CHAPTER 29

Metabolic Bone Disease

JOSEPH A. LORENZO • ERNESTO CANALIS • LAWRENCE G. RAISZ

STRUCTURE AND FUNCTION OF THE SKELETON

The skeleton, one of the largest organ systems in the body, consists of a mineralized matrix and a highly active cellular fraction. Its multiple functions include providing structural integrity to the body, serving as a storehouse of minerals, playing an essential role in the maintenance of serum calcium and phosphate levels, and being the site of hematopoiesis. Imbalances between the structural and metabolic functions of the skeleton appear to be important in the pathogenesis of bone diseases.¹

Embryology and Anatomy

In the embryo, skeletal development begins with the condensation of mesenchyme into cartilage. Bone formation then occurs through endochondral or intramembranous bone formation.² The growth of long bones and of the vertebrae involves endochondral bone formation (Fig. 29-1). The cartilage cells in the growth plate proliferate and undergo hypertrophy; this is followed by partial degradation of the matrix, which then mineralizes. The cartilage is invaded by vessels, and the spicules of mineralized

cartilage are covered by osteoblasts to form a cancellous or trabecular bone called *primary spongiosa*. These structures are resorbed and replaced by trabecular plates made up entirely of bone, called *secondary spongiosa*. This process is most abundant at the ends of the long bones and in the bodies of the vertebrae.

Intramembranous bone formation occurs adjacent to the cartilage template, typically in flat bones, such as the skull, scapula, and ileum, and on the outer surfaces of long bones, leading to periosteal apposition. Initially, relatively disorganized woven bone is formed, but this rapidly converts into more organized lamellar bone produced by oriented layers of osteoblasts. The main difference between endochondral and intramembranous bone formation is that the latter does not use calcified cartilage as a direct template for osteoblasts.

Cortical bone is dense bone found in the shafts of long bones. It makes up 80% of the mass of the skeleton, determines its shape, and provides much of its strength. During longitudinal skeletal growth, endochondral and periosteal appositional bone formation determine the length and width of the bones.³ As new bone is formed, it is shaped by a process called *modeling*, which is carried out by uncoupled osteoblasts and osteoclasts. Modeling of cortical bone alters skeletal shape (see Fig. 29-1). Modeling is influenced

Figure 29-1 Steps in endochondral bone formation. CC, calcified cartilage; F, formation; LB, lamellar bone; R, resorption; Rev, reversal; WB, woven bone. (Redrawn from Baron R. *Anatomy and ultrastructure of bone*. In Favus MJ, ed. *Primer on the Metabolic Bone Diseases and Disorders of Mineral Metabolism*, 2nd ed. New York, NY: Lippincott-Raven; 1993:3-9. Copyright 1993, American Society for Bone and Mineral Research.)

by mechanical forces and is increased during the adolescent growth spurt.⁴ The wide cortex at the epiphyseal plate of long bones must be resorbed by the modeling process because these bones elongate to maintain the narrow tubular structure of the diaphysis.

In contrast to bone modeling, bone remodeling is a temporally regulated process, which results in the coordinated resorption and formation of bone. It is carried out in basic multicellular units throughout life. Remodeling is more active in cancellous or trabecular bone than in cortical bone.⁵ In smaller animals, such as rodents, cortical bone can remain lamellar. In large animals and humans, lamellar cortical bone is gradually replaced through haversian remodeling to form cylindrical osteons.

Chemistry of Bone Matrix and Mineral

The bone matrix consists of fibers of type I collagen laid down in layers that have various orientations, which may add to the strength of the matrix. The matrix contains many additional proteins, including small amounts of other collagen types that may be important in the interaction of type I collagen with noncollagen proteins. The noncollagen proteins represent about 10% of the total protein in bone and may direct the formation of fibers, mineralize bone, regulate the attachment of bone cells to its matrix, and play a role in the function of bone forming and resorbing cells (Table 29-1).

Protein composition of the matrix may vary, particularly between woven and lamellar bone.⁶ These proteins range from the large cell-attachment proteins (e.g., thrombospondin, fibronectin), which have molecular masses

higher than 400 kd, to the small, vitamin K-dependent γ -carboxylated proteins (e.g., matrix Gla protein, osteocalcin), which are 6-kd calcium-binding proteins. Some noncollagen proteins (e.g., biglycan, decorin, bone sialoprotein, osteopontin, osteoadherin) are highly acidic. In addition to cell-attachment sequences, these proteins contain various amounts of carbohydrate and are called *glycoproteins* or *proteoglycans*. Noncollagen proteins of bone are often highly phosphorylated, which enables them to bind calcium, and they may regulate mineralization. The use of targeted gene deletion in experimental murine models has provided important information on the function of noncollagenous proteins. For example, null mutations of the osteonectin gene lead to osteopenia, indicating that this matrix protein is important for the maintenance of a normal bone structure.⁷

Collagen Synthesis

Type I collagen is the most abundant protein of the bone matrix. It is a rigid, rodlike, insoluble molecule composed of two $\alpha 1$ chains and one $\alpha 2$ chain.^{8,9} Collagen chains consist of repeating triplets of amino acids, with glycine in every third position and a high content of proline and lysine (Fig. 29-2). The two $\alpha 1$ and the $\alpha 2$ collagen chains form a triple helix that is stabilized by the hydroxylation

TABLE 29-1

Noncollagen Proteins of Bone

Name	Possible Function
γ-Carboxyglutamic Acid-Containing Proteins	
Osteocalcin	May regulate bone mineral maturation; negative regulator of bone formation and osteoblast function
Matrix Gla protein	Inhibits mineralization
Rgd-Containing Glycoproteins	
Fibronectin	Binds to cells; binds to gelatin and collagen
Thrombospondins	Cell attachment; binds to heparin, type I collagen, thrombin, laminin
Vitronectin	Cell attachment; binds to collagen and heparin
Fibrillin	May regulate elastic fiber formation
Osteopontin	Binds to cells; mediates effect of mechanical stress on osteoclasts and osteoblasts
Bone sialoprotein	Binds cells, binds calcium; may initiate mineralization
Glycoproteins	
Alkaline phosphatase	Hydrolyzes mineralization inhibitors
Osteonectin	Binds to growth factors; may regulate mineralization
Tetranectin	May regulate mineralization
GAG-Containing	
Biglycan	May bind to collagen and TGF- β
Decorin	Binds to collagen and may regulate fibril diameter; binds to TGF- β
Fibromodulin	Binds to collagen and may regulate fibril diameter; binds to TGF- β
Osteoadherin	Promotes integrin-mediated cell attachment
Hyaluronan	Synthesized during early bone formation; may capture space destined to become bone

of proline and lysine residues, which requires ascorbic acid. Collagen is synthesized as a soluble propeptide with large nonhelical extensions at the carboxyl- and amino-terminal ends. Procollagen also contains C-terminal interchain disulfide bonds that help to initiate formation of the triple helical structure. Procollagen is released into the cisternae of the rough endoplasmic reticulum, packaged in the Golgi vesicles, and secreted extracellularly. The procollagen peptide ends are then removed by specific peptidases to produce mature insoluble collagen molecules, which are further stabilized by intramolecular and intermolecular cross-links. The major cross-links are formed by lysine and hydroxylysine residues that ultimately form pyridinium ring structures.

Mineralization

Bone mineral is formed by small, imperfect hydroxyapatite crystals, which contain carbonate, magnesium, sodium, and potassium. Mineralization occurs by two distinct mechanisms. The initial mineralization of calcified cartilage and woven bone probably occurs by means of matrix vesicles.¹⁰ These membrane-bound bodies are released from chondrocytes and osteoblasts, contain alkaline

phosphatase, and can form a nidus for crystallization. In contrast, in lamellar bone, the collagen fibers are tightly packed, and matrix vesicles are rarely seen. Mineralization does not occur immediately after collagen deposition, and there is a layer of 10 to 100 μ m of unmineralized osteoid between the mineralization front and the osteoblast. Changes in the packing of the fibrils and in the composition of the noncollagen proteins may be required for mineralization. Mineralization of collagen fibrils begins in the *hole zones*, where there is more room for inorganic ions to accumulate (Fig. 29-3). Mineralization requires calcium, phosphate, and alkaline phosphatase. This process is impaired in vitamin D deficiency and hypophosphatasia.

