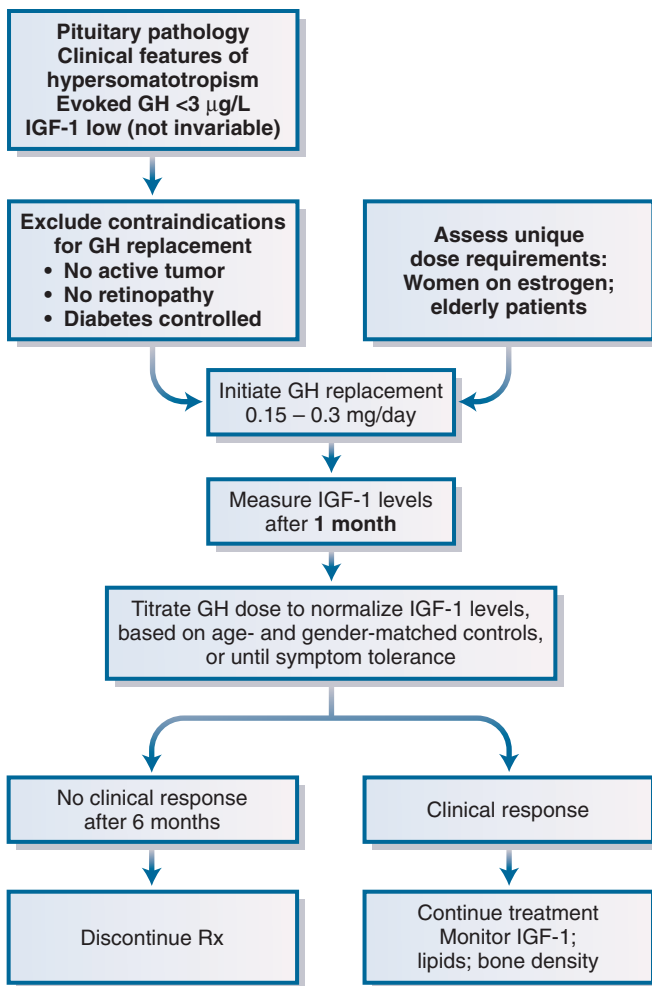

Figure 8-23 Management of somatotropin deficiency in adults. Patients older than 60 years require lower maintenance doses. Women receiving transdermal estrogen require lower doses than those receiving oral estrogen preparations. GH, growth hormone; IGF-I, insulin-like growth factor I; Rx, treatment.

showed that GH together with calcitonin increased spine and total hip bone mineral density,³¹⁵ although the response was less marked than that observed with estrogen or bisphosphonate therapy. A double-blind, placebo-controlled treatment study for 18 months observed improvements in bone mineral content at the lumbar spine, in the femoral neck, and of the whole skeleton by up to 14%, and these improvements were sustained at 4

years.³¹⁶ There was a delayed, extended, and dose-dependent effect of GH. These striking findings provide evidence for consideration of GH as a therapeutic option for osteoporosis in the menopause. Unclear long-term side effects and lack of comparative studies with other beneficial therapies for osteoporosis necessitate the need for further study of potential use of GH in treating osteoporosis.

Human Immunodeficiency Virus Infection. GH is approved by the U.S. Food and Drug Administration for adult patients with HIV-associated cachexia, and treatment results in positive nitrogen balance, increased lean body mass, decreased body fat, and improved work output.³¹⁷ Ten HIV-infected subjects with fat redistribution syndrome associated with protease inhibitor therapy received GH 6 mg/day subcutaneously for 12 weeks and showed decreased weight-hip ratios and enhanced midhigh circumference.^{318,319} One large study using supraphysiologic GH doses of 4 mg/day reported impairment in glucose tolerance.³²⁰ A more recent study using a physiologic dosing approach to maintain IGF1 in the high-normal range reported body compositional changes of lesser magnitude, no changes in HDL or LDL cholesterol, and no adverse changes in fasting glucose or insulin.³²¹ However, long-term beneficial effects of GH on survival and quality of life in HIV infection have not yet been reported.

Sports. The public policy issues regarding GH abuse in competitive sports have received much attention. GH has been widely abused by athletes to enhance performance.³²² Whether persistent GH use is accompanied by increased muscle strength is unclear. A systematic review concluded that claims of GH enhancement of physical performance are not supported by the scientific literature evaluating effects on aerobic capacity, strength, and power³²³ and that more research is needed to conclusively determine the effects of GH on athletic performance. A recent double-blind, placebo-controlled study reported that GH enhances sprint capacity, but not aerobic capacity, strength, or power, in recreational athletes.³²⁴

Aging. There has been considerable interest in the use of GH as an anti-aging hormone to prevent the body composition changes and physical decline of the aging process that superficially recapitulate features of adults with organic GHD for which beneficial effects of GH replacement have been demonstrated. A systematic review of literature published on randomized, controlled trials in healthy elderly subjects indicated that GH supplementation is associated with small changes in body composition, no functional benefit, and increased rates of adverse events. On the basis of the evidence, GH cannot be recommended as an anti-aging therapy.³²⁵ GH is increasingly marketed and distributed for anti-aging therapy under “off-label” use. Off-label marketing of GH as anti-aging therapy is not approved by the FDA in the United States.³¹⁴

Adrenocorticotrophic Hormone

Physiology

The hypothalamic-pituitary-adrenal (HPA) axis plays a critical role in maintaining homeostasis and in mounting an appropriate response to stress. Key components of the stress response are aimed at providing adequate amounts of glucocorticoids that exert vital pleiotropic effects on energy supply, fuel metabolism, immunity, and cardiovascular function.

Figure 8-24 Corticotroph cell. The periodic acid-Schiff stain documents the presence of corticotrophs in the normal pituitary, reflecting glycosylation of the ACTH peptide. Some cells have clear cytoplasmic vacuoles corresponding to the so-called enigmatic body. ACTH, corticotropin. (From Asa SL. Tumors of the pituitary gland. In: Rosai J, ed. *Atlas of Tumor Pathology*, Series III, Fascicle 22. Washington, DC: Armed Forces Institute of Pathology, 1997:21.)

Corticotroph Cells. Corticotroph cells comprise about 20% of functional anterior pituitary cells and are the earliest detectable human fetal pituitary cell type, appearing by the 8th week of gestation. Corticotrophs are clustered mainly in the central median pituitary wedge. They are large, irregular cells, and their ultrastructural features include prominent neurosecretory granules (150-400 nm), endoplasmic reticulum, and Golgi bodies (Fig. 8-24).³²⁶ These cells produce the POMC gene products, including ACTH(1-39), β -lipotropin, and endorphins. Because of the rich carbohydrate moiety of these molecules, the cells are strongly positive for periodic acid-Schiff (PAS) staining. In the presence of excess glucocorticoid, characteristic hyaline deposits develop (Fig. 8-25). In normal human pituitary, POMC is expressed only in corticotroph cells. Most mammals possess an intermediate lobe comprising POMC-expressing melanotroph cells, but this lobe is not developed in adult humans. TPIT has been identified³¹ as a critical transcriptional factor for corticotroph cell differentiation during pituitary development and for transcription of the POMC gene.

Structure. POMC is the precursor for ACTH, which acts on the adrenal glands to induce synthesis and secretion of adrenal steroids. The primary translation product of POMC is a 266-amino-acid pre-prohormone molecule encoding corticotrophic, opioid, and melanotrophic peptides. The peptide contains a leader sequence and multiple dibasic proteolytic cleavage sites for glycosylation, acetylation, and amidation. Products of this processing include ACTH(1-39) and β -lipotropin, which in turn give rise to α -lipotropin and β -endorphin, also containing met-enkephalin. ACTH itself may also be cleaved to a form of

Figure 8-25 Crooke's hyalinization. Pituitary corticotrophs subjected to glucocorticoid excess develop cytoplasmic hyalinization that displaces ACTH-positive secretory material to the cell periphery. The clear vacuoles correspond to complex lysosomes known as enigmatic bodies. (From Asa SL. Tumors of the pituitary gland. In: Rosai J, ed. *Atlas of Tumor Pathology*, Series III, Fascicle 22. Washington, DC: Armed Forces Institute of Pathology, 1997:23.)

α -melanocyte-stimulating hormone, α -MSH(1-13), and corticotropin-like intermediate lobe peptide, CLIP(18-39).

The 8-kb human POMC gene, located on chromosome 2p23,^{31,327} consists of three exons interspersed with two intervening introns (Fig. 8-26). The first exon encodes a leader sequence, the second exon encodes the signal initiation sequence and the N-terminal portion of the POMC peptide, and the third exon encodes most of the mature peptide sequences, including ACTH and β -lipotropin.³²⁸ The POMC gene is expressed in pituitary and nonpituitary tissues including brain, skin, placenta, gonads, gastrointestinal tissues, liver, kidney, adrenal medulla, lung, and lymphocytes.

Figure 8-26 Structure of the POMC gene. Exon 1 encodes the RNA leader sequence. Exon 2 encodes the initiator methionine (ATG), the signal peptide, and several amino-terminal residues of the precursor peptide, the remainder of which is encoded by exon 3. Corticotroph expression is determined by the upstream "pituitary" promoter (longer arrowhead), whereas peripheral expression of the short POMC mRNA is determined by the "downstream" promoter (shorter arrowhead). Translation of these shorter transcripts initiates from the initiator methionines (ATG) indicated in exon 3. The precursor peptide coding region is lightly shaded, and the ACTH coding region is darkly shaded. (Reproduced from Adrian JL, Clark AJL, Swords FM. Molecular pathology of corticotroph function. In Rappaport R, Amselem S, eds. *Hypothalamic-Pituitary Development*. Basel, Switzerland: Karger; 2001.)

In corticotroph cells, a pituitary-selective promoter region for POMC generates a POMC messenger RNA (mRNA) transcript of approximately 1200 nucleotides. The 800 nucleotides of the coding region are translated into a pre-POMC molecule that includes a 26-amino-acid signal peptide that is rapidly cleaved. The parent POMC protein of 241 amino acids enters the secretory pathway for subsequent processing (see later discussion).

In extrapituitary tissues, POMC gene expression is quantitatively and qualitatively different from that in the pituitary. An upstream promoter generates a longer transcript (approximately 1350 nucleotides). A downstream promoter generates short truncated transcripts of approximately 800 nucleotides that arise from the 5' end of exon 3. In the brain, however, neurons in the arcuate nucleus express POMC mRNA that is identical to that of the pituitary.³²⁹ In these neurons, POMC serve as a precursor to brain β -endorphin, α -MSH, and other peptides that have important brain functions including a major role in energy homeostasis.

Transcriptional Regulation

Elements of the promoter regions mediate POMC regulation by glucocorticoids, cAMP, AP1, and STAT signaling molecules.³³⁰

Multiple signals act in synergy to activate POMC gene expression, including corticotropin-releasing hormone (CRH), cytokines, vasopressin, catecholamines, and VIP. Glucocorticoids inhibit POMC gene expression. The CRH type 1 receptor (CRH-R1) is predominantly expressed on the corticotroph,³³¹ and its activation increases cAMP, protein kinase A, and CREB induction of CRH-binding protein (CRHBP) to the promoter, leading to POMC transcription.³³²

CRH also activates an AP1 site within the first exon by a MAP kinase-mediated pathway. In addition to mediating ACTH secretion, this receptor also appears to be critical for fear and anxiety responses, possibly through a related ligand, urocortin.³³³

The CRH-R2 is predominantly important for cardiovascular function.³³⁴ Leukemia inhibitory factor (LIF), a pro-inflammatory cytokine that is expressed in the pituitary and hypothalamus, signals via the JAK/STAT pathway and acts in synergy with CRH to potentiate POMC expression.³³⁵ This mechanism of immunoneuroendocrine interfacing facilitates stimulation of ACTH secretion by inflammation-derived STAT-inducing cytokines.

Glucocorticoid receptor activation leads to transcriptional suppression via two cooperative binding sites. The intracellular glucocorticoid receptor binds directly to 5'-regulatory elements to suppress POMC transcription.³²⁹ CRH action is also potentiated by vasopressin (acting via phospholipase C) and β -adrenergic catecholamines, which enhance POMC mRNA levels, increase ACTH secretion, or both. The net effect of these intracellular signals is the regulation of POMC gene transcription, peptide synthesis, and ACTH secretion for mediating appropriate neuroendocrine responses.³³⁰

POMC Processing. Several post-translational POMC modification steps are required for polypeptide hormone secretion (Fig. 8-27). First, the N-terminal signal sequence is removed, and this is followed by glycosylation via an O-linkage to Thr45 and N-linkage to Asn65.³³⁶ Serine-phosphorylation then occurs within the Golgi apparatus. After being transported to secretory vesicles, the constituent peptides are cleaved at dibasic amino acid residues, and ACTH-related peptides are stored in dense secretory

Figure 8-27 Processing and cleavage of pro-opiomelanocortin (POMC). The mature POMC precursor peptide is sequentially cleaved by prohormone convertase 1 (PC1) in the anterior pituitary corticotroph. In the neurointermediate lobe and other cell types, cleavage by PC2 allows release of β -MSH or β -endorphin (β -EP) or both. Carboxypeptidase H (not shown) removes residual basic amino acids at cleavage sites. ACTH, adrenocorticotrophic hormone; CLIP, corticotropin-like intermediate lobe peptide; JP, joining peptide; EP, endorphin; LPH, lipotropin; MSH, melanocyte-stimulating hormone; N-POC, N-terminal pro-POMC fragment. (Reproduced from Clark AJL, Swords FM, Molecular pathology of corticotroph function. In: Rappaport R, Amselem S, eds. *Hypothalamic-pituitary development*. Basel, Switzerland: Karger; 2001.)

granules for ultimate regulated release. Some POMC products also undergo C-terminal amidation mediated by peptidylglycine-amidating monooxygenase (PAM) and peptidylhydroxyglycine-amidating lyase (PAL),³³⁷ and N-terminal acetylation.

POMC proteolytic processing occurs at Lys-Arg or Arg-Arg residues by enzymes called *prohormone convertases* (PCs), which are a superfamily of subtilisin/kexin proteinases. They play a critical role in determining the manifestation and function of the peptides at the tissue level through site-specific cleavages. PC1 is most abundant in the pituitary and hypothalamus, whereas PC2 is present in the central nervous system, skin, and pancreatic islets but is absent in the pituitary. In corticotrophs, PC1 expression results in cleavage limited to four sites, with ACTH being a major end product (see Fig. 8-27). In the hypothalamus and central nervous system, the presence of both PC1 and PC2 allows coordinated proteolysis, resulting in the generation of smaller fragments such as α -, β -, and γ -MSH and CLIP. Heterozygous mutations of the PC1 gene have been associated with childhood obesity, adrenal insufficiency, hyperproinsulinemia, and postprandial hypoglycemia³³⁸ with elevated levels of plasma ACTH precursors.

Biologic Actions of POMC-Derived Peptides

POMC products in blood are derived from corticotrophs and are secreted in equimolar amounts. However, circulating concentrations differ in accordance with the half-life of each molecule.

Adrenal Action. Full-length ACTH is the only POMC-derived peptide with adrenocorticotroph function, and it is the ligand of the melanocortin receptor type 2 receptor (MC2R). MC2R activation results in production of adrenal glucocorticoids, androgenic steroids, and, to a lesser extent, mineralocorticoids. There is evidence that the N-terminal peptide, POMC(1-28), exerts an independent mitogenic and growth-sustaining effect on the adrenal gland.³³⁹

Skin Pigmentation. Melanocyte stimulation occurs through activation of MC1R. ACTH, β -lipotropin (β -LPH), and γ -LPH produced from the corticotroph share a common heptapeptide sequence (Met-Glu-His-Phe-Arg-Trp-Gly) that

is required to activate MC1R. These peptides are responsible for inducing skin pigmentation in Addison's disease because the other melanostimulating peptides, α -MSH and β -MSH, are not produced in the pituitary. There is also evidence for a paracrine system regulating skin pigmentation. Local production of ACTH and α -MSH occurs in melanocytes and keratinocytes and is stimulated by cytokines and ultraviolet irradiation in parallel with PC1 and PC2 expression.³⁴⁰

Appetite Regulation. POMC-derived peptides, and in particular α -MSH, play a critical role in the central regulation of appetite. The melanocortin system mediates feedback suppression of appetite by leptin through activation of MC3R and MC4R by α -MSH in the hypothalamus. Genetic and pharmacologic abrogation of the melanocortin system causes profound obesity. POMC-deficient mice and humans are hyperphagic, whereas intraventricular infusion of α -MSH or synthetic agonists induces weight loss.^{341,342}

Immune Modulation. α -MSH influences the inflammatory process by modulating the function of antigen-presenting cells and T cells. It suppresses fever induced by IL-6 and inhibits macrophage function and leukocyte migration.³⁴³

Analgesia. β -Endorphin is produced by corticotrophs, and circulating concentrations may be high in Addison's disease. The peptide exerts a potent analgesic effect through opiate receptors. These are unlikely to be of physiologic significance because the peptide does not cross the blood-brain barrier.

Placenta-Derived POMC Peptides. Full-length pituitary-like POMC mRNA is expressed in human placenta along with ACTH, LPH, endorphin, and α -MSH. Intact POMC is not detectable in the nonpregnant state but becomes measurable in early gestation, rising 3- to 10-fold in the second trimester, plateauing thereafter, and returning to prepregnancy levels within 3 days after delivery.³⁴⁴ The physiologic function of this placental molecule is unknown, and blood levels do not correlate with those of ACTH or cortisol, both of which also increase during pregnancy.

Ectopic Synthesis of ACTH

POMC is also expressed in the gonads, lung, skin, gastrointestinal and adrenal medullary neuroendocrine cells, and white blood cells. Nevertheless, the overwhelming source of circulating ACTH is derived from the anterior pituitary or from neuroendocrine tumor ectopic production. Nonpituitary tumors demonstrate a spectrum of altered POMC gene expression and processing. The ectopic ACTH syndrome occurs in tumors capable of generating high amounts of the pituitary-like 1072-nucleotide mRNA. Processing may not occur because of the lack of PC enzyme or may be abnormal, resulting in preferential generation of smaller fragments such as CLIP and β -MSH.³⁴⁴ Small cell lung cancers preferentially release intact POMC, whereas carcinoid tumors tend to overprocess the precursor, releasing ACTH and smaller peptides.³⁴⁴ Defective POMC processing indicates an impaired state of neuroendocrine differentiation in poorly differentiated tumors.

Extrapituitary neuroendocrine tumors associated with ectopic ACTH secretion do not process the prohormone efficiently because of a general defect in PC expression. Because ACTH is synthesized in nontumorous neuroendocrine cells, ectopic tumor hormone production may in fact reflect inappropriate ACTH processing. These patients also exhibit a higher ratio of circulating ACTH precursors and smaller peptides, including CLIP.

ACTH Regulation

The complex control of ACTH secretion patterns is critical for maintenance of adrenal cortex function and reflects the integrated neuroendocrine control of stress homeostasis. Essential metabolic and endocrine functions require a sensitively controlled, nonstress pattern of HPA axis function. This baseline pattern allows the axis to mount an appropriate stress response and to maintain a well-buffered reserve capacity to counteract life-threatening insults.

As with other anterior pituitary hormones, ACTH regulation is subserved by at least three tiers of control. First, the brain and hypothalamus release regulatory molecules (including CRH, vasopressin, and other peptides) that traverse the portal system and directly signal to corticotroph secretory and mitotic activity. Second, intrapituitary cytokines and growth factors act locally to regulate ACTH, either in concert with hypothalamic factors or independently. These paracrine controls often overlap and are redundant, and they have been shown to induce sensitive intracellular molecules that limit the ACTH response and prevent chronic ACTH hypersecretion.³⁴⁴ Third, glucocorticoids maintain a potent feedback inhibition control of corticotroph secretion and replication. The HPA axis is inhibited by a long feedback inhibition, whereby cortisol rapidly inhibits hypothalamic CRH and pituitary ACTH. These effects may also be delayed 30 to 60 minutes by inhibition of ACTH release rather than synthesis,³⁴⁵ especially after a single glucocorticoid bolus. After chronic glucocorticoid exposure (>24 hours), HPA suppression may persist for days or longer. In a short feedback loop, pituitary ACTH inhibits hypothalamic CRH, and in an ultrashort loop it may also suppress the corticotroph itself.

Stress Response. Both exogenous and endogenous stress stimuli activate the HPA axis to produce sufficient glucocorticoid in an attempt to counteract the insult. The HPA stress response occurs in the context of a wide variety of peripheral and central adaptors to stress, including vasovagal and catecholamine activation and cytokine secretion and action. A tightly controlled immuno-neuroendocrine interface regulates the ACTH response to peripheral stressors, which include pain, infection, inflammation, hemorrhage, hypovolemia, trauma, psychological stress, and hypoglycemia. These signals vary in their ability to generate ACTH secretion and to sensitize the glucocorticoid response to ACTH. In addition to CRH, peripheral and centrally released pro-inflammatory cytokines potentially induce POMC transcription and ACTH secretion.³³⁰ Sensitive intracellular signals within the corticotroph also serve to override the ACTH response to stress, thus preventing persistent and chronic hypercortisolemia.

Cytokines such as IL-6 and LIF activate the HPA axis and enhance glucocorticoid production, thus protecting the organism against lethality by constraining the inflammatory response.³³⁵ Mice with inactivated CRH or LIF genes mount an inadequate neuroendocrine response to stress, inflammation, or endotoxins. During stress, glucocorticoid inhibition of ACTH is also prevented by activation of nuclear factor κ B, which interferes with pituitary glucocorticoid receptor function, further exaggerating enhanced ACTH secretion.³⁴⁶

Exercise is a physiologic stimulus of ACTH release. Exercising to 90% of maximum oxygen capacity causes a significant elevation of ACTH, similar to levels observed during surgery or hypoglycemia.³⁴⁷ Levels may remain elevated for up to 6 minutes after the cessation of exercise. Although lower-intensity exercise does not evoke ACTH,³⁴⁸

well-trained athletes exhibit hypercortisolism, possibly because of decreased adrenal ACTH sensitivity.

Secretion. ACTH is secreted with both circadian periodicity and ultradian pulsatility under the control of the suprachiasmatic nucleus. This centrally controlled pattern is influenced by peripheral corticosteroids. The circadian pattern of ACTH secretion typically begins at about 4 a.m., peaking before 7 a.m., and both ACTH and adrenal steroid levels reach their nadir between 11 p.m. and 3 a.m. Within this overall 24-hour diurnal cycle, periodic ACTH secretory bursts occur at a frequency of 40 pulses per 24 hours; amplitude rather than frequency modulation contributes to diurnal changes in ACTH profile.^{349,350}

ACTH circadian rhythm is entrained by visual cues and the light-dark cycle, and it is centrally controlled by CRH and other factors.³⁵¹ The mode of CRH signal determines ACTH response, with a continuous signal desensitizing the ACTH response and a pulsatile CRH signal restoring cortisol secretion without depleting the pituitary ACTH pool.³⁵² Daily ACTH but not cortisol secretion is higher in males, who also exhibit higher pulse frequency and higher peak amplitudes than females,³⁵³ possibly reflecting gender-specific set points for cortisol feedback or a relative male adrenal insensitivity to ACTH. Endogenous and exogenous stress, including hypoglycemia, act centrally to increase ACTH pulse amplitude, whereas corticosteroids directly suppress basal or stimulated ACTH pulse amplitude.³⁵⁴

Action. ACTH is a polypeptide of 39 amino acids with a molecular weight of 4.5 kd. The highly conserved 12 N-terminal amino acid residues are critical for adrenal gland steroid synthesis. The primary action of ACTH is to maintain adrenal gland size, structure, and function; ACTH induces adrenal steroidogenesis by activating ACTH receptors situated on the adrenal cortex cell surface. ACTH signals via adenyl cyclase to regulate cytochrome P450 enzyme transcription, cortisol aldosterone (10%), 17-hydroxyprogesterone, and, to a lesser extent, synthesis and secretion of adrenal androgens.³⁵⁵ ACTH stimulates mitochondrial cholesterol transport and regulates the rate-limiting side-chain cleavage of cholesterol to pregnenolone.³⁵⁶ Secretory cortisol pulses follow ACTH pulses within 5 to 10 minutes, with a linear dose dependency that is especially evident after physiologic CRH stimulation.³⁵⁷

Adrenal cortisol response to ACTH is sensitive to the background ambient ACTH milieu. In states of chronic ACTH deficiency, adrenal reserve is compromised; during ongoing ACTH hypersecretion, the gland is primed such that a given ACTH bolus elicits a higher cortisol response. Both basal and stimulated (e.g., by CRH) ACTH secretion are blunted by glucocorticoids. Conversely, low or absent circulating glucocorticoids (e.g., after adrenalectomy) result in exaggerated ACTH secretion^{358,359} and in corticotroph cell hyperplasia.³⁶⁰

Disorders of ACTH Secretion

ACTH Deficiency

Causes. Congenital ACTH deficiency may occur as an isolated pituitary defect or as a component of a wider spectrum of multiple pituitary hormone deficiencies. A mutation of TPIT, a transcription factor involved in corticotroph differentiation, has been identified as a cause of isolated ACTH deficiency.³¹ Mutations of transcription factors involved in early stages of pituitary cell differentiation or midline brain development may also give rise to ACTH deficiency as a component of multiple hormone deficiencies. These include Lhx4 and HESX1 (Table 8-6). Secondary causes include pituitary tumors, sellar mass lesions, trauma,

irradiation, and lymphocytic hypophysitis, which may be associated with other autoimmune manifestations (Table 8-7).

Clinical Features. The manifestations of ACTH deficiency are clinically indistinguishable from those of glucocorticoid deficiency from any cause. Glucocorticoids exert pleiotropic effects on metabolism, appetite, cardiovascular function, fluid homeostasis, and inflammation. The clinical features are dependent on the severity, time of onset, and clinical context. In the newborn, ACTH deficiency may manifest as hypoglycemia and failure to thrive. In the adult, there is slowly progressive weight and appetite loss, anorexia, and generalized fatigue mimicking a wasting syndrome. Because adrenal mineralocorticoid secretion is largely unimpaired, salt wasting, volume contraction, and hyperkalemia—features commonly encountered in Addison's disease—are not manifest. Hyperpigmentation, usually associated with exuberant ACTH-related peptide secretion in the face of adrenal damage, does not occur.

Evaluation. Diagnostic evaluation of adrenal insufficiency involves assessment of glucocorticoid status with concurrent measurement of ACTH. Morning serum cortisol levels lower than 3 µg/dL suggest ACTH deficiency, whereas basal morning cortisol levels greater than 18 µg/dL usually indicate normal ACTH reserve. Patients with ACTH deficiency have low to normal serum cortisol levels and low to normal plasma ACTH levels. Blunted responses to provocative tests such as insulin-induced hypoglycemia or metyrapone are required to document a partial deficiency. Fluctuating levels of cortisol-binding globulin (CBG) may confound interpretation of cortisol values. Cirrhosis and hyperthyroidism lower CBG and cortisol levels, whereas estrogens elevate CBG concentrations.

ACTH Excess

Causes. Excessive ACTH production can arise from a corticotroph adenoma or from an extrapituitary ectopic source. Small cell lung carcinomas, bronchial carcinoids, and neuroendocrine tumors are common causes of ectopic ACTH production.

Clinical Features. ACTH-induced adrenal hyperfunction causes a syndrome of hypercortisolism and androgen excess in women. Manifestations arise from appetite stimulation (weight gain), altered fat distribution (moon facies, buffalo hump, central obesity), catabolism (skin thinning, muscle wasting), mood disturbance (depression, anxiety), sodium retention (hypertension), and androgen excess (menstrual irregularity, hirsutism, acne, and oily skin). The evaluation and management of patients with Cushing's disease is fully described in Chapter 15.

Measurement of ACTH

RIA and IRMA assays employ antisera specifically directed against intact ACTH(1-39) or other POMC fragments. In general, the IRMA is more sensitive, reproducible, and rapid.³⁶¹ Most IRMAs have a sensitivity of less than 0.5 ng/L with precise variations of less than 10%. Intact ACTH or POMC precursor peptides are detectable, depending on the sequence specificity of the assay employed. Awareness of the assay peptide specificity may be especially critical when evaluating ectopic POMC products secreted by lung tumors. ACTH precursors are assessed by specific IRMA employing unique monoclonal antibodies to ACTH, N-POMC, β-LPH, or β-endorphin.³⁶²

Ideally, nonstressed resting subjects should have venous blood withdrawn between 6 a.m. and 9 a.m. Because ACTH is relatively unstable at room temperature and has a propensity to adhere to glass, plasma samples should immediately be separated in iced siliconized glass tubes containing

TABLE 8-6

Hereditary Pituitary Deficiency Caused by Transcription Factor Mutations*

Gene	Chromosome	Pituitary Deficiency	MRI Findings	Associated Malformations	Inheritance Mode
POU1F1 [†]	3p11	GH, PRL, \pm TSH	Normal or hypoplastic anterior pituitary		Recessive, dominant

In: Rappaport R, Amselem S, eds. *Hypothalamic Pituitary Development*. Basel, Switzerland: Karger; 2001:94-108; and Romero CJ. Molecular basis of hypopituitarism. *Trends Endocrinol Metab*. 2009;20:506.)

ethylenediaminetetra-acetic acid (EDTA) and stored below -20°C for transport. Morning (8 a.m.) plasma ACTH levels range from 8 to 25 ng/L as measured by IRMA. Episodic secretion and short plasma half-life result in wide and rapid fluctuation of plasma measurements. Cortisol values at 4 p.m. are about half those of morning levels, and at 11 p.m. levels are usually less than 5 $\mu\text{g}/\text{dL}$.

Random ACTH values do not on their own provide an accurate assessment of HPA function unless concurrent cortisol levels are obtained. Therefore, an integrated assessment of both hormone levels is required for interpreting the significance of an appropriately obtained ACTH value. Often, measurement of the cortisol level alone provides a useful surrogate end point for assessing ACTH action and HPA axis integrity. Plasma ACTH levels fluctuate broadly within the same individual and are highly sensitive to stress, time of collection, and gender. Pregnant women have higher ambient ACTH levels, possibly because of placental CRH secretion.³⁶³

Dynamic Testing for ACTH Reserve

Hypothalamic Testing. Insulin hypoglycemia is a potent endogenous stressor that evokes ACTH secretion.²²² Insulin (0.1 to 0.15 U/kg) is injected intravenously after an overnight fast to achieve symptomatic hypoglycemia and a blood glucose level of less than 40 mg/dL. This test must be performed under supervision. A normal HPA response to this stressor evokes cortisol levels higher than 20 $\mu\text{g}/\text{dL}$. Because hypoglycemia acts centrally, a normal response implies integrity of all three tiers of HPA axis control. Up to 20% of patients may require greater amounts of insulin

(0.3 U/kg or more) to achieve symptoms of glucopenia, including sweating, hunger, palpitations, and tremors.³⁶⁴ Venous samples are collected at -15 , 0, 15, 30, 45, 60, 90, and 120 minutes for measurement of glucose, ACTH, and cortisol levels. GH can also be measured. After the test, oral glucose should be administered. Intraindividual variations in blood glucose levels attained after a given dose of insulin, as well as fluctuations in central sensitivity to glucose and activation of catecholamines, can lead to difficulties in reproducibility. The test is contraindicated in subjects with a history of seizures, active coronary or cerebral ischemia, and pregnancy. If pronounced adrenal insufficiency is likely, insulin injection may provoke an adrenal crisis due to inadequate adrenal reserve, and hydrocortisone (100 mg) should be available for urgent intravenous use, if required.

Metyrapone blocks cortisol synthesis by inhibiting adrenal 11β -hydroxylase. The drug releases the HPA axis from negative feedback by cortisol, which normally results in an ACTH surge and elevated levels of 11-deoxycortisol (compound S). A single oral dose (2 to 3 g) is given at midnight, and serum levels of ACTH, 11-deoxycortisol, and cortisol are measured at 8 a.m. the following morning. The test is only valid in the face of documented suppressed cortisol levels lower than 10 $\mu\text{g}/\text{dL}$. In normal subjects, peak ACTH values higher than 200 ng/L are achieved. Side effects include nausea, gastrointestinal upset, and insomnia.³⁶⁵ False-positive results may be obtained when phenytoin is being administered because the drug prevents adequate enzymatic blockade. This test should be performed under observation in the hospital because acute adrenal insufficiency may ensue.

Pituitary Stimulation. Pituitary ACTH secretion may be evoked by injecting CRH or vasopressin. Ovine or human CRH (100 µg or 1 µg/kg) is administered intravenously, and cortisol and ACTH are measured at -5, -1, 0, 15, 30, 60, 90, and 120 minutes. Normally, maximal ACTH responses (twofold to fourfold above baseline) are evoked at 30 minutes,³⁶⁶ whereas cortisol levels peak (>20 µg/dL) at 60 minutes or increase more than 10 µg/dL above baseline. Although CRH readily induces ACTH secretion and may demonstrate corticotroph ACTH deficiency or ACTH excess, the wide variation of responses observed has limited the utility of this test. The CRH test

is usefully applied in making the diagnosis of Cushing's disease with or without dexamethasone pretreatment and in the context of petrosal venous sampling for diagnosing the presence of an ACTH-secreting pituitary adenoma. CRH injection allows a sensitive and specific arteriovenous ACTH gradient to be established, which effectively distinguishes peripheral from pituitary sources of excess ACTH secretion.³⁶⁷

Because of the suppressive impact of circulating glucocorticoids on pituitary CRH responsiveness, it may be difficult to distinguish a corticotroph adenoma from pseudo-Cushing's disease, because hypercortisolism is

associated with both conditions. In such circumstances, combining the CRH test with dexamethasone suppression may be useful. In the combined dexamethasone-CRH test, dexamethasone 0.5 mg is administered every 6 hours for 48 hours starting at noon and ending at 6 a.m., after which CRH is administered intravenously at 8 a.m.³⁶⁸ In normal subjects and those with pseudo-Cushing's disorder, cortisol levels do not rise and are lower than 1.4 µg/dL. If cortisol levels elicited at 15 minutes exceed 4 µg/dL, the presence of an ACTH-secreting pituitary tumor is established, with 100% sensitivity and specificity.³⁶⁸ CRH responsiveness (≥35% cortisol rise) is usually retained in ACTH-secreting adenomas but is not apparent in more than 90% of ectopic ACTH-producing tumors, in which ACTH increases of less than 35% above baseline are usually encountered. The test does not distinguish ACTH-secreting adenomas from a pseudo-Cushing's disorder.³⁶⁹

Adrenal Stimulation. The acute response of the adrenal gland to a bolus ACTH injection reflects ambient ACTH concentrations to which the gland has been exposed. The cortisol response to an acute ACTH injection will be blunted if the subject has experienced chronic pituitary ACTH hyposecretion with resultant adrenal atrophy and diminished cortisol reserve. Conversely, persistently elevated ACTH levels lead to adrenal hypertrophy and augmented cortisol responses.³⁷⁰ A dose of 250 µg ACTH(1-24) (Cortrosyn) is injected intramuscularly or intravenously, and cortisol levels are measured at 0, 30, and 60 minutes. The normal adrenal reserve response is a cortisol value greater than 20 µg/dL or a doubling of the baseline value.

Basal cortisol levels correlate inversely with the incremental response to ACTH.³⁷³ Low-dose stimulation with 1 µg Synacthen evokes maximal serum cortisol levels at 30 minutes, and these correlate well with values observed after insulin or high-dose ACTH administration.³⁷² A cutoff value of 500 nmol/L provides almost 100% sensitivity and a specificity of 80% to 100%.³⁷⁴ Failure to respond to low-dose ACTH should be corroborated by use of a standard dose of insulin or ACTH stimulation.

The utility of this test in diagnosing diminished pituitary ACTH reserve has been challenged on the basis that the commonly employed dose of Cortrosyn or Synacthen is pharmacologic and may evoke a "normal" cortisol response in subjects with hypopituitarism. An unacceptably high false-negative rate (approximately 65%) was reported in a large series,³⁷¹ although peak cortisol levels at 30 minutes have been shown to correlate well with peak responses to ITT.³⁷²

Adrenal Steroid Replacement

Hydrocortisone is widely used for glucocorticoid replacement. The normal secretory rate of cortisol is 15 to 20 mg/day, and this is the recommended total daily dose for correcting hypoadrenalism and maintaining blood pressure. Because the plasma circulating half-life of cortisol is less than 2 hours, three-times-daily dosing of a total daily requirement of 10 to 20 mg (5 to 10 mg in the morning, 2.5 to 5 mg at noon, and 2.5 to 5 mg in the evening) is recommended.³⁷⁵ However, conventional regimens cannot provide the physiologic pattern of cortisol release, and this may explain the high prevalence of poor quality of life in these patients.³⁷⁶ There is no consensus for monitoring of treatment, although salivary, plasma, and urinary measurements have been advocated.

Doses must be increased during stress and before operative procedures. Cortisone acetate is metabolized to cortisol and has a slower onset of action and longer biologic

activity than hydrocortisone. Other synthetic glucocorticoids, including prednisolone (2.5 to 5 mg/day) and dexamethasone (0.25 to 0.5 mg/day), are suitable alternatives. Because of their longer half-lives, they can be administered once daily, but they are less useful because they are difficult to monitor biochemically. Even modest cortisol overplacement can result in bone mineral loss.³⁷⁷

Central diabetes insipidus may rarely be unmasked after initial glucocorticoid replacement. Mineralocorticoid replacement is not required for treatment of secondary hypoadrenalism. Adrenal androgen replacement with dehydroepiandrosterone (DHEA) at doses of 25 mg/day may improve the sense of well-being, fatigue, and sexual function in patients with primary and secondary adrenal insufficiency.^{378,379}

Gonadotropins

Physiology

Gonadotrophs. Gonadotroph cells secreting FSH and LH comprise 10% to 15% of the functional anterior pituitary cells. Two classes of electron-dense secretory granules are evident: large (350 to 450 nm) and small (150 to 250 nm). The granules are packaged in vesicles (Figs. 8-28 and 8-29). They contain large, round cell bodies with prominent rough endoplasmic reticulum and Golgi apparatus. LH secretory granules often accumulate peripherally, and their Golgi structures may be less prominent. SF1 and DAX1 orphan nuclear receptor determine gonadotroph-specific gene expression.

Structure of Gonadotropins. FSH and LH function to regulate gonadal steroid hormone biosynthesis and to initiate and maintain germ cell development, in concert with peripheral hormones and paracrine soluble factors. The four glycoprotein hormones—LH, FSH, TSH, and human chorionic gonadotropin (hCG)—share structural homology, having evolved from a common ancestral gene. Although the homologous LH and FSH molecules are cosecreted by the gonadotroph cell, their regulatory mechanisms are not uniformly concordant. The α - and β -subunits are encoded by different genes, located on chromosomes

Figure 8-28 Normal gonadotroph cells contain immunoreactive β -follicle-stimulating hormone scattered throughout acini of the nontumorous pituitary. These round cells have evenly dispersed cytoplasmic immunoreactivity for α and β gonadotrophic subunits. (From Asa SL. Tumors of the pituitary gland. In: Rosai J, ed. *Atlas of Tumor Pathology*, Series III, Fascicle 22. Washington, DC: Armed Forces Institute of Pathology, 1997:26.)

Figure 8-29 Electron micrograph of gonadotroph cell shows large, round to elongated cells with ovoid nuclei with occasional nucleoli. Short profiles of rough endoplasmic reticulum are scattered throughout the cytoplasm; they are dilated and frequently contain electron-lucent material. The Golgi complex is usually well developed and in a juxtanuclear location. Secretory granules are highly variable in size, shape, and electron density, and lysosomes are prominent. (From Asa SL. Tumors of the pituitary gland. In: Rosai J, ed. *Atlas of Tumor Pathology*, Series III, Fascicle 22. Washington, DC: Armed Forces Institute of Pathology, 1997:26.)

6, 11, and 19 respectively (Fig. 8-30). The heterodimeric structure of the common α GSU and unique β subunit is essential for biologic activity of the glycoprotein hormones. Disulfide linkages maintain noncovalent subunit linkage, which determines the ultrastructure of the mature folded molecule.³⁸⁰ After processing of hormonal protein precursors, glycosylation occurs by transfer of oligosaccharide complexes to asparaginyl residues.³⁸¹ Post-translational processing of carbohydrate side chains is critical for hormone signaling; it may be species specific and is not uniformly similar for human LH and FSH.

The complex human LH β gene cluster comprises seven CG-like genes, one of which encodes LH β , whose promoter and transcriptional start site differ from that of hCG.^{382,383} The three exons and two introns encode a 24-amino-acid leader peptide and a 121-amino-acid mature protein. Unlike LH β , hCG is present only in primate and equine species, and the hCG peptide product contains a 24-amino-acid C-terminal extension.³⁸⁴ Cell-specific LH gene expression and GnRH responsiveness of LH are subserved by different transcriptional mechanisms.^{385,386} GnRH induces LH β transcription, as does SF1.³⁸⁷ The rat LH β promoter contains an estrogen-responsive motif and an NF-Y binding site that appears to be important for basal, but not GnRH-mediated, transcription.³⁸⁵ The FSH β gene comprises three exons and two introns located on chromosome 11.³⁸⁸ The gene promoter is dissimilar from that of LH β , and the structure-function mechanisms for transcriptional regulation of the human gene by GnRH and sex steroids are not well clarified.³⁸⁹

Regulation

Hypothalamic GnRH neurons represent the pivotal integrator of peripheral signals in the regulation of the pituitary-gonadal axis. Considerable insight has been gained into the process controlling the development, migration from the olfactory placode, and regulation of the GnRH neuron.

Kisspeptin peptides and their cognate receptor, orphan G protein-coupled receptor 54 (GPR54), were identified in 2004 as key regulators of GnRH neuronal function.³⁹⁰ Kisspeptins are a family of peptides encoded by the KISS1 gene whose products also suppress the metastatic potential of breast cancer and melanomas. Loss-of-function mutations of GPR54 lead to hypogonadotropic hypogonadism, whereas administration of kisspeptin stimulates the hypothalamic-pituitary-gonadal axis in animal models.³⁹¹ Acute administration of kisspeptin to normal men increases FSH, LH, and testosterone concentrations; in normal women, the peptide stimulates gonadotropin release most potently during the preovulatory surge.³⁹² There is strong evidence that kisspeptin acts as the endogenous GnRH secretagogue across many species, including humans.

Leptin, a product of peripheral adipose tissue, is a positive regulator of the hypothalamic-pituitary-gonadal axis. This adipokine enables a pivotal link between body fat and reproduction, signaling energy availability centrally.³⁹³ Leptin receptors are expressed specifically on GnRH-secreting neurons, and leptin accelerates GnRH pulsatility.³⁹⁴ The concentration of leptin in blood is tightly related to body fat mass, and a threshold level is required to activate the hypothalamic-pituitary-gonadal axis. Delayed sexual maturation of food-restricted female rats can be accelerated by central leptin administration, despite decreased body weight. Increasing serum leptin levels during weight gain in treated patients with anorexia nervosa correlate positively with changes in LH, FSH, testosterone, and gonadal steroids.³⁹⁵

Figure 8-30 Schematic depiction of the subunit structure and glycosylation sites of the four glycoprotein hormone heterodimers (α -subunit, blue; β -subunit, green). (From the University of Glasgow protein crystallography website, Available at: <http://www.chem.gla.ac.uk/protein/glyco/GPH.html> [accessed September 2010]).

Secretion of Follicle-Stimulating Hormone and Luteinizing Hormone. FSH and LH secretion patterns reflect the integration of sensitive and complex hypothalamic, pituitary, and peripheral signals. GnRH pulse amplitude and frequency determine the physiologic patterns of LH and FSH secretion (Fig. 8-31).³⁹⁶ In patients with hypothalamic GnRH deficiency, intravenous GnRH injections (25 ng/kg) that achieve GnRH levels similar to those present in primate hypophyseal-portal blood replicate the physiologic pattern of LH secretion.³⁹⁷ The magnitude of the LH response exceeds that of FSH. Decreasing GnRH pulse frequency enhances LH pulse amplitudes, whereas increasing GnRH pulse frequency to more than every 2 hours downregulates the subsequent LH response. The interpulse LH secretory interval is 55 minutes, and the pulse amplitude is approximately 40% of basal tonic secretion. Changes in gonadotropin secretion during infancy, childhood, puberty, and aging are described in Chapter 25. A log-linear relationship is evident between the GnRH dose and the quantity of pituitary secretion of LH, FSH, and free α -subunit.

Both pituitary and hypothalamic targets for testosterone signals mediate FSH and LH regulation, and in males, testosterone attenuates gonadotropin secretion (Fig. 8-32). After castration, elevated gonadotropin levels can be partially overcome by testosterone replacement. Mechanisms for these observations are complex, because testosterone also exerts a stimulatory effect on FSH β mRNA levels. Although estrogen administration decreases LH pulse amplitude in normal and GnRH-deficient male subjects,^{398,399} depending on the clinical situation, estrogen may either stimulate or inhibit pituitary gonadotropin synthesis and secretion, and it also can inhibit GnRH synthesis or action. This pattern is manifest in the cyclic control of gonadotropin secretion during the menstrual cycle and during puberty. LH, FSH, free α -subunit, and testosterone pulses are usually concordant in male subjects.⁴⁰⁰ Deconvolution pulse analysis allows estimation of "real-time"

Figure 8-31 Serum luteinizing hormone (LH) levels (open symbols) and follicle-stimulating hormone (FSH) levels (solid symbols) in men as a function of age from three studies. (From Tenover JL. hormone secretion rates, with an assumed disappearance rate constant. The characteristic secretory episodes characterized for LH and FSH indicate daily production rates of 1000 IU and 200 IU, respectively, and a disappearance half-life of 90 and 500 minutes for each respective β -subunit.⁴⁰¹

Gonadal Peptides. Pituitary gonadotropin secretion is regulated by gonadal peptides including inhibin A, an α : β A heterodimer; inhibin B, an α : β B heterodimer; and follistatin peptides. The activin A β A- and activin AB (β B) homodimers stimulate in vitro FSH secretion.⁴⁰² These proteins, which are related to transforming growth factor- β and müllerian-inhibiting factor, are fully described in Chapter 22.

Actions of Follicle-Stimulating Hormone and Luteinizing Hormone

Female. Luteal cell LH receptors signal to enhance cAMP levels and induce cholesterol availability for ovarian steroidogenesis. The steroidogenic acute regulatory (StAR) protein⁴⁰³ is induced by LH and mediates cholesterol delivery to the inner membrane. LH enhances cytochrome P450-linked enzyme activity in the synthesis of pregnenolone and induces 3 β -hydroxysteroid dehydrogenase, 17 α -hydroxylase, and 17,20-lyase synthesis.

The FSH receptor, a G protein-linked seven-transmembrane molecule, shares 50% extracellular domain and 80% transmembrane homology with the LH receptor.⁴⁰⁴ FSH regulates ovarian estrogen synthesis by inducing 17 β -hydroxysteroid dehydrogenase and aromatase and also induces follicular growth. Estrogens are also permissive for FSH action and enhance FSH-induced cAMP levels.⁴⁰⁵

Male. Leydig cell LH receptor signaling induces intratesticular testosterone synthesis mediated by enhanced cAMP production. FSH function in male subjects is not readily apparent but probably mediates the development of spermatozoa from spermatids in concert with testosterone, especially because failed spermatogenesis leads to elevated FSH levels.

Gonadotropin Assays

Because of the high homology of the glycoprotein hormones, development of highly specific assays, especially distinguishing free α GSU from intact hormones, has been challenging. Heterogeneity of circulating LH and FSH molecules; insufficient assay sensitivity, especially for normal healthy measurements; and lack of rigorously pure reference preparations have hampered assay development. Immunofluorometric assays detect LH with a sensitivity of 0.1 mIU/mL.⁴⁰⁶ Differences in carbohydrate moieties result in isoelectric charge heterogeneity for LH, accounting for some of the disparities in biologic and immunoreactive LH ratios observed after GnRH agonist treatment, in acute critical illness, or with aging.

LH bioassays include assessment of testosterone generation by cell culture,⁴⁰⁷ and FSH bioassays include measurement of granulosa cell or Sertoli cell aromatase generation.⁴⁰⁸ Because only intact molecules, not free α - or β -subunits, are biologically active, these assays, although cumbersome, are useful for measuring bioactive hormone without the potential cross-reaction of free subunits.

α -Subunit Secretion

Both GnRH and TRH increase circulating levels of free α -subunit derived from gonadotrophs or thyrotrophs, especially in patients with hypothyroidism, after castration and during menopause. GnRH agonist treatment, TSH-secreting tumors, and nonfunctioning pituitary adenomas may result in discordant ratios due to free α -subunit secretion.

Gonadotropin Deficiency

Causes. Gonadotropin deficiency may be congenital or acquired and may arise from hypothalamic or pituitary lesions. Congenital causes include gene mutations governing the processes of migration and function of GnRH neurons and development of the gonadotroph. Hypogonadotropic hypogonadism may arise from functional or organic disorders. Functional causes are frequently encountered and include stress, malnutrition, chronic illness, depression, excessive exercise, and low body weight. Several centrally acting drugs, including opiates, tranquilizers, antidepressants, and antipsychotic medications, suppress gonadotropin secretion directly or indirectly via induction of hyperprolactinemia. Organic causes include malignant disease, developmental tumors, infiltrative disease, and hypothalamic or pituitary damage from surgery or radiotherapy. Acquired and congenital causes of central hypogonadism are considered fully in Chapter 20.

Isolated Hypogonadotropic Hypogonadism. The genetic basis of isolated hypogonadotropic hypogonadism (IHH) was recognized more than 60 years ago with the description by Kallmann of hypogonadism and anosmia in two families. It was not until 1991 that anosmin, a glycoprotein encoded by the KAL1 gene, was identified.⁴⁰⁹ The realization that KAL1 defects account for only a small proportion of patients with Kallmann's syndrome led to genotype-phenotype studies that provided important insights into the molecular genetics underlying IHH occurring with and without anosmia (Table 8-8). Gene mutations affecting olfactory bulb and GnRH neuronal migration tend to give rise to the Kallmann phenotype, whereas defects in the regulation of GnRH are usually associated with normosmia.

Clinical Features. Gonadotropin deficiency causes hypogonadism with decreased sex steroid production of varying

TABLE 8-8

degree, depending on the severity of the insult (Table 8-9). This disorder may occur at any stage of life. In its complete form (e.g., panhypopituitarism; Kallmann's syndrome), primary amenorrhea or total failure of male sexual development may occur. Later in life, a varying spectrum of sexual dysfunction develops, ranging from luteal abnormalities or oligomenorrhea to amenorrhea in women, or to absence of libido, potency, and fertility in men. Women exhibit secondary amenorrhea, vaginal dryness, hot flashes, decreased bone density, decreased breast tissue, and infertility. Men have impotence, testicular hypoplasia or atrophy, decreased libido, low energy, infertility, loss of secondary sexual characteristics, decreased muscle strength and mass, decreased bone mass, decreased body hair growth, and fine facial wrinkling. In both men and women, serum gonadotropin levels are inappropriately low in the face of decreased sex steroids and sexual dysfunction. In women with amenorrhea or oligomenorrhea, serum levels of LH, FSH, and estradiol should be measured. Endogenous estrogen sufficiency can also be assessed by the response to a progesterone challenge (100 mg intramuscularly, or 10 mg/day Provera orally for 5 days). Men should have serum gonadotropin and testosterone levels measured.

Because FSH is required for normal spermatogenesis, isolated FSH deficiency is associated with oligospermia or azoospermia in normally androgenized men in the face of normal testosterone and LH levels.⁴¹⁰ Isolated LH deficiency may manifest with eunuchoid body proportions as a result of low testosterone levels. Low LH levels in these patients lead to low intratesticular testosterone concentrations with resultant decreased spermatogenesis.⁴¹¹ Serum testosterone levels are restored in this "fertile eunuch" syndrome by hCG administration. IHH⁴¹² occurring after

TABLE 8-9

Clinical Features of Hypogonadotropism

Skeletal proportions Penis length Scrotal rugae Prostate size

apparently normal puberty manifests with relatively mature secondary sex characteristics or even secondary infertility. These patients have abundant gonadotropin responses to pulsatile GRH therapy, which restores reproductive function and fertility.

Management

Evaluation. In evaluating hypogonadal patients without an obvious pituitary or gonadal disorder, the primary diagnostic challenge is to distinguish constitutional pubertal delay from other causes of hypogonadotropism.⁴¹³ If puberty is delayed beyond 14 years of age, a primary developmental disorder, hypogonadotropic hypogonadism, should be considered in the absence of acquired causes. No single test clearly distinguishes constitutional delayed puberty from true hypogonadotropism, and expectant follow-up is often helpful because many patients enter puberty spontaneously. To enable androgenization, testosterone replacement should be intermittently provided until age 18 years, with periodic interruptions to unmask physiologic pubertal advance.

Sex Steroid Replacement Therapy. Estrogen or testosterone replacement is required to induce and maintain primary and secondary sexual functions, to minimize cardiovascular risk factors, and to maintain normal body composition and integrity of bone mineral density and muscle mass. For patients not desirous of fertility, sex steroid therapy is warranted to correct central hypogonadism. However, monitoring of LH and FSH responses does not accurately reflect adequate steroid hormonal replacement, because basal gonadotropin levels are already low or undetectable.

Estrogens are available in tablet, patch, gel, and implant forms. For premenopausal women with pituitary deficiency, conjugated equine estrogens (0.625 mg) or estradiol valerate (2 mg) provide relatively physiologic steroid replenishment. Estrogen patches or transcutaneous gels usually enable daily absorption of 50 to 100 µg estradiol. Estrogens in the form of oral contraceptive formulations

are to be avoided, because the doses are pharmacologic and can potentially impair hepatic metabolic function. Concomitant cyclic progesterone therapy (e.g., medroxyprogesterone acetate 5 mg or dydrogesterone 10 mg) is indicated for women with an intact uterus to prevent unopposed endometrial proliferation and bleeding.

Although early replacement lessens the risk of developing osteoporosis, effects of estrogen replacement on cardiovascular function are unresolved. In patients with hypopituitarism, estrogen replacement should be maintained at least until 50 years of age, after which continuation should be determined on an individual basis by assessing risks and benefits, especially in terms of bone mineral integrity, cardiovascular function, and cancer risk. In women with ovarian deficiency, addition of androgen may improve libido and sexual function. Estrogen treatment may be associated with thromboembolic disease, breast tenderness, and possibly enhanced risk for breast cancer.

For men, androgen replacement preparations are available in intramuscular gel, patch, and oral forms. Intramuscular injection of testosterone undecanoate, 1000 mg, provides satisfactory long-term replacement for 3 to 4 months. The improved pharmacokinetic profile reduces fluctuations in sexual potency, energy level, and mood that are often seen with shorter-acting testosterone 17α-hydroxyl esters (testosterone enanthate and testosterone cypionate), which are usually administered in 200-mg doses every 2 or 3 weeks.⁴¹⁴ Administration of lower doses on a more frequent basis (e.g., 100 mg weekly or 150 mg every 14 days) may also stabilize fluctuations of hormone levels. Elderly men require lower doses, as do boys with delayed puberty. Transdermal testosterone patch and gel systems deliver 4 to 6 mg and sustain testosterone profiles. Patch sites may develop skin irritation, blisters, or vesicles in about 25% of patients.⁴¹⁵ Some patients require combined patches and low-dose injections to maintain adequate potency and energy levels.^{416,417} There is no apparent cost-benefit advantage of patch delivery over intramuscular injection. Oral androgen replacement therapy with 17α-hydroxyl ester testosterone undecanoate requires frequent dosing (two to four times daily), and, because absorption is not uniform, testosterone levels may not be adequately maintained. Oral 17α-methyltestosterone is not recommended because of hepatotoxicity.

Testosterone may cause acne, gynecomastia, urinary retention due to prostatic obstruction (rarely), and polycythemia. Although there is no compelling evidence that testosterone replacement causes prostate cancer, benign prostatic hypertrophy could be exacerbated, especially in elderly patients. Testosterone replacement should not be administered to men with diagnosed prostate cancer.

Fertility. In patients with hypogonadotropic hypogonadism, fertility may be achieved with gonadotropin or GnRH therapy. In male patients, coexistence of primary testicular dysfunction precludes the success of direct gonadotropin replacement or GnRH; however, the relatively low sperm counts induced by gonadotropin or GnRH may be adequate for impregnation. Because testosterone therapy may suppress spermatogenesis, the steroid should be discontinued before treatment is initiated. hCG is administered subcutaneously or intramuscularly (1000 to 2000 IU two to three times weekly) to induce spermatogenesis. Lower doses may also be effective.⁴¹⁸ If necessary, after 6 months, human menopausal gonadotropin (hMG) or purified FSH (75 IU three times weekly) should be added to improve sperm quantity, and doses may be doubled after a further 6 months. If testosterone levels are increased,

subsequent conversion to estradiol may be enhanced, resulting in gynecomastia. Gonadotropin therapy may also cause androgenized oily skin and acne. Therefore, both testosterone and estradiol levels should be monitored.

Pulsatile GnRH therapy is indicated for patients with normal pituitary function (i.e., those with idiopathic hypogonadotropic hypogonadism or Kallmann's syndrome). GnRH is infused subcutaneously by continuous mini-pump (5 mg every 2 hours); the dose is titrated to maintain normal gonadotropin and testosterone levels and may be marginally more effective and cause less gynecomastia. These approaches require strong patient commitment, because adequate spermatogenesis may not be attained for 2 years or longer despite normalized testosterone levels. Aliquots of successfully generated sperm samples should be frozen for future impregnation.

In women with central hypogonadism, fertility may be effectively achieved by GnRH or gonadotropin therapy (see Chapter 17). Although ovulation is often induced and pregnancy achieved by gonadotropin treatment, a high rate of development of multiple follicles remains a concern. A pregnancy rate of 83% was achieved in 77 patients with hypogonadotropic hypogonadism who were treated with gonadotropins or pulsatile GnRH.⁴¹⁹ If residual pituitary gonadotroph reserve is sufficiently robust, GnRH therapy is more likely to result in ovulation of a single rather than multiple follicles, thereby reducing the chances of multiple gestation.⁴²⁰ The beneficial role of adding GH to these treatments remains unresolved,⁴²¹ except for those women with known hypopituitarism and GHD (see Chapter 17).

Gonadotropin-Releasing Hormone Stimulation Test. A single bolus of GnRH (25 to 100 μ g) dose-dependently evokes serum LH and FSH levels within 20 to 30 minutes. LH rises more abundantly than FSH, and peak values range from 8 to 34 mIU/mL; patients with low testosterone levels exhibit more exuberant responses.⁴²² In contrast, patients with hypogonadotropic hypogonadism and no demonstrable hypothalamic-pituitary lesion have blunted LH responses and reversal of the LH/FSH ratio. The test cannot adequately distinguish hypothalamic from pituitary lesions, and similar patterns are observed in patients with anorexia nervosa. Repetitive GnRH pulses may in fact normalize responses, as would be expected from an intact hypothalamic-pituitary unit. GnRH responses may vary during the stages of puberty, reflecting altered pituitary sensitivity.

Clomiphene (100 mg), administered daily for up to 4 weeks, usually doubles LH levels, whereas FSH increases about 50% over baseline. Because an abnormal or absent response does not distinguish hypothalamic from pituitary lesions, the utility of this test is limited.

Thyroid-Stimulating Hormone

Physiology

The hypothalamic-pituitary-thyroid system plays a critical role in development, growth, and cellular metabolism, with thyroid hormone availability and action controlled by complex mechanisms at the tissue level.

Thyrotrophs. Thyrotroph cells comprise approximately 5% of the functional anterior pituitary cells and are situated predominantly in the anteromedial areas of the gland. They are smaller than the other cell types. They are irregularly shaped, with flattened nuclei and relatively small secretory granules ranging from 120 to 150 μ m (Figs. 8-33 and 8-34).

Figure 8-33 Normal thyrotrophs have angular cell bodies with elongated processes. (From Asa SL. Tumors of the pituitary gland. In: Rosai J, ed. *Atlas of Tumor Pathology*, Series III, Fascicle 22. Washington, DC: Armed Forces Institute of Pathology, 1997:19.)

Structure. TSH is a glycoprotein hormone comprising a heterodimer of noncovalently linked α - and β -subunits.⁴²³ The α GSU is common to TSH, LH, FSH, and hCG, whereas the β -subunit is unique and confers specificity of action.⁴²⁴ The α GSU is the earliest hormone gene expressed embryonically; activation of the β -subunit gene occurs later,

Figure 8-34 Electron micrograph of normal thyrotrophs shows angular cell bodies with elongated processes. (From Asa SL. Tumors of the pituitary gland. In: Rosai J, ed. *Atlas of Tumor Pathology*, Series III, Fascicle 22. Washington, DC: Armed Forces Institute of Pathology, 1997:19.)

under the influence of GATA2 and POU1F1.⁴²⁵ The 13.5-kb α GSU gene is located on chromosome 6 and consists of four exons and three introns.⁴²⁶ Although the α GSU gene is expressed in thyrotroph, gonadotroph, and placental cells, its regulation is uniquely cell specific. The downstream promoter region (–200 and further) is required for placental expression, intermediate sequences are required for gonadotroph expression, and upstream promoter elements are required for thyrotroph-specific expression.⁴²⁷

α -GSU transcription is inhibited by triiodothyronine (T_3) at regions close to the transcriptional initiation site, in concert with other nuclear corepressors.⁴²⁸ The 4.9-kb TSH β -subunit gene, located on chromosome 1, comprises three exons and two introns.⁴²⁹ POU1F1 binds directly to the gene promoter to confer tissue-specific expression.⁴³⁰ TSH- β gene transcription is suppressed by the thyroid hormone receptor acting directly on exon 1.⁴³¹ This potent suppression is evident within 30 minutes after T_3 exposure and is a critical determinant of TSH synthesis and secretion. TSH α - and β -subunit gene transcription is induced by TRH, and depletion of cAMP by dopamine leads to suppressed gene transcription.⁴³² Intrapituitary TSH is stored in secretory granules, and the mature hormone (molecular weight, 28 kd) is released into the venous circulation, primarily in response to hypothalamic TRH. The predicted structural model of the TSH molecule is that of a cystine knot growth factor. The tertiary TSH structure comprises three hairpin loops separated by central disulfide bonds, with the longest loop straddling one side.^{433,434}

Production of the mature heterodimeric TSH molecule requires complex cotranslational glycosylation and folding of nascent α - and β -subunits.⁴²⁴ After subunit translation and signal peptide cleavage, glycosylation occurs at Asn23 on the β -subunit and at Asn52 and Asn78 on the α -subunit.⁴³⁵ Appropriate glycosylation is required for accurate molecular folding and subsequent combination of α - and β -subunits within the rough endoplasmic reticulum and Golgi apparatus. Both TRH and T_3 regulate TSH glycosylation, albeit in opposite directions. TRH administration (e.g., in hypothyroidism) or T_3 deprivation (e.g., in T_3 resistance) enhances oligosaccharide addition to the TSH molecule.⁴³⁶

Secretion

Daily TSH production is approximately 100 to 400 mU,⁴³⁷ with a calculated circulating half-life of approximately 50 minutes. Secretion rates are enhanced up to 15-fold in hypothyroid subjects and are suppressed in states of hyperthyroidism. The degree of TSH glycosylation determines the metabolic clearance rate and the bioactivity; in hypothyroidism, the molecule appears to be highly sialylated, enhancing bioactivity.⁴³⁵ Immunoreactive fetal pituitary TSH is detectable by 12 weeks.

Immediately after full-term birth, there is a brisk rise in TSH, which remains elevated for up to 5 days before stabilizing at adult levels.⁴³⁸ Although TSH secretion is pulsatile, the low pulse amplitudes and long TSH half-life result in modest circulating variances. Secretory pulses every 2 to 3 hours are interspersed with periods of tonic, nonpulsatile TSH secretion.⁴³⁹ Circadian TSH secretion peaks between 11 p.m. and 5 a.m., mainly due to increased pulse amplitude, which does not appear to be sleep-entrained.⁴⁴⁰ Pulsatile and circadian TSH secretory patterns are largely determined by ambient thyroid hormone levels and TRH release. Thyroid hormones suppress tonic TSH secretion and pulse amplitude. Within hours after T_3 administration, basal TSH levels fall and TRH-evoked TSH levels are attenuated. Primary

hypothyroidism is associated with enhanced TSH pulse amplitudes occurring throughout the day, and nocturnal TSH surges are abrogated in patients with critical illness.⁴⁴¹

Regulation

The TRH neuron plays a central role in determining the set point of the hypothalamic-pituitary-thyroid axis by regulating pituitary TSH release. Located in the paraventricular nucleus, TRH neurons receive direct projections from the leptin system that regulates energy homeostasis, the POMC system that promotes weight loss, and the neuropeptide Y (NPY)/agouti-related protein (AgRP) system that promotes weight gain.⁴⁴² Fasting results in reduction of TRH expression, mediated by suppression of the POMC system and stimulation of the NPY/AgRP system.

Feedback regulation of TRH and TSH by thyroid hormones is elaborated through a complex system of local paracrine control. In the hypothalamus, deiodinase 2 (D2), which converts thyroxine (T_4) to triiodothyronine (T_3), is expressed in surrounding glial cells.⁴⁴³ In contrast, the TRH neuron expresses thyroid hormone receptors, thyroid hormone transporters, and D3, which inactivates T_3 , indicating the existence of a level of TRH regulation at the cellular level. T_3 suppresses hypothalamic TRH synthesis and decreases the number of pituitary TRH receptors.

In the anterior pituitary gland, immunoreactive D2 and thyroid hormone transporters are found in folliculo-stellate cells, whereas immunoreactive thyroid hormone receptors and D3 are expressed in thyrotrophs.⁴⁴³ These findings indicate an important role for glial and folliculo-stellate cells in processing and activating T_4 . Production and action of local T_3 occur in separate cell types of the hypothalamus and anterior pituitary gland, setting the level of TSH output.

Other Factors. SRIF inhibits TSH pulse amplitude and blocks the nocturnal TSH surge⁴⁴⁴ directly at the pituitary level; it may also suppress TRH release and possibly TRH receptor abundance.⁴⁴⁵ Although SRIF analogs are used to treat TSH-secreting pituitary adenomas (see later discussion), long-term SRIF treatment for acromegaly does not lead to hypothyroidism in adult subjects, although T_4 levels may be lowered within the normal range.⁴⁴⁶ Dopamine inhibits TSH β -subunit gene expression, and dopamine infusions suppress TSH pulse amplitude by 70% and abrogate the nocturnal TSH surge.⁴⁴⁷ Prolonged use of dopamine agonists, however, does not result in hypothyroidism. Glucocorticoids suppress TSH secretion, and in patients with adrenal failure without autoimmune thyroid damage, TSH levels may be elevated. Sex steroids and cytokines alter TSH secretion in animal models, but their contribution to human TSH physiology is as yet unclear. Nonsteroidal anti-inflammatory agents, especially meclofenamate and fenclofenac, decrease serum TSH levels, albeit still within the normal range. The mechanism for this observation may involve displacement of thyroid hormone ligands from their binding proteins or direct inhibition of pituitary TSH.⁴⁴⁸

Action of TSH

TSH acts on the thyroid gland to induce thyroid hormone synthesis and release and to maintain trophic thyroid cell integrity.⁴⁴⁹ The TSH G protein-coupled receptor is located on the thyrocyte plasma membrane and is encoded by a gene on chromosome 11q31. Its regulation is comprehensively described in Chapter 11.

Disorders of TSH Secretion

TSH Deficiency

Causes. Congenital isolated TSH deficiency may arise from mutational defects of the TSH or TRH receptor gene. Genetic disorders of pituitary gland development involved in cell differentiation give rise to TSH deficiency as a component of multiple pituitary hormone deficiencies. These include mutations of LHX3, PROP1, and POU1F1 (see Table 8-6). Pituitary damage may result in functional TSH deficiency, often without a clearly demonstrable reduction in serum TSH levels.

Clinical Features. The consequences of TSH deficiency are those of thyroid hormone deficiency, which causes mental or growth retardation, or both, in children and in adults is associated with a broad spectrum of clinical features including hypothermia, fluid retention, voice and skin changes, and, ultimately if untreated, frank myxedema and death.

Thyroid-Stimulating Hormone Assays. Because feedback control of TSH secretion by peripheral thyroid hormones is sensitive, most thyrotroph disorders can be diagnosed by measuring basal TSH and thyroid hormone levels.

The challenge of a clinically compelling robust TSH assay is to readily distinguish circulating TSH levels in euthyroid subjects from levels in both hyperthyroid and hypothyroid patients. The development of immunoradiometric TSH assays has provided high specificity with little or no cross-reactivity with other glycoprotein hormones. These assays detect quantifiable TSH levels in euthyroid control subjects with no overlap with the low values associated with hyperthyroidism.^{450,451} The most sensitive commercially available third-generation assays have a functional sensitivity of 0.01 to 0.02 mU/L, and newer fourth-generation assays portend greatly enhanced sensitivity (0.001 to 0.002 mU/L). Levels of free α -subunit (normal range, 0.1 to 1.6 μ g/L) are elevated in patients harboring TSH-secreting or nonfunctional pituitary adenomas, in choriocarcinoma, and in several malignancies.

TSH measurement is not helpful in diagnosing central hypothyroidism, which is identified by concurrent measurement of thyroid hormone levels. Only about one third of patients with secondary hypothyroidism have abnormally low basal TSH levels.⁴⁵² TSH deficiency is therefore associated with low T_4 levels concomitant with low, normal, or even minimally elevated TSH levels. Importantly, this biochemical profile may also be encountered in critically ill patients with low TSH and T_4 levels but no evidence of pituitary disease.

However, evoked dynamic TSH measurements elicited by TRH may be required to fully assess the integrity of the hypothalamic-pituitary-thyroid axis.⁴⁵³ TRH (200 to 500 μ g) is administered intravenously, and TSH levels are measured at -15, 0, 15, 30, 60, and 120 minutes after injection. In euthyroid subjects, peak TSH levels (up to 22-fold higher than basal concentrations) are observed after 30 minutes.⁴⁵¹ Because feedback suppression of elevated thyroid hormone levels on TSH overrides positive hypothalamic signals, hyperthyroid subjects have undetectable basal TSH levels that do not respond to TRH. In subjects with secondary thyroid failure due to pituitary disease, TSH levels do not change in response to TRH. Within hours after T_3 administration, basal TSH levels fall and TRH-evoked TSH levels are attenuated. Thyroid hormones suppress tonic TSH secretion and pulse amplitude but do not appear to regulate TSH pulse frequency.

Treatment. L-Thyroxine is used for replacement therapy, and dosing variables are similar to those required for treatment of primary hypothyroidism. Hypothyroid features are effectively ameliorated by administration of T_4 (0.075 to 0.25 mg/day). The molecule is converted peripherally into the active T_3 and has a 7-day half-life with stable blood levels. The dose of levothyroxine in hypopituitary patients is titrated to achieve mid-normal clinically euthyroid serum free T_4 levels, because serum TSH levels are low or undetectable in patients with damaged pituitary function. Measurement of TSH levels is not useful in determining thyroid hormone replacement because the damaged thyrotroph is unlikely to adequately reflect appropriate feedback suppression.

Many women with pituitary failure are also receiving estrogen replacement, and in these patients measurement of free T_4 levels is required due to increased levels of thyroxine-binding globulin (TBG). T_4 overdosing may lead to osteopenia and cardiac arrhythmias. Some patients have associated ACTH deficiency, and thyroid hormone replacement should not be initiated until adrenal reserve has been evaluated and, if necessary, treated. Thyroid hormone replacement may also accelerate cortisol metabolism or requirements and may therefore exacerbate primary hypoadrenalism or precipitate adrenal crisis in patients with perturbed adrenal function.

DEVELOPMENTAL AND GENETIC CAUSES OF PITUITARY FAILURE

Developmental Pituitary Dysfunction

Congenital absence of the pituitary gland (aplasia), partial hypoplasia, or ectopic tissue rudiments are rarely encountered. Pituitary development follows midline cell migration from Rathke's pouch, and impaired midline anomalies, including failed forebrain cleavage and anterior commissure and corpus callosum defects, lead to structural pituitary anomalies. Craniofacial developmental anomalies, including anencephaly, result in cleft lip and palate, basal encephalocele, hypertelorism, and optic nerve hypoplasia with varying degrees of pituitary dysplasia and aplasia. If these infants survive, lifelong appropriate pituitary hormone replacement is required. Children with mild forms of midline anomalies are also more prone to GHD.

With sensitive MRI techniques for pituitary visualization, several anatomic features characteristic of hypopituitarism are now apparent. Evidence for acquired pituitary gland damage or destruction is often clearly visible on MRI, whereas patients presenting with hypopituitarism of undetermined etiology may exhibit decreased gland volume, partial or complete empty sella, disturbed sella turcica architecture, absent or transected pituitary stalk, and an absent or ectopic posterior pituitary bright intensity signal.⁴⁵⁴ An absent infundibulum noted on MRI is associated with pituitary hormone deficits, and approximately 40% of patients with GHD of unclear cause show imaging evidence of mild stalk defects, reflecting a midline developmental anomaly. Congenital basal encephalocele may result in herniation of the pituitary through the sphenoid sinus roof, resulting in pituitary failure and diabetes insipidus.

Heritable Disorders of Pituitary Failure

Mutations at each level of pituitary function, including hormones, receptors, and transcription factors that

determine anterior pituitary development, may lead to pituitary deficiency syndromes (see Tables 8-10 and 8-6).⁴⁵⁵ Furthermore, mutations in specific pituitary genes, including those for GH, GHRH receptor, POMC, TSH, LH, and FSH, all lead to single-hormone deficiencies, fully described in Chapter 24). Patients heretofore diagnosed with idiopathic isolated or polyhormonal pituitary failure may in fact harbor a mutation. As the genetic control of pituitary development is further clarified, increasing numbers of mutant genes have become apparent.

PROP1

PROP1 (Online Mendelian Inheritance in Man [OMIM] 601538) gene expression is required for subsequent POU1F1 activation. The gene, located on chromosome 5q, encodes a 223-amino-acid protein expressed in GH-, PRL-, and

TSH-secreting cells.⁴⁵⁶ The Ames dwarf mouse harbors a missense PROP1 mutation (Ser83Pro) and exhibits a hypoplastic pituitary gland with combined GH, PRL, and TSH deficiency. This mutation abrogates POU1F1 activation and results in failed development of POU1F1-dependent cell lineages.⁴⁵⁷ Several human mutations have been associated with GH, PRL, TSH, and gonadotropin deficiencies. The most commonly encountered mutation is a 2-base-pair deletion (301-302delAG) that results in early translational termination and a nonfunctional protein product. The clinical spectrum of combined pituitary hormone deficiency associated with PROP1 mutations is variable and temporal. The phenotype varies with both the type of mutation and the age of the patient.⁴⁵⁸

Human PROP1 mutations are associated with deficiencies in POU1F1-dependent lineages (GH, PRL, and TSH) and impaired FSH, LH, and ACTH reserve function.²⁴³ Because development and mature function of these latter cell types are not POU1F1 dependent, it appears that additional critical developmental factors are disrupted in these patients, leading to the clinical phenotype. Heterogeneous patients with PROP1 mutations leading to combined pituitary hormone deficiency have been described since the original report in 1996,⁴⁵⁹ and this disorder appears to be the most common heritable cause of combined pituitary hormone deficiency.