Collagen Degradation

As part of the bone remodeling process, collagen is cleaved and degraded by a group of proteases called *collagenases*. They are matrix metalloproteases (MMPs) that can initiate cleavage of collagen fibrils at neutral pH, and they are central to the process of collagen degradation, matrix breakdown, and bone remodeling. Three collagenases have been described: collagenase 1 (MMP1), 2 (MMP8), and 3 (MMP13).^{11,12} Human osteoblasts express the collagenase 1 and 3 genes (MMP1 and MMP13). Unstimulated osteoblasts

Figure 29-3 The staggered arrangement of individual molecules in collagen fibrils results in hole zones between the head of one molecule and the tail of the next. Mineral deposition (bottom) begins within the hole zones. (From Glimcher MJ, Krane SM. *Treatise on Collagen 2: Part B*. New York, NY: Academic Press, 1968:67-251.)

secrete limited amounts of collagenase, and changes in the synthesis of collagenase correlate with changes in bone resorption. Collagenase plays a critical function in bone remodeling. Mice with deletions of the collagenase 3 gene or mutations of the $\alpha 1^I$ type I collagen gene have resistance to collagenase 3 cleavage and fail to resorb bone after exposure to parathyroid hormone (PTH).¹³ The synthesis of collagenase by osteoblasts is regulated by hormones and by cytokines in the bone microenvironment that act by transcriptional and post-transcriptional mechanisms.¹⁴

Osteoblast Differentiation and Function

Bone is formed by *osteoblasts*, which are highly differentiated cells with many unique features (Fig. 29-4).¹⁵ Osteoblasts are derived from mesenchymal cells in the skeletal microenvironment.¹⁶ Osteogenic precursors may appear in the circulation, but they originate from skeletal tissue, and their contribution to bone formation is not well documented.¹⁷ Osteoprogenitor cells, or preosteoblasts, replicate and differentiate into active osteoblasts that exhibit various phenotypic characteristics.¹⁵ For example, osteoblasts in early development and during repair produce woven bone, whereas more mature osteoblasts produce lamellar bone. Osteoblast activity varies during bone formation. Some cells are tall and closely packed and produce a large amount of matrix in a small area; others are flatter and produce matrix at a slower rate over a larger area. Nevertheless, all differentiated osteoblasts share certain

Figure 29-4 Electron micrograph of rat calvarial bone shows mature osteoblasts with their dense, rough endoplasmic reticulum and large Golgi apparatus (a), an osteocyte embedded in the bone (b), and a less differentiated cell that may represent a preosteoblast (c). (Courtesy of Dr. Marijke E. Holtrop.)

features. They are connected by gap junctions and contain a dense network of rough endoplasmic reticulum and a large Golgi complex, and they secrete collagen and noncollagen proteins in an oriented fashion. Some products, such as osteocalcin, are produced almost uniquely by osteoblasts, and changes in serum levels of osteocalcin directly reflect changes in osteoblast activity.

Mature osteoblasts have a finite capacity to produce matrix, and bone formation is sustained by the arrival of new populations of cells at the bone surface. The number and the function of osteoblasts are determined by hormones and local signals. Some act as classic cell mitogens and increase the population of preosteoblastic cells, some determine their differentiation into mature osteoblasts, and others modify the function of mature cells.¹⁸ The ultimate fate of mature osteoblasts varies. They may die by apoptosis, they may become embedded in the matrix and become an osteocyte, or they may be converted to flattened lining cells, which cover a large percentage of the surface of bone with a thin cytoplasmic layer.

Bone marrow stroma contain pluripotent cells with the potential to differentiate into diverse cells of mesenchymal lineage, including osteoblasts, chondrocytes, and adipocytes.¹⁶ The ultimate cellular phenotype depends on factors present in the cellular microenvironment and their effects on intracellular signals and gene expression. Transcription factors are nuclear proteins that bind to DNA to regulate gene transcription. Some play a role in determining the fate of undifferentiated cells.

CCAAT/enhancer binding proteins (CEBPs) β and δ play an essential role in the differentiation of cells toward adipocytes, whereas runt-related transcription factor (RUNX2) plays a central role in the differentiation of cells toward osteoblasts.^{19,20} Targeted disruption of the *RUNX2* gene results in disorganized chondrocyte maturation and a complete lack of bone formation due to an arrest of osteoblast development.²¹

Osterix is another transcription factor that is required for endochondral and intramembranous bone formation. *Osterix*-null mice fail to develop a mineralized skeleton because of an arrest of late stages of osteoblast differentiation. Interactions between nuclear factors are common steps in the regulation of transcription and differentiation.²² Osterix associates and acts cooperatively with nuclear factor of activated T cells (NFAT), a transcription factor that regulates osteoblastogenesis and osteoclastogenesis.²³ CEBPs can interact with RUNX2 and with the activator of transcription (ATF)/cyclic adenosine monophosphate (cAMP) response element-binding protein (CREB) family of proteins. ATF4 plays a central role in osteoblastic function, and its activity is regulated by a nuclear matrix attachment region binding protein, SATB2, which interacts with ATF4 and RUNX2 to regulate osteoblast differentiation.²⁴

The conversion of osteoblasts to osteocytes involves a reduction but not a complete loss of metabolic activity.²⁵ A critical feature is the development of an extensive network of cytoplasmic connections. The osteoblasts have multiple cell processes that are connected to underlying osteocytes through small canaliculi. After mineralization is complete and the osteocyte is encased in mineralized bone, these processes maintain connections among osteocytes (Fig. 29-5). This extended syncytium is probably important for maintaining the viability of the osteocytes, which otherwise would be separated from the extracellular fluid.

Initially, osteocytes may continue to synthesize collagen and play a role in mineralization. Later, the major role of the osteocyte-osteoblast syncytium may be to sense mechanical forces.²⁶ Osteocytes probably sense bone

Figure 29-5 **A**, Cross-section of an osteon. **B**, Cultured cells from avian bone, showing osteocytes and their cytoplasmic connections. (From Aarden EM, Burger EH, Nijweide PJ. Function of osteocytes and bone. *J Cell Biochem.* 1994;55:287-299. Reprinted by permission of Wiley-Liss, Inc., a subsidiary of John Wiley & Sons, Inc.)

deformation and provide signals for the adaptive remodeling of bone size and shape.²⁷ One hypothesis is that small strains produce fluid shear stress in the canaliculi between osteocytes. This effect may result in intracellular signaling through changes in ion channels or in the production of biologically active molecules. Regions of bone microdamage contain apoptotic osteocytes, which may provide signals for the initiation of bone remodeling by osteoclasts and the consequent removal of damaged bone.⁸

Cells of the osteoblastic lineage are important for forming bone and for initiating bone resorption. Both mature osteoblasts and osteocytes may play a role in activating resorption. Most of the hormonal factors that stimulate bone resorption act on cells of the osteoblastic lineage. They release receptor activator for nuclear factor κ B ligand (RANKL) and colony-stimulating factor 1 (CSF1), which are essential for osteoclastogenesis. Osteoblasts also produce additional factors that regulate bone resorption, including cytokines, prostaglandins, and local growth factors. In cell culture, contact between osteoblastic cells and hematopoietic cells appears to be necessary for osteoclast formation (Fig. 29-6). Osteoblasts may also play a role in initiating bone resorption by releasing collagenases, other metalloproteinases, and plasminogen activator. These enzymes may remove the surface proteins of bone, which prevent the access of osteoclasts to the mineralized matrix. Osteoblasts also influence the development and maintenance of the marrow through their production of growth factors, cytokines, and chemokines that regulate the growth and development of hematopoietic cells.

Osteoclast Differentiation and Function

Osteoclasts are derived from hematopoietic progenitors and appear to be myeloid in origin. Hematopoietic stem cells under the direction of cytokines and possibly cell-cell interactions express transcription factors that define their

Figure 29-6 Osteoclast formation. Osteoclasts form from osteoclast precursor cells, which are derived from hematopoietic-lineage cells. They express C-FMS (CSF1R, the receptor for M-CSF) and RANK and attach to stromal/osteoblastic cells, which express membrane-bound and soluble M-CSF, membrane-bound RANKL, and OPG under the influence of stimulators of resorption (i.e., PTH, 1,25-Vit D, IL-1, TNF, IL-6, IL-11, or PGs). If stromal or osteoblastic cells produce more RANKL than OPG, osteoclasts are formed and activated, which increases bone resorption. If stromal or osteoblastic cells produce more OPG than RANKL, OPG binds the available RANKL, and new osteoclast formation is prevented. During states of inflammation, T lymphocytes are activated and produce membrane-bound and soluble RANKL, which can stimulate osteoclast-mediated bone resorption. IL-1 and TNF can augment the effects of RANKL and M-CSF on osteoclast formation and bone resorption by directly stimulating osteoclast precursor cells and mature osteoclasts. IL, interleukin; M-CSF, macrophage colony-stimulating factor; OPG, osteoprotegerin; PG, prostaglandin; PTH, parathyroid hormone; RANK, receptor activator of nuclear factor κ B; RANKL, RANK ligand; TNF, tumor necrosis factor; 1,25 Vit D, 1,25-dihydroxyvitamin D.

commitment to the osteoclast lineage. Colony-stimulating factor 1 (i.e., macrophage colony-stimulating factor [M-CSF]) appears to be the major cytokine, which regulates the replication and development in bone marrow of progenitor cells that are capable of differentiating into osteoclasts. Expression of the transcription factor SPI1 (formerly called PU.1) is also necessary for the osteoclast precursor cell to develop.²⁸ In bone marrow the osteoclast precursor cell is multipotent and can differentiate into monocyte-macrophages, dendritic cells, or preosteoclasts.²⁹ The latter fuse to form highly differentiated, multinucleated osteoclasts that resorb bone (see Fig. 29-6). Progression through the osteoclast pathway probably involves multiple local and systemic hormones that may include 1,25-dihydroxyvitamin D [$1,25(\text{OH})_2\text{D}$], prostaglandins, and the cytokines interleukin-1 (IL-1), IL-6, and tumor necrosis factor (TNF).

The nature of the osteoblast-lineage cell products, which directly regulate osteoclast formation and function, has been clarified.³⁰ The principal stimulator of osteoclast formation is RANKL, a member of the TNF protein superfamily. This protein was originally identified as a product of activated T lymphocytes, but it is also recognized as a critical stimulator of osteoclastogenesis.

Production of RANKL in osteoblast-lineage cells is stimulated by essentially all agents that enhance osteoclast formation, including PTH, $1,25(\text{OH})_2\text{D}$, prostaglandins, and many cytokines. Mice that are deficient in RANKL do not form osteoclasts and have osteopetrosis. In contrast, injection of RANKL into mice stimulates osteoclast formation and bone resorption. RANKL is produced as a membrane protein. In activated T lymphocytes, RANKL is cleaved from the cell membrane and is released as a soluble factor.³¹ It is unclear whether similar events occur in osteoblast-lineage cells, although there is some evidence that cleavage and release of soluble RANKL occurs in malignant cells that metastasize to bone.

Osteoprotegerin (OPG) is an inhibitor of osteoclastogenesis. OPG is a soluble receptor for RANKL that binds this ligand and prevents interaction of RANKL with its cognate receptor, RANK. OPG is produced widely. In bone marrow cultures, a number of stimulators of resorption, including PTH, $1,25(\text{OH})_2\text{D}$, and prostaglandin E_2 (PGE_2), inhibit OPG production. For these factors, there is a reciprocal relationship between RANKL stimulation and OPG inhibition that causes activation of osteoclastogenesis and enhanced resorption. Mice that are deficient in OPG have osteoporosis, whereas mice that overexpress OPG have increased bone mass. These results, together with those for RANKL-deficient mice and mice injected with RANKL, demonstrate that osteoclast-mediated bone resorption is tightly regulated by the combined actions of RANKL and OPG.

The active receptor for RANKL is RANK, a member of the TNF receptor superfamily. Osteoclasts and their immediate precursor cells express RANK, and this expression is induced by M-CSF.³² Binding of RANKL to RANK activates a series of intracellular pathways that activate NF- κB and mitogen-activated protein (MAP) kinases, as well as NFAT and the activator protein-1 (AP1) family of transcription factors. The TNF receptor-associated factors (TRAFs), and particularly TRAF-6, bind RANK intracellularly and are involved in RANK responses. Mice deficient in TRAF-6, like those deficient in RANK, develop osteopetrosis. In addition to its effects on bone, the RANKL/RANK system is involved in lymphocyte function and in breast and lymph node development. Mature osteoclasts express RANK, and treatment of these cells with RANKL inhibits apoptosis and stimulates resorptive activity.³³

In addition to RANKL, M-CSF is essential for osteoclast formation. Mice that are deficient in M-CSF have osteopetrosis and few osteoclasts.³⁴ In cultures of isolated osteoclast precursor cells, both M-CSF and RANKL must be present for mature osteoclasts to form. M-CSF enhances RANK production in osteoclast precursors and inhibits apoptosis of osteoclast precursors and mature osteoclasts. The receptor for M-CSF, CSF1R (formerly designated C-FMS), is present on osteoclast precursors and mature osteoclasts.^{32,35} Binding of CSF1R by M-CSF activates tyrosine kinase activity in the receptor, which initiates a series of intracellular downstream events.

A series of coactivator molecules is critical for osteoclast development. These molecules include members of the cytoplasmic immunoreceptor tyrosine-based activation motif (ITAM) family, namely FC-receptor common γ subunit ($\text{FCR}\gamma$) and DNAX activator protein 12 (DAP12). ITAM proteins interact with receptor proteins in the cell membrane of osteoclast precursor cells. The search for receptors associated with these ITAM adaptors in myeloid cells has identified at least two candidates that associate with $\text{FCR}\gamma$ —osteoclast-associated receptor (OSCAR) and PIR—and two that associate with DAP12—the triggering receptor expressed by myeloid cells-2 (TREM2) and the signal regulatory protein- β 1 (SIRPB1). Mice that are deficient in $\text{FCR}\gamma$ and DAP12 have osteopetrosis and deficient osteoclast formation despite their ability to express RANKL, RANK, M-CSF, and CSF1R.^{23,36} This signaling pathway responds to ligands that have not yet been established genetically; together with RANK, it stimulates the accumulation of intracellular calcium, which is required for NFAT activity in the nucleus.

The formation of multinucleated osteoclast-like cells in vitro requires hematopoietic precursors and cells of the mesenchymal/osteoblast lineage. In vivo and in cultures with devitalized bone, mononuclear preosteoclasts attach to the bone surface and form multinucleated osteoclasts by fusion. The accumulation of additional nuclei into osteoclasts by fusion probably continues while the cell is actively resorbing. The life span of the osteoclast is limited. As osteoclasts become inactive, they die by apoptosis. Hormones that enhance bone resorption may delay apoptosis, and inhibitors of resorption probably accelerate it. The mechanisms that limit the extent of osteoclastic resorption are incompletely understood and may involve inhibition by calcium ions, which accumulate under the osteoclast resorbing surface, or by local inhibitory factors, such as transforming growth factor- β (TGF- β), which are released and activated during resorption.

The mature osteoclast is a unique and highly specialized cell (Fig. 29-7). It usually contains 10 to 20 nuclei, but giant osteoclasts with up to 100 nuclei can be seen in Paget's disease and in giant cell tumors of bone. The large size of osteoclasts is probably essential for their resorptive function. The best evidence for this comes from studies of dendritic cell-specific transmembrane protein (DC-STAMP), because inhibition of this protein or its complete deficiency in mouse models results in the generation of only mononuclear osteoclasts that have impaired resorptive activity.^{37,38}

The capacity of osteoclasts to resorb bone depends on their ability to isolate a region of the bone surface from the extracellular fluid and produce a local environment that can dissolve bone mineral and degrade matrix. The osteoclast must polarize and produce a basolateral membrane opposite the resorption space, which facilitates the excretion of resorption products. The resorbing apparatus consists of a central ruffled border area, which secretes

Figure 29-7 Functional elements of the fully differentiated osteoclast. Osteoclasts attach to bone by means of podosomes containing $\alpha_v\beta_3$ integrin. Protons are generated through the actions of carbonic anhydrase II (CAII), which is transported into the resorption space by the vacuolar-type H^+ -ATPase proton pump. A chloride channel coupled to the proton pump facilitates charge neutrality across the membrane while passive exchange of chloride (Cl^-) for bicarbonate (HCO_3^-) in the basolateral membrane removes excess bicarbonate. Cathepsin K is an important enzyme for the removal of the organic components of bone in the acid environment of the resorption space. (Redrawn from Tolar J, Teitelbaum SL, Orchard PJ. Osteopetrosis. *N Engl J Med*. 2004;351:2839-2849.)

hydrogen ions and proteolytic enzymes, surrounded by a clear or sealing zone in a structure called the *podosome*. The podosome contains filamentous actin linked to $\alpha_v\beta_3$ integrin, and it anchors the cell to the bone surface. The osteoclast attaches to bone through the interaction of integrins in the podosome with noncollagenous proteins such as vitronectin and osteopontin in the matrix.

Acidification of the resorption space adjacent to the ruffled border membrane requires that osteoclasts have a vacuolar proton pump (H^+ -ATPase) and a chloride channel that is charged coupled to H^+ secretion across the ruffled membrane to preserve electron neutrality. These osteoclast H^+ -ATPase pumps are similar to the vacuolar proton pumps that acidify intracellular organelles, but in the osteoclast they are exteriorized to increase the extracellular hydrogen ion concentration in the resorption space.³⁹ The hydrogen ions dissociate from carbonic acid, which is synthesized by carbonic anhydrase II; the bicarbonate generated by this dissociation is removed from the cell by chloride-bicarbonate exchange at the basolateral membrane of the osteoclast. Ion pumps can transport the dissolved calcium from the bone surface through the cell to the extracellular fluid.

However, calcium can also reach the extracellular fluid directly if the sealing zone is disrupted. The proteolytic enzymes produced by the osteoclast include lysosomal enzymes and metalloproteinases. Lysosomal proteases can degrade collagen at the low pH present in the ruffled border area. Cathepsin K is probably the most important of these.⁴⁰

Metalloproteinases, which are active at neutral pH, have also been detected at the resorption site.⁴¹ The products of resorption are transported across the ruffled border membrane and excreted through the basolateral membrane of the osteoclast by a process called *transcytosis*.⁴² In trabecular bone, osteoclasts characteristically resorb to a limited depth and then move laterally to produce irregular, plate-like resorption areas called *Howship's lacunae*. In cortical remodeling, the path of directed resorption is longer, possibly because of renewal of osteoclasts from hematopoietic cells brought to the site through the haversian canal.