Molecular Analysis. Inheritance modes of PROP1 mutations usually reflect autosomal recessive patterns. Patients are usually homozygous for either deletion or missense frameshift mutations leading to truncated PROP1 protein products devoid of functional activity.^{243,460} A hot spot in PROP1 has been identified at a GA repeat in exon 2. Combination of a GA or AG deletion in this repeat results in a coding frameshift and premature termination at codon 109. Nonaffected siblings are either heterozygous or bear a normal PROP1 sequence on both alleles. Mutations in the transactivation domain at codon 582 lead to features of hypogonadism as the presenting phenotype.⁴⁶¹

Clinical Features. The frequency of PROP1 gene mutations in patients with combined pituitary hormone deficiency is high, 30% to 50% of affected subjects.⁴⁶² However, in families with multiple affected members, PROP1 mutations account for almost all affected individuals. Patients harboring PROP1 mutations exhibit a predominantly hypogonadal phenotype. Puberty is often delayed or absent, with markedly attenuated LH and FSH responses to GnRH stimulation.¹⁵⁵ Some patients enter puberty spontaneously and subsequently features of central hypogonadism, akin to an acquired presentation.⁴⁶⁰ A broad spectrum with variable time of onset and degree of pituitary loss is characteristic of the syndrome. Some older patients also exhibit blunted cortisol responses to Cortrosyn administration, and others present with panhypopituitarism.⁴⁶³ Although the size of the pituitary gland usually is small or normal, patients have been described with grossly hyperplastic pituitary glands with cystic changes and development of a secondary empty sella.

Slowing of linear growth usually becomes apparent after the age of 3 years, and these patients typically do not enter puberty. Height standard deviation score (SDS) may be severely impaired and may range to -10 with eunuchoid proportions and reduced upper/lower body ratios. Affected adults are short and have infantile external genitalia. The onset of clinically evident pituitary failure usually is with GHD (about 80%) or thyroid failure (TSH deficiency, about 20%), followed by hypogonadism and later subclinical or

*Developmental deficits may be hypothalamic or pituitary or both.

ACTH, adrenocorticotrophic hormone; CNS, central nervous system; CRH, corticotropin-releasing hormone; FSH, follicle-stimulating hormone; GH, growth hormone; GHRH, growth hormone-releasing hormone; GnRH, gonadotropin-releasing hormone; GPR, orphan G protein-coupled receptor; LH, luteinizing hormone; POMC, pro-opiomelanocortin; PRL, prolactin; TSH, thyroid-stimulating hormone; TRH, thyrotropin-releasing hormone.

overt adrenal insufficiency.⁴⁶⁴ PROP1 excess has been described in a mouse model.⁴⁶⁵ These animals have hypothyroidism, hypogonadism, persistent Rathke's cleft cysts, and, after 1 year, pituitary adenomas.

Pituitary Size. Heterogeneous changes in pituitary size may reflect a combination of apoptotic signals for the POU1F1 lineage, compensatory cystic expansion of nonaffected pituitary cell types with subsequent autoinfarction, and the absence of other unknown factors required for mature pituitary function.⁴⁶⁶

Evaluation. Combined hypothalamic hormone stimulation (GnRH, TRH, CRH, and GHRH) or insulin-evoked hypoglycemia reveals blunted responses consistent with varying degrees of pituitary hormone deficiencies. Serum IGF1 and IGFBP3 levels are usually low, and peripheral thyroid hormone levels are low or at the lower limits of normal ranges. In the face of low or absent TSH responses, these findings are consistent with secondary hypothyroidism. Most older patients also exhibit blunted cortisol responses to CRH or ACTH (or both) or insulin stimulation.⁴⁶¹

POU1F1

The POU1F1 gene is located on chromosome 3p11 (OMIM 173110) and encodes a 290-amino-acid protein. The N-terminal POU-specific domain activates gene transcription, whereas two DNA-binding domains recognize a TATNCAT consensus sequence that is present in GH, PRL, and TSH hormones and in the GHRH receptor gene.⁴⁶⁷ The POU1F1 nuclear protein activates transcription of the GH, PRL, TSH, and GHRH receptor genes and also partners with coactivators including thyroid hormone, estrogen, and retinoic acid receptors and with other transcription factors (e.g., CREB, P-LIM, Ptx1, HESX1, and Zn15). POU1F1 autoregulates its own expression, rendering POU1F1 critical for maintaining appropriate POU1F1 expression. Because of the absolute requirement of POU1F1 for GH, PRL, and TSH cell development and specific gene expression, inactivating mutations of the gene result in a spectrum of pituitary hormone deficiencies.⁴⁶⁸ Two dwarf mouse strains harbor *Pou1f1* gene mutations. The Snell dwarf mouse harbors a tryptophan → cysteine missense mutation (Trp261Cys).⁴⁶⁹ The Jackson mouse, although also a dwarf, harbors a truncated POU1F1 protein with defective DNA binding.

Several POU1F1 mutations exhibit characteristic clinical phenotypes.⁴⁷⁰ Arg172Tyr mutants are associated with neonatal hypothyroidism and GH and PRL deficiency. Both sporadic patients and multiplex families with multiple pituitary hormone defects have been described, with at least 10 recessive and 3 dominant POU1F1 mutations identified so far. Recessive mutations result in a varied spectrum of loss of DNA binding or transcriptional activation of TSH, GH, or PRL. Impaired retinoic acid activation of the POU1F1 distal enhancer has been described for a POU1F1 Lys-261Glu mutation. This mutant protein also behaves as a dominant negative inhibitor of POU1F1 activation. A sporadic mutation (Arg271Try) binds well to DNA but dominantly inhibits pituitary gene transcription. Compound heterozygosity for a single-base-pair deletion (747delA) and a missense mutation (Trp193Arg) cause defective DNA binding and transcriptional activation with severe combined GH, PRL, and TSH deficiencies.²⁹¹ Both p300/CBP1 protein recruitment and POU1F1 dimerization are required for appropriate POU1F1 activation of target hormone genes.⁴⁷¹ Lhx4 appears to activate POU1F1, and mutations of Lhx4 also lead to growth retardation.⁴⁷²

HESX1

HESX1 (Rpx) is one of the earliest transcriptional markers of the primitive pituitary, with expression restricted to Rathke's pouch.⁴⁷³ Coincidentally with the appearance of specific pituitary cell types, *HESX1* expression declines and is extinguished in the mature anterior pituitary,⁴⁷⁴ leading to PROP1 activation. The gene is located on chromosome 3p212, encodes an 185-amino-acid protein, and competes with PROP1 for DNA binding. The heterogeneous syndrome of septo-optic dysplasia (hypoplastic optic nerves, absent corpus callosum and septum pellucidum, and panhypopituitarism) is associated with 14 mutations.⁴⁷⁵ Although the mutant molecule exhibits reduced DNA binding, panhypopituitarism may also occur secondarily to profound anatomic defects in midline development.

Lhx3

Missense and deletion mutations of LHX3 are associated with panhypopituitarism except for intact ACTH reserve.⁴⁷⁶ These patients also exhibit defective neck rotation ability due to a rigid cervical spine.⁴⁷⁷

Lhx4

Patients with LHX4 mutations are unable to activate both PROP1 and POU1F1, and the result is pituitary failure.⁴⁷²

Ptx2

Ptx2 Rieger's syndrome (anterior eye, teeth, and umbilical maldevelopment) may be associated with GHD and haploinsufficiency of the *RIEG* (*PITX2*) homeobox gene.⁴⁷⁸

TPIT

TPIT mutations result in early-onset isolated ACTH deficiency and hypocortisolism.³¹ Associated phenotypes include those for POMC deficiency—obesity, red hair pigmentation, and other associated pituitary deficiencies.

Heritable pituitary hormone deficiencies caused by transcription factor defects are rare. Among them, PROP1 mutations appear to be the most prevalent cause, accounting for well over 50% of patients in retrospective reports and more than 90% of those with more than one affected sibling. POU1F1 mutations are less commonly encountered.⁴⁷⁹ Patients with a family history of pituitary dysfunction and those who exhibit blunted hormonal response to TRH, GHRH, or GnRH stimulation should be subjected to molecular screening for PROP1 or POU1F1 defects (Fig. 8-35).³² The pronounced clinical phenotype of HESX1 mutations determines the need for further molecular analysis. Approaches to patients harboring rare SOX2,⁴⁸⁰ Six6, or Otx2 mutations (see Table 8-6) are described in Chapters 23 and 24.

Lawrence-Moon-Biedl Syndrome. Lawrence-Moon-Biedl syndrome is an autosomal recessive disorder characterized by hypogonadotropic hypogonadism, mental retardation, obesity, retinitis pigmentosa, and hexadactyly, brachydactyly, or syndactyly. By 30 years of age, most patients are blind.⁴⁸¹ Although most patients have evidence of GnRH deficiency, about 25% of afflicted males have primary testicular failure.

Prader-Willi Syndrome. Patients with Prader-Willi syndrome have marked hyperphagia and obesity with retarded mental development, muscle hypotonia, and diabetes mellitus. Related conditions include micrognathia, absent auricular cartilage, and acromicria.⁴⁸² The condition has been ascribed to deletion or translocation of chromosome

Figure 8-35 Partitioning of pituitary hormone deficiencies in 110 unrelated patients affected by congenital pituitary deficiency without stalk pituitary interruption or septal optic dysplasia (SOD). Patients were studied for mutations in *PROP1*, *POU1F1*, and *LHX3* according to hormonal deficit (D) phenotype. Twenty mutations of *PROP1* and one mutation of *POU1F1* were found. Gonadotroph function was unavailable for prepubertal-age patients (ppa). ACTH, adrenocorticotropic hormone; FSH, follicle-stimulating hormone; GH, growth hormone; LH, luteinizing hormone; TSH, thyroid-stimulating hormone. (From Reynaud R, Gueydan M, Saveanu A, et al. Genetic screening of combined pituitary hormone deficiency: experience in 195 patients. *J Clin Endocrinol Metab*. 2006;91:3329-3326.)

15. In hypogonadal patients, bilateral cryptorchidism and absent scrotal folds are accompanied by evidence of attenuated GnRH secretion.⁴⁸³ LH and FSH levels have been restored in some patients with chronic GnRH treatment. Defective oxytocin and vasopressin synthesis have also been reported.

Kallmann's Syndrome

Kallmann's syndrome consists of defective GnRH synthesis with olfactory nerve agenesis or hypoplasia and variable anosmia. Associated developmental disorders include optic atrophy, color blindness, cranial nerve VIII deafness, cleft palate, renal agenesis, cryptorchidism, and movement disorders.⁴⁸⁴ This X-linked recessive disorder has been ascribed to a defective *KAL* gene located on chromosome Xp22.3.⁴⁸⁵ The *KAL* protein mediates hypothalamic migration of GnRH cells from the primitive olfactory placode, and its absence leads to defective GnRH synthesis and anosmia.^{486,487} Both autosomal recessive and autosomal dominant forms of the disorder have been described, indicating the involvement of *FGF1* receptor mutations in the pathogenesis of the disorder.⁴⁸⁸

Clinical Features. Patients with Kallmann's syndrome are exposed to low or absent sex steroids from birth. Consequently, females are tall and present with primary amenorrhea and absent secondary sexual development, and males have delayed puberty and micropenis.⁴⁸⁹

Laboratory. Absent GnRH secretory pulses result in characteristically low LH and FSH levels in the face of very low concentrations of estradiol or testosterone. Because the nonprimed normal pituitary may not respond initially to GnRH stimulation (25 to 100 µg intravenously), this test is of little value in distinguishing the hypothalamic defect. In some patients, repetitive GnRH priming elicits normal pituitary LH and FSH responses, indicating a hypothalamic defect in GnRH secretion.

The differential diagnosis of congenital hypogonadotropic hypogonadism includes Kallmann's syndrome (*KAL*

gene mutation), congenital adrenal hypoplasia (*DAX1/NROB1* mutation),⁴⁹⁰ GnRH receptor mutations, leptin and leptin receptor mutations, *PROP1* gene mutations, and mutations of the LH or FSH molecules. These conditions are characterized by absent or low GnRH-mediated LH secretory patterns in the presence of a structurally normal pituitary gland. The cause of hypogonadotropic hypogonadism remains elusive in more than 80% of patients. In the absence of a structural pituitary defect, genetic evaluation of these patients should be undertaken.^{455,479}

Acquired Pituitary Failure

Causes

In the absence of demonstrable hypothalamic-pituitary anatomic damage, and after exclusion of genetic and syndromic causes of pituitary insufficiencies, acquired (often transient) causes of pituitary failure should be considered (see Table 8-7). Causes of pituitary insufficiency discussed earlier include pituitary tumors, parasellar masses, hypophysitis, aneurysms, and pituitary apoplexy (Fig. 8-36).

Hypothalamic damage reflected by the presence of a large parasellar mass leading to decreased GnRH production is associated with hyperphagia, obesity, and central hypogonadism with low levels of FSH and LH (Frohlich's syndrome). Marked caloric restriction, anorexia,^{491,492} weight loss of other etiologies, and strenuous exercise may also attenuate GnRH secretion or action. Hypogonadotropic hypogonadism occurs in both men and women (see Chapter 20). Exogenous anabolic steroid and glucocorticoid therapies suppress the reproductive and adrenal axes, respectively. Patients with severe critical illnesses or chronic debilitating disease (including cirrhosis) may have impaired GH-IGF1, adrenal, and gonadal axes. Hyperprolactinemia causes sexual dysfunction by inhibiting GnRH pulsatility via a short feedback loop. Hypothyroidism, hypoadrenalism, or hypogonadism causes hyperplasia of specific trophic cells due to lack of negative feedback and sometimes actual pituitary tumor formation.⁴⁹³

Figure 8-36 Features of hypopituitarism and hypogonadism, including central adiposity, proximal muscle wasting, loss of body hair, and gynecomastia. Notice the contrast between the hypogonadal patient (**A**, right side) and his unaffected identical twin (left side). Laboratory tests confirmed secondary hypogonadism, with a testosterone level of 0.4 ng/mL (normal range, 2.9 to 8.0 ng/mL), a follicle-stimulating hormone level of 2.8 IU/L (normal, 1.5 to 12.4 IU/L), and a luteinizing hormone level of 1.5 IU/L (normal, 1.7 to 8.6 IU/L). Coronal (**B**) and sagittal (**C**) Magnetic resonance images showed a lobulated, contrast-enhancing suprasellar mass (arrow). Pathologic analysis confirmed the diagnosis of pituitary tumor. (From Newnham HH, Rivera-Woll LM. Images in clinical medicine: hypogonadism due to pituitary tumor in an identical twin. *N Engl J Med*. 2008;359:2824.)

AIDS is associated with suppressed pituitary function independent of other associated infections.⁴⁹⁴ Drugs such as estrogens, which suppress FSH and LH, and GnRH analogs used for treatment of prostate cancer inhibit gonadotropin action. In addition to pituitary apoplexy, other vascular accidents such as aneurysms, strokes, cavernous sinus thrombosis, and arteritis can cause pituitary hormone insufficiency. Isolated pituitary hormone deficiencies may also occur as a manifestation of vascular abnormalities, including arteritis, or subarachnoid hemorrhage (Table 8-11).

Head Trauma. The pituitary may be partially or totally damaged by birth trauma, cranial hemorrhage, fetal asphyxia, or breech delivery. Head trauma may lead to direct pituitary damage from a sella turcica fracture, pituitary stalk section, trauma-induced vasospasm, or ischemic infarction after blunt trauma.⁴⁹⁵ The most common traumatic cause of compromised pituitary function in the adult is iatrogenic neurosurgical trauma. Pituitary manipulation or damage during surgery leads to transient or permanent diabetes insipidus and varying degrees of anterior pituitary dysfunction.

Although hypopituitarism after head trauma is usually manifest within 1 year after the insult, some patients only develop overtly manifest signs of pituitary failure after several decades. Seventy-five percent of patients with post-traumatic pituitary failure are young men (<40 years) who were involved in a motor vehicle accident within 1 year before diagnosis. Almost all patients with subsequent pituitary failure have a history of loss of consciousness after trauma, and half of all such patients have documented skull fracture.⁴⁹⁵ One third of these patients have demonstrable signs of hypothalamic or posterior pituitary hemorrhage or anterior lobe infarction on MRI. Diabetes insipidus is the most common endocrine disorder, encountered in about 30% of these patients. Gonadotropin failure, amenorrhea, and hyperprolactinemia may occur in the months following head trauma or may manifest even years later.^{496,497}

Pituitary testing performed within the first 48 hours after hospital admission shows that approximately 75% of patients have evidence of hypopituitarism,⁴⁹⁸ and the degree of pituitary failure correlates with the severity of head trauma (Table 8-12). Prospective studies of patients retested after 12 months have documented worsening of

*No stimulation test for ACTH.

[†]No stimulation test for GH (11 patients had low IGF1).

ACTH, adrenocorticotropic hormone; GH, growth hormone; LH, luteinizing hormone; FSH, follicle-stimulating hormone; TSH, thyroid-stimulating hormone. Modified from Schneider H, Aimaretti G, Kreitschmann-Andermahr I, et al. Hypopituitarism. *Lancet*. 2007;369:1461-1470.

pituitary function despite improvement in some trophic hormone axes. About 20% of patients developed posterior pituitary dysfunction (either diabetes insipidus or SIADH) after traumatic brain injury.⁴⁹⁹

Irradiation. Pituitary irradiation, usually indicated for pituitary adenoma therapy, directly causes atrophy of the gland, in addition to the damaging impact of irradiation on hypothalamic synthesis of hypophysiotropic hormones.⁵⁰⁰ Pituitary function in children and adolescents is particularly sensitive to head and neck therapeutic irradiation.⁵⁰¹ Radiation dose exposure, time interval after completion of radiotherapy, and distance of the pituitary or hypothalamus from the central energy field correlate with development of pituitary hormone deficits (Figs. 8-37 and 8-38).

After a median dose of 5000 rads directed at the skull base, nasopharynx, or cranium, up to 75% of patients develop pituitary insufficiency within 10 years.⁵⁰² Later manifestations of pituitary failure usually reflect hypothalamic damage rather than atrophy of irradiated pituitary cells. Although the degree of hormone loss after radiation therapy is variable, the pattern of loss usually occurs sequentially: GH, then FSH and LH, followed by ACTH and

TSH.⁵⁰³ Evidence for secondary thyroid or adrenal failure usually implies that the GH and gonadotropin axes are also compromised. Stereotactic radiosurgery directed to the pituitary gland also results in pituitary deficits within 48 to 96 months in 23% of patients.⁵⁰⁴ Previously irradiated patients should undergo lifelong periodic anterior pituitary hormone testing. Ideally, rigorous long-term screening will unmask incipient pituitary failure before the onset of morbidity.⁵⁰⁵

Empty Sella Syndrome. Damage to the sellar diaphragm may lead to arachnoid herniation into the sellar space. An empty sella may develop as a consequence of a primary congenital weakness of the diaphragm in those patients in whom no secondary cause is evident. Up to 50% of patients with primary empty sella have associated benign intracranial hypertension.⁵⁰⁶ A secondary empty sella may develop subsequent to infarction of a pituitary adenoma or as a result of surgical or radiation-induced damage to the sellar diaphragm. On MRI, these patients usually exhibit demonstrable pituitary tissue compressed against the sellar floor, with lateral stalk deviation. Although an empty sella is usually an incidental finding, pituitary failure occurs if more than 90% of pituitary tissue is compressed or

*Thirty-two patients had low morning cortisol; only 5 patients had cortisol <500 nmol/L after ACTH stimulation.

[†]No stimulation test for ACTH.

[‡]Endocrine testing was done only if there was clinical suspicion of hypopituitarism (n = 99).

Modified from Schneider H, Aimaretti G, Kreitschmann-Andermahr I, et al. Hypopituitarism. *Lancet*. 2007;369:1461-1470.

Figure 8-37 Life-table analysis indicating probabilities of initially normal hypothalamic-pituitary-target gland axes remaining normal after radiotherapy (3750 to 4250 cGy). Of the anterior pituitary hormones, growth hormone (GH) secretion is the most sensitive, and thyroid-stimulating hormone (TSH) secretion is the most resistant. In two thirds of patients, gonadotropin deficiency develops before adrenocorticotrophic hormone (ACTH) deficiency; the reverse occurs in the remaining third. (From Littley MD, Shalet SM, Beardwell CG, et al. Hypopituitarism following external radiotherapy for pituitary tumors in adults. *QJM*. 1989;70:145-160.)

atrophied. About 10% of patients develop small GH- or PRL-secreting adenomas within the rim of compressed pituitary tissue.

Clinical Features of Hypopituitarism

Patients with pituitary failure, regardless of course, have been found to have excess mortality primarily due to respiratory and vascular disease.²³⁹ Age at diagnosis, female gender, and history of craniopharyngioma were the most striking determinants of increased mortality. The spectrum of clinical features of pituitary insufficiency depends on several factors. In acquired pituitary insufficiency, the clinical spectrum depends on the degree of hormone deficiency, the number of hormones impaired, and the rapidity of onset.⁵¹⁷ In congenital forms, the earlier the age at onset, the greater the severity of thyroid, gonadal, adrenal, growth, or water disturbances. Patients with heritable genetic disorders invariably exhibit the most severe phenotypic changes, although later changes may also occur in these disorders (e.g., with PROP1 mutations).

The resilience of the individual pituitary cell lineages to compressive, inflammatory, vascular, radiation, and invasive insults also varies. The lactotroph cell is often hyperfunctional as a result of decreased tonic inhibitory signals. Therefore, PRL deficiency is exceedingly rare, except that resulting from complete pituitary destruction or genetic syndromes. The order of diminished trophic hormone reserve function related to pituitary compression usually is as follows: GH > FSH > LH > TSH > ACTH. The corticotroph cell appears to be particularly resistant to hypothalamic or

pituitary destruction, and it is usually the last cell to lose function.

The qualitative phenotypic manifestations of pituitary failure are determined by which specific trophic hormones are lost (see earlier descriptions of individual hormone deficiencies).

Screening for Pituitary Failure

Because the onset of hypopituitarism can be extremely slow, subclinical pituitary failure is often not apparent to the patient or physician. Screening for pituitary dysfunction should be undertaken in patients with hypothalamic or pituitary mass lesions, developmental craniofacial abnormalities, inflammatory disorders, brain granulomatous disease, prior head or neck irradiation, head trauma, prior skull base surgery, newly discovered empty sella, or previous pregnancy-associated hemorrhage or blood pressure changes^{307,510} (Table 8-13).

PRL should be measured, because many patients with hypopituitarism also present with secondary hyperprolactinemia. Up to two thirds of patients harboring pituitary macroadenomas, craniopharyngiomas, or other parasellar lesions have compromised pituitary reserve function. Less commonly, patients with intrasellar aneurysms, pituitary metastases, parasellar meningiomas, optic gliomas, or hypothalamic astrocytomas also have pituitary failure.

Although about one third of patients with hypopituitarism undergoing pituitary surgery recover function after decompression, about 25% experience further loss of pituitary function after surgery and require annual screening. Treatment of pituitary failure is described in Table 8-14.

Figure 8-38 The incidence of growth hormone (GH) deficiency in children receiving 27 to 32 Gy or 35 Gy of cranial irradiation for a brain tumor, in relation to time from irradiation (dxt). The speed at which individual pituitary hormone deficits develop is dose dependent: the higher the radiation dose, the earlier GH deficiency occurs. Philadelphia, PA: Saunders, 2001.)

TABLE 8-13

Assessment of Anterior Pituitary Function

Test	Dose	Normal Response	Side Effects
ACTH			
Insulin tolerance	0.1-0.15 U/kg IV	Peak cortisol response >18 µg/dL, or ↑ ≥5 µg/dL	Sweating, palpitation, tremor
Metirapone	30 mg/kg PO at 11 p.m.	Peak 11-DOC ≥ 7 µg/dL Peak cortisol ≤7 µg/dL Peak ACTH >75 pg/mL	Nausea, insomnia, adrenal crisis
CRH stimulation	100 µg IV	Peak ACTH ≥2-4-fold Peak cortisol ≥20 µg/dL or ↑ ≥7 µg/dL	Flushing
ACTH stimulation	250 µg IV or IM, or 1 µg IV	Peak cortisol ≥20 µg/dL	Rare
TSH			
Serum T ₄ (free T ₄)	200-500 µg IV	Peak TSH ≥2.5-fold, or ↑ ≥5-6 mU/L (females) or ≥2-3 mU/L (males)	Flushing, nausea, urge to micturate
Total T ₃			
TSH—third generation			
TRH stimulation			
PRL			
Serum PRL	200-500 µg IV	PRL ↑ ≥2.5-fold	Flushing, nausea, urge to micturate
TRH stimulation			
LH/FSH			
Serum LH and FSH	100 µg IV	Elevated in menopause and in men with primary testicular failure (otherwise normal) 300-900 ng/mL	Rare
Serum testosterone		LH ≥2-3-fold, or ↑ by 10 IU/L	
GnRH Stimulation		FSH ≥1.5-2-fold, or ↑ ≥2 IU/L	
GH			
Insulin tolerance	0.1-0.15 U/kg	GH peak >5 µg/L	Sweating, palpitation, tremor
L-Arginine	Arginine 0.5 g/kg (maximum, 30 g) IV over 30-120 min	GH peak >0.4 µg/L	Nausea
plus			
GHRH	GHRH 1-5 µg/kg	GH peak >4 µg/L	Flushing

ACTH, adrenocorticotrophic hormone; CRH, corticotropin-releasing hormone; 11-DOC, 11-deoxycorticosterone; FSH, follicle-stimulating hormone; GH, growth hormone; GHRH, growth hormone-releasing hormone; GnRH, gonadotropin-releasing hormone; LH, luteinizing hormone; PRL, prolactin; T₃, triiodothyronine; T₄, thyroxine; TSH, thyroid-stimulating hormone; TRH, thyrotropin-releasing hormone.

TABLE 8-14

Replacement Therapy for Adult Hypopituitarism*

Deficient Hormone	Treatment	Remarks
ACTH	Hydrocortisone: 10-20 mg/day in divided doses Cortisone acetate: 15-25 mg/day in divided doses	
TSH	L-Thyroxine: 0.05-0.2 mg/day according to T ₄ levels	
FSH/LH (in males)	Testosterone enanthate: 200 mg IM q2-3 wk Testosterone skin patch: 2.5-5.0 mg/day (or up to 7.5 mg/day) Testosterone gel: 3-6 g/day	For fertility: hCG three times weekly, or hCG + either FSH or menopausal gonadotropin or GnRH
FSH/LH (in females)	Conjugated estrogen: 0.3-0.625 mg/day Micronized estradiol: 1 mg/day Estradiol valerate: 2 mg Piperazine estrone sulfate: 1.25 mg Estradiol skin patch: 4-8 mg twice weekly	All of the estrogens are administered with progesterone or progestin sequentially or in combination if uterus is present For fertility: Menopausal gonadotropin, and hCG, or GnRH
Growth hormone	Somatotropin (in adults): 0.2-1.0 mg/day SC Somatotropin (in children): 0.02-0.05 mg/kg per day	
Vasopressin	Intranasal desmopressin: 10-20 µg bid Oral DDAVP: 300-600 µg/day, usually in divided doses	

*Doses shown should be individualized and reassessed during stress, surgery, or pregnancy. Male and female fertility management are fully discussed in Chapter 20.

ACTH, adrenocorticotrophic hormone; DDAVP, desmopressin acetate; FSH, follicle-stimulating hormone; GnRH, gonadotropin-releasing hormone; hCG, human chorionic gonadotropin; LH, luteinizing hormone; T₄, thyroxine; TSH, thyroid-stimulating hormone.

Pituitary Masses and Tumors

SHLOMO MELMED • DAVID KLEINBERG

PITUITARY MASSES

Pituitary Mass Effects

An expanding pituitary mass may inexorably alter the sellar size and shape through bony erosion and remodeling (Fig. 9-1). Although the exact time course for this process is unknown, it appears to be slowly progressive over years or decades. The tumor may invade soft tissue, and the dorsal sellar roof presents the least resistance to expansion from within the confines of the bony sella. Nevertheless, both suprasellar and parasellar compression and invasion may occur with an enlarging mass, with resultant clinical manifestations (Table 9-1).

As tumors impinge on the optic chiasm, they interfere with vision. Because of the anatomy of the chiasm, pressure from below affects temporal visual fields, starting superiorly and ultimately extending to the entire temporal field. Continued growth and pressure on the optic apparatus can extend visual loss to the nasal field and may result in blindness. Long-standing optic chiasmal pressure results in optic disc pallor. Extension of pituitary lesions laterally may impinge on or invade the dural wall of the cavernous sinus. Despite invasion, they only rarely affect the function of the third, fourth, and sixth cranial nerves and the

ophthalmic and maxillary branches of the fifth cranial nerve. Although tumors in the cavernous sinus often surround the internal carotid artery, vascular clinical sequelae are rare. Varying degrees of diplopia, ptosis, ophthalmoplegia, and decreased facial sensation may occur infrequently, depending on the extent of the neural involvement by the cavernous sinus mass.

In contrast to cavernous invasion by slow tumor progression, sudden insults to the cavernous sinus caused by hemorrhage or infarction of a pituitary tumor may affect nerves coursing through the sinus. Downward extension into the sphenoid sinus indicates that the parasellar mass has eroded the bony sellar floor. Aggressive tumors may invade the roof of the palate and cause nasopharyngeal obstruction, infection, and leakage of cerebrospinal fluid (CSF). Infrequently, temporal or frontal lobes are invaded, causing uncinate seizures, personality disorders, and anosmia. In addition to the anatomic lesions caused by the expanding mass, direct hypothalamic involvement by the encroaching mass may lead to important metabolic sequelae (see Chapter 7).

Intrasellar tumors commonly manifest with headaches, even in the absence of demonstrable suprasellar extension. Small changes in intrasellar pressure caused by a microadenoma within the confined sella are sufficient to stretch

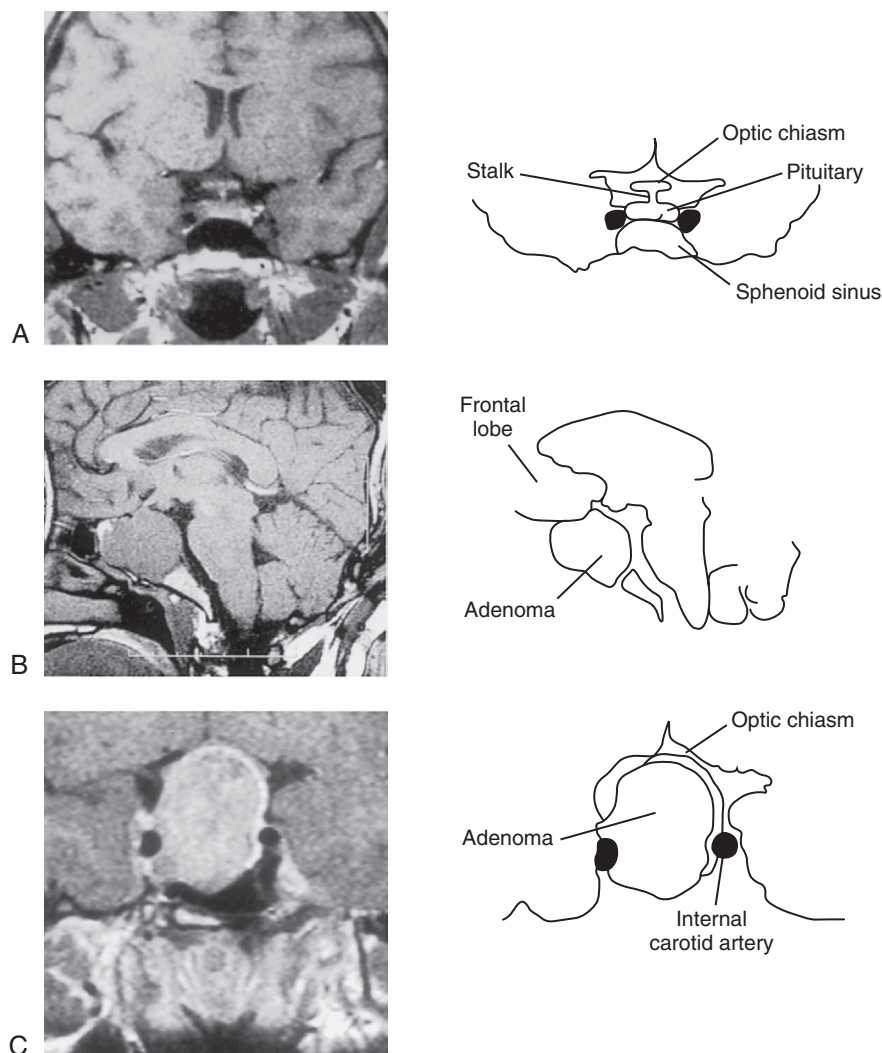

Figure 9-1 Magnetic resonance images of the pituitary. **A**, Coronal section of a normal pituitary gland. **B**, Sagittal view of a large pituitary adenoma lifting and distorting the optic chiasm, invading the sphenoid sinus, and impinging on the frontal lobe. **C**, Coronal view of a large macroadenoma elevating the optic chiasm and invading the right cavernous sinus.

the dural plate with resultant headache. Headache severity does not correlate with the size of the adenoma or the presence of suprasellar extension.¹ Relatively minor diaphragmatic distortions or dural impingement may be associated with persistent headache. Successful medical management of small functional pituitary tumors with dopamine agonists or somatostatin analogues is often accompanied by remarkable headache improvement. In a retrospective assessment of transsphenoidal surgery for microadenomas, headaches resolved or disappeared in 90% of patients with nonfunctioning tumors and in 56% of those with functioning tumors.²

Regardless of their etiology or size, pituitary masses, including adenomas, may be associated with compression of surrounding healthy tissue and resultant hypopituitarism. In 49 patients undergoing transsphenoidal resection of pituitary adenomas, mean intrasellar pressure was elevated twofold to threefold in patients with pituitary failure. Furthermore, prevalence of headache and elevated levels of prolactin (PRL) correlated positively with intrasellar pressure levels,³ suggesting interrupted portal delivery of hypothalamic hormones. Therefore, surgical decompression of a sellar mass may lead to recovery of compromised anterior pituitary function. In patients who do not recover pituitary function postoperatively, ischemic necrosis is likely to have occurred. Stalk compression may result in

pituitary failure caused by encroachment on the portal vessels that normally provide pituitary access to the hypothalamic hormones. Stalk compression also usually leads to hyperprolactinemia and concomitant failure of other pituitary trophic hormones.

Evaluation of Pituitary Masses

Approach to the Patient Harboring a Pituitary Mass

Ninety-one percent of 1120 patients undergoing transsphenoidal surgery for sellar masses were diagnosed as harboring pituitary adenomas.⁴ Therefore, the differential diagnosis of a pituitary mass should be aimed at excluding the diagnosis of a pituitary adenoma before other rare sellar lesions are considered. Pituitary adenomas arise from differentiated cells secreting trophic hormones including growth hormone (GH), PRL, adrenocorticotrophic hormone (corticotropin, or ACTH), thyroid-stimulating hormone (TSH), and gonadotropins. Tumors that immunostain for gonadotropins or, less frequently, ACTH may hypersecrete their respective hormones, or they may be clinically non-secreting (Fig. 9-2).

The management and prognosis of anterior pituitary adenomas differ markedly from those of other

TABLE 9-1

Local Effects of an Expanding Pituitary, Parasellar, or Hypothalamic Mass

Impacted Structure	Clinical Effect
Pituitary	Growth failure, adult hyposomatotropism, hypogonadism, hypothyroidism, hypoadrenalism
Optic tract	Loss of red perception, bitemporal hemianopsia, superior or bitemporal field defect, scotoma, blindness
Hypothalamus	Temperature dysregulation, obesity, diabetes insipidus; thirst, sleep; appetite, behavioral and autonomic nervous system dysfunctions
Cavernous sinus	Ptosis, diplopia, ophthalmoplegia, facial numbness
Temporal lobe	Uncinate seizures
Frontal lobe	Personality disorder; anosmia
Central	Headache, hydrocephalus, psychosis, dementia, laughing seizures
Neuro-ophthalmologic tract	Field Defects: Bitemporal hemianopia (50%), amaurosis with hemianopia (12%), contralateral or monocular hemianopia (7%) Scotomas—junctional; monocular central, arcuate, altitudinal; hemianopic Homonymous hemianopia Acuity Loss: Snellen Contrast sensitivity Color vision Visual evoked potential Pupillary Abnormality: Impaired light reactivity Afferent defect Optic Atrophy: Papilledema Cranial nerve palsy—oculomotor, trochlear; abducens; sensory trigeminal Nystagmus Visual hallucinations Postfixation blindness

Adapted from Snyder P, Melmed S. In: DeGroot L, Jameson JL. Clinically nonfunctioning sellor masses. *Endocrinology*, 5th ed. Philadelphia: Elsevier; 2010:312-323, and Arnold A. In: Melmed S. *The Pituitary*. Blackwell; 2002.

nonpituitary masses, and an important diagnostic challenge is to effectively distinguish a pituitary adenoma from other parasellar masses. Several physiologic states are associated with pituitary enlargement. Lactotroph hyperplasia occurs during pregnancy, and thyrotroph, gonadotroph, or, rarely, corticotroph hyperplasia occurs in the presence of long-standing primary thyroid, gonadal, or adrenal failure, respectively.⁵ Pituitary enlargement may also occur as a result of ectopic secretion of growth hormone–releasing hormone (GHRH) or corticotropin-releasing hormone from carcinoid tumors or hypothalamic gangliocytomas, with resultant hyperplasia of somatotroph or corticotroph cells.

Autopsy series show that up to 20% of individuals harbor an incidental clinically silent pituitary adenoma (incidentaloma). With the widespread use of sensitive imaging techniques for nonpituitary indications including head trauma, chronic sinusitis, and headaches, previously inapparent pituitary lesions are being identified with increasing frequency. Incidental pituitary cysts, hemorrhages, and infarctions are also discovered at autopsy.

Pituitary abnormalities compatible with the diagnosis of microadenoma are detectable in about 10% of the normal adult population undergoing magnetic resonance imaging (MRI).⁶ Because about 90% of observed pituitary lesions represent pituitary adenomas, initial assessment should determine whether the mass is hormonally functional and whether local mass effects are apparent at the time of diagnosis or likely to develop in the future.

The onset of clinical features associated with disordered hormone secretion is insidious and may be unnoticed for years or decades; therefore, endocrine function should always be tested (Table 9-2). Clinical evaluation for changes compatible with hypersecretion or hyposecretion of GH, gonadotropins, PRL, or ACTH may reveal unique long-term sequelae requiring distinct therapies. In the absence of clinical features of a humoral hypersecretory syndrome, cost-effective laboratory screening should be performed. Serum PRL levels greater than 200 µg/L strongly suggest the presence of a microprolactinoma or macroprolactinoma. Any elevation in serum PRL from minimal to high can occur when a microadenoma is present. A minimal to moderate elevation can also indicate secondary stalk interruption by a pituitary mass (usually a nonfunctioning macroadenoma). A PRL level greater than 500 ng/mL in a nonpregnant individual is considered to be pathognomonic of a prolactinoma, although significant PRL elevations can be caused by drugs such as Risperdal.⁷

Elevated concentrations of insulin-like growth factor type 1 (IGF1) for the patient's age and gender indicate the presence of a GH-secreting adenoma, and a high 24-hour urinary free cortisol level or an elevated nighttime salivary cortisol level⁸ is an effective screen for most patients with Cushing's disease. Nevertheless, the incidence of functional

TABLE 9-2

Screening Tests for Functional Pituitary Adenomas

Disorder	Test	Comments
Acromegaly	IGF1 OGTT with GH obtained at 0, 30, and 60 min	Interpret IGF1 relative to age- and gender-matched controls. Normal subjects should suppress GH to <1 µg/L.
Prolactinoma	Serum PRL level	A level >500 µg/L is pathognomonic for macroprolactinoma. If >200 µg/L, prolactinoma is likely.*
Cushing's disease	24-hr UFC Nighttime salivary cortisol Dexamethasone (1 mg) at 11 p.m. and fasting plasma cortisol measured at 8 a.m. ACTH assay	Ensure that urine collection is total and accurate by measuring urinary creatinine. Free salivary cortisol reflects circadian rhythm and elevated levels may indicate Cushing's disease. Normal subjects suppress to <1.8 µg/dL. Distinguishes adrenal adenoma from ectopic ACTH or Cushing's disease.
TSH-secreting tumor	TSH measurement Free T ₄ by dialysis Total T ₃	If T ₄ or T ₃ is elevated and TSH is measurable or elevated, a TSH-secreting tumor may be present.

*Risperidol may result in prolactin levels >200 µg/L.

ACTH, adrenocorticotrophic hormone; GH, growth hormone; IGF1, insulin-like growth factor type 1; OGTT, oral glucose tolerance test; PRL, prolactin; T₃, triiodothyronine; T₄, thyroxine; TSH, thyroid-stimulating hormone; UFC, urinary free cortisol.

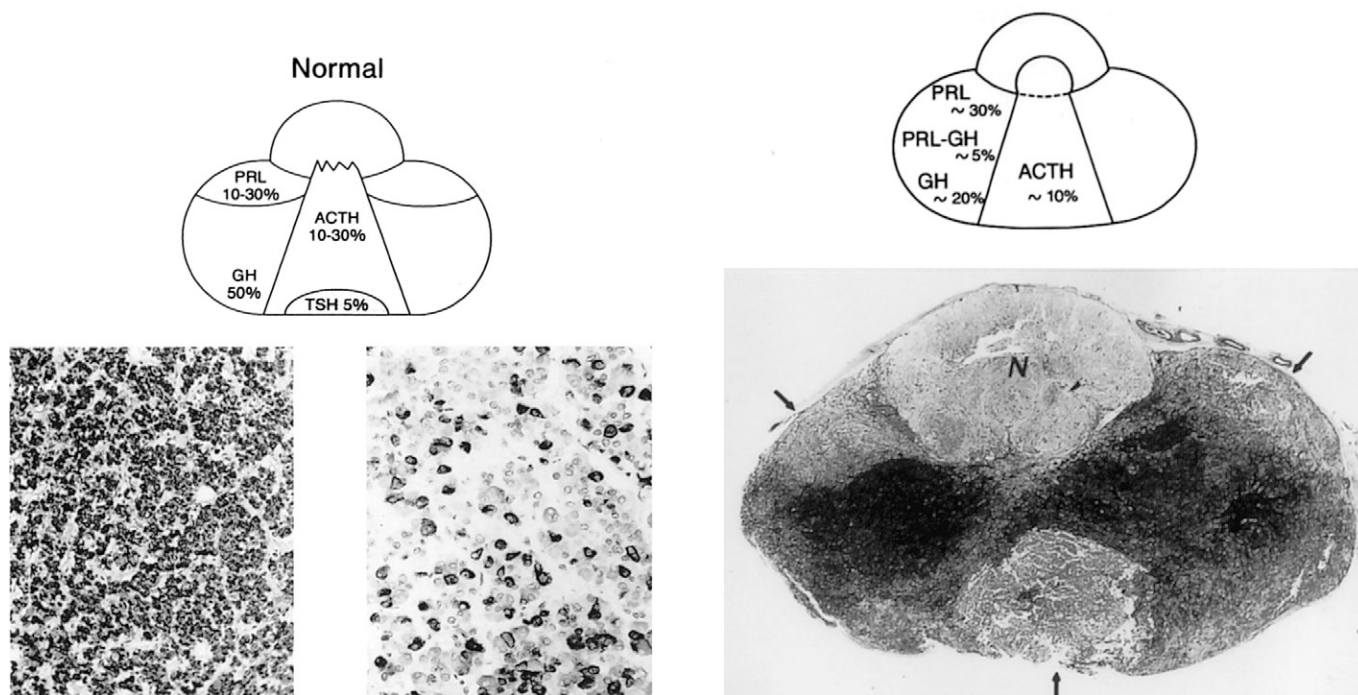

Figure 9-2 Distribution of normal adenohypophyseal cells is reflected in pituitary adenomas. Left panels, normal pituitary with GH cells in lateral wings (lower left) and also diseased (lower right). Right panels depict adenoma distribution with multiple incidental adenomas shown by arrows. Nonfunctioning tumors, on the other hand, are typically macroadenomas that efface pituitary landmarks. The localization and frequency of functioning microadenomas reflect the maximal concentration of their corresponding normal pituitary cells. ACTH, adrenocorticotrophic hormone; GH, growth hormone; N, neurohypophysis; PRL, prolactin; TSH, thyroid-stimulating hormone. (Reproduced from Scheithauer BW, Horvath E, Lloyd RV, et al. Pathology of pituitary adenomas and pituitary hyperplasia. In: Thapar K, Kovacs K, Scheithauer BW, et al., eds. *Diagnosis and Management of Pituitary Tumors*. Totowa, NJ: Humana Press; 2001:91-154.)

hormone-secreting tumors in asymptomatic subjects with incidentally discovered pituitary masses is low.

The presence of, or the potential for, local compressive effects must also be considered. Because the risk for progression of a microadenoma to a compressive macroadenoma is low, no direct intervention may be warranted. For parasellar masses of uncertain origin, histologic tissue examination may be the best approach to yield an accurate diagnosis. Clearly, the benefits and risks of surgery should be considered in such cases, especially for lesions that are not growing or not causing a functional deficit. Although MRI or computed tomographic (CT) imaging features may be helpful in diagnosing the cause of a nonpituitary sellar mass, the final diagnosis may remain elusive until pathologic confirmation is obtained.

Parasellar masses include neoplastic and non-neoplastic lesions and are manifested clinically by local compression of surrounding vital structures or metabolic or hormonal derangements. Rarely, sellar masses or infiltrative processes may be the presenting feature of a previously undiagnosed systemic disorder such as lymphoma, tuberculosis, sarcoidosis,⁹ or histiocytosis.¹⁰ Fever with or without associated sterile or septic meningitis may rarely be caused by fluid leakage into the subarachnoid space from Rathke's cleft, dermoid or epidermoid cysts, craniopharyngioma, or apoplexy.¹¹⁻¹³

Pituitary masses may manifest with hemorrhage and infarction, especially during pregnancy (see earlier discussion), when there is a pituitary tumor, or when an elderly individual with an unsuspected pituitary tumor becomes hypotensive because of another illness. Rarely, these adenomas manifest with CSF leakage, which may predispose to meningitis. Pituitary masses may also undergo silent infarction, leading to the development of a partial or totally

empty pituitary sella with normal pituitary reserve, implying that the surrounding rim of pituitary tissue is fully functional. Large sellar cysts may be mistaken for an empty sella.

Rarely, functional pituitary adenomas arise within the remnant pituitary tissue, and these tumors may not be visible on sensitive MRI (i.e., <2 mm in diameter) despite their endocrine hyperactivity. More than one kind of tumor may be found in the same patient, such as a pituitary tumor and a meningioma¹⁴ or a pituitary adenoma with a craniopharyngioma component.¹⁵ Acute or chronic infection with abscess formation may rarely occur within the mass. Compromised pituitary hormone hyposecretion may result from direct pressure effects of the expanding mass on hormone-secreting cells or from parasellar pressure effects that attenuate synthesis or secretion of hypothalamic hormones, with resultant pituitary failure.

Imaging

Tumors of the pituitary gland are best diagnosed with MRI, because this technique has better resolution than other radiologic modalities for identifying soft tissue changes (see Fig. 9-1). If a pituitary tumor or other parasellar mass is suspected, an MRI specifically focused on the pituitary should be requested, because the more widely spaced cuts made during a routine brain MRI are often inadequate to visualize relatively small pituitary tumors.^{16,17} This technique permits high-contrast, detailed visualization of tumor mass effects on neighboring soft tissue structures, including the cavernous sinus¹⁸ and optic chiasm. A pituitary MRI includes images of the optic chiasm, hypothalamus, pituitary stalk, and cavernous and sphenoid sinuses.^{19,20} High-resolution T1-weighted sections in the coronal and sagittal planes, obtained both before and after gadolinium pentetic acid contrast administration, will

distinguish most pituitary masses.²¹ Slice thickness should be less than 3 mm to obtain a pixel of 1 mm. Contiguous sections are required to diagnose lesions of 1 to 3 mm.²² If necessary, especially for diagnosis of high-signaling hemorrhage, T2-weighted images will provide additional diagnostic information.

MRI clearly delineates the pituitary gland, stalk, optic tracts, and surrounding soft tissues. The gland may be concave, convex, or flat. The posterior pituitary lobe exhibits a discrete bright spot of high signal intensity on T1-weighted images, which declines with age and is absent in diabetes insipidus and in most posterior pituitary lesions. This T1 shortening may reflect the presence of antidiuretic hormone (ADH) localized within neurosecretory vesicle phospholipid.²³ The pituitary gland may transiently enlarge during adolescence, pregnancy, and the postpartum period, with teenage girls exhibiting increasing gland convexity during the menstrual cycle.²⁴ During pregnancy, the gland should normally not exceed 10 to 12 mm, and the stalk should not exceed 4 mm in diameter. Pregnant women may rarely develop visual field deficits due to an enlarging pituitary gland even in the absence of a pituitary tumor. A thickened stalk may indicate the presence of hypophysitis, granuloma, or chordoma.

After administration of gadolinium, microadenomas usually appear hypodense compared with the normal gland, especially when multiple thin-section echo sequences are examined during the first few minutes after contrast injection. It has been suggested that this hypointensity may reflect a compromised microadenoma vasculature.²⁵ Microadenomas can also cause gland asymmetry or stalk deviation. In contrast, macroadenomas, which are significantly more vascular than microadenomas, have a higher affinity for gadolinium. They often enlarge the sella turcica by remodeling the bony fossa, suggesting a gradual, long-term process. These tumors can grow upward toward the optic apparatus and cause draping of the nerves over the tumor, often accompanied by visual field abnormalities. Tumors can also extend into the sphenoid sinus, and not infrequently they invade the connective tissue separating the pituitary from the cavernous sinus.

Radiologically, visible tumor tissue surrounding the carotid artery confirms cavernous sinus invasion. Infrequently, these patients develop palsies of the third, fourth, or sixth cranial nerve. MRI can readily distinguish pituitary adenomas from other masses, including hyperplasias, craniopharyngiomas, meningiomas, chordomas, cysts, and metastatic lesions. Visualization of a distinct pituitary gland adjacent to a parasellar mass (Fig. 9-3), suggests that the mass is not of pituitary origin.²⁶ Secondary distinguishing features such as visualization of noninvolved pituitary tissue, mass consistency, calcification, hemorrhage, and suprasellar involvement usually allow an imaging diagnosis of these masses, but often this can be confirmed only by direct tissue histology. Preoperative localization of carotid artery aneurysms can also be confirmed by MRI or magnetic resonance angiography. Administration of gadolinium may be contraindicated in patients with impaired renal function because it can cause acute renal failure or be associated with nephrogenic systemic fibrosis.^{27,28}

Pituitary CT allows visualization of bony structures, including the sellar floor and clinoid processes, and identification of bony invasion. CT also recognizes calcifications that characterize craniopharyngiomas, meningiomas, and, rarely, aneurysms that are not evident on MRI. Rarely, pituitary adenomas may calcify. Pituitary CT is indicated for discovery of hemorrhagic lesions, metastatic deposits, chordomas, and evidence of calcification.

Figure 9-3 Sagittal magnetic resonance image of a craniopharyngioma with cystic and solid components. The tumor is in the suprasellar area, sitting above a normal pituitary gland. The presence of a separate pituitary gland indicates that the suprasellar tumor is not of pituitary origin. (Courtesy of Nikki Karavitaki Oxford University, UK.)

Receptor Imaging. Because prolactinomas express dopamine 2 (D_2) receptors, they can be imaged with a radiolabeled D_2 receptor antagonist (^{123}I -iodobenzamine) using single-photon emission computed tomography (SPECT). Failure to visualize nonfunctioning tumors by this technique has led some to advocate its use to distinguish the two tumor types.²⁹ Radiolabelled indium pentetreotide has been used for in vivo tumor imaging. Most pituitary adenomas express somatostatin receptor subtypes to a varying degree, thus limiting the specificity of the procedure. Because the sensitivity of SPECT is about 1 cm, and because it also detects normal pituitary tissue receptor expression, its utility is limited for pituitary tumor detection, but it may be helpful for imaging ectopic ACTH-secreting tumors.

Neuro-Ophthalmologic Assessment of Pituitary Masses

The optic tracts are particularly vulnerable to compression by expanding pituitary masses. Accurate neuro-ophthalmologic evaluation is helpful for diagnosing tumors, determining pretreatment baseline visual status for posttreatment monitoring, and detecting mass recurrence.³⁰ The relationship of the optic chiasm and intracranial components of the optic nerves to the pituitary gland and surrounding vessels is depicted in Figure 9-4. A 10-mm, posteriorly angled gap separates the optic chiasm and the diaphragma sellae (Fig. 9-5). Therefore, extensive suprasellar mass extension is required before visual function becomes compromised. Decussation of neural fibers originating from the nasal half of each retina occurs at the chiasm, whereas those fibers originating from the temporal retinal halves are situated ipsilaterally.³¹ Fibers from the superior and inferior retinal aspects are segregated in the corresponding chiasmal regions. Local vascular compromise or chiasmal stretching contributes to the

Figure 9-4 Coronal section of the sellar structures and cavernous sinus, showing the relationship of the oculomotor (III) and trochlear (IV) cranial nerves to the pituitary gland. (From Silver SI, Sharpe JA. Neuro-ophthalmologic evaluation of pituitary tumors. In: Thapar K, Kovacs K, Scheithauer BW, et al., eds. *Diagnosis and Management of Pituitary Tumor*. Totowa, NJ: Humana Press; 2001:173-200.)

pathogenesis of selective visual compromise. Reversibility of visual effects may correlate inversely with the acuteness of the compressive insult.

Visual Symptoms. An abnormal visual examination may unmask the presence of a pituitary mass in an asymptomatic patient. Before sophisticated assay and imaging techniques became available, almost all pituitary masses manifested with visual loss. Currently, fewer than 10% of patients present with visual loss.³² These usually have non-functioning macroadenomas. Unilateral or bilateral temporal or central visual loss is usually asymmetric and may be quite insidious, remitting or recurring. Rarely, sudden visual loss occurs in a previously asymptomatic patient. Other symptoms include diplopia, impaired depth perception, and, very rarely, visual hallucinations (Fig. 9-6).³³

Figure 9-5 Relationship of the pituitary gland to the optic chiasm. The intracranial optic nerve/chiasm complex lies up to 10 mm above the diaphragma sellae. C, Anterior clinoid process; D, dorsum of the sella turcica. (From Miller NR. *Walsh and Hoyt's Clinical Neuro-Ophthalmology*, 4th ed, vol. 1. Baltimore: Williams and Wilkins; 1985:60-69.)

Clinical Signs. Impingement of the inferior crossing chiasmatic fibers leads to bitemporal visual loss, especially in the superior field portions, accounting for most pituitary-related visual defects. Rarely, tumors can compress the optic chiasm from above and cause inferior temporal compromise. As damage to the optic chiasm becomes more extreme, field cuts can extend into the nasal field and can also cause optic atrophy. Isolated impairment of nasal visual fields is seen mostly in patients with glaucoma. Pituitary-related defects preferentially marginate at the vertical field midline,³⁰ in contrast to other causes of bitemporal defects, which tend to occur away from the midline (Fig. 9-7). Despite prominent field defects, many of which can be directly correlated with defined tumor location by MRI, visual acuity in the remaining fields is normal in more than 95% of patients.³⁴ Anterior tumor extension may damage central visual acuity, and this is detected with the use of the Snellen chart or by loss of color discrimination, especially in the red-green spectrum. Rarely, pupillary abnormalities, optic atrophy, papilledema, cranial nerve palsies, and nystagmus may be encountered. Visual fields are assessed by bedside confrontational testing, Goldmann perimetry, the Amsler grid, and automated quantitative perimetry. Because red vision is lost before white, a small pin (<10 mm in diameter) with the two colors can be employed. The patient should be asked to cover one eye so that the examiner can evaluate both temporal and nasal fields without compromise.

Management of Pituitary Masses

The goals of therapy for masses are to alleviate local compressive mass effects and to suppress hormone hypersecretion or relieve hormone hyposecretion while maintaining intact pituitary trophic function. Three modes of therapy are available: surgical, radiotherapeutic, and medical approaches. In general, the benefits of each therapy should be weighed against the respective risks, and comprehensive physician and patient awareness is required to individualize treatment approaches.

Surgical Management of Pituitary Tumors and Sellar Masses

Pituitary surgery is indicated for excision of mass lesions causing central pressure effects including visual compromise, for primary correction of hormonal hypersecretion,

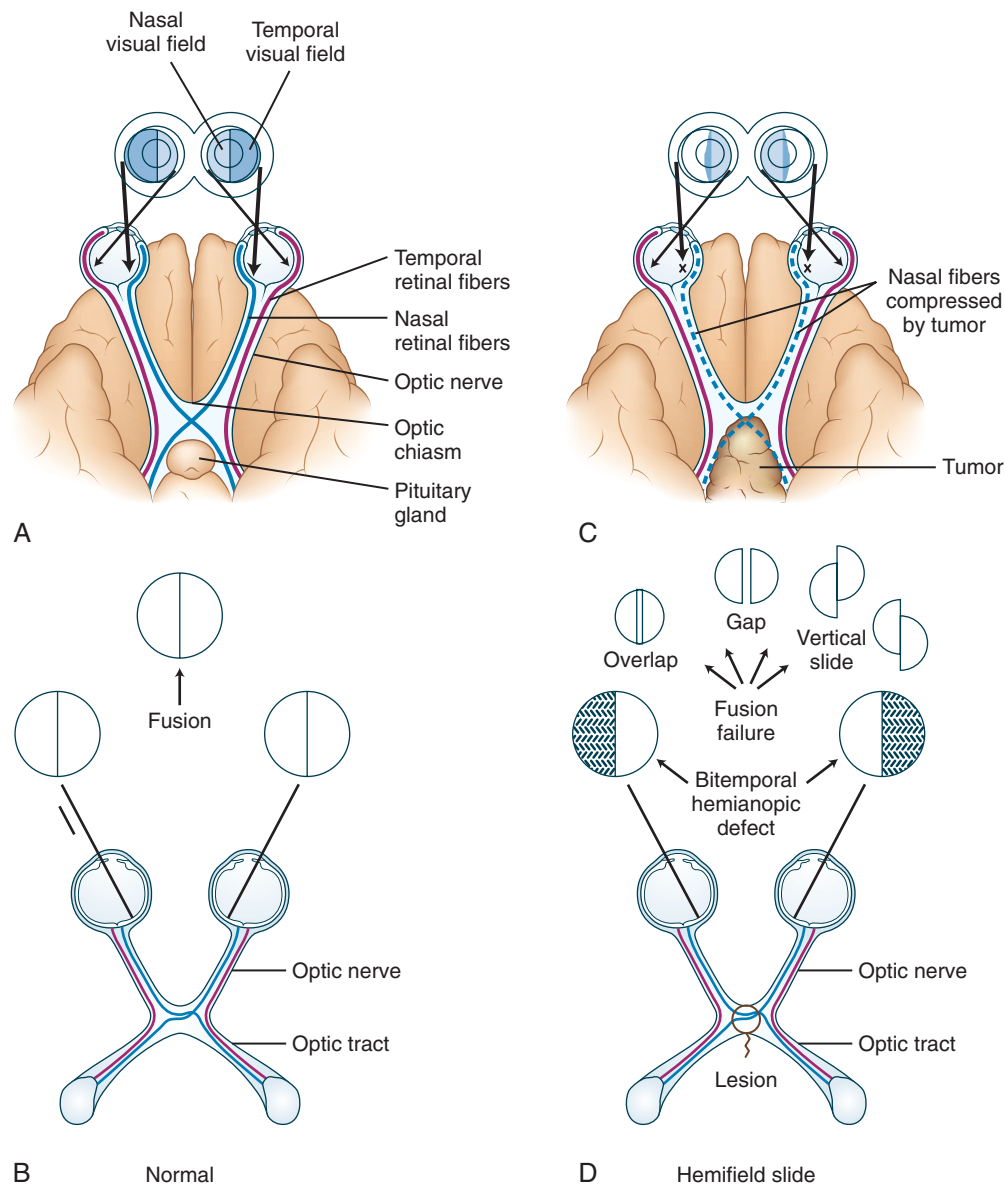

Figure 9-6 Local effects of an expanding pituitary tumor causing visual field defects. **A**, Normal vision; **C**, bitemporal hemianopia. **B** and **D**, Hemifield slide phenomena arising in the setting of bitemporal hemianopia from fusion instability. The nasal and temporal fields lose their linkage, resulting in overlap of the preserved visual fields. (**A** and **C** Reproduced from Newell-Price J. Endocrine assessment. In: Sheaves R, Jenkins PJ, Wass JAH, eds. *Clinical Endocrinology Oncology*. Boston: Blackwell Science; 1997:152-157.) (**B** and **D** Reproduced from Stiver SI, Sharpe JA. Neuro-ophthalmologic Evaluation of Pituitary Tumors. In: Thapar K, Kovacs K, Scheithauer BV, et al., eds. *Diagnosis and Management of Pituitary Tumors*. and for resection of functional tumors that are resistant or not immediately responsive to medical treatment. Unusual sellar lesions may require diagnostic tissue evaluation, and in rare instances, primary or secondary parasellar malignancies require wide excision.

In 1904, Horsley reported the surgical resection of a pituitary tumor by means of a lateral middle fossa approach.³⁵ The first successful transsphenoidal approach for pituitary tumor resection was reported by Schloffer in 1907³⁶ and subsequently refined by Cushing, who between 1910 and 1925 operated on 231 patients harboring pituitary tumors with a remarkably low mortality rate of 5.6%.^{35,37} Cushing used a sublabial incision to enable an endonasal approach for removal of the septum and improved visualization by using Kanavel's headlight. Hardy later improved the technique by using the operating

microscope and intraoperative fluoroscopy, resulting in markedly reduced morbidity and mortality compared with that usually encountered with craniotomy, and this became the mainstay surgical technique for resecting these tumors.

The transsphenoidal approach precludes invasion of the cranial cavity and removes the need for brain tissue manipulation, as is required during a subfrontal surgical approach (Fig. 9-8). A ventral sphenoid approach for resection of pituitary masses likewise does not violate the cranial fossa. Transsphenoidal surgery is associated with minimal morbidity and mortality; most patients are ambulatory within 6 to 9 hours, and the hospital stay is usually about 3 days. Furthermore, the transsphenoidal approach allows for a clearly visible operative field with high magnification and internal illumination. Normal pituitary can be clearly distinguished from tumor tissue, facilitating microdissection

Figure 9-7 Threshold field test showing superior bitemporal hemianopsia in a patient with a pituitary tumor compressing the optic chiasma (A), which later advanced to bitemporal hemianopsia (B).

and resection of small tumors (Fig. 9-9). The utility of the transsphenoidal approach has been greatly enhanced by several technologic advances, including head immobilization techniques, microinstrumentation, and novel-angled endoscopes. Enhanced MRI sensitivity and precision, as well as the use of intraoperative MRI, allow for clear delineation of tumor location, size, and invasiveness—all critical determinants of surgical success.

The endoscopic surgical technique has enabled an approach to both intrapituitary and some extrasellar masses. Most approaches are endonasal,³⁸ but some are via the cranial base,³⁹ and suprasellar lesions are reached by transposing the pituitary to access the lesion.⁴⁰ In experienced hands, the endoscopic technique results in complication rates and outcomes, similar to those of the traditional transsphenoidal approach.^{41,42}

Craniotomy is indicated for the rare invasive suprasellar mass extending into the frontal or middle cranial fossa or optic nerve and for extensive posterior clival invasion. Suprasellar extension contained by a small diaphragmatic aperture (hourglass configuration) may also require a transcranial approach. Rarely, tumors that are too solid to be

removed transsphenoidally may require a combination of transsphenoidal and intracranial surgery.

Goals of Surgery. The goal of pituitary surgery is for total resection limited to the lesion without compromise of postoperative endogenous pituitary function. Careful selective mass resection may be difficult in cases of poorly encapsulated lesions, those embedded deeply within the gland body, those extending into the wall or the body of the cavernous sinuses, and suprasellar lesions. However, suprasellar tumors (e.g., craniopharyngiomas) may also be successfully removed via a transnasal approach. Poor operative field visibility also limits precise resection. Excision of normal pituitary tissue and intraoperative manipulation of the gland should be avoided unless critical for effective tumor dissection. Occasionally, hemihypophysectomy or even nonselective total gland resection may be indicated for multifocal tumors, if the surrounding normal gland is necrotic, or if no mass lesion is discernible despite an accurate clinical and biochemical diagnosis (especially for ACTH-cell tumors). Successful surgery should decompress central visual defects and compromised trophic hormone secretion.

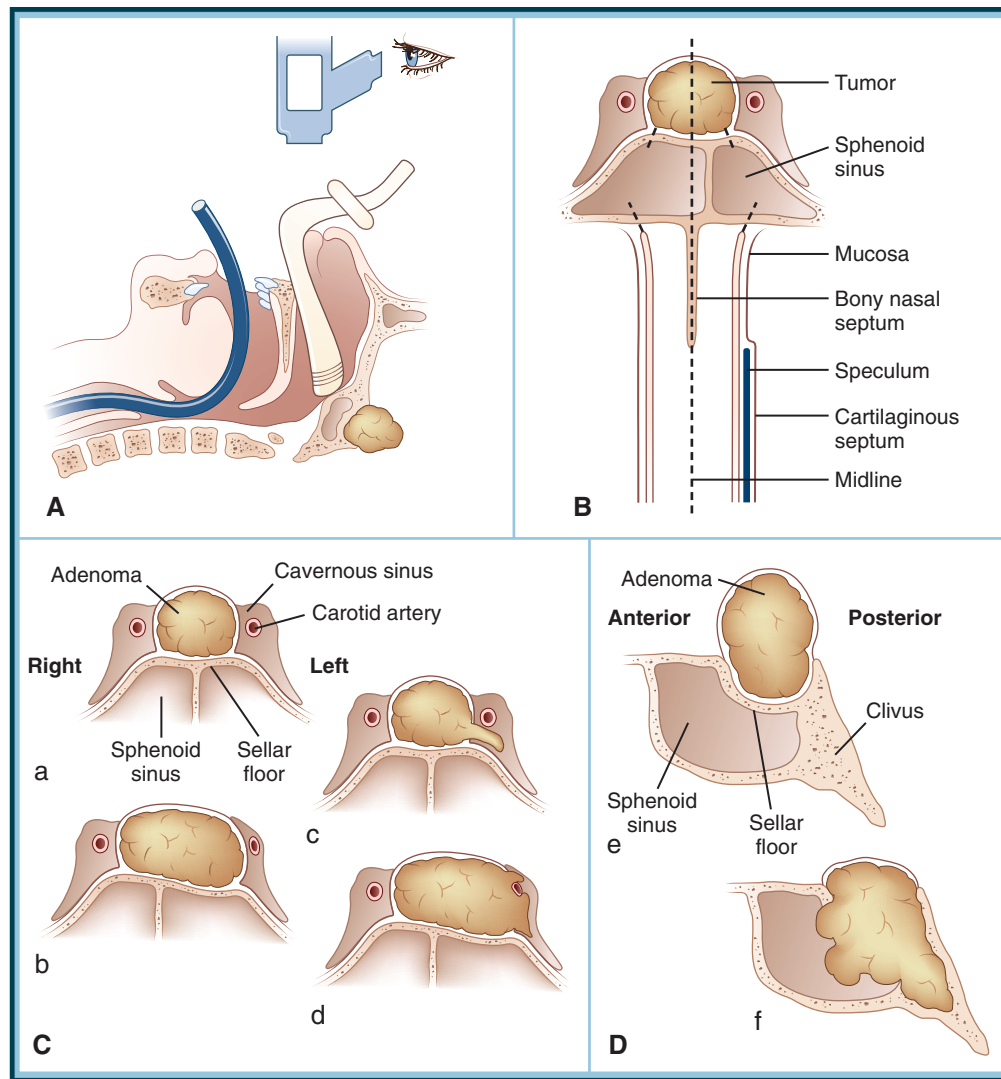

Figure 9-8 Transsphenoidal pituitary surgery. **A**, The route of the transsphenoidal approach (lateral view) and the surgical corridor and positioning of the retractor. **B**, The extent of removal of bone structures including the nasal septum and sphenoid sinus floor and roof is indicated (gray areas). **C**, Parasellar extensions of pituitary adenomas (coronal sections) are shown: a, intraseptal adenoma; b, displacement of the cavernous sinus; c, focal invasion of the cavernous sinus; and d, diffuse invasion of the cavernous sinus by the adenoma. **D**, Extensions of a pituitary adenoma (sagittal sections): e, suprasellar extension; f, invasion of the sphenoid sinus and of the clivus. (Adapted from Honegger J, Buchfelder M, Fahlbusch R. Surgery for pituitary tumors. In: Sheaves R, Jenkins PJ, Wass JAH, eds. *Clinical Endocrinology Oncology*. Boston: Blackwell Science; 1997:176-184.)

For children and young adults, the need for adequate normal tissue for subsequent growth patterns and reproductive function is an important determinant for intraoperative decision-making. Nevertheless, especially for functional tumors, small residual remnants attached to the dura are difficult to access and remain hypersecretory with persistent clinical progression. Therefore, the skilled neurosurgeon carefully balances maximally effective tumor removal with the requirement to preserve nontumorous pituitary trophic function.

Recent advances have enabled improved surgical results, although long-term outcomes using new techniques have not yet been rigorously compared with the results of standard operations performed by skilled surgeons.⁴³ Image-guided approaches enable intraoperative surgical neuronavigation by three-dimensional imaging. Intraoperative ultrasound and MRI technologies allow for real-time assessment of the dimensions and extent of the pituitary mass and the progress of surgery. Intraoperative MRI is performed while the surgical field is still open; this

allows the surgeon to directly assess the need for further dissection and also provides an excellent baseline for postoperative follow-up.⁴⁴ If there is suspicion of a vascular lesion, carotid and intracranial angiography is indicated before surgery. In contrast, postoperative image stabilization may not be evident for months after surgery, and MRI may be useful only after 1 year or longer, especially after resection of secretory tumors with measurable serum biomarkers.⁴⁵

Endonasal transsphenoidal endoscopy avoids the use of a retractor or speculum, does not require nasal packing, and sometimes leads to a shorter operating time, allowing for improved postoperative morbidity and a shorter hospital stay (Fig. 9-10). The advantages of the technique include a clear panoramic view of bony landmarks and the ability to access suprasellar and parasellar tumor extensions into the cavernous sinuses.⁴² Disadvantages of this approach include perioperative intrasellar bleeding and CSF leaks. Combining both techniques may allow the advantages of both approaches.

Figure 9-9 Transsphenoidal resection of pituitary adenoma.

Indications for Transsphenoidal Surgery. A pituitary mass that may or may not be compressing local vital structures should be evaluated for surgical resection (Table 9-3). Although surgical resection offers rapid resolution of hormone hypersecretion and many of the resultant clinical features of functioning adenomas, indications for the procedure differ depending on tumor type (see later discussion). In general, patients who are intolerant or resistant to medical therapy require surgery. Surgery is primarily

Figure 9-10 Endoscope-assisted microsurgery provides a panoramic view of the sphenoid sinus. Using a 30-degree endoscope, a view “around the corner” is possible. Parasellar structures can be visualized and residual tumor detected and resected. (Reproduced from Fahlbusch R, Buchfelder M, Kreutzer J, et al. Surgical management of acromegaly. In: Wass J, ed. *Handbook of Acromegaly*. Bristol, UK: BioScientifica; 2001.)

TABLE 9-3

Transsphenoidal Pituitary Surgery

Primary Indications

General

- Visual tract or central nervous compression arising from within sella
- Relief of compressive hypopituitarism by presenting, residual, or recurrent tumor tissue
- Tumor recurrence after surgery or irradiation
- Pituitary hemorrhage
- Cerebrospinal fluid leak
- Resistance to medical therapy
- Intolerance of medical therapy
- Personal choice
- Desire for immediate pregnancy with macroadenoma
- Requirement for diagnostic tissue histology

Specific

- Acromegaly
- Cushing's disease
- Clinically nonfunctioning macroadenoma
- Prolactinoma
- Nelson's syndrome
- TSH-secreting adenoma

Side Effects

Transient

- Diabetes insipidus
- Cerebrospinal fluid leak and rhinorrhea
- Inappropriate ADH secretion
- Arachnoiditis
- Meningitis
- Postoperative psychosis
- Local hematoma
- Arterial wall damage
- Epistaxis
- Local abscess
- Pulmonary embolism
- Narcolepsy

Permanent (up to 10%)

- Diabetes insipidus
- Total or partial hypopituitarism
- Visual loss
- Inappropriate ADH secretion
- Vascular occlusion
- CNS damage—oculomotor palsy, hemiparesis, encephalopathy
- Nasal septum perforation

Surgery-Related Mortality (up to 1%)

- Brain, hypothalamic injury
- Vascular damage
- Postoperative meningitis
- Cerebrospinal fluid leak
- Pneumocephalus
- Acute cardiopulmonary disease
- Anesthesia-related
- Seizure

ADH, antidiuretic hormone; CNS, central nervous system; TSH, thyroid-stimulating hormone.

indicated for patients with well-circumscribed GH-secreting adenomas, TSH-secreting adenomas, all ACTH-secreting tumors, and nonfunctioning macroadenomas that require surgery. Surgery may also be indicated when tissue histology is required for diagnosis of the nature of an enigmatic sellar mass. Progressive compressive features such as visual field loss, compromised pituitary function, and other central nervous system (CNS) functional changes are indications for surgical debulking and sellar decompression. Hemorrhage into the encased bony sella turcica, usually occurring within a known or previously unknown

adenoma, may require immediate surgical decompression. Urgent surgical decompression is required for acute pituitary hemorrhage, especially in patients who have developed sudden visual field compromise.

Hypopituitarism resulting from increased portal vessel pressure may resolve shortly after decompressive surgery.⁴⁶ When pituitary function after surgery was assessed in 234 patients, 52 were found to have developed new trophic hormone dysfunction, whereas 45 of 93 patients with preoperative evidence for hypopituitarism had recovered between one and three previously suppressed axes. Significant factors determining restoration of postoperative pituitary function were no visible tumor remnants as assessed by MRI and no tumor invasion as determined both by the neurosurgeon and by pathologic examination of surrounding tissue.⁴⁷ Therefore, because some patients with preoperative pituitary failure recover function, depending on the clinical circumstance, patients should be considered for retesting of pituitary reserve before postoperative substitution therapy is initiated (except for adrenal steroid replacement, which requires greater caution). Indications for a second surgery in the same patient include tumor recurrence, persistent hormonal hypersecretion by tumor remnants, and repair of a CSF leak.

After surgery, patients should be kept on bedrest at an angle of 30 to 45 degrees, with urine and serum osmolality and serum electrolytes measured every 6 hours. Indications for postoperative vasopressin replacement include polyuria, especially with elevated serum sodium and osmolality and inappropriately low urine osmolality. Postoperative polyuria alone is not an indication for vasopressin replacement, unless it is a reflection of compromised posterior pituitary function. Excess fluid given intraoperatively may also result in postoperative polyuria. Requirements for fluid replacement should take into consideration both fluid intake and urine output.

Side Effects. The success of surgery is largely determined by the skill and experience of the neurosurgeon. Higher-volume pituitary centers and experienced surgeons report superior postoperative outcomes and shorter hospital stays.^{48,49} Tumor size, degree of invasiveness, preoperative hormone levels, and previous pituitary surgery are all determinants of surgical outcome. CSF leakage, transient diabetes insipidus, and the syndrome of inappropriate antidiuretic hormone secretion (SIADH) are the most commonly encountered transient side effects, occurring in up to 20% of patients (see Table 9-3). Local damage may also result in arachnoiditis, vascular bleeding, hematoma formation, and epistaxis. Rarely, pulmonary embolism, narcolepsy, and local abscess have been reported. Iatrogenic hypopituitarism, diabetes insipidus, or SIADH is reported in up to 10% of patients. Rarely, the CNS may be permanently damaged, resulting in hemiparesis, cranial nerve palsies, or encephalopathy.