BONE REMODELING AND ITS REGULATION

Bone remodeling is a temporally regulated process that results in the coordinated resorption and formation of skeletal tissue carried out in basic multicellular units.⁵ Bone remodeling occurs throughout life. Signals determining the fate, function, and death of cells of the osteoclast, and osteoblast lineages define the populations of cells that resorb and form bone in basic multicellular units. Osteoblasts appear at sites vacated by osteoclasts, a process called *coupling*. As resorption by osteoclasts is terminated, the resorptive surface is covered by a thin layer of cement, where osteoblasts assemble to form bone and fill the cavity.^{3,5} The remodeling cycle has four steps: activation, resorption, reversal, and formation (Figs. 29-8 and 29-9). Cells of the osteoblast and osteoclast lineages produce factors that regulate each other's function.^{43,44}

Similar sequences are seen in trabecular and cortical remodeling, although remodeling is more active in trabecular bone.⁸ In young adults, this cycle is tightly coupled and the amount of new bone formed by osteoblasts is equal to the amount resorbed by osteoclasts. However, during the menopausal years, remodeling of bone occurs at a higher rate than in the premenopause, and rates of resorption exceed formation, which results in a net loss of bone and an increased risk of developing osteoporosis.⁴⁵

Although 80% of skeletal mass is cortical bone, the surface area of cortical bone is only about one fifth that of cancellous bone. Moreover, more osteoclast precursor cells are available in cancellous bone and on the endosteal surfaces of cortical bone. Consequently, turnover is greater on these surfaces than on those of periosteal bone, which normally undergoes little remodeling. However, subperiosteal resorption can be activated in hyperparathyroidism, and the periosteal surface contains preosteoblasts that may become active late in life and cause an age-related increase in the periosteal diameter of long bones. This periosteal expansion may maintain bone strength and compensate for losses at the endosteal surfaces and in cancellous bone.

Remodeling can be activated by systemic and local factors, and it is necessary to maintain skeletal strength and the serum levels of calcium. Changes in mechanical force can activate remodeling to improve skeletal strength, and remodeling removes and repairs bone that has undergone microdamage. This occurs particularly in cortical bone and may explain the fact that remodeling is sustained in the aging skeleton.⁴⁶ However, loss of osteocytes with age may impair this response.⁴⁷ Systemic hormones influence bone remodeling to regulate the movement of mineral from bone to the extracellular fluid to maintain serum calcium levels and as part of their overall effects on growth. During pubertal growth, bone modeling and remodeling

Figure 29-8 Stages of bone remodeling. The resorptive, reversal, and formative phases of bone remodeling and a completed bone structural unit (BSU) on a trabecular surface are shown. The morphologic features of the activation step have not been defined. (Courtesy of Dr. Robert E. Schenk, University of Berne, Switzerland.)

intensify and correlate with serum levels of insulin-like growth factor 1 (IGF1).⁴ Studies performed in mice lacking molecular clock genes suggest that bone remodeling is subject to circadian regulation.⁴⁸

Calcium-Regulating Hormones

Parathyroid Hormone

PTH acts on bone to stimulate resorption but does not act on osteoclasts in the absence of cells of the osteoblastic lineage. PTH receptors are abundant on osteoblasts but not on osteoclasts.⁴⁹ PTH acts on osteoblasts to cause cell contraction; to induce immediate-early response genes, including FOS and the inducible form of prostaglandin G/H synthase (i.e., cyclooxygenase), and to increase the synthesis of local mediators, IGF1 and IL-6.^{49,50} High concentrations of PTH in vitro inhibit the expression of type I collagen, but intermittent administration of PTH in vivo or in vitro can stimulate bone formation.⁵⁰ PTH induces the production of RANKL and inhibits the production of osteoprotegerin by cells of the osteoblast lineage, thereby increasing osteoclastogenesis and the activity of osteoclasts. In some settings, PTH increases proliferation of cells of the osteoblast lineage and decreases their death by apoptosis.⁵¹

Vitamin D

The hormonal form of vitamin D, 1,25(OH)₂D₃, is necessary for intestinal calcium and phosphorus absorption and therefore for mineralization. This form of vitamin D also has effects on the skeleton, but its physiologic role in bone remodeling is not clear.⁵² By increasing RANKL production on osteoblasts or osteoblast progenitor cells, vitamin D is a potent stimulator of osteoclast formation in cell culture. High concentrations increase osteocalcin synthesis by osteoblasts and inhibit collagen synthesis. Lower concentrations may increase bone formation, although not to the extent seen with intermittent administration of PTH.

Figure 29-9 Three-dimensional reconstruction of the remodeling sequence in human trabecular bone. 1, Early bone resorption with osteoclasts (OCL); 2, late bone resorption with mononuclear cells (MON); 3, reversal phase with preosteoblasts (POB); 4, early matrix formation by osteoblasts (OB); 5, late bone formation with mineralization; 6, completed remodeling cycle with reversion to lining cells. (From Eriksen EF. Normal and pathological remodeling of human trabecular bone: three dimensional reconstruction of the remodeling sequence in normals and in metabolic bone disease. *Endocr Rev.* 1986;7:379-408. Copyright 1986 by The Endocrine Society.)

Calcitonin

Calcitonin inhibits bone resorption by acting directly on the osteoclast, but it appears to play a small role in the regulation of bone turnover in adults. Bone mass is not greatly altered in patients with medullary thyroid carcinoma, who have an excess of calcitonin production, or in athyrotic patients receiving adequate thyroid hormone replacement, who have low calcitonin levels.⁵³ Bone turnover is increased in patients with medullary thyroid carcinoma.⁵⁴ Mice with a deletion of the gene for calcitonin/calcitonin-related polypeptide- α (*CALCA*), which is responsible for the production of calcitonin and its alternate transcript calcitonin gene-related peptide, have increased bone mass and enhanced rates of bone formation.⁵⁵ In contrast, mice with a deletion of only the calcitonin gene-related peptide have decreased bone mass.⁵⁶ These results imply that calcitonin influences bone formation and bone resorption. However, the mechanisms by which calcitonin affects bone formation are unknown.

Other Systemic Hormones

Growth Hormone

Deficiency and excess of growth hormone have marked effects on skeletal growth.⁵⁷ Growth hormone increases circulating and local levels of IGF1, which mediates many of the skeletal effects of growth hormone. Exogenous growth hormone and IGF1 increase bone remodeling. Growth hormone also stimulates cartilage growth, probably through an increase in local and systemic IGF1 production and possibly by direct stimulation of cartilage cell proliferation, because low levels of growth hormone receptors are present in skeletal cells.

Glucocorticoids

Glucocorticoids exert profound effects on bone remodeling.⁵⁸ Glucocorticoids decrease the intestinal absorption of calcium and have the potential to induce osteoclastogenesis and bone resorption because they increase the expression of RANKL and CSF1 in osteoblasts.⁵⁹ However, the most significant effect of glucocorticoids is their ability to suppress bone remodeling through depletion of the osteoblastic cell population.⁶⁰ Glucocorticoids inhibit the replication of osteoblast precursors and their differentiation into mature osteoblasts. This occurs in part because they suppress Wnt signaling, factors necessary for osteoblastic differentiation.⁶¹ Glucocorticoids induce the apoptosis of osteoblasts and osteocytes, contributing to the decrease in bone forming cells.⁶² Glucocorticoids inhibit the differentiated function of the osteoblast and bone formation. This results from direct effects of glucocorticoids on the osteoblast and suppression of IGF1 transcription.⁶³

Thyroid Hormones

In children, hyperthyroidism is associated with increased skeletal growth, and hypothyroidism results in decreased growth.⁶⁴ Thyroid hormones are crucial for cartilage growth and differentiation and enhance the response to growth hormone. Thyroid hormones increase bone resorption and turnover, although their effects on bone formation are less clear.⁶⁵ Coupled with their effects on bone resorption, thyroid hormones increase the transcription of collagenase and gelatinase by osteoblasts.⁶⁶ As thyroid hormones increase bone remodeling, they may also increase bone formation. Thyroid hormones also have indirect effects on skeletal metabolism by suppressing the synthesis of

thyroid-stimulating hormone (TSH), which can inhibit osteoclast formation and survival and as a consequence bone resorption.^{67,68}

Insulin

Normal skeletal growth depends on an adequate amount of insulin.⁶⁹ Excess insulin production by the fetuses of mothers with uncontrolled diabetes results in excessive growth of the skeleton and other tissues, and undertreated diabetes mellitus impairs skeletal growth and mineralization. Children and adolescents with type 1 diabetes are at increased risk for decreased bone mineral acquisition.⁷⁰ In vitro, insulin at physiologic concentrations selectively stimulates osteoblastic collagen synthesis by a pretranslational mechanism. Insulin can mimic the effects of IGF1, although only at supraphysiologic levels.⁷¹ Mice deficient in insulin receptor substrate 1, a major substrate of insulin and IGF1 receptor tyrosine kinases, exhibit impaired osteoblastic function and low-bone-turnover osteopenia, documenting the central role of insulin and IGF1 signaling in the maintenance of bone remodeling.⁷²

Gonadal Hormones

Estrogens and androgens are critical for skeletal development and maintenance. Bone cells contain estrogen and androgen receptors, but it has been difficult to demonstrate direct effects of gonadal steroids on bone formation or resorption in cell and organ culture. Gonadal hormones are crucial for the pubertal growth spurt, and estrogen is necessary for epiphyseal closure.⁷³ Deficiency of estrogen or androgen increases bone resorption in vivo, possibly by increasing the local synthesis or sensitivity to cytokines, such as IL-1 and IL-6 or TNF- α , and to prostaglandins. Androgens can increase bone formation in vivo.⁷⁴ The effect of estrogens on bone formation is less clear. The absolute rate of bone formation is increased in estrogen deficiency states because of an increase in bone remodeling. However, estrogen deficiency causes bone loss, implying a relative deficiency in bone formation that is not sufficient to compensate for the increased resorption.⁴⁵

Local Regulators

Characterization of local regulators produced within the bone itself represents a major advance in bone biology.^{75,76} These local factors can be synthesized by bone cells or by adjacent hematopoietic cells and can interact with each other and with systemic hormones. They are critical in the repair of skeletal damage and in the response to mechanical forces.

Cytokines

The proinflammatory cytokines IL-1 α , IL-1 β , TNF- α , and TNF- β are potent stimulators of bone resorption and inhibitors of bone formation, which may play a role in the bone loss after estrogen withdrawal.^{77,78} IL-6 increases osteoclastogenesis in cell cultures and may mediate some of the resorbing activity of PTH. IL-6 is produced by osteoblasts, and its production is stimulated by PTH,⁷⁹ PGE₂, and other factors that increase bone resorption. IL-11, another member of the IL-6 cytokine family, also stimulates resorption. Colony-stimulating factors regulate the early stages of osteoclast precursor cell development.

IL-4 and IL-13 inhibit resorption and prostaglandin synthesis in bone cells,⁸⁰ and leukemia inhibitory factor has biphasic effects on bone formation.⁸¹ IL-7 stimulates B lymphopoiesis, which may be involved in osteoclastogenesis.⁸² IL-10⁸³ is an inhibitor of osteoclastogenesis and bone

resorption. IL-15 and IL-17 stimulate resorption, whereas IL-18 is inhibitory through its ability to increase production of granulocyte-macrophage colony-stimulating factor (GM-CSF).⁸⁴

Interferon- β and interferon- γ inhibit resorption by blocking RANK signaling pathways.⁸⁵ In addition to direct effects, responses to cytokines can be blocked by inhibitors, such as the IL-1 receptor antagonist and the soluble TNF receptor, or they can be enhanced by activators such as the soluble IL-6 receptor.

Transforming Growth Factor- α and Epidermal Growth Factor

These peptides stimulate bone resorption through the same receptor and act by prostaglandin-dependent and prostaglandin-independent pathways. TGF- α and epidermal growth factor (EGF) are potent mitogens in bone that probably act on mesenchymal and hematopoietic precursors.^{86,87} TGF- α is produced by neoplasms and may play a role in the increased bone resorption that occurs in certain malignancies.

Prostaglandins

Prostaglandins are potent regulators of bone cell metabolism and are synthesized by many cell types in the skeleton.⁸⁸ Prostaglandin production in bone is regulated by the effects on the inducible cyclooxygenase 2 (COX2) of local and systemic hormones and mechanical forces. Increased prostaglandin production may contribute to the increase in bone resorption that occurs with immobilization, the enhanced bone formation seen with impact loading, and the bone loss after estrogen withdrawal. Many of the hormones, cytokines, and growth factors that stimulate bone resorption also increase prostaglandin production.

Prostaglandins have biphasic effects on bone formation. Stimulation of bone formation is seen in vivo, and inhibition of collagen synthesis occurs in osteoblast cultures. Bone cells produce PGE₂, PGF_{2 α} , prostacyclin, and lipoxigenase products (e.g., leukotriene B₄), which may also stimulate bone resorption.

Growth Factors

Skeletal cells synthesize a variety of growth factors that regulate the replication, differentiation, and function of bone cells. These growth factors are not synthesized specifically by skeletal cells, and some are present in the systemic circulation and can act as local and systemic regulators of bone remodeling. Skeletal cells also synthesize growth factor binding proteins. These regulate the activity and storage of a specific factor and its interactions with other proteins in the extracellular matrix.⁷⁵

Fibroblast Growth Factors

Fibroblast growth factors (FGFs) form a large family of polypeptides characterized by their affinity to glycosaminoglycan heparin binding sites.⁸⁹ FGF1 and FGF2, which have been studied extensively, have mitogenic properties for cells of the osteoblastic lineage, which eventually differentiate into mature osteoblasts, but FGFs do not stimulate osteoblast differentiation or function.⁷¹ FGF2 inhibits Wnt signaling and the synthesis of IGF1, which results in a decrease in osteoblastogenesis and in osteoblastic function.^{90,91} In vivo experiments have confirmed this action of FGF, and mice overexpressing FGF2 are osteopenic.⁹² However, studies in *Fgf2*-null mice indicate that FGF is necessary for osteoblast formation, possibly because of its

effects on cell replication.⁹³ FGF can stimulate bone resorption by prostaglandin-dependent and independent pathways.⁹⁴

Platelet-Derived Growth Factors, Vascular Endothelial Growth Factors, Hypoxia-Inducible Factors, and Reactive Oxygen Species

Platelet-derived growth factor (PDGF) was originally isolated from human platelets, and four members of the *PDGF* gene family have been identified: *PDGFA*, *PDGFB*, *PDGFC*, and *PDGFD*.⁹⁵ Vascular endothelial growth factor (VEGF) shares a high degree of sequence homology with PDGF, and these factors are often referred to as members of the PDGF/VEGF family.⁹⁶

PDGFs must form homodimers or heterodimers to exhibit activity. PDGF-AA, -AB, and -BB are the isoforms studied more extensively in skeletal cells, and they exert similar biologic actions. The primary function of PDGF in bone is the stimulation of cell replication, and PDGF impairs osteoblast differentiation and function.⁹⁷ PDGF also stimulates bone resorption. In mice, null mutations of *Pdffa* or *Pdffb* and their receptors cause embryonic lethality or perinatal death, not allowing the study of the function of PDGF in the postnatal skeleton.⁹⁸ Although skeletal cells express products of the *Pdffa*, *Pdffb*, and *Pdffc* genes, the major source of PDGF is the systemic circulation and skeletal cells become exposed to PDGF after platelet aggregation.

Vascular endothelial growth factor A (VEGFA) is essential for angiogenesis, and *VEGFA* and VEGF receptor genes are expressed by chondrocytes and osteoblasts.⁹⁹ VEGFA is required for blood vessel formation and vessel invasion into cartilage during the process of endochondral bone formation and for chondrocyte survival during skeletal development.¹⁰⁰ VEGFA is required for intramembranous bone formation and osteoblastic maturation.¹⁰¹ Osteoblast expression of PDGF and VEGF is regulated by other growth factors.

Hypoxia-inducible factors (HIFs) are produced locally in response to low oxygen tension and mediate pathways that lead to angiogenesis, including production of VEGF. It was shown that more bone was produced during fracture repair in a mouse model with constitutively active HIF-1 α in osteoblasts. Conversely, mice deficient in HIF-1 α in osteoblasts had defective bone healing.¹⁰²

Reactive oxygen species (ROS), which are free radicals that include peroxides, are products of cell metabolism that are normally inactivated to prevent cell damage. In a mouse model, some changes that occur in bone turnover and cell metabolism with aging and the loss of sex steroid were associated with increases in the levels of ROS in bone cells.¹⁰³ The study authors found that the effects on bone of the loss of sex steroids could be reversed by antioxidant treatment of the mice.

Insulin-Like Growth Factors

IGFs increase the differentiated function of the osteoblast, and bone formation.¹⁰⁴ The systemic circulating and locally synthesized IGF1 contribute to bone formation.¹⁰⁵ Transgenic mice overexpressing IGF1 have increased bone mass, whereas *Igf1*-null mice exhibit decreased bone formation and decreased cortical bone.^{106,107} IGF1 increases osteoclastogenesis and bone remodeling.¹⁰⁸ IGF1 and IGF2 are synthesized by bone cells and are stored in the bone matrix, but IGF1 is a more potent stimulator of osteoblastic function.¹⁰⁴ Six IGF-binding proteins have been identified in bone. IGF-binding proteins can inhibit or enhance IGF

responses. PTH and PGE₂ are major inducers of skeletal IGF1 synthesis and glucocorticoids suppress IGF1 transcription.¹⁰⁴ IGFs mediate selected effects of these hormones on bone formation.

Transforming Growth Factor- β

TGF- β belongs to a family of closely related polypeptides with various degrees of structural homology and important effects on cell function.¹⁰⁹ Skeletal cells express TGF- β 1, TGF- β 2, and TGF- β 3. TGF- β has complex and somewhat contradictory actions in bone cells. TGF- β can stimulate osteoblastic cell replication and bone formation, but it does not favor osteoblastic cell differentiation.^{110,111} The effects of TGF- β depend on the target cell and experimental conditions. The actions of TGF- β on bone resorption have been a source of controversy. TGF- β has a biphasic effect on osteoclastogenesis, but it decreases bone resorption.¹¹² Targeted disruption of the mouse *Tgfb1* gene is lethal but does not result in abnormal skeletal development.¹¹³ TGF- β is secreted as a latent high-molecular-weight complex consisting of the C-terminal remnant of the TGF- β precursor and a TGF- β -binding protein.¹¹⁴ The biologically active levels of TGF- β depend on changes in its synthesis and in its activation from its latent form.