A triphasic course of postoperative diabetes insipidus has been described in which the transient disorder is followed by an interphase on days 6 through 11 with no polydipsia or polyuria. During this latter phase, hyponatremia with features of SIADH have been reported even in patients who show no signs and symptoms of diabetes insipidus after surgery.^{50,51} The third phase is return of polyuria and polydipsia. Cognitive dysfunction, including anterograde memory deficits and deficits in executive function, were reported in several retrospective studies after transsphenoidal surgery.^{52,53} Mortality has been reported in up to 1% of patients undergoing pituitary surgery and may be related to direct hypothalamic or cerebrovascular damage,

meningitis, pneumocephalus formation, or complications of anesthesia. Surgical failure may result from a non-pituitary-related event such as an anesthesia-related complication or bleeding disorder. Incomplete tumor removal may also result from inaccurate preoperative MRI localization or identification. Rarely, a previously undiagnosed functioning pituitary tumor or ectopic source of ACTH may be unmasked after initially unsuccessful pituitary surgery.

Pituitary Irradiation

Principles. High-energy ionizing radiation can be delivered to deep tissues by megavoltage techniques. The challenge of this approach is to provide maximal localized necrotizing irradiation to the pituitary lesion while minimally exposing surrounding normal structures to radiation damage. Several advances have improved both efficacy and safety, including highly precise tumor localization, a high-voltage (6 to 15 MeV) linear accelerator, and accurate simulation models with isocentric rotational arcing that allow repeated head positioning at exactly the same points for each recurrent patient visit. Up to a maximum of 5000 rads is administered in 180-rad daily fractions for 5 to 6 weeks.

High-precision techniques such as stereotactic conformal radiotherapy,⁵⁴ gamma knife,²⁴ and proton beam procedures⁵⁵ allow delivery of high energy to the pituitary lesion while minimizing the mass of normal brain exposed to radiation (Fig. 9-11).

Indications. The use of radiation for treatment of pituitary tumors is highly individualized and depends on the expertise of the treating center, the conviction of the treating physician in weighing the potential benefits and risks of the procedure, and patient preference based on informed choice (Table 9-4). In general, radiation techniques are indicated for persistent hormone hypersecretion or residual mass effects after surgery, or when surgical resection of a compressive mass is contraindicated. Because GH-secreting and PRL-secreting tumors are generally amenable to

Figure 9-11 Pituitary radiotherapy. An 8-mV X-ray isodosimetric plan is used. The three fields restrict high-dose volume to the target. Numbered areas reflect radiation exposure. (Plowman PN. Pituitary radiotherapy: Techniques and potential complications. In: Sheaves R, Jenkins PJ, Wass JAH, eds. *Clinical Endocrinology Oncology*. Boston: Blackwell Science; 1997:185-188.)

Glioma arising after radiation therapy for pituitary adenoma. A report of four patients and estimation of risk. *Cancer*. 1993;72:2227-2233.

medical therapy, indications for their irradiation are rare. Most indications for irradiation are adjuvant to either surgical or medical treatment. Radiation therapy may be indicated after resection of a potentially recurring or inadequately resected pituitary mass, such as a nonfunctioning pituitary adenoma, craniopharyngioma, or chordoma. In acromegaly, the use of irradiation as primary treatment is generally not recommended,⁵⁶ but for aggressively growing prolactinomas that are resistant to medical therapy, the procedure may prevent further local invasion. Recurrent pituitary-dependent Cushing's disease appears to be particularly suited for radiation therapy, especially in younger patients.

Side Effects

Hypopituitarism. Pituitary failure occurs commonly in patients who have received pituitary irradiation. Within 10 years after radiation treatment, up to 80% of patients have gonadotroph, somatotroph, thyrotroph, or corticotroph deficits.⁵⁶⁻⁵⁸ The mechanism for hypopituitarism appears to involve damage to hypothalamic hormone-releasing cells as well as direct pituitary damage. These patients require lifelong endocrine follow-up for pituitary reserve testing and hormone replacement when appropriate.

Second Brain Tumors. Glioma may occur after conventional pituitary irradiation for adenoma or craniopharyngioma with a mean latency period of 11.5 years (see Table 9-4).⁵⁹ Among patients receiving radiotherapy for pituitary tumors, it appears that the standardized incidence ratio (SIR) for a second brain tumor is approximately 6 (confidence interval, 3.16 to 10.69), with a latency of 6 to 24 years in separate cohorts.⁶⁰⁻⁶³ Because patients harboring pituitary tumors are more likely to undergo routine brain imaging during follow-up, it is not entirely clear whether observed meningiomas are coincidental findings. However, children undergoing radiation therapy for brain tumors have a higher incidence of postradiation meningioma.⁶⁴ This complication, which occurs in fewer than 5% of patients, also appears to be dose-related, so fractionated doses not exceeding 5000 rads should be given. Use of confocal radiation techniques to irradiate a smaller tissue volume, including radiosurgery, fractionated stereotactic radiotherapy, and proton beam therapy, may minimize this adverse effect, but prospectively controlled surveillance studies are required to rigorously evaluate this critical question.

Cerebrovascular Disease. Mortality from cerebrovascular disease appears to be higher among previously irradiated pituitary-deficient patients.⁶⁵⁻⁶⁸ The direct causality of this relationship is unclear, but direct effects on cerebral vasculature, including atherosclerotic occlusive lesions, have been reported.⁶⁹

Visual Damage. Approximately 2% of patients develop impaired vision due to optic nerve damage after radiotherapy for pituitary tumors.⁷⁰ The risk of visual damage is minimized by fractionating dosages to less than 200 rads per treatment session. Although consequent blindness was reported in 2 patients who received 4500 rads in 180-rad fractions,⁷¹ the incidence of reported visual damage in patients undergoing radiosurgery is negligible.²⁴

Brain Necrosis. Dose-related radiation-induced brain necrosis was documented by MRI in 14 of 45 patients, with temporal lobe atrophy and cystic and diffuse cerebral atrophy.⁷² Cognitive dysfunction, especially memory loss, has also been reported.⁷³

Radiosurgery. Proton beam therapy, gamma knife using focused cobalt-60 emissions, and linear accelerators deliver high-dose radiation while sparing surrounding tissue (Fig. 9-12). The delivery of high energy by gamma knife directly targeted at the pituitary tumor minimizes radiation exposure to surrounding tissues.⁷⁴ This procedure is best suited for intrasellar and cavernous lesions distant from the optic nerves. Intermediate review of 1621 patients undergoing radiosurgery reported from 35 independent centers emphasized the heterogeneous efficacy rates and the need for controlled prospective comparative trials, especially to assess efficacy and safety in comparison with surgery and medical therapy.²⁴ In a long-term study of 76 patients with a mean follow-up of 96 months, about half were in remission, 23% developed new-onset hypopituitarism, and 3 patients developed oculomotor palsies.⁷⁴ Therefore, there is no current evidence that stereotactic radiosurgery exhibits superior efficacy or safety compared with fractionated treatments.⁷⁵

Medical Management

Pituitary tumors often express receptors mediating hypothalamic control of hormone secretion, and appropriate therapeutic ligands for the D₂ receptor and the somatotropin release-inhibiting factor (SRIF) receptor subtype 2 (SSTR2) are employed to effectively suppress PRL, GH, and/

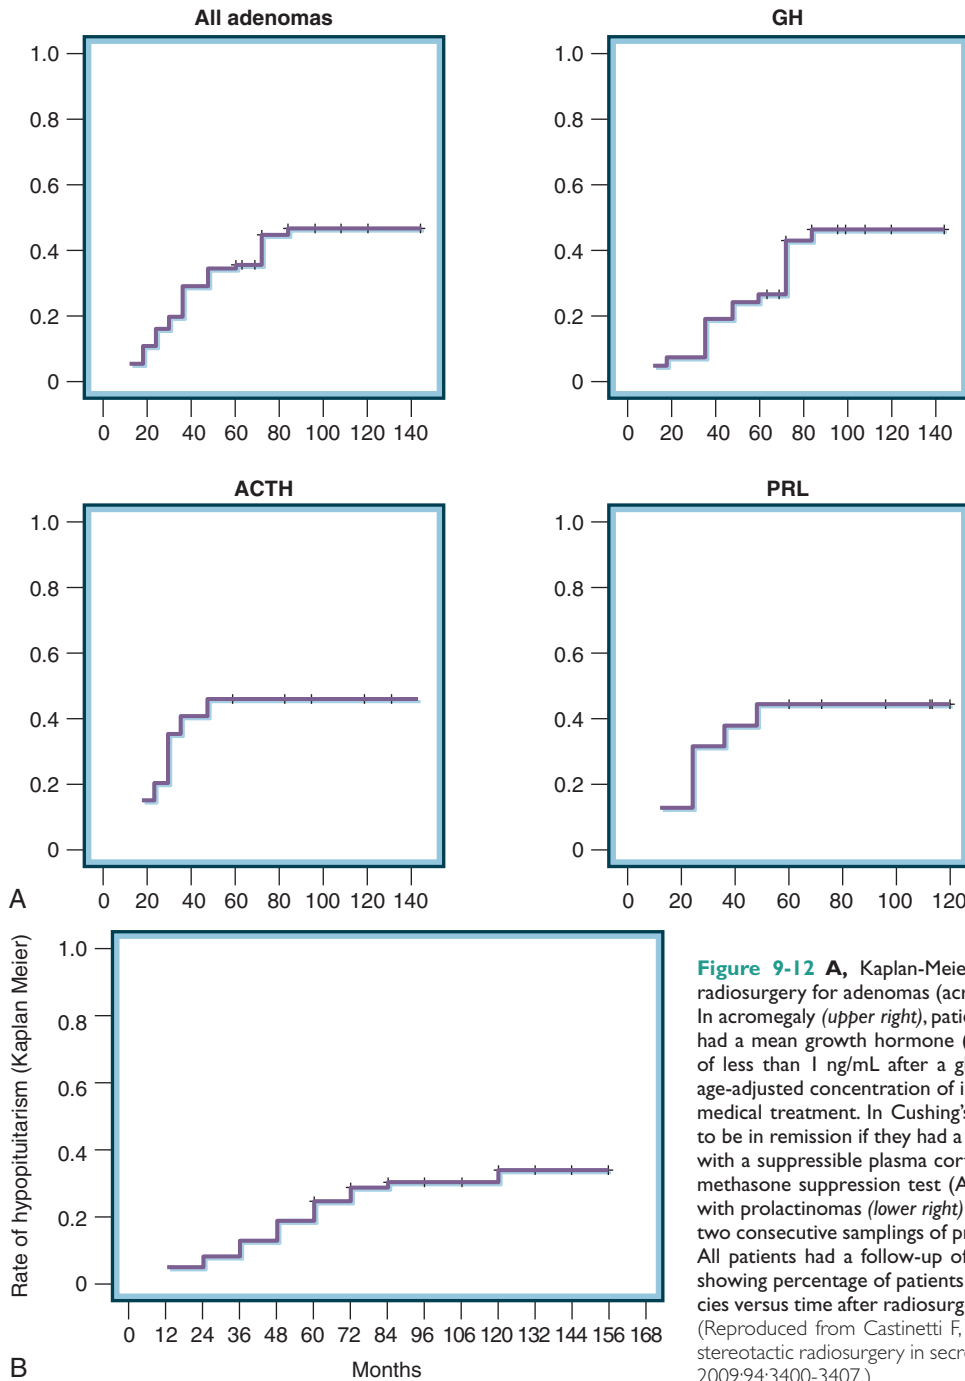

Figure 9-12 A, Kaplan-Meier analysis according to time (months) after radiosurgery for adenomas (acromegaly, Cushing's disease, and prolactinomas). In acromegaly (*upper right*), patients were considered to be in remission if they had a mean growth hormone (GH) level of less than 2 $\mu\text{g/mL}$ or a GH level of less than 1 ng/mL after a glucose tolerance test (or both) and a normal age-adjusted concentration of insulin-like growth factor type I (IGF1) without medical treatment. In Cushing's disease (*lower left*), patients were considered to be in remission if they had a normalized 24-hour urinary free cortisol value with a suppressible plasma cortisol level (<50 nmol/L) after a low-dose dexamethasone suppression test (ACTH, adrenocorticotrophic hormone). Patients with prolactinomas (*lower right*) were considered to be in remission if they had two consecutive samplings of prolactin (PRL) in the normal range (<20 ng/mL). All patients had a follow-up of at least 60 months. **B**, Kaplan-Meier analysis showing percentage of patients with new anterior pituitary hormone deficiencies versus time after radiosurgery. x-axis = monthly; y-axis = rate of remission. (Reproduced from Castinetti F, Nagai M, Morange I, et al, Long-term results of stereotactic radiosurgery in secretory pituitary adenomas. *J Clin Endocrinol Metab*. 2009;94:3400-3407.)

or TSH hypersecretion, to block tumor growth, and often to shrink tumor size. A peripheral receptor antagonist blocks GH action and IGF1 generation without targeting the pituitary tumor source. Medical ablation of target glands, including the thyroid and adrenal glands, may also be useful in mitigating the deleterious impact of pituitary tumor hypersecretion. Each of these medical approaches is fully considered later in this chapter.

PARASELLAR MASSES

Hypothalamic masses are fully described in Chapter 7, and parasellar masses are depicted in Table 9-5.⁷⁶

Types of Parasellar Masses

Rathke's Cyst

The anterior and intermediate lobes of the pituitary gland arise embryologically from Rathke's pouch. Inadequate pouch obliteration results in cysts or cystic remnants at the interface between the anterior and posterior pituitary lobes, found in about 20% of pituitary glands at autopsy (Fig. 9-13).⁷⁷ Pituitary adenomas may also occasionally contain small cleft cysts,⁷⁸ which are lined by cuboidal or columnar ciliated epithelium surrounding mucoid cyst fluid. They arise from midline rudiments of failed Rathke's cyst invagination and account for about 3% of pituitary mass lesions.⁷⁹ In contrast, pituitary epidermoid cysts are

lined by squamous epithelium which may rarely become malignant.

Rathke's cysts vary in size and may also extend to the suprasellar region. These lesions have heterogeneous MRI characteristics and may rarely manifest with panhypopituitarism with or without diabetes insipidus.⁸⁰ Most, however, are not symptomatic and should be observed expectantly. The extent of headache or visual disturbance is determined by the size and location of the cyst. Cyst formation is associated with sellar enlargement. MRI reveals hyperdense or hypodense masses on either T1- or T2-weighted images, whereas CT scans show homogeneous hypodense areas that may be distinguished from pituitary adenomas.⁸⁰ These patients should all be evaluated for hypopituitarism. After surgical resection or drainage, MRI should be performed during long-term follow-up for signs of cyst recurrence.^{77,79}

Arachnoid, epidermoid, and dermoid cysts develop mainly in the cerebellopontine angle, but they may also arise in the suprasellar region. Dermoid cysts containing greasy sebaceous products or hair follicles are rarely encountered in the pituitary, and the cyst lining may be calcified. Acquired pituitary cysts may arise secondarily to intrapituitary hemorrhage, usually associated with an underlying adenoma, and these rarely cause pituitary failure.⁸¹ Cyst compression causes internal hydrocephalus, visual disturbances, GH or ACTH deficiency, hyperprolactinemia, and diabetes insipidus. Rarely, squamous cell carcinoma arises in the cyst.⁸²

Granular Cell Tumors

Pituitary choristomas, or schwannomas, usually manifest only after the age of 20 years. Their abundant cytoplasmic granules do not contain pituitary hormones, but these lesions may manifest with diabetes insipidus. Pituitary adenomas are occasionally coincidentally associated with these tumors.⁸³

Chordomas

Chordomas are slow-growing, cartilaginous tumors that arise from midline notochord remnants; they are locally invasive and may metastasize.⁸⁴ Most arise from the vertebrae, although about one third involve the clivus region. Chordomas contain a mucin-rich matrix that allows diagnosis by fine-needle aspiration. They manifest with headaches, asymmetric visual disturbances, hormone deficiency, and, occasionally, nasopharyngeal obstruction. The tumor mass is associated with osteolytic bony erosion and calcification, and MRI may allow the normal pituitary gland to be distinguished from the very heterogeneous and often flocculent tumor mass. At surgery, the tumors are rough, heterogeneous, and lobular. Markers for epithelial cells, including cytokeratin and vimentin, are present. Recurrences commonly occur after surgical excision, with a mean patient survival time of about 5 years. Rarely, chordomas undergo sarcomatous transformation with an aggressive natural history and require extensive surgical dissection.⁸⁵ Because of their anatomic location, the endoscopic endonasal approach may be preferable for surgical resection of chordomas.⁸⁶

Craniopharyngiomas

Craniopharyngiomas are parasellar tumors that constitute about 3% of all intracranial tumors and up to 10% of childhood brain tumors. The tumors are commonly diagnosed during childhood and adolescence. However, they show a bimodal age distribution, with peaks occurring in children

Figure 9-13 Pathogenesis of Rathke's cysts. Schematic diagram of the embryologic progenitors of sellar and parasellar structures. Rathke's pouch arises from an outpocketing of stomodeum (ectoderm) and gives rise to the adenohypophysis. The pharyngohypophyseal stalk, which connects the stomodeum and Rathke's pouch, is divided by the sphenoid bone as it grows together (arrows), isolating Rathke's pouch and the neurohypophysis within the sella. (Reproduced from Harrison MJ, Morgello S, Post KD. Epithelial cystic lesions of the sellar and parasellar region: a continuum of ectodermal derivatives? *J Neurosurg.* 1994;80:1018-1025.)

between 5 and 14 years of age and in adults from 50 to 74 years.⁸⁷ The tumors arise from embryonic squamous remnants of Rathke's pouch extending dorsally toward the diencephalon. They may be large (>10 cm in diameter) and may invade the third ventricle and associated brain structures. More than 60% arise from within the sella, and others arise from parasellar cell rests.⁸⁸⁻⁹⁰ When intrasellar, they can often be distinguished from pituitary adenomas by the presence of a separate rim of normal pituitary tissue visible on MRI (see Fig. 9-1A).

The cystic mass is usually filled with a cholesterol-rich viscous fluid that may leak into the CSF, causing aseptic meningitis. The tumor may also contain calcifications and immunoreactive human chorionic gonadotropin. Histologic analysis shows that these tumors comprise two cell populations: cysts are lined with a squamous epithelium containing islands characterized by columnar cells, and a mixed inflammatory reaction may also occur with calcification. Although large craniopharyngiomas may obstruct CSF flow, they rarely undergo malignant transformation. Increased intracranial pressure results in headache, projectile vomiting, papilledema, and somnolence, especially in children. Only about one third of patients are older than 40 years of age, and they commonly present with asymmetric visual disturbances, including papilledema, optic atrophy, and field deficits. If cavernous sinus invasion is present, other cranial nerves may also be involved.

On CT imaging, most children and about half of affected adults exhibit characteristic flocculent or convex calcifications. Rarely, however, pituitary adenomas, other parasellar tumors, and vascular lesions within the sella are also calcified. Although pituitary adenomas rarely cause diabetes insipidus, it is often the earliest feature of craniopharyngioma. These patients may also develop partial or complete pituitary deficiency. GH deficiency, with short stature, diabetes insipidus, and gonadal failure, is common. Pituitary stalk compression or damage to hypothalamic dopaminergic neurons results in hyperprolactinemia. Therefore, craniopharyngioma may mimic a prolactinoma on intrapituitary imaging, by the presence of hyperprolactinemia, and by a favorable biochemical response to dopamine agonists.

Treatment of primary or recurrent craniopharyngioma may involve radical surgery, radiotherapy, or a combination of these modalities.^{87,90,91} Recent studies have indicated that postoperative irradiation improves outcome. Although transsphenoidal surgery has been successfully employed for intrasellar craniopharyngiomas,^{92,93} the expanded endoscopic transnasal approach has been successfully crafted to approach suprasellar tumors.⁹⁴ Stereotactic irradiation has also successfully been employed. A detailed discussion of the neurosurgical management of this disorder is beyond the scope of this text. However, regardless of the form of therapy chosen, ablation of the mass invariably results in anterior and/or posterior pituitary hormone deficits.

Postoperative recurrence may occur in about 20% of patients undergoing radical surgical excision, and there is no difference in outcome when a subtotal surgical excision is followed by radiotherapy. Pure papillary squamous cellular elements in the tumor may portend a higher surgical recurrence rate. Long-term effects of childhood irradiation for these tumors are considered elsewhere (see Chapter 24).

Meningiomas

Meningiomas arise from arachnoid and meningioendothelial cells, and those occurring in the sellar and parasellar

region account for about one fifth of all meningiomas.⁹⁵ Sellar meningiomas are usually well circumscribed and do not attain the size of craniopharyngiomas. Suprasellar meningiomas may invade the pituitary ventrally, and intrasellar tumor origins are rare.⁹⁶ Coexisting functional pituitary adenomas have been described in patients with parasellar meningiomas. Secondary hyperprolactinemia occurs in up to half of patients, who usually present with local mass effects including headache and progressive visual disturbances accompanied by optic atrophy.

The differential distinction of a suprasellar meningioma with downward extension from an upwardly extending pituitary adenoma can be difficult. On MRI, meningiomas are isodense on both T1 and T2 imaging, in contrast to other parasellar lesions, which are usually hyperdense on T2 imaging. Dural calcification may be evident on CT scanning. Because of their rich vascularization, these tumors pose an intraoperative risk for hemorrhage and a resultant higher surgical mortality rate than is usually encountered during resection of pituitary adenomas.

Gliomas

Optic gliomas and low-grade astrocytomas arise from within the optic chiasm or optic tract, often infiltrating the optic nerve; fewer than one third are intraorbital. Von Recklinghausen's disease is the underlying cause in about one third of these patients, and occasionally these tumors are associated with growth retardation and delayed or precocious puberty and with mass effects including visual disturbances, diencephalic syndrome, diabetes insipidus, and hydrocephalus. Rarely, gliomas arise within the sella in association with hyperprolactinemia and should be considered in the uncommon differential diagnosis of a PRL-secreting pituitary adenoma.⁹⁷ Important distinguishing features include the young age of these patients (80% are <10 years old), the relatively intact pituitary function, gross visual disturbances, and localization of the mass as visualized on MRI. Gliomas, unlike hamartomas, usually enhance after contrast injection.

Mucocoele

Mucocoeles are expanding accumulations of fluid within the sphenoid sinus and may compress parasellar structures. Headaches, visual disturbances (usually unilateral), and exophthalmos are characteristic features. On MRI, the homogenous sphenoid mass may be quite prominent but distinguishable from the pituitary gland dorsally.

Parasellar Aneurysms

A parasellar aneurysm may mimic a pituitary adenoma, and intraoperative rupture can be catastrophic, underscoring the absolute need for preoperative diagnosis. Differentiating features of aneurysms from other pituitary masses may be subtle and include eye pain, very intense headaches, and relatively sudden onset of cranial nerve palsies (Fig. 9-14). Although imaging techniques usually distinguish blood and hemorrhage from solid tumor or tissue, a highly vascular meningioma may be confused with an aneurysm.

Pituitary Infections

Acute pituitary abscesses and parasellar arachnoiditis are encountered with sinus infections, especially after transsphenoidal surgery. Pituitary abscesses may develop from hematogenous or direct local spread of infectious agents,⁹⁸ or they may arise within a preexisting pituitary adenoma. They can be difficult to distinguish from an adenoma, because these patients may not have fever or signs of

Figure 9-14 **A**, Coronal T1-weighted magnetic resonance image (MRI) without intravenous contrast. A mildly hypointense mass within the sella and left cavernous sinus is shown. **B**, Coronal T1-weighted MRI after gadolinium contrast. The mass enhances heterogeneously. **C**, Computed tomographic angiogram with maximum-intensity projection reconstruction. The arrow in each image indicates the origin of a left internal carotid artery giant cavernous aneurysm. (Reproduced from Lawson EA, Buchbinder BR, Daniels GH. Image in endocrinology: hypopituitarism associated with a giant aneurysm of the internal carotid artery. *J Clin Endocrinol Metab*. 2008;93:4616.)

meningitis. Patients often present with diabetes insipidus and headache, and some have pituitary insufficiency.^{99,100} On MRI imaging, an isointense central cavity with surrounding ring enhancement is characteristic of an abscess.⁴

Gram-positive streptococci or staphylococci may originate from nasopharyngeal passages and infect the pituitary.¹⁰¹ Disseminated *Entamoeba histolytica*, *Pneumocystis jiroveci* (formerly *Pneumocystis carinii*), or *Klebsiella* can also seed to the pituitary.^{102,103} Immunosuppressed patients may develop pituitary infections including cytomegalovirus infection, toxoplasmosis, aspergillosis, histoplasmosis, and coccidiosis. Syphilitic gumma can also lead to pituitary damage and insufficiency. Common viral infections, including influenza, measles, mumps, and herpes, are rarely associated with pituitary damage and insufficiency. Although tuberculosis is rarely confined to the pituitary gland, most of the fewer than 20 reported patients exhibited suprasellar extension of the pituitary mass, compromised pituitary function, and visual defects. Although systemic tuberculosis was usually present, isolated sellar tuberculomas have been described.¹⁰⁴

Hematologic Malignancies

Primary CNS lymphomas are usually B-cell non-Hodgkin's types, and fewer than 20 patients with pituitary lymphoma

have been described.¹⁰⁵⁻¹⁰⁷ The pituitary mass may be an isolated presentation of the underlying disease. The disorder is usually diagnosed by histologic study of tissue obtained by excision biopsy. In one report, six of nine patients had headache, and five had cranial nerve abnormalities with varying degrees of hypopituitarism. MRI reveals cavernous sinus invasion and isodense T1- and T2-weighted images that enhance after gadolinium administration. Patients with solitary pituitary plasmacytoma may or may not develop classic multiple myeloma.¹⁰⁸ Acute lymphoblastic leukemia may be associated with periglandular pituitary infiltrates with minimal pituitary dysfunction.

Pituicytoma

Pituicytoma is a rare, benign suprasellar glial cell tumor that manifests with mass effects or hypopituitarism.^{109,110} The tumor arises from cells in the neurohypophysis and stains for vimentin, S100 protein, and glial fibrillar acidic protein.¹¹¹

Sarcoidosis

Hypothalamic granulomatous involvement is commonly encountered in patients with CNS sarcoidosis and may be the sole manifestation of the disease.¹¹² These patients

may present with varying degrees of anterior pituitary failure with or without diabetes insipidus.¹¹³ The hypothalamus, pituitary stalk, and posterior pituitary are diffusely invaded by noncaseating granulomas consisting of giant cells, macrophages, and lymphocytes.¹¹⁴ Sarcoidosis may be progressive and may eventually result in pituitary damage and even an empty sella. Onset of diabetes insipidus with no obvious features of a pituitary disorder should alert the physician to exclude hypothalamic sarcoid deposits, especially if there is a thickened stalk on MRI.¹¹⁵ Systemic steroids have been used to treat CNS sarcoid, and cladribine may reverse diabetes insipidus caused by sarcoid.¹¹⁶

Hand-Schüller-Christian Disease (Histiocytosis X)

Sleep disorders, adipsia, and morbid obesity are components of Hand-Schüller-Christian disease, also known as histiocytosis X. Other features of granulomatous involvement include axillary skin rash, history of recurrent pneumothorax, classic bony lesions, and new-onset diabetes insipidus.¹¹⁷ The disorder may be associated with granulomatous damage to the hypothalamus and/or posterior pituitary, resulting in characteristic diabetes insipidus.¹¹⁸ Pituitary lesions are composed of dendritic Langerhans cells, and pituitary MRI may reveal stalk thickening or a diminished posterior pituitary bright spot. Adults with the disorder should be carefully evaluated for anterior pituitary hormone deficits, and these should be appropriately replaced. Multisystem Langerhans-cell histiocytosis causes long-term morbidity extending into adulthood.¹¹⁹ Whereas surgery and irradiation have been, for many years, the mainstay treatments for this disorder, a novel chemotherapeutic approach using cladribine has been successful in some patients.¹²⁰

Metastases to the Pituitary Region

Pituitary metastases are found in up to 3.5% of cancer patients,^{121,122} especially in older patients with diffuse malignant disease. Because the vascular supply to the posterior pituitary is derived directly from the systemic circulation via the internal carotid arteries, the posterior pituitary is the preferred site for bloodborne metastatic spread. Carcinomas that metastasize to the pituitary include breast, lung, and gastrointestinal tract lesions. Up to one quarter of patients with metastatic breast cancer have pituitary metastases. Symptomatic pituitary metastases (usually diabetes insipidus) may be the presenting sign of occult malignancy and of malignancy of unknown origin. Rarely, isolated metastatic stalk deposits also manifest with pituitary failure. If extensive bony erosion is present and disease onset is rapid, the diagnosis is more readily apparent. However, pituitary imaging may not clearly distinguish metastatic deposits from a pituitary adenoma; these lesions may masquerade as adenomas, with the diagnosis made only by histologic study of the resected specimen.¹²² When the diagnosis is clearcut in the presence of a primary cancer, relatively low-dose pituitary irradiation may be sufficient to shrink the metastasis and improve morbidity.

Iron storage diseases, including hemochromatosis and hemosiderosis, result in predominantly gonadotroph cell damage. Idiopathic retroperitoneal fibrosis may also be associated with a suprasellar mass and hypothalamic panhypopituitarism.¹²³

Primary Hypophysitis

Pituitary mass lesions comprising inflammatory cells may arise as primary disorders of the anterior and posterior

pituitary glands or the neurohypophysis.^{124,125} At least three clinicopathologic forms have been described.

Lymphocytic Hypophysitis

Lymphocytic hypophysitis is an apparently autoimmune inflammatory disorder that occurs during or shortly after parturition¹²⁶ but has also been reported after menopause¹²⁵ and in males (approximately 15% of reported cases).¹²⁷ Of the 57% of patients who develop the disorder in association with pregnancy, most do so during the last month of pregnancy or the first 2 months after delivery.¹²⁵

The disorder is characterized by a lymphocytic and plasma cell pituitary infiltrate that may be isolated or associated with other recognized endocrinopathies. Circulating anti-pituitary antibodies have occasionally been reported, and the presence of isolated pituitary hormone deficiency may imply an autoimmune process selectively targeted to pituitary cell types. Although the natural history is often short, the few comprehensive pathologic evaluations that have been performed suggest that secondary adenohypophyseal cell atrophy, with a resultant empty sella, is a frequent outcome.

Pathologic criteria for diagnosis include islands of anterior pituitary cells surrounded by diffuse lymphocytic (T- and B-cell) infiltrates. More than 268 histologically confirmed cases have been reported. The defining feature is lymphocytic infiltration comprising T and B lymphocytes. In a recent review, Caturegli and colleagues reported that plasma cells were found in 53%, eosinophils in 12%, and macrophage histiocytes and neutrophils in 6% of patients.¹²⁵ Mast cells have also been identified in hypophysitis.¹²⁸

Clinical Features. More than half of the patients with lymphocytic hypophysitis present with headache, visual field impairment, and hyperprolactinemia¹²⁵; pituitary deficiency accounts for the remaining cases (Table 9-6). Fifty-six percent of patients have secondary hypoadrenalism, followed in frequency by hypothyroidism, hypogonadism, and GH or PRL deficiency. This contrasts with hypopituitarism caused by pituitary adenomas. Hypothyroidism and hyperthyroidism may occur later, even after 9 months. MRI reveals a pituitary mass, often indistinguishable from an adenoma. Associated partially empty sella and contrast enhancement of the pituitary mass may be helpful distinguishing features on MRI.¹²⁹

The inflammatory process often resolves with time, and initially abnormal pituitary function may be restored or may remain chronically compromised. Limited numbers of patients have been reported with histologically proven lymphocytic hypophysitis and documented spontaneous regression of the pituitary mass on follow-up imaging. There can be intrasellar and suprasellar pituitary enlargement, and the pituitary stalk may be thickened, especially when diabetes insipidus is present.¹²⁴ In two patients with

TABLE 9-6

Features of Lymphocytic Hypophysitis

Feature	Percentage
Pituitary enlargement	80-95
Headache, visual disturbances	55-70
Hypopituitarism	63-68
Hyperprolactinemia	20-38
Associated autoimmune disease	30
Diabetes insipidus	14-19

histologically proven hypophysitis, spontaneous resolution of the pituitary mass was followed by successful pregnancies.^{130,131} Diabetes insipidus is encountered in up to 20% of patients and may be attributed to posterior pituitary or stalk infiltration.¹³² In one third of patients, other autoimmune conditions, such as thyroiditis, hypoadrenalism, parathyroid failure, atrophic gastritis, systemic lupus erythematosus, or Sjögren's syndrome, are also present.¹³³ The differential diagnosis includes prolactinoma and other sellar masses. A careful history and demonstrated loss of the posterior pituitary bright spot on MRI are useful for supporting the diagnosis.

Laboratory Findings. The erythrocyte sedimentation rate is often elevated. Antibodies to a 49-kd cytosolic protein were detected in 70% of patients with histologically confirmed lymphocytic hypophysitis and in 10% of controls.¹³⁴ Although the presence of this and two additional antibodies (to 68- and 43-kd human pituitary membrane antigens) has high specificity, all three were detected in only 5 of 13 patients with lymphocytic hypophysitis and 1 of 12 patients with infundibuloneurohypophysitis.¹³⁵ Similar results were obtained with the use of radioligand assays for pituitary proteins.¹²⁵ PRL levels are usually elevated in both female and male patients. Hyperprolactinemia is expected during pregnancy and the early postpartum period, and the mass effect of the infiltrate may also contribute to stalk compression and secondary hyperprolactinemia. GH and ACTH responses to hypothalamic hormone challenges may be blunted. Rarely, isolated ACTH or TSH deficiencies have been reported.¹³⁶

Management. If the diagnosis is convincingly supported, and in the absence of compressive visual field disturbances, surgical therapy should be withheld, pituitary hormone deficits appropriately replaced, and spontaneous resolution of the inflammatory mass expectantly monitored. Treatment with adrenal steroids is advocated, and it often resolves the sellar mass and improves endocrine dysfunction. Steroids are also indicated if the adrenal reserve is compromised. Transsphenoidal surgery may be required to confirm a tissue diagnosis and may also relieve symptoms of compression,¹³⁷ but the degree of surgical resection should be constrained by the need to conserve viable pituitary tissue, particularly in view of frequent spontaneous resolutions.

Granulomatous Hypophysitis

Granulomatous hypophysitis is not usually associated with pregnancy and has an equal incidence in female and male patients. Rarely, the condition may coexist with lymphocytic hypophysitis in the same gland.¹³⁷ Pituitary histology shows histiocytes, multinucleated giant cells, and other features of chronic inflammation and granuloma.¹³⁸ Patients present with headache and may have aseptic meningitis. MRI studies can reveal a thickened pituitary stalk or a characteristic tongue-shaped extension of the lesion under the hypothalamus. Granulomatous hypophysitis may reflect an underlying systemic disorder such as sarcoidosis¹³⁹ or Takayasu's disease.¹⁴⁰

Xanthomatous Hypophysitis

Xanthomatous hypophysitis, the least common primary pituitary inflammatory process, occurs at equal frequency in both sexes and consists of lipid-laden macrophages resembling postinfectious cell debris. MRI often reveals a highly cystic lesion, leading to the suggestion that this entity reflects an inflammatory response to a damaged or ruptured pituitary cyst.¹⁴¹

Hemorrhage and Infarction

Intrapituitary hemorrhage and infarction is usually caused by ischemic damage to the hypophyseal-portal system and can be catastrophic. These acute events cause significant damage to the pituitary gland, and small, clinically silent microinfarcts are found in up to 5% of unselected autopsies. Pituitary cells are relatively resilient to vascular insult, and pituitary insufficiency is clinically apparent only after approximately 75% of the gland is chemically damaged. Ten percent residual functional pituitary cell mass appears sufficient to mask complete pituitary failure. Ischemic damage is limited to the anterior lobe, and posterior pituitary function usually remains intact, reflecting the predominant neural control of oxytocin and ADH secretion. Acute intrapituitary hemorrhage can cause significant life-threatening damage to the pituitary and its surrounding vital structures.¹²

Postpartum Pituitary Infarction

During pregnancy, the pituitary gland normally enlarges in response to estrogen stimulation. The hypervascular gland is particularly vulnerable to arterial pressure changes and prone to hemorrhage. Sheehan's syndrome, classically described after severe postpartum hemorrhage, is less commonly encountered since the advent of modern obstetric care,¹⁴² but it occurs much more frequently in developing countries.¹⁴³ The presentation varies from the development of hypovolemic shock resulting in adenohypophyseal vessel vasospasm and pituitary necrosis¹⁴⁴ to the gradual onset of partial to complete pituitary insufficiency over months to years. Most prominent among the symptoms are inability to nurse and postpartum amenorrhea.¹⁴³ Pituitary autoimmunity has been implicated in gland failure after postpartum hemorrhage.¹⁴⁵

Pituitary Apoplexy

Pituitary apoplexy may result from spontaneous hemorrhage into a pituitary adenoma (pituitary tumor apoplexy), or it may occur after head trauma or skull base fracture or in association with hypertension and diabetes mellitus, sickle cell anemia, or acute hypovolemic shock.¹⁴⁶ Precipitating factors include major surgery, pregnancy, gamma knife irradiation, anticoagulant therapy, coagulopathy secondary to liver failure,¹⁴⁷ and administration of thyrotropin-releasing hormone (TRH), gonadotropin-releasing hormone (GnRH) agonists, bromocriptine, or cabergoline.¹⁴⁸⁻¹⁵⁰

Clinical Features. Pituitary apoplexy is often an endocrine emergency.¹³ The condition may evolve over 1 to 2 days, and patients usually present with severe headache and ocular palsies or visual field defects. Cardiovascular collapse, change in consciousness, neck stiffness, and sometimes hypoglycemia may occur. Acute adrenal insufficiency is a frequent occurrence caused by loss of ACTH; it may also be superimposed as a result of disordered intravascular clotting disorders, heparin administration, or acute effects of CNS hemorrhage. Pituitary imaging without contrast (CT or MRI) usually reveals signs of intrapituitary or intra-adenoma hemorrhage, stalk deviation, and compression of normal pituitary tissue, as well as signs of parasellar hemorrhage in severe cases.¹⁵¹ In a study of 13 consecutive patients with pituitary apoplexy, the baseline serum cortisol level was lower than 5 µg/dL in 7, between 5 and 15 µg/dL in 4, and higher than 15 µg/dL in 2 patients. Five patients also had low levels of thyroxine (T₄), and all 13 had evidence of gonadal dysfunction. Therefore, these patients with underlying pituitary tumors most likely had

Data from Bills DC, Meyer FB, Laws ER Jr, et al. A retrospective analysis of pituitary apoplexy. *Neurosurgery*. 1993;33:602-608; discussion 608-609; Randeva HS. 1999. *Classical pituitary apoplexy: clinical features, management and outcome*. Randeva HS, Schoebel J, Byrne J, et al. *Clin Endocrinol (Oxf)*. 1999 Aug;51(2):181-188; Lubina A, Olchovsky D, Berezin M, et al. Management of pituitary apoplexy: clinical experience with 40 patients. *Acta Neurochir (Wien)*. 2005;147:151-157; discussion 157.

preexisting pituitary insufficiency.¹⁵² Apoplexy, like Sheehan's syndrome, is one of the few pituitary tumor presentations in which hyperprolactinemia is not a feature (unless the infarction occurs within a prolactinoma). Patient characteristics, signs and symptoms, and outcomes of 112 patients in three series are shown in Table 9-7.¹³

Management. Patients with visual field compromise require emergency transsphenoidal surgery. Others may recover spontaneously but may develop long-term pituitary insufficiency. Patients who are fully alert and conscious with no visual symptoms may be observed. The decision to initiate therapy with high-dose glucocorticoids depends on the clinical status,¹² but the high incidence of adrenal dysfunction either before or after treatment indicates a need for replacement or stress doses of cortisone in most cases.

Ophthalmoplegia, which is common, may resolve spontaneously over time.¹² Postoperative recovery of visual function correlates inversely with the time elapsed since the acute hemorrhage.¹⁵³ Cranial nerve palsies, however, often improve regardless of whether surgery is undertaken. Pituitary function does not commonly recover after resolution of the acute hemorrhage, and patients require adrenal, thyroid, and/or gonadal steroid hormone replacement.¹⁵⁴ The subsequent atrophy of infarcted pituitary tissue often results in development of a complete or partially empty sella evident on MRI.

Pituitary Adenomas

Pathogenesis

Pituitary tumors account for about 15% of all intracranial neoplasms and are commonly encountered at autopsy. The

Brain Tumor Registry of Japan reported that 15.8% of 28,424 cases were histologically confirmed pituitary adenomas.^{155,156} The prevalence of pituitary tumors in Belgium was 1 in 1064 inhabitants,¹⁵⁷ and in Banbury, United Kingdom, 63 pituitary tumors were noted among 89,334 inhabitants (i.e., a population prevalence of about 77 cases per 100,000). Of these, 57% were prolactinomas, 28% were nonfunctioning adenomas, 11% were GH-secreting adenomas, and 2% were Cushing's adenomas. The median age at onset was 37 years, but nonfunctioning tumors were most commonly encountered in patients older than 60 years of age.¹⁵⁸

These benign monoclonal adenomas may express and secrete hormones autonomously, leading to hyperprolactinemia, acromegaly, Cushing's disease, and hyperthyroidism, or they may be functionally silent and initially diagnosed as a sellar mass. Although they are almost invariably benign, the neoplastic features of these adenomas represent a unique tumor biology that is reflected in their important local and systemic manifestations. These neoplasms have a slow doubling time and rarely resolve spontaneously. Nevertheless, they can be aggressive and locally invasive or compressive to vital central structures (Fig. 9-15). Pituitary adenomas usually express a single gene product; polyhormonal expression may reflect a primitive stem cell or mature bimorphous cellular origin.

Pituitary Trophic Activity

Benign Adenomas. Several transgenic animal models have been described in which pituitary growth factors or genes were overexpressed or deleted to recapitulate both functional and nonfunctional pituitary adenomas (Table 9-8). Benign human monoclonal pituitary adenomas arise from differentiated pituitary cells (see Fig. 9-2). The pituitary gland responds to central and peripheral signals that regulate both hormone production and cell proliferation. For example, during pregnancy, hypothalamic and peripheral hormones act to regulate pituitary trophic activity, resulting in increased pituitary volume, whereas prolonged target gland failure (e.g., hypothyroidism) causes pituitary hyperplasia. There is, however, no compelling direct evidence in humans that pituitary hyperplasia is a prerequisite for tumor development. Therefore, lactotroph hyperplasia occurring with pregnancy and lactation does not result in increased frequency of prolactinomas. Oral contraception use is also not associated with pituitary adenoma development, and somatotroph hyperplasia caused by ectopic GHRH production¹⁵⁹ is not commonly associated with true adenoma formation. Adenohypophyseal tissue surrounding pituitary tumors is usually not hyperplastic, supporting the notion that hypothalamic hormones, pituitary growth factors, and sex steroid hormones enable a permissive environment that potentiates cell mutation and subsequent tumor growth. Pituitary trophic signals may enhance or restrain expansion of a monoclonal tumor cell population by regulating the intrapituitary milieu.¹⁶⁰

Malignant Pituitary Tumors. Very rarely, pituitary tumors metastasize either outside the CNS or as a separate focus within the brain.¹⁶¹ Because no cell markers clearly distinguish aggressive invasiveness from malignancy, demonstration of extracranial metastasis is a prerequisite for the diagnosis of pituitary malignancy. When they occur, these cancers most often secrete either ACTH or PRL.

RAS family mutations are rare in pituitary adenomas. HRAS gene mutations have been identified in invasive prolactinoma¹⁶² and in distant metastatic pituitary

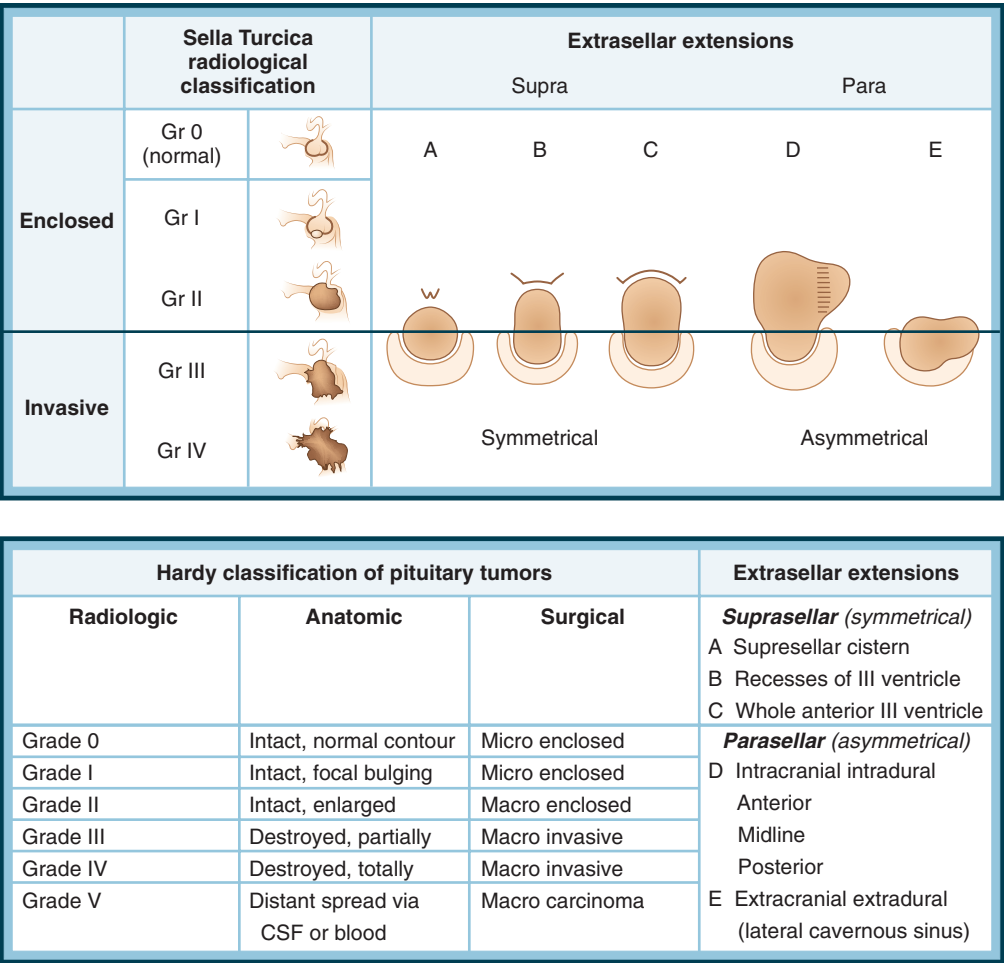

Figure 9-15 Classification of pituitary tumors. CSF, cerebrospinal fluid; Gr, grade. (Adapted from Thapar K, Laws ER. Growth hormone-secreting pituitary tumors: operative management. In: Krisht AF, Tindall GT, eds. *Pituitary Disorders*. Philadelphia: Lippincott Williams & Wilkins; 1999:243-258; and Asa SL. Tumors of the pituitary gland: pituitary adenomas. In: *Atlas of Tumor Pathology*, series 3, vol 22. Washington, DC: Armed Forces Institute of Pathology; 1998:51.)

carcinomas, but not in their respective primary pituitary tumors, nor in noninvasive adenomas.^{163,164} Therefore, *RAS* genetic alterations may be important in the very rare progression to metastatic formation and growth.

Hormonal Factors. Hypothalamic factors may have a specific role in the pathogenesis of pituitary tumors, in addition to regulating pituitary hormone gene expression and secretion (Table 9-9). Ectopic GHRH-secreting tumors (bronchial carcinoids, pancreatic islet-cell tumors, and small-cell lung carcinomas) result in GH hypersecretion, acromegaly, somatotroph hyperplasia, and, rarely, somatotroph adenoma formation.^{159,165} In transgenic mice overexpressing a GHRH transgene, the pituitary size increases dramatically due to somatotroph hyperplasia, and older mice develop GH-secreting adenomas.¹⁶⁶ However, adenomatous hormone secretion is usually independent of physiologic hypothalamic control, and the surgical resection of small, well-defined adenomas usually results in definitive cure of hormone hypersecretion. Such observations imply that these tumors do not arise because of excessive polyclonal pituitary cell proliferation resulting from generalized hypothalamic stimulation. However, hypothalamic factors may promote and maintain the growth of already transformed adenomatous pituitary cells.

Normal and hyperplastic pituitary tissues are polyclonal, and pituitary adenomas arise as the result of monoclonal

pituitary cell proliferation. X-chromosome inactivation analysis was used to confirm the monoclonal origin of GH-, PRL-,¹⁶⁷ and ACTH-secreting adenomas^{168,169} and nonfunctioning pituitary tumors in female patients heterozygous for variant alleles of the X-linked genes hypoxanthine phosphoribosyl transferase (*HPRT* or *CDC73*) and phosphoglycerate kinase (*PGK*). Therefore, an intrinsic somatic pituitary cell genetic alteration likely gives rise to clonal expansion of a single cell, resulting in adenoma formation (Table 9-10).

Genetic Factors. Activating mutations of the stimulatory G protein (*G_s*) are present in up to 40% of human GH-secreting adenomas.¹⁷⁰⁻¹⁷² These are somatic heterozygous activating point mutations of the portion of the *GNAS* complex locus that encodes the *G_s* α-subunit (*G_sα*) and involve either arginine 201 (replaced by cysteine or histidine) or glutamine 227 (replaced by arginine or leucine). These mutations constitutively activate the *G_sα* protein, resulting in the so-called *GSP* oncogene. This G-protein activation increases levels of cyclic adenosine monophosphate (cAMP) and activates protein kinase A, which in turn phosphorylates the cAMP response element-binding protein (CREB) and leads to sustained constitutive GH hypersecretion and cell proliferation.

GSP-bearing adenomas are smaller, have mildly lower GH levels and enhanced intratumoral cAMP, do not

TABLE 9-8

Transgenic Mouse Models for Pituitary Tumors

Genes	Hyperplasia/Adenoma*
Gene Overexpression[†]	
CMV.HMGA1	GH, PRL
CMV.HMGA2	GH, PRL
Ubiquitin C.hCG	PRL
α GSU.bLH	Pit1 lineage
GH.galanin	GH, PRL
PRL.galanin	PRL [‡]
PRL.TGF α	PRL
α GSU.PTTG1	LH, GH, TSH
α GSU.Prop1	Nonfunctioning
PRL.pdt-FGFR4	PRL
Gene Inactivation	
p27/Kip1 $-/-$	ACTH, α MSH
p18/INK4c $-/-$	ACTH, α MSH
Rb $+/-$	ACTH, α MSH
	α GSU, GH, β TSH
D2R-deficient	PRL
Men1 $+/-$	PRL
PRL $-/-$	Nonfunctioning

*Hormone immunoreactivity/secretory profile.

[†]Genes are listed in bold and are preceded by the promoter that determines transcriptional control.

[‡]Pituitary hyperplasia, with no tumor formation.

ACTH, adrenocorticotrophic hormone; bLH, bovine active luteinizing hormone; CMV, cytomegalovirus; D2R, dopamine 2 receptor; GH, growth hormone; α GSU, glycoprotein α -subunit; hCG, human chorionic gonadotropin; HMGA, high mobility group A; pdt-FGFR4, pituitary tumor-derived fibroblast growth factor receptor 4; Men1, multiple endocrine neoplasia type 1; MSH, melanocyte-stimulating hormone; p18/INK4c, cyclin-dependent kinase inhibitor 2C; p27/Kip1, cyclin-dependent kinase inhibitor 1B; PRL, prolactin; Prop1, prophet of Pit1 (paired-like homeodomain transcription factor); PTTG, pituitary tumor-transforming gene; Rb, retinoblastoma; TGF, transforming growth factor; TSH, thyroid-stimulating hormone.

(Modified from Melmed S. Pathogenesis of pituitary tumors. *Nat Rev Endocrinol*. 2011.)

respond briskly to GHRH, and are sensitive to the inhibitory effect of somatostatin.¹⁷³ *GSP* activating mutations do not occur in PRL-secreting and TSH-producing adenomas and are rarely present in nonfunctioning pituitary tumors and ACTH-secreting tumors (<10%). Similar early postzygotic somatic mutations in codon 201 of the gene encoding $G_s\alpha$ were identified in tissues derived from patients with McCune-Albright syndrome.¹⁷⁴ Transgenic mice overexpressing an inactive pituitary CREB mutant exhibited a dwarf phenotype and somatotroph hypoplasia.¹⁷⁵ Therefore, cAMP likely stimulates somatotroph proliferation mediated by CREB phosphorylation. This hypothesis was borne out by the observation that 15 human GH-secreting pituitary adenomas expressed elevated levels of phosphorylated CREB.¹⁷⁶ However, only four of these tumors also contained the mutant *GSP* oncogene, and CREB phosphorylation was also demonstrated in adenomas overexpressing wild-type $G_s\alpha$ protein, suggesting a trophic role of CREB independent of G-protein actions.

Other signaling pathways overexpressed in pituitary tumors include those for the serine/threonine kinase AKT and mitogen-activated protein kinase (MAPK).¹⁶⁰

Pituitary tumor-transforming gene (*PTTG*) was isolated from experimental pituitary tumors and shown to be highly abundant in all pituitary tumor types, especially prolactinomas.^{177,178} The PTTG protein, a mammalian

securin homologue, also induces production of fibroblast growth factor (FGF) and angiogenesis and is upregulated by estrogen.¹⁷⁹ PTTG overexpression may lead to dysregulated chromatid separation and cell aneuploidy,^{180,181} and pituitary-targeted *PTTG* transgene expression leads to functional adenomas secreting luteinizing hormone (LH), GH, or TSH.¹⁸² *PTTG* mutations have not been identified in pituitary tumors.

Mice with heterozygous inactivation of the retinoblastoma *Rb1* gene develop pituitary tumors with high penetrance, whereas mice with deregulated pituitary E2f transcription factor activity develop tissue hyperplasia without progression to tumor formation, most likely because sustained E2f activity ultimately triggers premature

TABLE 9-9

Factors Involved in Pituitary Tumor Pathogenesis

Hereditary
MEN1 Transcription factor defect (e.g., PROPI excess) Carney complex AIP mutations
Hypothalamic
Excess GHRH or CRH production Receptor activation Dopamine deprivation
Pituitary
Signal transduction mutations or constitutive activation (e.g., GSP, CREB, McCune-Albright syndrome) Disrupted paracrine growth factor or cytokine action (e.g., FGF2, FGF4, LIF, BMP, EGF) Activated oncogene or cell cycle disruption (e.g., PTTG; RAS; P27; HMG) Intrapituitary paracrine hypothalamic hormone action (e.g., GHRH, TRH) Loss of tumor suppressor gene function with LOH (11q13, 13, GADD45y)
Environmental
Estrogens Irradiation
Peripheral
Target failure (ovary, thyroid, adrenal) Ectopic hypothalamic hormone secretion
Evidence for an Intrinsic Pituitary Defect in the Pathogenesis of Pituitary Tumors
Pituitary adenomas are monoclonal. There is no hyperplasia surrounding the adenomas. Surgical resection of well-circumscribed small adenomas leads to control in ~75% of patients. Unrestrained pituitary hormonal hypersecretion persists independently of feedback regulation by elevated target hormones. Hormonal pulsatility pattern is often restored after adenoma resection.

AIP, aryl hydrocarbon receptor-interacting protein; BMP, bone morphogenetic protein; CREB, cyclic adenosine monophosphate response element-binding protein; CRH, corticotropin-releasing hormone; EGF, epidermal growth factor; FGF, fibroblast growth factor; GADD45y, growth arrest and DNA damage-inducible gamma gene; GHRH, growth hormone-releasing hormone; GSP, stimulatory G protein α -subunit oncogene; HMG, high mobility group; LIF, leukemia inhibitory factor; LOH, loss of heterozygosity; MEN1, multiple endocrine neoplasia type 1; P27, cyclin-dependent kinase inhibitor 1B; PROPI, prophet of Pit1 (paired-like homeodomain transcription factor); PTTG, pituitary tumor-transforming gene; RAS, RAS family of oncogenes; TRH, thyrotropin-releasing hormone.

TABLE 9-10

Selected Molecular Events Related to Human Pituitary Tumorigenesis

Protein or Gene	Tumor Type	Mechanism of Activation/Inactivation
Activating		
GSP	GH-secreting adenomas	Activating mutation
CREB	GH-secreting adenomas	Increased Ser-phosphorylated CREB promoted by GSP overexpression
Cyclin B2 (CCNB2)	All tumor types examined	Overexpression
Cyclin D1 (CCND1)	Nonfunctioning	Overexpression
EGF/EGFR	Nonfunctioning	Overexpression
PTTG	All tumor types examined	Overexpression
Gal-3	Prolactinomas	Overexpression
HMGA2	Nonfunctioning ACTH-secreting adenomas	Overexpression
FGF4	Prolactinomas	Overexpression
Inactivating		
RB1	Negative pRB in ~25% of GH-secreting adenomas	Promoter methylation
13q14	Aggressive tumors	13q14 loss of heterozygosity
AIP	15% of FIPA 2% of sporadic GH-secreting adenomas	Inactivating mutation
MEN1	Prolactinomas in familial MEN1	Inactivating mutation
P16INK4a (CDKN2A)	All tumor types examined	Promoter methylation
P27KIP1 (CDKN1B)	All tumor types examined	Reduced expression
MEG3a	Nonfunctioning GH-secreting adenomas	Promoter methylation
GADD45-γ	Nonfunctioning GH-secreting adenomas Prolactinomas	Promoter methylation

ACTH, adrenocorticotrophic hormone; FIPA, familial isolated pituitary adenomas; GH, growth hormone; MEN1, multiple endocrine neoplasia type 1; pRB, retinoblastoma protein.

(Reproduced from Donangelo I, Melmed S. Molecular pathogenesis of pituitary tumors. In Oxford Textbook of Endocrinology and Diabetes. Wass J, Stewart P [eds]. 2010.)

senescence in an Rb-, p16-, and p19-dependent manner.¹⁸³ Loss of heterozygosity (LOH) in chromosomes 11q13, 13, and 9 is present in about 15% of spontaneous pituitary adenomas in humans, often correlating with tumor size and invasiveness. Although highly invasive pituitary tumors and pituitary metastases exhibit LOH in region 13q14 (the *RB1* locus), no distinct tumor suppressor gene has been identified for sporadic pituitary tumors,¹⁸⁴ suggesting that another suppressor gene may be located adjacent to the *RB1* locus. Nevertheless, approximately 25% of GH-secreting adenomas do exhibit loss of RB expression, most likely associated with promoter hypermethylation.¹⁸⁵ *TP53* gene mutations have not been detected in pituitary adenomas, nor in pituitary carcinomas or their metastases.¹⁶⁴

Cyclin D1, D2, and D3 are upregulated when quiescent cells (G_0 phase) enter the proliferative cell cycle, and

complexes of cyclin with cyclin-dependent kinase (CDK) lead to RB phosphorylation, releasing E2F to promote cell cycle progression. Allelic imbalance at the *CCND1* locus encoding cyclin D1 is frequently observed in invasive, non-functioning pituitary adenomas.¹⁸⁶ The CDK4 and CDK6 inhibitor p16INK4a, encoded by the *CDKN2A* gene, maintains RB in the unphosphorylated state. In nonfunctioning pituitary tumors, the p16INK4a promoter is hypermethylated and consequently not expressed; less frequently, the *CDKN2B* gene, which encodes p15INK4b, is also silenced. Mice that are deficient in p18INK4c develop features of gigantism with intermediate-lobe pituitary hyperplasia and tumors.¹⁸⁷ When the CDK1 and CDK2 inhibitor, p27Kip1 (CDKN1B), is knocked out in mice, multiorgan hyperplasia occurs with development of intermediate-lobe propiomelanocortin-secreting POMC-cell pituitary tumors.¹⁸⁸

Basic FGF (FGF2) is abundantly expressed in the pituitary, and pituitary expression of PTTG and FGF2 is increased in a time- and dose-dependent manner in estrogen-treated rats.¹⁷⁹ A truncated FGF receptor isoform is expressed in prolactinomas and induces PRL secretion from normal and pituitary adenoma cells.¹⁸⁹ Human prolactinomas express FGF4, and transfected FGF4 enhances PRL secretion and tumor vascularity.¹⁹⁰

Epidermal growth factor (EGF) exhibits potent mitogenic activity in pituitary cells, and both EGF and its receptor, EGFR, are overexpressed in pituitary tumors, particularly in nonfunctioning adenomas. Both of the receptors ERBB2 and ERBB3 are expressed in aggressive, recurrent prolactinomas.¹⁹¹ Gefitinib, the EGFR antagonist, decreases experimental prolactinoma cell proliferation and PRL secretion in vitro and in vivo and is associated with abrogated EGFR/ERK signaling.¹⁹² Whether ERBB receptors participate in pituitary tumor cell transformation is unclear.

The growth arrest and DNA damage-inducible protein γ (GADD45G), a tumor growth suppressor, is absent in most pituitary adenomas, as well as in immortalized pituitary cell lines. Pituitary tumor GADD45-γ silencing probably occurs through methylation of CpG islands in the gene promoter.¹⁷¹ An isoform of maternally expressed gene 3 containing an extra exon (*MEG3A*) is undetectable in both nonfunctioning and GH-secreting pituitary adenomas, conferring a tumor growth advantage, probably as a result of hypermethylation of the promoter region.¹⁹³

Transgenic overexpression of the high mobility group genes *HMGA1* and *HMGA2* causes murine GH-secreting adenomas and prolactinomas, whereas trisomy of chromosome 12, the locus for *HMGA2*, is frequently encountered in human PRL-secreting pituitary adenomas. *HMGA2* was overexpressed in 38 (39%) of 98 pituitary adenomas, in 15 (68%) of 22 adenomas secreting follicle-stimulating hormone (FSH) and/or LH, in 5 (31%) of 15 prolactinomas, and in 12 (67%) of 18 ACTH-secreting adenomas, but it was rarely detected in GH-secreting adenomas.¹⁹⁴ *HMGA2* levels correlated with tumor size, invasiveness, and proliferation markers. *HMGA2* tumorigenic effects may also be mediated by induction of cyclin B2 expression¹⁹⁵ and activation of the E2F pathway. *HMGA2* is suppressed by *Let-7* (*MIRLET7A1*) microRNA, and expressions of *HMGA2* and *Let-7* are inversely correlated in human pituitary adenoma samples.¹⁹⁴

Pituitary Senescence

Cellular senescence, or cell growth arrest, is induced by age-linked telomere shortening, DNA damage, oxidative stress, chemotherapy, and oncogene activation.

Oncogene-induced premature cell cycle arrest is protective of the cellular response to oncogenic events, is largely irreversible, and is mediated through upregulation of cell cycle inhibitors including p16INK4a, p15INK4b, p21Cip1 (CDKN1A), and TP53. p21CIP1 induction and senescence markers were elevated in all of 38 GH-secreting adenomas tested. In contrast, p21 was undetectable in GH-producing pituitary carcinomas, nonsecreting pituitary oncocytomas, and null cell adenomas.¹⁹⁶ Activity of senescence-associated β -galactosidase (SA- β -gal), a marker of senescence, is also strongly positive in GH-secreting adenomas (Fig. 9-16). Cellular senescence is protective for malignant transformation,¹⁹⁷ and this process may underlie the invariably benign nature of pituitary adenomas.

Familial Syndromes

The rare familial syndromes are summarized in Table 9-11.

Multiple Endocrine Neoplasia Type 1

Multiple endocrine neoplasia type 1 (MEN1) is an autosomal dominant hereditary disorder that is characterized by tumor formation or hyperfunction of parathyroid, pancreatic islets, anterior pituitary, and, less commonly, carcinoid, thyroid, and adrenal tumors.^{198,199} The MEN1 syndrome (fully described in Chapter 41) is associated with germ cell inactivation of the *MEN1* gene (also called *MENIN*) located on chromosome 11q13.²⁰⁰ Unlike pituitary tumors comprising the MEN1 syndrome, *MEN1* gene mutations were not identified in non-MEN1 familial pituitary adenomas.²⁰¹ Mutations of other genes may also confer an MEN1 clinical syndrome. Approximately 20% of patients with a clinical diagnosis of MEN1 do not exhibit identifiable *MEN1* mutations. Rarely, the gene for p27Kip1 (*CDKN1B*) is mutated in patients with clinical features of MEN1 but with no *MEN1* mutations.²⁰²

Familial Isolated Pituitary Adenomas

Fewer than 5% of prolactinomas and GH-secreting tumors are inherited on a familial basis.²⁰³ In familial acromegaly, about 25% of afflicted individuals are diagnosed as

teenagers or young adults, usually with gigantism. These patients have been linked to LOH at the 11q13.1-11q13.3 locus.²⁰⁴ Germline mutations of the gene encoding aryl hydrocarbon receptor-interacting protein (AIP) were found to predispose to familial pituitary tumors.^{205,206} Eleven of 73 families with familial isolated pituitary adenomas were found to have 10 germline aryl hydrocarbon receptor-interacting protein (*AIP*) gene mutations associated with GH- and PRL-secreting tumors,^{207,208} and one *AIP* mutation was found in 41 patients with sporadic tumors.²⁰⁹

Carney Complex

Carney complex is an autosomal dominant disorder comprising benign mesenchymal tumors including cardiac myxomas, schwannomas, and thyroid and pituitary adenomas associated with spotty skin pigmentation.²¹⁰ The disorder has been mapped to chromosome 17q24 and results from a mutated type 1 α regulatory subunit of the cAMP-dependent protein kinase A (*PRKARIA*).²¹¹ These patients may have elevated levels of GH, IGF1, or PRL, and 10% exhibit clinical acromegaly with GH-secreting tumor formation associated with inactivating mutations of *PRKARIA*, leading to constitutive protein kinase A catalytic subunit activation. In some patients, the wild-type *PRKARIA* allele is retained in tumor tissue, and haploinsufficiency may be sufficient for tumorigenesis.

McCune-Albright Syndrome

McCune-Albright syndrome is discussed in detail later in this chapter. In summary, multifactorial mechanisms subserve the multistep pathogenetic process of pituitary adenoma formation, including early initiation of chromosomal mutations that result in mutated pituitary stem or progenitor cells (see Table 9-9). The transformed pituitary cell is subjected to signals facilitating clonal expansion. Permissive factors including hypothalamic hormone receptor signals, intrapituitary growth factors, and disordered cell cycle regulation may determine the ultimate biologic fate of the tumor. Autonomous anterior pituitary hormone production and secretion and cell proliferation, which are the hallmarks of pituitary adenomas, result. However, proximal subcellular events initiating the formation of

TABLE 9-11

Genetic Syndromes Involving Pituitary Tumors

Syndrome	Clinical Features	Chromosome Location	Gene	Protein	Proposed Function
Multiple endocrine neoplasia type I (MEN1)	Parathyroid, endocrine pancreas, and pituitary (mostly prolactinomas) tumors	11q13	<i>MEN1</i>	MEN1	Nuclear tumor suppressor protein; interacts with JunD and TGFB
Carney syndrome	Skin and cardiac myxomas, adrenal Cushing's syndrome, GH-secreting adenomas	17q24 and 2p16	<i>PRKARIA</i> and ?	PRKARIA, the regulatory subunit isoform 1A of PKA	Tumor suppressor; inactivating <i>PRKARIA</i> mutation results in constitutive activation of PKA catalytic subunit
Familial isolated pituitary adenomas (FIPA)	Two or more members in a family harboring anterior pituitary tumors without evidence of MEN1 or Carney complex	11q13	<i>AIP</i>	AIP	Cytoplasmic tumor suppressor protein; binds to AHR transcription factor
McCune-Albright syndrome	Polyostotic fibrous dysplasia, large café-au-lait spots, precocious puberty, GH excess (may be due to GH-secreting adenomas)	20q13	<i>GNAS1</i>	Gs α	Signal transduction activation; constitutive Gs α activation results in elevated cAMP independent of GHRH

AHR, aryl hydrocarbon receptor; AIP, aryl hydrocarbon receptor-interacting protein; cAMP, cyclic adenosine monophosphate; GH, growth hormone; GHRH, growth hormone-releasing hormone; GNAS, stimulatory G protein α -subunit; PKA, protein kinase A; PRKARIA, cAMP-dependent protein kinase type 1 α regulatory subunit; TGFB, transforming growth factor- β .

most sporadic pituitary adenomas have not yet been elucidated.¹⁵⁶

CLASSIFICATION OF PITUITARY TUMORS

Pituitary tumors arise from hormone-secreting adenohypophyseal cells, and their secretory products depend on the cell of origin (Table 9-12). Previously clinically inapparent pituitary adenomas are found in about 11% of autopsies (Table 9-13). They localize to unique areas of the gland, reflecting relative cell type abundance and intragland distribution (see Fig. 9-2). Although 46% of a subset of these lesions immunostain for PRL,²¹² expectant management may still be indicated.²¹³ In a study of 100 normal volunteers, 10 were found to have focal abnormalities on MRI consistent with microadenomas; the lesions measured from 3 to 6 mm in diameter.^{6,214,215} Such tumors have been called *incidentalomas*. In a survey of incidentalomas in 506 patients, 20% were found to be nonfunctioning; of these, 20% increased in size during a mean follow-up period of 50 months.²¹⁵ When larger, particularly nonfunctioning, tumors are encountered inadvertently, pituitary function should be assessed, including measurements of PRL, IGF1, LH, FSH, and sex steroids. A 24-hour urinary free cortisol or salivary cortisol concentration may help exclude Cushing's disease.²¹⁶ In a study of 52 macroadenomas incidentally discovered by CT or MRI, 22 were gonadotroph cell adenomas, 21 were null cell adenomas, and 9 were clinically nonfunctioning but immunostained for various pituitary hormones.²¹⁷ Radiologic and surgical classifications are based on tumor localization, size, and degree of invasiveness (see Fig. 9-15). Microadenomas are intrasellar and usually less than 10 mm in widest diameter. Macroadenomas are 10 mm or larger and usually impinge upon adjacent sellar structures.

Specific tumor types for each respective cell type are considered in the following sections. Immunocytochemistry detects pituitary cell gene products at both the light and electron microscopic level and allows classification of pituitary tumors based on their function. Unlike the corticotroph, somatotroph, lactotroph, and thyrotroph cell tumors which hypersecrete their respective hormones,²¹⁸ gonadotroph cell tumors are usually clinically silent and do not efficiently secrete their gene products.²¹⁹ Double immunostaining identifies mixed tumors expressing combinations of hormones; these are often macroadenomas secreting GH concomitantly with PRL or TSH or ACTH. In general, immunohistochemical identification of pituitary hormones correlates with tumor-specific messenger RNA (mRNA) markers measured either in whole tissue extracts by Northern analysis or at the single cell level by in situ hybridization techniques.²²⁰ With the exception of the glycoprotein α -subunit, immunohistochemical positivity in greater than 5% of cells comprising the tumor is usually reflective of peripheral circulating hormone levels.

Quantification of immunostaining intensity is subjective, and a scale of intensity should also include a description of the extent of staining, such as whether staining was occasional and scattered or whether most tumor cells expressed the immunodetectable protein. Electron microscopy is useful for assessing the ultrastructure of hormone secretory granules, their size, and their distribution. Other subcellular features important for diagnosis include visualization of large mitochondria in nonfunctioning oncocytomas and the secretory nature of Golgi and endoplasmic

reticulum, especially for prolactinomas. Peroxidase or colloid gold particles of different diameters are also sensitive electron microscopic markers for identifying and localizing intracellular hormone signals. Because even invasive pituitary tumors are slow growing, the use of mitotic markers such as proliferating cell nuclear antigen (PCNA) and Ki-67 is of limited utility.²²¹

PROLACTIN-SECRETING ADENOMAS

Prolactinomas are the most frequently encountered secretory pituitary tumor, occurring with an annual incidence of approximately 30 per 100,000 persons.¹⁵⁸ This incidence would be much higher if the estimate included microadenomas, discovered in approximately 11% of pituitaries at autopsy, 46% of which immunostain positively for PRL.²¹⁵ The female-to-male ratio for microprolactinomas is 20:1, whereas for macroadenomas it is roughly 1:1. PRL levels and tumor size usually remain stable, although in some patients the PRL level falls over time. Microadenomas may disappear after discontinuation of dopamine agonist therapy, but 7% to 14% of microadenomas continue to grow.²²²

Macroprolactinomas have a greater propensity to grow, and tumor size correlates with serum PRL levels (Fig. 9-17), so that a PRL level of greater than 200 ng/mL is strongly indicative of a PRL-secreting pituitary tumor. Although prolactinomas account for more than 75% of all female pituitary adenomas,¹⁵⁸ men tend to harbor larger tumors. Among 45 men and 51 women with prolactinomas, the mean serum PRL levels were 2789 ± 572 ng/mL and 292 ± 74 ng/mL, respectively. Tumor size was larger in men than in women (26 ± 2 mm versus 10 ± 1 mm), and the tumors were more invasive and showed histologic evidence of more rapid growth.²²³

PRL levels greater than 200 ng/mL are not always indicative of a prolactinoma and may reflect use of a drug such as Risperdal, whereas levels greater than 500 ng/mL are exclusively observed in patients with prolactinomas.²²⁴ In contrast, a PRL concentration of less than 200 ng/mL in a patient harboring a macroadenoma indicates that the tumor is probably not producing PRL; hyperprolactinemia occurs as a result of mass pressure on the pituitary stalk or portal circulation, which most likely interrupts inhibitory control by dopamine.²²⁵ Importantly, microprolactinomas can be associated with PRL levels ranging from minimal elevations to hundreds of nanograms per milliliter. However, when a patient with a small macroadenoma and a PRL level of approximately 200 ng/mL is first encountered, it is prudent to first treat medically. If the tumor is indeed a prolactinoma, dopamine agonist treatment should lower PRL levels and shrink the tumor. If the tumor does not shrink, the mass is probably not secretory, and hyperprolactinoma is caused by compressive stalk effect.

Pathology and Pathogenesis

Although more than 99% of prolactinomas are benign and are often sharply demarcated without evidence of invasion, about half invade local structures (Fig. 9-18).²²⁶ Invasive tumors may have higher mitotic activity and are more cellular and more pleomorphic than noninvasive types. Invasion into adjacent dura, bone, or venous structures may represent an intermediate form of prolactinoma between the sharply demarcated benign variety and the exceedingly rare malignant tumor. Invasive tumors that do not metastasize are considered benign.²²⁷ Immunostaining for PRL

TABLE 9-12

Clinical and Pathologic Characteristics of Pituitary Adenomas

Adenoma Type	Incidence			Prevalence (Total Cases/10 ⁶)	Messenger RNA Expression	Immunohistochemistry	Electron Microscopic Secretory Granules (nm)	Clinical Syndrome
	Pathologic (%)	Clinical (%)	Annual Incidence (New Cases/10 ⁶)					
Lactotroph				60-100				
Sparsely granulated	28	29	6-10		PRL	PRL	150-500	Hypogonadism, galactorrhea
Densely granulated	1				PRL	PRL	400-1200

Modified from Molitch ME. Pituitary incidentalomas. In: de Herder WW, ed. *Functional and Morphological Imaging of the Endocrine System*. Norwell, MA: Kluwer Academic; 2000:59-70; and Buurman H, Saeger W. Subclinical adenomas in postmortem pituitaries: classification and correlations to clinical data. *Eur J Endocrinol*. 2006;154:753-758.

confirms the diagnosis of prolactinoma; the lesion is usually distinct from the adjacent normal pituitary, but it is not truly encapsulated. These tumors have a “pseudocapsule” composed of compressed adenohypophyseal cells and a reticulin fiber network.²²⁷ For a prolactinoma to be considered malignant, a distant extracranial metastasis must be demonstrated.²²⁸

Figure 9-17 Prolactin (PRL)-secreting tumors are more often macroadenomas in men ($n = 31$) than in women ($n = 45$). Serum PRL levels highly correlate with tumor size. (Adapted from Danila DC, Klibanski A. Prolactin-secreting pituitary tumors in men. *The Endocrinologist*. 2001;11:105-111.)

Figure 9-18 **A**, Resected prolactinoma tissue with no dopamine agonist pretreatment. **B**, Prolactin-producing pituitary adenoma removed by surgery from a patient treated with dopamine agonist in the preoperative period. The adenoma cells are small, possessing dark nuclei and a narrow rim of cytoplasm. Mild accumulation of interstitial connective tissue is apparent. (Hematoxylin-eosin stain; original magnification $\times 400$.) (Photomicrograph kindly provided by Kalman Kovacs, University of Toronto, Toronto, Canada.)

Prolactinomas are mostly slow growing, arise sporadically, usually occur singly, and are monoclonal.¹⁶⁷ Infrequently, more than one prolactinoma arises within the gland.²²⁹ Prolactinomas are the pituitary tumors most commonly associated with MEN1, occurring in approximately 20% of one large kindred,²³⁰ although prolactinoma occurrence is not evenly distributed. Familial prolactinomas have been described in patients with no other features of MEN1.²³¹

Clinical Features

Prolactinomas usually come to attention because of symptoms or signs associated with either hyperprolactinemia or tumor size or invasiveness (Table 9-14).

Hyperprolactinemia

Both large and small PRL-secreting tumors can manifest with signs and symptoms of hyperprolactinemia. Menstrual irregularities, sexual dysfunction, galactorrhea,²³² and osteopenia²³³ are attributable to elevated PRL levels. Elevated PRL causes sexual dysfunction via a short-loop feedback effect on gonadotropin pulsatility that presumably inhibits GnRH²³⁴ as well as LH pulse frequency and amplitude. High PRL also directly inhibits ovarian and testicular function. Women with prolactinomas may present with primary or secondary amenorrhea, oligomenorrhea, menorrhagia, delayed menarche, or regular menses with a short

TABLE 9-14

Signs and Symptoms of Prolactinomas

Signs and Symptoms Associated with Tumor Mass	Signs and Symptoms Associated with Hyperprolactinemia
Visual field abnormalities	Amenorrhea, oligomenorrhea, infertility
Blurred vision or decreased visual acuity	Decreased libido, impotence, premature ejaculation, erectile dysfunction, oligospermia
Symptoms of hypopituitarism	Galactorrhea
Headaches	Osteoporosis
Cranial nerve palsies	
Pituitary apoplexy	
Seizures (temporal lobe)	
Hydrocephalus (rare)	
Unilateral exophthalmos (rare)	

luteal phase that may result in infertility. Patients may also report changes in libido and vaginal dryness. Sexual dysfunction in men usually manifests as loss or decrease in libido, impotence, premature ejaculation or intracoital erection loss, oligospermia, or azospermia.²³⁵

Up to 50% of women and 35% of men with prolactinomas have galactorrhea.²³⁶ This gender difference may occur because male mammary tissue is less susceptible to lactogenic effects of hyperprolactinemia.²³⁷ Galactorrhea can be overlooked unless actively elicited. Bone density may decrease in both men and women as a result of hyperprolactinemia-induced sex steroid deficiency.²³⁸

Tumor Mass Effects

Prolactinomas may manifest with signs and symptoms resulting from tumor size or invasiveness. Microadenomas range from entirely asymptomatic tumors found at autopsy that are as small as 2 to 3 mm to larger ones that are still less than 10 mm in diameter. These tumors can be invasive despite their small size. In contrast, macroadenomas range in size from noninvasive or diffuse tumors approximately 1 cm in diameter to huge tumors that may impinge on parasellar structures.

Signs and symptoms caused by large or invasive tumors are often related to compressive effects on visual structures. The most frequent ophthalmic complaint in a series of 1000 patients with tumors was loss of vision.²³⁹ The most frequent objective findings were bitemporal hemianopsia, superior bitemporal defects, and decreased visual acuity. Headaches are common, but seizures (a result of extension into the temporal lobe) and hydrocephalus²⁴⁰ are rare, as is unilateral exophthalmos. Many tumors invade the cavernous sinuses, yet cranial nerve palsies are only rarely encountered. A sudden insult, such as pituitary apoplexy, is the more common cause of such palsies and may be a presenting symptom. Prolactinomas can also be found inadvertently on an MRI or CT scan performed for another purpose.

Evaluation

All patients with pituitary tumors should have serum PRL levels measured. Conversely, patients with elevated serum PRL levels not fully explicable by an obvious cause (such as pregnancy or exposure to neuroleptic medications) should be evaluated for the presence of a pituitary tumor. Prolactinomas may also coexist with another cause of hyperprolactinemia, such as neuroleptic drug administration (see

Chapter 8).²⁴³ Even minimal to moderate PRL elevations are important to investigate, because they may indicate the presence of a large pituitary tumor that does not secrete PRL. PRL levels correlate strongly with tumor size and are usually higher in male patients. Occasionally, a patient with a very high serum PRL level can have a “normal” result reported if serum dilutions are not assayed—a phenomenon called the high-dose hook effect.²⁴¹ In contrast, serum PRL may be elevated by the presence of high-molecular-weight PRL, which is a weaker lactogen than the monomeric PRL molecule.

Although they are usually clinically inactive, pituitary tumors also can result in macroprolactinemia. Pituitary adenomas were diagnosed in approximately 20% of patients with macroprolactinemia, and some were associated with galactorrhea, oligomenorrhea or amenorrhea, or erectile dysfunction and decreased libido.²⁴² Therefore, assessment of macroprolactinemia by polyethylene glycol precipitation should be performed in patients with reported high levels of PRL and few or absent clinical features of hyperprolactinemia.²⁴³

A careful history often unmasks symptoms or signs of a space-related mass, such as visual field abnormalities, impaired visual acuity, blurred or double vision, CSF rhinorrhea, headaches, diabetes insipidus, rare hydrocephalus,²⁴⁰ and hypopituitarism. Patients should also be questioned carefully about their sexual history, including onset of menarche, regularity of menses, fertility, libido, potency, and ability to maintain an erection. A history of galactorrhea should also be ascertained. The coexistence of galactorrhea and amenorrhea suggests a diagnosis of pituitary adenoma until otherwise proven.

PRL is elevated in up to 50% of patients with acromegaly.²³² Patients in the early stages of acromegaly and those who have mild disease or harbor acidophil stem cell adenomas may have few obvious signs of GH excess. Because the human GH molecule exhibits lactogenic properties similar to those of PRL,²⁴⁴ signs and symptoms of a prolactinoma may be mimicked by a purely GH-secreting tumor, and serum IGF1 should be measured. Elevated PRL levels are occasionally encountered in patients with TSH-secreting tumors. Other pituitary hormone functions should be ascertained to determine the presence of hypopituitarism. An MRI is required to establish a definitive diagnosis of prolactinoma.

Treatment

Optimal treatment outcomes for a prolactinoma include normalization of PRL levels (and associated signs and symptoms) and complete tumor removal or shrinkage with a reversal of tumor-mass effects (Table 9-15). Specifically, previously abnormal sexual function and fertility should be restored, galactorrhea stopped, impaired bone density improved, tumor eliminated or reduced in size without impairing pituitary or hypothalamic function, and vision normalized, if impaired.²⁴⁵

Medical Treatment

Medical management of prolactinomas with dopamine agonist drugs has been widely recommended as the treatment of choice.

Bromocriptine. Bromocriptine, a semisynthetic ergot alkaloid dopamine agonist, lowers elevated PRL levels, restores abnormal menstrual function in 80% to 90% of patients,²⁴⁶ shrinks prolactinomas, restores impaired sexual function, and improves galactorrhea.²⁴⁷ Improvement in

TABLE 9-15

Dopamine Agonist Treatment of Prolactinomas (% of Patients)*

Outcome	Bromocriptine (2.5-7.5 mg/day)	Cabergoline (0.5-1 mg twice weekly)
Microadenomas		
PRL normalized	70	80
Menses resumed	70	80
Macroadenomas		
PRL normalized	65	70
Menses resumed	85	80
Tumor shrinkage:		
None	20	20
≤50%	40	55
≥50%	40	25
Visual field improvement	90	70
Drug intolerance	15	5

*Long-acting cabergoline has improved patient compliance and fewer gastrointestinal side effects. For fertility, bromocriptine is preferred because it is short-acting and can be discontinued immediately on pregnancy confirmation.

PRL, prolactin.

Values derived from Webster J, Piscatelli G, Polli A, et al. A comparison of cabergoline and bromocriptine in the treatment hyperprolactinemic amenorrhea. Cabergoline Comparative Study Group. *N Engl J Med*. 1994;331:904-909; and Verhelst J, Abs R, Maiter D, et al. Cabergoline in the treatment of hyperprolactinemia: a study in 455 patients. *J Clin Endocrinol Metab*. 1999;84:2518-2522.

visual field abnormalities occurs in approximately 90% of affected patients.^{248,249} Drug withdrawal can result in rapid tumor expansion.²⁵⁰ In contrast, tumors that have shrunk during bromocriptine therapy occasionally do not enlarge after drug withdrawal.²⁵¹ In a subset of patients, hyperprolactinemia disappears spontaneously after long-term observation.²⁵² Very occasionally, bromocriptine lowers PRL despite continued tumor expansion,²⁵³ although when tumors grow during dopamine agonist therapy there is usually a simultaneous PRL elevation.

Some patients have lesions that are entirely or partially resistant to the effects of bromocriptine even at high doses, as well as those of cabergoline.²⁵⁴ Not infrequently, it is difficult to completely normalize the PRL concentration in patients with initially very high levels, although they may respond to treatment with impressive tumor shrinkage and sometimes with improved sexual function. Although use of higher doses or a change in the form of dopamine agonist has been reported to further PRL normalization in some cases,²⁵⁵ many such patients continue to have elevated PRL concentrations regardless of the treatment employed. Resistance to dopamine agonists may reflect reduced D₂ receptor binding site²⁵⁶ or receptor gene polymorphisms.²⁵⁷

Bromocriptine shrinks prolactinomas by shrinking tumor cell size, including cytoplasmic, nuclear, and nucleolar areas.^{258,259} Histologic sections appear very dense as a result of small cell size and clumping of nuclei (see Fig. 9-18). PRL mRNA and PRL synthesis are inhibited, exocytoses are reduced, PRL secretory granules decrease, and structures of the rough endoplasmic reticulum and Golgi apparatus involute. The net effect is reduced cell volume. Tumor necrosis may also occur.²⁶⁰

Perivascular fibrosis noted in prolactinomas derived from patients treated with bromocriptine²⁶¹ has been

attributed to difficulty in tumor removal. However, others found no effect of prior treatment with bromocriptine on surgical success rates.²⁶² In contrast, bromocriptine was a helpful adjunct to transsphenoidal microsurgery for macroprolactinomas.²⁶³ Even the largest tumors and those with the highest PRL levels respond well to treatment with 2.5 mg bromocriptine three times daily. Higher doses are often not more effective.²³⁶ Once positive effects on tumor size and amenorrhea and galactorrhea are established, some patients can be satisfactorily maintained with smaller doses,²⁶⁴ but rarely without medication.

Cabergoline. Cabergoline has a longer duration of action than bromocriptine and is usually administered once or twice weekly. Since its introduction, it has surpassed bromocriptine as the first-line therapeutic choice for most patients, unless pregnancy is desired.²⁶⁵ The long half-life of cabergoline is a result of its high affinity for lactotroph D₂ receptors on lactotrophs and a greater propensity of the drug to remain in pituitary tissue.²⁶⁶ In pharmacokinetic studies, cabergoline lowered PRL in a dose-related manner.²⁶⁷ PRL levels were normalized in 83% of 459 women with hyperprolactinemia treated with cabergoline (0.5 to 1 mg twice weekly) and in 52% of women treated with bromocriptine (2.5 to 5 mg twice daily). Cabergoline was also more effective than bromocriptine in restoring ovulatory cycles and fertility (72% versus 52%; $P < .001$), was better tolerated than bromocriptine, and caused fewer but similar side effects (Fig. 9-19). Tumor size decreased in 11 of 15 patients with macroadenomas, and menses resumed in 3 of 4 premenopausal women.²⁶⁸ Among 85 patients with macroprolactinomas treated with cabergoline (0.25 to 10.5 mg/week), PRL concentrations were normalized in 61% of patients and decreased by at least 75% in an additional 24 patients, and tumor size decreased in 66% of patients (see Table 9-15). Nine patients were resistant to cabergoline despite doses of up to 7 mg/week.^{255,269} Despite the continued experience that a subset of hyperprolactinemic patients are resistant to dopamine agonists, cabergoline normalized PRL in 15 of 19 patients with macroprolactinomas previously resistant to other dopamine agonists.²⁷⁰ Cabergoline also may result in dramatic improvement of prolactinoma-associated headache.²⁷¹

Prolactinomas completely or substantially resistant to medication are infrequently encountered. Most "resistant" patients have only partial resistance (i.e., tumors shrink and PRL levels are lowered but do not normalize). With the

Figure 9-19 Comparison of bromocriptine and cabergoline in suppressing prolactin levels in women with hyperprolactinemia. (Reproduced from Webster J, Piscatelli G, Polli A, et al. A comparison of cabergoline and bromocriptine in the treatment of hyperprolactinemic amenorrhea. *N Engl J Med*. 1994;331:904-909.)

tumor growth controlled on treatment, persistently elevated PRL levels should be addressed by evaluation and treatment of specific disorders caused by hyperprolactinemia.

Administration. Attention to the mode of dopamine agonist administration may avoid or minimize potential adverse effects (Fig. 9-20). Usual starting doses are 1.25 mg bromocriptine (daily), or 0.25 mg cabergoline (weekly). Doses of medication are either increased gradually, as tolerated, or decreased depending on tolerability, and therapy should begin with a small dose taken with food before bedtime. Patients should initially avoid activities that cause peripheral vasodilatation (e.g., hot baths), to decrease the risk of postural hypotension. If side effects are troublesome, the subsequent dose should be halved and doses increased gradually thereafter to achieve effective levels. Switching from one medication to another may be beneficial.²⁷² Intravaginal bromocriptine administration has been used to alleviate adverse gastrointestinal events.²⁷³

Adverse Effects of Dopamine Agonists. Side effects of dopamine agonists are common. Nausea occurs in up to 50% of patients. Nasal stuffiness, depression, and digital vasospasm occur, the latter more frequently with higher doses, as seen in patients with Parkinson's disease. Postural hypotension can cause loss of consciousness, occurs infrequently, and is usually avoided by careful dosing. Signs and symptoms of psychosis or exacerbation of preexisting psychosis are encountered in up to 1.3% of patients receiving bromocriptine.²⁷⁴ In our personal experience, psychosis also occurs with other dopamine agonists, including cabergoline. A history of psychotic symptoms should raise concerns about the use of these medications. If psychosis occurs in a patient in whom dopamine agonists are clearly the treatment of choice, the judicious combination of this agent and antipsychotic medication can be effective. A neuroleptic that is not a potent PRL stimulator, such as olanzapine, is preferred. CSF rhinorrhea occurred during dopamine agonist treatment in up to 6.1% of patients with macroadenomas, some of which were more resistant to

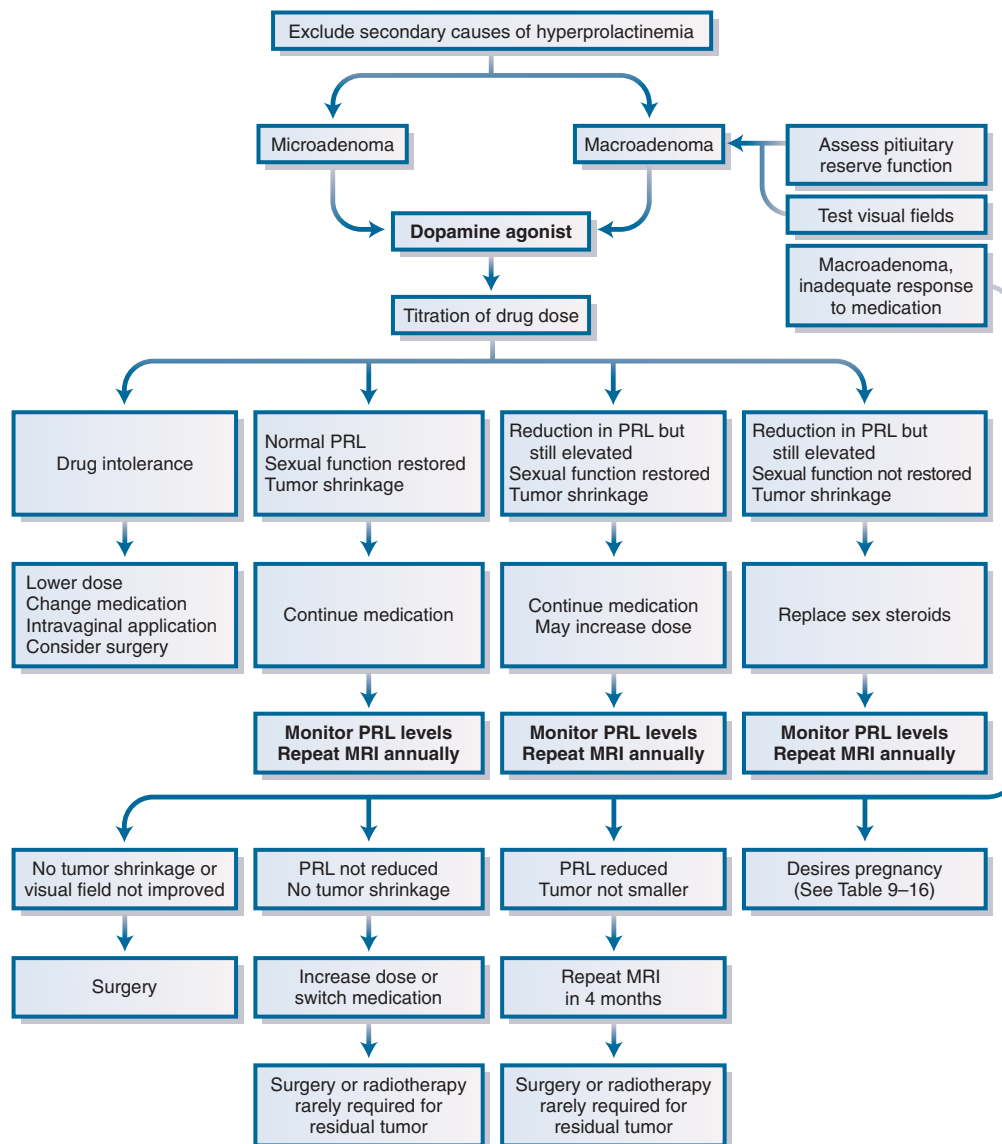

Figure 9-20 Management of prolactinomas. After secondary causes of hyperprolactinemia have been excluded, subsequent management decisions are based on clinical imaging and biochemical criteria. MRI, magnetic resonance imaging; PRL, prolactin.

dopamine agonists.^{275,276} Other, rarely reported serious side effects include hepatic dysfunction and cardiac arrhythmias.^{244,276} Retroperitoneal fibrosis, pleural effusions, and thickening and restrictive mitral regurgitation have been reported in patients taking high doses of bromocriptine.^{277,278}

High doses of dopamine agonists with serotonergic properties were associated with a risk for heart valve regurgitation²⁷⁹ in 155 patients with Parkinson's disease taking high doses of ergot-derived dopamine agonists. Clinically, significant heart valve regurgitation (moderate to severe, grade 3 to 4) was observed in patients taking pergolide (23.4%) or cabergoline (28.6%) but not in patients taking non-ergot-derived dopamine agonists (0%); valvular regurgitation was noted in 5.6% of control subjects.²⁸⁰ These observations in patients with Parkinson's disease receiving high ergot doses raise concern for patients with pituitary tumors who mostly take far lower drug doses. Although one study showed an increase in mild tricuspid regurgitation among patients receiving cabergoline for hyperprolactinemia,²⁸¹ most reports have shown no evidence to indicate that low doses of cabergoline place patients at risk for significant valve disease.²⁸²⁻²⁸⁵ A randomized controlled trial will be helpful in firmly establishing the safety of low-dose cabergoline.

Radiation Therapy

Linear accelerator radiotherapy is effective in controlling or reducing the size of prolactinomas. However, this therapy takes years to achieve maximal effect. The usual recommended radiation dose is 4500 to 4600 centigray (cGy), and normalization of PRL was achieved in 18 of 36 patients at a mean of 7.3 years after such treatment.²⁸⁶ Hypopituitarism occurs as a side effect of irradiation. Five years after radiotherapy (3750 to 4250 cGy)²⁸⁷ in 165 patients, all were GH deficient, 91% were gonadotrophin deficient, 77% were ACTH deficient, and 42% were TSH deficient. Of 36 patients with prolactinomas, of whom 83% had normal GH responses to insulin-induced hypoglycemia before therapy, 34 were GH deficient at 9 to 12 years after radiotherapy.²⁸⁶ Therefore, although radiotherapy is useful in the control of tumor growth, it is not as effective as dopamine agonists. Although stereotactic confocal radiotherapy with a linear accelerator can provide greater tumor focus and a smaller radiation field,⁵⁴ there are as yet no large-scale results of prolactinoma treatment with gamma knife radiotherapy.

Surgery

The success rate of pituitary surgery correlates inversely with tumor size and serum PRL concentration.²⁶² In a compilation of results from 31 published surgical series, serum PRL was normalized in 71% of 1224 patients with microprolactinomas. Although surgical cure rates for microprolactinomas are high, the rate of hyperprolactinemia recurrence is also relatively high,²⁸⁸ occurring in an estimated 17% of patients initially considered cured.²⁸⁹ In contrast, complete resection of macroprolactinomas, especially large invasive ones, is difficult to achieve, and postoperative serum PRL levels are normalized in only 32% of patients, with a 19% recurrence rate. The experience of the surgeon is of major importance, because the cure rate is not as favorable in the hands of neurosurgeons who perform a limited number of procedures.

Although results of medical therapy are superior to those of surgery, there remains a role for surgery in these patients. Patients with prolactinomas that are resistant to dopamine agonist therapy are particularly well suited for

surgery. If tumor removal is only partial, adjunctive radiation therapy should be considered. Prophylactic transsphenoidal surgery should also be considered in women whose prolactinomas are large enough to potentially threaten vision during pregnancy. A subset of patients cannot tolerate available dopamine agonists, and others prefer surgery and refuse medication.

Chemotherapy

There has been growing interest in the use of chemotherapeutic agents for aggressive PRL-secreting tumors unresponsive to other therapies. Temozolomide, an alkylating compound that readily crosses the blood-brain barrier, may control tumor growth in individual patients.²⁹⁰⁻²⁹² The response to temozolomide may be predicted by low tumor staining for O⁶-methylguanine-DNA-methyltransferase (MGMT).²⁹³

Pregnancy

The normal pituitary enlarges during pregnancy, and prolactinomas may also increase in size during pregnancy.²¹² The incidence of pregnancy-associated tumor enlargement, as determined by development of abnormal visual fields, has been estimated at 1.4% of women with microadenomas and 16% of women with macroadenomas.²⁹⁴ In other reports, the risk for macroadenoma enlargement has been estimated to be as high as 36%. In a prospective analysis in which 57 patients with microprolactinomas were monitored by formal visual field examinations during pregnancy, none developed visual disturbances. In contrast, six of eight primiparous women with macroadenomas developed visual loss.²⁹⁵ The results for the patients with macroadenomas were likely skewed, because these patients had been recommended for surgery before pregnancy.

Although dopamine agonists have been used during pregnancy to prevent tumor growth (Fig. 9-21),²⁹⁶ it seems prudent to reduce fetal exposure to medication if possible. It is recommended that menstrual periods be allowed to occur naturally for a period of time (3 to 4 months), long enough to predict that a missed period might be a result of pregnancy (Table 9-16). Barrier contraception is recommended during this period. Within several days to 1 week after a positive human chorionic gonadotropin test is obtained, medication should be discontinued. In a study

TABLE 9-16

Management of Prolactinomas in Patients Planning Pregnancies

Microadenoma	Macroadenoma
Discontinue dopamine agonist when pregnancy test is positive	Consider surgery before pregnancy
Periodic visual field examinations during pregnancy	Ensure bromocriptine sensitivity before pregnancy
Postpartum MRI after 6 wk*	Monitor visual fields expectantly and frequently
	Administer bromocriptine if vision becomes compromised
	Or, continue bromocriptine throughout pregnancy if tumor previously affected vision
	Consider high-dose steroids or surgery during pregnancy if vision is threatened or adenoma hemorrhage occurs
	Postpartum MRI after 6 wk

*Pituitary MRI may be required during pregnancy if deemed necessary.

Figure 9-21 Shrinkage of macroadenoma by treatment with cabergoline in a woman harboring a macroadenoma at 22 weeks' gestation (A), when the prolactin concentration was 488 µg/L (B), and with further reduction at 3 weeks after delivery (C). (Reproduced from Liu C, Tyrrell JB. Successful treatment of large macroprolactinoma with cabergoline during pregnancy. *Pituitary*. 2001;4:179-185.)

of 6239 pregnancies in patients managed in this manner, bromocriptine therapy was not associated with increased abortions or terminations, prematurity, multiple births, or infant malformations beyond the incidence expected in the control population. There is no evidence that other dopamine agonists are less safe, but pregnancy exposure to the other agonist forms is less comprehensively documented.

Treatment options for patients harboring prolactinomas whose vision becomes impaired during pregnancy include administration of bromocriptine, use of high-dose steroids, and surgical resection.²⁹⁴ Of 53 pregnant women receiving bromocriptine, mean offspring birth weight was normal, congenital abnormalities occurred in 4 babies, and physical and intellectual development of children was normal for up to 9 years. In an observational report on 380 pregnancies in women treated with cabergoline, early fetal exposure did not increase the risk of miscarriage or fetal malformation.²⁹⁷

To avoid neurologic complications of tumor enlargement during pregnancy, it is recommended that women with prolactinomas be tested for sensitivity to dopamine agonists before proceeding with a pregnancy. If tumors are insensitive to dopamine agonists (i.e., do not respond with tumor shrinkage), prophylactic surgery could be appropriate. If the tumor is a macroadenoma approximating the optic chiasm, the likelihood of visual difficulties is greater, and it could be prudent to undertake surgery before the patient becomes pregnant.²⁹⁸

**GONADOTROPIN-PRODUCING
(CLINICALLY NONFUNCTIONING)
PITUITARY TUMORS**

Nonfunctioning pituitary tumors comprise 25% to 35% of pituitary tumors.²⁹⁹ Most arise from gonadotroph cells, and they are monoclonal^{167,169} and usually chromophobic. Although they most frequently manifest as clinically nonfunctioning masses and are not associated with elevated serum gonadotrophins, they produce sufficient gonadotrophin subunits to be detectable by immunohistochemistry. In one study, 13 of 14 nonfunctioning gonadotroph tumors produced gonadotrophic hormone subunits detected by immunohistochemistry.³⁰⁰ In another series of nonfunctioning adenomas, 42% of tumors immunostained for the

TSH β -subunit, 83% for the LH β -subunit, 75% for the FSH β -subunit, and 92% for the α -subunit³⁰¹; some also expressed chromogranin A.³⁰² Although LH, FSH, and/or α -subunit are released from these nonfunctioning tumors when they are maintained in culture, production is usually not sufficient to elevate blood levels.²¹⁹ In the past, when immunochemistry was unavailable, these tumors were often classified as null cell adenomas, which do not express glycoprotein subunits.³⁰³ A small subset of tumors secrete sufficient hormone to elevate serum gonadotrophin or α -subunit levels, occasionally resulting in clinical syndromes.

Presentation

Clinically Nonfunctioning Gonadotroph Tumors

Clinically nonfunctioning tumors usually come to attention because of their large size or are detected incidentally (incidentaloma) (Table 9-17).³⁰⁴ Of 506 incidentally discovered pituitary masses, 324 were clinically nonfunctioning tumors, and the remainder were cystic or parasellar masses.³⁰⁵ A gradual visual deficit arising from optic chiasmal compression is common, and patients are often unaware of the disturbance. Recognition of visual field deficits is often delayed because formal visual fields are not routinely evaluated unless a defect is suspected clinically. In the absence of associated space-occupying or hormonal disorders, these large tumors may go unrecognized for many years and then be inadvertently detected on scans or x-ray studies performed for other purposes (incidentaloma). Sinusitis evaluation, pituitary apoplexy, or a brain

TABLE 9-17

Presentation of Gonadotroph Adenomas

Common	Uncommon
Clinically nonfunctioning macroadenoma	Intact gonadotrophin overproduction
Immunostain for gonadotrophin subunits (usually more than one)	Immunostain for subunits or intact hormone being hypersecreted
Usually discovered because of space-occupying effects, or inadvertently	Usually discovered because of space-occupying effects, or inadvertently
Pituitary deficiency	May cause clinical syndrome due to hormone overproduction
	Other pituitary hormones may be deficient

MRI performed for an unrelated indication (e.g., head trauma) may bring these tumors to clinical attention.

Although it is not often the initial presenting complaint, these patients are commonly deficient in one or more pituitary hormones (e.g., in two thirds of 56 patients with nonfunctioning macroadenomas⁴⁷). Although the most commonly encountered endocrine symptoms are related to gonadotrophin deficiency, quality of life may be decreased³⁰⁶ or not altered,³⁰⁷ and daytime somnolence has also been reported.³⁰⁸

Functioning Gonadotroph Tumors

The small subset of gonadotroph adenomas that produce elevated serum FSH, LH, and/or α -subunit concentrations are considered to be functioning adenomas but are not often associated with specific endocrine syndromes. High serum FSH, usually with low LH levels, is generally the only sign that a pituitary tumor is secreting FSH. Paradoxically, these patients may present with hypogonadism due to gonadal downregulation. However, female patients with such tumors may present with pelvic pain due to ovarian hyperstimulation.³⁰⁹ High gonadotrophin levels associated with menopause or testicular failure may complicate the interpretation of gonadotrophin levels, but both LH and FSH are high in cases of primary gonadal failure. LH-producing tumors are exceedingly rare and in males cause elevations in serum testosterone with acne and skin oiliness.

Evaluation

MRI, visual field examination, and pituitary hormone concentrations should be evaluated, the latter not only to detect hypopituitarism but also to exclude hormone overproduction that may not be clinically apparent. LH, FSH, α -subunit, PRL, T_4 , triiodothyronine (T_3), TSH, cortisol, and IGF1 levels should be measured. A serum cortisol measurement at 8 a.m., cortisol response to cosyntropin, or an insulin tolerance test can be helpful in excluding secondary adrenal insufficiency. The extent of hormonal evaluation requires clinical judgment.

If LH or FSH is elevated, the values must be interpreted in light of the patient's physiologic state. An elevated serum FSH value would be interpreted differently in a woman with regular menstrual cycles and in a menopausal patient. Gonadotrophin elevations in patients with primary gonadal failure are not typically limited to one hormone, and circulating α -subunit elevation is consistent with a pituitary tumor but not with gonadal failure. TRH stimulation may differentiate elevated gonadotropin levels ascribed to end-organ failure from those due to independent tumor production. In patients harboring gonadotroph adenomas, increased levels of FSH, LH, LH β -subunit, or α -subunit are evoked in response to TRH.³¹⁰ Calculating the molar ratio of LH or FSH to α -subunit may assist in the diagnosis.

Treatment

Clinical judgment should be used in determining the appropriate therapy: surgery, surgery followed by radiotherapy, radiotherapy alone, or expectant observation (Fig. 9-22). No reliable tumor marker is predictive of mass growth or recurrence.

Surgery and Radiotherapy

If a patient's tumor threatens vision or is a macroadenoma whose size threatens vital structures, transsphenoidal surgery is recommended. Vision improves in

Figure 9-22 Management of nonfunctioning pituitary adenomas. Skilled interpretation of magnetic resonance images (MRI) is crucial to diagnose a nonadenomatous mass such as a meningioma, aneurysm, or other sellar lesion.

approximately 75% of patients with impaired vision.^{311,312} Among 100 patients undergoing transsphenoidal surgery, 72 had visual disturbances, 61 had hypopituitarism, and 36 had headache. Vision improved in 53 of 72 patients after surgery, and headache improved in all.³¹³ Expectant follow-up of 65 patients after pituitary surgery for nonfunctioning adenoma showed that 32% of patients not receiving postoperative radiotherapy exhibited tumor regrowth (mean follow-up, 76 months).³¹⁴ Similar recurrence rates were observed in a retrospective follow-up study of 212 patients.³¹⁵ In another study, tumor recurrence or regrowth occurred in 6% to 46% of patients not receiving radiotherapy after transsphenoidal surgery, whereas patients who underwent radiotherapy had a recurrence rate of 0% to 36%.³¹⁶

Nevertheless, despite the relatively high incidence of postoperative tumor regrowth even after apparently complete resection, many neurosurgeons avoid routine postoperative radiation therapy. This approach requires advising careful follow-up, with periodic annual MRIs and visual evaluations, and encouraging patients to maintain medical follow-up. Radiation can be offered if the tumor mass re-expands.³¹¹

The role of gamma knife radiosurgery versus fractionated radiotherapy remains unclear.³¹⁷ In a retrospective study of 62 patients with nonfunctioning pituitary tumors treated with gamma knife radiosurgery, 60% experienced decreased tumor size, and 37% of tumors remained unchanged. However, the risk of developing new anterior pituitary hormone deficits at 5 years was 32%.³¹⁸ Because

patients experience tumor regrowth even after radiation therapy, all radiated patients should undergo periodic post-treatment MRIs, albeit less frequently.³¹⁹

Expectant Observation

For nonfunctioning microadenomas or small macroadenomas (incidentalomas), patients may be observed expectantly.³²⁰ Some tumors do not grow over years or even decades.³⁰⁵ However, regular MRI follow-up is obligatory, especially for those patients with postoperative remnants or tumors that immunostain positively for ACTH (silent corticotroph adenomas).³²¹ Nonfunctioning adenomas may grow insidiously after surgery and are usually asymptomatic until they become large enough to affect vision. Periodic, but less frequent, endocrine evaluation is also suggested according to the clinical situation. Microadenomas only very rarely impair vision during pregnancy; macroadenomas do so with greater frequency.³²² Because macroadenomas do not respond to medical therapy, the risk of visual impairment arising during a pregnancy must be weighed carefully, and tumor resection may be indicated before pregnancy is undertaken.

Medications

Medications are not usually effective in reducing tumor size and visual compromise. Although GnRH antagonists and somatostatin analogues modestly shrink tumors in a few patients, they are not sufficiently effective to be recommended as therapy. Rarely, dopamine agonists have been reported to shrink some nonfunctioning tumors³²³ or to prevent regrowth.³²⁴

ACROMEGALY

In 1886, Pierre Marie published the first clinical description of disordered somatic growth and proportion and proposed the name “acromegaly.” He also recognized cases previously described by others.³²⁵ After the relation of this syndrome to a pituitary tumor was recognized, Benda showed in 1900 that these tumors comprise mainly adenohypophyseal eosinophilic cells, which he proposed to be hyperfunctioning.³²⁶ Cushing, Davidoff, and Bailey documented the clinicopathologic features of acromegaly and demonstrated clinical remission of soft tissue signs after adenoma resection.³²⁷ Evans and Long induced gigantism in rats injected with anterior pituitary extracts, confirming the association of a pituitary factor with somatic growth.³²⁸ Establishment of the unequivocal pathophysiologic link between hyperfunctioning adenoma and acromegaly made this the earliest example of a clinically and pathologically recognized pituitary disorder to be appropriately managed by surgical excision of a hypersecreting source.

Incidence

The prevalence of acromegaly is estimated to range from 38 to 80 cases per million population, and the annual incidence of new patients is 3 to 4 cases per million.^{158,329-331} Based on these findings, it is apparent that more than 1000 new cases of acromegaly are diagnosed annually in the United States.

Pathogenesis

GH and IGF1 act both independently and dependently to induce features of hypersomatotropism. Acromegaly is caused by pituitary tumors that secrete GH or, very rarely,

by extrapituitary disorders (Fig. 9-23).³³² Regardless of the etiology, the disease is characterized by elevated levels of GH and IGF1 with resultant signs and symptoms of hypersomatotropism.

Pituitary Acromegaly

More than 95% of patients with acromegaly harbor a GH-secreting pituitary adenoma (Table 9-18). Pure GH-cell adenomas contain either densely or sparsely staining cytoplasmic GH granules, and these two variants are slow and rapidly growing, respectively.³³³ The former arise insidiously and manifest during or after middle age, whereas the latter arise in younger subjects with more florid disease.

Mixed GH-cell and PRL-cell adenomas are composed of distinct somatotrophs expressing GH and lactotrophs expressing PRL. Monomorphous acidophil stem cell adenomas arise from the common GH and PRL stem cell and also often contain giant mitochondria and misplaced GH granule exocytosis. They grow rapidly, are invasive, and manifest with predominant features of hyperprolactinemia.³³⁴ Monomorphous mammosomatotroph adenomas express both GH and PRL from a single cell, whereas plurihormonal tumors may express GH with any combination of PRL, TSH, ACTH, or α -subunit.³³⁵ These patients present with clinical features of acromegaly as well as hyperprolactinemia, Cushing's disease, or, rarely, hyperthyroxinemia. Somatotroph hyperplasia is difficult to distinguish from a GH-cell adenoma, and silver staining displays a well preserved reticulin network without a surrounding pseudocapsule. The rigorous morphologic diagnosis of GH-cell hyperplasia is usually associated with stimulation by ectopic GHRH derived from an extrapituitary tumor causing acromegaly.

So-called silent somatotroph adenomas immunostain positively for GH and are apparently clinically nonfunctional, although GH and/or PRL levels may be modestly elevated in more than half of these patients.

Pathogenesis of Somatotroph Cell Adenomas. Both pituitary and hypothalamic factors influence pituitary tumor pathogenesis.^{336,337} Even when exhibiting marked nuclear pleomorphism, mitotic activity, and invasiveness, these tumors are usually benign.

Disordered GHRH Secretion or Action. Adenomas express receptors for GHRH, ghrelin,³³⁸ and SRIF, but no activating mutations of the GHRH or SRIF receptor have been reported. GHRH directly stimulates GH gene expression and also induces somatotroph mitotic activity. Transgenic GHRH expression causes somatotroph hyperplasia and, ultimately, adenoma. Clinically, GHRH production by hypothalamic, abdominal, or chest neuroendocrine tumors causes somatotroph hyperplasia and, rarely, adenoma, with resultant unrestrained GH secretion and acromegaly.¹⁶⁵ However, histologic examination of most pituitary GH-cell adenoma tissue specimens does not show hyperplastic somatotroph tissue surrounding the adenoma, implying no generalized hypothalamic overstimulation.

Failure to downregulate GH secretion during prolonged GHRH stimulation also points to a role for GHRH in maintaining persistent GH hypersecretion. Furthermore, a GHRH antagonist was found to reduce production of human growth hormone (hGH) in 50 patients with acromegaly, suggesting a role for endogenous GHRH.³³⁹ Expression of intra-adenomatous GHRH correlates with tumor size and activity, implying a paracrine role for GHRH in mediating adenoma pathogenesis.³⁴⁰ GHRH modestly stimulates PRL secretion, and up to 40% of patients with acromegaly also have hyperprolactinemia.

Figure 9-23 Pathogenesis of acromegaly. GH, growth hormone; GHRH, growth hormone–releasing hormone; GHS, growth hormone secretagogue; IGF-I, insulin-like growth factor type I; PRL, prolactin; SRIF, somatostatin. (Reproduced from Melmed S. Acromegaly. *N Engl J Med*. 2006;355:2558-2573.)

Complete surgical resection of well-defined GH-secreting microadenomas usually results in a definitive cure of excess hormone secretion with very low postoperative tumor recurrence rates, strongly suggesting intact hypothalamic function in these patients. Although basal GH levels are usually high in acromegaly, the episodic pulsatile pattern of GH release is intact, and the nocturnal GH surge is usually preserved.³⁴¹ Patients treated with SRIF analogues also retain GH pulsatility, and GH pulse amplitude and sensitivity to GHRH appear to remain intact.

Disordered Somatotroph Cell Function. A somatotroph mutation may be a prerequisite for the abnormal growth response to disordered GHRH secretion or action (see earlier discussion). The monoclonal origin of somatotroph adenomas was determined by X-chromosome inactivation analysis of somatotroph tumor DNA.¹⁶⁷ An altered $G_s(\alpha)$ protein identified in a subset of GH-secreting pituitary adenomas leads to high levels of intracellular cAMP and GH hypersecretion.¹⁷³ Point mutations in two critical sites, Arg201, the site for adenosine diphosphate ribosylation, and Gly227, the guanosine triphosphate (GTP)-binding domain of $G_s(\alpha)$, prevent GTPase activity and result in constitutive adenyl cyclase activation. This dominant *GSP* mutant mimics GHRH effects results in elevated cAMP levels and is present in about 30% of GH-secreting tumors. Germline inactivating mutations of *AIP* were found in a subset of familial somatotrophinomas,^{208,342} especially in younger patients with acromegaly or gigantism. This

mutation may have been inherited from an ancestor 57 to 66 generations earlier. *AIP* mutation is pituitary adenomal. However, no defined tumor suppressor gene has been isolated for sporadic nonfamilial GH-secreting tumors.

The sequence of events leading to somatotroph clonal expansions appears to be multifactorial. An activated oncogene may be required for initiation of tumorigenesis, whereas promotion of tumor growth may require stimulation of GHRH and other growth factors. The cellular mutation may not be sufficient to provide a growth advantage for a GH-secreting adenoma without additional disordered hypothalamic or paracrine growth factor signaling.

Extrapituitary Acromegaly

The source of excess GH secretion in acromegaly may not necessarily be pituitary in origin.³⁴³ Because management of ectopic acromegaly differs from that for pituitary GH hypersecretion, rigorous clinical and biochemical criteria should be fulfilled to confirm the diagnosis of ectopic acromegaly.³⁴⁴ These include demonstration of elevated circulating GHRH or GH levels in the absence of a primary pituitary lesion, a significant arteriovenous hormone gradient across the ectopic tumor source, biochemical and clinical cure of acromegaly after resection of the ectopic hormone-producing tumor, and normalization of the GHRH-GH-IGF1 axis. Finally, GHRH or GH gene product expression should be shown. Patients with nonconclusive imaging, biochemical, or clinical features of pituitary

TABLE 9-18

Causes of Acromegaly

Cause	Prevalence (%)	Hormonal Products	Clinical Features	Pathologic Characteristics
Excess GH Secretion				
Pituitary	98			
Densely granulated GH-cell adenoma	30	GH	Slow-growing, clinically insidious	Resemble normal somatotrophs, numerous large secretory granules
Sparsely granulated adenoma	30	GH	Rapidly growing, often invasive	Cellular pleomorphism, characteristic ultrastructure
Mixed GH-cell and PRL-cell adenoma	25	GH and PRL	Variable	Densely granulated somatotrophs, sparsely granulated lactotrophs
Mammotroph cell adenoma	10	GH and PRL	Common in children; gigantism, mild hyperprolactinemia	Both GH and PRL in same cell, often same secretory granule
Acidophil stem cell adenoma		PRL and GH	Rapidly growing, invasive, hyperprolactinemia dominant	Distinctive ultrastructure, giant mitochondria
Plurihormonal adenoma		GH (PRL with α GSU, FSH/LH, TSH, or ACTH)	Often secondary hormonal products are clinically silent	Variable; either monomorphous or plurimorphous
GH-cell carcinoma or metastases		GH	Usually aggressive	Documented metastasis
MEN1 (adenoma)		GH or PRL	Pancreatic, parathyroid, or pituitary tumors	Adenoma
McCune-Albright syndrome		GH, PRL	Classic triad	Hyperplasia
Ectopic sphenoid or parapharyngeal sinus pituitary adenoma		GH	Ectopic mass	Adenoma
Familial acromegaly		GH	Young patients	Large adenomas
Carney syndrome		GH	Classic syndrome	Adenoma
Extrapituitary Tumor				
Pancreatic islet-cell tumor	<1			Small pituitary
Excess GHRH Secretion				
Central—hypothalamic hamartoma, choristoma, ganglioglioma	<1		Hypothalamic mass	Somatotroph hyperplasia
Peripheral—bronchial carcinoid, pancreatic islet-cell tumor, small cell lung cancer, adrenal adenoma, medullary thyroid carcinoma, pheochromocytoma	1	GH, PRL	Systemic features	Somatotroph hyperplasia, rarely adenoma

ACTH, adrenocorticotropic hormone; FSH, follicle-stimulating hormone; GH, growth hormone; GHRH, growth hormone-releasing hormone; α GSU, glycoprotein α -subunit; LH, luteinizing hormone; MEN1, multiple endocrine neoplasia type 1; PRL, prolactin; TSH, thyroid-stimulating hormone.

Adapted from Melmed S. Acromegaly. *N Engl J Med*. 2006;355:2558-2573; and Melmed S, Braunstein GD, Horvath E, et al. Pathophysiology of acromegaly. *Endocr Rev*. 1983;4:271-290.

acromegaly may inadvertently be diagnosed as harboring a nonpituitary source of excess GH secretion and be inappropriately treated.

GHRH Hypersecretion. Hypothalamic tumors, including hamartomas, choristomas, gliomas, and gangliocytomas, may produce GHRH with subsequent somatotroph hyperplasia or even a pituitary GH-cell adenoma and resultant acromegaly (see Fig. 9-23).¹⁶⁵ Primary mammotroph hyperplasia with no evidence for pituitary adenoma or an extrapituitary tumor source of GHRH has been described in gigantism.³⁴⁵ In fact, the structure of hypothalamic GHRH was elucidated from material extracted from pancreatic GHRH-secreting tumors in patients with acromegaly.¹⁵⁹ GHRH immunoreactivity is detectable in about 25% of carcinoid tumor samples, and bronchial carcinoids comprise most tumors associated with ectopic GHRH secretion.³⁴⁶ However, acromegaly in patients with carcinoid is uncommon. In a retrospective survey of 177 patients with acromegaly, only a single patient was identified with elevated plasma GHRH levels.³⁴⁷ Rare pancreatic cell tumors, small-cell lung cancers, adrenal adenomas, pheochromocytomas, and medullary thyroid, endometrial, and breast

cancers express GHRH and may cause acromegaly.^{348,349} Surgical resection of the tumor secreting ectopic GHRH should reverse the GH hypersecretion, and pituitary surgery is not required in these patients. Carcinoid syndrome with ectopic GHRH secretion can also be managed with somatostatin analogues, which lower GH and IGF1 levels and also suppress ectopic tumor elaboration of GHRH.³⁵⁰

Ectopic Pituitary Adenomas. GH-secreting adenomas may arise from ectopic pituitary remnants in the sphenoid sinus, petrous temporal bone, or nasopharyngeal cavity.³⁵¹ Very rarely, pituitary carcinoma may spread to the meninges, CSF, or cervical lymph nodes, resulting in functional GH-secreting metastases that may be diagnosed by radio-labelled octreotide imaging (Octreoscan).³⁵²

Peripheral Growth Hormone-Secreting Tumors. Lung adenocarcinoma, breast cancer, and ovarian tissues can contain immunoreactive GH without clinical evidence of acromegaly. Rarely, a GH-secreting intramesenteric pancreatic islet cell tumor³⁴⁴ or a non-Hodgkin's lymphoma³⁵³ causes acromegaly. These patients have a normal-sized or small pituitary gland on MRI, no GH response to TRH injection, and normal levels of circulating plasma GHRH.

Acromegaloidism. Rarely, patients who exhibit soft tissue and skin changes usually associated with acromegaly but normal baseline and dynamic GH and IGF1 with no demonstrable pituitary or extrapituitary tumor have been termed *acromegaloid*. Pachydermoperiostosis should be considered in the differential diagnosis. Insulin resistance and defective IGF1 binding have been demonstrated in cells derived from some patients with acanthosis nigricans, and treatment is symptomatic.

McCune-Albright Syndrome. The rare hypersecretory syndrome known as McCune-Albright syndrome consists of polyostotic fibrous dysplasia, cutaneous pigmentation, sexual precocity, hyperthyroidism, hypercortisolism, hyperprolactinemia, and acromegaly due to somatotroph hyperplasia.³⁵⁴ Although few patients have definitive evidence for a pituitary adenoma, G_{α} mutations have been detected in both endocrine and nonendocrine tissues.¹⁷⁴ GH hypersecretion can be controlled by somatostatin analogues or pituitary irradiation.

Multiple Endocrine Neoplasia. GH-cell pituitary adenoma is a well-documented component of the autosomal dominant multiple endocrine neoplasia type 1 (MEN1) syndrome, which also includes parathyroid and pancreatic tumors (see Chapter 41). MEN1, associated with germ cell inactivation of the *MENIN* tumor suppressor gene,²⁰⁰ appears to be intact in sporadic GH-cell adenomas. Rarely, functional pancreatic tumors in patients with MEN1 also express GHRH.

Clinical Features

Manifestations of acromegaly are caused by either central pressure effects of the pituitary mass or peripheral actions of excess GH and IGF1. Central features of the expanding pituitary mass are common to all pituitary masses³⁵⁵ and have already been described. In acromegaly, headache is often severe and debilitating. Local signs are especially important presenting features, because a higher preponderance of macroadenomas (>65%) is encountered in acromegaly, compared with mostly microadenomas for PRL-secreting tumors.³⁵⁶

Gigantism

Tall stature may be caused by a GH-secreting pituitary tumor or hyperplasia.³⁵⁷ About 20% of patients with gigantism have the McCune-Albright syndrome, with somatotroph hyperplasia or, rarely, pituitary adenoma. Somatotroph hyperplasia and acidophilic stem cell adenomas may rarely cause gigantism during infancy or early childhood, suggesting early hypersecretion of GHRH or disordered pituitary cell differentiation.^{345,358} Pituitary gigantism should be considered in children who are more than 3 standard deviations above normal mean height for age or more than 2 standard deviations over their adjusted mean parental height. The biochemical diagnosis is similar to that for acromegaly: GH levels are in excess of 1 μ g/L after a glucose load, and serum IGF1 concentrations are elevated. In children undergoing pubertal growth spurts, GH responses to glucose may be paradoxical, and serum IGF1 concentrations are often physiologically elevated. Therefore, the diagnosis requires clearcut MRI evidence for a pituitary lesion. The differential diagnosis includes familial tall stature, redundancy of Y chromosomes, Marfan's syndrome, and homocystinuria.

Clinical Features of Acromegaly

Effects of hypersomatotropism on acral and soft tissue growth and on metabolic function occur insidiously over

TABLE 9-19

Clinical Features of Acromegaly*

Local Tumor Effects	Endocrine-Metabolic Effects
Pituitary enlargement Visual field defects Cranial nerve palsy Headache	Reproductive Menstrual abnormalities Galactorrhea Decreased libido, impotence, low sex hormone-binding globulin
Somatic Effects	Multiple Endocrine Neoplasia Type 1 (MEN1) Hyperparathyroidism Pancreatic islet cell tumors
Acral Enlargement Thickness of hand and feet soft tissue	Carbohydrates Impaired glucose tolerance Insulin resistance and hyperinsulinemia Diabetes mellitus
Musculoskeletal Gigantism Prognathism Jaw malocclusion Arthralgias and arthritis Carpal tunnel syndrome Acroparesthesia Proximal myopathy Hypertrophy of frontal bones	Lipids Hypertriglyceridemia
Skin Hyperhidrosis Oily Skin tags	Minerals Hypercalciuria, increased 1,25-hydroxy vitamin D3 Urinary hydroxyproline
Colon Polyps	Electrolytes Low renin Increased aldosterone
Cardiovascular Left-ventricular hypertrophy Asymmetric septal hypertrophy Cardiomyopathy Hypertension Congestive heart failure	Thyroid Low thyroxine-binding globulin Goiter
Pulmonary Sleep disturbances Sleep apnea—central and obstructive Narcolepsy	
Visceromegaly Tongue Thyroid Salivary gland Liver Spleen Kidney Prostate	

*Most soft tissue and metabolic changes are reversible by tight hormonal control. Bony changes, hypertension, and central sleep apnea are generally not reversible.

several years (Table 9-19; Figs. 9-24 and 9-25).³⁵⁹ The slow onset and elusive symptomatology often result in delayed diagnosis ranging from 6.6 to 10.2 years, with a mean delay of almost 9 years.³⁶⁰ Patients may seek care for dental, orthopedic, rheumatologic, or cardiac disorders. Only 13% of 256 patients diagnosed during a 20-year period presented with primary symptoms of altered facial appearance or enlarged extremities.³⁶¹ In a review of several hundred patients presenting with acromegaly worldwide, 98% had acral enlargement, and hyperhidrosis was prominent in

Figure 9-24 Harvey Cushing's first acromegaly patient, some years before presentation (**A**) and at admission (**B**). (Reproduced from Jane JA, Laws ER. History of acromegaly. In: Wass J, ed. *Handbook of Acromegaly*. Bristol, UK: BioScientifica; 2001:3-15.)

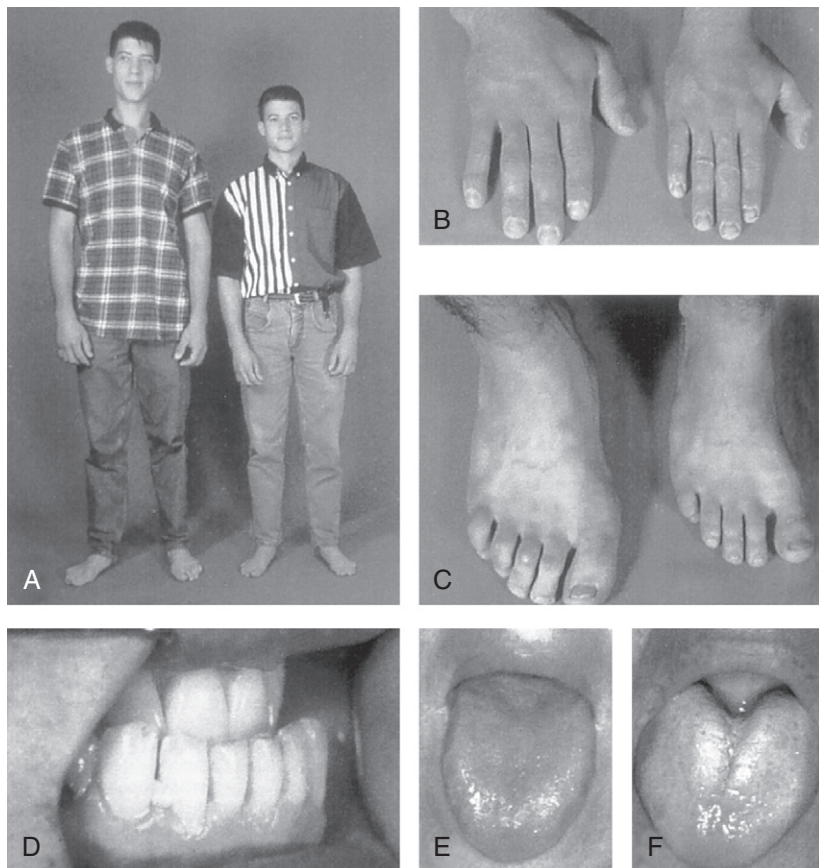

Figure 9-25 Clinical features of acromegaly. Features of acromegaly/gigantism in identical twins whose clinical features began to diverge at the age of approximately 13 years. A 22-year-old man with gigantism due to excess growth hormone is shown to the left of his identical twin. The increased height and prognathism (**A**) and enlarged hand (**B**) and foot (**C**) of the affected twin are apparent. (Reproduced from Gagel R, McCutcheon IE. Images in clinical medicine: pituitary gigantism. *N Engl J Med*. 1999;324:524, with permission.) **D**, Increased incisor spacing and prognathism in patient with acromegaly. **E**, Macroglossia; **F**, a normal tongue. 70%.³⁵⁹ When patients present early, facial and peripheral features are usually not obvious; serial review of old photographs often accentuates the progress of subtle physical changes. Characteristic features include large fleshy lips and nose, spade-like hands, frontal skull bossing, and cranial ridges. Enlarged tongue, bones, salivary glands, thyroid, heart, liver, and spleen are the effects of generalized visceromegaly. Clinically apparent hepatosplenomegaly, however, is rare. Increase in shoe, ring, or hat size is commonly reported.

Progressive acral changes may lead to facial coarsening and skeletal disfigurement, especially if excess GH secretion begins before epiphyseal closure.³⁶² These changes include mandibular overgrowth with prognathism, maxillary widening, teeth separation, jaw malocclusion overbite, and a large nose and coarse, oily skin with large pores.²⁴⁸ Sonorous voice deepening occurs in association with laryngeal hypertrophy and enlarged paranasal sinuses. Up to half of patients experience joint symptoms severe enough to limit daily activities. Arthropathy occurs in about 70% of patients, most of whom exhibit joint swelling, hypermobility, and cartilaginous thickening.³⁶³ These signs often persist after complete remission.³⁶⁴ Local periarticular fibrous tissue thickening may cause joint stiffening or deformities and nerve entrapment. Knees, hips, shoulders, lumbosacral joints, elbows, and ankles are affected as monoarticular or polyarticular arthritides, but joint effusions rarely develop.³⁶⁵ Spinal involvement includes osteophytosis, disc space widening, and increased anteroposterior vertebral length that may result in dorsal kyphosis.

Neural enlargement and wrist tissue swelling may lead to carpal tunnel syndrome in up to half of all patients. Median and ulnar nerve cross-sectional areas increase, and nerve conduction is abnormal.^{366,367} Chondrocyte proliferation with increased joint space occurs early, and ulcerations and fissures of weight-bearing cartilage areas are often accompanied by new bone formation. Debilitating osteoarthritis may result in bone remodeling, osteophyte formation, subchondral cysts, narrowed joint spaces, and lax periarticular ligaments. Osteophytes commonly occur at the phalangeal tufts and over the anterior aspects of spinal vertebrae. Ligaments may ossify, and periarticular calcium pyrophosphate deposition occurs. Although the duration of hypersomatotropism correlates with clinical severity of the joint changes, it is unclear whether higher GH levels correlate with increased articular disease activity. Therapeutic responses usually depend on the degree of irreversible bony changes already in place. Hyperhidrosis and malodorous oily skin are common early signs, occurring in up to 70% of patients. Facial skin wrinkles, nasolabial folds and heel pads thicken, and body hair may become coarsened³⁶⁸; these changes are attributed to glycosaminoglycan deposition and increased connective tissue collagen production.³⁶⁹ Skin tags are common and may be markers for the adenomatous colonic polyps.³⁷⁰ Raynaud's phenomenon is reported in up to one third of patients.

Symptomatic cardiac disease is present in about 20% of patients and is a major cause of morbidity and mortality.³⁷¹ Hypertension is present in about 50% of patients with active acromegaly, and half of them have evidence of left ventricular dysfunction.³⁷² Left ventricular hypertrophy is also observed in about half of normotensive patients with acromegaly. Asymmetric septal hypertrophy is common, and cardiac failure with increased ventricular ejection fraction may occur with early or mild cardiomegaly. Subclinical left ventricular diastolic dysfunction results from myocardial hypertrophy, interstitial fibrosis, and lymphocytic myocardial infiltrates. Resting electrocardiograms are

abnormal in about 50% of patients, with S-T segment depression, T-wave abnormalities, conduction defects, and arrhythmias. Plasma renin levels are suppressed, and endogenous plasma digitalis-like activity with chronic volume expansion has been identified in acromegaly.³⁷³ Renal sodium channel activity is induced by GH at the aldosterone-sensitive distal nephron.³⁷⁴ The presence of cardiovascular disease at the time of diagnosis portends a high risk of mortality despite improved cardiac function after effective GH and IGF1 control.³⁷⁵

Prognathism, thick lips, macroglossia, and hypertrophied nasal structures may obstruct airways.²⁴⁸ Irregular laryngeal mucosa, cartilage hypertrophy, tracheal calcification, and cricoarytenoid joint arthropathy lead to unilateral or bilateral vocal cord fixation or laryngeal stenosis with voice changes. Tracheal intubation may be particularly difficult in patients undergoing anesthesia, and tracheostomy may be required. Both central respiratory depression and airway obstruction lead to paroxysmal daytime sleep (narcolepsy), sleep apnea, and habitual excessive snoring. Obstructive sleep apnea, characterized by excessive daytime sleepiness with at least five episodes of apnea per hour of sleep, causes daytime somnolence, especially in men with acromegaly who also have a ventilation-perfusion defect with hypoxemia. Sleep apnea may also be central in origin and associated with higher GH and IGF1 levels.³⁷⁶

Synovial edema leads to hyperplastic wrist ligaments and tendons that contribute to painful median nerve compression. Peripheral acroparesthesias and symmetric peripheral neuropathy should be distinguished from diabetic neuropathy, which may occur secondarily to acromegaly.³⁷⁷ Proximal myopathy may also be accompanied by myalgias, cramps, and nonspecific myopathic changes on electromyography. Exophthalmos may be present but may be masked by frontal bossing. Hypertrophied tissue surrounding the canal of Schlemm may impede aqueous filtration, leading to open-angle glaucoma. Progressive facial and bodily disfigurement often leads to lowered self-esteem. Depression and mood swings may occur secondarily to physical deformity.³⁷⁸ Quality of life is also impaired.³⁷⁹

Growth Hormone and Tumor Formation

The early practice of hypophysectomy for management of metastatic carcinoma was based on evidence implicating GH as a factor in tumor development. GH and IGF1 exhibit direct and indirect mitogenic effects on mammalian cells and act as permissive growth stimulators of cells previously exposed to other growth factors.³⁸⁰ The IGF binding protein 3 IGFBP3, also induced by GH (see Chapter 8), inhibits cell proliferation and promotes apoptosis.³⁸¹ Therefore, the ultimate impact of elevated GH levels on cell proliferation reflects a balance of apoptotic versus growth-promoting signals.³⁸²

A compelling cause-and-effect relationship between acromegaly and cancer has not been established.³⁸³⁻³⁸⁶ Benign colon polyps were reported in 45% of 678 patients in 12 prospective studies (Table 9-20). The presence of more than three skin tags in patients older than 50 years of age may be a peripheral marker for adenomatous colon polyps, unrelated to GH or IGF1 serum levels.³⁸⁷ Hypertrophic mucosal folds and colonic hypertrophy are commonly present, and dolichomegacolon may be visualized by CT colonography.³⁸⁸ Although elevated IGF1 levels may correlate with colon polyp prevalence when patients are retested,³⁸³ a recent controlled, prospective study of 161 patients showed no increased incidence of colon polyps in acromegaly.^{382,389} Colonoscopy is warranted every 3 to 5

years after diagnosis, depending on the presence of other risk factors.

Increased mortality from colon cancer is largely related to uncontrolled GH levels, rather than an enhanced incidence of the disease in acromegaly (Table 9-21). Analysis of nine retrospective reports (1956-1998) encompassing 21,470 person-years at risk yielded no significant overall increased cancer incidence.³⁸² Cancer incidence was in fact lower than expected in 1362 patients with acromegaly in the United Kingdom, and the enhanced colon cancer mortality observed in that study correlated with GH levels.³⁸⁵ In contrast, a nationwide study in Finland on cancer incidence in patients with acromegaly found an increased incidence of thyroid, bladder, and kidney cancers.³⁹⁰ Therefore, although disordered cell proliferation and an increased risk for promotion of coexisting neoplasms could be anticipated from elevated GH and IGF1 levels, a significantly enhanced cancer incidence has not consistently been reported in acromegaly (Table 9-22). Colon cancer appears to be of particular concern, and a screening colonoscopy should be performed at diagnosis in all patients. Because

patients are now living longer due to improved biochemical control, long-term prospective, controlled studies are required to resolve this question in an aging population.

Endocrine Complications

About 30% of patients exhibit elevated serum PRL levels (up to 100 µg/L or more), with or without galactorrhea.³⁹¹ Functional pituitary stalk compression by a pituitary mass prevents access of hypothalamic dopamine to the lactotroph, releasing the cell from tonic hypothalamic inhibition. GH-secreting adenoma subtypes may also concomitantly secrete PRL. Because GH behaves as an agonist for breast PRL-binding sites, the tumor may cause galactorrhea in the face of normal PRL levels. Tumor mass compressing surrounding normal pituitary tissue may also cause hypopituitarism. More than half of all patients have

TABLE 9-21

Post-Treatment Growth Hormone (GH) Levels and Mortality in Acromegaly*

Mortality % (Range)	Post-Treatment GH (ng/mL)			Probability Value
	<2.5 (n = 541)	2.5-9.9 (n = 493)	>10 (n = 207)

NA, not applicable; NS, not significant; O/E, observed/expected ratio.

amenorrhea or impotence,^{356,392} and secondary thyroid or adrenal failure is present in about 20% of patients. Gonadal dysfunction may result in reduced bone.

The direct anti-insulin effects of GH cause carbohydrate intolerance, and patients may also develop insulin-requiring diabetes mellitus. Carbohydrate intolerance and insulin requirements improve rapidly when GH is lowered after surgery or somatostatin analogue therapy. Hypertriglyceridemia (type IV), hypercalciuria, and hypercalcemia also occur. Thyroid dysfunction in acromegaly may be caused by diffuse or nodular, toxic or nontoxic goiter or by Graves' disease, especially because IGF1 is a major determinant of thyroid cell growth.³⁹³ Associated MEN1 features may be present in affected individuals, including hypercalcemia with hyperparathyroidism or pancreatic tumors. Benign prostatic hypertrophy has been documented in acromegaly with no apparent increase in prostate cancer rates.³⁹⁴

Morbidity and Mortality

In a meta-analysis of 16 studies, overall mortality was reported to be increased in acromegaly, with a standardized mortality ratio (SMR) of 1.72. Higher mortality rates were observed before 1993, most likely reflecting the positive impact of the introduction of somatostatin analogues, improved surgical technique, and enhanced cardiac therapies after that date.³⁹⁵ Cardiovascular disease, respiratory disorders, and diabetes contribute to a threefold enhanced mortality rate in acromegaly.³⁹⁶⁻⁴⁰¹ Cardiovascular disease is the leading cause of death, followed by respiratory causes (18%) and cerebrovascular disease (14%). Diabetes mellitus, occurring in 20% of patients, is associated with 2.5 times the predicted mortality, and hypertension is present in about half of all patients (Fig. 9-26).⁴⁰¹

The most significant mortality determinants are GH levels greater than 2.5 $\mu\text{g/L}$, elevated IGF1 levels, the presence of coexisting hypertension and cardiac disease, older age, a history of pituitary irradiation, and inadequately replaced ACTH-dependent adrenal insufficiency.⁶⁸ Importantly, overtreatment of adrenal insufficiency with doses of hydrocortisone greater than 25 mg/day also is predictive of mortality.⁶⁸ Moreover, control of GH levels to less than 2.5 $\mu\text{g/L}$ and normal IGF1 levels after surgical or medical

treatments significantly reduce both morbidity and mortality (see Fig. 9-26).⁴⁰²

Diagnosis

Measurement of Growth Hormone Levels

The diagnosis of acromegaly requires measurement of a GH nadir during oral glucose tolerance testing that is greater than 0.4 $\mu\text{g/L}$ or 1 $\mu\text{g/L}$ (depending on GH standards employed) together with elevation of age-adjusted IGF-1 levels.⁴⁰³⁻⁴⁰⁵ In healthy subjects, serum GH levels initially fall after oral glucose administration and subsequently increase as plasma glucose declines. However, in patients with acromegaly, oral glucose fails to suppress GH, and GH levels are equally likely to increase, remain unchanged, or fall modestly.

Basal morning (a.m.) and random GH levels are usually elevated in acromegaly. Because of the episodic nature of GH secretion, however, serum concentrations may normally fluctuate from "undetectable" up to 30 $\mu\text{g/L}$. Unlike the largely undetectable nadir GH levels in normal subjects, patients with acromegaly from whom samples were obtained over 24 hours had detectable levels of GH ($>2 \mu\text{g/L}$).⁴⁰⁶ Evoked GH responses to GHRH administration are not of diagnostic utility. A higher episodic GH pulse frequency occurs, which often persists after surgical adenoma resection. Random GH levels measured with sensitive assays in acromegaly may be as low as 0.37 $\mu\text{g/L}$ with persistently elevated postoperative concentrations of IGF1.⁴⁰⁰

Serum IGF1 levels are high⁴⁰⁷ and correlate with the log of serum GH determinations. IGF1 elevations (compared with age- and gender-matched subjects) may persist for several months after GH levels become biochemically controlled in response to treatment.⁴⁰⁸ Increased IGF1 levels are also encountered during pregnancy and late puberty. A high IGF1 level is therefore highly specific for acromegaly and correlates with clinical indices of disease activity. IGFBP3 levels are also elevated but provide little added diagnostic value. GH-secreting adenomas exhibit discordant GH responses to TRH and GnRH administration in up to 50% of patients, but these adjunctive tests are rarely required to confirm the diagnosis.

Differential Diagnosis of Acromegaly

The overwhelming majority of patients with acromegaly harbor a GH-cell pituitary adenoma; rarely, extrapituitary acromegaly should be considered. Nevertheless, distinguishing pituitary from extrapituitary acromegaly is important for planning effective management. Regardless of the cause of unrestrained GH secretion, IGF1 levels are invariably elevated and GH levels are not suppressed (i.e., to $<1 \mu\text{g/L}$) after an oral glucose load.⁴⁰⁵ When clinical features of acromegaly are associated with normal GH and IGF1 levels, "burned out" or "silent" acromegaly associated with an infarcted pituitary adenoma, often with a secondary empty sella, should be considered.⁴⁰⁹ About 5% of consecutive patients with proven GH-cell adenomas have normal GH and increased IGF1 levels. It is likely that improved GH assay sensitivity will unmask abnormal GH secretion in these patients.

Dynamic pituitary testing (response to TRH and dopamine) does not distinguish patients with pituitary adenomas from those harboring extrapituitary tumors. Plasma GHRH levels are invariably elevated in patients with peripheral GHRH-secreting tumors but are normal or low in patients with pituitary adenomas.⁴¹⁰ GHRH plasma level measurement is precise and cost-effective for diagnosis

Figure 9-26 Mortality in acromegaly. Mortality outcome in acromegaly. (Data integrated from Holdaway IM, Rajasoorya RC, Wong J, et al. The natural history of treated functional pituitary adenomas. In: Webb S, ed. *Pituitary Tumors*. Bristol, UK: BioScientifica; 1998:31-42.)

of ectopic acromegaly. Peripheral GHRH levels are not elevated in patients with hypothalamic GHRH-secreting tumors, presumably because eutopic hypothalamic GHRH secretion into the hypophyseal portal system does not appreciably enter the systemic circulation.

The presence of unique or unexpected clinical features, such as respiratory wheezing or dyspnea, facial flushing, peptic ulcers, or renal stones, sometimes indicates the diagnosis of a nonpituitary endocrine tumor. Hypoglycemia, hyperinsulinemia, hypergastrinemia, and, rarely, hypercortisolism—all not usually encountered in pituitary acromegaly—should justify an evaluation for an extrapituitary source of GH excess. MRI and CT scanning may be employed to localize pituitary or extrapituitary tumors. Routine abdominal or chest imaging of all patients yields a very low incidence of true-positive cases of ectopic tumor, and such screening is not recommended as cost-effective. The presence of a normal or small-sized pituitary gland, or of clinical and biochemical features of other tumors known to be associated with extrapituitary acromegaly and elevated circulating GHRH levels, is an indication for extrapituitary imaging. However, an enlarged pituitary is often present in patients with peripheral GHRH-secreting tumors, and the radiologic diagnosis of a pituitary adenoma can be difficult to exclude. The McCune-Albright syndrome should be considered after definitive exclusion of pituitary and extrapituitary tumors.

Treatment

Aims

A comprehensive strategy for treatment of acromegaly should aim to manage the pituitary mass, suppress GH and IGF1 hypersecretion, and prevent long-term clinical sequelae of hypersomatotropism while maintaining normal anterior pituitary function.^{403,405} An elevated GH level per se is associated with a threefold increased morbidity rate and is the single most important determinant of mortality.^{396,398-401} It is important to reverse the mortality rate to that of age-matched healthy subjects by aiming for tight GH control.⁴¹¹ Serum GH levels should be suppressed to at least 1 µg/L (or lower) after an oral glucose load, and IGF1 levels should be normalized for age and gender. With good control, there should also be a normal 24-hour integrated

secretion of GH (<2.5 µg/L). GH may not be measurable for most of the day, yet the tumor may still be hypersecreting, as reflected by increased levels of IGF1. Current therapeutic modes for acromegaly management, including surgery, irradiation, and medical treatment, do not uniformly fulfill these goals.

Surgical Management

Well-circumscribed somatotroph-cell adenomas should preferably be resected by transsphenoidal surgery.⁴¹²⁻⁴¹⁴ Successful resection alleviates preoperative compression effects and compromised trophic hormone secretion and, in the hands of a skilled surgeon, balances the extent of maximal tumor tissue removal with preservation of anterior pituitary function. Within 2 hours after successful resection, metabolic dysfunction and soft tissue swelling start improving, and GH levels are sometimes controlled within 1 hour. Surgical outcome correlates well with adenoma size, with preoperative serum GH levels, and particularly with the experience of the surgeon. Smaller tumors (<5 mm), tumor totally confined within the sella, and preoperative serum GH levels lower than 40 µg/L portend a favorable surgical outcome.

Up to 90% of patients with microadenomas achieve postoperative GH levels lower than 2.5 µg/L, whereas fewer than 50% of patients with macroadenomas of any size had postoperative GH levels lower than 2 µg/L after glucose administration.⁴¹⁵ Fewer than one third of all patients achieve control after resection of adenomas larger than 10 mm, but about 75% of patients with preoperative GH levels lower than 5 µg/L have normalized IGF1. Overall, in 17 studies of 1284 patients published between 1995 and 1999, 82% of patients harboring microadenomas had normalized IGF1 levels and 47% of those with macroadenomas achieved control (Table 9-23). A study of 2665 patients from a single center showed that 72% of patients with microadenomas and 50% of those with macroadenomas achieved GH levels lower than 1.0 µg/L during glucose loading and normal serum IGF1 levels.⁴¹⁶ Eight percent of these patients experienced a recurrence after 10 years.

Endoscopic transnasal surgery offers promise as a less invasive procedure for resection of pituitary tumors⁴¹⁷ and for accessing a cavernous sinus tumor mass, although long-term comparative results are not yet available.