Bone Morphogenetic Proteins and WNTs

Bone morphogenetic proteins (BMPs) are members of the TGF- β superfamily of polypeptides, and they were originally identified because of their ability to induce endochondral bone formation. BMPs are expressed by osteoblasts and play an autocrine role in osteoblastic differentiation and function.⁷⁵ The fundamental function of BMPs is the induction of osteoblastic cell differentiation, endochondral ossification, and chondrogenesis.^{75,115} The genesis and differentiation of osteoblasts and osteoclasts are coordinated events, and BMPs also induce osteoclastogenesis and osteoclast survival.¹¹⁶

BMP activity is regulated by a large group of secreted polypeptides that bind and limit BMP action. These extracellular BMP antagonists prevent BMP signaling. Extracellular BMP antagonists include noggin, follistatin, twisted gastrulation, the chordin family, and the Dan/Cerberus family of proteins.⁷⁵

The Wnt family of secreted glycoproteins, like BMPs, plays a critical role in directing osteoblastogenesis. In skeletal cells, many Wnt family members use the canonical Wnt/ β -catenin signaling pathway.¹¹⁷ In the absence of Wnt, the proteins axin, adenomatous polyposis coli (APC), and β -catenin form a complex that facilitates the phosphorylation and degradation of β -catenin. Binding of Wnt family proteins to specific frizzled membrane receptors and their coreceptors (typically, lipoprotein receptor-related protein [LRP] family members), leads to the stabilization of β -catenin. This allows β -catenin to be translocated to the nucleus, where it can regulate the transcription of target genes. The Wnt/ β -catenin signaling pathway is central to osteoblastogenesis and bone formation, and Wnt and BMPs act in concert to regulate cell differentiation. Deletions of Wnt or β -catenin genes result in the absence of osteogenesis and of skeletal tissue, and inactivating mutations of Wnt coreceptors result in osteopenia.¹¹⁸ Wnt/ β -catenin signaling induces osteoprotegerin, and through this mechanism, Wnts are negative regulators of osteoclastogenesis.^{119,120} Wnt activity, like that of BMPs, is controlled by extracellular antagonists and intracellular signaling proteins.⁷⁶ Extracellular antagonists such as sclerostin and dickkopf-1 (DKK1) prevent interactions between Wnt family members and their receptors and coreceptors. This

limits Wnt signaling, which decreases osteoblast function and bone mass.^{117,121} Conversely, deletion of sclerostin in mice produces a high bone mass phenotype.¹²² Sclerostin, made predominantly by osteocytes, is regulated by systemic factors such as PTH and by mechanical forces on bone. Precisely how sclerostin, an osteocyte product, regulates bone formation and resorption, is an important unanswered question.

CLINICAL EVALUATION OF METABOLIC BONE DISEASE

Bone Densitometry

The most widely used procedure for measuring bone mass is dual-energy x-ray absorptiometry (DEXA).¹²³ Other methods include quantitative computed tomography (QCT), quantitative radiography, single-energy x-ray absorptiometry, and ultrasonography.¹²⁴⁻¹²⁷ Correlations among these methods vary broadly.

Densitometry and ultrasound data are reported in terms of *T-scores* (i.e., standard deviations from the young adult norm for that instrument) or *Z-scores* (i.e., standard deviations from the expected value for individuals of the same sex, age, and body size). These values depend on the normative data that have been obtained for each instrument. Moreover, the normative data are likely to be different for men and women and for members of different racial and ethnic groups. The combination of BMD measurements with other risk factors using a computer algorithm (FRAX) has probably strengthened the utility of BMD measurements and diagnosis¹²⁸ (the osteoporosis diagnosis is discussed later). Further enhancement could occur if practical methods for measuring changes in microarchitecture were developed using magnetic resonance imaging (MRI) or quantitative high-resolution QCT.^{122,129,130}

Dual-Energy X-Ray Absorptiometry

DEXA can provide accurate and reproducible values for *bone mineral content* (BMC) and *bone mineral density* (BMD) in the lumbar spine, the proximal femur, the distal radius, and the whole body. BMD is calculated from the BMC and the area of bone scanned (g/cm²); it represents a real bone density rather than true volumetric density.

DEXA has many advantages. Radiation exposure is minimal (<10 mrem), and scanning time is short (5 to 20 minutes). If quality control is maintained, variability of repeated readings is less than 1% for phantom standards; less than 2% for lumbar spine, total body, and radius; and less than 3% for proximal femur.

DEXA has some major disadvantages. Changes with disease progression or therapy are small in relation to the variability of the measurement.¹³¹ The test is moderately expensive. Anteroposterior measurements of the lumbar spine in older patients are subject to errors caused by aortic calcification and osteoarthritic changes. The latter disadvantage can be overcome by performing lateral densitometry of the lumbar spine, but this measurement is less precise. Newer DEXA systems may have sufficient resolution to measure changes in vertebral body height in the thoracic and lumbar vertebrae. Detection of new vertebral compressions by this method may be particularly useful in patients with prior vertebral fractures, height loss, or thoracic back pain (Fig. 29-10).¹³² Although there is agreement that BMD measurements are useful in diagnosis, there is debate about whether both spine and hip should be measured initially.¹³³ Although there is evidence that follow-up

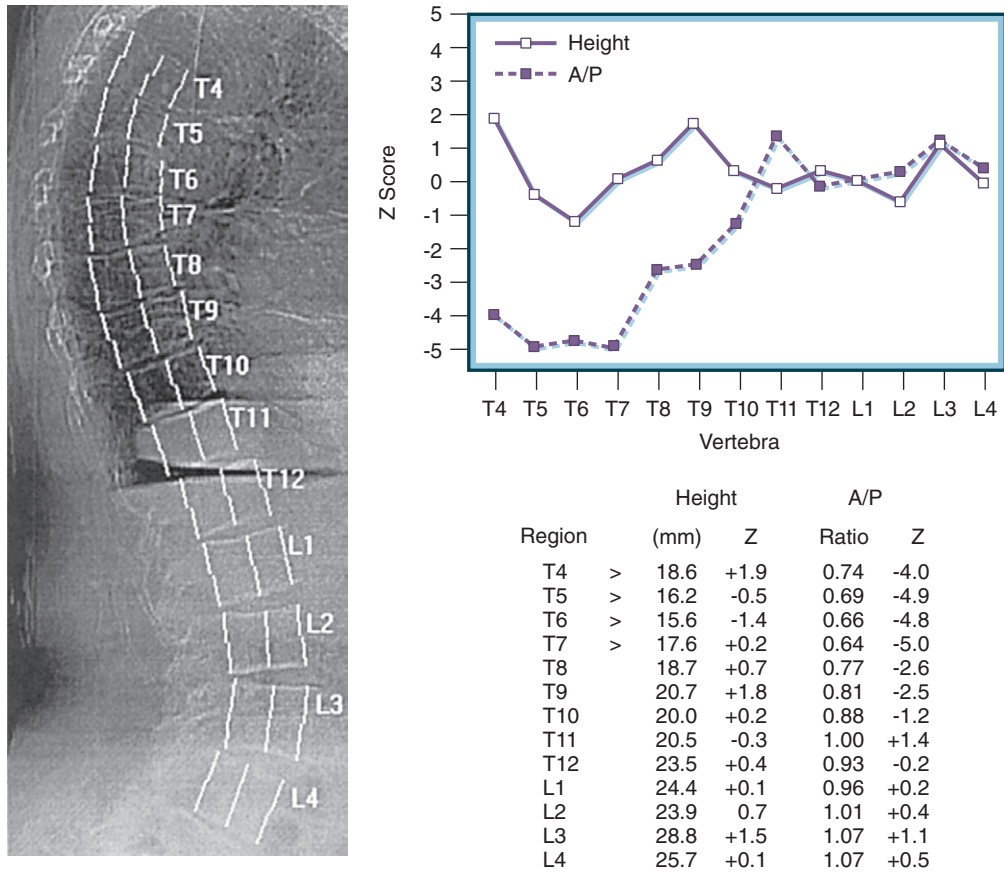

Figure 29-10 Use of dual-energy x-ray absorptiometry for vertebral body morphometry. Posterior vertebral body heights and the ratio of anterior to posterior (A/P) height are presented in terms of standard deviation scores. Minor anterior wedging alone may not indicate an osteoporotic fracture. (Courtesy of Dr. Richard B. Mazess.)

BMD measurements are useful in predicting clinical response, there is debate about its cost-effectiveness.^{134,135}

Quantitative Computed Tomography

QCT, which employs instruments available in most radiology departments, can be used to assess true bone density (g/cm^3) and to separate cancellous and cortical bone in the vertebral body. It can measure trabecular BMD in the presence of osteoarthritis.¹³⁶ QCT has also been used to measure cortical and trabecular bone density in the appendicular skeleton. The radiation exposure (100 to 300 mrem) is larger than for DEXA, and the precision and accuracy are lower but within the acceptable range. A major disadvantage may be cost, although it varies widely.