TABLE 9-23

Results of Primary Transsphenoidal Surgery for Growth Hormone–Secreting Pituitary Adenomas

Study	No. Cases	Total Cure Rate (%)	Microadenomas	Macroadenomas	Criteria for Remission
Fahlbusch 1992	222	57	72	49	GH < 2 µg/L OGTT
		71	81	65	GH < 5 µg/L
Sheaves 1996	100	42	61	23	GH ≤ 2.5 µg/L
Abosch 1998	254	76	75	71	GH < 5 µg/L
Freda 1998	115	61	88	53	GH < 2 µg/L (OGTT) or normal IGF1
Swearingen 1998	149	70	91	48	GH < 2.5 µg/L (OGTT), normal IGF1
Laws 2000	117	67	87	50.5	GH ≤ 2.5 µg/L, GH ≤ 1 µg/L (OGTT), normal IGF1
Kreutzer 2001	57	70	N/A	N/A	GH ≤ 2.5 µg/L, GH < 1 µg/L (OGTT), normal IGF1
Shimon 2001	98	74	84	64	GH < 2 µg/L (OGTT), normal IGF1
De 2003	90	54	72	50	GH ≤ 2.5 µg/L, GH < 1 µg/L (OGTT), normal IGF1
Krieger 2003	181	56	80	31	Random GH < 2 µg/L
Beauregard 2003	103	65	82	47	GH < 1 µg/L (OGTT), normal IGF1
Mortini 2005	320	59	83	53	GH < 1 µg/L (OGTT), normal IGF1
Nomikos 2005	490	56	78	50	Basal GH ≤ 2.5 µg/L, GH ≤ 1 µg/L (OGTT), normal IGF1

GH, growth hormone; IGF1, insulin-like growth factor type I; OGTT, oral glucose tolerance test.

Modified from Wass, JAH, ed. *Acromegaly: A Handbook of History, Current Therapy and Future Prospects*. Bristol, UK: BioScientifica; 2009:142.

Difficulties in endotracheal intubation resulting from macroglossia or severe kyphosis may necessitate tracheostomy for anesthesia.

Side Effects. Although they are often transient, surgical complications may require lifelong pituitary hormone replacement. New hypopituitarism develops in up to 20% of patients, reflecting operative damage to the surrounding normal pituitary tissue.⁴¹⁸ Permanent diabetes insipidus, CSF leaks, hemorrhage, and meningitis occur in up to 10% of patients (see Table 9-3). The extent and prevalence of local complications depend on tumor size and invasiveness. Experienced pituitary surgeons report more favorable postoperative complication rates.⁴⁹ Biochemical or anatomic recurrence (approximately 7% over 10 years) or postoperative tumor persistence may indicate incomplete resection of adenomatous tissue, surgically inaccessible cavernous sinus tissue, or nesting of functional tumor tissue within the dura.

Radiation Therapy

Primary or adjuvant irradiation of GH-secreting tumors may be achieved by conventional external deep x-ray therapy or by heavy-particle (proton beam)^{56,419-421} or gamma knife radiosurgery.⁴²² Maximal tumor irradiation should ideally be attained with minimal soft tissue damage. Precise MRI localization, accurate simulation, isocentral rotational techniques, and high-voltage (6 to 15 MeV) delivery have improved the efficacy of radiation therapy. Radiotherapy is a highly individualized choice, depending on the expertise and experience of the treating radiotherapist as well as physician and patient choice, considering the benefits of therapy weighed against potential risks. Up to 5000 rads is administered in split doses of 180-rad fractions divided over 6 weeks.

Radiation arrests tumor growth, and most pituitary adenomas ultimately shrink.⁴²¹ GH levels fall gradually during the first year after treatment, and levels are lower than 10 $\mu\text{g/L}$ in 70% of patients after 10 years. Radiation therapy effectively shrinks GH-cell adenomas and lowers GH levels over 20 years in more than 90% of patients (Fig. 9-27).⁴²³ However, when pretreatment GH levels were greater than 100 $\mu\text{g/L}$, only 60% of patients had GH levels lower than 5 $\mu\text{g/L}$ after 18 years. During the first 7 years after irradiation, IGF1 levels were normalized in fewer than 5% of patients with acromegaly in one report,⁴¹⁹ whereas in another study, approximately 70% of patients exhibited normal levels when tested during longer follow-up.⁴²⁰ Radiotherapy does not normalize GH secretory patterns, and this probably accounts for persistently elevated IGF1 levels in the face of apparently controlled GH levels.⁴²⁴ Therefore, during the initial years after irradiation, most patients are still exposed to unacceptably high levels of circulating GH and IGF1.

Stereotactic pituitary tumor ablation by the gamma knife has been reported,⁴²⁵ and 82% of those treated had normal serum IGF1 levels; some of these patients were being treated simultaneously with somatostatin analogues.⁴²⁶ About 50% of patients achieved glucose-induced GH suppression to less than 1 ng/mL and normal IGF1 levels within 66 months after treatment.⁴²²

Side Effects. After 10 years, about half of all patients receiving radiotherapy have signs of pituitary trophic hormone disruption, and this prevalence increases annually thereafter, necessitating replacement of gonadal steroids, thyroid hormone, and/or cortisone. Side effects of conventional irradiation, including hair loss, cranial nerve

Figure 9-27 Radiation treatment of acromegaly. Long-term effects of radiation therapy on secretion of growth hormone (GH), using a GH nadir after oral glucose load (OGTT) of 2 $\mu\text{g/L}$ or less as the cure criterion, and the probability of not being cured with time after radiotherapy. The number of patients not cured at 5, 10, and 20 years after pituitary irradiation are indicated in parentheses. Each step represents one cure; each cross (+) denotes a patient not cured at the latest follow-up. (Reproduced from Barrande G, Pittino-Lungo M, Coste J, et al. Hormonal and metabolic effects of radiotherapy in acromegaly: long term results in 128 patients followed in a single center. *J Clin Endocrinol Metab.* 2000;85:3779-3785.)

palsies, tumor necrosis with hemorrhage, and, rarely, loss of vision or pituitary apoplexy, have been documented in up to 2% of patients.⁴²⁷ Lethargy, impaired memory, and personality changes may also occur.³⁹⁷ The incidence and extent of local complications have been markedly diminished by the use of highly reproducible simulators, precise rotational isocentric arc capability, and doses of less than 5000 rads. The use of Bragg-peak proton beam therapy is contraindicated in patients with suprasellar tumor extension because of unacceptable optic tract exposure to the radiation field. The rare development of second brain tumors in these patients has been reported at a cumulative risk frequency of 1.9% over 20 years.^{62,63} In a 10-year follow-up study of 35 patients treated with gamma knife radiosurgery, half the patients developed pituitary hormone deficiencies (40% hypoadrenalism, 11% hypothyroidism, 13% hypogonadism, and 6% GH deficiency).⁴²⁶

GH deficiency may result from radiation therapy.⁴²⁸ Importantly, even patients treated with surgery alone can become GH deficient,⁴²⁹ and in these patients, quality of life is reduced.⁴³⁰ Because of side effects, radiation therapy should be employed as an adjuvant when control is not achieved by surgery or medical management and for patients who refuse these other therapies.

Medical Management

Dopamine Agonists. Because dopamine attenuates GH secretion in about one third of patients with acromegaly, D_2 receptor agonists, including bromocriptine and cabergoline, have been used as primary or adjuvant therapy for acromegaly.²⁷⁰ Usually, up to 20 mg/day of bromocriptine lowers GH—a dose that is higher than that required to suppress PRL in patients harboring prolactinomas. Approximately 15% of patients worldwide have been reported to have suppressed GH levels (<5 $\mu\text{g/L}$) when taking the medication (7.5 to 80 mg/day),⁴³¹ and IGF1 is normalized in

fewer than 10% of patients. Dopamine agonist efficacy appears to be independent of PRL concentration.⁴³² The drug causes minimal tumor shrinkage, but some patients experience subjective clinical improvement despite persistently elevated serum GH or IGF1 levels.

Side effects of bromocriptine are more marked than those of cabergoline, especially because high doses are required. These side effects include gastrointestinal upset, transient nausea and vomiting, headache, transient postural hypotension with dizziness, nasal stuffiness, and, rarely, cold-induced peripheral vasospasm (see earlier discussion). In an open study, cabergoline was reported to suppress GH to less than 2 µg/L and to normalize IGF1 in up to one third of patients with acromegaly.⁴³³ Side effects included gastrointestinal symptoms, dizziness, headache, and mood disorders.

SRIF Receptor Ligands. Of the five SRIF receptor subtypes, SSTR2 and SSTR5 are preferentially expressed on somatotroph and thyrotroph cell surfaces and mediate suppression of GH and TSH secretion.^{269,434} Several SRIF receptor ligands (SRLs) have been employed as approved or investigational drugs for acromegaly (Fig. 9-28). For more than 20 years, these analogues have proved safe and effective for controlling acromegaly. Octreotide (D-Phe-Cys-Phe-D-Trp-Lys-Thr-Cys-Thr-OH), an octapeptide SRIF analogue, binds predominantly to SSTR2 and less avidly to SSTR5⁴³⁵ and inhibits GH secretion with a potency 45 times greater than that of native SRIF, but its potency for inhibiting insulin release is only 1.3-fold that of SRIF. The in vivo half-life of the analogue is prolonged (up to 2 hours) because of its relative resistance to enzymatic degradation. Rebound GH hypersecretion, seen after SRIF infusion, does not occur after octreotide injection. These properties are highly advantageous for long-term use of somatostatin analogues in acromegaly.⁴³⁶ In vivo Octreoscan imaging

with visualization of SRIF receptors demonstrates that GH responsiveness directly correlates with the abundance of pituitary receptors, and patients who are resistant to octreotide do not have visible in vivo receptor binding sites.⁴³⁷ Transfection of the *SSTR2* gene to somatotrophs enhances responsiveness to somatostatin analogues.⁴³⁸

A single subcutaneous administration of octreotide (50 or 100 µg) suppresses GH secretion for up to 5 hours. In a double-blind, placebo-controlled trial, octreotide (injections every 8 hours) significantly attenuated GH and IGF1 levels overall in more than 90% of patients.⁴³⁹ In patients with microadenomas, integrated GH and IGF1 levels are almost invariably normalized, whereas the response in those with larger tumors is less pronounced. A combination of octreotide and bromocriptine or cabergoline may provide added efficacy. Efficacy of octreotide action is determined by the frequency of drug administration, total daily dose, tumor size, presence of densely granulated tumors,⁴⁴⁰ and pretreatment GH levels. Increasing the frequency of administration more effectively suppresses GH levels, and continuous subcutaneous infusion (up to 600 µg/day) provides sustained GH control.⁴⁴¹ Total daily octreotide doses of 300 to 1500 µg subcutaneously are optimal, and further dose increases usually are not beneficial for patients with resistant tumors. Elderly male patients are particularly sensitive to the GH-lowering effects of octreotide, and in the long term, desensitization does not occur.⁴⁴²

Long-acting somatostatin analogue formulations are convenient, enhance compliance, and allow sustained biochemical control (Fig. 9-29). Serum levels of a long-acting release (LAR) octreotide depot preparation (octreotide LAR, 20 to 30 mg intramuscularly)⁴⁴³ peak at 28 days after a single injection, with integrated GH levels effectively suppressed for up to 49 days. Monthly injections for 9 years were shown to reduce integrated serum GH levels to less than 2 µg/L in more than 75% of patients.⁴⁴⁴ Overall, IGF1 levels are normalized in 60% to 70% of patients,⁴⁴⁵ and increasing the monthly dose of octreotide (Sandostatin LAR) to as high as 40 to 60 mg may improve efficacy.⁴⁴⁶

Lanreotide is a slow-release (SR), long-acting depot SRL that is administered as a fixed, 30-mg injectable dose every 7, 10, or 14 days. GH levels lower than 2.5 µg/L were achieved in 60% of 56 patients treated for 48 weeks, and suppression to less than 2.5 µg/L was achieved in about one third of 22 patients treated for up to 3 years, whereas IGF1 levels were normalized in almost two thirds of patients.⁴⁴⁷ A longer-acting preparation of lanreotide (lanreotide Autogel, Somatuline Depot) is administered by monthly deep subcutaneous injection. In a randomized, placebo-controlled, multicenter study with a 52-week open extension, serum GH levels decreased by more than 50% from baseline in 63% of patients receiving lanreotide Autogel, compared with 0% of controls, and the medication was effective throughout the trial.⁴⁴⁸ In one study, use of either of these SRL formulations was found to control GH levels in 100% and IGF1 levels in 97.8% of patients.²⁸¹

In a critical analysis, octreotide LAR and Somatuline Depot were shown to be equivalent in the control of acromegaly symptoms and biochemical markers (Fig. 9-30).⁴⁴⁹ In 166 patients with acromegaly, results of oral glucose tolerance tests were concordant for appropriate diagnosis and to establish efficacy of surgery and radiotherapy but were not helpful to evaluate effectiveness of medical SRL therapy. Measurement of serum IGF1 levels was sufficient to assess the effectiveness of SRL therapy.⁴⁵⁰

Effects of SRLs on Pituitary Adenoma. Tumors rarely grow while patients are receiving depot preparations of

Figure 9-28 Amino acid sequences of somatostatin release-inhibiting factor (SRIF) receptor ligands. Amino acid sequences of the two available somatostatin analogues are shown compared with endogenous somatostatin-14 (SS-14). Color overlay depicts ligand-binding regions. Comparison of primary octreotide treatment in 25 previously untreated patients (open circles) and in 80 patients who had previously undergone surgical resection or irradiation or both (filled circles). (From Newman C, Melmed S, George A, et al. Octreotide as primary therapy for acromegaly. *J Clin Endocrinol Metab*. 1998;83:3034-3040.) **B**, Pharmacodynamics of octreotide long-acting release (LAR). Twelve-hour mean serum octreotide and GH concentrations in a representative patient treated with a single 30-mg injection of Sandostatin LAR and monitored for 60 days. After injection, drug levels peaked at 28 days, and nadir GH levels were sustained for 4 weeks. (Adapted from Lancranjan I, Bruns C, Grass P, et al. Sandostatin LAR: a promising therapeutic tool in the management of acromegalic patients. *Metabolism*. 1996;45[8 suppl 1]:67-71.) **C**, Mean GH concentrations in patients with acromegaly after long-term treatment with octreotide LAR. Serum GH levels after monthly injections in 12 patients for 12 months and in 8 patients for 31 months. (From Davies PH, Stewart SE, Lancranjan I, et al: Long-term therapy with long-acting octreotide [Sandostatin-LAR] for the management of acromegaly. *Clin Endocrinol*. 1998;48:311-316.) **D**, Clinical impact of octreotide in reducing soft tissue swelling in a patient with acromegaly and obstructive sleep apnea before octreotide treatment (left). Note the macroglossia, tracheotomy for airway obstruction, and intranasal feeding tube. After 6 months of treatment with octreotide (right), tongue size was reduced by half, the tracheotomy and nasal tube were removed, and sleep apnea had resolved. (Courtesy of Seymour Reichlin University of Arizona, Treson.)

SRIF analogues. Significant tumor size decrease was reported in 52% of patients on primary therapy.⁴⁵¹ A critical analysis of 14 studies reported that 37% of patients treated primarily by SRL experienced significant tumor shrinkage.⁴⁵² Tumor shrinkage was reported in 75% and 78% of patients receiving octreotide LAR or Somatuline Depot, respectively, for up to 5 years.²⁸¹ In a systematic review of the effects of lanreotide SR and lanreotide Autogel, about one third of patients experienced tumor shrinkage (ranging from 10% to 77%).⁴⁵³ Fifty-nine patients undergoing pituitary surgery were randomly assigned to treatment arms, and the 22 patients who received preoperative octreotide for 3 to 6 months demonstrated improved postoperative outcomes.⁴⁵⁴⁻⁴⁵⁶

Effects on Clinical Features. More than 70% of patients experience improved general well-being, and soft tissue swelling dissipates within several days after treatment. Headache, a common symptom in acromegaly, usually resolves within minutes after injection of octreotide,⁴⁵⁷ most likely reflecting a specific central analgesic effect. Short-acting octreotide is preferable to long-acting formulations for acute headache resolution. Asymptomatic patients experience significant decreases in blood pressure, heart rate, and left ventricular wall thickness.⁴⁵⁸ In patients with cardiac failure, octreotide reversibly reduces systemic

arterial resistance, oxygen consumption, and fluid volume and restores functional activity. In 30 patients, improved left ventricular ejection fraction, with unchanged diastolic filling, was associated with octreotide-induced GH suppression to less than 2.5 μg/L. Control of IGF1 and GH levels was associated with improved left ventricular ejection function, but cardiac performance worsened in those who did not achieve such control.⁴⁵⁹ Joint function and crepitus improved, there was ultrasound evidence of bone or cartilage repair, and, after several months, sleep apnea improved.²⁴⁸

Side Effects. SRLs are generally safe and well tolerated. Gastrointestinal side effects predominate; they include transient loose stools, nausea, mild malabsorption, and flatulence and are reported in about one third of patients. Hypoglycemia and hyperglycemia are not commonly encountered, and insulin requirements in diabetic patients with acromegaly are dramatically reduced within hours after receipt of octreotide, concomitant with GH lowering. Overall, SRLs do not cause major effects on glucose homeostasis, and hyperglycemia is likely associated with uncontrolled underlying disease.⁴⁶⁰ The drug attenuates gallbladder contractility, delays emptying, and leads to reversible sludge formation evidenced by ultrasonography in up to 25% of patients.⁴⁶¹ Frank cholecystitis is very rarely reported

Figure 9-30 Summary of biochemical end points of studies comparing the efficacy of octreotide long-acting release (LAR) versus lanreotide Autogel (ATG). GH, growth hormone; IGF-I, insulin-like growth factor type I; LAN, lanreotide ATG; OCT, octreotide LAR; SRIF, somatotropin release-inhibiting factor. (Adapted from Murray R. Melmed S.A critical analysis of clinically available somatostatin analog formulations for therapy of acromegaly. *J Clin Endocrinol Metab.* 2008;93:2957-2968.)

in these patients. The incidence of gallbladder sludge or stones is geographically variable, with higher rates reported in China, Australia, and the United Kingdom than elsewhere. In the United States, up to 30% of patients have demonstrable evidence of echogenic gallbladder deposits within the first 18 months after treatment. Thereafter, further sludge formation is not usually encountered.⁴⁴³

Octreotide may interact with several drugs, including cyclosporine, enhancing the risk of transplant rejection. SRL dose adjustments should be carefully titrated in patients who require insulin or oral hypoglycemic agents, calcium channel blockers, or β -blockers. Asymptomatic sinus bradycardia has also been recognized.

Growth Hormone Receptor Antagonist. GH action through the surface membrane GH receptor is mediated by ligand-induced receptor signaling.⁴⁶² The postreceptor GH signal is not elicited if the receptor is bound (Fig. 9-31) by pegvisomant, a GH-receptor antagonist, which blocks subsequent generation of IGF1.⁴⁶² The pegylated molecule also binds to the GH receptor dimer and interacts with growth hormone binding protein.⁴⁶³ In earlier studies, daily injections of pegvisomant (20 mg) normalized IGF1 levels in more than 90% of patients and dose-dependently improved fatigue, decreased soft tissue swelling as assessed by ring size, and diminished perspiration.⁴⁶²

More recently, median 15-mg and mean 16.4-mg daily doses of pegvisomant were shown to normalize IGF1 in 55% of 273 patients in a national database at 6 months and in 71% of 202 patients after 24 months of treatment.⁴⁶⁴ However, in a 91-month follow-up study (median follow-up, 18 months), IGF1 levels were controlled in 95% of patients treated in two centers.⁴⁶⁵ The drug is particularly useful for patients whose tumors are resistant to SRL therapy because it effectively normalizes IGF1 levels in these patients.^{466,467} However, rebound tumor enlargement after discontinuation of somatostatin analogues and tumor

growth while receiving pegvisomant should be carefully monitored.⁴⁶⁸

Side Effects. Elevated hepatic transaminases have been reported,⁴⁶⁹ and liver enzymes should be measured every 6 months. In one study analyzing liver function in 273 patients treated with pegvisomant, there were abnormalities in 20 patients, and 3 developed hepatobiliary failure.⁴⁶⁴ Local injection site inflammation and lipodystrophy have been reported. Long-term impact of the drug on pituitary tumor growth is not yet evident, and MRIs should be performed periodically. Levels of GH rise as the IGF1 negative feedback on the pituitary is lost, and IGF1 should be monitored in these patients.⁴⁷⁰

SRIF Receptor Ligand and Growth Hormone Receptor Antagonist Combination. Combination treatment for acromegaly is most effective for patients in whom treatment with a somatostatin analogue has led to tumor shrinkage with reduction, albeit inadequate, in GH or IGF1 levels (Fig. 9-32). In 11 such uncontrolled patients, dual blockade of the GH axis with pegvisomant and SRLs was shown to exhibit greater efficacy than treatment with either drug alone.⁴⁷¹ Monthly doses of long-acting somatostatin analogue have been successfully combined with weekly doses of pegvisomant.⁴⁷² A study of 63 patients showed that 4 years of combination treatment was safe; however, 23 patients developed elevated liver enzymes, particularly if they were diabetic.⁴⁷³

Choice of Therapy

Although challenging, tight control of GH secretion and normalization of IGF1 levels should be sought, because adverse mortality rates correlate strongly with GH levels. If GH and IGF1 results after treatment are discordant, the respective assays should be repeated by a reputable laboratory using rigorous assay standardizations and appropriate sensitivity cutoffs.⁴⁷⁴ Assessment of clinical activity may

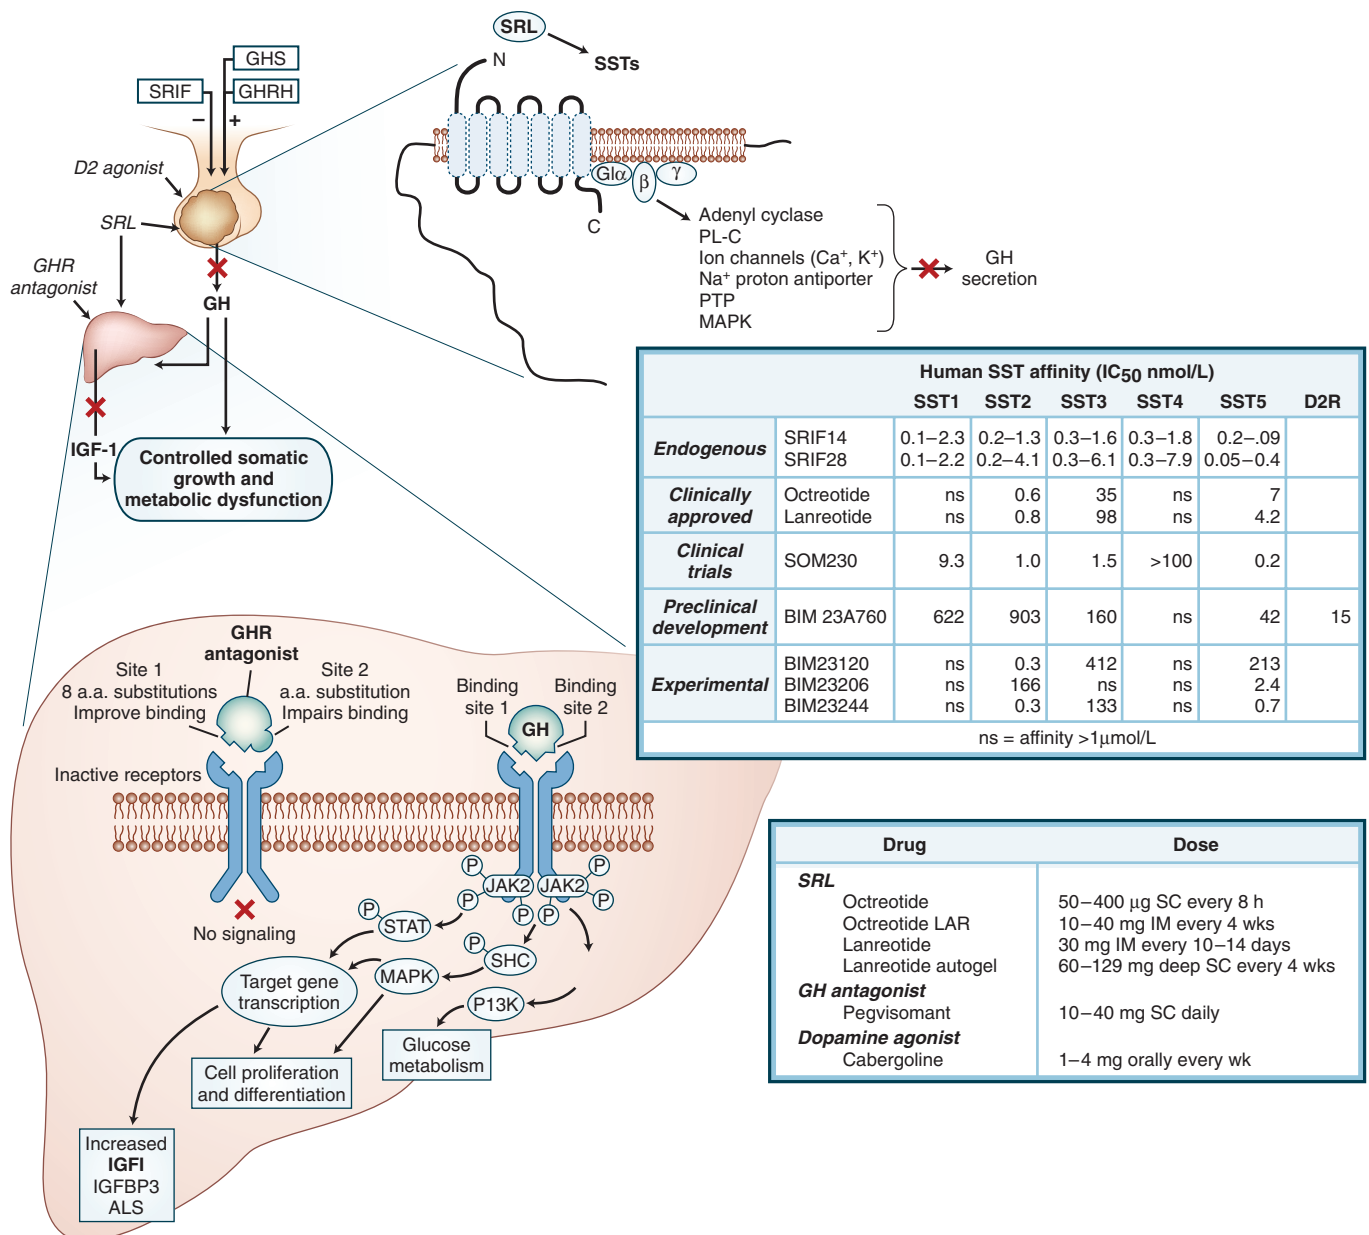

Figure 9-31 Action of growth hormone receptor (GHR) antagonist, somatostatin receptor ligands (SRLs), and dopamine (D2) agonists. Normally a single molecule of growth hormone (GH) binds two GH receptors through sites 1 and 2, and the GH signal transduction pathway is activated. Pegvisomant increases binding of GH receptor to site 1 and blocks binding at site 2 to prevent functional GH-receptor signaling, initiation of GH action, and induction of insulin-like growth factor type I (IGF1) synthesis and secretion. The peripheral effects of excess GH are antagonized at the cellular level, independent of the presence of somatostatin (SST) or D2 receptors on the pituitary tumor. SRLs inhibit GH secretion and IGF1 synthesis and suppress pituitary tumor growth. GH-secreting adenomas express predominantly somatostatin (SST) receptors 2 and 5. The figure depicts affinities for SST receptor subtypes and for the D2 receptor: a.a., amino acid; ALS, acid-labile subunit; C, carboxyl terminal; GHRH, gonadotropin hormone-releasing hormone; GHS, gonadotropin hormone secretagogue; IC₅₀, 50% inhibitory concentration; IGF1, insulin-like growth factor-1; IGF1BP3, insulin-like growth factor-binding protein 3; JAK2, Janus kinase 2 tyrosine kinase; MAPK, mitogen-activated protein kinase; N, amino terminal; ns, not significant; P, elemental phosphorus; PI3K, phosphoinositide 3 kinase; PL-C, phospholipase C; PTP, protein tyrosine phosphatase; SHC, Src homology-containing protein; SRIF, somatotropin release-inhibiting factor (somatostatin); STAT, signal transducer and activator of transcription. (Adapted from Melmed S. Acromegaly. *N Engl J Med*. 2006;355:2558-2573; and Heaney AP, Melmed S. Molecular targets in pituitary tumours. *Nat Rev Cancer*. 2004;4:285-295.)

indicate mild disease with suppressed GH and residual elevated IGF1 levels. Alternatively, normal or low IGF1 levels may be encountered in cases of systemic disease or malnutrition, with GH elevations reflecting persistent disease activity. Each treatment modality has advantages and disadvantages that must be weighed to individualize patient care (Fig. 9-33; Table 9-24).

Selective surgical excision of a well-defined pituitary mass is recommended for most patients with

microadenomas. Remission rates are unacceptably low for patients with macroadenomas and locally invasive tumors. Attempted medical debulking of the sellar mass before surgery is desirable, and early controlled, prospective studies have confirmed the validity of this approach to improve surgical morbidity and possibly enhance subsequent postoperative outcomes, especially for patients with surgically inaccessible tumor tissue and cavernous sinus invasion. Debulking may improve subsequent

Figure 9-32 Concentrations of insulin-like growth factor type I (IGF-I) in serum of 31 patients with acromegaly before (•) and after (○) 138 weeks (range, 35 to 149 weeks) of combined therapy. Shaded area indicates age-dependent normal range for IGF-I. SRIF, somatostatin. (Reproduced from Neggers S, van Aken M, et al. Long-term efficacy and safety of combined treatment of somatostatin analogs and pegvisomant in acromegaly. *J Clin Endocrinol Metab*. 2007;92:4598-4601.)

responsiveness to SRL therapy.⁴⁷⁵ Postoperatively, patients with uncontrolled disease can also be treated with cabergoline; although the efficacy of this drug is low, it is relatively inexpensive and free of major side effects. A long-acting SRIF analogue should be administered, because the utility of an initial test dose of short-acting octreotide has been questioned.⁴⁷⁶ Some patients may benefit by the addition of bromocriptine or cabergoline to the SRL.

Gallbladder ultrasonography should be performed only in symptomatic patients, and those with demonstrable sludge or gallstones may require prophylactic anticholelithogenic agents or laparoscopic cholecystectomy if symptomatic. Primary therapy with SRLs may be offered to those patients in whom complete tumor removal is not likely and to those who refuse surgery or in whom the risks of surgery or anesthesia are unacceptable. Invasive macroadenomas invariably hypersecrete GH postoperatively and require SRL treatment. In patients whose pituitary lesion does not compress vital structures, primary medical management may therefore be an appropriate therapeutic option.^{281,477-479} Preoperative SRL treatment may also enhance subsequent surgical outcomes, especially for macroadenomas.⁴⁵⁶ Pegvisomant, either alone or in combination with an SRL, should be offered to patients with resistant disease. Radiation should be administered to patients who are resistant to or cannot tolerate medications, prefer not to receive long-term injections, or cannot afford medication. After irradiation, medications are required for several years until GH levels are effectively controlled.

Tumors that recur despite medical therapy or irradiation may rarely require reoperation. Although tight GH control is critical, these patients also require counseling for anxiety engendered by disfigurements and interpretation of laboratory test results. Patients should be monitored quarterly until biochemical control is achieved. Thereafter, hormone evaluation is performed semiannually. For those patients who are in biochemical remission and have no residual tumor tissue, MRI should be repeated every 1 to 2 years.

Follow-up evaluation includes documentation and treatment of new skin tag and lipoma growths, nerve entrapments, and jaw overbites; rheumatologic, dental, and cardiac evaluations; and metabolic assessments. Visual field perimetry (for macroadenomas) and pituitary reserve testing should be repeated semiannually, and pituitary MRI should be performed annually, especially for patients who have residual tumor or require hormone replacement or medical treatment. Mammography and colonoscopy should be performed as clinically indicated for patients older than 50 years of age and for those harboring polyps. Maximal and sustained long-term GH and IGF1 control should ameliorate the deleterious effects of these hormones through judicious use of available treatment modalities. A recent guideline for the approach to treatment has been recommended by the Acromegaly Consensus Group.⁴⁰⁵

ACTH-SECRETING TUMORS (CUSHING'S DISEASE)

The evaluation and management of Cushing's disease is fully described in Chapter 15. Briefly, the diagnosis of an ACTH-secreting pituitary tumor is suggested by features of hypercortisolism, elevated 24-hour urinary free cortisol levels, and/or elevated late-night salivary cortisol values,⁴⁸⁰⁻⁴⁸² together with nonsuppressed serum ACTH levels. Failure to suppress morning cortisol levels to less than 1.8 µg/dL after administration of 1 mg dexamethasone at 11 p.m. supports the diagnosis.⁴⁸² In healthy subjects, glucocorticoid feedback suppresses corticotropin-releasing hormone and ACTH, attenuating cortisol secretion.

Surgical resection of an ACTH-secreting adenoma is the treatment of choice. Because these tumors are usually small, sometimes less than 2 mm in diameter, they may be localized incorrectly, or not at all, by venous sampling for ACTH (see earlier discussion) and sensitive MRI. Therefore, these tumors pose a significant challenge even for the experienced surgeon. Furthermore, the disorder is also characterized by venous hypertension leading to turgid venous sinuses,⁴⁸³ requiring control by the anesthetist. Bilateral petrosal venous sampling for ACTH levels and cavernous sinus venography should ideally be performed before surgery. However, if sellar venous sinus drainage is predominately unilateral, left-right ACTH gradients may not reliably lateralize the lesion. Hemihypophysectomy may be curative in 80% of patients with clearly defined biochemical features of ACTH-dependent Cushing's disease in whom an ACTH gradient is indeed detected and venous drainage patterns are normal. Meticulous surgical exploration of both anterior and posterior lobes is required for these tiny tumors, which are often off-white and speckled by petechiae and may be inadvertently suctioned. Even carefully performed preoperative lateralization is not infallible, and the so-called normal side should also be carefully explored.

Assessment of Surgical Outcome

Transsphenoidal resection is the preferred treatment for these adenomas.⁴⁸⁴ After selective adenomectomy of a clearly identifiable adenoma, remission was achieved in 75% of 295 patients. However, partial hypophysectomy in 31 patients in whom an adenoma could not be identified resulted in biochemical remission in only 10 patients.⁸⁹ On the third postoperative day, 1 mg dexamethasone may be given at 10 p.m. and cortisol levels measured the following

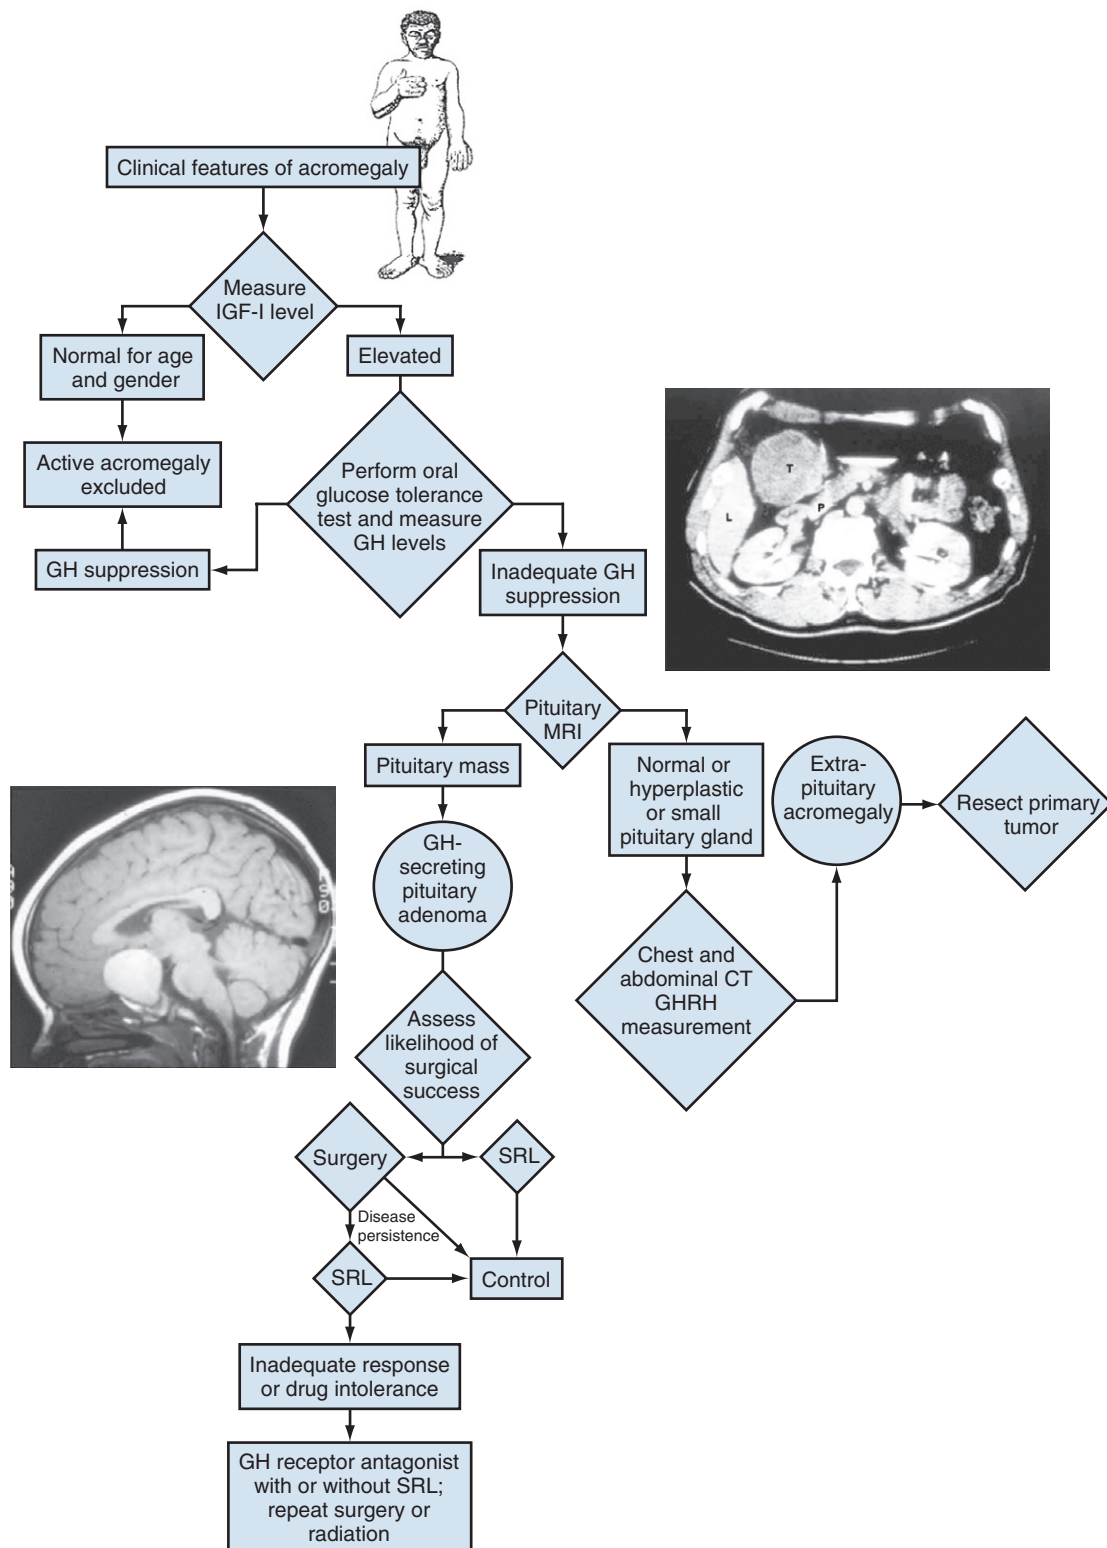

Figure 9-33 Diagnosis and treatment of acromegaly. An oral glucose tolerance test (OGTT) is performed with administration of 75 g glucose and measurements of growth hormone (GH) during the following 2 hours. Disease control implies a nadir GH level of less than 1 $\mu\text{g/L}$ after OGTT with an age- and gender-normal level of insulin-like growth factor type I (IGF-I). CT, computed tomography; GHRH, growth hormone-releasing hormone; MRI, magnetic resonance imaging; SRL, somatostatin receptor ligand. Inset on the right shows extrapituitary acromegaly. L, liver; P, pancreas; T, tumor secreting GH. (From Melmed S. Acromegaly. *N Engl J Med*. 2006;355:2558-2573. Clinical features figure is reproduced from Minkowski O. Ueber einen Fall von Akromegalie Berliner: *Klin Wochenschr* 1887;21:371-374.)

TABLE 9-24

Management of Acromegaly

GOALS					
Control GH and IGF1 secretion Control tumor growth Relieve central compressive effects, if present Preserve or restore pituitary trophic hormone function Treat comorbidities (hypertension, cardiac failure, hyperglycemia, sleep apnea, arthritis) Normalize mortality rates Prevent biochemical recurrence					
TREATMENTS					
Characteristic	Surgery	Radiotherapy	SRL	GHR Antagonist	Dopamine Agonist
Advantages					
Mode	Transsphenoidal resection	Noninvasive	Monthly injection	Daily injection	Oral
Biochemical Control					
GH < 2.5 µg/L	Macroadenomas, <50% Microadenomas, >80%	~35% in 10 yr	~80%	Increases	<15%
IGF1 normalized		<30%	~70%	>90%	<15%
Onset	Rapid	Slow (years)	Rapid	Rapid	Slow (weeks)
Patient compliance	Onetime consent	Good	Must be sustained	Must be sustained	Good
Tumor mass	Debulked or resected	Ablated	Growth constrained or shrinks ~50%	Unknown	Unchanged
Disadvantages					
Cost	One-time	One-time	Ongoing	Ongoing	Ongoing
Hypopituitarism	~10%	>50%	None	Very low IGF1 if overtreated	None
Other	Tumor persistence or recurrence, 6% Diabetes insipidus, 3% Local complications, 5%	Local nerve damage Second brain tumor Visual and CNS disorders, ~2% Cerebrovascular risk	Gallstones, 20% Nausea, diarrhea	Elevated liver enzymes (rare)	Nausea, ~30% Sinusitis High dose required
OUTCOMES					
Feature	Evaluation		Treatment		
Safe Biochemical Activity					
Nadir GH < 0.4 µg/L Age-matched normal IGF1 Asymptomatic No comorbidities	Assess GH/IGF1 axis Evaluate adrenal, thyroid and gonadal axes Periodic but less frequent MRI		None or no change in current treatment		
Unsafe Biochemical Activity					
Nadir GH > 0.4 µg/L Elevated IGF1 Discordant GH and IGF1 Asymptomatic No comorbidities	Assess GH/IGF1 axis Evaluate pituitary function Periodic MRI		Weigh treatment benefit vs risks Consider new treatment if being treated		
Unsafe Biochemical and Clinical Activity					
Nadir GH > 1 µg/L Elevated IGF1 Clinically active tumor growing	Assess GH/IGF1 axis Evaluate pituitary function Assess cardiovascular, metabolic, and tumoral comorbidity Periodic MRI		Actively treat or change treatment		

GH, growth hormone; GHR, growth hormone receptor; IGF1, insulin-like growth factor type I; MRI, magnetic resonance imaging; SRL, somatostatin receptor ligand. Modified from Melmed S. Acromegaly. *N Engl J Med*. 2006;355:2558-2573.

morning, before initiation of hydrocortisone therapy. If the immediate postoperative cortisol level is lower than 3 µg/dL, a 95% 5-year remission rate can be expected. In 21 of 27 patients tested before glucocorticoid administration, postoperative cortisol levels lower than 10 mcg/dL, or lower than those obtained from preoperative midnight sampling, were predictive of remission.⁴⁸⁵

Silent Corticotroph Adenoma

The basophilic tumors known as silent corticotroph adenomas are usually nonfunctional and yet exhibit POMC product immunoreactivity. ACTH secretion is unaltered, and there are no associated clinical or biochemical features of hypercortisolism, although these tumors are

morphologically indistinguishable from adenomas associated with Cushing's disease. They may represent up to 7% of all surgically removed adenomas⁴⁸⁶ and are usually hemorrhagic and invariably macroadenomas. In contrast to Cushing's disease, they have a 2:1 male preponderance, often present with mass effects, and show preoperative evidence for pituitary insufficiency in about one third of cases. About half of these tumors exhibit cavernous sinus or bony invasion, hemorrhage, necrosis, and cyst formation. These tumors often recur, and postoperative irradiation and reoperation are required to eradicate tumor regrowth or residual mass.⁴⁸⁷ Unless appropriate immunostaining is performed, many of these tumors remain undiagnosed and are classified as recurrent nonfunctioning macroadenomas.

THYROTROPIN (TSH)-SECRETING TUMORS

TSH-producing pituitary tumors are rare. During the period 1979 to 1992, Mindermann and Wilson analyzed tumor type by immunohistochemistry and found that the overall prevalence of TSH-secreting tumors was 0.85% (19/2225). Between 1989 and 1991, the same group found a prevalence of 2.8%.⁴⁸⁸ It is not clear whether the incidence of this tumor type is increasing or whether tumors are now more readily recognized, perhaps as a result of the development of high-sensitivity TSH assays that can distinguish between frankly low values and those that are apparently normal but in fact inappropriately elevated in relation to thyroid hormone levels in some patients with TSH-producing tumors. TSH-secreting tumors can also cosecrete other hormones, including GH, PRL, and, rarely, ACTH,⁴⁸⁹ and they can cause elevated serum IGF1 or PRL levels.⁴⁹⁰

Pathology

These tumors are invasive but for the most part benign, and distant metastases are extremely rare. The secretory pattern is determined by a panel of immunoreactive antibodies to TSH- β , α -subunit, GH, PRL, and ACTH. Twenty-four-hour sampling indicates that the pulse frequency of TSH is increased and the diurnal rhythm is preserved at a higher mean hormone level.⁴⁹¹ TSH-secreting tumors exhibit positive immunostaining for α -subunit and TSH- β in 20% to 75% of cells, as well as for the pituitary-specific transcription factor, Pit-1.⁴⁹² These tumors express SSTR2 mRNA and, in some cases, SSTR3 and SSTR5 mRNA.⁴⁹³

Presentation

Patients with TSH-secreting tumors present with symptoms resulting from tumor growth (including visual field abnormalities, cranial nerve palsies, and headache) or from hormone overproduction. Signs and symptoms of hyperthyroidism including palpitations, arrhythmias, weight loss, tremor and nervousness, or goiter are common. A case of periodic paralysis has been reported.⁴⁹⁴ Serum TSH is often, but not invariably, elevated, and the combination of abnormally high thyroid hormone and a TSH value within the normal range points to a TSH-producing pituitary tumor. A relatively long period of hyperthyroidism, initially thought to be Graves' disease and treated accordingly, often predates the realization that the hyperthyroidism is caused by a TSH-secreting pituitary tumor. Alternatively, thyroid hormone insensitivity can manifest with similar laboratory profiles.⁴⁹⁵ TSH-secreting tumors are usually large: 88% are macroadenomas, and 12% are

microadenomas. More than 60% are also locally invasive.⁴⁹⁶ From an analysis of 10 reports involving a total of 164 patients, it appears that TSH was frankly elevated in 58% of patients (see Table 9-25), with the remainder having normal, albeit inappropriately elevated, TSH levels. Patients previously treated with radioactive iodine for presumed Graves' disease had significantly higher TSH levels at presentation than did patients who had not undergone radioablation (mean concentration, 56 versus 9 mU/L, respectively).⁴⁹⁷ An ectopic TSH-producing tumor has also been reported.⁴⁹⁸ Serum T₄ is high in the majority of patients, as is the glycoprotein hormone α -subunit. Approximately two thirds⁴⁹⁷ of patients with TSH-producing pituitary tumors have a goiter with elevated radioactive iodine uptake. Signs or symptoms of acromegaly or hyperprolactinemia may also be presenting complaints, reflecting a mixed tumor type.

Evaluation

Serum T₄, T₃, TSH (by high-sensitivity assay), and α -subunit should be measured. The combination of high T₄, T₃, and α -subunit; high or inappropriately normal TSH; and a pituitary tumor strongly confirms the diagnosis of a TSH-producing pituitary adenoma. TRH stimulation differentiates between TSH overproduction by a TSH-secreting tumor and thyroid hormone insensitivity. In TSH-secreting tumors, the TSH response elicited by TRH is blunted. In contrast, TSH usually rises in response to TRH in patients with thyroid hormone insensitivity and in normal subjects. Concomitant measurement of α -subunit at each point during the TRH test is helpful because the molar ratio of α -subunit to TRH is high (>1) in almost 85% of patients with TSH-secreting tumors. A T₃ suppression test is helpful in that complete inhibition of TSH does not occur in patients with TSH-secreting tumors. This test can also identify subclinical hypothyroidism in patients who were previously treated with radioactive iodine for hyperthyroidism but later found to have an incidental pituitary tumor.

TSH elevation may also result from inadequate thyroid hormone replacement. A pituitary MRI should be performed, and IGF1 and PRL levels should be determined to exclude acromegaly and hyperprolactinemia. The presence of other pituitary hormones in immunostained histologic sections does not necessarily imply elevated serum levels. Importantly, the degree of hyperthyroidism should be assessed to determine whether control of these signs and symptoms should be undertaken before further evaluation or treatment of the pituitary tumor. Hyperthyroidism in this condition was characterized as being severe in 14 of 25 patients and was judged to have been present in most patients for years before the diagnosis was made.⁴⁹⁶ Perioperative deaths in patients with TSH-secreting tumors have been reported, which might possibly be attributed to poorly controlled hyperthyroidism.

Management

Surgery

Surgery has been recommended as first-line treatment, but surgical cures occur in fewer than 40% of patients (Table 9-25; Fig. 9-34).^{499,500} However, the rarity of this tumor type has precluded large controlled studies. Fourteen of 22 patients had cavernous or sphenoid sinus invasion and tumors were fibrous and unusually hard; 8 of these patients were considered cured after surgery.⁴⁸⁹ In another study, surgery normalized T₄ levels in 15 and normalized parameters of cure in 7 of 17 patients. More than half of the

patients exhibited evidence of residual tumor when assessed by MRI at 6 months after surgery.⁵⁰¹

Radiation Therapy

There are no large series reporting treatment of TSH-secreting tumors with radiotherapy alone. Radiation has mostly been employed as adjunctive therapy to surgery, especially when the latter was not curative.

Somatostatin Analogues

Octreotide, used as either primary or adjunctive treatment, normalizes T₄ and T₃ and reduces TSH levels by half.⁵⁰² Overall, tumor shrinkage occurs in about one third of patients. In 18 patients with TSH-secreting adenomas, lanreotide (30 mg every 10 or 14 days) significantly decreased TSH levels (from 2.72 to 1.89 mU/L) and decreased T₄ levels but did not shrink tumors. Responsiveness to octreotide LAR (up to 30 mg monthly) appeared similar to that observed for the subcutaneous preparation in 7 patients.⁵⁰³ Octreotide suppressed TSH in 90% of patients with TSH-secreting tumors and reduced tumor size in 50% of these patients.⁵⁰⁴

Unless vision is threatened, patients should be evaluated to determine whether clinical signs of hyperthyroidism warrant immediate treatment (see Table 9-25). Propranolol,

thyroid ablation with radioactive iodine, thyroidectomy, anti-thyroid medications including Tapazole and propylthiouracil, and somatostatin analogues are employed.⁵⁰⁵ Both radioactive iodine and anti-thyroid medications are targeted to the thyroid gland rather than the pituitary seat of the disorder. This approach also inhibits the remaining negative feedback of T₃ on TSH and leads to increased tumor TSH production.⁵⁰² Surgery and somatostatin analogues simultaneously treat hyperthyroidism and tumor TSH hypersecretion. Somatostatin analogues lower TSH, α -subunit, and T₄ and are recommended as first-line drugs in the initial control of hyperthyroidism caused by TSH-secreting tumors, because their onset of action is faster than that of other therapeutic approaches and tumor shrinkage occurs in up to 40% of patients.

No single treatment is expected to cure patients with TSH-secreting adenomas. Surgery is curative in only a minority of patients, and although tumor debulking may normalize thyroid function when invasive tumor tissue persists, patients continue to have abnormal TSH responses to TRH and require somatostatin analogue therapy. The relative rarity of TSH-secreting tumors renders large-scale studies difficult, but there is growing evidence for successful treatment of these tumors with somatostatin analogues as first-line therapy.

CHAPTER

10

Posterior Pituitary

ALAN G. ROBINSON • JOSEPH G. VERBALIS

ANATOMY

Normal Anatomy

The posterior pituitary is neural tissue and consists only of the distal axons of the hypothalamic magnocellular neurons that make up the neurohypophysis. The perikarya (cell bodies) of these axons are located in paired paraventricular and supraoptic nuclei of the hypothalamus. During embryogenesis,¹ neuroepithelial cells of the lining of the third ventricle mature into magnocellular neurons while migrating laterally to and above the optic chiasm to form the supraoptic nucleus and to the walls of the third ventricle to form the paraventricular nuclei. In the posterior pituitary, the axon terminals of the magnocellular neurons contain neurosecretory granules, membrane-bound packets of hormones stored for subsequent release. The blood for the anterior pituitary is supplied via the hypothalamic-pituitary portal system, but the posterior pituitary blood supply is directly from the inferior hypophyseal arteries, which are branches of the posterior communicating and internal carotid arteries. The drainage is into the cavernous sinus and internal jugular vein.

The hormones of the posterior pituitary, oxytocin and vasopressin, are synthesized in individual hormone-specific magnocellular neurons. The supraoptic nucleus is

relatively simple, with 80% to 90% of the neurons producing vasopressin² and virtually all axons projecting to the posterior pituitary.¹ The organization of the paraventricular nuclei is much more complex and varies among species. In the human, there are five subnuclei² and parvocellular (smaller cells) divisions that synthesize other peptides, such as corticotropin-releasing hormone (CRH), thyrotropin-releasing hormone, somatostatin,³ and opioids.⁴ The parvocellular neurons project to the median eminence, brain stem, and spinal cord,⁵ where they take part in a variety of neuroendocrine autonomic functions. The suprachiasmatic nucleus, which is located in the midline at the base of and anterior to the third ventricle, also synthesizes vasopressin and controls circadian and seasonal rhythms.²

The major stimulatory neurotransmitter in the neurohypophysis is glutamate; noradrenergic stimulatory inputs act by stimulating glutamate.^{6,7} Glutamate receptors account for 25% of synapsis on magnocellular neurons.⁶ The major inhibitory input is γ -aminobutyric acid (GABA), which accounts for 20% to 40% of the synaptic input to the magnocellular neurons.⁸ Steroid hormone actions on the magnocellular neurons are mediated by GABA or glutamate receptors.⁹

One of the most remarkable aspects of the magnocellular system is the plasticity of the system in response to

prolonged stimulation. Plasticity is demonstrated in animals by prolonged osmotic stimulation with hypertonic saline, but it is probably most often of import in humans during parturition and lactation.⁸ During prolonged stimulation, the perikarya themselves enlarge and the glia retract, diminishing astrocyte coverage of the neurons and increasing extracellular space between cells so that neurotransmitters can spread among cells. These two events interact to increase the contact between cells, which enhances the synchrony and the pulsatile secretion, which for oxytocin is especially important during parturition and milk let-down of lactation. Secretion of oxytocin by dendrites of the neurons produces a positive feedback in a paracrine/autocrine fashion to enhance the further secretion of the hormone; vasopressin release similarly produces a positive feedback enhancement. Neurotransmitter receptors may increase on the neuron and the astrocytes themselves and contribute to the plasticity, not just by altering their shape but because they function to clear neurotransmitters from the extracellular space and release active substances themselves. This structural plasticity during stimulation is enabled by the continued presence in the supraoptic and paraventricular nuclei of cytoskeleton proteins and cell adhesion molecules that are present elsewhere in the brain only during embryogenesis.¹⁰

Ectopic Posterior Pituitary

With the development of magnetic resonance imaging of the brain, it was discovered that T1-weighted images with MRI produced a bright signal in the posterior pituitary.¹¹ This new diagnostic imaging technology (described in detail later) allowed the identification of children with abnormal anatomy of the posterior pituitary in whom the “bright spot” was recognized in the base of the hypothalamus. These cases are referred to as *ectopic posterior pituitary* or *ectopic posterior lobe*. Etiologies include traumatic delivery (these patients have a higher incidence of breech delivery and perinatal injuries) and genetic abnormalities of the transcription factors that regulate pituitary embryogenesis.¹² Cases are recognized in children with growth retardation and anterior pituitary deficiency rather than posterior pituitary deficiency. The degree of anterior pituitary deficit depends on the persistence of a pituitary stalk and a retained portal vasculature from the hypothalamus to the anterior pituitary.¹³⁻¹⁵ Deficiency of adrenocorticotrophic hormone (ACTH) is common and should be investigated, because the patients may not respond appropriately to stress.¹²

SYNTHESIS AND RELEASE OF NEUROHYPOPHYSEAL HORMONES

Vasopressin and oxytocin are nonapeptides consisting of a 6-amino-acid ring with a cysteine-to-cysteine bridge and a 3-amino-acid tail (Fig. 10-1). All mammals have arginine vasopressin and oxytocin, as illustrated in Figure 10-1, with the exception of the pig. In the pig, a lysine is substituted for arginine in position 8 of vasopressin, producing lysine vasopressin. Both genes are found on chromosome 20,¹⁶ although they are situated in a tail-to-tail position and transcribed in opposite directions.¹⁷ The hormones are each synthesized as part of a precursor molecule consisting of the nonapeptide and a hormone-specific neurophysin and for vasopressin only an additional glycopeptide.¹⁸ The precursor is packaged in neurosecretory granules and cleaved to the products during transport to the posterior pituitary.

A Arginine vasopressin

B Oxytocin

C Desmopressin

Figure 10-1 Comparison of the chemical structures of, **A**, arginine vasopressin, **B**, oxytocin, and, **C**, desmopressin. The differences are illustrated by the shaded areas. Oxytocin differs from vasopressin in position 3 (Ile for Phe) and position 8 (Leu for Arg). Desmopressin differs from arginine vasopressin in that the terminal cystine is deaminated and the arginine in position 8 is a D rather than an L isomer. (From A. G. Robinson, University of California at Los Angeles, CA, with permission.)

When a stimulus for secretion of vasopressin or oxytocin acts on the appropriate magnocellular cell body, an action potential is generated and propagates down the long axon to the posterior pituitary. The action potential causes an influx of calcium, which induces neurosecretory granules to fuse with the cell membrane and extrude their entire contents into the perivascular space and subsequently into the capillary system of the posterior pituitary. At the physiologic pH of plasma, there is no binding of these hormones (vasopressin or oxytocin) to their respective neurophysins, so each peptide circulates independently in the bloodstream.

The control of hormone synthesis is at the level of transcription. Stimuli for secretion of vasopressin or oxytocin also stimulate transcription and increase the messenger RNA (mRNA) content in the magnocellular neurons. This has been studied in most detail in rats, where dehydration¹⁹ accelerates transcription and increases the levels of vasopressin (and oxytocin) mRNA²⁰⁻²² and where hypoosmolality produces a decrease in the content of vasopressin mRNA.²³

The transport of neurosecretory vesicles from the site of synthesis to the posterior pituitary along microtubule tracks²⁴ is also regulated. When synthesis is turned off, transport stops, and when synthesis is increased, transport is upregulated.²⁴ Thus, there is coordination of stimulated release of hormone, transport of hormone, and synthesis of new hormone. There is, however, asynchrony in the timing of these events. The asynchrony is demonstrated by changes in the content of vasopressin stored in the posterior pituitary. The absolute content varies considerably among species but is a remarkable store, generally equivalent to the amount of hormone required to sustain basal release for 30 to 50 days or maximum release for 5 to 10 days.²⁵ In animals, prolonged and intense stimulation of

vasopressin release (e.g., in dehydration or salt-loading) produces a depletion of stored hormone in the posterior pituitary.^{22,26,27} When the animals are returned to normal water intake, there is within 7 to 14 days a gradual recovery of pituitary content back to baseline (or higher) levels. This phenomenon was modeled by Fitzsimmons,²⁸ who provided experimental evidence that a long half-life of the vasopressin message (approximately 2 days) is, from a minimalist point of view, a plausible explanation of the events. When a strong or sustained stimulus releases vasopressin, there is an immediate stimulus for transcription of new mRNA. Because it requires several days for the peak level of mRNA to be reached, translation increases slowly. When the stimulus is removed, the elevated mRNA slowly declines while synthesizing hormone that repletes the store in the posterior pituitary to the previous baseline level.

PHYSIOLOGY OF SECRETION OF VASOPRESSIN AND THIRST

The physiologic regulation of vasopressin synthesis and secretion involves two systems: osmotic and pressure/volume (Fig. 10-2). Functions of these two systems are so distinct that historically it was thought there were two hormones—an antidiuretic hormone (ADH) and a vasopressor hormone (AVP). Hence, the two names are used interchangeably for (8-arginine) vasopressin. There are separate systems at the level of the receptors on the end organs of response. The V_{1a} receptors on blood vessels are distinct from V_2 receptors on renal collecting duct epithelia. A third receptor, V_3 or V_{1b} , is responsible for the non-traditional biologic action of vasopressin to stimulate ACTH secretion from the anterior pituitary. V_2 receptors also regulate the nontraditional action of vasopressin to stimulate production of factor VIII and von Willebrand factor.

Figure 10-2 Comparison in humans of the release of vasopressin in response to increased osmolality (open triangles) or to decreased blood pressure (filled circles) or blood volume (open circles). Plasma vasopressin is much more sensitive to change in osmolality, responding to as little as a 1% increase, whereas a change of 10% to 15% or greater in volume or pressure is required to stimulate release of vasopressin. (Redrawn from Robertson GL, Berl T. Water metabolism. In: Brenner B, Rector F Jr, eds. *The Kidney*, 3rd ed., vol. 1. Philadelphia, PA: Elsevier; 1986:385. Figure by A. G. Robinson, University of California at Los Angeles, CA, with permission.)

Vasopressin is the main hormone involved in the regulation of water homeostasis and osmolality, whereas the renin-angiotensin-aldosterone system (RAAS) is mainly responsible for regulation of blood pressure and volume. Pathologic disorders of the neurohypophysis are primarily expressed as abnormalities of osmolality produced by abnormal excretion or retention of water. In the case of osmoregulation, vasopressin secretion is relatively uncomplicated, with small increases in osmolality producing a parallel increase in vasopressin secretion and small decreases in osmolality causing a parallel decrease in vasopressin secretion. The regulation of volume and blood pressure is significantly more complicated (see review by Thrasher²⁹), and experimental models of vasopressin and baroreceptor regulation in animals often involve inhibiting or measuring other concurrent sympathetic inputs to the system, or both, to ascertain direct effects of any stimulus on secretion of vasopressin (see Fig. 10-2). Other influences on vasopressin secretion, such as the inhibiting influence of glucocorticoids and the potent stimulus of nausea and vomiting, are less important as physiologic regulators of vasopressin but may be important in pathologic situations.

Volume and Pressure Regulation

High-pressure arterial baroreceptors are located in the carotid sinus and aortic arch, and low-pressure volume receptors are located in the atria and pulmonary venous system.²⁹ The afferent signals from these receptors are carried from the chest to the brain stem through cranial nerves IX and X. Interruption of the vagal input by vagotomy or vagal cold block in dogs³⁰⁻³² or destruction of the A1 area of the medulla (which receives input from nerves IX and X) in rabbits³³⁻³⁵ results in an increase in vasopressin secretion. These and other data led to the concept that baroreceptors and volume receptors normally inhibit the magnocellular neurons and that decreases in this tonic inhibition result in release of vasopressin. Arterial and venous constriction induced by vasopressin action on V_{1a} receptors contracts the vessels around the existing plasma volume to effectively “increase” plasma volume and reestablish the inhibition of secretion of vasopressin.

Vasopressin’s action at the kidney to retain water does help replace volume, but the major hormonal regulation to control volume is the RAAS, which stimulates sodium reabsorption in the kidney (see Chapter 15). The concept of tonic inhibition of vasopressin secretion by baroreceptors has been questioned,^{29,36} but there is agreement that the volume receptor and baroreceptor responses that lead to increased vasopressin release in humans are much less sensitive than the osmoreceptors (see Fig. 10-2). This lesser response has been attributed to the fact that changes in blood volume and central venous pressure have little effect to increase vasopressin in humans as long as arterial pressure can be maintained by alternative regulatory mechanisms such as RAAS and sympathetic reflexes.²⁹ When the hypovolemia is sufficient to cause a decrease in blood pressure, there is a sudden and exponential increase in the level of vasopressin in plasma (see Fig. 10-2).^{29,37} There is also agreement that changes in volume or pressure that are insufficient to cause direct increases in vasopressin can nonetheless modify the response of the vasopressin system to osmoregulatory inputs.^{37,38}

Increases in pressure or central volume decrease the secretion of vasopressin,³⁹ but again, the response of the RAAS to cause sodium excretion is much more sensitive to increases of pressure and volume than is the response to

decrease secretion of vasopressin.²⁹ Consequently, changes in blood pressure and volume involve both excitatory and inhibitory influences from the brain stem to magnocellular neurons, with the dominant influence depending on the physiologic circumstances.

Osmotic Regulation

The primary receptors for sensing changes in osmolality are located in the brain. Most of the brain is within the blood-brain barrier, which is generally impermeable to polar solutes. The osmostat is insensitive to urea and glucose, which readily cross cellular membranes but not the blood-brain barrier; this provides evidence that the osmoreceptors must be outside the blood-brain barrier. Experimental brain lesions in animals have strongly implicated cells in the organum vasculosum of the lamina terminalis (OVLT) and in areas of the adjacent anterior hypothalamus near the anterior wall of the third cerebral ventricle as the primary osmoreceptors. Because these and other circumventricular organs are perfused by fenestrated capillaries, they are outside the blood-brain barrier. Surgical destruction of the OVLT abolishes vasopressin secretion and thirst responses to hyperosmolality but not responses to hypovolemia.⁴⁰ Essentially the same occurs in humans with brain damage that destroys the region around the OVLT, and these patients cannot maintain normal plasma osmolalities even under basal conditions.⁴¹ In contrast, destruction of the magnocellular neurons of the supraoptic and paraventricular nuclei eliminates dehydration-induced secretion of vasopressin but does not alter thirst, clearly indicating that osmotically stimulated thirst must be generated at a site proximal to the magnocellular cells.

Extracellular fluid (ECF) osmolality (predominantly determined by the sodium concentration, $[Na^+]$) varies from 280 to 295 mOsm/kg H_2O in normal subjects, but in any individual it is maintained within a narrower range. The ability to maintain this narrow range depends on the sensitive response of plasma vasopressin to changes in plasma osmolality; the sensitive response of urine osmolality to changes in plasma vasopressin; and then the gain in the system achieved by the response of urine volume to changes in plasma vasopressin (Fig. 10-3). Basal plasma vasopressin is in the range of 0.5 to 2 pg/mL. As little as a 1% increase or decrease in plasma osmolality causes a rapid increase or decrease of vasopressin released from the store of hormone in the posterior pituitary.³⁷ Rapid metabolism of vasopressin is also characteristic of the hormone, which circulates in plasma with a half-life of approximately 15 minutes, allowing rapid changes in levels of vasopressin in plasma. In this way, small increases in osmolality produce a concentrated urine, and small decreases in osmolality produce a water diuresis.

Figure 10-3 illustrates the linear relationship between plasma osmolality and plasma vasopressin that has been described in humans.³⁷ This linear relationship persists well above the normal excursion of osmolalities, as demonstrated when the increase is induced by infusion of hypertonic saline or is observed during dehydration of patients with nephrogenic diabetes insipidus.⁴² Similarly, Figure 10-3 illustrates that there is a sensitive and linear relationship between the level of vasopressin in plasma and the induced osmolality of the urine. Although plasma vasopressin may increase above the normal physiologic range, the urine osmolality plateaus at approximately 1000 to 1200 mOsm/kg H_2O because the maximum concentration that can be reached by the fluid in the renal collecting duct is the osmolality of the inner medulla.

Figure 10-3 Effect of change in plasma osmolality (pOsm, in mOsm/kg of H_2O) on plasma arginine vasopressin (PAVP, in pg/mL) and consequent effects on urine osmolality (UOsm, in mOsm/kg of H_2O) and urine volume (L/day). The shaded area represents the normal range. **A**, Small changes in pOsm induce changes in PAVP, typically between less than 0.5 and 5 to 6 pg/mL. **B**, Changes in PAVP induce changes in UOsm through the full range, from maximally dilute to maximally concentrated urine. Although PAVP can rise to higher levels than 6 pg/mL, this does not translate into increased UOsm, which has a maximum determined by the osmolality of an inner medulla of the kidney. **C**, The relationship of urine volume to UOsm is logarithmic, assuming a constant osmolar load and the urine volume that would excrete that osmolar load at the UOsm indicated. As a result, urine volume changes relatively little with small changes in the other parameters until there is almost complete absence of PAVP, after which the urine volume increases dramatically. (Calculated from a formula presented in Robertson G, Shelton R, Athar S. The osmoregulation of vasopressin. *Kidney Int.* 1976;10:25-37. Figure by A. G. Robinson, University of Los Angeles, CA, with permission of Macmillan Publishers, Ltd.)

Figure 10-3 also shows the relationship of plasma vasopressin to urine volume. This is a calculated relationship based on the urine volume necessary to excrete a fixed quantity of osmolytes (800 milliosmoles) at the urine osmolality produced by the change in plasma vasopressin. These graphs demonstrate the gain in the system that can be observed when the changes in urine volume relative to plasma vasopressin are considered. If vasopressin is absent, 18 to 20 L/day of urine is excreted, but with an increase in vasopressin of as little as 0.5 to 1 pg/mL, urine volume is reduced to less than 4 L/day. This illustrates the important point that small changes at low plasma levels of vasopressin are much larger determinants of polyuria than are greater changes at higher plasma levels.

In the kidney, water is conserved by the combined functions of the loop of Henle and the collecting duct. The loop of Henle generates a high osmolality in the renal medulla by means of the countercurrent multiplier system. Vasopressin acts in the collecting duct to increase its permeability to water (and urea), thereby allowing osmotic equilibration between the urine and the hypertonic medullary interstitium. The net effect of this process is to extract water from the urine (which is removed from the medulla by interstitial blood vessels, vasa recta), resulting in increased urine concentration and decreased urine volume (antidiuresis).

Vasopressin produces antidiuresis by binding to V_2 receptors on the epithelial principal cells of the renal collecting tubule. Binding activates adenylate cyclase, increasing the level of cyclic adenosine monophosphate (cAMP), which then stimulates protein kinase A and leads to insertion of aquaporin 2 into the luminal membrane.⁴³ Aquaporin 2 is one of the widely expressed family of water channels that mediate rapid water transport across cell membranes.⁴⁴ In the kidney, water moves from the collecting duct into the hypertonic inner medulla, producing a concentrated urine.⁴⁵ Aquaporins 3 and 4 are constitutively synthesized and are expressed at high levels in the basolateral plasma membranes of principal cells, where they are responsible for the high water permeability of the basolateral plasma membrane.^{44,45} Dissociation of vasopressin from the V_2 receptor allows intracellular cAMP levels to decrease, and the water channels are then reinternalized into the intracytoplasmic vesicles, terminating the increased water permeability. The aquaporin-containing vesicles remain just below the apical membrane and can be quickly “shuttled” into and out of the membrane in response to changes in intracellular cAMP levels. This mechanism allows minute-to-minute regulation of renal water excretion in response to changes in ambient levels of vasopressin in plasma.

There is also long-term regulation of collecting duct water permeability in response to prolonged high levels of circulating vasopressin. Chronically high levels of vasopressin induce increased synthesis of aquaporin 2 and aquaporin 3 water channels in the collecting duct principal cells and hence high levels of those proteins. This response requires at least 24 hours and is not as rapidly reversible. Increased numbers of aquaporin 2 and 3 water channels, combined with the short-term effect of vasopressin to insert aquaporin 2 into the apical plasma membrane, allows the collecting ducts to achieve extremely high water permeabilities and water conservation during prolonged dehydration.^{44,45} Hypertonicity per se may augment aquaporin 2 expression. A variety of accessory proteins that regulate fusion attachment to membranes as well as factors that control remodeling of the cytoskeleton have also been described as controlling movement of aquaporins.⁴⁶

Thirst

Urine volume can be reduced to a minimum but not completely eliminated, and insensible water loss is a continuous unregulated process. To maintain water homeostasis, water must be consumed to replace the obligate urinary and insensible fluid losses. This is regulated by thirst. As with vasopressin, thirst can be stimulated by increases in osmolality of the ECF or by decreases in intravascular volume. Furthermore, there is evidence that the receptors are similar; that is, osmoreceptors in the anterior hypothalamus and low- and high-pressure baroreceptors in the chest mediate the thirst stimulus (with a likely contribution from circulating angiotensin II to stimulate thirst during more severe degrees of intravascular hypovolemia and hypotension).⁴⁷ Studies in humans using quantitative estimates of subjective symptoms of thirst have confirmed that increases in plasma osmolality of 2% to 3% are necessary to produce an unequivocal sensation described as “thirst.”⁴¹ As with vasopressin secretion, the threshold for producing thirst by hypovolemia is significantly higher.

Although osmotic changes clearly are effective stimulants of thirst, most humans consume the bulk of their ingested water as a result of the relatively unregulated components of fluid intake. Beverages are consumed with food for reasons of palatability or taken for desired secondary effects (e.g., caffeine) or for social or habitual reasons (e.g., sodas, alcoholic beverages). As a result, humans typically ingest volumes in excess of what can be considered to be an actual “need” for fluid. Consistent with this observation is the fact that, under most conditions, plasma osmolalities in humans remain within 1% to 2% of basal levels—levels thought to be below the threshold levels that stimulate thirst. This suggests that, despite the obvious vital importance of thirst during pathologic situations of hyperosmolality and hypovolemia, under normal physiologic conditions water balance in humans is accomplished more by free water excretion regulated by vasopressin than by water intake regulated by thirst. This also explains why water intake must be consciously restricted in cases of persistent unregulated secretion of vasopressin (see later discussion of SIADH).

Clinical Consequences of Osmotic and Volume Regulation

In most physiologic situations, there is concurrence and synergy between the effect of increased osmolality and that of decreased volume to stimulate release of vasopressin. For example, with dehydration, osmolality increases and volume decreases, and each of these changes stimulates the release of vasopressin. Furthermore, there is good evidence that a decrease in volume shifts the plasma vasopressin/plasma osmolality response curve to the left, resulting in a greater release of vasopressin at any given osmolality.^{29,48} Similarly, excess of fluid produces a decrease in osmolality and an increase in volume, both of which cause a decrease in vasopressin secretion.

The physiology of the relationships among plasma osmolality, plasma vasopressin, and, most importantly, urine volume determine some of the pathophysiologic features of decreased or increased secretion of vasopressin. As shown in Figure 10-3, a regular loss of vasopressin neurons that might decrease the secretory capacity of the neurohypophysis from a level that is able to produce a blood vasopressin concentration of 10 to 20 pg/mL one that is only sufficient to maintain a blood level 5 pg/mL

would not cause any significant change in the ability to attain a maximum urine osmolality. Below 5 pg/mL, there is a linear decrease in the ability to maximally concentrate the urine. However, from the volume curve it can be seen that this results in only a modest increase in urine volume. It is only when the last few vasopressinergic neurons are lost and the maximum vasopressin concentration that can be maintained drops from 1 to 0.5 pg/mL that there is a large increase in urine volume. These responses, therefore, allow water conservation even with minimal ability to secrete vasopressin, and they may explain why patients with diabetes insipidus that has persisted for a relatively long period (e.g., after surgery or head injury) may eventually be able to discontinue treatment with vasopressin. The number of vasopressinergic neurons that need to recover to maintain an asymptomatic urine volume is small. The same pathophysiology is important in considering the syndrome of inappropriate secretion of antidiuretic hormone (SIADH). For example, a patient who is unable to suppress vasopressin to less than 1 pg/mL can excrete 2 L/day at a standard osmolar load, but if fluid intake increases to greater than that which can be excreted with the fixed level of vasopressin (1 pg/mL), then fluid will be retained and the sequence of events that causes hyponatremia in SIADH will be initiated.

An analysis of what is presently known about the regulation of thirst and secretion of vasopressin in humans demonstrates a simple but elegant system to maintain water balance. Under normal physiologic conditions, the sensitivity of the osmoregulatory system for secretion of vasopressin accounts for maintenance of plasma osmolality within narrow limits by adjusting renal water excretion in response to small changes in osmolality. Stimulated thirst does not represent a major regulatory mechanism under these conditions, because unregulated fluid ingestion and water from metabolized food supplies water in excess of true "need." However, when unregulated water intake does not supply body needs even with maximal antidiuresis, plasma osmolality rises to levels that stimulate thirst, producing water intake proportional to the elevation in osmolality. This arrangement has the advantage of freeing animals and humans from frequent episodes of thirst and water-seeking behavior when the water deficiency is sufficiently mild to be compensated for by renal water conservation yet it does stimulate water ingestion when water deficiency reaches a potentially harmful level.

Reset Osmostat during Pregnancy

Major shifts of fluid during normal pregnancy produce a decreased plasma osmolality of about 10 mmol/kg and an increase in plasma volume⁴⁹ and is the best example of a true resetting of the osmostat. The shift in osmotic threshold appears at about 5 to 8 weeks of gestation and persists throughout pregnancy, returning to normal by 2 weeks after delivery.⁴⁹ The physiology of the reset osmostat has been considered in relation to the expanded plasma volume. Total body water in pregnant women is increased by 7 to 8 L due to profound vasodilatation.⁵⁰ This volume is sensed as normal, and vasopressin responds appropriately to decreases and increases of the expanded volume.^{49,51} Both the changes in volume and the changes in osmolality have been reproduced by infusion of relaxin, a normal hormone of pregnancy that is a member of the insulin-like growth factor (IGF) family, into virgin female and normal rats,^{52,53} and they have been reversed in pregnant rats by immunoneutralization of relaxin,⁵⁴ so relaxin is the accepted mediator of the effect.

In women, the placenta produces an enzyme, cysteine aminopeptidase, that is released into the plasma and is known as oxytocinase.^{49,55} However, this enzyme degrades vasopressin with equal potency. The activity of oxytocinase (vasopressinase) increases markedly at about 20 weeks of gestation and increases further to 40 weeks, returning slowly to normal over a few weeks after delivery.⁵⁶ The potential pathology produced by this condition is described later (see "Diabetes Insipidus").

Osmotic Regulation in Aging

Numerous studies have reported that elderly humans are at risk for both hypernatremia and hyponatremia.^{57,58} In older subjects, there is a decrease in glomerular filtration rate (GFR),⁵⁷ and the collecting duct in the aged kidney may be less responsive to vasopressin-stimulated increases in aquaporin 2 water channels, thus limiting the ability to excrete free water.⁵⁹ Elderly subjects are reported to have a lower nocturnal plasma level of arginine vasopressin and a prolonged effect of administered desmopressin.⁶⁰ Many other abnormalities of fluid and electrolyte balance in the elderly result from comorbid conditions or the numerous pharmacologic agents these patients are often taking. Studies of responses to dehydration, osmolar stimulation, or volume stimulation in the elderly are complicated by the fact that, by age 75 to 80 years, there is a decline in total body water to 50% of the level seen in normal young adults.⁶¹ The elderly have a decreased thirst with dehydration and a lesser fluid intake during recovery from dehydration.⁶²⁻⁶⁴ At the other end of the spectrum, elderly patients have been found to excrete a water load less well than younger subjects and at least part of this is due to decreased suppression of vasopressin.⁶⁵

In summary, there are age-related changes in body volumes and renal function that predispose the elderly to abnormalities in water and electrolyte balance. Diseases that are more common in the elderly aggravate this condition, and the therapies for these diseases also affect water balance. Healthy elderly humans probably have at least a normal (or increased) ability to secrete vasopressin but a decreased appreciation for thirst and a decreased ability to achieve either a maximum concentration of urine to retain water or maximum dilution of urine to excrete water. This demonstrates the necessity of paying attention to fluid balance problems in the elderly, because undetected hypernatremia or hyponatremia can lead to increased morbidity and mortality.⁶⁶

DIABETES INSIPIDUS

Diabetes insipidus (DI) is a disorder in which the patient secretes a large volume of urine ("diabetes") that is hypotonic, dilute, and tasteless ("insipid"). This is opposed to the hypertonic and sweet urine of *diabetes mellitus* ("honey"). DI is caused by absence of the hormone vasopressin or inadequate response to vasopressin. The four syndromes of DI—primary polydipsia, hypothalamic DI, DI of pregnancy, and nephrogenic DI—can be explained by the pathophysiology of excess intake of water, decreased synthesis or secretion of vasopressin, accelerated metabolism of vasopressin, or lack of appropriate response to vasopressin by the kidney. The absence of vasopressin produces pathology related only to water, not blood pressure. Most patients have an intact thirst mechanism, so they do not become dehydrated but present with polyuria and polydipsia. Patients with DI who have inadequate thirst can rapidly

become dehydrated and develop severe hypernatremia with devastating effects on the central nervous system (CNS). Hypertonic encephalopathy with obtundation, coma, and seizures may be produced by brain shrinkage. A decreased volume of the brain in the skull may lead to subarachnoid hemorrhage, intracerebral bleeding, or petechial hemorrhage.⁶⁷ However, the problems associated with severe hypernatremia usually are not observed in patients with DI because of intact thirst. Hypernatremic encephalopathy is a risk only when the patient is unable to respond to thirst because of age or level of consciousness (see later discussion).

To determine whether there is a large volume of urine, one can measure a 24-hour urine volume, but it is easier for an adult patient to keep a diary for 24 hours, recording the volume and time of each voided urine. Simultaneously, there is a determination of whether polyuria is caused by an osmotic agent (e.g., glucose) or intrinsic renal disease. Usually, routine laboratory studies and the clinical setting distinguish these disorders from DI. There is universal agreement that the diagnosis of DI is made when there is some dehydration to stimulate the normal release of vasopressin, but with a less than normal concentration of the urine. The gold standard is a dehydration test in a controlled environment followed by measurement of vasopressin in plasma and of response to administered vasopressin or its analogue, desmopressin. The description that follows is for adults. Special attention is required in children, and testing should be done only by a pediatrician; it should not be done in infants.⁴³ In children, care should be taken to prevent hyponatremia after administration of desmopressin.^{43,68}

If the adult patient has mild polyuria, the test may begin in the evening, with the majority of dehydration carried out overnight. If the patient gives a history of large volumes of urine during the night, it is best to perform the test during the day, when the patient can be observed. The patient voids at the beginning of the test, and the starting weight is recorded. A sample for measurement of serum $[Na^+]$ is obtained, and nothing is allowed by mouth (certainly no fluid) during the test. Each voided urine is then recorded, and the corresponding urine osmolality is measured. The patient is weighed after each liter of urine is passed. When two consecutive measurements of urine osmolality differ by no more than 10% and the patient has lost 2% of body weight, a plasma sample for $[Na^+]$, osmolality, and vasopressin level is drawn, and the patient is given 2 μ g of desmopressin intravenously or intramuscularly. Urine output and osmolality are recorded hourly for an additional 2 hours.^{69,70} The dehydration is stopped and measurements are taken if the patient loses greater than 3% of body weight or at any time if the $[Na^+]$ becomes elevated above the normal range. The duration of the test varies among patients. Patients with complete diabetes insipidus reach a maximum but low urine osmolality within a few hours, whereas patients with other disorders may take up to 18 hours.

There is no difficulty determining the diagnosis in severe hypothalamic DI or severe nephrogenic DI. In the former, urine is minimally concentrated despite dehydration and there is a marked increase in urine osmolality in response to administered desmopressin—at least a 50% increase but often 200% to 400%. At the end of the test, these patients will have undetectable vasopressin in plasma. In patients with nephrogenic DI, there will similarly be little concentration of the urine despite dehydration, but the urine osmolality will also show little or no increase in response to administered desmopressin. Patients with

nephrogenic DI are unequivocally distinguished from those with hypothalamic DI by high levels of vasopressin in plasma at the end of the dehydration, often greater than 5 pg/ μ L.

There may be difficulty in differentiating patients with partial hypothalamic DI from those with primary polydipsia. With dehydration, both have some concentration of the urine, often beyond the degree of plasma osmolality, but the urine osmolality does not approach the level of 800 to 1200 mOsm/kg that is characteristic of normal subjects. In response to the administered desmopressin, patients with partial hypothalamic DI usually have a further concentration of the urine, by at least 10%, whereas patients with primary polydipsia have no further increase. The reliability of the response to desmopressin is debated, however. Some patients with primary polydipsia achieve a plateau level in urine osmolality before reaching their maximum urine osmolality and therefore respond to desmopressin. On the other hand, some patients with partial hypothalamic DI secrete sufficient vasopressin in severe dehydration to achieve the maximum attainable urine osmolality and do not have a further increase in response to administered desmopressin. Investigators who have a highly sensitive radioimmunoassay for vasopressin are able to distinguish between partial hypothalamic DI and primary polydipsia by measuring vasopressin at the end of the dehydration test^{71,72}; they also report that these disorders may be confused on the basis of the standard dehydration test. However, a longitudinal clinical study of patients with autoimmune hypothalamic DI reported good correlation between results of the dehydration test and measured vasopressin to diagnose partial DI.⁷³ If the diagnosis is in doubt, patients should have adequate follow-up to ensure that a good therapeutic response to desmopressin is obtained and that the patients do not develop hyponatremia. This clinical follow-up and response are a continuation of the diagnosis with the trial of desmopressin as a test agent. If on follow-up desmopressin is found to produce a decrease in polyuria, a decrease in thirst, and a normal $[Na^+]$, the patient almost certainly has partial hypothalamic DI. However, if the polydipsia does not improve and the patient develops hyponatremia, the patient has some abnormality of thirst and primary polydipsia.^{71,74}

The clinical presentation is often helpful in the differential diagnosis. In a patient with onset of polyuria or polydipsia immediately after surgery in the hypothalamic-pituitary area or after head trauma (especially with skull fracture and loss of consciousness), the diagnosis of hypothalamic DI is highly likely. Patients with hypothalamic DI often have a sudden onset of symptoms and persistent thirst throughout the day and night associated with a desire for cold liquids.⁷⁵ Patients with DI usually have serum $[Na^+]$ in the high range of normal, whereas patients with primary polydipsia have serum $[Na^+]$ in the low range of normal. The blood urea nitrogen concentration is often low in both hypothalamic DI and primary polydipsia because of the high renal clearance, but there is a difference in serum uric acid concentrations. Serum uric acid is elevated in hypothalamic DI because of the modest volume contraction and the absence of the normal action of vasopressin on V_1 receptors in the kidney to increase urate clearance. A serum uric acid value greater than 5 μ g/dL was reported to separate hypothalamic DI from primary polydipsia. Presumably in patients with primary polydipsia, there is modest volume expansion and intermittent secretion of vasopressin to act on V_1 receptors to clear serum urate.⁷⁶ Urine volume greater than 18 L is highly suggestive of primary polydipsia because it exceeds the amount of

urine delivered to the collecting duct. Most patients with hypothalamic DI have modest dehydration, decreased GFR, and urine volumes in the range of 6 to 12 L/day.

Recently there have been publications about the measurement of copeptin, the glycopeptide that, with neurophysin and vasopressin, is part of the prohormone for vasopressin. Copeptin is secreted equimolar to vasopressin and has the advantage of being stable in plasma and more readily measurable than vasopressin by radioimmunoassay. Although the results of clinical testing are promising, the value of copeptin as a distinguishing marker in confusing cases of DI (or SIADH) has not been demonstrated.⁷⁷

Imaging of the Neurohypophysis

On T1-weighted images, MRI produces a bright spot in the sella¹¹ caused by stored hormone in neurosecretory granules in the posterior pituitary.^{26,78-81} The bright spot is present in approximately 80% of normal subjects^{82,83} and is absent in most patients with DI. Some studies have reported a bright spot in patients with clinical evidence of DI.⁸⁴ For example, patients with familial hypothalamic DI (discussed later) may have a bright spot early in the disease (especially if the DI is partial), but the bright spot disappears with increasing severity of the DI.⁸⁵ The role of stored oxytocin as a source of the pituitary bright spot has been ignored, and it is possible that a persistent bright spot in patients with DI is caused by pituitary content of oxytocin.

The posterior pituitary bright spot decreases with a prolonged stimulus to vasopressin secretion⁸⁶ and has been variably reported in other polyuric disorders. In primary polydipsia, the bright spot usually is seen.^{80,87} In nephrogenic DI, the bright spot has been reported to be absent in some patients⁸⁰ but present in others.^{80,88} Patients with nephrogenic DI have high levels of vasopressin in plasma and are chronically dehydrated, so the posterior pituitary might be depleted of vasopressin stores. Similarly, with the osmotic stress of untreated diabetes mellitus or the transient DI of pregnancy, the posterior pituitary may be depleted and the bright spot lost, but then it returns with recovery.^{86,89}

Imaging of the hypothalamus is also an important diagnostic tool for diseases of the neurohypophysis. As described earlier, the hormones of the neurohypophysis are synthesized in the paired paraventricular nuclei, located bilaterally in the walls of the third ventricle, and in the supraoptic nuclei, located at the extremes of the optic chiasm. Knowledge of this large area, coupled with the understanding that 90% of the vasopressinergic neurons must be destroyed to produce symptomatic DI,^{90,91} makes it apparent that for a mass lesion or a destructive lesion to produce DI it must either destroy a large area of the hypothalamus or be located where the tracks of these four nuclei converge at the base of the hypothalamus and the top of the pituitary stalk. Tumors confined to the sella do not cause DI.⁹¹ The region of interest is the discrete area immediately above the diaphragm sella. The hormones are synthesized in cell bodies and travel in axons to the posterior lobe. With section of the axons or pressure on the axons at the level of the posterior lobe, there is a reaccumulation of neurosecretory material and the appearance of a posterior lobe above the site of injury.^{86,92,93} The pituitary stalk can also be readily identified on MRI, and this has been an additional tool in the differential diagnosis of diseases of the neurohypophysis. Enlargement of the stalk is reported with the diseases listed in Table 10-1. When there is a diagnosis of DI, thickening of the stalk is usually associated with absence of the

TABLE 10-1

Diseases Associated with Enlarged Infundibular Stalk

1. Germinoma
2. Craniopharyngioma
3. Metastases to the hypothalamus and long portal vessels (e.g., carcinoma of the breast or lung)
4. Granulomatosis diseases
 - a. Langerhans cell histiocytosis
 - b. Sarcoidosis
 - c. Wegener's granulomatosis
 - d. Non-Langerhans cell histiocytosis (e.g., Erdheim-Chester disease)
5. Tuberculosis
6. Lymphocytic infundibulohypophysitis

posterior pituitary bright spot, and a search for systemic diseases is indicated.⁹⁴ If a diagnosis is still in doubt, MRI should be repeated every 3 to 6 months, especially in children, in whom enlargement may indicate a germinoma.^{95,96} If follow-up shows a decrease in size of the stalk, a likely diagnosis is infundibulolymphohypophysitis.⁹⁷

Clinical Causes and Treatment of Diabetes Insipidus

Diabetes Insipidus Due to Excess Intake (Primary Polydipsia)

Primary polydipsia and subsequent polyuria must be differentiated from DI and may also contribute to SIADH. Primary polydipsia may be induced by any organic structural lesion in the hypothalamus that causes hypothalamic DI (described later), and it may be especially associated with sarcoidosis of the hypothalamus.⁹⁸ It may also be produced by drugs that cause a dry mouth or by any peripheral disorder causing an elevation of renin or angiotensin or both.⁹⁹ If there is no identifiable pathologic etiology, the disorder may be associated with psychiatric syndromes, or it may be habitual throughout a lifetime. Studies of series of polydipsic patients in psychiatric hospitals have shown an incidence as high as 42% of patients with some form of polydipsia, and for more than half of those patients, there was no obvious explanation for the polydipsia.^{100,101}

Treatment of Primary Polydipsia

If there is no structural lesion, primary polydipsia is usually refractory to treatment.⁹⁹ Propranolol has been used with some success, presumably because of its ability to inhibit the renin-angiotensin system.¹⁰²

Diabetes Insipidus Due to Decreased Synthesis or Secretion (Hypothalamic Diabetes Insipidus)

Genetic Abnormalities of the Vasopressin Gene. Familial neurohypophyseal DI is characterized by the onset of classic DI with polydipsia and polyuria in childhood or young adulthood; during infancy, these patients may be asymptomatic.^{103,104} In contrast, in familial nephrogenic DI the defect is expressed as a polyuric disease at birth (see later discussion). MRI findings are variable even within affected family members, but the most constant finding is the presence of a posterior pituitary bright spot in children, which progressively disappears with time.¹⁰⁵ The genetic defect is usually in the biologically inactive neurophysin or in the signal peptide of the pre-prohormone. Although

the condition is genetically heterozygous, with the defect expressed in only one allele, the clinical phenotype is autosomal dominant. Lack of normal cleavage of the signal peptide from the prohormone and abnormal folding of the vasopressin/neurophysin precursor are thought to produce accumulation of mutant prohormone in the endoplasmic reticulum; this is cytotoxic to the neuron, explaining the dominant phenotype. Autopsy studies have confirmed neuronal cell death.¹⁰⁶ Genetic testing of asymptomatic children in affected families negates the need for repeated dehydration testing and allows early treatment.¹⁰⁷

Wolfram's syndrome is a rare autosomal recessive disease that manifests with DI, diabetes mellitus, optic atrophy, and deafness (DIDMOAD). The genetic defect is for the protein wolframin, which is localized to chromosome 4. Wolframin is involved in beta cell proliferation and in intracellular protein processing and calcium homeostasis; its deficiency produces a wide spectrum of endocrine and CNS disorders, with DI usually being a late manifestation.¹⁰⁵

Mass Lesions of the Neurohypophysis: Malignancies, Granulomas, and Infundibulitis. Some tumors, such as craniopharyngiomas and primary germ cell tumors in children, characteristically occur in a suprasellar basal hypothalamic area and are frequently associated with DI.¹⁰⁸⁻¹¹⁰ It is not uncommon for DI to be the presenting complaint, although other evidence of hypopituitarism is often present. The MRI often shows a thickened stalk¹¹¹ and may show a hypothalamic mass. Tumor markers in plasma or CSF may confirm the tumor type in children, but absence of markers does not rule out any specific etiology.¹¹²

Metastatic disease involving the pituitary is usually found in association with widespread metastatic disease and may be asymptomatic and reported only at autopsy. Metastases are twice as likely to involve the posterior pituitary as the anterior pituitary,^{113,114} probably because of a more direct arterial blood supply to the posterior pituitary.¹¹⁵ Most primary tumors in the hypothalamic-pituitary area that cause DI are relatively slow growing, and any tumor in this area that shows rapid growth should be considered as a possible metastatic tumor.^{116,117} Pituitary abscess is a rare cause of a pituitary mass and DI.^{110,118}

DI is reported to occur with lymphomas in the hypothalamic-pituitary area.¹¹⁹ There may be some increased incidence of lymphoma manifesting with DI due to the increased incidence lymphoproliferative disease in patients with human immunodeficiency virus (HIV) or hepatitis C infection.¹²⁰ DI is also associated with leukemia. The mechanism is thought to be infiltration of the hypothalamus, thrombosis, or infection.^{121,122} DI is distinctly more common in cases of nonlymphocytic leukemia.¹²³⁻¹²⁶ MRI studies in patients with leukemia may show infiltration or an infundibular mass¹²³ but often are normal, even when leukemic cells are found in the CSF.¹²⁶

In most cases of DI caused by granulomatous disease, there is clear evidence of characteristic disease elsewhere in the body.^{94,127,128} The MRI shows involvement of the hypothalamus and absence of the posterior pituitary bright spot on T1-weighted images, with widening of the stalk (see Table 10-1). Although there are occasional reports of resolution of the DI with appropriate therapy, in most cases, once it is established, the DI is permanent.¹²⁹⁻¹³¹

If a definitive cause of DI is not found, most cases of DI will be labeled "idiopathic," and an autoimmune process will be considered. A now well-recognized cause of autoimmune DI is lymphocytic infundibuloneurohypophysitis.^{132,133} Since the advent of MRI, lymphocytic

infundibuloneurohypophysitis has been diagnosed based on the appearance of a thickened stalk or enlargement of the posterior pituitary mimicking a pituitary tumor. The characteristic bright spot on MRI T1-weighted images is lost, so the appearance is identical to that of granulomatous disease.¹³⁴ Treatment of these patients with prednisone may establish the diagnosis if there is a decrease in size of the stalk, and such a decrease also may occur spontaneously.¹³⁵ Some cases have coexistence of adenohypophysitis with infundibuloneurohypophysitis.^{136,137}

Surgery or Trauma to the Neurohypophyseal System.

Although DI is well known to occur after hypothalamic or pituitary surgery, this diagnosis should be made with caution.^{138,139} Vasopressin is normally secreted in response to the stress of surgical procedures, and fluid may be retained and then excreted normally after surgery. Stress of surgery may also induce insulin resistance and exacerbate diabetes mellitus, producing an osmotic diuresis from glucose. The patterns of diabetes mellitus after surgery have been described in detail elsewhere.^{140,141} As many as 50% to 60% of patients have some transient diabetes mellitus within 24 hours after pituitary surgery, and this usually resolves (especially with transsphenoidal surgery in which the resection of a tumor is confined to the sella), with only a small number of such patients having permanent DI.¹⁴² The introduction of endoscopic pituitary surgery has not increased the incidence of DI,¹⁴³ and there continues to be greater morbidity with surgery for craniopharyngioma.¹⁴⁴

With complete stalk section, patients may exhibit a pattern known as triphasic DI (Fig. 10-4). The first phase is DI with onset within the first 24 hours after surgery, and it is thought to be caused by axon shock and inability of action potentials to be propagated from the cell body to the axon terminals in the posterior pituitary. The second phase is an antidiuretic phase; it was originally described as a normal interphase, but it is not normal and is thought to be due to unregulated release of vasopressin from the store of hormone in the degenerating axons of the posterior pituitary. Because the release of vasopressin in this phase is unregulated, excess administration of fluids will produce hyponatremia and SIADH. After the entire

Figure 10-4 Typical triphasic response of urine volume after sectioning of the pituitary stalk induced by surgery or head trauma. The first phase of diabetes insipidus occurs immediately postoperatively and continues to day 6. The second phase of antidiuresis occurs from day 7 and continues to day 12. The third stage is the reoccurrence of diabetes insipidus on day 13. Durations vary; see text for detailed discussion. (From A. G. Robinson, University of Los Angeles, CA, with permission.)

hormone content has been released DI returns, constituting the third phase. The course of DI may be permanent, or it may resolve to partial or clinically inapparent disease.

An important observation is that the second phase of the triphasic response (i.e., uncontrolled release of vasopressin due to axon trauma) may occur without preceding or subsequent DI.^{145,146} This has been reported clinically and has been produced experimentally in the rat by unilateral lesion of the supraopticohypophyseal track.¹⁴⁶ The interpretation is that the trauma is to only some of the axons coursing to the posterior pituitary, with the remaining intact axons having sufficient vasopressin function to avoid the clinically apparent DI that is characteristic of the first and third phases of the triphasic response. However, the store of hormone in the posterior pituitary is sufficiently large that necrosis of even a fraction of these vasopressin neurons will cause enough uncontrolled release of vasopressin to produce hyponatremia if excess fluid is administered. The hyponatremia is often symptomatic, and patients present with headache, nausea and emesis, or seizure.¹⁴⁷ After all the vasopressin from the damaged neurons has been secreted, the stimulus for water retention resolves, and the retained water is excreted, producing recovery from the hyponatremia. Therefore, the clinical picture is one of hyponatremia occurring at about 7 to 10 days after pituitary surgery, persisting for a few days, and then returning to normal. This syndrome of transient hyponatremia has been referred to as *isolated second phase*¹⁴⁶ to emphasize the pathophysiologic etiology. Isolated hyponatremia has been reported in 10% to 25% of patients after pituitary surgery.^{140,148,149}

The same patterns of DI that occur after surgery can be seen also in patients who have experienced closed-head trauma,⁹¹ and the incidence may be increasing because of better care and increased survival of patients with severe head injury.¹⁵⁰ Patients with penetrating injury¹⁵⁰ and children¹⁵¹ are especially at risk. Three quarters of these cases are due to motor vehicle accidents.^{91,152} Computed tomography or MRI in a large group of patients with post-traumatic hypopituitarism including DI revealed hemorrhage in the hypothalamus or posterior pituitary in 55% of patients, and approximately 5% of patients had stalk resection or infarction of the posterior pituitary.¹⁵³

There are several important clinical points to be made with regard to DI induced by head trauma. First, these patients are almost always unconscious and do not have the normal ability to sense thirst. Second, it is a situation in which large volumes of fluid might be given because of blood loss or other volume deficits, and this fluid loss or stress can induce diabetes mellitus and an osmotic diuresis. Third, there may be a greater risk if the second phase is unrecognized, because hyponatremia produces cerebral edema, which may aggravate any edema caused by the trauma. Therefore, in administering desmopressin, the effect of one dose should be allowed to wane before another is administered, to ensure that the patient has not entered the second phase. There is a high incidence of anterior pituitary deficiency in association with DI induced by head trauma.¹⁵³ The possibility of cortisol deficiency should be considered immediately, because it can be life-threatening in these patients.¹⁵¹ Cortisol deficiency should also be considered subsequently if DI appears to "improve" because of decreased water excretion in the absence of an administered antidiuretic agent.⁹¹ Lastly, in a long-term follow-up of these patients, partial DI may be found,^{154,155} but there may be sufficient return of vasopressin function that the patient no longer has the symptom of a large urine output under basal conditions.^{91,154}

Absent Release of Vasopressin and Absent Thirst in Response to Osmotic Stimulation. Lack of thirst in response to increased osmolality indicates an abnormality of the osmostat. This may be seen in neurohypophyseal DI if the initial lesion or surgical damage is so severe that it harms not only the neurohypophysis but also to the central, anteriorly placed osmostat,¹⁵⁶ or if there is isolated damage of the osmostat with intact baroreceptors (described as essential hypernatremia). In the former case, there is no release of vasopressin in response to either osmotic or baroreceptor stimulation; in the latter, there is adequate synthesis of vasopressin and release with baroreceptor stimulation, but there is no release with osmotic stimulation. Massive damage to the hypothalamus is necessary for the former condition. It is most commonly seen in patients with craniopharyngioma or a pituitary tumor with extremely large suprasellar extension, and it often occurs together with other manifestations of hypothalamic syndrome, such as hyperphagia, sleep apnea, defects of thermoregulation, or seizures.^{156,157} Abnormalities of thirst with primary hypothalamic lesions are most common in patients with sarcoidosis, but the pattern of essential hypernatremia with absent osmostat and intact baroreceptor is most commonly reported after clipping of an anterior communicating artery aneurysm.^{156,157} In these latter cases, there is evidence that vasopressin is synthesized and stored, in that maneuvers to stimulate baroreceptors increase secretion of vasopressin and concentration of the urine.^{158,159} The pathophysiologic explanation of essential hypernatremia is that inadequate water intake and excess water excretion produce a degree of dehydration with hypernatremia; when the dehydration is sufficient to stimulate the baroreceptors, vasopressin is released, urine is concentrated, and the patient remains in a steady state of hypernatremia with modest dehydration. The increased concentration of sodium itself also causes sodium excretion to help maintain the new steady state.¹⁶⁰

Diabetes Insipidus and Brain Death. DI is reported in 50% to 90% of patients with brain death.^{161,162} There is growing consensus that treatment of DI and other hormonal and metabolic abnormalities will increase the number and quality of organs that can be harvested.^{163,164}

Treatment of Hypothalamic Diabetes Insipidus

Mass Lesions of the Neurohypophysis: Malignancies, Granulomas, Infundibulitis. A major goal of therapy is to decrease the thirst and polyuria to a level that allows the patient to maintain a normal lifestyle. The timing and quantity of medication should be individually prescribed and easy for the patient to accommodate. Safety of the prescribed agent and avoidance of the detrimental effects of overtreatment are primary considerations because of the relatively benign course of DI and the adverse consequences of hyponatremia. The therapeutic agents used to treat DI are shown in Table 10-2. Water is considered a therapeutic agent because if it is taken in sufficient quantity there is no metabolic abnormality. As noted, therapy is designed to reduce the necessary water intake (and polyuria) to an acceptable level, but occasional lapses in pharmacologic therapy are not detrimental, may avoid overtreatment producing hyponatremia, and allow recognition of any spontaneous recovery.

The drug of choice is desmopressin,^{71,165} a synthetic analogue of vasopressin in which the substitution of D-arginine markedly reduces pressor activity and removal of the terminal amine increases the half-life (see Fig. 10-1). The two changes produce an agent almost 2000 times

TABLE 10-2

Therapeutic Agents for Treatment of Diabetes Insipidus

1. Water
2. Water-retaining agents
 - a. L-Arginine vasopressin
 - b. Desmopressin, 1-(3-mercaptopropionic acid)-8-D-arginine vasopressin
 - c. Chlorpropamide
 - d. Carbamazepine*
 - e. Clofibrate*
 - f. Indomethacin
3. Natriuretic agents
 - a. Thiazide diuretics
 - b. Amiloride
 - c. Indapamide

*Not recommended.

more specific for antidiuresis than naturally occurring L-arginine vasopressin.¹⁶⁶ Most patients prefer desmopressin tablets (0.1 and 0.2 mg), although many continue to be successfully treated with the intranasal spray. Because of the variability among patients, it is desirable to determine the duration of action of individual doses in each patient.^{167,168} The patient is first allowed to escape from the effects of any previous medication, and for each voided urine, the time and volume are recorded and, if possible, the osmolality is measured. A dose of desmopressin is given, and the patient is allowed to drink fluid ad lib. A decrease in urine volume is seen in 1 to 2 hours, and the total duration of action is usually 6 to 18 hours. If a dose is sufficient to elicit a stable therapeutic response, further increasing the dose (e.g., doubling the dose) produces only a moderate increase in duration of a few hours,^{167,168} consistent with the half-life of desmopressin in plasma.¹⁶⁷ Usually, a satisfactory schedule is achieved with a modest dose, and the maximum dose rarely exceeds 0.2 mg orally or 20 μ g intranasally (two sprays) given two or three times a day (usually three times for tablets and two times for intranasal sprays).¹⁶⁸ Use of the tablets allows considerable flexibility in dosage, because either whole or split tablets may be used. For intranasally administered desmopressin, there is less flexibility with the metered spray, which is fixed at 10 μ g in 100 μ L. For greater flexibility with intranasal administration, the patient should be taught to use the rhinal catheter. Specific directions are described elsewhere.¹⁶⁵ Rarely is it necessary to resort to parenterally administered desmopressin (2-mL vials containing 4 μ g/mL) for ambulatory patients. If an intercurrent illness or allergy makes this desirable, a dose of 0.5 to 2.0 μ g can be administered subcutaneously with the use of an insulin syringe (low dose if necessary) and needle.¹⁶⁸ Parenterally administered desmopressin yields a virtually identical therapeutic response when given as an intravenous bolus, intramuscularly, or subcutaneously,¹⁶⁸ and the parenteral administration is 5 to 20 times as potent as an intranasally administered dose.^{165,168}

Therapeutic agents such as chlorpropamide or thiazide diuretics are especially useful for cases in which only a modest decrease in urine volume will make the patient asymptomatic. The major action of chlorpropamide is on the renal tubule to increase the hydroosmotic action of residual vasopressin,¹⁶⁹ but the agent can produce significant antidiuresis even in patients with severe hypothalamic DI.⁷¹ The usual dose is 250 to 500 mg/day, with a response noted in 1 to 2 days and a maximum antidiuresis

in 4 days.^{71,165} This is an off-label use of the drug. Chlorpropamide should not be used in pregnancy and is not recommended for children, especially those with concurrent hypopituitarism, because of the possibility of severe hypoglycemia. The therapeutic agents that induce water retention (see Table 10-2) have other clinical indications, and if they are used off-label in patients with DI, they might augment the effect of administered desmopressin, exposing the patient to excess water retention and hyponatremia.

Hyponatremia is a rare complication of desmopressin therapy and occurs only if the patient is continually antidiuretic while maintaining a fluid intake sufficient to become volume expanded and natriuretic. Thirst may be protective, and most patients on standard therapy are not continuously maximally antidiuretic or may occasionally delay a dose to excrete any excess retained water. Treatment of infants requires special attention and expertise. Infants consume a large part of their calories as liquid formula or breast milk and have corresponding high-volume dilute urine. Treatment of infants with oral or intranasal desmopressin is reported to result in swings of both elevated serum sodium and symptomatic hyponatremia.¹⁷⁰ In Europe a lyophilisate of desmopressin is used orally,¹⁷¹ and in the United States pediatricians have used desmopressin subcutaneously or substituted a low-solute formula with a thiazide diuretic.¹⁷⁰ As noted earlier, normal elderly individuals have reduced ability to concentrate their urine or to excrete a water load. Therefore, treatment of an elderly person with DI requires special attention to avoid hyponatremia.¹⁷¹

Diabetes Insipidus after Hypothalamic or Pituitary Surgery or Injury. The surgeon often knows how severely the posterior pituitary or stalk was injured. Sometimes diuresis after surgery is the result of water retention during the procedure. Vasopressin is released during surgical procedures, and administered fluid may be retained. When the stress of surgery abates, the vasopressin level falls, and retained fluid is excreted. If an attempt is made to match the urine output with further fluid infusion, persistent polyuria could be mistaken for DI. If there is doubt, fluid may be withheld until there is a modest increase in $[Na^+]$. If the urine output decreases and the serum $[Na^+]$ remains normal, the polyuria was the result of excretion of physiologically retained fluid. If the serum $[Na^+]$ begins to rise while urine osmolality is low and there is a response to desmopressin, the diagnosis of DI can be established.¹³⁸ Sometimes the DI is transient, and the surgeon may prefer to treat it only with parenteral or oral fluid replacement (i.e., if the patient is awake and able to respond to thirst). In treating DI, desmopressin may be given parenterally: 0.5 to 2 μ g subcutaneously, intramuscularly, or intravenously. The intravenous route may be preferable because there is no question about absorption. Urine output is reduced in 1 to 2 hours, and the duration of effect is 6 to 24 hours. If the patient is alert, thirst is a good guide to fluid replacement. Care should be taken that intravenous fluids (especially hypotonic fluids) are not given excessively after administration of desmopressin, because this can lead to profound hyponatremia.¹⁷² Because the DI may be transient and some patients may develop the triphasic pattern described previously, it is desirable to allow polyuria to return before subsequent doses of desmopressin are administered.¹⁴¹

Acute DI after blunt trauma to the head can be treated similarly to postoperative DI, except that the patient with a head injury is more likely to be comatose and unable to

respond to thirst and therefore is more likely to develop hypernatremia. Because a comatose patient must be given fluids parenterally, some clinicians prefer to use a continuous infusion of low-dose vasopressin. The vasopressin can be added directly to the crystalloid solution that is being administered¹⁷³ or infused separately to maintain a constant antidiuresis while adjusting the fluid intake appropriately to address any persistent polyuria and to cover insensible water loss. Doses of 0.25 to 2.7 mU/kg per hour have been described.¹⁷⁴⁻¹⁷⁶ If this method is used, there is a potential to produce hyponatremia^{173,174} and serum $[Na^+]$ must be checked regularly. Moreover, with continuous replacement it is not possible to know whether there is return of normal function or whether a patient is entering the second of a triphasic pattern.

Diabetes Insipidus with Inadequate Thirst. With lack of thirst and continuing polyuria, patients develop severe hypernatremia, and if they are encouraged to drink and an antidiuretic agent is administered, they are at risk for hyponatremia. Therefore, these patients are subject to wide swings in osmolality, but most characteristically they have persistent hypernatremia. The first therapeutic agent to try is chlorpropamide, because it is useful to treat DI and has been reported to increase the thirst response.^{177,178} If chlorpropamide does not produce adequate control, treatment with desmopressin and fluid intake are balanced. The patients are not thirsty, and it is difficult to balance water intake, so a better regimen is a rigid fixed dose of desmopressin to maintain chronic antidiuresis and a prescribed quantity of water that must be drunk every 6 to 8 hours.^{157,179} Daily weight can be used to guide intake, and regular follow-up with measurements of serum $[Na^+]$ is essential to ensure that these patients do not develop water intoxication with hyponatremia or recurrent dehydration with hypernatremia.

Organ Donors. As noted earlier, DI is a common accompaniment of brain death. Because these patients are candidates for organ donation, it has been suggested that maintaining fluid homeostasis is desirable for maintenance of the health of the organs. Continuous administration of low-dose vasopressin intravenously, as described earlier for postsurgical DI, may be easier than maintaining antidiuresis with intermittent doses of desmopressin.

Diabetes Insipidus Due to Accelerated Metabolism of Vasopressin (Diabetes Insipidus of Pregnancy)

It is important for the clinician to be aware of the expanded volume and decreased osmolality and serum $[Na^+]$ that occur in normal pregnancy (described earlier). Pregnant patients with polyuria may have serum $[Na^+]$ levels that would be in the normal range for a nonpregnant patient but are indicative of DI in a pregnant patient and require evaluation. There are two types of transient DI in pregnancy, both caused by the enzyme, cysteine aminopeptidase (oxytocinase).¹⁸⁰ In the first type, the activity of this enzyme (which is also a vasopressinase) is extremely and abnormally elevated. This syndrome has been referred to as *vasopressin-resistant DI of pregnancy*.¹⁸¹ The co-occurrence of preeclampsia, acute fatty liver, and coagulopathies has been noted.^{50,182,183} Usually in subsequent pregnancies, these women have neither DI nor acute fatty liver.

In the second type of pregnancy-related DI, the accelerated metabolic clearance of vasopressin produces DI in a patient with borderline vasopressin function resulting from a specific disease, such as mild nephrogenic DI or partial hypothalamic DI.^{55,184,185} Vasopressin is rapidly

destroyed, and the neurohypophysis is unable to keep up with the increased demand. Labor and parturition usually proceed normally, and patients have no trouble with lactation.¹⁸⁶ There is the threat of chronic and severe dehydration if DI is unrecognized, and this may pose a threat to a pregnant woman.¹⁸⁷

Treatment of Diabetes Insipidus in Pregnancy

Desmopressin is the only therapy recommended for treatment of DI during pregnancy. Desmopressin has 2% to 25% the oxytocic activity of lysine vasopressin or arginine vasopressin,¹⁶⁶ and it can be used with minimal stimulation of the oxytocin receptors in the uterus.^{186,188} The physician must be cognizant of the naturally occurring volume expansion and reset osmostat that occurs in pregnancy and give sufficient therapy to satisfy thirst and to maintain the serum $[Na^+]$ at the low level that is normal during pregnancy. Desmopressin is not destroyed by the oxytocinase of pregnancy^{186,189,190} and is reported to be safe for both the mother and the child.^{191,192}

During delivery, these patients can maintain adequate oral intake and continue administration of desmopressin. Physicians should be cautious about overadministration of fluid parenterally during delivery, because these patients are not able to excrete the fluid and may develop water intoxication and hyponatremia. After delivery, oxytocinase decreases in plasma and the patients may recover completely or be asymptomatic with regard to volume of fluid intake and urine excretion.

Diabetes Insipidus Due to Lack of Renal Response (Nephrogenic Diabetes Insipidus)

Genetic Abnormalities. Infants with nephrogenic DI present with vomiting, constipation, failure to thrive, fever, and polyuria. Symptoms usually occur during the first week of life,^{193,194} and on testing, the patients are found to have hypernatremia and a low urine osmolality. The diagnosis is established by high levels of vasopressin in the plasma in the presence of hypotonic polyuria and then the absence of response to administered desmopressin. Special attention should be given if a dehydration test is used in children, and this test should not be done in infants. Care should be taken to avoid hyponatremia when desmopressin is given at the end of the test, because hypotonic fluid is the normal diet.⁴³ Considered here are disorders related directly to the function of vasopressin, but there are other inherited complex disorders of the kidney that cause loss of electrolytes as well as water.¹⁹⁵ There are two causes of nephrogenic DI: mutation in the V_2 receptor and mutations of the aquaporin 2 water channels. The presentation is independent of the genotype.¹⁹³⁻¹⁹⁵

More than 90% of cases of nephrogenic DI are X-linked recessive disorders in males who have one of more than 200 different mutations of the V_2 receptor.¹⁹⁶ Five classes of mutations of the V_2 receptor have been described¹⁹⁷:

- Class I produces abnormal mRNA with untranslated or truncated proteins.
- Class II produces translated proteins with abnormal structure that are trapped in the endoplasmic reticulum.
- Class III produces proteins that are processed but improperly signal.
- Class IV produces proteins that are fully expressed but do not bind vasopressin.
- Class V produces proteins that are routed to incorrect organelles within the cell.

In clinical series, approximately 10% of the V₂ receptor defects causing congenital nephrogenic DI are thought to arise *de novo*. This high incidence of *de novo* cases coupled with the large number of potential mutations hinders the clinical use of genetic identification because it is necessary to sequence the entire open reading frame of the receptor gene rather than short sequences of DNA. Although most female carriers of the X-linked V₂ receptor defects have no clinical disease, some female carriers have a decreased maximum urine osmolality in response to the plasma level of vasopressin that they achieve.¹⁹⁸ Rarely, heterozygous females have a defect as severe as that seen in males, and this is thought to be due to inactivation of the normal X chromosome.^{199,200}

When the proband is a girl, it is likely that the defect is a mutation of the aquaporin 2 water channel gene producing an autosomal recessive disease.²⁰¹ This should be especially considered if consanguinity is known in the family and the disease is expressed in both males and females. The patients may be heterozygous for two different recessive mutations²⁰² or homozygous for the same abnormality from both parents.²⁰³ Most of the mutations of aquaporin are class II or class III.¹⁹⁷ Mutations of the aquaporin 2 protein may produce an autosomal dominant nephrogenic DI if the mutant aquaporin 2 protein associates with the wild-type normal protein to inhibit normal intracellular routing and function.¹⁹⁷

Acquired Nephrogenic Diabetes Insipidus. Producing a concentrated urine depends on maintaining hyperosmolality of the inner medulla of the kidney. Producing and maintaining hyperosmolality of the inner medulla requires that the kidney architecture be intact, with an intact tubular structure of the loop of Henle, which is essential to the development of the countercurrent multiplier, and then a normal anatomy of the collecting duct to pass back through the inner medulla. The vascular structure must be anatomically intact so that the hyperosmolality of the inner medulla is not washed away by normal blood flow. The broad definition of nephrogenic DI may include numerous chronic renal diseases that distort the architecture of the kidney (e.g., polycystic kidney disease), renal infarcts with neovascularization (e.g., in sickle cell anemia), infiltrative disease of the kidney, washout of the medullary gradient, and a low-protein diet with reduced medullary urea concentration. Vascular and anatomic causes of reduced concentration of urine are not considered here as DI because these are not disorders caused by abnormal function of vasopressin.²⁰⁴ Cases of acquired nephrogenic DI associated with hypokalemia, hypercalcemia, or release of bilateral urinary tract obstruction are associated with downregulation of aquaporin 2 and decreased function of vasopressin.^{197,201}

Administration of lithium to treat psychiatric disorders is the most common cause of drug-induced acquired nephrogenic DI and illustrates the mechanisms.¹⁹⁷ Lithium produces a decrease in urea transporters, which reduces vasopressin-stimulated urea uptake and decreasing urea recycling, reducing intermedullary osmolality.^{201,205} Even more dramatic is the reduction in aquaporin 2 levels, which decreases water transport in the collecting duct.¹⁹⁷ There is as much as a 95% decrease in aquaporin 2 content, and even the 5% of aquaporin 2 protein that persists is not normally transported to the principal membrane.²⁰⁶ The defect of aquaporins that occurs with lithium administration is slow to correct, both in experimental animals and in humans, and may be permanent.^{197,207} Demeclocycline is another commonly recognized drug that causes

nephrogenic DI and is used clinically to treat SIADH (discussed later). See the review by Bendz and Aurell²⁰⁸ for a list of drugs that cause nephrogenic DI.

Treatment of Nephrogenic Diabetes Insipidus

Adequate water intake should always be maintained and may be life-saving in cases of congenital nephrogenic DI. By definition, these forms of DI do not respond to vasopressin or desmopressin, although there may rarely be some partial defects with some response to high doses of desmopressin.^{209,210} In congenital nephrogenic DI, therapy is aimed at reducing symptomatic polyuria. This is done primarily by causing volume contraction with a low-sodium diet and a thiazide diuretic. The antidiuretic effect has been interpreted as resulting from ECF volume contraction, decreased GFR, proximal sodium and water reabsorption, and decreased delivery of fluid to the collecting duct, resulting in a decreased volume of urine.²¹¹ Studies have also demonstrated that thiazide diuretics may increase aquaporin 2 independent of vasopressin.²¹² All of the thiazide diuretics appear to have similar effects. Potassium replacement or coadministration of a potassium-sparing antidiuretic, or both, may be desirable. There is an added effect obtained by coadministration of nonsteroidal anti-inflammatory drugs, but duodenal ulcer and gastrointestinal hemorrhage may be produced. Newer selective cyclooxygenase 2 inhibitors with less gastrointestinal effect have been reported to decrease water loss, but long-term safety has not been documented.¹⁹⁷

Drug-induced nephrogenic DI should be treated by stopping the offending agent if possible. Persistence of nephrogenic DI can be treated with hydrochlorothiazide and amiloride. With the induced volume contraction, these patients should be closely monitored for the development of renal or other toxicity of the drug that caused the DI.²¹³ For example, volume contraction produced by thiazide diuretics used to treat lithium-induced nephrogenic DI may decrease lithium excretion and predispose to lithium toxicity.^{208,214} The diuretic amiloride blocks Na⁺ channels in the luminal membrane of the collecting duct cells and inhibits lithium reabsorption, a unique advantage in treating lithium-induced nephrogenic DI.²¹⁵ In animal studies of lithium-induced nephrogenic DI, treatment with amiloride increased the levels of both aquaporin 2 and urea transporters.²⁰⁵

Studies have reported the possibility of rescuing abnormal proteins in nephrogenic DI. In class II autosomal dominant nephrogenic DI, the misfolded receptor protein is trapped in the endoplasmic reticulum, but the defect may be sufficiently mild that, were the receptor to reach the cell membrane, it would respond to vasopressin. In this situation, V₂ receptor antagonists working as pharmacologic chaperones might combine with the misfolded receptor, changing the conformation and stabilizing the structure so that the receptor can pass through the endoplasmic reticulum and be transported to the plasma membrane, where it may be normally activated by vasopressin.²¹⁶ Other types of chaperones might be used to rescue abnormal aquaporins.²¹⁷

Testing for mutations in families with congenital nephrogenic DI can be especially useful. In X-linked disorders, carrier females can be distinguished from noncarrier females, thereby identifying which siblings' children are at risk and require special observation at birth. Molecular testing of newborns will confirm the need for long-term treatment to avoid complications in the affected children and obviate the need for dehydration or other testing in unaffected children.^{200,218}

Diabetes Insipidus in Association with Other Therapeutic Decisions

Routine Surgical Procedures

In all cases, there should be preoperative consultation among the surgeon, the anesthesiologist, and the endocrinologist/nephrologist. For most routine surgical procedures, the patient is not unconscious for a sufficiently long period to require anything more than administration of the usual dose of desmopressin and careful monitoring of fluids during the surgery to ensure against overhydration. If the patient is taking desmopressin orally and is NPO, a parenteral dose can be administered before the procedure. If the procedure is especially long, one might consider low-dose vasopressin given continuously with fluid, as described earlier for postoperative or trauma-induced hypothalamic DI. Close monitoring of the serum $[Na^+]$ is essential. In nephrogenic DI, there may be a greater emphasis on fluid replacement to avoid dehydration and hyponatremia.²¹⁹

Panhypopituitarism

Because hypothyroidism and adrenal insufficiency have direct actions on the kidney to inhibit the ability to excrete water, any patient who has anterior pituitary deficiency in association with DI is at risk for hyponatremia if treatment of DI is continued while treatment with thyroid hormone and (more dramatically) hydrocortisone is stopped. It is important that such patients maintain treatment of all anterior and posterior pituitary deficiencies continuously, because the balance among these replacements is essential.

Promoting a Saline Diuresis

There are clinical situations, such as chemotherapy or use of certain contrast agents, in which a diuresis is desirable to minimize renal toxicity. If desmopressin is continued and a large volume of normal saline is given, natriuresis and hyponatremia will be induced. Withholding desmopressin and replacing fluids with 5% dextrose in water (D5W) may lead to hyperglycemia, whereas normal saline may lead to hypernatremia. It has been reported that very-low-dose vasopressin administered continuously intravenously (as with comatose patients, described earlier) can be used. In this case, the dose of vasopressin is even lower, such as 0.08 to 0.1 mU/kg per hour, to allow a moderate and controlled diuresis.²²⁰ As with any situation in which vasopressin is given continuously, serum $[Na^+]$ must be checked regularly and the amount of fluids infused must be monitored carefully.

Hypertonic Encephalopathy

Hypertonic encephalopathy is uncommon in DI and is seen only with inadequate fluid intake in an adipsic patient or in a patient who is unconscious and not receiving adequate fluid supplementation. Conditions other than DI are the more common causes of hypernatremic encephalopathy. It may be caused by loss of hypotonic fluids by the kidney or the gut or insensible losses, or it may occur secondary to hypertonic fluid administration with sodium-containing fluids or hyperalimentation.²²¹ Sodium is mainly an extracellular electrolyte, and hypernatremia invariably leads to movement of water out of cells and cellular dehydration.

Studies indicate that in the brain so-called idiogenic osmoles are generated intracellularly, and the degree of cell shrinkage is therefore less than would be expected based

on the extent of hypernatremia. These idiogenic osmoles comprise three organic classes: polyols, trimethylamines, and amino acids and their derivatives.²²² Loss of water from the brain occurs in minutes, and electrolytes enter the brain in a few hours, but the increase in organic osmoles occurs over several days.⁶⁷ Similarly, when fluid is replaced, these intracellular organic osmoles decrease more slowly than the decrease in osmolality of ECF. This asynchrony increases the potential for cerebral edema and worsening of the neurologic condition with overzealous treatment of hypernatremia.⁶⁷ In most cases of DI seen immediately after surgery or diagnosed promptly after head injury, the diagnosis is made within a few hours and therapy may be instituted promptly. If the duration of the hypernatremia is not known, the degree of correction of hypernatremia should not exceed 0.5 mEq/L per hour, to prevent cerebral edema and convulsions.^{67,221}

THE SYNDROME OF INAPPROPRIATE ANTIDIURETIC HORMONE SECRETION

SIADH is produced when plasma levels of arginine vasopressin are elevated at times when the physiologic secretion of vasopressin from the posterior pituitary would normally be suppressed. The clinical abnormality is a decrease in the osmotic pressure of body fluids, so the hallmark of SIADH is hypoosmolality. This fact led to the identification of the first well-described cases of this disorder in 1957²²³ and the subsequent clinical investigations that resulted in delineation of the essential characteristics of the syndrome.²²⁴ In the following sections, hypoosmolality and hyponatremia are reviewed, after which details specific to SIADH are discussed.

Hypoosmolality and Hyponatremia

Incidence

Hypoosmolality is the most common disorder of fluid and electrolyte balance encountered in hospitalized patients. The incidence and prevalence of hypoosmolar disorders depend on the nature of the patient population studied and the laboratory methods and criteria used to diagnose hyponatremia. Most investigators have used the serum $[Na^+]$ to determine the clinical incidence of hypoosmolality. When hyponatremia is defined as a serum $[Na^+]$ of less than 135 mEq/L, incidences as high as 15% to 30% have been reported in studies of acutely and chronically hospitalized patients. However, incidences decrease to the range of 1% to 4% when only patients with serum $[Na^+]$ lower than 130 to 131 mEq/L are included; this represents a more appropriate level at which to define the occurrence of clinically significant cases of this disorder. Even using these more stringent criteria, incidences from 7% to 53% have been reported among institutionalized geriatric patients.²²⁵ All studies to date have noted a high proportion of iatrogenic or hospital-acquired hyponatremia, which has accounted for as many as 40% to 75% of all cases studied.²²⁶

Therefore, although hyponatremia and hypoosmolality are quite common, most cases are relatively mild and most are acquired during the course of hospitalization. Nonetheless, hyponatremia is important clinically because

1. Severe hypoosmolality (serum $[Na^+] < 120$ mEq/L) is associated with substantial morbidity and mortality.²²⁷

2. Even relatively mild hypoosmolality can quickly progress to more dangerous levels during the course of therapeutic management of other disorders.
3. Overly rapid correction of hyponatremia can itself cause severe neurologic morbidity and mortality.²²⁸
4. It has been observed that mortality rates are much higher (3-fold to 60-fold) in patients with even asymptomatic degrees of hypoosmolality compared with normonatremic patients.²²⁹

Osmolality, Tonicity, and Serum Sodium Concentration

As discussed previously, the osmolality of body fluid normally is maintained within narrow limits for each individual by osmotically regulated vasopressin secretion and thirst. Although basal plasma osmolality can vary appreciably among individuals, the range in the general population under conditions of normal hydration is between 280 and 295 mOsm/kg H₂O. Plasma osmolality can be determined directly by measuring the freezing-point depression or the vapor pressure of plasma. Alternatively, it can be calculated indirectly from the concentrations of the three major solutes in plasma:

$$pOsm = (2 \times [Na^+]) + \text{glucose}/18 + \text{BUN}/2.8$$

where plasma osmolality (pOsm) is measured in mOsm/kg H₂O, [Na⁺] in mEq/L, plasma glucose concentration in mg/dL, and blood urea nitrogen (BUN) in mg/dL.

The direct and indirect methods produce comparable results under most conditions. However, whereas either of these methods produces a valid measure of *total* osmolality, this is not always equivalent to the *effective* osmolality, which is commonly referred to as the “tonicity” of the plasma. Only solutes such as Na⁺ and Cl⁻ that are impermeable to the cell membrane and remain relatively compartmentalized within the ECF space are “effective” solutes, because they create osmotic gradients across cell membranes and regulate the osmotic movement of water between the intracellular fluid (ICF) compartment and the ECF compartment. Solute that readily permeate cell membranes (e.g., urea, ethanol, methanol) are not effective solutes. Therefore, only the concentrations of effective solutes in plasma should be used to ascertain whether clinically significant hyperosmolality or hypoosmolality is present.

Sodium and its accompanying anions represent the major effective plasma solutes, so hyponatremia and hypoosmolality are usually synonymous. However, there are two situations in which hyponatremia does not reflect true hypoosmolality. The first is *pseudohyponatremia*, which is produced by marked elevations of either lipids or proteins in plasma. In this situation, if the serum [Na⁺] is measured by flame photometry, the concentration of sodium per liter of plasma is artifactually decreased because of the larger relative proportion of plasma volume that is occupied by the excess lipids or proteins.²³⁰ However, the increased protein or lipid does not appreciably change the total number of solute particles in solution, so the directly measured plasma osmolality will not be significantly affected. Measurement of serum [Na⁺] by ion-specific electrodes, a method that is now commonly employed by most clinical laboratories, is less influenced by high concentrations of lipids or proteins compared with flame photometry.

The second situation in which hyponatremia does not reflect true plasma hypoosmolality occurs when high

concentrations of effective solutes other than Na⁺ are present in the plasma. The initial hyperosmolality produced by the additional solute causes an osmotic shift of water from the ICF to the ECF, which in turn produces a dilutional decrease in serum [Na⁺]. Once equilibrium between the two fluid compartments is achieved, the total effective osmolality remains relatively unchanged. This situation most commonly occurs with hyperglycemia and represents a frequent cause of hyponatremia in hospitalized patients, accounting for up to 10% to 20% of all cases.²²⁹ Misdiagnosis of true hypoosmolality in such cases can be avoided by measuring plasma osmolality directly or by correcting the measured serum [Na⁺] for glucose elevation. Traditionally, this correction factor has been 1.6 mEq/L for each 100-mg/dL increase in serum glucose concentration above normal levels,²³¹ but studies have shown a more complex relation between hyperglycemia and serum [Na⁺], and a correction factor closer to 2.4 mEq/L is now considered to be more accurate.²³² When the plasma contains significant amounts of unmeasured solutes, such as osmotic diuretics, radiographic contrast agents, and some toxins (e.g., ethanol, methanol, ethylene glycol), plasma osmolality cannot be calculated accurately. In these situations, osmolality must be ascertained by direct measurement, although even this method does not yield an accurate measure of the true effective osmolality if the unmeasured solutes are noneffective solutes that freely permeate cell membranes (e.g., ethanol).

Pathogenesis of Hypoosmolality

Because water moves freely between the ICF and ECF, osmolality is equivalent in both of these fluid compartments. Because the bulk of body solute is composed of electrolytes, namely, the exchangeable Na⁺ (Na_E⁺) in the ECF and the exchangeable K⁺ (K_E⁺) in the ICF along with their associated anions, total body osmolality (OSM_T) is largely a function of these parameters²³³:

$$OSM_T = OSM_{ECF} = OSM_{ICF}$$

$$OSM_T = (\text{ECF solute} + \text{ICF solute})/\text{body water}$$

$$OSM_T = (2 \times [Na^+_E] + 2 \times [K^+_E] + \text{nonelectrolyte solute})/\text{body water}$$

According to this definition, the presence of plasma hypoosmolality indicates a relative excess of water over solute in the ECF. This can be produced either by an excess of body water, resulting in a *dilution* of remaining body solute, or by a *depletion* of body solute (i.e., Na⁺ or K⁺) relative to body water. This classification is an oversimplification, because most hypoosmolar states involve significant components of both solute depletion and water retention. Nonetheless, it is conceptually useful for understanding the mechanisms underlying the pathogenesis of hypoosmolality and as a framework for treatment of hypoosmolar disorders.

Solute Depletion. Depletion of body solute can result from any significant losses of ECF. Body fluid losses by themselves rarely cause hypoosmolality because excreted or secreted body fluids are usually isotonic or hypotonic relative to plasma and therefore tend to increase plasma osmolality. When hypoosmolality accompanies ECF losses, it is the result of replacement of lost body fluids (either by drinking or by infusion) with more hypotonic solutions that dilute the remaining body solutes. If the solute losses are marked, these patients show signs of volume depletion (e.g., Addisonian crisis). However, such patients often have a more deceptive clinical presentation because

the volume deficits have been partially replaced. Moreover, they may not manifest signs or symptoms of cellular dehydration because osmotic gradients draw water into the ICF, which is relatively hypertonic to the solute-depleted ECF. Therefore, although clinical evidence of hypovolemia strongly supports solute depletion as the cause of plasma hypoosmolality, absence of clinically evident hypovolemia never completely eliminates this as a possibility. Although ECF solute losses are responsible for most cases of depletion-induced hypoosmolality, ICF solute loss can also cause hypoosmolality as a result of osmotic water shifts from the ICF into the ECF. This mechanism likely contributes to some cases of diuretic-induced hypoosmolality in which depletion of total body K^+ often occurs.²³⁴

Water Retention. Despite the importance of solute depletion in some patients, most cases of clinically significant hypoosmolality are caused by increases in total body water rather than primary losses of extracellular solute. Total body water can increase as a result of impaired renal free water excretion or excessive free water intake. The former accounts for most hypoosmolar disorders, because normal kidneys have sufficient diluting capacity to allow excretion of up to approximately 18 L/day of free water. Intakes of this magnitude are occasionally seen in some psychiatric patients but not in most patients with SIADH, in whom fluid intake averages only 2 to 3 L/day.²³⁵ Therefore, dilutional hypoosmolality usually is the result of an abnormality of renal free water excretion.

The renal mechanisms responsible for impairments in free water excretion can be grouped according to whether the major impairment occurs in proximal or distal parts of the nephron, or both. Any disorder that leads to a decrease in GFR causes increased reabsorption of Na^+ and water in the proximal tubule. As a consequence, the ability to excrete free water is limited because of decreased delivery of tubular fluid to the distal nephron. Disorders that cause solute depletion through nonrenal mechanisms (e.g., gastrointestinal fluid losses) also produce this effect. Disorders that produce a decreased GFR in the absence of significant ECF fluid losses are, for the most part, edema-forming states associated with decreased effective arterial blood volume (EABV) and secondary hyperaldosteronism.²³⁶ Although these conditions are characterized by increased proximal reabsorption of both Na^+ and fluid, water retention also results from increased distal reabsorption due to nonosmotic, baroreceptor-mediated, stimulated increases in plasma vasopressin levels.

Distal nephron impairments in free water excretion are characterized by an inability to dilute tubular fluid maximally. These disorders are usually associated with abnormalities in the secretion of vasopressin from the posterior pituitary. However, just as depletion-induced hypoosmolar disorders usually include an important component of secondary impairments of free water excretion, so most dilution-induced hypoosmolar disorders involve significant degrees of secondary solute depletion (see later discussion of SIADH).

Some dilutional disorders do not fit well into either category, specifically the hyponatremia that sometimes occurs in patients who ingest large volumes of beer with little food intake for prolonged periods ("beer potomania").²³⁷ Even though the volume of fluid ingested may not seem sufficiently excessive to overwhelm renal diluting mechanisms, free water excretion is limited by very low urinary solute excretion, leading to water retention and dilutional hyponatremia.

Adaptation to Hyponatremia: ICF and ECF Volume Regulation

Many past studies have intimated that the combined effects of water retention and urinary solute excretion cannot adequately explain the degree of plasma hypoosmolality observed in patients.^{224,238} This observation led to the theory of "cellular inactivation of solute," which suggested that as ECF osmolality falls, water moves into cells along osmotic gradients, thereby causing the cells to swell. At some point during this volume expansion, the cells osmotically "inactivate" some of their intracellular solutes as a defense mechanism to prevent continued cellular swelling and subsequent detrimental effects on cell function and survival. This action decreases the intracellular osmolality, and water then shifts back out of the ICF into the ECF, further worsening the dilution-induced hypoosmolality. Despite the appeal of this theory, its validity has never been demonstrated conclusively in either human or animal studies.

An alternative theory is that cell volume is maintained under hypoosmolar conditions by extrusion of intracellular solutes such as potassium.²³⁹ Whole-brain volume regulation via electrolyte losses was first described by Yannet²⁴⁰ and has long been recognized as the mechanism by which the brain is able to adapt to hyponatremia and limit brain edema to sublethal levels.²⁴¹ After the recognition that low-molecular-weight organic compounds, called organic osmolytes, also constitute a significant osmotic component of a wide variety of cell types, studies demonstrated that both kidney²⁴² and brain²⁴³ accumulate these compounds in response to hyperosmolality. Conversely, the brain loses organic osmolytes in addition to electrolytes during volume regulation to hypoosmolar conditions in experimental animals^{244,245} and human patients.²⁴⁶ These losses occur relatively quickly (within 24 to 48 hours in rats) and can account for as much as one third of brain solute losses during hyponatremia.²⁴⁷ Such coordinated losses of electrolytes and organic osmolytes from brain cells allow effective regulation of brain volume during chronic hyponatremia.

Although studies of volume regulation during hyponatremia have focused on the brain, all cells regulate volume by cellular losses of both electrolytes and organic solutes to varying degrees. However, volume regulatory processes are not limited to cells. In most cases of hyponatremia induced by stimulated antidiuresis and water retention, natriuresis also regulates the volumes of the ECF and intravascular spaces.

Many experimental and clinical observations are consistent with ECF volume regulation via secondary solute losses. First, the concentrations of most blood constituents other than Na^+ and Cl^- are not decreased in patients with SIADH,²⁴⁸ suggesting that plasma volume is not nearly as expanded as would be predicted simply by the measured decreases in serum $[Na^+]$. Second, an increased incidence of hypertension has never been observed in patients with SIADH, again evidence against significant expansion of the arterial blood volume. Third, results of animal studies in both dogs²⁴⁹ and rats²⁵⁰ have indicated that a significant component of chronic hyponatremia is attributable to secondary Na^+ losses rather than water retention. Furthermore, the relative contributions from water retention versus sodium loss vary with the duration and severity of the hyponatremia: water retention was found to be the major cause of decreased serum $[Na^+]$ during the first 24 hours of induced hyponatremia in rats, but Na^+ depletion then became the predominant etiologic factor after longer periods of sustained hyponatremia (7 to 14 days),

particularly at very low serum $[Na^+]$ levels (<115 mEq/L).²⁵⁰ Finally, multiple studies of body fluid compartment volumes in hyponatremic patients have not demonstrated either plasma or ECF expansion. For example, a report of body fluid space measurements using isotope dilution techniques in hyponatremic and normonatremic patients with small-cell lung carcinoma showed no differences between the two groups with regard to exchangeable Na^+ space, ECF volume by $^{35}SO_4$ distribution, or total body water.²⁵¹ Such results have generally been explained by the relative insensitivity of isotope dilution techniques for measurement of body fluid compartment spaces, but an equally plausible explanation is that body fluid compartments have the ability to regulate back toward normal via a combination of extracellular (predominantly electrolyte) and intracellular (electrolyte and organic osmolyte) solute losses.²⁵²

Figure 10-5 schematically illustrates volume regulatory processes that occur in response to water retention induced by inappropriate antidiuresis.

Differential Diagnosis of Hyponatremia and Hypoosmolality

Because of the multiplicity of disorders causing hypoosmolality and the fact that many involve more than one pathologic mechanism, a definitive diagnosis is not always possible at the time of initial presentation. Nonetheless, an approach based on clinical parameters of ECF volume status and urine Na^+ concentration usually allows a sufficient categorization for appropriate decisions regarding initial therapy and further evaluation (Table 10-3).

Decreased Extracellular Fluid Volume. Clinically detectable hypovolemia always signifies total-body solute depletion. A low urine $[Na^+]$ indicates a nonrenal cause and an appropriate renal response. A high urine $[Na^+]$ suggests that a renal cause of solute depletion is more likely. Therapy with thiazide diuretics is the most common cause of renal solute losses,²³⁴ particularly in the elderly,²⁵³ but one must also consider mineralocorticoid deficiency caused by adrenal insufficiency or mineralocorticoid resistance²⁵⁴ and, less commonly, renal solute losses due to salt-wasting nephropathy such as polycystic kidney disease, interstitial nephritis, or chemotherapy.

Increased Extracellular Fluid Volume. Clinically detectable hypervolemia always signifies total-body Na^+ excess. In these patients, hypoosmolality results from an even greater expansion of total body water caused by a marked reduction in the rate of water excretion (and sometimes an increased rate of water ingestion). The impairment in water excretion is secondary to a decreased EABV,²³⁶ which increases the reabsorption of glomerular filtrate not only in the proximal nephron but also in the distal and collecting tubules by stimulated secretion of vasopressin. These patients typically have a low urine $[Na^+]$ because of secondary hyperaldosteronism. However, under certain conditions urine $[Na^+]$ may be elevated if there is concurrent diuretic therapy or a solute diuresis (e.g., glucosuria in diabetics) or after successful treatment of the underlying disease (e.g., improved cardiac output in patients with congestive heart failure).

Normal Extracellular Fluid Volume. Many different hypoosmolar disorders manifest with euvolemia, and measurement of urinary $[Na^+]$ is an especially important first step.²⁵⁵ A high urine $[Na^+]$ usually implies a distally mediated, dilution-induced hypoosmolality such as SIADH.

Figure 10-5 Schematic illustration of potential changes in whole-body fluid compartment volumes at various times during adaptation to hyponatremia. **A**, Under basal conditions, the concentrations of effective solutes in the extracellular fluid ($[S]_{ECF}$) and in the intracellular fluid ($[S]_{ICF}$) are in osmotic balance. **B**, During the first phase of water retention resulting from inappropriate antidiuresis, the excess water distributes across total body water, causing expansion of both ECF and ICF volumes (dotted lines), with equivalent dilutional decreases in both $[S]_{ICF}$ and $[S]_{ECF}$. **C**, In response to the volume expansion, compensatory volume regulatory decreases (VRD) occur to reduce the effective solute content of the ECF (via pressure diuresis and natriuretic factors) and the ICF (via increased electrolyte and osmolyte extrusion mediated by stretch-activated channels and downregulation of synthesis of osmolytes and osmolyte uptake transporters). **D** and **E**, If both processes go to completion, such as under conditions of fluid restriction, a final steady state can be reached in which ICF and ECF volumes have returned to normal levels but $[S]_{ICF}$ and $[S]_{ECF}$ remain low. In most cases, this final steady state is not reached, and moderate degrees of ECF and ICF expansion persist, although they are significantly less than would be predicted from the decrease in body osmolality (**D**). Consequently, the degree to which hyponatremia is the result of dilution due to water retention versus solute depletion from volume regulatory processes can vary markedly, depending on which phase of adaptation the patient is in and the relative rates at which the different compensatory processes occur. For example, delayed ICF VRD can worsen hyponatremia because of shifts of intracellular water into the ECF as intracellular organic osmolytes are extruded and subsequently metabolized; this likely accounts for some component of the hyponatremia that was unexplained by the combination of water retention and sodium excretion in early clinical studies. (From Verbalis JG. Hyponatremia: epidemiology, pathophysiology, and therapy. *Curr Opin Nephrol Hypertens*. 1993;2:626-652.)

However, glucocorticoid deficiency can mimic SIADH so closely that these two disorders are often indistinguishable in terms of water balance. Hyponatremia from diuretic use also can manifest without clinically evident hypovolemia, and the urine $[Na^+]$ is usually elevated.²³⁴ A low urine $[Na^+]$ suggests a depletion-induced hypoosmolality from ECF losses with subsequent volume replacement by water or

TABLE 10-3

Common Etiologies of the Syndrome of Inappropriate Antidiuretic Hormone Secretion (SIADH)

Tumors

Pulmonary/mediastinal (bronchogenic carcinoma, mesothelioma, thymoma)
Nonchest (duodenal carcinoma, pancreatic carcinoma, ureteral/prostate carcinoma, uterine carcinoma, nasopharyngeal carcinoma, leukemia)

Central Nervous System Disorders

Mass lesions (tumors, brain abscesses, subdural hematoma)
Inflammatory diseases (encephalitis, meningitis, systemic lupus erythematosus, acute intermittent porphyria, multiple sclerosis)
Degenerative/demyelinative diseases (Guillain-Barré syndrome, spinal cord lesions)
Miscellaneous (subarachnoid hemorrhage, head trauma, acute psychosis, delirium tremens, pituitary stalk section, transsphenoidal adenectomy, hydrocephalus)

Drug-Related

Stimulated release of AVP (nicotine, phenothiazines, tricyclics)
Direct renal effects and/or potentiation of AVP antidiuretic effects (dDAVP, oxytocin, prostaglandin synthesis inhibitors)
Mixed or uncertain actions (ACE inhibitors, carbamazepine and oxcarbazepine, chlorpropamide, clofibrate, clozapine, cyclophosphamide, 3,4-methylenedioxymethamphetamine ["ecstasy"], omeprazole; serotonin reuptake inhibitors, vincristine)

Pulmonary

Infections (tuberculosis, acute bacterial and viral pneumonia, aspergillosis, empyema)
Mechanical/ventilatory causes (acute respiratory failure, COPD, positive-pressure ventilation)

Other Causes

Acquired immunodeficiency syndrome (AIDS) and AIDS-related complex
Prolonged strenuous exercise (marathon, triathlon, ultramarathon, hot-weather hiking)
Senile atrophy
Idiopathic

ACE, angiotensin-converting enzyme; AVP, arginine vasopressin; COPD, chronic obstructive pulmonary disease; dDAVP, desmopressin.

other hypotonic fluids. The solute loss often is nonrenal, but an important exception is recent cessation of diuretic therapy, because urine $[Na^+]$ can decrease to low values within 12 to 24 hours after discontinuation of the drug. A low urine $[Na^+]$ also can be seen in some cases of hypothyroidism, in the early stages of decreased EABV before the development of clinically apparent salt retention and fluid overload, and during the recovery phase from SIADH. Hence, a low urine $[Na^+]$ is less meaningful diagnostically than is a high value.

Clinical Syndrome of Inappropriate Secretion of Antidiuretic Hormone (SIADH)

SIADH is the most common cause of euvoletic hyposmolality, and it is also the most common cause of hyposmolality among all etiologies encountered in clinical practice, with prevalence rates of 20% to 40% among all hyposmolar patients.^{229,235} The clinical criteria necessary to diagnose SIADH remain basically those set forth by Bartter and Schwartz in 1967²²⁴:

1. Decreased effective osmolality of the ECF (plasma osmolality <275 mOsm/kg H_2O)—Pseudohyponatremia and hyperglycemia alone must be excluded.
2. Inappropriate urinary concentration at some level of hyposmolality—This does not mean that urine osmolality must be greater than plasma osmolality, only that it is less than maximally dilute (i.e., urine osmolality >100 mOsm/kg H_2O). Also, urine osmolality need not be elevated inappropriately at all levels of plasma osmolality, because in the reset osmostat variant form of SIADH, vasopressin secretion can be suppressed with resultant maximal urinary dilution if plasma osmolality is decreased to sufficiently low levels.²⁵⁶
3. Clinical euvoletic, as defined by the absence of signs of hypovolemia (orthostasis, tachycardia, decreased skin turgor, dry mucous membranes) or hypervolemia (subcutaneous edema, ascites). Hypovolemia and hypervolemia strongly suggest different causes of hyposmolality. Patients with SIADH can become hypovolemic or hypervolemic for other reasons, but in such cases it is impossible to diagnose the underlying inappropriate antidiuresis until the patient is rendered euvoletic and is found to have persistent hyposmolality.
4. Elevated urinary Na^+ excretion with a normal salt and water intake—This criterion is included because of its utility in differentiating between hyposmolality caused by a decreased EABV, in which case renal Na^+ conservation occurs, and distal dilution-induced disorders, in which case urine Na^+ excretion is normal or increased secondary to ECF volume expansion. Patients with SIADH can have low urine Na^+ excretion if they subsequently become hypovolemic or solute depleted, conditions that sometimes follow severe salt and water restriction. Consequently, a high urine Na^+ excretion is the rule in most patients with SIADH; its presence does not guarantee this diagnosis, and its absence does not rule out the diagnosis.
5. Absence of other potential causes of euvoletic hyposmolality, such as hypothyroidism, hypocortisolism (Addison's disease or pituitary ACTH insufficiency), and diuretic use.

Several other criteria support, but are not essential for, a diagnosis of SIADH. Volume expansion and vasopressin acting on V_1 receptors in the kidney increase the clearance of uric acid, so hypouricemia is found with SIADH. When patients are hyponatremic, values of uric acid are reported to be lower than 4 mg/dL (<0.24 mmol/L).²⁵⁷ A water-loading test is of value if there is uncertainty regarding the etiology in a patient with euvoletic and a modest degree of hyposmolality, but it does not add useful information if the plasma osmolality is already lower than 275 mOsm/kg H_2O . Inability to excrete a standard water load normally (defined as a cumulative urine output of at least 90% of the administered water load within 4 hours and suppression of urine osmolality to <100 mOsm/kg H_2O) confirms the presence of an underlying defect in free water excretion. However, water excretion is abnormal in almost all disorders that cause hyposmolality, whether dilutional or depletion-induced with secondary impairments in free water excretion. Two exceptions are primary polydipsia, in which hyposmolality can rarely be secondary to excessive water intake alone, and the reset osmostat variant of SIADH, in which normal excretion of a water load can occur once the plasma osmolality falls below the new set point for vasopressin secretion.