Peripheral Densitometry

Several methods to measure bone mass and density in the appendicular skeleton have been developed that are less expensive, faster, and more portable than DEXA or QCT.¹³⁷ Measurement of cortical bone in the shaft of the radius and ulna and trabecular bone in the distal radius or calcaneus by radiography, x-ray absorptiometry, or CT scanning is precise and can be used to predict fracture risk in populations, but it cannot predict BMD of the spine and hip in individual patients. The advantages of ultrasonography, particularly of the calcaneus, are that it does not use x-rays, it is rapid and portable, and it can predict fracture risk.¹³⁸ These measurements may be particularly useful for large-scale screening programs.

Biochemical Measurements

One of the most important advances in metabolic bone disease has been development of more accurate biochemical measurements that can assess rates of bone formation and resorption. In population studies, these methods have been used to show that increased turnover (i.e., high rates of resorption and formation) correlates inversely with bone mass and may predict a high rate of bone loss and an increased risk of fracture.¹³⁹⁻¹⁴¹ However, the available markers are characterized by a wide normal range and considerable variability, which limit their use in individual patients.¹⁴² Efforts to standardize these measurements should improve their utility.¹⁴³ The most common clinical use of these assays in patient care is as a rapid assessment of the response to antiresorptive agents. Typically, decreases in resorption markers as a result of therapy can be detected at 3 to 6 months, which is before changes in BMD are measurable by DEXA.^{144,145}

Markers of Bone Formation

Alkaline Phosphatase

Total serum alkaline phosphatase is measured to assess osteoblastic activity in Paget's disease, primary hyperparathyroidism, osteomalacia, and rickets.^{146,147} An immunoassay that selectively measures the bone isoenzyme may increase the usefulness of this test for osteoporosis, in

which changes in osteoblastic activity are smaller. High serum bone-specific alkaline phosphatase values in postmenopausal women have been shown to predict bone loss and fracture incidence.¹⁴⁸

Osteocalcin

Osteocalcin, a bone carboxyglutamic acid-containing protein, is one of the few proteins that are relatively specific for skeletal tissue. A fraction of the osteocalcin synthesized by osteoblasts is released into the circulation. C-terminal cleavage of the molecule may occur after release, but the intact and N-terminal portions can be measured by specific immunoassays. Serum osteocalcin correlates with skeletal growth rates in childhood and puberty and is increased when bone turnover is accelerated (e.g., hyperparathyroidism, hyperthyroidism).^{146,147} In Paget's disease, the osteocalcin level is elevated to a lesser degree than alkaline phosphatase.

Because osteocalcin production is increased by 1,25(OH)₂D, its levels may be low in osteomalacia and rickets, even when the alkaline phosphatase level is elevated. Conversely, osteocalcin levels may be selectively reduced in patients given glucocorticoids to a greater degree than other formation markers. Undercarboxylated osteocalcin is present in patients with vitamin K and vitamin D deficiency and older patients, and it is associated with increased fracture risk.¹⁴⁹ Osteocalcin has been implicated in energy metabolism, but the utility of serum measurements in assessing diabetes, obesity, and atherosclerosis has not been established.^{150,151}

Procollagen Peptides

The N-terminal and C-terminal extension peptides of procollagen (see Fig. 29-2), which are removed during processing of collagen, are released into the circulation. Their measurement is an index of total-body synthesis of collagen, the bulk of which is derived from bone. Procollagen peptide levels correlate with histologic measures of bone formation.¹⁵² Levels of procollagen peptides are high in infants and may provide a clinically useful index of growth. Increases in N-terminal procollagen peptide levels (P1NP) can predict the BMD response to intermittent PTH therapy.¹⁵² High levels of P1NP can predict bone loss and fracture risk¹⁵³ and bone metastases in cancer.¹⁵⁴

Markers of Bone Resorption

Calcium

Measurement of fasting urinary calcium excretion is convenient but shows wide variation, reflecting the net result of intestinal absorption, bone resorption, and mineralization and the renal tubular handling of calcium. Increased urinary calcium occurs when there is a marked increase in osteoclastic activity without a change in formation, as in some patients with osteolytic bone metastases. The association of hypercalciuria with or without nephrolithiasis and low bone mass makes this an important measurement. A new experimental approach has been the measurement of urinary excretion of the stable isotope ⁴¹Ca as a measure of bone resorption.¹⁵⁵ Although the assay is highly accurate, it is currently too expensive for clinical use.

Hydroxyproline

Collagen degradation releases hydroxyproline into the circulation in free and peptide-bound forms. Because bone resorption is by far the largest contributor to collagen breakdown, urinary hydroxyproline excretion has been used as a measure of bone resorption. However, 80% to

90% of the released hydroxyproline is metabolized, and hydroxyproline from collagen or gelatin in the diet is also excreted in urine. Because cross-link excretion can also be used in these conditions, hydroxyproline assays are used infrequently in clinical assessment.

Collagen Cross-Links

Unlike hydroxyproline, the pyridinoline and deoxypyridinoline cross-links that stabilize collagen in the extracellular matrix (Fig. 29-11) are not metabolized but are excreted in the urine in a free or peptide-bound form. The deoxypyridinoline cross-link is largely derived from skeletal tissue and therefore is a more sensitive indicator of bone resorption than pyridinoline, which is also found in skin and other connective tissues.

Measurement of total urinary pyridinoline and particularly deoxypyridinoline by high-performance liquid chromatography (HPLC) probably provides the best measure of bone resorption, but this assay is expensive and time-consuming. Immunoassays have been developed for free pyridinoline and deoxypyridinoline and for peptides that include these cross-links, such as C-terminal telopeptide (CTX) and N-terminal telopeptide (NTX), which are released during resorption. These assays can be carried out in serum or urine, which may increase precision.^{156,157} Measurements correlate with bone turnover and change in response to agents that affect resorption. They are useful in assessing changes in resorption in the course of disease or in response to therapy. They may also be valuable in identifying patients with high bone turnover, who have low bone mass, lose bone rapidly, and are more likely to develop osteoporosis.

All of these assays have shown diurnal variation and may be affected by meals.¹⁵⁸ Fasting serum or fasting, second-voided morning urine samples are probably the most reliable assays.

Other Assays

Tartrate-resistant acid phosphatase 5b is secreted by osteoclasts into serum and may be useful as a measure of bone resorption.^{159,160} Measurements of enzymes such as cathepsin K and other degradation products of bone matrix are being developed.¹⁶¹

Bone Biopsy

Transiliac bone biopsy can provide direct information about cancellous bone volume, the density of connections between trabecular plates (connectivity), and the function of bone cells.¹⁶² The rate of bone formation and mineralization can be measured by this technique with the use of dynamic histomorphometry after tetracycline labeling (Fig. 29-12), but bone resorption is more difficult to assess by bone biopsy. Bone biopsy necessitates the use of a large needle with a 7- to 9-mm internal bore and the technical skill to obtain a sample that is not crushed or distorted. The sample must be processed without decalcification and stained appropriately. Unstained sections are needed to see fluorescent tetracycline labels. Special stains may be used to identify mast cells in mastocytosis or aluminum in renal osteodystrophy.

Bone biopsies are critical for the assessment of therapeutic responses in clinical trials.¹⁶³ They are rarely indicated in the clinical care of patients with osteoporosis, but they may be indicated for patients with unusual skeletal lesions or for young men or women who have fragility fractures with no evident secondary cause. Therapeutic decisions usually can be made without performing biopsies; but they

Figure 29-11 Collagen cross-links. Cross-links are formed between the COOH-terminal and NH₂-terminal nonhelical portions of collagen and adjacent helical molecules. Immunoassays are available for the pyridinoline and deoxypyridinoline molecules and for the adjacent nonhelical peptides. (Redrawn from Eyre DR. The specificity of collagen crosslinks as markers of bone and connective tissue degradation. *Acta Orthop Scand*. 1995;266:166-170.)

may be indicated in renal osteodystrophy because the different forms of this disorder are managed differently.¹⁶⁴

Skeletal Imaging

The use of radiographs, CT, bone scans, and MRI in diagnosis is discussed with specific disorders throughout this chapter. All of these methods are useful in detecting fractures.¹⁶⁵ Methods for assessing microarchitectural changes in the skeleton using high-resolution CT or MRI are rapidly being developed^{122,129,130} but are not ready for general clinical use. High-resolution radiographs and CT images have also been used to assess cortical porosity.

Bone scans using technetium 99m linked to a bisphosphonate are useful in localization of bone lesions. Uptake is a function of blood flow to the region and the amount of mineralizing bone. The test does not give information about the nature of the lesion but may serve as a guide for further studies. Radiographs or CT scans cannot differentiate old from new fractures, but increased uptake on bone scan or edema on MRI can indicate that the fracture is relatively recent.

OSTEOPOROSIS

Primary Osteoporosis

Definition

Osteoporosis is by far the most common metabolic bone disease. One of two white and Asian postmenopausal women and at least one of eight older men and women of other racial backgrounds are likely to have an osteoporotic fracture at some time during their lifetimes (Fig. 29-13).

However, osteoporosis should not be defined simply by the occurrence of fractures. An international Consensus Development Conference¹⁶⁶ more correctly labeled it as “a disease characterized by low bone mass and microarchitectural deterioration of bone tissue, leading to enhanced bone fragility and a consequent increase in fracture risk.”