Another supportive criterion is an inappropriately elevated plasma vasopressin level in relation to plasma osmolality. With the development of sensitive vasopressin

Figure 10-6 Plasma arginine vasopressin (AVP) levels in patients with the syndrome of inappropriate antidiuretic hormone secretion (SIADH) as a function of plasma osmolality. Each point depicts one patient at a single point in time. The shaded area represents AVP levels in normal subjects over physiologic ranges of plasma osmolality. The lowest measurable plasma AVP level that could be measured with this radioimmunoassay was 0.5 pg/mL. (From Robertson GL, Aycinena P, Zerbe RL. Neurogenic disorders of osmoregulation. *Am J Med.* 1982; 2:339-353.)

radioimmunoassays capable of detecting the small physiologic concentrations of this peptide that circulate in plasma,²⁵⁸ there was hope that measurement of plasma vasopressin levels might become the definitive test for diagnosing SIADH. This has not occurred for several reasons. First, although plasma vasopressin levels are elevated in most patients with this syndrome, the elevations generally remain within the normal physiologic range and are abnormal only in relation to plasma osmolality (Fig. 10-6). Second, 10% to 20% of patients with SIADH do not have measurably elevated plasma vasopressin levels (Fig. 10-7) and are at the limits of detection by radioimmunoassay.²⁵⁹ Third, and perhaps most important, most disorders causing solute and volume depletion or decreased EABV are associated with elevations of plasma vasopressin secondary to nonosmotic hemodynamic stimuli.

Etiology

Although the list of disorders associated with SIADH is long (see Table 10-3), these disorders can be divided into four major etiologic groups: tumors, CNS disorders, drugs, and pulmonary disorders.

Tumors. The most common association of SIADH is with tumors. Many different types of tumors have been associated with SIADH, but bronchogenic carcinoma of the lung has been uniquely associated with SIADH since the first description of this disorder in 1957.²²³ In virtually all cases, the bronchogenic carcinomas causing this syndrome have been of the small-cell (or oat cell) variety. The incidence of hyponatremia is reported to be as high as 11% among all patients with small-cell carcinoma²⁶⁰ or 33% among those with more extensive disease.²⁶¹ The unusually high incidence of small-cell carcinoma of the lung, together with the relatively favorable therapeutic response of this type of tumor, makes it imperative that all adult patients presenting with an otherwise unexplained SIADH be investigated thoroughly and aggressively for a possible lung tumor. The evaluation should include chest computed tomography or MRI and, in selected cases, bronchoscopy with cytologic

analysis of bronchial washings even if the results of routine chest radiography are normal, because several studies have reported hyposmolality predating radiographic abnormalities by 3 to 12 months.

Head and neck cancers account for another group of malignancies associated with relatively higher incidences of SIADH,²⁶² and some of these tumors have clearly been shown to synthesize vasopressin.²⁶³ A report from a large cancer hospital showed an incidence of hyponatremia for all malignancies of 3.7%, with approximately one third of these cases associated with SIADH.²⁶⁴

Central Nervous System Disorders. A large number of CNS disorders have been associated with SIADH, but there has been no common denominator linking them. This is not surprising when one considers the neuroanatomy described earlier. Magnocellular vasopressin neurons receive excitatory inputs from osmoreceptive cells located in the anterior hypothalamus but also a major innervation from brain stem cardiovascular regulatory and emetic centers. Although various components of these pathways have yet to be elucidated fully, many of them appear to have inhibitory as well as excitatory components. Consequently, any diffuse CNS disorder can potentially cause vasopressin hypersecretion, either by nonspecifically exciting these pathways via irritative foci or by disrupting them and thereby decreasing the level of inhibition. The wide variety of diverse CNS processes that can potentially cause SIADH stands in contrast to CNS causes of DI, which are limited to lesions of the suprasellar hypothalamus.

Drugs. Drug-induced hyponatremia is a common cause of hyposmolality.²⁶⁵ Table 10-3 lists some of the agents that have been associated with SIADH, but new drugs are added continually. Pharmacologic agents may stimulate secretion of vasopressin, activate renal V_2 receptors, or potentiate the

Figure 10-7 Schematic summary of four patterns of arginine vasopressin (AVP) secretion in patients with the syndrome of inappropriate antidiuretic hormone secretion (SIADH). Each line (a through d) represents the relation between plasma AVP and plasma osmolality in an individual patient in whom osmolality was increased by infusion of hypertonic NaCl. The shaded area represents plasma AVP levels in normal subjects over physiologic ranges of plasma osmolality. See text for details. (From Robertson GL. Thirst and vasopressin function in normal and disordered states of water balance. *J Lab Clin Med.* 1983;101:351-371.)

antidiuretic effect of vasopressin. Not all of the drug effects are fully understood, and many appear to work through a combination of mechanisms. A particularly interesting and clinically important class of agents is the selective serotonin reuptake inhibitors (SSRIs). In studies in rats, serotonergic agents increase secretion of vasopressin,²⁶⁶ whereas in humans SSRIs have been found to have inconsistent measurable effects on secretion of vasopressin.²⁶⁷ Hyponatremia following SSRI administration has been reported almost exclusively in the elderly, with rates as high as 22% to 28%, although in larger series an incidence closer to 1 in 200 has been reported.²⁶⁸ A similar effect is likely also responsible for the reports of severe fatal hyponatremia caused by use of the recreational drug 3,4-methylenedioxymethamphetamine ("ecstasy"), which possesses substantial serotonergic activity.²⁶⁹

Pulmonary Disorders. A variety of pulmonary disorders have been associated with SIADH, but except for tuberculosis, acute pneumonia, and advanced chronic obstructive lung disease, the occurrence of hypoosmolality has been noted only sporadically. Hypoxia stimulates secretion of vasopressin in animals,²⁷⁰ but in humans hypercarbia is more associated with abnormal water retention. Elevated vasopressin may be limited to the initial days of hospitalization, when respiratory failure is most marked. In patients with SIADH in non-tumor-related pulmonary disease, the pulmonary disease is usually obvious with severe dyspnea or extensive radiographically evident infiltrates, and the inappropriate antidiuresis is usually limited to the period of respiratory failure.

Mechanical ventilation can cause inappropriate secretion of vasopressin, and it can worsen SIADH caused by other factors. The mechanism is thought to be decreased venous return.

Other Causes. In patients with acquired immunodeficiency syndrome (AIDS), AIDS-related complex, or HIV infection, the incidence of hyponatremia has been reported to be as high as 30% to 38% in adults and children.²⁷¹ Although there are many potential etiologies, including dehydration, adrenal insufficiency, and pneumonitis, between 12% and 68% of AIDS patients who develop hyponatremia appear to meet criteria for a diagnosis of SIADH.²⁷¹ Not unexpectedly, some of the medications used to treat these patients can cause the hyponatremia, through either direct renal tubular toxicity or induced SIADH.²⁷²

Elderly patients often develop SIADH without any apparent underlying etiology, and the high incidence of hyponatremia in geriatric patients^{225,273} suggests that the normal aging process may be accompanied by abnormalities of regulation of water balance and secretion of vasopressin (see earlier discussion). Such an effect could potentially account for the fact that drug-induced hyponatremia occurs much more frequently in elderly patients. In a series of 50 consecutive elderly patients meeting criteria for SIADH, 60% of the cases remained idiopathic despite rigorous evaluation, leading the authors to conclude that extensive diagnostic procedures are not warranted in such elderly patients if the routine history, physical examination, and laboratory evaluation fail to suggest an underlying etiology.²⁷⁴

Pathophysiology

Sources of Vasopressin Secretion. Elevated plasma levels of vasopressin can be broadly divided into those associated with paraneoplastic (ectopic) secretion of vasopressin and those related to pituitary hypersecretion of vasopressin.

There is substantial cumulative evidence that tumor tissue can synthesize vasopressin,²⁷⁵ but it is not certain that all tumors associated with SIADH do so, because only about half of small-cell carcinomas have been found to contain vasopressin immunoreactivity, and many of the tumors listed in Table 10-3 have not been so studied.

Pituitary Vasopressin Secretion: Inappropriate Versus Appropriate. In most cases of SIADH, the vasopressin secretion originates from the posterior pituitary. This is also true of more than 90% of all cases of hyponatremia, including hypovolemic and hypervolemic hyponatremia.²²⁹ This raises the question of what is "inappropriate" secretion of vasopressin. Secretion of vasopressin in response to a hypovolemic stimulus is clearly physiologically appropriate, but when it leads to symptomatic hyponatremia it could be considered inappropriate for the osmolality. Despite these semantic difficulties, the diagnosis of SIADH should rest on the original criteria and should specifically exclude other clinical conditions that cause known impairments in free water excretion even when these are mediated by a secondary stimulation of vasopressin. Without maintaining these distinctions, arguable as some may be, the definition of SIADH becomes too broad to retain any practical clinical utility.

Patterns of Vasopressin Secretion. Studies of plasma vasopressin levels in patients with SIADH during graded increases in plasma osmolality produced by hypertonic saline administration have defined four patterns of secretion, which are displayed in Figure 10-7, lines a through d, respectively²⁵⁹:

1. Random hypersecretion of vasopressin
2. Inappropriate nonsuppressible basal vasopressin release but normal secretion in response to osmolar changes above basal plasma osmolality
3. A reset osmostat system whereby vasopressin is secreted at an abnormally low threshold of plasma osmolality but otherwise displays a normal response to relative changes in osmolality
4. Low or even undetectable plasma vasopressin levels despite classic clinical characteristics of SIADH.

The first pattern, unregulated vasopressin secretion, is often observed in patients exhibiting paraneoplastic vasopressin production. Resetting of the osmotic threshold for vasopressin secretion has been well described in volume depletion²⁷⁶ and in edema-forming states with EABV,²³⁶ but most patients with reset osmostat are clinically euvolemic²⁵⁶ and may have SIADH. The best physiologic example of a reset osmostat is pregnancy, as discussed earlier. Perhaps the most perplexing aspect of the reset osmostat pattern is its occurrence in patients with tumors, which suggests that in some of these cases a tumor-related mechanism may affect pituitary vasopressin secretion.²⁵⁹

The pattern of SIADH that occurs without measurable vasopressin secretion is not yet well understood, but the positive response of one such patient to a vasopressin V_2 receptor antagonist suggests that this condition may represent increased renal sensitivity to low circulating levels of vasopressin.²⁷⁷ Studies of two pediatric patients with hyponatremia and unmeasurable plasma vasopressin levels led to the discovery of an activating mutation of the vasopressin V_2 receptor as the cause of their inappropriate antidiuresis.²⁷⁸ It is more appropriate to call these cases the *nephrogenic syndrome of inappropriate antidiuresis*, reserving "SIADH" only for those cases in which measured plasma vasopressin levels are really inappropriate. Although the incidence of nephrogenic syndrome of inappropriate

antidiuresis in the general population is unknown, the description of a Belgian kindred with this mutation suggests that it can manifest later in life as well as in childhood.

It is surprising that no correlation has been found between any of these patterns of secretion of vasopressin and the various etiologies of SIADH.²⁵⁹ It seems likely that in many cases a heterogeneous group of CNS processes are involved, including osmotic and nonosmotic stimulatory and inhibitory pathways, rather than a single dominant cause.

Contribution of Natriuresis to the Hyponatremia of SIADH. Since the original cases studied by Schwartz and Bartter, increased renal Na^+ excretion has been one of the cardinal manifestations of SIADH and indeed has become embedded in the requirements for its diagnosis.²²⁴ The fact that the natriuresis accompanying administration of anti-diuretic hormone is not due to vasopressin but rather to the volume expansion produced as a result of water retention was unequivocally demonstrated by Leaf and coworkers even before the disorder itself was described.²⁷⁹

Although a negative Na^+ balance occurs during the development of hyponatremia in patients with SIADH, eventually urinary Na^+ excretion simply reflects daily sodium intake.²²³ So-called renal sodium wasting is seen as continued excretion of Na^+ despite hyponatremia, but in reality a new steady state has been established in which the patient is in neutral sodium balance. Studies of long-term antidiuretic-induced hyponatremia in dogs and rats have indicated that a large proportion of the hyponatremia was attributable to secondary Na^+ losses rather than water retention,^{249,250} but the natriuresis did not actually worsen the hyponatremia; rather, it allowed volume regulation of ECF. Secondary natriuresis in patients with SIADH likely explains the failure to find expanded plasma or ECF volumes using tracer dilution techniques.²⁵¹

Cerebral Salt Wasting. The degree to which hyponatremia occurs mainly as a result of primary natriuresis is controversial. Cerebral salt-wasting syndrome was proposed by Peters and associates in 1950²⁸⁰ as an explanation for the natriuresis and hyponatremia that sometimes accompanies intracranial disease, particularly subarachnoid hemorrhage, in which up to one third of patients develop hyponatremia. After the description of SIADH in 1957, such patients were generally assumed to have hyponatremia secondary to vasopressin hypersecretion with a secondary natriuresis. However, subsequent interpretation of clinical and experimental data indicated that some patients with subarachnoid hemorrhage and other intracranial diseases indeed have a primary natriuresis leading to volume contraction rather than SIADH,^{281,282} and the elevated plasma vasopressin levels may be physiologically appropriate for the degree of volume contraction. The sensitivity of measures of volume contraction are limited, so some authors have suggested that in most cases there is insufficient evidence of volume contraction,²⁸³ whereas others have argued that the combined measures used to estimate ECF volume do support hypovolemia in such patients.²⁸⁴

With regard to the potential mechanisms of natriuresis, both plasma and CSF levels of atrial natriuretic peptide are elevated in many patients with subarachnoid hemorrhage and have been found to correlate variably with hyponatremia in patients with intracranial diseases.²⁸⁵ However, clearly documented SIADH also is frequently associated with elevated plasma levels of atrial natriuretic peptide, so this finding does not prove causality. In other disorders of

hyponatremia due to Na^+ wasting (e.g., Addison's disease) and in diuretic-induced hyponatremia, infusion of saline restores normal ECF volume and plasma tonicity by shutting off the secondary vasopressin secretion. In patients with subarachnoid hemorrhage, however, administration of large volumes of isotonic saline sufficient to maintain plasma volume did not change the incidence of hyponatremia.²⁸⁶ It seems most likely that subarachnoid hemorrhage and many other intracranial diseases represent a mixed disorder in which some patients have both exaggerated natriuresis and inappropriate vasopressin secretion; which mechanism predominates in the clinical presentation depends on its relative intensity and the effects of concomitant therapy.

Those authors who have distinguished cerebral salt wasting from SIADH have emphasized that in cerebral salt wasting the primary disorder, salt wasting, produces convincing evidence of decreased ECF volume.^{287,288} There are now a few case reports of patients undergoing traumatic brain injury or neurosurgery who, while being observed in the hospital, had acute onset of massive diuresis and natriuresis with clear evidence of volume contraction by weight loss, decreased central venous pressure, increased BUN, or increased hematocrit (i.e., they fulfilled the strict criteria for cerebral salt wasting). Decreased ECF is incompatible with natriuresis produced by volume expansion in SIADH. Most of these cases have been in children²⁸⁹⁻²⁹² and have responded to replacement with normal or hypertonic saline, but concurrent treatment with fludrocortisone has also been advocated.^{291,293}

Renal Adaptation. In addition to excreting osmoles to bring volumes back toward normal, there are adaptations that allow excretion of more water. As stated earlier, vasopressin stimulates water retention by increasing the activity and abundance of aquaporin 2 water channels in the renal collecting duct epithelium. Chronic stimulation by vasopressin in SIADH produces dramatic increases above normal levels of aquaporin 2 content and insertion into the epithelial cell membranes, increasing the efficiency of water retention and aggravating the pathology. However, the induced volume expansion and hypotonicity act on the tubular cells of the collecting duct to decrease the content and action of aquaporin 2, thereby decreasing the amount of water resorbed in spite of high vasopressin. This may occur through downregulation of vasopressin V_2 receptor expression in the kidney.²⁹⁴ This renal "escape" represents another adaptation (in addition to natriuresis) that allows patients with persistent SIADH to come into a new steady state of Na^+ and water balance despite low serum $[\text{Na}^+]$ levels.²⁹⁵

Clinical Manifestations of Hypoosmolar Disorders

Regardless of the cause of hypoosmolality, most clinical manifestations are similar. Non-neurologic symptoms are relatively uncommon, although a number of cases of rhabdomyolysis have been reported, presumably secondary to osmotically induced swelling of muscle fibers. Hypoosmolality is primarily associated with a broad spectrum of neurologic manifestations, ranging from mild, nonspecific symptoms (e.g., headache, nausea) to more significant disorders (e.g., disorientation, confusion, obtundation, focal neurologic deficits, seizures).²²⁶ This neurologic symptom complex has been termed *hyponatremic encephalopathy*,²⁹⁶ and it primarily reflects brain edema resulting from osmotic water shifts into the brain due to decreased effective plasma osmolality. Significant neurologic symptoms generally do not occur until the serum $[\text{Na}^+]$ falls below 125 mEq/L, and

the severity of symptoms is roughly correlated with the degree of hyposmolality.^{226,297} However, individual variability is marked. For any single patient, the level of serum $[\text{Na}^+]$ at which symptoms appear cannot be predicted, and once the brain has volume-adapted via solute losses, thereby reducing brain edema, neurologic symptoms may be virtually absent.

In animal studies, the rate of fall of serum $[\text{Na}^+]$ is often more strongly correlated with morbidity and mortality than is the actual magnitude of the decrease.^{226,297} The reason is that the volume-adaptation process takes a finite period of time to complete, and the more rapid the fall in serum $[\text{Na}^+]$, the more brain edema will be accumulated before the brain is able to volume-regulate. Therefore, there is a much higher incidence of neurologic symptoms, as well as a higher mortality rate, in patients with acute hyponatremia than in those with chronic hyponatremia.²²⁶ For example, the most dramatic cases of death due to hyponatremic encephalopathy have been reported in postoperative patients in whom hyponatremia develops rapidly as a result of intravenous infusion of hypotonic fluids.^{226,298} In such cases, nausea and vomiting are frequently overlooked as potential early signs of increased intracranial pressure. Because hyposmolality does not cause any direct effects on the gastrointestinal tract, unexplained nausea or vomiting in a hyposmolar patient should be assumed to be of CNS origin. Similarly, critically ill patients with unexplained seizures should be immediately evaluated for possible hyponatremia, because as many as one third of such patients have a serum $[\text{Na}^+]$ lower than 125 mEq/L as the cause of their seizure activity.²⁹⁹ Underlying neurologic disease and non-neurologic metabolic disorders (e.g., hypoxia,³⁰⁰ acidosis, hypercalcemia) can raise the level of plasma osmolality at which CNS symptoms occur.

In the most severe cases of hyponatremic encephalopathy, death results from respiratory failure after tentorial cerebral herniation and brain stem compression. One quarter of patients with severe postoperative hyponatremic encephalopathy had hypercapnic respiratory failure, the expected result of brain stem compression, but three quarters had pulmonary edema as the apparent cause of their hypoxia.³⁰¹ Further, studies of acute hyponatremia after marathon races have shown hypoxia and pulmonary edema in association with brain edema.³⁰² These results suggest the possibility that hypoxia from noncardiogenic pulmonary edema may represent an early sign of developing cerebral edema even before the brain stem compression and tentorial herniation. Clinical studies have suggested that menstruating women²⁹⁸ and young children³⁰³ may be particularly susceptible to the development of neurologic morbidity and mortality during hyponatremia, especially in the acute postoperative setting.²⁹⁶ However, other studies have failed to corroborate these findings.^{304,305} Consequently, the true clinical incidence as well as the underlying mechanisms responsible for these sometimes catastrophic cases is not certain.

Treatment of Hyposmolar Disorders

Despite some areas of continuing controversy concerning correction of osmolality in hyposmolar patients, a relative consensus has evolved regarding the most appropriate treatment of this disorder.

Initial Evaluation

The ECF volume status determines the treatment of hyponatremia. If volume is expanded, the treatment of the underlying disease should take precedence over correction

of plasma osmolality. Often this involves treatment with diuretics, which should simultaneously improve plasma tonicity by stimulating excretion of hypotonic urine. If hypovolemia is present, the patient must be considered to have depletion-induced hyposmolality, in which case volume repletion with isotonic saline (0.9% NaCl) at a rate appropriate for the estimated fluid deficit should be initiated. If diuretic use is known or suspected, the isotonic saline should be supplemented with potassium (30 to 40 mEq/L), even if the serum $[\text{K}^+]$ is not low, because of the propensity of such patients to develop total-body potassium depletion.

Most often, the hyposmolar patient is clinically euvolemic. However, a possibility of depletion-induced, rather than dilution-induced, hyposmolality still exists, and it is most appropriate to treat the patient initially with isotonic saline, regardless of whether signs of hypovolemia are present. An improvement in, and eventual correction of, the hyponatremia verifies solute and volume depletion. On the other hand, if the patient has SIADH rather than solute depletion, the administration of a limited volume (e.g., 1 to 2 L) of isotonic saline will produce Na^+ and water excretion without significantly changing plasma osmolality.²²³

A patient who meets the essential criteria for SIADH but has a low urine osmolality should be observed on a trial of modest fluid restriction. If the hyposmolality is attributable to transient SIADH or severe polydipsia, the urine will remain dilute and the plasma osmolality will be fully corrected as free water is excreted. If, however, the patient has the reset osmostat form of the disorder, the urine will become concentrated at some point before the plasma osmolality and serum $[\text{Na}^+]$ return to normal ranges. If either primary or secondary adrenal insufficiency is suspected, glucocorticoid replacement should be initiated immediately after the completion of a rapid ACTH stimulation test. A prompt water diuresis after initiation of glucocorticoid treatment supports a diagnosis of glucocorticoid deficiency, but absence of a quick response does not necessarily negate this diagnosis, because several days of glucocorticoid replacement are sometimes required for normalization of plasma osmolality.³⁰⁶ If hypothyroidism is suspected, thyroid function tests should be measured. Usually, replacement therapy is withheld pending these results unless the patient is obviously myxedematous.

Acute Therapy

In any hyponatremic patient, one must decide how quickly the plasma osmolality should be increased, and to what level. This decision depends on the risks of uncorrected hyponatremia versus the risks of the correction. It has become clear that correcting severe hyponatremia too rapidly is dangerous because it can sometimes be associated with pontine and extrapontine myelinolysis, a brain demyelinating disease that causes severe neurologic morbidity and mortality.²²⁸ Consequently, appreciation of the appropriate therapy for hyponatremia requires understanding this disease as well as the pathophysiology underlying hyponatremic encephalopathy.

Pontine and Extrapontine Myelinolysis. The demyelinating disease of central pontine myelinolysis (CPM) occurs with a significantly higher incidence in patients with hyponatremia,³⁰⁷ and in both animal³⁰⁸ and human studies,²²⁸ brain demyelination has clearly been shown to be associated with rapid correction of existing hyponatremia. In animal models of chronic hyponatremia, this pathologic disorder is most likely precipitated by the brain

dehydration that has been demonstrated to occur after correction of serum $[Na^+]$ toward the normal range.^{309,310} Magnetic resonance studies in animals have shown that chronic hypoosmolality predisposes rats to opening of the blood-brain barrier after rapid correction of hyponatremia and that disruption of the barrier is highly correlated with subsequent demyelination.³¹¹ Opening of the blood-brain barrier might lead to myelinolysis via an influx of complement, which is toxic to the oligodendrocytes that manufacture and maintain myelin sheaths of neurons.³¹²

Studies in patients³¹³ and in experimental animals³⁰⁸ support the notion that both the rate of correction of hyponatremia and the total magnitude of the correction over the first few days determine the risk of demyelination. In rats, an initial rate of correction of hyponatremia of less than 20 mEq/L in 24 hours³¹⁴ has less risk, and clinical data indicate that the initial magnitude of correction represents the major risk factor in regard to subsequent neurologic morbidity and mortality. Initial reports implicated increases in serum $[Na^+]$ greater than 25 mEq/L over the first 24 to 48 hours of treatment,³¹⁵ whereas later studies suggested occurrence of CPM with even smaller increases in serum $[Na^+]$ (>12 mEq/L in 24 hours or 18 mEq/L in 48 hours).³¹⁶ Although overcorrection of hyponatremia to supranormal levels is clearly a risk factor for neurologic deterioration, clinical and experimental studies have found that demyelination can occur after corrections to serum $[Na^+]$ levels still below normal ranges. Both experimental studies³⁰⁸ and clinical reports^{228,317,318} have demonstrated that demyelination occurs independently of the method used to correct the hyponatremia.

The susceptibility to demyelination after correction of hyponatremia is influenced importantly by the severity and duration of the preexisting hyponatremia. The more severe the hyponatremia and the longer it has been maintained, the greater the degree of intracellular solute loss that has occurred during the process of brain volume regulation. Solute loss impairs the ability of the brain to buffer volume in response to subsequent increases in plasma osmolality. Clinical studies show that CPM rarely occurs in patients with a starting serum $[Na^+]$ greater than 120 mEq/L, and it does not occur in patients with psychogenic polydipsia who develop hyponatremia acutely from massive water ingestion and then correct rapidly as they diurese the excess fluid.³¹⁹ Other independent risk factors for the occurrence of CPM are chronic alcoholism, malnutrition, and hypokalemia.³²⁰ It seems likely that the threshold for increases in serum $[Na^+]$ that increase the risk for CPM will be lower in alcoholic, malnourished, or hypokalemic patients, and a case report of myelinolysis in a patient with beer potomania in whom the rate of correction stayed within the recommended guidelines supports this likelihood.³²¹ Uremia appears to protect hyponatremic patients from myelinolysis after rapid correction of hyponatremia, purportedly because the urea acts as an intracellular osmolyte to stabilize intracellular volume and thus reduces the degree of brain dehydration produced after rapid correction of hyponatremia.³²²

The term *central pontine myelinolysis* is historically correct but anatomically too limited.³⁰⁷ Demyelination after correction of hyponatremia frequently occurs in white matter areas of the brain other than the pons; hence, the term *osmotic demyelination syndrome* (ODS).²²⁸ Apropos of the widespread nature of the neuropathologic lesions, a much broader range of neurologic disorders is now being reported in patients after correction of hyponatremia. These include cognitive, behavioral, and neuropsychiatric disorders, presumably caused by demyelination in

subcortical, corpus callosal, and hippocampal white matter, and movement disorders resulting from demyelination in the basal ganglia. Although the presence of positive MRI findings strongly supports a diagnosis of ODS, scans often fail to demonstrate the characteristic demyelinating lesions because scans are usually negative until sufficient time (usually 3 to 4 weeks) has passed since the correction of hyponatremia and the onset of neurologic symptoms.^{323,324}

Although most cases of osmotically induced ODS have been associated with rapid correction of hyponatremia, the disorder has also been reported with severe hypernatremia in both animal models³²⁵ and patients.³²⁶ It is clear that one cannot predict with any degree of certainty which patients will develop demyelination. Many patients undergo a very rapid and large change in their serum $[Na^+]$ without subsequent neurologic complications, and this is clearly true of experimental animals as well.^{308,314} Consequently, overly rapid correction of hyponatremia should be viewed as a factor that puts patients at risk for ODS but does not inevitably precipitate the disorder.

Individualization of Therapy. Based on the previous discussions of hyponatremic encephalopathy and pontine and extrapontine myelinolysis, it follows that optimal treatment of hyponatremic patients must entail balancing the risks of hyponatremia against the risks of correction for each patient individually.^{295,327} Three factors should be taken into consideration when making a treatment decision for a hypoosmolar patient: the severity of the hyponatremia, the duration of the hyponatremia, and the patient's neurologic symptomatology.

Acute Hyponatremia. Patients with acute hyponatremia (arbitrarily defined as ≤ 48 hours in duration) are usually symptomatic if the hyponatremia is severe (i.e., <125 mEq/L). These patients are at greatest risk for neurologic complications from the hyponatremia but rarely develop demyelination,³¹⁹ presumably because sufficient brain volume regulation has not yet occurred. Consequently, serum $[Na^+]$ in such patients should be corrected relatively quickly. Hypoosmolar patients should always be evaluated quickly for the presence of neurologic symptoms so that appropriate therapy can be initiated, if indicated, even while other results of the diagnostic evaluation are still pending. Postoperative patients,³²⁸ and particularly young women and children in some studies,^{298,303} appear to be at somewhat greater risk for rapidly progressing hyponatremic encephalopathy. They should be treated especially promptly, and administration of hypotonic fluids should be avoided in such patients postoperatively.²⁹⁶

Chronic Asymptomatic Hyponatremia. Patients with chronic hyponatremia (arbitrarily defined as >48 hours in duration) who have minimal neurologic symptomatology are at little risk from complications of hyponatremia itself but can develop demyelination after rapid correction because of their greater degree of brain volume regulation through electrolyte and osmolyte losses.²⁴⁷ There is no indication to correct these patients rapidly, regardless of the initial serum $[Na^+]$, and they should be treated with slower-acting therapies such as fluid restriction or vasopressin receptor antagonists (see later discussion).

Chronic Symptomatic Hyponatremia. Although the first two extremes have clear treatment indications, most hypoosmolar patients have hyponatremia of indeterminate duration and some varying degree of neurologic symptomatology. Such patients should be treated promptly because of their symptoms but with methods that allow a *controlled and limited increase* of their hypoosmolality.³²⁹

Some studies have suggested that correction parameters should consist of a maximal rate of correction of serum $[Na^+]$ in the range of 1 to 2 mEq/L per hour as long as the total magnitude of correction does not exceed 25 mEq/L over the first 48 hours³¹⁵; others recommend that these parameters should be even more conservative, with maximal correction rates of no more than 0.5 mEq/L per hour and magnitudes of correction that do not exceed 12 mEq/L in the first 24 hours and 18 mEq/L in the first 48 hours.³¹⁶ A reasonable approach would be to choose correction parameters within these limits depending on patient symptomatology: In patients who are only minimally symptomatic, one should proceed at the lower recommended limits of 0.5 mEq/L or less per hour, whereas in those who manifest more severe neurologic symptoms, an initial correction at a rate of 1 to 2 mEq/L per hour (or even 3 to 5 mEq/L per hour in comatose or seizing patients who are at risk for imminent tentorial herniation and respiratory arrest) would be more appropriate.

Regardless of the initial rate of correction chosen, acute treatment should be interrupted once any of three end points is reached: (1) the patient's symptoms are abolished, (2) a safe serum $[Na^+]$ (usually >125 mEq/L) is achieved, or (3) a total magnitude of correction of 18 mEq/L is achieved. Once any of these end points is reached, the active correction should be stopped and treatment should continue with slower-acting therapies such as oral rehydration, fluid restriction, or vasopressin receptor antagonists, depending on the etiology of the hyposmolality. It follows from these recommendations that serum $[Na^+]$ levels must be carefully monitored at frequent intervals (at least every 4 to 6 hours) during the active phases of treatment to adjust therapy and keep the correction within these guidelines.

Choice of Interventional (Active) Therapies for Acute Corrections. Controlled limited corrections can be accomplished with either isotonic or hypertonic saline infusions, depending on the cause of the hyposmolality. Patients with volume-depletion hyposmolality (e.g., clinical hypovolemia, diuretic use, urine $[Na^+] <30$ mEq/L) usually respond well to isotonic saline infusion.²⁵⁵ However, patients with diuretic-induced hyponatremia are especially susceptible to adverse effects from rapid corrections because (1) they are usually only minimally volume depleted; (2) they are often small, elderly women with correspondingly small plasma volumes; (3) with cessation of diuretic therapy they often develop a free water diuresis as their urinary diluting defect dissipates; and (4) the hypokalemia that frequently accompanies the hyponatremia in these patients appears to be an additional risk factor for demyelination after correction. Consequently, in the absence of marked neurologic symptomatology, such patients should simply be treated by institution of a regular sodium diet (4 to 6 g/day) and discontinuation of all diuretics. If isotonic saline is infused, it should be done so judiciously (e.g., 50 to 75 mL/hour) with appropriate K^+ replacement.

Patients with euvolemic hyposmolality (including patients with SIADH) typically do not respond to isotonic saline infusion^{223,255} and are best treated with hypertonic (3%) NaCl given by continuous infusion or with a vasopressin receptor antagonist. Although several different formulas have been proposed to guide the safe use of hypertonic NaCl, an initial infusion rate can be estimated most simply by multiplying the patient's body weight by the desired rate of increase in serum $[Na^+]$. For example, in a 70-kg patient, an increase in serum $[Na^+]$ of approximately 1 mEq/L per hour can be achieved by infusion of 3% NaCl at 70 mL/hour, whereas an infusion of 35 mL/

hour will increase serum $[Na^+]$ by about 0.5 mEq/L per hour.

For patients with known cardiovascular disease, furosemide may be used to treat volume overload.³³⁰ An alternative therapy in patients who do not have severe neurologic symptoms (e.g., seizures, obtundation, coma, respiratory distress) is use of a vasopressin receptor antagonist. As described later, such agents reliably produce an increased excretion of free water with a mean correction of serum $[Na^+]$ of 4 to 8 mEq/L in 24 to 48 hours, which is usually sufficient to achieve a safer level of plasma osmolality. Whichever therapy is chosen, it cannot be emphasized too strongly that it is necessary to correct the plasma osmolality acutely only to a safe range, rather than completely to normonatremia.

Spontaneous (Passive) Correction. Rarely, patients spontaneously correct their hyponatremia by means of a water diuresis. If the hyponatremia is acute, as in water intoxication from psychogenic polydipsia, spontaneous correction appears to carry little risk for subsequent demyelination.³¹⁹ However, if the hyponatremia has been chronic, the patient is at risk for demyelination,^{318,331} and one should consider intervention (e.g., administration of desmopressin, intravenous infusion of hypotonic fluid) to limit the rate and magnitude of correction of serum $[Na^+]$. In some cases, an overcorrection of serum $[Na^+]$ occurs spontaneously before it is recognized. Animal models of this scenario have demonstrated that delayed lowering of the serum $[Na^+]$ can prevent subsequent occurrence of brain damage,³²⁵ and this is consistent with a reduced amount of immunologic demyelination from complement influx into the brain after a sustained blood-brain barrier disruption.³¹² Experimental studies in rats indicate that treatment with pharmacologic doses of corticosteroids may prevent subsequent osmotic demyelination by stabilizing the blood-brain barrier.³³²

Long-Term Therapy

Several methods for treatment of chronic hyponatremia can be effective in selected clinical situations. The treatment of chronic SIADH entails a choice among several therapeutic regimens. Any drugs known to be associated with SIADH should be discontinued.

Fluid Restriction. Fluid restriction represents the least toxic treatment choice and is the preferred treatment for most cases of mild to moderate SIADH. Several points should be remembered when using this approach:

1. All fluids, not only water, must be included in the restriction.
2. The degree of restriction required depends on urine output plus insensible fluid loss; usually, discretionary (i.e., non-food) fluids should be limited to 500 mL/day below the average daily urine volume.
3. Several days of restriction are usually necessary before a significant increase in plasma osmolality occurs.
4. Only fluid, not salt, should be restricted; because of the ongoing natriuresis, patients with chronic SIADH often have a negative total body sodium balance and therefore should be maintained on a relatively high NaCl intake unless otherwise contraindicated.

Failure to improve after several days of confirmed negative fluid balance should prompt reconsideration of other possible causes, including solute depletion and clinically inapparent hypovolemia.

As described earlier, the expanded volume and hypotonicity of SIADH downregulates the vasopressin-induced

increase of aquaporin 2 water channels in the collecting duct, and this “escape” allows more water excretion.²⁹⁵ Unfortunately from a therapeutic standpoint, correction of expanded volume and hyponatremia by restriction of fluid reduces this “escape” phenomenon. Consequently, aquaporin content and action will increase again in response to the persistently elevated level of vasopressin, and the efficiency of extraction of free water will increase. This is a plausible explanation for the clinical observation that a patient with stable hyponatremia on modest fluid intake often requires an increasingly severe water restriction to correct the serum $[Na^+]$ to normal levels.

Pharmacologic Therapies. Pharmacologic intervention is reserved for refractory cases in which the degree of fluid restriction required to avoid hypoosmolality is so severe that the patient is unable, or unwilling, to maintain it. Pharmacologic intervention should also be avoided initially in patients with SIADH that is secondary to tumors, because successful treatment of the underlying lesion may eliminate or reduce the inappropriate vasopressin secretion. Pharmacologic therapies can be divided into several categories based on their mechanism of action.

Agents That Inhibit Vasopressin Secretion. Several drugs have been reported to decrease vasopressin hypersecretion in some cases (e.g., diphenylhydantoin, opiates, ethanol), but in general this approach has not been successful because responses are erratic and unpredictable. One potential exception is the use of agonists selective for κ -opioid receptors; in animal studies they were more specific for inhibition of vasopressin hypersecretion than a vasopressin receptor antagonist,³³³ and in clinical trials they successfully produced an aquaresis in patients with cirrhosis.³³⁴

Urea. Urea has been used successfully as an alternative treatment for SIADH and other hyponatremic disorders.³³⁵ It acts by producing an osmotic excretion of water while reducing urinary Na^+ excretion.

Agents That Interfere with Vasopressin Signaling. The tetracycline derivative, demeclocycline, produces a nephrogenic DI by reducing vasopressin-stimulated generation of cAMP in renal collecting duct principal cells, thereby decreasing urine concentration even in the presence of high plasma vasopressin levels.³³⁶ Appropriate doses of demeclocycline range from 600 to 1200 mg/day administered in divided doses. Treatment must be continued for several days to achieve maximal diuretic effects, and one should wait 3 to 4 days before deciding to increase the dose. Demeclocycline can cause reversible azotemia, and sometimes nephrotoxicity, especially in patients with cirrhosis.³³⁷ Renal function should therefore be monitored on a regular basis in patients treated with demeclocycline, and the medication should be discontinued if increasing azotemia is noted. Other agents, such as lithium, have similar renal effects but are less desirable because of inconsistent results and significant side effects.³³⁸

Vasopressin Receptor Antagonists. Antagonists of the kidney vasopressin V_2 receptors (called *vaptans*) have long been predicted to be the ideal agent for treatment of patients with dilutional hyponatremia. These agents stimulate renal free water excretion (aquaresis) and thereby lead to increased serum $[Na^+]$ in most patients with dilutional hyponatremia due to SIADH, congestive heart failure, or cirrhosis. Several nonpeptide vasopressin receptor antagonists have been described.³³⁹⁻³⁴¹ In 2005 the U.S. Food and

Drug Administration (FDA) approved conivaptan, a combined V_{1a} and V_2 vasopressin receptor antagonist, for treatment of euvolemic hyponatremia, and in 2006 this approval was extended to patients with hypervolemic hyponatremia.³⁴² Phase 3 clinical trials of conivaptan demonstrated a prompt correction of serum $[Na^+]$ in most treated hyponatremic patients, averaging 6 to 8 mEq/L over a 2- to 4-day course of treatment. However, because this agent is both a substrate and an inhibitor of the hepatic cytochrome P450 isoenzyme CYP3A4, and therefore diminishes hepatic metabolism of other drugs metabolized by this enzyme, conivaptan use has been limited to short-term (<4 days) intravenous administration in hospitalized patients. Nonetheless, conivaptan was found to be useful in that it corrected serum $[Na^+]$ more rapidly than fluid restriction in patients with non-life-threatening degrees of hyponatremia.

In 2009, tolvaptan, a selective V_2 vasopressin receptor antagonist, was approved by the FDA for treatment of euvolemic and hypervolemic hyponatremia. Clinical trials of tolvaptan showed normalization of serum $[Na^+]$ in most hyponatremic patients treated, and this effect was sustained over a 30-day treatment period with recurrence of the hyponatremia by 7 days after cessation of the drug. Although clinical trials of patients with heart failure failed to demonstrate long-term benefit for tolvaptan in clinical outcomes, patient-reported mental symptoms showed a significant and clinically relevant improvement after 30 days of tolvaptan treatment. The use of tolvaptan in the United States is limited to patients with severe hyponatremia (serum $[Na^+] < 125$ mEq/L) and those with milder degrees of hyponatremia who are symptomatic and for whom treatment with fluid restriction has failed. Whether these indications may be broadened in the future in large part depends on whether initial studies that have suggested gait instability and an increased incidence of falls and fractures in hyponatremic patients, as well as a worsening of resorptive bone losses as a result of hyponatremia itself, are verified in larger clinical studies.

Future clinical trials of vasopressin receptor antagonists will enable investigators to answer some long-standing questions about the role of vasopressin receptor activation in producing antidiuresis in various disease states (e.g., hyponatremic patients without measurable vasopressin levels) and the potential reversibility of long-term adverse effects of hyponatremia. Such effects may account for the increased mortality rate of hyponatremic patients across multiple different comorbidities and in community-dwelling elders without known underlying disease. Patients corrected too rapidly with vasopressin receptor antagonists will still be at risk for pontine and extrapontine myelinolysis, which has been documented in animals.³⁴³ However, appropriate dosing and monitoring should allow successful adherence to the same guidelines for limited controlled correction that apply to other methods of treatment. No cases of pontine and extrapontine myelinolysis have yet been reported in any of the clinical trials of vasopressin receptor antagonists, nor after 3 years of clinical use of conivaptan. We are therefore poised to begin a new era in the evaluation and treatment of patients with SIADH and other forms of dilutional hyponatremia.

OXYTOCIN

Study of the normal physiologic regulation of oxytocin secretion and action is complicated by the fact that experimental mammals exhibit marked variation in the secretion

and function of oxytocin. The sites of synthesis in the ovary and in tissues of the uterus also vary by species. Because it is difficult to study pregnant women and human tissue, physiologic regulation of oxytocin secretion and function is less well understood in humans than in other species. The classic roles of oxytocin are smooth muscle activation promoting milk let-down with nursing and uterine myometrial contraction at parturition.

Lactation

A characteristic of all mammals is lactation, and all mammals secrete oxytocin to stimulate milk let-down associated with nursing.³⁴⁴ The other hormone critical to lactation is prolactin. Each of these pituitary/hypothalamic hormones is importantly influenced and regulated by gonadal steroid hormones. The milk-producing unit of the breast is the alveolar system, which is composed of multiple clusters of milk-producing cells surrounded by specialized myoepithelial cells. The alveoli are directly connected to ductules, and the ducts converge and lead to the nipple. Milk is synthesized in the glandular cells of the alveoli.³⁴⁵ Oxytocin receptors are located on glandular cells, and oxytocin in the systemic circulation acts on these receptors to cause myoepithelial contraction. Oxytocin also acts on myoepithelial cells along the duct, shortening and widening the ducts to enhance milk flow to the nipple.³⁴⁶

When an infant begins sucking at the breast, an afferent signal is transmitted from the mechanoreceptors or tactile receptors in the breast to the spinal cord and from the spinal cord to the lateral cervical nucleus. These ascending fibers cross in the medulla and eventually ascend to the oxytocinergic magnocellular neurons in the supraoptic nucleus and the paraventricular nucleus.³⁴⁶⁻³⁴⁸ Numerous neurotransmitters and neuropeptides are activated by different inputs to stimulate or inhibit the magnocellular neurons,³⁴⁶ producing a synchronous pulsatile depolarization of oxytocin neurons.^{349,350} The plasticity of the neurohypophysis to promote synchrony was described earlier with an emphasis on increased neuron-to-neuron apposition, which promotes signaling between cells. The pulsatile release of oxytocin by the posterior pituitary produces a pulsatile pumping action on the alveoli, which promotes maximum emptying of milk from them.³⁴⁵ Whereas these plastic changes are sufficient for synchrony within a single nuclear group, they do not explain the synchrony that must occur between the four nuclear groups (paired paraventricular and paired supraoptic nuclei). There is no evidence of a central pacemaker, so the synchrony among these nuclei must result from the common suckling stimulus with some gating phenomenon of the neuro input. It is postulated that nitric oxide may be involved in regulation of the gating.³⁵¹

The importance of oxytocin in maintaining milk secretion was demonstrated by studies of transgenic mice with a knockout that inhibits oxytocin synthesis. These animals delivered their young normally and had normal milk production, but there was no milk release despite normal suckling. The pups died of dehydration with no milk in the stomach.^{352,353} Administration of oxytocin to these oxytocin-deficient mice rescued the ability to secrete milk and allowed the pups to survive. Similarly, oxytocin may promote successful lactation in women who have difficulty with lactation and milk production.³⁵⁴

Although in most species the sequence of events leading to milk let-down must be initiated by suckling, and, indeed, several minutes of suckling may be required,³⁵⁵ in humans

suckling is not essential, because oxytocin secretion and milk let-down are well known to occur in response to psychological stimuli such as preparing for nursing or hearing a baby cry.³⁵⁶⁻³⁵⁸ However, if oxytocin is not secreted, only 20% to 30% of stored milk is released during nursing.³⁵⁹

The role of steroids in oxytocin secretion is complex. Estrogen stimulates oxytocin release by dendrites,³⁶⁰ and progesterone withdrawal in an estrogen-primed animal stimulates oxytocin synthesis.^{361,362} Changes in the steroid hormones at the time of parturition probably modulate the lactation response both by modulating oxytocin synthesis and secretion and by modulating oxytocin receptors. As breast-feeding continues in humans, the basal levels of oxytocin decrease, but pulses of oxytocin in response to suckling continue and may increase.³⁶³ Humans with DI have been able to successfully breast-feed infants and this has caused some to question of the importance of oxytocin in humans.³⁶⁴ However, oxytocin secretion may be preserved in the absence of vasopressin in patients with DI, even in those with traumatic section of the stalk.

Parturition

The isolation of oxytocin was followed quickly by the description of its ability to stimulate uterine contractions and then by clinical use of oxytocin as a uterotonic agent.³⁶⁵ Unlike many physiologic events for which studies of other mammals can give information consistent with human physiology, the mechanism of parturition in humans is unique. Two reviews have summarized the physiology of parturition in humans, which is much more complex than just the role of oxytocin.^{366,367} In all species, the uterus must grow during pregnancy, and estrogen is a promoter of this growth; prostaglandins are important in the initiation of labor; and secretion of oxytocin is greatest at the expulsive stage of parturition.³⁶⁶⁻³⁶⁸

Teleologically, it is appealing that the developing fetus, as it reaches maturation, would be a controlling factor in the initiation of labor. In the sheep the action of the fetal hypothalamic-pituitary-adrenal axis is essential to initiating parturition, and in the human the role of CRH in parturition has been extensively studied. CRH is the hypothalamic trophic peptide that stimulates secretion of ACTH from the anterior pituitary, but in primates CRH is also synthesized by the placenta and increases exponentially throughout pregnancy, with a peak during labor.³⁶⁶ CRH is secreted into the maternal plasma, where, as pregnancy advances, it stimulates ACTH and cortisol. Feedback of cortisol on the pituitary and increasing CRH binding proteins in plasma moderate this effect.³⁶⁷ In the fetus, stimulation of pituitary ACTH and cortisol promotes maturation of the fetal lungs. In the pregnant uterus, glucocorticoids have a paradoxical feed-forward action to increase the production of CRH, and CRH has a paracrine action to stimulate production of prostaglandins in fetal membranes.³⁶⁶

Parturition is an inflammatory process, and prostaglandins play a key role as cytokines induce enzymes that digest extracellular matrix to soften and ripen the cervix.³⁶⁸ Oxytocin is not known to increase during gestation or at the initiation of parturition, but oxytocin receptors in the myometrium increase with gestation and receptor function increases at parturition.³⁶⁹ Oxytocin receptors are prominent in the fundus of the uterus, where they stimulate myometrial contraction, and in decidual cells, where they stimulate the production of prostaglandins. At parturition, increased oxytocin activity in the fundus pushes the fetus toward the cervix, which has been thinned and relaxed by the effects of prostaglandins.^{366,368}

The uterine myometrial cells have intrinsic contractile activity. During pregnancy, the uterus is maintained in a quiet state by the actions of progesterone and relaxin (produced by the corpus luteum and decidual tissue).³⁷⁰⁻³⁷² The initiation of labor is accomplished by a relative increase in estrogen activation and decrease in progesterone activation. Progesterone withdrawal may be an initiating factor of parturition in several species, but in the human estrogen and progesterone both rise throughout pregnancy, although the rate of increase for estrogen is greater than that for progesterone as parturition approaches.³⁷³ In humans, a decreasing effect of progesterone may be caused by changes in the levels and functions of progesterone receptors.³⁶⁸

Oxytocin remains the most common pharmacologic agent to induce and augment labor,³⁷⁴ and oxytocin/ergometrine to treat postpartum hemorrhage. For the latter purpose, addition of prostaglandin or oxytocin agonists has been found to give no better outcome.^{375,376}

Parturition is a complicated cascade of events that interact with each other and feed forward with cross-stimulation. It is not surprising that a physiologic event as important to the species as pregnancy and parturition would have many redundant systems to ensure species survival. Additionally, the complicated interactions among these redundant systems and the feed-forward nature of the responses make it unlikely that interruption of any single hormonal response after parturition is initiated would be sufficient to inhibit completion of delivery.³⁷⁷

An obvious lack in understanding of the physiology of pregnancy in humans is the role of cysteine aminopeptidase (oxytocinase). If this enzyme developed as a protective mechanism, then it might be assumed that oxytocin secretion by the neurohypophysis increases throughout pregnancy, but the very presence of oxytocinase and the inability to study the hypothalamus in vivo makes this possibility uncertain. However, the presence of the oxytocin-associated neurophysin throughout pregnancy supports this point of view.³⁷⁸

Behavior

This chapter concerns the functions of vasopressin and oxytocin as traditional endocrine hormones secreted by the posterior pituitary. There is another literature related to purported functions of these hormones as neurotransmitters, especially with regard to influencing behavior. Some studies have been based on pathways of neurons in the supraoptic and paraventricular nuclei that project to other sites in the brain, sometimes through dendrites rather than axons; other studies have investigated synthesis of these hormones elsewhere in the brain.

The major actions of oxytocin are as a maternal hormone, and studies of the effects of oxytocin on behavior have focused on maternal actions. Most of these studies have been in rodents. It is reported that intracerebroventricular infusions of oxytocin induce maternal behavior in estrogen-primed virgin rats, and inhibition of oxytocin centrally inhibits maternal activity in a new mother. Oxytocin facilitates maternal acceptance of newborns and protection of newborns against intruders.³⁷⁹

Many of these studies of behavior suggest that oxytocin enhances sociability; for example, female prairie voles that are monogamous and form long-term bonds have higher levels of oxytocin and oxytocin receptors than do promiscuous meadow voles.³⁸⁰ Vasopressin may play a similar role in male prairie voles.³⁷⁹ In general, there has been more interest in vasopressin in male animals, in whom it may promote more aggressive behavior.

Other studies have suggested that oxytocin is related to satiety, an effect that may be blunted in pregnancy to increase food intake.³⁸¹ Vasopressin is known to stimulate the hypothalamic-pituitary-adrenal axis, and there is interest in vasopressin as a neurotransmitter in response to stress.³⁸² Numerous studies have linked vasopressin to memory.³⁸³

In all cases, the functions of these hormones as neurotransmitters affecting behavior in humans is less well defined than in animals, and consideration of these activities in behavioral and psychiatric disorders is beyond the scope of this brief illustration of ongoing work.³⁸²

CHAPTER II

Thyroid Physiology and Diagnostic Evaluation of Patients with Thyroid Disorders

DOMENICO SALVATORE • TERRY F. DAVIES • MARTIN-JEAN SCHLUMBERGER • IAN D. HAY • P. REED LARSEN

Dysfunction and anatomic abnormalities of the thyroid are among the most common diseases of the endocrine glands. This chapter provides the physiologic and biochemical background and describes the various tests for evaluating patients with suspected thyroid disease based on the pathophysiology of these conditions.

PHYLOGENY, EMBRYOLOGY, AND ONTOGENY

Phylogeny

The phylogeny, embryogenesis, and certain aspects of thyroid function are closely interlinked with the gastrointestinal tract. The capacity of the thyroid to metabolize iodine and incorporate it into a variety of organic compounds occurs widely throughout the animal and plant

kingdoms. However, the anatomy of the thyroid gland differs considerably among the vertebrate classes. Monoiodotyrosine (3'-monoiodo-L-tyrosine [MIT]) and diiodotyrosine (3,5-diiodo-L-tyrosine [DIT]) are present in a variety of invertebrate species, including mollusks, crustaceans, coelenterates, annelids, insects, and certain marine algae. However, no recognizable thyroid tissue is present in these lower forms. Thyroid tissue is confined to vertebrates, and is present in all vertebrates. A close link to the thyroid of higher vertebrates is evident in the ammocoete, the larval form of the lamprey, where the ventral part of the pharynx is the origin of a structure present only during larval life, the endostyle. The epithelium of the endostyle is capable of carrying out iodinations, and these cells are fated to become follicular cells only after metamorphosis, when they form classic thyroid follicles.¹

The phylogenetic association of the thyroid gland and the gastrointestinal tract is evident in several functions.

Thyroid development and its disorders: genetic and molecular mechanisms. *Endocr Rev.* 2004;25:722-746. Copyright 2004 by the Endocrine Society.)

The salivary and gastric glands, like the thyroid, are capable of concentrating iodide in their secretions, although iodide transport in these sites is not responsive to stimulation by thyrotropin (thyroid-stimulating hormone [TSH]). The salivary gland contains enzymes that are capable of iodinating tyrosine in the presence of hydrogen peroxide, although it forms insignificant quantities of iodoproteins under normal circumstances.

Structural Embryology

The morphogenesis of the thyroid gland, the anterior-most organ that buds from the gut tube, begins with a thickening of the endodermal epithelium in the foregut, which is referred to as thyroid anlage. The human thyroid anlage is first recognizable at embryonic day 16 or 17. This median thickening deepens and forms first a small pit and then an outpouching of the endoderm adjacent to the developing myocardial cells (Fig. 11-1). With continuing development, the median diverticulum is displaced caudally, following the myocardial cells in their descent. The primitive stalk connecting the primordium with the pharyngeal floor elongates into the thyroglossal duct. During its caudal displacement, the primordium assumes a bilobate shape, coming into contact and fusing with the ventral aspect of the fourth pharyngeal pouch when it reaches its final position at about embryonic day 50.

Normally, the thyroglossal duct undergoes dissolution and fragmentation by about the second month after conception, leaving at its point of origin a small dimple at the junction of the middle and posterior thirds of the tongue, the *foramen caecum*. Cells of the lower portion of the duct differentiate into thyroid tissue, forming the pyramidal lobe of the gland. At the same time, the lobes contact the ultimobranchial glands, leading to incorporation of C cells into the thyroid. Concomitantly, histologic alterations occur throughout the gland. Complex, interconnecting, cord-like arrangements of cells interspersed with vascular connective tissue replace the solid epithelial mass and become tubule-like structures at about the third month of fetal life; shortly thereafter, follicular arrangements devoid of colloid appear, and by 13 to 14 weeks the follicles begin to fill with colloid.

Investigations of thyroid gland development in mice using gene-targeting techniques are beginning to identify

the critical factors that are required for normal thyroid gland development.^{2,3} The roles of these various proteins are currently being evaluated with respect to the potential for defects in the synthesis or formation of the thyroid gland (see Chapter 13).

Functional Ontogeny

The ontogeny of thyroid function and its regulation in the human fetus are fairly well defined.⁴ Future follicular cells acquire the capacity to form thyroglobulin (Tg) as early as the 29th day of gestation, whereas the capacities to concentrate iodide and synthesize thyroxine (T_4) are delayed until about the 11th week. Radioactive iodine inadvertently given to the mother would be accumulated by the fetal thyroid soon thereafter. Early growth and development of the thyroid do not seem to be TSH-dependent, because the capacity of the pituitary to synthesize and secrete TSH is not apparent until the 14th week. Subsequently, rapid changes in pituitary and thyroid function take place. Probably as a consequence of hypothalamic maturation and increasing secretion of thyrotropin-releasing hormone (TRH), the serum TSH concentration increases between 18 and 26 weeks' gestation, after which levels remain higher than those in the mother.⁴ The higher levels may reflect a higher set point of the negative feedback control of TSH secretion during fetal life than at maturity. Thyroxine-binding globulin (TBG), the major thyroid hormone-binding protein in plasma, is detectable in the serum by the 10th gestational week and increases in concentration progressively to term. This increase in TBG concentration accounts in part for the progressive increase in the serum T_4 concentration during the second and third trimesters, but increased secretion of T_4 must also play a role, because the concentration of free T_4 also rises.

Several aspects of thyroid development are of note from the clinical standpoint. Rarely, thyroid tissue may develop from remnants of the thyroglossal duct near the base of the tongue. Such lingual thyroid tissue may be the sole functioning thyroid present; if so, its surgical removal will lead to hypothyroidism. More commonly, elements of the thyroglossal duct persist and later give rise to thyroglossal duct cysts, and ectopic thyroid tissue may be present at any location in the mediastinum or, rarely, in the heart.

AC, Adenyl cyclase; ATPase, adenosine triphosphatase; cAMP, cyclic adenosine monophosphate; D1, thyroidal deiodinase type 1; D2, thyroidal deiodinase type 2; DAG, diacylglycerol; DEHAL1, iodotyrosine dehalogenase 1 (IYD); DIT, diiodotyrosine; DUOX, dual oxidase; IP3, inositol triphosphate; MIT, monoiodotyrosine; NADP⁺, oxidized form of nicotinamide adenosine dinucleotide phosphate; NADPH, reduced nicotinamide adenosine dinucleotide phosphate; NIS, sodium-iodide symporter; PDS, pendrin (SLC26A4); PLC, phospholipase C; T₃, triiodothyronine; T₄, thyroxine; Tg, thyroglobulin; TPO, thyroid peroxidase TSHR, thyrotropin receptor.

ANATOMY AND HISTOLOGY

The thyroid is one of the largest of the endocrine organs, weighing approximately 15 to 20 g in North American adults. Moreover, the potential of the thyroid for growth is tremendous. The enlarged thyroid, commonly termed a *goiter*, can weigh many hundreds of grams. The normal thyroid is made up of two lobes joined by a thin band of tissue, the isthmus, which is approximately 0.5 cm thick, 2 cm wide, and 1 to 2 cm high. The individual lobes normally have a pointed superior pole and a poorly defined, blunt inferior pole that merges medially with the isthmus. Each lobe is approximately 2.0 to 2.5 cm in thickness and width at its largest diameter, and it is approximately 4.0 cm in length. Occasionally, and especially if the remainder of the gland is enlarged, a pyramidal lobe is discernible as a finger-like projection directed upward from the isthmus, usually on the left, just lateral to the midline.

The right lobe is normally more vascular than the left; it is often the larger of the two and tends to enlarge more in disorders associated with a diffuse increase in gland size. Two pairs of vessels constitute the major arterial blood supply: the superior thyroid artery, which arises from the external carotid artery, and the inferior thyroid artery, which arises from the subclavian artery. Estimates of thyroid blood flow range from 4 to 6 mL/minute per gram, well in excess of the blood flow to the kidney (3 mL/minute per gram). In diffuse toxic goiter resulting from Graves' disease, blood flow may exceed 1 L/minute and may be associated with an audible bruit or even a palpable thrill.

The gland is composed of closely packed, spherical units termed *follicles*, which are invested with a rich capillary network. The interior of the follicle is filled with the clear, proteinaceous colloid that normally is the major constituent of the total thyroid mass. On cross-section, thyroid tissue appears as closely packed, ring-shaped structures

consisting of a single layer of thyroid cells surrounding a lumen. The diameter of the follicles varies considerably, even within a single gland, but averages about 200 nm. The follicular cells vary in height with the degree of glandular stimulation, becoming columnar when active and cuboidal when inactive. The epithelium rests on a basement membrane that is rich with glycoproteins and separates the follicular cells from the surrounding capillaries. Between 20 and 40 follicles are demarcated by connective tissue septa to form a lobule supplied by a single artery. The function of a given lobule may differ from that of its neighbors.

On electron microscopy, the thyroid follicular epithelium has many features in common with other secretory cells and some that are peculiar to the thyroid. From the apex of the follicular cell, numerous microvilli extend into the colloid. It is at or near this surface of the cell that iodination, exocytosis, and the initial phase of hormone secretion (i.e., colloid resorption) occur (Fig. 11-2). The nucleus has no distinctive features, and the cytoplasm contains an extensive endoplasmic reticulum (ER) laden with microsomes. The ER is composed of a network of wide, irregular tubules that contain the precursor of Tg. The carbohydrate component of Tg is added to this precursor in the Golgi apparatus, which is located apically. Lysosomes and mitochondria are scattered throughout the cytoplasm. Stimulation by TSH results in enlargement of the Golgi apparatus, formation of pseudopodia at the apical surface, and the appearance in the apical portion of the cell of many droplets that contain colloid taken up from the follicular lumen (see Fig. 11-2).

The thyroid also contains parafollicular cells, or C cells, that bilaterally migrate from the neural crest and are the source of calcitonin. These cells originate during embryonic development from the last pair of pharyngeal pouches but ultimately come to rest among the cells of the follicular epithelium or in the thyroid interstitium. They differ from

the cells of the follicular epithelium in that they never border on the follicular lumen and they are rich in mitochondria. The C cells undergo hyperplasia early in the syndrome of familial medullary carcinoma of the thyroid (multiple endocrine neoplasia type 2) and give rise to this tumor in both its familial and its sporadic forms (see Chapter 41).

IODINE AND THE SYNTHESIS AND SECRETION OF THYROID HORMONES

The function of the thyroid is to generate the quantity of thyroid hormone necessary to meet the demands of the peripheral tissues. This requires iodide uptake by the thyroidal sodium-iodide symporter (NIS), its transfer to the colloid, and its oxidation by thyroid peroxidase (TPO). The result is the daily synthesis of approximately 110 nmol/L (85 µg) of T₄, which is 65% iodine by weight. This requires the synthesis of Tg, a glycoprotein with a molecular weight of approximately 330 kd. Specific tyrosine residues of Tg homodimers are then iodinated at the apical border of the thyroid cell to form MIT and DIT (see Fig. 11-2). This requires formation of hydrogen peroxide by dual oxidase 1 (DUOX1) and DUOX2 and of TPO, which catalyzes the oxidation of iodide and its transfer to tyrosine. TPO also catalyzes the coupling of two molecules of DIT or one of DIT and one of MIT, leading to formation of T₄ and T₃, respectively (see later discussion). These products are then stored within the colloid, still as part of the Tg molecule. Pinocytosis of stored colloid leads to the formation of phagolysosomes, the colloid droplets in which Tg is digested by specific proteases to release T₄, T₃, DIT, and MIT as the droplet is translocated toward the basal portion of the cell. T₄ and T₃ are transported out of the phagolysosomes and across the basolateral cell membrane, exit the cell, and enter circulation; DIT and MIT are deiodinated by the iodotyrosine dehalogenase to allow recycling of the iodide.

The synthesis of thyroid hormones requires the expression of a number of thyroid cell-specific proteins. In addition to Tg and TPO, the TSH receptor (TSHR) is also required to transduce the effects of extracellular TSH for efficient hormone synthesis. In addition to TSH, a number of transcription factors, including NKX2-1 (TTF-1), Pax8, FOXE1 (TTF-2), and FOXM1 (HNF-3) are necessary to achieve functional differentiation of the thyroid follicular cells and the onset of hormonogenesis.^{1,3} Although the biochemical details of these processes are beyond the scope of this discussion, those aspects with clinical relevance are reviewed in greater detail in the following sections.

Dietary Iodine

Formation of normal quantities of thyroid hormone requires the availability of adequate quantities of exogenous iodine to allow thyroidal uptake of approximately 60 to 75 µg daily, taking into account fecal losses of about 10 to 20 µg iodine of iodothyronines as glucuronides and about 100 to 150 µg as urinary iodine in iodine-sufficient populations.⁵ Plasma iodide (I⁻), the form of the element in biologic solutions, is completely filterable, with 60% to 70% of the filtered load reabsorbed passively. At least 100 µg of iodine per day is required to eliminate all signs of iodine deficiency (Table 11-1). In healthy adults, the absorption of iodide is greater than 90%. In North America, the daily dietary iodine intake is in the range of 150 to 300 µg, largely owing to the iodination of salt; in Japan,

TABLE 11-1
Recommended and Typical Values for Dietary Iodine Intake

	µg/day
Recommended Daily Intake	
Adults	150
During pregnancy	200
Children	90-120
Typical Iodine Intakes	
North America	75-300
Chile	<50-150
Belgium	50-60
Germany	20-70
Switzerland	130-160

where large quantities of foods rich in iodine are consumed, intakes may be as high as several milligrams per day. Notably, iodine intake in the United States is decreasing due to a reduction in salt consumption, with a median urinary iodine of 160 µg/L but a low urinary iodine content (<5 µg/dL) in 11% of the population.⁶

The daily dietary intake of iodine varies widely throughout the world, depending on the iodine content of soil and water and on dietary practice (see Table 11-1). Even in a single area, iodine intake varies among different individuals and in the same individual from day to day. Iodine may also enter the body via medications, diagnostic agents, dietary supplements, and food additives. As discussed more extensively later, iodine deficiency is common, especially in mountainous and formerly glaciated regions of the earth.⁷ An estimated 1 billion individuals live in iodine-deficient areas of the world, and they often develop TSH-induced compensatory enlargement of the thyroid (*endemic goiter*). If iodine deficiency is severe during pregnancy, fetal thyroid hormone production falls, causing irreparable damage to the developing central nervous system (CNS). This is manifested by varying degrees of mental retardation and is termed *endemic cretinism*. Iodine-deficiency disorders, including endemic goiter and cretinism, are the most common thyroid-related human illnesses and, indeed, the most common endocrine disorders worldwide.

Plasma iodide is partly replenished by that lost from the thyroid into the blood and by iodide liberated through deiodination of iodothyronines in peripheral tissues. Ultimately, however, the diet is its most important source. Iodine is ingested in both inorganic and organically bound forms. Iodide per se is rapidly and efficiently absorbed from the gastrointestinal tract (within 30 minutes), and little is lost in the stool. In the body, iodide is confined largely to the extracellular fluid. It is also found in red blood cells and is concentrated in the intraluminal fluids of the gastrointestinal tract, notably the saliva and gastric juice, from which it is reabsorbed, thereby re-entering the extracellular fluid. Iodide is also concentrated in milk. Until it is oxidized and bound to tyrosyl residues in Tg, iodide entering the thyroid by active transport is in rapid equilibrium with the main iodide pool. The concentration of iodide in the extracellular fluid is normally 10 to 15 µg/L (approximately 10⁻⁷ mol/L), and the content of the peripheral pool is approximately 250 µg. The thyroid contains the largest pool of body iodine, under normal circumstances approximately 8000 µg, most of which is in the form of DIT and

MIT. Normally, this pool of iodine turns over slowly (about 1% per day).

Iodide Metabolism by the Thyroid Cell

Because the concentration of iodide in plasma is so low, a mechanism is required for the thyroid cell to concentrate the required amounts of this element. This process, iodide trapping, is accomplished by a membrane protein, the *sodium-iodide symporter (NIS)*, encoded by the gene *SLC5A5*. Human NIS is a 643-amino-acid glycoprotein with 13 membrane-spanning domains. The transport of iodide is an active process that depends on the presence of a sodium gradient across the basal membrane of the thyroid cell such that downhill transport of 2 Na⁺ ions results in the entry of one iodide atom against an electrochemical gradient (see Fig. 11-2). In addition to being expressed in the basolateral membrane of the thyroid cell, NIS has also been identified in other iodide-concentrating cells, including salivary and lactating mammary glands, choroid plexus, and gastric mucosa, and in the cytotrophoblast and syncytiotrophoblast.^{8,9} In the lactating mammary gland, NIS plays an important role by concentrating iodide in the milk, thereby supplying newborns with iodide for thyroid hormone synthesis.

The iodide transport system generates an iodide gradient of 20 to 40 over the cell membrane, and NIS will also transport pertechnetate (TcO₄⁻), perchlorate (ClO₄⁻), and thiocyanate (SCN⁻), accounting for the utility of radioactive TcO₄⁻ as a thyroid scanning tool and the capacity of KClO₄ to block iodide uptake.^{10,11} On the other hand, the affinity of NIS for iodide is much higher than it is for the other inorganic anions, such as bromide and chloride, accounting for the selectivity of the thyroid transport mechanism. Transcription of the NIS gene is increased by TSH, and TSH also prolongs NIS protein half-life and targets the protein to the cell membrane. That the iodide-concentrating mechanism is required for normal thyroid function has been known for decades; its absence is associated with congenital hypothyroidism and goiter unless large quantities of inorganic iodide are provided.¹² A number of families have now been identified in which various mutations in the NIS gene are associated with congenital hypothyroidism and an iodide transport defect. Importantly, several studies have documented decreases in NIS expression in human thyroid adenomas and carcinomas that contribute to the loss of iodine uptake in neoplastic thyroid cells which, therefore, present as “cold” nodules on radioisotopic imaging.¹² However, changes in the subcellular location of NIS may also explain this phenomenon.

Pendrin is a highly hydrophobic membrane glycoprotein that is located at the apical membrane of thyrocytes, where it could function as an apical iodide transporter in thyroid cells.¹³ Pendrin is also expressed in the kidney and in the inner ear.¹⁴ In the kidney, pendrin plays an important role in acid-base metabolism as a chloride/bicarbonate exchanger.¹⁵ In the inner ear, pendrin is important for generation of the endocochlear potential.¹² Pendrin belongs to the SLC26A family and is encoded by *SLC26A4*. Mutations in *SLC26A4* lead to Pendred syndrome, an autosomal recessive disorder characterized by sensorineural deafness, goiter, and a partial defect in iodide organification.^{16,17} Deafness or hearing impairment is the major phenotypic manifestation in Pendred syndrome, and goiter usually develops during childhood. However, there is substantial variation within and between families and among different geographic regions. Curiously, targeted inactivation of

SLC26A4 does not result in thyroid dysfunction in mice. This argues against a rate-limiting role for this protein for apical follicular transport, at least in this animal.

Other proteins (SLC5A8 and chloride channel 5, CLCN5) have been proposed to mediate apical iodide efflux.¹⁸ Functional studies performed in *Xenopus* oocytes and polarized cells of the Madin-Darby canine kidney (MDCK) line clearly demonstrate that SLC5A8, originally designated as human apical iodide transporter (hAIT),¹⁸ does not mediate iodide uptake or efflux.¹⁹ Localization of the CLCN5 protein at the apical membrane of thyrocytes and a thyroidal phenotype of the *CLCN5*-deficient mice that is reminiscent of Pendred syndrome suggest that CLCN5 could be involved in mediating apical iodide efflux or iodide/chloride exchange, possibly in conjunction with other chloride channels.²⁰

In addition to active transport of iodide from the extracellular fluid, intracellular iodide is also generated by the action of the enzyme, iodotyrosine dehalogenase 1 (DEHAL1), also called iodotyrosine deiodinase (IYD). IYD transcription is stimulated by cyclic adenosine monophosphate (cAMP) and encodes a membrane protein concentrated at the apical cell surface that catalyzes the reduced nicotinamide adenosine dinucleotide phosphate (NADPH)-dependent deiodination of MIT and DIT, with greater activity against MIT.²¹ The iodide thereby released is immediately reconstituted to newly synthesized Tg after exiting the apical membrane of the cell. This process is interrupted by the thiourea class of antithyroid drugs, including methimazole, carbimazole, and propylthiouracil (PTU), which inhibit TPO, resulting in intrathyroidal iodine deficiency in patients receiving these agents.²² Mutations in homozygosity in the *IYD* gene have been identified in patients with hypothyroidism, goiter, and an elevated DIT level.²³ Functional studies revealed that the mutations abolished the capacity of IYD to deiodinate MIT and DIT.

Iodide Oxidation and Organification

Within the thyroid, iodide participates in a series of reactions that lead to synthesis of the active thyroid hormones. The first of these involves oxidation of iodide and incorporation of the resulting intermediate into the hormonally inactive iodotyrosines, MIT and DIT, a process termed *organification*. Iodide is normally oxidized rapidly, immediately appearing in organic combination in Tg. The iodinations that lead to formation of iodotyrosines occur within Tg, rather than on the free amino acids. Oxidation of thyroidal iodide is mediated by the heme-containing protein TPO and requires the H₂O₂ generated by the calcium-dependent DUOX1 and DUOX2 enzymes. The protein contains a membrane-spanning region near the carboxy terminus, and it is oriented in the apical membrane of the thyroid cell, with residues 1 through 844 in the follicular lumen where iodination occurs (see Fig. 11-2). TPO is the major thyroid microsomal antigen, and recombinant human TPO is now used for the detection of antithyroid microsomal antibodies commonly present in the serum of patients with Hashimoto's thyroiditis. The evanescent product of the peroxidation of iodide (i.e., the active iodinating form) may be free hypoiodous acid, I₂, or iodinium (I⁺).²⁴

The *DUOX1* and *DUOX2* genes (also termed *THOX1* and *THOX2*) encode glycoflavoproteins predominantly expressed at the apical thyrocyte membrane, where they constitute the catalytic core of the H₂O₂ generator required for thyroid hormone synthesis (see Fig. 11-2).²⁵ These calcium- and NADPH-dependent oxidases catalyze the

formation of the H_2O_2 required for TPO-catalyzed Tg iodination. Dual oxidase maturation factor 2 (DUOX2), a resident ER protein, is required for the maturation and plasma membrane localization of DUOX2 and for H_2O_2 generation.²⁶ Iodide excess inhibits DUOX2 glycosylation, which may be an additional mechanism for the Wolff-Chaikoff effect. DUOX-catalyzed generation of H_2O_2 has been found to be an early event of the wound response in zebrafish larvae that is required for rapid recruitment of leukocytes to the wound.²⁷

The rate of organic iodination is dependent on the degree of thyroid stimulation by TSH (see later discussion). Congenital defects in the organic binding mechanism cause goitrous congenital hypothyroidism or, if less severe, goiter without hypothyroidism. In some families, thyroidal TPO is absent.²⁸ Homozygous nonsense mutations in the *DUOX2* gene, as well as heterozygous mutations that prematurely truncate the protein, have been found in patients with mild transient congenital hypothyroidism and a partial iodide organification defect.^{29,30} Furthermore, a mutation in the *DUOX2* gene was found in a patient with congenital hypothyroidism and partial iodine organification defect (see Chapter 13).^{31,32}

Iodothyronine Synthesis

MIT and DIT are precursors of the hormonally active iodothyronines, T_4 and T_3 . Synthesis of T_4 from DIT requires the TPO-catalyzed fusion of two DIT molecules to yield a structure with two diiodinated rings linked by an ether bridge (the coupling reaction). Concomitantly, a residual dehydroalanine is formed at the site of the DIT residue, contributing the phenolic hydroxyl group.

Efficient synthesis of T_4 and T_3 in the thyroid requires Tg. The Tg messenger RNA (mRNA) is approximately 8.5 kb in length and encodes a 330-kd (12S) subunit that is 10% carbohydrate by weight. There are 134 tyrosyl residues in the 660-kd homodimer. Only 25 to 30 of these are iodinated; only residues 5, 1290, and 2553 form T_4 and residue 2746, T_3 .³³ The T_4 -forming, readily iodinated, and iodothyronine-forming acceptor residues of Tg from different species are in a Glu/AspTyr or a Thr/SerTyrSer sequence, suggesting an important role of primary sequence in these reactions. There are three to four T_4 molecules in each molecule of human Tg under conditions of normal iodination (25 atoms per Tg molecule, approximately 0.5% iodine by weight), but only about one in five molecules of human Tg contains a T_3 residue. In Tg from patients with untreated Graves' disease, the content of T_4 residues remains approximately the same, but the number of T_3 residues doubles to an average of 0.4 per molecule. This difference is independent of the iodination state of the Tg and is a consequence of thyroidal stimulation. Because the coupling reaction is catalyzed by TPO, virtually all agents that inhibit organic binding (e.g., the thiourea drugs) also inhibit coupling.

Storage and Release of Thyroid Hormone

The thyroid is unique among the endocrine glands because of the large store of hormone it contains and the low rate at which the hormone turns over (1% per day). This aspect of thyroid hormone economy has homeostatic value in that the reservoir provides prolonged protection against depletion of circulating hormone if synthesis ceases. In normal humans, the administration of antithyroid agents for as long as 2 weeks has little effect on serum T_4 concentrations. There is approximately 250 μg T_4 per gram of wet

weight in normal human thyroid, or about 5000 μg in a 20-g gland.²² This is sufficient to maintain a euthyroid state for at least 50 days. When it is released rapidly in an uncontrolled fashion during subacute or painless thyroiditis, this quantity of T_4 will cause significant transient thyrotoxicosis. Tg is present in the plasma of normal individuals at concentrations up to 80 ng/mL, and it probably leaves the thyroid through the lymphatics. However, peripheral hydrolysis of Tg does not contribute significantly to the thyroid hormones in the circulation, even during thyroiditis when large quantities of this protein are present.

The first step in thyroid hormone release is the endocytosis of colloid from the follicular lumen, which is accomplished through two processes: macropinocytosis by pseudopods formed at the apical membrane and micropinocytosis by small coated vesicles that form at the apical surface (see Fig. 11-2). Both processes are stimulated by TSH, but the relative importance of the two pathways varies among species, with micropinocytosis thought to predominate in humans. After endocytosis, endocytotic vesicles fuse with lysosomes, and proteolysis is catalyzed by cathepsin D and D-like thiol proteases, all of which are active at the acidic pH of the lysosome. The iodotyrosines released from Tg are rapidly deiodinated by the NADPH-dependent IYD, and the released iodine is recycled. Thyroid hormones are released from Tg in the lysosome, but it is not clear how their transfer into the cytosol and subsequently into the plasma is effected. Given the expression of the thyroid hormone transporter MCT8 in the thyroid gland (see later discussion), it is possible that this transporter could be involved in the exit of T_4 or T_3 , or both, from the phagolysosome or thyroid cell. It has been shown that T_4 can be released from Tg within the thyroid cell with minimal disruption of its molecular weight. This presumably is a consequence of selective proteolysis, which is facilitated by the fact that the major hormonogenic peptides of the Tg molecule are located at the amino-terminus and the C-terminus of the Tg monomer.

Presumably, the T_4 becomes accessible to the thyroidal type 1 and 2 deiodinases (D1 and D2, respectively), because basal and TSH-stimulated conversion of T_4 to T_3 is readily demonstrated in the perfused dog thyroid. Because this conversion is inhibited by PTU, it is catalyzed by D1. The contribution of thyroidal T_4 deiodination to T_3 secretion in humans under physiologic conditions is not known. The fact that the ratio of T_4 to T_3 in human Tg is 15:1, whereas estimates of the molar ratio of T_4 to T_3 in thyroid secretion is approximately 10:1, suggests that this does occur. Stimulation of D1- and D2-catalyzed 5'-deiodination of T_4 in the thyroid of patients with Graves' disease may enhance that pathway and contribute to the marked increase in the ratio of T_3 to T_4 production in that condition.³⁴ Inhibition of the D1-catalyzed T_4 -to- T_3 conversion may contribute to the rapid effect of PTU in reducing circulating T_3 in the patient with Graves' disease (see Chapter 12).^{34,35} That deiodinases in thyroid-derived cells can modulate the systemic conversion of T_4 to T_3 has been shown in several patients with metastatic thyroid carcinoma. The high expression of D2 in one large mediastinal tumor mass was associated with a high-normal T_3 with reduced T_4 and a normal TSH. Removal of the tumor reversed these abnormalities.³⁶

T_4 release from thyroid cells is inhibited by several agents, the most important of which is iodide. Inhibition of hormone release is responsible for the rapid improvement that iodide causes in hyperthyroid patients. The mechanism by which this effect is mediated is uncertain, but iodide inhibits the stimulation of thyroid adenylate cyclase by TSH and by the stimulatory immunoglobulins

produced in Graves' disease. Increasing the iodination of Tg also increases its resistance to hydrolysis by acid proteases in the lysosomes. Lithium inhibits thyroid hormone release, although its mechanism of action is poorly understood and may differ from that of iodide.³⁷

Role and Mechanism of Thyrotropin Effects

All steps in the formation and release of thyroid hormones are stimulated by TSH secreted by pituitary thyrotrophs (see Chapter 8). Thyroid cells express the TSHR, a member of the glycoprotein G protein-coupled receptor family. This protein contains a large extracellular N-terminal domain, seven membrane-spanning domains, and an intracellular domain that transduces the signal by promoting exchange of guanosine diphosphate for guanosine triphosphate on the α -subunit of G proteins.^{1,3,38} In fact, the TSHR has been reported to couple to 11 different G protein α -subunits in vitro, so much remains to be learned about signaling through it. Although the TSHR mainly couples to the stimulatory protein, G_s , when activated by high concentrations of TSH (100 times the physiologic level), it couples also to G_q/G_{11} , activating the inositol-phosphate diacylglycerol cascade. The induction of signal via the phospholipase C (PLC) and intracellular Ca^{2+} pathways regulates iodide efflux, H_2O_2 production, and Tg iodination, whereas the signal via the protein kinase A (PKA) pathway mediated by cAMP regulates iodine uptake and transcription of Tg, TPO, and NIS mRNAs, leading to thyroid hormone production (Table 11-2).^{39,40}

Despite the discovery that mutations in various regions of the TSHR molecule resulted in its intrinsic activation and the identification of important domains for intramolecular TSHR signal transduction (see Chapter 12), the precise mechanisms of receptor activation and the early events of TSHR signal transduction are not fully understood.³⁸ Studies using mutational analyses suggested that the interactions between the ectodomain and the extracellular loops of the

transmembrane domains in the TSHR may be critical for the maintenance of an inactive state with no constitutive activity. When these constraints are removed, an open conformation ensues. Therefore, it has been proposed that the TSHR exists in both a closed (inactive) and an open (active) format. This model predicts that only the open format of the receptor is able to bind ligand and become activated. Further support for this model comes from the development of constitutive activation when the TSHR ectodomain is truncated, suggesting that its presence dampens a constitutively active α -subunit.

The TSHR, in addition to TSH, also binds TSHR-stimulating antibody, thyroid-blocking antibodies, and neutral antibodies to the TSHR (see Chapter 12). The closely related luteinizing hormone (LH) and human chorionic gonadotropin (hCG) also bind to and activate TSHR signaling.³⁸ The latter accounts for the physiologic hyperthyroidism of early pregnancy.

Besides the thyrocyte, TSHR is also expressed in a variety of tissues such as osteoclasts, fibroblasts, and adipocytes, as well as retroorbital adipocytes and skin.^{38,41} As discussed earlier, certain activating and inactivating mutations, either germline or somatic, have been identified in the membrane-spanning and intracellular portions of the TSHR molecule that cause generalized or nodular hyperfunction and congenital hypofunction.^{38,42}

THYROID HORMONES IN PERIPHERAL TISSUES

Plasma Transport

The metabolic transformations of thyroid hormones in peripheral tissues determine their biologic potency and regulate their biologic effects. Consequently, an understanding of thyroid physiopathology requires knowledge of the pathways of thyroid hormone metabolism. A wide variety of iodothyronines and their metabolic derivatives exist in plasma. Of these, T_4 is highest in concentration and the only one that arises solely from direct secretion by the thyroid gland. In normal humans, T_3 is also released from the thyroid, but approximately 80% is derived from the peripheral tissues by enzymatic removal of a single 5' iodine atom from T_4 (outer ring or 5' monodeiodination).⁴³ The remaining iodothyronines and their derivatives are generated in the peripheral tissues from T_4 and T_3 . Principal among them are 3,3',5'-triiodothyronine (reverse T_3 , or rT_3) and 3,3'-diiodo-L-thyronine (3,3'- T_2) (Fig. 11-3). Trace concentrations of other diiodothyronines and moniodothyronines and their conjugates with glucuronic or sulfuric acid are also present.^{44,45} Deaminated derivatives of T_4 and T_3 that bear an acetic acid rather than an alanine side chain (tetrac and triac) are also present in low concentrations (see Fig. 11-3). The major iodothyronines are poorly soluble in water and therefore bind reversibly to plasma proteins. The plasma proteins with which T_4 is mainly associated are TBG, transthyretin (TTR, formerly termed T_4 -binding prealbumin [TBPA]), and albumin (Table 11-3). About 75% to 80% of T_3 is bound by TBG, and the remainder by TTR and albumin.

Thyroxine-Binding Globulin

TBG is a glycoprotein with a molecular mass of about 54 kd, about 20% of which is carbohydrate, that is encoded by a 3.8-kb transcript located on the X chromosome.⁴⁶ The protein sequence of TBG resembles that of the serpin family of serine antiproteases. Because there is one

TABLE 11-2

Thyroid Cell Functions Stimulated by Thyrotropin

Function Affected	General Mechanism
Iodide Metabolism	
Increase I^- in follicular lumen	PLC
Delayed increased in NIS expression	cAMP
Increase thyroid blood flow	\uparrow NO synthesis (\downarrow cellular iodide)
Increase in I^- efflux from thyroid cell	?
Thyroid Hormone Synthesis	
\uparrow Hydrogen peroxide	PLC
\uparrow Thyroglobulin and TPO synthesis	cAMP
\uparrow NADPH via pentose-phosphate pathway	?
Thyroid Hormone Secretion	
\uparrow Pinocytosis of thyroglobulin	cAMP
\uparrow Release of thyroglobulin into plasma via the basolateral membrane	cAMP (?)
Mitogenesis	cAMP; PLC; IGF1 ⁻ and FGF-mediated kinase activation

cAMP, cyclic adenosine monophosphate; FGF, follicular growth factor; IGF1⁻, insulin-like growth factor 1; plasma iodide; NADPH, reduced nicotinamide adenosine dinucleotide phosphate; S, sodium-iodide symporter; NO, nitric oxide; PLC, phospholipase C; TPO, thyroid peroxidase.

Figure 11-3 Major deiodinative and nondeiodinative pathways of thyroid hormone metabolism. Arrows indicate monodeiodination of the outer or inner ring of the iodothyronine nucleus, termed 5' or 5 by convention, by D1, D2, or D3 (type 1, 2, or 3 deiodinase, respectively). Thyroxine (T₄) is activated by monodeiodination of the phenolic thyronine ring by D1 or D2 to form triiodothyronine (T₃). Deiodination of the tyrosyl ring by D1 or D3 inactivates T₄ and T₃, respectively. This inactivation pathway is markedly favored by sulfation of the phenolic hydroxyl to form T₄SO₄ (T₄S) or T₃SO₄ (T₃S). Glucuronidated T₄ (T₄G) and T₃ (T₃G) are excreted into the bile but may be partially reabsorbed after deglucuronidation in the intestine.

iodothyronine binding site per TBG molecule, the T₄ or T₃ binding capacity of TBG in normal human serum is equivalent to its concentration, which is approximately 270 nmol/L (1.5 µg/dL). The half-life of the protein in plasma is about 5 days. A congenital deficiency of TBG is common, occurring in 1 of every 5000 newborns, and is associated with the complete absence of the protein in males. L-Asparaginase blocks the synthesis of TBG, which accounts for the low T₄ concentrations in patients receiving this agent.

The glycosylation of TBG influences its clearance from the plasma and its behavior during isoelectric focusing. In estrogen-treated patients, there is an increase in the prevalence of the more acidic bands of TBG. The more highly sialylated TBG is cleared more slowly from plasma than the more positively charged TBG, because sialylation inhibits the hepatic uptake of glycoproteins. Sera from pregnant patients, women receiving oral contraceptives, and patients with acute hepatitis have increased fractions of acidic TBG. Patients with inherited TBG excess have normal amounts of highly sialylated TBG, as do men and nonpregnant women. Because TBG is the principal T₄- and T₃-binding protein, changes in TBG or its binding are paralleled by changes in total plasma T₄ and T₃ even though T₄ and T₃ production is little changed.

Another post-translational modification affecting TBG occurs in septic patients or after cardiopulmonary bypass surgery.⁴⁷ TBG is subjected to cleavage by a serine protease

released from polymorphonuclear leukocytes; this results in the release of a 5-kd C-terminal loop with a consequent decrease in affinity for T₄. An analogous reaction has been described for cortisol-binding globulin, which releases cortisol at the site of inflammation.⁴⁸ It has been postulated that the released T₄ plays a critical role in the response to injury, perhaps by providing a supply of iodine for antibacterial purposes.⁴⁷ The cleaved TBG of approximately 49 kd circulates and, because it binds T₄ with lower avidity, may account for the increased ratio of free to bound T₄ in acute illness, even when TBG saturation studies or immunoassays indicate that the TBG concentration is normal (see "Thyroid Function during Fasting or Illness").

Transthyretin

TTR exists in part as a complex with retinol (vitamin A)-binding protein, hence its name. It consists of four identical polypeptide chains with a total molecular mass of approximately 55 kd, and it is not glycosylated. Its concentration in plasma is approximately 4 mmol/L (250 µg/mL). Each mole of TTR binds 1 mole of T₄ with high affinity, and a second T₄ molecule is bound with lower affinity at high concentrations of T₄. The half-life of TTR in plasma is normally about 2 days but is less during illness. TTR is expressed in the choroid plexus, and it is the major thyroid hormone-binding protein in the cerebrospinal fluid.⁴⁹ Targeted TTR gene disruption in mice shows that there is no impairment of uptake of T₄ into the brain, leaving the role

TABLE 11-3

Comparison of the Major Human Thyroid Hormone-Binding Proteins

Parameter	Thyroxine-Binding Globulin	Transthyretin	Albumin
Molecular weight of holoprotein (kd)	54,000	54,000 (4 subunits)	66,000
Plasma concentrations (μmol/L)	0.27	4.6	640
T ₄ binding capacity as μg T ₄ /dL	21	350	50,000
Association constants of the major binding site (L/M)			
T ₄	1 × 10 ¹⁰	7 × 10 ⁷	7 × 10 ⁵
T ₃	5 × 10 ⁸	1.4 × 10 ⁷	1 × 10 ⁵
Fraction of sites occupied by T ₄ in euthyroid plasma	0.31	0.02	<0.001
Distribution volume (L)	7	5.7	7.8
Turnover rate (% day)	13	59	5
Distribution of iodothyronines (% protein)			
T ₄	68	11	20
T ₃	80	9	11

L/M, Liters/Mol; T₃, triiodothyronine; T₄, thyroxine.

of TTR in cerebrospinal fluid undefined in regard to thyroid physiology.^{50,51}

Variant forms of TTR are associated with familial amyloidotic polyneuropathy.^{52,53} In affected families, the TTR monomer has one of several different point mutations, and TTR accumulates in the amyloid tissue deposits. Neither thyroid dysfunction nor altered vitamin A metabolism has been reported, although there is altered affinity of some of the mutant proteins for T₄. Families with high-affinity TTR and a few with increased TTR levels have been reported.

Competition for T₄ and T₃ Binding to TBG and TTR by Therapeutic Agents

The TBG binding site has an affinity for T₃ that is about 20-fold less than that for T₄ (see Table 11-3). Binding of T₄ and T₃ by TBG is inhibited by phenytoin,⁵⁴ salicylate,⁵⁵ salsalate, furosemide, fenclofenac, and mitotane. The affinity of these compounds for TBG is much weaker than that of the iodothyronines, but their concentration in plasma is sufficiently high to compete with T₄ and T₃ binding and reduce total hormone levels (although free T₄ remains normal). Because all methods used for estimating the free fractions of T₄ and T₃ in human serum except ultrafiltration dilute the serum, euthyroid patients receiving these drugs may appear to have low total and free T₄ or T₃ concentrations even though the free fraction is normal in vivo.

Albumin

The affinity of albumin for T₄ and T₃ binding is much lower than that of either TBG or TTR, but because of its high concentration this protein binds 10% of the plasma thyroid hormones (see Table 11-3). Changes in albumin

concentration per se have little influence on total hormone levels unless accompanied by alterations in TBG and TTR, all three of which are synthesized in the liver. Hepatic failure or nephrotic syndrome leads to decreases in the plasma concentration of all three, and the serum albumin concentration in patients with these illnesses may serve as a surrogate for estimating TBG concentrations.

The role of albumin in thyroid physiology becomes clinically important in patients with familial dysalbuminemic hyperthyroxinemia.^{56,57} In this autosomal dominant disorder, the plasma contains high amounts of a usually minor albumin variant that binds T₄ (but not T₃) with increased avidity. This increases total T₄, but free T₄ and total and free T₃ remain normal in an otherwise euthyroid patient. However, such patients may have a confusing pattern of test results, especially when analogue methods or labeled T₃ is used to estimate the free T₄ or T₃ (see Chapter 6).

Other Plasma Thyroid Hormone-Binding Proteins

Between 3% and 6% of plasma T₄ and T₃ are bound to lipoproteins. The T₄-binding lipoprotein is a 27-kd homodimer with an affinity for T₄ that is lower than that of TBG. This binding is of uncertain physiologic significance but could play a role in targeting T₄ delivery to specific tissues.

Free Thyroid Hormones

Because most of the circulating T₄ and T₃ is bound to TBG, the concentration and degree of saturation of TBG are the major determinants of the free fraction of T₄. Binding of the thyroid hormones to plasma proteins alters their metabolism. The negligible urinary excretion of T₃ and T₄ is due to the limited filterability of the hormone-protein complexes at the glomerulus. In vitro, the interaction between thyroid hormones and their binding proteins conforms to a reversible binding equilibrium that can be expressed by conventional equilibrium equations. For the formulations that follow, T₄ is used as the prototype, with the understanding that similar interactions apply in the case of T₃. The interaction between T₄ and TBG can be expressed as follows:

where TBG represents the *unoccupied* binding protein, k_a is the equilibrium association constant for the interaction, T₄ is the concentration of *free* T₄, and T₄ · TBG is T₄ bound to TBG (approximately 68% of total T₄ is bound to TBG).

The relationship can be expressed as follows:

$$\frac{T_4 \cdot TBG}{(T_4)(TBG)} = k_a$$

$$\frac{T_4}{T_4 \cdot TBG} = \frac{1}{(TBG)k_a}$$

Thus, the free fraction of T₄ (i.e., T₄/T₄ · TBG) is inversely proportional to the concentration of *unoccupied* TBG binding sites. Estimates of the free T₄ concentration in serum can be generated by direct or indirect assays. In normal serum, the free T₄ is approximately 0.02% of the total (about 20 pmol/L, or 1.5 ng/dL). The approximately 20-fold lower affinity of TBG for T₃ results in a higher proportion of unbound T₃ (0.30%) (see Table 11-3).

It is the free hormone that is available to the tissues for intracellular transport and feedback regulation, that

Figure 11-4 Potential pathways for entry of triiodothyronine (T_3) into the central nervous system. Thyroid hormones are transported through the blood-brain barrier via the action of an organic anion transporting polypeptide (OATP) or through the blood-CSF barrier via OATP and monocarboxylate transporter 8 (MCT8). In the astrocytes and tanycytes, thyroxine (T_4) is converted to T_3 , which then enters the neurons, possibly via MCT8. In the neurons, both T_4 and T_3 are degraded by type 3 deiodinase (D3). T_3 from the tanycytes may reach the portal vessels in the median eminence. Other transporters may be present on the astrocyte or tanycyte membranes. In most cases, transport could be bidirectional, although only one direction is shown. CSF, cerebrospinal fluid; D2, type 2 iodothyronine deiodinase; MCT10, monocarboxylate transporter 10; T_2 , diiodothyronine.

induces its metabolic effects, and that undergoes deiodination or degradation. The bound hormone acts merely as a reservoir. It follows that the concentration of the free hormone is the determinant of the metabolic state, and it is this concentration that is defended by homeostatic mechanisms. If a change in TBG occurs, the free T_4 and T_3 concentrations can be maintained at normal levels only if the bound hormone changes in the same direction. For example, if TBG concentrations are increased by administration of estrogen, the reduction in free T_4 lessens T_4 clearance, allowing an increase in the plasma total T_4 concentration. This is an iterative process that eventually normalizes the free T_4 at a new equilibrium without a change in T_4 secretion rate. The transient decrease in free thyroid hormones also slightly reduces the negative feedback on the hypothalamic-pituitary-thyroid axis, which causes an increase in thyroid hormone production as an additional compensation.⁵⁸

The formulation just described is termed the *free thyroid hormone hypothesis*.^{59,60} The question then arises: If it is the free hormone that is available for cellular entry, what is the role, if any, of the hormone-binding proteins? Protein binding facilitates the distribution of the hydrophobic thyroid hormones throughout the vascular system. For example, if a protein-free solution containing tracer T_3 is perfused through rat liver via the portal vein, there is a steep concentration gradient with a decreasing quantity of T_3 in the solution as the distance from the center of the portal lobule increases. In fact, almost all of the T_3 is taken up by the first cells to be contacted by the bolus. In contrast, if albumin is added to the perfusate, the distribution of tracer is uniform throughout the lobule. Both influx and efflux of thyroid hormone from tissues is rapid. Therefore, intracellular free T_3 and T_4 are in equilibrium with the free hormone pool in plasma, although transporter activity and metabolism will influence the magnitude of the ratio. In the steady state, it is the rate of T_3 and T_4 metabolism, not the dissociation rate from plasma proteins, that is rate-limiting in the exit of hormones from the plasma.

T_4 and T_3 Transport across Cell Membranes and Intracellular T_3 Binding

Although it was assumed for a long time that transport of iodothyronines across the plasma membrane occurs by

passive diffusion, it has become increasingly clear that cellular uptake and efflux of thyroid hormone is mediated by transporter proteins.⁶¹ Several specific thyroid hormone transporters have been identified, including monocarboxylate transporter 8 (MCT8, encoded by *SLC16A2*), MCT10 (encoded by *SLC16A10*), and organic anion transporting polypeptide 1C1 (OATP1C1, encoded by *SLCO1C1*). MCT8 and MCT10 are expressed in multiple tissues where they facilitate transport of T_3 , T_4 , rT_3 , and T_2 across cell membranes; OATP1C1 is expressed predominantly in the brain and transports preferentially T_4 .

A defect in a single thyroid hormone transporter molecule, MCT8, has been shown to cause a severe developmental neurologic phenotype.^{61,62} The Allan-Herndon-Dudley syndrome is an X-linked condition characterized by severe mental retardation, dysarthria, athetoid movements, muscle hypoplasia, and spastic paraplegia associated with an elevated serum T_3 concentration. All patients with this syndrome who were tested were found to have mutations in the MCT8 gene.^{58,62} More than 40 different mutations have been identified, including loss of one or more exons; frameshift deletions; single-amino-acid substitutions, insertions, or deletions; and nonsense mutations resulting in truncation of the MCT8 protein. Although most of these mutations result in complete functional inactivation of the MCT8 protein, significant residual activity has been observed with a number of MCT8 mutations, some of which are associated with a milder clinical phenotype.⁶³ MCT8-null mice, despite the presence of markedly increased T_3 levels, lack any overt neurologic abnormalities, a rather unexpected finding in light of the severe human phenotype.^{64,65} Animal studies show high expression of this protein in the choroid plexus, cerebral cortex, hippocampus, and medulla, with a distribution suggesting that the protein is expressed in neurons rather than glial cells.⁶⁶

OATP1C1 is expressed in capillaries throughout the brain and may be involved in the transport of T_4 across the blood-brain barrier.⁶¹ This suggests that the supply of T_3 to neurons may occur according to the schema shown in Figure 11-4⁶⁷: T_4 is transferred into the choroid plexus or into tanycytes by the action of OATP1C1, which is negatively regulated in brain capillaries by thyroid hormone. In the tanycyte or astrocyte, T_4 is converted to T_3 by D2 and exits the cell, possibly via the MCT8/MCT10 transporters,

where it becomes available for neuronal uptake, also via MCT8.^{68,69} Neurons express the D3, which prevents activation of T₄ and catalyzes degradation of T₃ (see “**Iodothyronine Deiodination**”). This would provide a logical explanation of the association of the mutations in MCT8 with the attention deficit-hyperactivity disorder, although it still remains puzzling why the neurologic manifestations of this condition are so different from those seen in patients with untreated congenital hypothyroidism or severe iodine deficiency (see Chapter 13).

The transport field has become more complex as evidence accumulates of tissue-specific and generalized iodothyronine transporters belonging to a number of different transporter protein families. Each of these has many members with small variations in structure that alter the specificity of the target substance. A thorough review of this topic is beyond the scope of this chapter, and the interested reader is referred to excellent reviews for further information.⁶¹

In most cells, about 90% of the intracellular T₃ is located in the cytosol. The known exception is in the pituitary, where approximately 50% of the intracellular T₃ is present in the nucleus. The mechanisms determining this distribution are still unknown, but it would not be surprising if thyroid hormones were actively transported in and out of the nucleus and other intracellular compartments. An intracellular T₃-binding protein (mu crystallin) has been identified and is expressed at high levels in human brain and heart, although it is widely distributed. This or similar proteins may also play a role in the subcellular localization of the active hormone.

Iodothyronine Deiodination

The most important pathway for T₄ metabolism is its outer ring (5') monodeiodination to the active thyroid hormone, T₃. This reaction is catalyzed by D1 and D2 and is the source of more than 80% of the circulating T₃ in humans. Inner ring deiodination, an inactivating step, is catalyzed primarily by D3, which inactivates T₃ and prevents activation of T₄ by converting it to rT₃ (see Fig. 11-3).^{43,70} The structures of the three human deiodinases are similar. They are all homodimers and integral membrane proteins, and they contain the rare amino acid selenocysteine in the active catalytic center (Table 11-4). Selenocysteine has nucleophilic properties that make it ideal for catalysis of

oxidoreductive reactions such as iodothyronine deiodination and the reduction of H₂O₂ by another family of selenoenzymes, the glutathione peroxidases.^{71,72} Selenium is thought to be the iodine acceptor during deiodination reactions. Mutagenesis of selenocysteine in D1 to cysteine (i.e., replacement of selenium with sulfur) reduces the enzyme velocity approximately 200-fold.

The presence of selenocysteine has implications beyond catalytic activity, considering that the cellular processes for synthesizing selenoproteins are complex and inefficient.⁴³ A specific structural feature, the selenocysteine insertion sequence (SECIS) element, is present in the 3' untranslated region of the mRNAs encoding these proteins and works together with a specific group of selenocysteine-incorporating gene products. All of these elements are required for the complex cellular function by which the normal “STOP” codon UGA is recognized as the specific codon for insertion of the selenocysteine residue during protein translation.⁷³

Enzymology and Regulation of the Selenodeiodinases

Although both D1 and D2 activate T₄, they have several important differences (see Table 11-4). D1 catalyzes both 5' and 5 deiodination of T₄ to form T₃ and rT₃, respectively, although the Michaelis-Menten constant (K_m) for these reactions is approximately 3 orders of magnitude greater than that of D2 and D3 for this substrate. In fact, the preferred substrates of D1 are rT₃ (5' deiodination) and T₃SO₄ (5 deiodination). D1 is inhibited by PTU, unlike D2 and D3. D1 also differs from D2 in being markedly increased by excess thyroid hormone through increased gene transcription, whereas D2 mRNA and protein are reduced by thyroid hormones. D2 has a half-life of only 20 to 30 minutes, whereas that of D1 and D3 is more than 12 hours. This is due to the rapid ubiquitination of D2, a process that is accelerated by interaction with its substrate T₄ or rT₃. D1 and D3 are not thought to be ubiquitinated.

The cellular location of D2 close to the nucleus gives the T₃ formed by its catalytic action better access to the nucleus than that formed by D1.⁷⁴ The T₃ produced by D2 is especially effective in entering the nucleus and binding to thyroid hormone receptors, a property explained by its location in the ER. D1, on the other hand, is located in the plasma membrane, and the T₃ produced by this enzyme

preferentially enters the plasma pool.⁴³ Therefore, D2 serves the special purpose of providing nuclear T_3 from intracellular T_4 in a cell-specific fashion. This makes D2 especially important for regulating the hypothalamic-pituitary-thyroid axis, where its activity increases in response to a decrease in serum T_4 concentrations (e.g., iodine deficiency, early autoimmune thyroid disease) well before the serum T_3 falls. If the decrease in plasma T_4 is too great to be compensated for by the increase in D2 activity in the hypothalamic-pituitary feedback sensors, an increase in TRH and TSH will occur to stimulate the thyroid. For this reason, D2 has been thought of mainly as an enzyme that provides intracellular T_3 , although there is increasing evidence that D2 could also contribute to plasma T_3 . On the other hand, in thyrotoxicosis, the threefold to fourfold increase in D1, particularly in the thyroid, and the reduced D2 make D1 the major extrathyroidal source of T_3 . This can explain why PTU causes a much more rapid fall in circulating T_3 than does methimazole in the patient with Graves' disease.^{34,35}

D3 is the foremost thyroid hormone-inactivating enzyme that functions by deiodinating the inner ring of both T_3 and T_4 .^{75,76} D3 activity has been identified in only a limited number of postnatal tissues, including placenta and uterine endometrium, the CNS (where it is primarily in neurons), and skin. Much higher D3 expression has been demonstrated in various fetal tissues such as liver, brain, placenta, uterus, and the umbilical arteries and vein. In the adult, D3 has been identified in some malignant cell lines and in a number of human tumors, including astrocytomas, oligodendromas, gliosarcomas, glioblastomas, TSH-secreting pituitary adenomas, and in basal cell carcinomas.⁷⁷ Tumoral D3 activity can be robust, and the highest D3 activity reported so far in any human tissue has been in infantile hemangiomas. In infants with extensive hepatic lesions, D3 may overwhelm the secretory capacity of the infant's thyroid, causing hypothyroidism, a syndrome termed *consumptive hypothyroidism*.⁷⁸ D3 expression is increased by thyroid hormone at a transcriptional level.⁷⁹

Gene targeting studies have begun to provide further insights into the physiologic roles of the deiodinases in mammals.⁸⁰ Inactivation of the D2 gene (*Dio2*) results in a phenotypically normal mouse with an elevated serum T_4 , normal serum T_3 , and elevated serum TSH.^{70,81} These animals have hypothalamic-pituitary resistance to T_4 , impaired auditory function, impaired thermogenesis in response to cold stress, and relatively subtle defects in neurologic function, all consistent with the expectations based on earlier studies indicating an especially important role for D2 in brown fat cell function, cochlear maturation, and neurologic development. Mice with targeted inactivation of *Dio1* are phenotypically normal; they also have an elevated serum T_4 and a normal serum T_3 , but TSH is normal.⁸² The most striking finding in the D1-deficient mouse is a marked shift in the T_4 clearance pathway, from deiodination to biliary/fecal clearance. Interestingly, mice lacking both of the activating deiodinases D1 and D2 are still able (by increasing TSH and thyroidal T_3 secretion) to maintain normal T_3 concentrations in serum and do not suffer from systemic hypothyroidism, indicating that thyroidal T_3 production can guarantee T_3 homeostasis, at least in rodents.^{70,81} Mice with inactivation of *Dio3* show profound abnormalities. They have impaired fertility and develop central hypothyroidism in adult life, presumably due to hypothalamic thyrotoxicosis during developmental programming.⁸³ These problems have precluded more extensive studies at this time.

TABLE 11-5

Comparison of Triiodothyronine (T_3) and Thyroxine (T_4) in Humans*

Parameter	T_3	T_4
Production rate (nmol/day)	50	110
Fraction from thyroid	0.2	1.0
Relative metabolic potency	1.0	0.3
Serum concentration		
Total (nmol/L)	1.8	100.
Free (pmol/L)	5	20
Fraction of total hormone in free form ($\times 10^{-2}$)	0.3	0.02
Distribution volume (L)	40	10
Fraction intracellular	0.64	0.15
Half-life (days)	0.75	6.7

*To convert T_4 from nmol/L to $\mu\text{g/dL}$ (total) or from pmol/L to ng/dL (free), divide by 12.87; to convert T_3 from nmol/L to ng/dL (total) or from pmol/L to pg/dL (free), multiply by 65.1.

Quantitative and Qualitative Aspects of Thyroid Hormone Metabolism

Thyroid Hormone Turnover

In the normal adult, T_4 has a distribution volume of approximately 10 L (Table 11-5). The concentration of total T_4 in plasma is approximately 100 nmol/L (8 $\mu\text{g/dL}$), and the extrathyroidal T_4 pool is approximately 1 nmol (800 μg). In the adult, the fractional rate of turnover of T_4 in the periphery is about 10% per day (half-life, 6.7 days). Therefore, about 1.1 L of the peripheral T_4 distribution space is cleared of hormone daily, a volume containing approximately 110 nmol (85 μg) of T_4 .

The kinetics of T_3 metabolism differ from those of T_4 , partly because of its 10- to 15-fold lower affinity for TBG. The volume of distribution of T_3 in the normal adult is about 40 L, four times that of T_4 , and its fractional turnover rate is approximately 60% per day. At a mean normal serum T_3 concentration of 1.8 nmol/L (120 ng/dL), 50-fold lower than T_4 , the daily production of T_3 is approximately 50 nmol (33 μg), or about 46% that of T_4 (see Table 11-5). The rapid metabolic clearance rate of the product of inner-ring T_4 deiodination, rT_3 , and the low concentration in plasma (0.25 nmol/L, or 15 ng/dL) combine to yield daily production rates for rT_3 of about 45 nmol. Therefore, 80% to 85% of T_3 and 100% of rT_3 production in humans can be accounted for by peripheral deiodination of T_4 , findings consonant with the high ratio of T_4 to T_3 (15:1) and T_4 to rT_3 (100:1) in human Tg. Of the T_3 generated via T_4 5' deiodination in euthyroid humans, only 20% to 25% is inhibited by PTU, consistent with a significant contribution of D2-dependent T_3 production.⁸⁴ Although much of the T_3 and rT_3 produced from T_4 in peripheral tissues exits those tissues and enters the blood, an uncertain fraction of each is degraded intracellularly before exit. As discussed later, in some D2-containing tissues such as the pituitary, a significant fraction of T_3 in the cell nucleus is derived from deiodination of intracellular T_4 to T_3 , rather than from the plasma. This is particularly true in the thyrotroph.⁸⁵

Other pathways are also involved in T_4 and T_3 metabolism. In humans, T_4 undergoes glucuronidation of the phenolic hydroxyl group by the uridine diphosphate glucuronyl transferases (UDPGT), but only minimal amounts of T_3 undergo this process (see Fig. 11-3). This pathway is

clinically significant because certain pharmacotherapeutic agents enhance glucuronide conjugation through induction of UDPGT, leading to biliary excretion of T_4 -glucuronide into the intestine.⁸⁶ These agents include phenobarbital, phenytoin, rifampin, and, possibly, certain synaptosomal serotonin reuptake inhibitors such as sertraline. Because T_4 -glucuronide is not easily reabsorbed from intestinal contents, the significance of this pathway is that therapy with such agents generally increases levothyroxine requirements. In patients with an intact thyroid, this will not be apparent because internal adjustments will increase the T_4 production rate to compensate for the accelerated biliary excretion. In patients with hypothyroidism, however, an increase in levothyroxine dosage will often be required. Deamination and decarboxylation reactions that produce tetrac and triac and sulfation of T_4 and T_3 at the phenolic hydroxyl group account for an as yet unidentified fraction of T_4 and T_3 metabolism in humans.

Sources of Intracellular T_3

In view of the differential tissue distribution of the various deiodinases and their different K_m values and differential regulation, it is not surprising that tissues may derive intracellular T_3 via different pathways (Fig. 11-5). In several rat tissues, including tissues expressing D1 such as kidney and liver, most of the nuclear T_3 is derived from plasma T_3 . In D2-containing tissues, such as rat cerebral cortex, pituitary, brown fat, and possibly skeletal muscle, D2 functions as an additional intracellular source of T_3 , such that the nuclear T_3 concentration is higher because of the combination of T_3 from plasma and T_3 that is locally converted from T_4 . In these tissues, half or more of intracellular T_3 is generated locally from T_4 within the tissue. In the CNS, the D2-generated T_3 in neurons is likely to derive from paracrine sources in tanycytes and astrocytes (see Fig. 11-4). In the rat, the tissues that depend on D2 for nuclear T_3 are those in which a constant supply of thyroid hormone is critical for normal development (cerebral cortex), thyroid gland regulation (pituitary), or survival during cold stress (brown adipose tissue). These tissues are also characterized by a high degree of saturation of the nuclear T_3 receptors, compared with tissues such as liver and kidney, in which

Figure 11-5 Schematic diagram of the origin of the specifically bound nuclear triiodothyronine (T_3) in various rat tissues. Data were derived from studies in which the sources of specifically bound nuclear T_3 in rat tissues were estimated using double-isotope labeling techniques. In tissues in which receptor saturation was significantly greater than 50%, the additional T_3 was provided by type 2 iodothyronine deiodinase (D2)-catalyzed conversion of thyroxine (T_4) to T_3 . Approximately 40% of T_3 in rat plasma is derived from thyroid secretion, with the remainder from D1- and D2-catalyzed T_4 -to- T_3 conversion. BAT, brown adipose tissue; PIT, pituitary.

nuclear T_3 receptor sites are only about 50% occupied at normal serum T_3 concentrations (see Fig. 11-5).

Intracellular D2-catalyzed T_3 production has important implications for thyroid hormone physiology. First, because the T_3 produced from T_4 occupies a significant fraction of the receptors in those tissues, changes in serum T_4 or T_3 can change receptor occupancy. However, a fall in T_4 will also increase the D2 protein half-life by decreasing the rates of ubiquitination and proteasomal degradation, and the consequent rise in D2 activity will mitigate the impact of the reduction of serum T_4 in D2-expressing tissues, helping to maintain T_3 homeostasis.⁴³ The requirement for both T_3 and T_4 for normal saturation of pituitary and CNS T_3 receptors permits a response of the hypothalamic-pituitary axis to a reduction in plasma T_4 , which is the earliest manifestation of iodine deficiency or primary hypothyroidism (see “Regulation of Thyroid Function”). Because the D2 gene is positively regulated by cAMP, D2 activity and T_3 production increase rapidly in brown adipose tissue under stimulation by the sympathetic nervous system. This response is critical to adaptive thermogenesis during cold exposure in the human neonate and lifelong in the rodent.⁸⁷

Tissues expressing D3 have lower T_3 concentrations than would be expected from the plasma contribution and a gene expression profile similar to that of hypothyroid cells. This is explained by the inactivation of T_3 and T_4 that takes place immediately after these hormones enter the cell. The D3-mediated reduction in T_3 levels likely occurs in several physiologic settings (e.g., development, regeneration) or pathologic conditions (e.g., cancer cells, inflammation, myocardial infarction) in which D3 is upregulated.⁸⁸

Pharmacologic Agents That Inhibit Thyroid Hormone Deiodination

A number of commonly used pharmacologic agents have significant effects on thyroid hormone deiodination. Propylthiouracil inhibition of D1 was mentioned earlier. The antiarrhythmic drug amiodarone shares sufficient structural similarity with T_4 that it can inhibit deiodination of T_4 and rT_3 by D1 and possibly by D2 (Fig. 11-6). This causes an increase in plasma T_4 to maintain serum T_3 in the normal range. There is also an increase in TSH within the first weeks of therapy, which gradually returns to normal as the thyroid axis re-equilibrates.⁸⁹ The T_4 and rT_3 metabolic clearance rates are reduced by 20% to 25%, and the fractional T_4 -to- T_3 conversion rate is reduced by about 50%. Amiodarone also inhibits the active transport of T_4 and T_3 into hepatocytes, and the drug or one of its products may interfere with T_3 binding to thyroid hormone receptors.

The effects of amiodarone resemble those observed with the iodoaniline derivatives formerly used for gallbladder visualization (see Fig. 11-6). Iopanoic and iopodipic acid inhibit the deiodinases by competing with the iodothyronine substrates.⁴³ This makes them useful in the acute treatment of severe hyperthyroidism, although these agents are no longer available for clinical use in the United States.

High dosages of glucocorticoids (10 times replacement) will acutely reduce the ratio of T_3 to T_4 in plasma, suggesting that T_4 -to- T_3 conversion is blocked. The ratio of rT_3 to T_4 increases, raising the possibility that D3 action is also increased.⁹⁰ These effects resolve during long-term therapy such that thyroid function is little affected and thyroid hormone requirements are not increased by chronic glucocorticoid therapy.

Recombinant growth hormone increases the ratio of circulating T_3 to T_4 . Growth hormone deficiency is associated with a decrease in the ratio of T_3 to T_4 in serum,

Figure 11-6 Comparison of the chemical structure of thyroxine (T_4) with that of two agents that block the deiodination of the iodothyronines. The inhibition of T_4 -to- T_3 conversion that occurs in patients receiving amiodarone may be caused by the drug itself or by a metabolic product. Iopanoic acid and related iodoanilines are competitive inhibitors of all three iodothyronine deiodinases. T_3 , triiodothyronine.

possibly associated with a decrease in outer ring deiodination. As expected, dietary selenium deficiency also inhibits the synthesis of D1 in humans.⁹¹

Mechanism of Thyroid Hormone Action

Thyroid hormone acts by binding to a specific nuclear thyroid hormone receptor (TR), which, in turn, binds to DNA, usually as a heterodimer with retinoid X receptor (RXR) at specific sequences called thyroid hormone response elements, or TREs; these sites are dictated by the DNA binding-site preferences of the RXR-TR (or TR-TR) complex (Fig. 11-7). The general mechanism by which nuclear receptor-activating ligands such as T_3 produce their effects is discussed in Chapter 4. T_3 has a 15-fold higher binding affinity for TRs than does T_4 , explaining its function as the active thyroid hormone. In humans, there are two TR genes, α and β , that are found on different chromosomes (chromosomes 17 and 3, respectively). There are several alternatively spliced gene products from each of these genes forming both active and inactive gene products. The active proteins are $TR\alpha_1$, $TR\beta_1$, $TR\beta_2$, and $TR\beta_3$.⁹² The protein structure of TRs includes three major functional domains—one binding DNA, one binding ligand, and a major transcriptional activation domain in the C-terminus.

There are tissue-specific preferences in expression of the various TRs, suggesting that they serve different functions in different tissues.⁹³ In general, $TR\alpha$, particularly $TR\alpha_2$, is thought to be important in the hypothalamus and pituitary where regulation of thyroid function occurs.⁹⁴ In addition to differences in the N-terminus between $TR\beta_1$ and $TR\beta_2$, the two proteins are under the regulation of different promoters that can function in tissue-specific patterns. $TR\beta_2$ is downregulated by T_3 , whereas $TR\alpha_1$ mRNA expression is not affected by T_3 .⁹⁵ $TR\beta_2$ is also expressed in the cochlea. $TR\alpha_1$ is expressed in all tissues, although its mRNA is especially highly expressed in the kidney, liver,

Figure 11-7 Schematic diagram of thyroid hormone activation and inactivation in a cell expressing the iodothyronine deiodinases D2 and D3. The triiodothyronine (T_3) that enters the cell can be deiodinated to 3,3'-diiodothyronine (T_2), or it can enter the nucleus and bind to the thyroid hormone receptor (TR). An additional source of T_3 is that generated by outer ring deiodination of thyroxine (T_4) within the cell. The interaction of T_3 with the TR that is bound as a heterodimer with retinoid X receptor (RXR) to the thyroid hormone response element (TRE), often in the 5' flanking region of a T_3 -responsive gene, causes either an increase or a decrease in the transcription of that gene. This leads to parallel changes in the concentrations of critical proteins, thus producing the thyroid hormone response characteristic of a given cell. mRNA, messenger RNA; rT_3 , reverse T_3 .

brain, and heart. $TR\alpha_1$ mRNA is expressed in the brain, in brown adipose tissue, and, at lower levels, in skeletal muscle, lungs, and heart. $TR\beta_3$ mRNA is expressed at very low levels but is more abundant in the liver, kidneys, and lungs than in other tissues.

Experiments with inactivation of $TR\alpha$ and $TR\beta$ have illuminated their different physiologic roles. Disruption of the $TR\beta$ gene (both $TR\beta_1$ and $TR\beta_2$) in mice causes deafness, a marked reduction in feedback sensitivity of the hypothalamic-pituitary-thyroid axis, and a decrease in hepatic D1. These mice have marked elevations in both TSH and thyroid hormones, similar to those observed in human families with *resistance to thyroid hormone*, a condition in which $TR\beta$ mutations markedly reduce the binding affinity of $TR\beta$ for T_3 . This binding defect produces a $TR\beta_1$ or $TR\beta_2$ protein that acts as a dominant negative inhibitor of the intact $TR\beta$ proteins encoded by the normal allele (see Chapters 4 and 13). Despite evidence of impaired feedback regulation, there is relatively little abnormality in the brain and heart of $TR\beta$ -deficient mice. The effect of a $TR\alpha_1$ disruption in the mouse is quite different. The predominant phenotypic effects are modest bradycardia and hypothermia.

These studies have led to the generalization that feedback regulation of thyroid hormone effects and cochlear development are functions of $TR\beta$, whereas cardiac function and energy metabolism are more likely to be regulated by $TR\alpha$. It is likely that small differences in the ligand-binding domains of $TR\alpha$ and $TR\beta$ will allow design of thyroid hormone analogues selective for one or the other of these receptors. This may result in agents that could, for example, suppress TSH in patients with thyroid cancer, without inducing tachycardia, such as GC-1; another example is KB141, a potential treatment for obesity via stimulation of metabolic rate and oxygen consumption.⁹⁶

Other potential mechanisms for thyroid hormone action by interaction with the membrane are under investigation. These nongenomic effects are most likely mediated by cellular binding proteins other than TRs. Integrin $\alpha_v\beta_3$, has been identified as a putative plasma membrane thyroid hormone-binding site. Previously, T_4 , but not T_3 , was shown to promote actin polymerization and integrin interaction with laminin in neural cells.⁹⁷ Continuing investigations have shown that T_4 and thyroid hormone analogues such as GC-1 can activate mitogen-activated protein kinase (MAPK) and can have proangiogenic effects.⁹⁸ The MAPK signal results in serine phosphorylation of several nuclear proteins and occurs within minutes after exposure, analogous to the effects of 17β -estradiol. The physiologic relevance of these effects are not well characterized. The proteins include plasma membrane-associated T_3 transporters, calcium adenosine triphosphatase, adenylate cyclase, and glucose transporters; an ER-associated protein called prolyl hydroxylase; and monomeric pyruvate kinase. The effect of T_4 itself in initiating the ubiquitination of D2 is perhaps the most important nongenomic effect at physiologic concentrations of free T_4 .⁴³

REGULATION OF THYROID FUNCTION

The Hypothalamic-Pituitary-Thyroid Axis

The thyroid participates with the hypothalamus and pituitary in a classic feedback control loop (Fig. 11-8). In addition, there is an inverse relationship between the iodine level in the thyroid and the fractional rate of hormone

Figure 11-8 Roles of thyroxine (T_4) and triiodothyronine (T_3) in the feedback regulation of secretion of thyrotropin-releasing hormone (TRH) and thyroid-stimulating hormone (TSH). Secreted T_4 must be converted to T_3 to produce its effects. This conversion may take place in tissues such as the liver (L), kidney (K), and hypothalamus (D1). Type 2 (D2) is present in human thyroid (T), skeletal muscle (SM), possibly cardiac muscle (CM), and the pituitary and hypothalamus. SRIH, somatotropin release-inhibiting factor (somatostatin hormone).

formation. Such autoregulatory mechanisms stabilize the rate of hormone synthesis despite fluctuations in the availability of iodine. Stability in hormone production is achieved in part because the large intraglandular store of hormone buffers the effect of acute increases or decreases in hormone synthesis. Autoregulatory mechanisms within the gland, in turn, tend to maintain a constant thyroid hormone pool. Finally, the hypothalamic-pituitary feedback mechanism senses variations in the availability of free thyroid hormones, however small, and acts to correct them. There is a close relationship among the hypothalamus, the anterior pituitary, the thyroid gland, and still higher centers in the brain, the function of the entire complex being modified in a typical negative-feedback manner by the availability of the thyroid hormones. In addition, other hormones and neuropeptides also influence this axis (see Chapters 7 and 8).

Thyrotropin-Releasing Hormone Synthesis and Secretion

TRH, a modified tripeptide (pyroglutamyl-histidyl-proline-amide), is derived from a large pre-proTRH molecule of 29 kd that contains five progenitor sequences. The TRH peptides are released from the pre-proTRH molecule by a peptidase that acts at flanking lysine/arginine residues. TRH is expressed in the hypothalamus, the brain, the C cells of the thyroid gland, the beta cells of the pancreas, the myocardium, the reproductive organs (including prostate and testis), and the spinal cord. The parvocellular region of the paraventricular nuclei of the hypothalamus is the source of the TRH that regulates TSH secretion. The 5' flanking region of the gene encoding TRH has sequences for mediating responses to glucocorticoids and cAMP. In addition, at least two elements in this region are responsible for the negative regulation of this gene by thyroid hormone.⁹⁹ TRH travels in the axons of the peptidergic neurons through the median eminence and is released close to the hypothalamic-pituitary portal plexus. The neuron bodies producing TRH are innervated by catecholamine, leptin agouti-related peptide, neuropep-

tide Y or melanocyte-stimulating hormone (MSH), and somatostatin-containing axons, all of which potentially influence the rate of synthesis of the pre-proTRH molecule (see Chapter 7).

T₃ suppresses the levels of pre-proTRH mRNA in the hypothalamus,^{100,101} but normal feedback regulation of pre-proTRH mRNA synthesis by thyroid hormone requires a combination of T₃ and T₄ in the circulation, the latter giving rise to T₃ via T₄ 5' deiodination in the CNS in astrocytes and tanycytes (see Fig. 11-4). This regulation is observed *in vivo* exclusively in the parvocellular division of the paraventricular nuclei; in tissues outside the CNS expressing the TRH gene, negative regulation by thyroid hormone is absent. Therefore, part of the negative feedback induced by T₄ may be generated at the median eminence/arcuate nucleus at a point where neuropeptides and T₃ enter the pituitary portal system.¹⁰² In addition to inhibiting the synthesis of pre-proTRH mRNA, thyroid hormone also blocks the capacity of TRH to stimulate TSH release from the thyrotroph.

TRH is rapidly inactivated within the CNS by a cell-surface peptidase called TRH-degrading ectoenzyme (TRH-DE) or protein peptidase II. TRH-DE is very specific: no other ectopeptidase is known to be capable of degrading TRH, and TRH is the only known substrate of this unique enzyme.¹⁰³

Thyrotropin Synthesis and Secretion

Thyrotropin (TSH) is the major regulator of the morphologic and functional states of the thyroid. It is a glycoprotein secreted by the thyrotrophs in the anteromedial portion of the adenohypophysis (see Chapter 8). TSH is composed of an α -subunit of 14 kd (92 amino acids) that is common to LH, follicle-stimulating hormone (FSH), hCG, and a specific β -subunit of 112 amino acids that is synthesized in thyrotrophs. In normal thyrotrophs and in thyrotroph tumors, synthesis of α -subunit is in excess, indicating that the quantity of β -subunit is rate-limiting for TSH secretion. Levels of α -subunit in serum range from 0.5 to 5 μ g/L but are increased in postmenopausal women and in patients with pituitary tumors. TRH increases, and thyroid hormone suppresses, the transcription of both subunits, and these are the two most important influences on TSH synthesis.

The pretranslational regulation of TSH synthesis and secretion is a complex process. The physiologic glycosylation of TSH involves several post-translational steps, including excision of signal peptides from both subunits and cotranslational glycosylation with high-mannose oligosaccharides.¹⁰⁴ The glycosylation of the subunits protects them from intracellular degradation and permits normal folding of the protein chains so that internal disulfide linkages are correctly formed. Glycosylation is required for full biologic activity.^{105,106} TRH is required for this process, as illustrated by the inappropriately low biologic activity of the TSH in the serum of patients with pituitary tumors or hypothalamic disorders, compared with the level of immunologic activity resulting from TRH deficiency.

In normal serum, TSH is present at concentrations between 0.4 and 4.2 mU/L. The level is increased in primary hypothyroidism and reduced in thyrotoxicosis. The plasma TSH half-life is about 30 minutes, and production rates in humans are 40 to 150 mU/day. Circulating TSH displays both pulsatile and circadian variations. The former are characterized by fluctuations at 1- to 2-hour intervals. The magnitude of TSH pulsations is decreased during fasting or illness and after surgery. There is an acute reduction of TSH in fasted humans; this is associated with a fall in leptin

levels and is caused by a decrease in the amplitude of the TSH pulses.¹⁰⁷ The circadian variation is characterized by a nocturnal surge that precedes the onset of sleep and appears to be independent of the cortisol rhythm and of fluctuations in serum T₄ and T₃ concentrations.¹⁰⁸ When the onset of sleep is delayed, the nocturnal TSH surge is enhanced and prolonged; early onset of sleep results in a surge of lesser magnitude and shorter duration.

The degree of thyroid hypofunction after destruction of the hypothalamus is less severe than that which follows hypophysectomy, and residual thyroid function in the former circumstance can be altered by raising or lowering the concentration of thyroid hormones in the blood. Therefore, both T₄ and T₃ mediate the feedback regulation of TSH secretion, and TRH determines its set point (see Fig. 11-8). There is a linear inverse relationship between the serum free T₄ concentration and the log of the TSH (Fig. 11-9), making the serum TSH concentration an exquisitely sensitive indicator of the thyroid state of patients with an intact hypothalamic-pituitary axis. Gene targeting studies show that TRH secretion is probably the dominant factor mediating the thyroid hormone feedback regulation of TSH secretion, because the markedly elevated TSH secretion of mice with inactivation of TR β cannot be sustained in mice lacking the TRH gene.¹⁰⁹ This is somewhat surprising given the less severe hypothyroidism associated with hypothalamic (as opposed to primary) hypothyroidism, but it may be explained by the absolute nature of the TRH deficiency achieved by genetic manipulation compared with the clinical situation in humans with central hypothyroidism, in whom the TRH deficiency is not likely to be complete.

Somatostatin (somatotropin release-inhibiting factor [SRIF]), acting through inhibitory G protein (G_i), decreases TSH secretion *in vitro* and *in vivo*, but prolonged treatment with a somatostatin analogue does not cause hypothyroidism.^{110,111} Similar acute effects occur during dopamine infusion and the administration of bromocriptine, a dopamine agonist; both of these agents inhibit adenylate cyclase. Conversely, blockade of the dopamine receptor by metoclopramide increases the basal serum TSH concentration in both euthyroid and hypothyroid patients. These findings indicate that dopamine is a regulator of TSH secretion, but chronic administration of dopamine agonists (e.g., for the treatment of prolactinoma) does not cause central hypothyroidism, indicating that compensatory mechanisms negate these acute effects.¹¹²

A number of drugs or hormones may suppress or stimulate TSH secretion (Table 11-6). Glucocorticoids given in high doses transiently suppress TSH secretion, although prolonged therapy is not associated with central hypothyroidism.¹¹⁰ Patients with Cushing's disease have subnormal TSH production but with minimal effects on T₄ production.¹¹⁰ Bexarotene, an RXR agonist used for treatment of T-cell lymphoma, suppresses TSH sufficiently to cause central hypothyroidism, presumably by reducing transcription of the TSH β -subunit gene.^{113,114}

Neurotransmitters are important direct and indirect modulators in TSH synthesis and secretion. A complex network of neurotransmitter neurons terminates on the cell bodies of hypophysiotropic neurons, and several neurotransmitters (e.g., dopamine) are directly released into hypophyseal portal blood, exerting direct effects on anterior pituitary cells. Furthermore, many dopaminergic, serotonergic, histaminergic, catecholaminergic, opioidergic, and GABAergic systems project from hypothalamic or other brain regions to the hypophysiotropic neurons involved in TSH regulation. These projections are

Figure 11-9 The log/linear relationship between thyroid-stimulating hormone (TSH) and the concentration of free T_4 (FT_4) in serum. Typical FT_4 concentrations in hypothyroid, euthyroid, and hyperthyroid patients are shown.

important for maintenance of a normal TSH circadian rhythm and normal response to stress and cold exposure, whereas basal TSH secretion is mainly regulated by intrinsic hypothalamic activity.

Thyrostimulin, a noncovalent heterodimer of two glycoprotein hormone-like proteins (α_2 and β_5), is an agonist of the TSHR. It is synthesized in the corticotrophs and in placenta, has high affinity for TSHRs, and increases the levels of thyroid hormones in rats with a suppressed TSH.¹¹⁵ It is ineffective in activating LH or FSH receptors but is expressed in oocytes, where it acts as a paracrine regulator to activate the TSHR expressed in ovary.¹¹⁶ Thyrostimulin, which evolved before the appearance of gonadotropins, is considered to be the most ancestral glycoprotein

hormone. Studies are currently under way to determine whether this protein is present in the circulation and how it is regulated.

Iodine Deficiency

The response of vertebrates to iodine deficiency is designed to conserve this limited resource and to improve the efficiency of its utilization. The adjustments occur at the hypothalamic, pituitary, thyroid, and peripheral tissue levels. Removal of iodine from the diet causes a rapid decrease in the serum T_4 concentration and a simultaneous increase in serum TSH (Fig. 11-10).¹¹⁷ No detectable decrease in T_3 occurs, suggesting that the signal to increase TSH must derive from a decrease in the T_3 generated intracellularly from T_4 in the pituitary, the hypothalamus, or both. TSH increases NIS, Tg, and TPO synthesis; iodine organification; and Tg turnover (see Fig. 11-2). Because of the decrease in iodide supply and in the ratio of DIT to MIT, the ratio of T_4 to T_3 in Tg decreases, and the rate of thyroidal T_3 secretion may increase despite a fall in T_4 secretion. TSH also stimulates cell division, leading to goiter. In the rat model, the fall in plasma T_4 increases the level of D2 from 5- to 20-fold in the CNS, hypothalamus, and pituitary, increasing the efficiency of T_4 conversion to T_3 . With moderately severe iodine deficiency, D3 in the CNS is also reduced, prolonging the mean residence time of T_3 in that organ.¹¹⁸ This permits serum T_3 to remain normal and the CNS T_3 to be only moderately reduced despite decreases of up to 10-fold in circulating T_4 . Supporting an important role for D2 in humans is the positive association between mental retardation in an iodine-deficient region of China and two common single-nucleotide polymorphisms in the D2 gene.¹¹⁹

Despite the TSH elevation and the almost undetectable level of serum T_4 in acutely iodine-deficient rodents, growth, oxygen consumption, and thermal homeostasis can be maintained.¹²⁰ However, if iodine deficiency is prolonged and severe, hypothyroidism will supervene. In humans, these compensatory alterations in thyroid function come into operation when total iodine intake falls to

TABLE 11-6

Endogenous and Exogenous Agents That May Stimulate or Inhibit Thyrotropin Secretion

Stimulatory Agents	Inhibitory Agents
Thyrotropin-releasing hormone (TRH)	Thyroid hormones and analogues
Prostaglandins (?)	Dopamine and dopamine agonists
α -Adrenergic agonists (? via TRH)	Gastrin
Opioids (humans)	Opioids (rat)
Arginine vasopressin (AVP)	Glucocorticoids (in vivo, high dose)
Glucagon-like peptide I (GLP1)	Serotonin
Galanin	Cholecystokinin (CCK)
Leptin	Gastrin-releasing peptide (GRP)
Glucocorticoids (in vitro)	Vasopressin (AVP)
	Neuropeptide Y
	Interleukin 1β (IL- 1β) and IL-6
	Tumor necrosis factor α
	Bexarotene (retinoid X receptor agonist)
	Phenytoin
	Somatostatin and somatostatin analogues

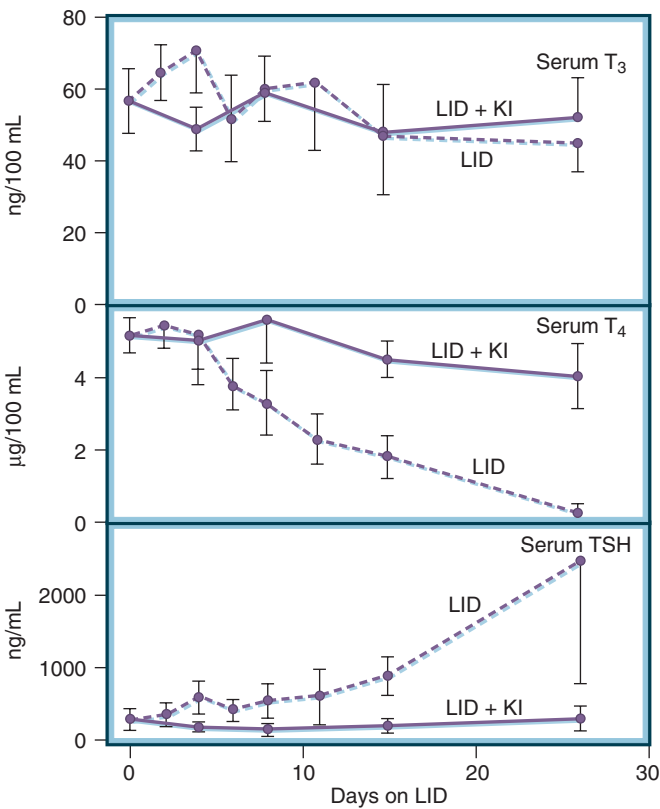

Figure 11-10 Effects of acute depletion of dietary iodine on serum levels of triiodothyronine (T₃), thyroxine (T₄), and thyroid-stimulating hormone (TSH) in rats. Animals received a low-iodine diet (LID) without or with supplementation of potassium iodide (KI) in drinking water. (From Riesco G, Taurog A, Larsen PR, et al. Acute and chronic responses to iodine deficiency in rats. *Endocrinology*. 1977;100:303-313.)

less than 75 µg/day (see Table 11-1). This situation can occur in some countries in Europe and South America and affects several hundred million individuals in China, India, Indonesia, and Africa.^{121,122}

Changes in serum hormones seen in experimental animals have been well documented in humans in areas of iodine deficiency and in patients with NIS mutations.¹¹ However, they may not be seen in older members of the population, in whom thyroid autonomy often develops. The physiologic response to iodine deficiency is similar to that which occurs during the development of primary hypothyroidism in humans. It is also reproduced when the efficiency of iodide trapping and organification is reduced in Hashimoto's disease or in patients with Graves' disease who are receiving thiourea drugs.²² The physiologic effects of this series of events are clear. T₃ has approximately 10 times the potency of the prohormone T₄ and contains only three iodine atoms. This results in a more efficient use of the iodine atom. Maintenance of normal circulating T₃ independent of serum T₄ concentrations should provide hormone for those tissues in which the nuclear T₃ is completely derived from the plasma, such as liver and kidney (see Fig. 11-5).

Iodine Excess

The thyroid is also protected against an excess of iodide that might otherwise lead to hyperthyroidism. As with the response to iodine deficiency, there are multiple levels of

defense against this eventuality. The usual source of excess iodine is pharmaceutical, with radiographic dyes, amiodarone, and povidone-iodine being the most common sources (Table 11-7).

Effects of Increased Iodine Intake on Thyroid Hormone Synthesis

The quantity of iodine organified in Tg, which includes T₄ and T₃, displays a biphasic response to increasing doses of iodide, at first increasing and then decreasing as a result of a relative blockade of organic binding. This decreasing yield of organic iodine from increasing doses of iodide, termed the *Wolff-Chaikoff effect*, results from a high concentration of inorganic iodide within the thyroid cell.¹²³ Susceptibility to the Wolff-Chaikoff effect can be increased by stimulation of iodide trapping (e.g., in patients with Graves' disease) or during persistent TSH stimulation, by impairment of iodine organification in the human fetus, in patients with Hashimoto's disease, or in thyroids previously irradiated by either iodine 131 (¹³¹I) or external beam radiotherapy. In such situations, goiter and hypothyroidism (iodide myxedema) can develop if excess iodide is given for long periods. The mechanism for organification inhibition may involve inhibitory effects of high iodide concentrations on TPO and DUOX2.

In normal subjects given iodide, the inhibition of iodothyronine formation is reduced over time. This escape or adaptation phenomenon occurs because iodide transport activity decreases, probably through a decrease in NIS expression. Consequently, thyroidal iodide falls to levels insufficient to maintain the full Wolff-Chaikoff effect.^{12,124} Importantly, this adaptation does not occur in the third-trimester fetus. As a result, chronic high iodine intake during pregnancy must be avoided because it will cause fetal hypothyroidism and compensatory, potentially obstructive goiter (Fig. 11-11).

Effects on Thyroid Hormone Release

An important practical effect of pharmacologic doses of iodine is the prompt inhibition of thyroid hormone release. This occurs to some extent normally but is especially apparent in patients with Graves' disease or toxic nodules (see Chapter 12). The mechanism is unknown, but the effect is mediated at the level of the thyroid cell, rather

TABLE 11-7

Iodine Content of Various Iodinated Pharmaceutical Agents*

Agent	Iodine Content
Saturated solution of potassium iodide	38 mg/drop
Lugol's solution	6 mg/drop
Iodized salt (1 part KI in 10,000 parts NaCl)	760 µg/10 g
Amiodarone	75-200 mg/tablet
Iopanoate, ipodate	350 mg/tablet
Angiographic and CT dyes	400-4000 mg/dose
Povidone-iodine	10 mg/mL
Kelp tablets	150 µg/tablet
Prenatal vitamins	150 µg/tablet
Iodinated glycerol	25 mg/mL
Quantity of iodine required to suppress radioactive iodine to <2%	>30 mg/day

CT, computed tomography; KI, potassium iodide; NaCl, sodium chloride.
*Typical iodide intake in the United States is 100 to 400 µg/day.

Figure 11-11 Newborn infant with iodide-induced goiter due to treatment of the mother with Lugol's solution during the third trimester. This illustrates the danger of chronic excess iodide administration during pregnancy.

than through an action on TSH. Iodine also diminishes the hypervascularity and hyperplasia that characterize the diffuse toxic goiter of Graves' disease. This effect facilitates surgical therapy for the disorder.

Thyroid Function in Pregnancy and in the Fetus and Newborn

Pregnancy affects virtually all aspects of thyroid hormone economy (Table 11-8).^{5,125,126} The total serum T_4 and T_3 concentrations rise to levels about 1.5 times those of non-pregnant women owing to the increase in TBG concentration in the first trimester (Fig. 11-12). The markedly increased TBG extracellular pool must steadily be filled with increasing amounts of T_4 until a new equilibrium is reached. During normal pregnancy, the direct stimulatory effect of hCG on thyrocytes induces a small and transient increase in free T_4 levels near the end of the first trimester (peak circulating hCG), resulting in a partial TSH suppression. When tested in bioassays, normal hCG is only about 1/100 as potent as TSH. This weak thyrotropic activity explains why, in normal conditions, the effects of hCG remain largely unnoticed.¹²⁷ In addition to the increase in serum TBG, there is also an increased plasma volume as well as accelerated inactivation of T_3 and T_4 by D3 expression in the fetal-placental-uterine unit.¹²⁸ Based on the changes in requirements for levothyroxine during gestation in women with primary hypothyroidism, the estimated increase in T_4 production required during this period is 20% to 40%.

TABLE 11-8

Effects of Pregnancy on Thyroid Physiology

Physiologic Change	Thyroid-Related Consequences
↑ Serum thyroxine-binding globulin	↑ Total T_4 and T_3 ; ↑ T_4 production
↑ Plasma volume	↑ T_4 and T_3 pool size; ↑ T_4 production; ↑ cardiac output
D3 expression in placenta and (?) uterus	↑ T_4 production
First-trimester ↑ in hCG	↑ Free T_4 ; ↓ basal thyrotropin; ↑ T_4 production
↑ Renal I^- clearance	↑ Iodine requirements
↑ T_4 production; fetal T_4 synthesis during second and third trimesters	
↑ Oxygen consumption by fetoplacental unit, gravid uterus, and mother	↑ Basal metabolic rate; ↑ cardiac output

D3, type 3 iodothyronine deiodinase; I^- , plasma iodide; hCG, human chorionic gonadotropin; T_3 , triiodothyronine; T_4 , thyroxine.

The requirement for increased T_4 secretion increases iodine requirements during pregnancy.¹²⁹ This need is compounded by the fact that the higher glomerular filtration rate during gestation enhances renal iodide clearance, leading to higher fractional urinary excretion of circulating iodide. In addition, maternal iodine intake must be increased to supply the requirements of the fetal thyroid during the second and third trimesters (see Table 11-8). If these increased requirements for iodide are not met, serum T_4 falls and TSH rises. This series of events is well documented in areas of endemic iodine deficiency or borderline iodine supply, such as Brussels, Belgium.⁵ In that city, 70% of pregnant women carefully monitored throughout pregnancy had a 20% or greater increase in thyroid volume during gestation due to increased TSH. After delivery, the

Figure 11-12 Changes in various critical components of the thyroid-pituitary axis during pregnancy. Notice the early increase in free thyroxine (T_4), which is probably a result of thyroidal stimulation by human chorionic gonadotropin (hCG), which causes a reciprocal modest suppression of serum thyroid-stimulating hormone (TSH) during the late first trimester. TBG, thyroxine-binding globulin. (From Burrow GN, Fisher DA, Larsen PR. Mechanisms of disease: maternal and fetal thyroid function. *N Engl J Med*. 1994;331:1072-1078.)

changes in thyroid function gradually return to normal, and serum TBG values reach normal levels within 6 to 8 weeks.

During pregnancy, autoimmunity is suppressed, affecting patients with Graves' or Hashimoto's disease (see Chapters 12 and 13). In general, TSHR-stimulating antibody-mediated thyroid stimulation in the patient with Graves' disease is exacerbated during the first trimester and attenuated during the second and third trimesters, only to exacerbate in the first several months after delivery. Thyroid autoantibody titers fall during gestation in patients with Hashimoto's disease, then rise sharply after delivery, in association with a phase of acute T cell-mediated thyroid cell destruction (postpartum thyroid disease), which occurs in about 30% of patients with Hashimoto's disease and significant residual thyroid tissue.¹³⁰

The basal metabolic rate increases during the second trimester owing to the increase in the total mass of body tissue resulting from the pregnancy. The changes of pregnancy, together with the decreased peripheral vascular resistance, vasodilatation, and modest tachycardia, may suggest thyrotoxicosis (see Table 11-8). It is important to appreciate that such changes are physiologic in pregnancy, especially when managing hyperthyroidism in a pregnant patient.

Fetal Thyroid Function

The peripheral metabolism of T_4 in the human fetus differs markedly from that in the adult, both quantitatively and qualitatively. Overall, rates of production and degradation of T_4 in terms of units per body mass exceed those in the adult by 10-fold. In addition, D1 catalysis is reduced and D3 is enhanced, favoring formation of the inactive rT_3 already introduced at the expense of T_3 . D3 is highly expressed in fetal tissues including the liver, skin, tracheobronchial, urothelial, and gastrointestinal epithelia.¹²⁸ This results in a persistently subnormal serum T_3 concentration and an elevated serum rT_3 . This permits the highly regulatable T_4 -to- T_3 conversion by D2 to be the major pathway for generating tissue T_3 .¹³¹

Fetal thyroid function begins at about the end of the first trimester. Thereafter, there are steady increases in fetal TBG and total T_4 and T_3 .^{5,126} Throughout gestation, the serum TSH values are greater than those in the maternal circulation and higher than would be expected in adults with normal thyroid function. This indicates that there is increasing hypothalamic-pituitary resistance to T_4 during fetal development which is speculated to be a consequence of increased TRH secretion.¹³² Despite the low circulating T_3 , the fetal concentration of free T_4 approximates that in the maternal circulation from gestational age 28 weeks onward.

Maternal-Fetal Interactions

The fetal pituitary-thyroid axis functions as a unit that is essentially independent from the mother.^{4,132} Transplacental passage of TSH from mother to fetus is negligible, but the same is not true of maternal T_4 . In infants with congenital hypothyroidism caused by genetic TPO deficiency or by athyreosis, serum concentrations of T_4 in cord blood are usually one third to one half of normal.²⁸ Therefore, at least when the maternal-fetal concentration gradient is high, transfer of maternal T_4 to the fetal circulation can occur. This transfer may be significant, given the capacity of the fetal brain to increase the efficiency of T_4 -to- T_3 conversion. Furthermore, T_4 can be found in coelomic and amniotic fluids before the onset of thyroid function.¹³³ The

major factor limiting T_4 and T_3 transfer from mother to fetus is the D3 expressed in the uterus, placenta, and fetal epithelium.

Thyroid Function in the Newborn

The mean total T_4 level in cord serum is 150 nmol/L (12 μ g/dL). Serum TBG concentrations are elevated, but not as high as in the maternal serum. At term, free T_4 concentrations are slightly lower than those in the mother. Cord serum T_3 concentrations are low (0.8 nmol/L or 50 ng/dL), and rT_3 and T_3SO_4 are elevated.^{4,134,135} After delivery, the serum TSH level in the neonate increases rapidly to a peak at about 2 to 4 hours after birth, returning to its initial value within 48 hours.¹³⁴ Levels greater than 60 mU/L are typical. This neonatal TSH surge is thought to occur because of the rapid reduction in environmental temperature after delivery. In response, the serum T_4 , T_3 , and Tg concentrations increase rapidly during the first few hours after delivery and are in the hyperthyroid range within 24 hours.¹³⁶ The TSH surge doubtless contributes to the increase in serum T_3 concentration, but enhancement of extrathyroidal conversion of T_4 to T_3 by D1 or D2 is thought to be a major factor as well.⁴³ Adrenergic stimulation of the D2 gene and reactivation of D2 by its deubiquitination in brown adipose tissue are likely to be important contributors to this increase.¹³⁷

Premature infants have an immature hypothalamic-pituitary-thyroid axis with low T_4 , T_3 , and TSH.^{134,138} Serum T_4 , TBG, and free T_4 all tend to correlate with gestational age. Preterm infants also have an attenuated TSH surge after delivery. In addition, when prematurity is accompanied by complications such as respiratory distress syndrome or nutritional problems, serum T_4 , and especially T_3 , may fall to low levels due to a combination of reduced TBG production, immaturity of the thyroid gland, suppression of the hypothalamic-pituitary axis by illness, impairment of T_4 -to- T_3 conversion, and increases in D3 activity.^{139,140} These changes are, in many respects, similar to those in adults with severe illness. All of these issues need to be taken into account when evaluating the thyroid status of the preterm infant, particularly given the increased prevalence of congenital hypothyroidism in this age group.¹³⁸

Thyroid hormone production rates are higher per unit of body weight in neonatal infants and children than in adults. The daily levothyroxine requirement is about 10 μ g/kg in the newborn and decreases progressively to about 1.6 μ g/kg in the adult.¹³⁸

Aging and the Thyroid

The thyroid gland undergoes several anatomic changes with age. There are reductions in the weight of the gland, in the size of follicles, and in the content of colloid. There is increased fibrosis, often with marked lymphocytic infiltration. However, these changes do not correlate with thyroid function.¹⁴¹ In the healthy elderly patient, there is a normal level of free T_4 , but serum T_3 may be lower, although studies of selected healthy people indicated that T_3 levels are unaffected by aging.¹⁴² TSH may increase or decrease with age in relation to the iodine intake¹⁴³; however, very elderly persons (≥ 80 years of age) may have a mild TSH decrease, suggesting the presence of an altered set point of the hypothalamic-pituitary-thyroid axis.¹⁴⁴ The requirement for complete levothyroxine replacement is reduced approximately 20% by the eighth decade.

TABLE 11-9

Changes in Thyroid Hormone Levels during Illness

Severity of Illness	Free T ₃	Free T ₄	Reverse T ₃	TSH	Probable Cause
Mild	↓	N	↑	N	↓ D2, D1
Moderate	↓↓	N, ↑↓	↑↑	N, ↓	↓↓ D2, D1, ?↑ D3
Severe	↓↓↓	↓	↑	↓↓	↓↓ D2, D1, ↑ D3
Recovery	↓	↓	↑	↑	?