Diagnostic categories for postmenopausal women are based on measurements of BMD (Table 29-2). Although these categories are arbitrary and do not define distinct clinical processes, they do give some indication of fracture risk. However, the risk of fracture at any given BMD increases markedly with age and can be affected by a number of other factors.^{167,168}

A more rational approach to diagnosis and management is to obtain an estimate of fracture risk based on all factors

TABLE 29-2

Diagnostic Categories for Osteoporosis Based on Measurements of Bone Mineral Density (BMD) and Bone Mineral Content (BMC)

Category	Definition
Normal	BMD or BMC \pm 1 SD of the young adult reference mean
Low bone mass (osteopenia)	BMD or BMC $>$ 1 SD and $<$ 2.5 SD lower than the young adult mean
Osteoporosis	BMD or BMC $>$ 2.5 SD lower than the young adult mean
Severe osteoporosis (established osteoporosis)	BMD or BMC $>$ 2.5 SD lower than the young adult mean in the presence of one or more fragility fractures

BMC, Bone mineral content; BMD, bone mineral density; SD, standard deviation.

Figure 29-12 Tetracycline labels sites of active mineralization and is deposited at the calcification front (Cf) (top). A double-label technique can be used to measure the rate of mineralization; label A was administered about 10 days before label B (bottom). The undecalcified iliac crest is seen under ultraviolet light (original magnification, $\times 113$). (From Aaron J. Histology and microanatomy of bone. In Nordin BEC, ed. *Calcium, Phosphate and Magnesium Metabolism*. Edinburgh, UK: Churchill Livingstone; 1976:298-356.)

Figure 29-13 Estimated prevalence of osteoporosis in the United States. On the basis of World Health Organization criteria, more than 9 million U.S. women have osteoporosis; more than one half of these women have established osteoporosis with fractures. Seventeen million postmenopausal women have osteopenia (i.e., low bone mass) and are at risk for osteoporosis. (From Melton LJ. How many women have osteoporosis now? *J Bone Miner Res*. 1995;10:175-177.)

TABLE 29-3

Estimated Lifetime Fracture Risk in Women and Men from Rochester, Minnesota, at Age 50 Years

Fracture Site	Women (% [95% CI])	Men (% [95% CI])
Proximal femur	17.5 (16.8-18.2)	6.0 (5.6-6.5)
Vertebra*	15.6 (14.8-16.3)	5.0 (4.6-5.4)
Distal forearm	16.0 (15.7-16.7)	2.5 (2.2-3.1)
Any of the above	39.7 (38.7-40.6)	13.1 (12.4-13.7)

*Clinically diagnosed fractures.

95% CI, 95% confidence interval.

in individual patients. The use of T-scores and FRAX analysis (discussed later) to categorize BMD measurements as indicating the presence or absence of osteoporosis is complicated by the fact that the estimation of fracture risk is site and method specific.¹⁶⁹

Epidemiology

Osteoporosis was once considered a disorder of postmenopausal women of Northern European descent because they have high rates of fractures.^{170,171} However, the frequency of fragility fractures is high in men and women throughout the world^{172,173} and is likely to increase further as life expectancy increases. Moreover, the age-adjusted incidence of hip fractures in many parts of the world is rising, possibly because of increased industrialization and decreased physical activity. Most of the epidemiologic data are for hip fractures, but vertebral fractures are equally common. In one study, the lifetime risk of osteoporotic fractures of the hip, spine, or wrist after age 50 years was about 40% in women and 13% in men (Table 29-3). The temporal pattern of the increase in fracture incidence differs for the hip, spine, and wrist (Fig. 29-14).

Pathogenesis

Understanding of the pathogenesis of primary osteoporosis remains largely descriptive.¹⁷⁴ Decreased bone mass and increased fragility can occur because of failure to achieve optimal peak bone mass, bone loss caused by increased bone resorption, or inadequate replacement of lost bone as

Figure 29-14 Age-specific incidence rates for hip, vertebral, and Colles' fractures in Rochester, Minnesota. (From Cooper C, Melton LJ. Epidemiology of osteoporosis. *Trends Endocrinol Metab*. 1992;3:224. Copyright 1992 by Elsevier Science Inc.)

a result of decreased bone formation. Moreover, an analysis of the pathogenesis of osteoporosis must take into account the heterogeneity of clinical expression.

Inadequate Peak Bone Mass and Strength. Studies of twins suggest that genetic determinants are responsible for up to 85% of the variation in peak bone mass and may also determine bone turnover and fracture risk.¹⁷⁵ Polymorphisms of candidate genes, including vitamin D and estrogen receptors, collagen, cytokines, neurotransmitters and growth regulators, have been analyzed to assess their possible roles in determining peak bone mass, remodeling, and fracture risk.¹⁷⁶⁻¹⁸⁰ Larger populations have been studied, but the results usually show small effects. This may reflect the fact that it is difficult to determine the appropriate control population or that these polymorphisms may reflect effects of linked genes.¹⁸¹ Moreover, gene effects may be influenced by environmental factors.

A broader search for quantitative trait loci associated with differences in bone mass has identified a number of chromosomes that may be involved in determining peak bone mass, architecture, and turnover. These loci may be different in men and women.¹⁸²⁻¹⁸⁴ Genome-wide association studies have identified a series of genes that make contributions to bone mass (reviewed by Ralston and Uitterlinden¹⁸⁵).

Although the major determinants of peak bone mass and strength are genetic, factors during childhood and adolescence can affect the ability to achieve optimal peak bone mass.¹⁸⁶ These factors include nutrition (particularly of calcium), physical activity, and a wide variety of intercurrent illnesses. Estrogen plays a critical role in men and women in regulating bone remodeling and in determining the time of epiphyseal closure.¹⁸⁷

Increased Resorption. Peak bone mass is probably achieved in the 20s. Over the next 3 decades, there is some bone loss, but fragility fractures are rare, even in those who have low peak bone mass.^{188,189} An increase in the rate of Colles' fractures occurs before menopause in women, whereas the increase in vertebral and hip fractures begins after menopause in women and in men in their 80s (see Fig. 29-14). Increased bone resorption is the major mechanism for increased skeletal fragility. The time required for resorption is much shorter than that for formation in the bone remodeling cycle; any increase in the number of resorption sites produces decreased bone mass and changes in microarchitecture, which lead to a more fragile skeleton.¹⁹⁰ High rates of bone remodeling, as reflected by high values for the biochemical markers of bone turnover, persist into old age and are associated with an increased risk of fracture, independent of BMD.¹⁹¹

Decreased Bone Formation. Skeletal bone mass increases during puberty and young adult life, even though the rate of resorption is high. Menopausal and age-related bone loss must involve an impairment of bone formation relative to resorption. With age, the amount of bone formed decreases with each bone structural unit, as evidenced by a decrease in mean wall thickness. This decrease may be due to an age-related decline in skeletal growth factors.¹⁹² Biopsies of patients with established osteoporosis often show decreased bone formation.¹⁹³

Biochemical Abnormalities. Classically, osteoporosis is differentiated from disorders such as osteomalacia and osteogenesis imperfecta by the fact that there is no obvious defect in mineralization or the structure of collagen.

However, polymorphisms in the collagen gene *COL1A*, glycation end products, or differences in circulating homocysteine levels may result in an increased risk of fracture independent of BMD.¹⁹⁴⁻¹⁹⁷ This may reflect subtle alterations in the collagenous matrix.^{198,199} Differences in crystal structure and alignment have also been described, but they may be the consequence of differences in turnover.²⁰⁰ The further possibility that one or more of the many noncollagen proteins in bone is abnormal in osteoporosis has not been adequately explored.

Pathogenetic Factors

Systemic Hormones. In the past, the search for pathogenetic factors in osteoporosis focused primarily on systemic hormones. A critical role for estrogen deficiency is supported by the fact that postmenopausal women have the highest incidence of osteoporosis and the lowest levels of estradiol. Moreover, estrogen levels correlate strongly with BMD in elderly men, and low estrogen levels are associated with increased fracture risk in men.²⁰¹⁻²⁰³

Osteoporosis can occur, albeit rarely, in the absence of any evidence of gonadal hormone deficiency, but defects in receptors for these hormones and other downstream events may be involved. Low BMD and osteoporosis are also associated with high levels of sex hormone-binding globulin (SHBG).^{204,205} This association may reflect decreased availability of sex hormones to the tissues when SHBG levels are high. Follicle-stimulating hormone (FSH) has been implicated as a mediator of increased turnover, but it does not appear to play a central role.²⁰⁶⁻²⁰⁸

Other systemic hormones may be involved in age-related bone loss. PTH levels increase with age, and fracture risk is increased in hyperparathyroidism.²⁰⁹ The increase is probably caused by decreased dietary intake and impaired intestinal absorption of calcium, which is often associated with vitamin D deficiency. Secondary hyperparathyroidism and vitamin D deficiency accelerate bone loss and impair neuromuscular functions. This increases the risk of falls and fractures.^{210,211} However, PTH levels in patients with vertebral fractures are not different from those in age-matched control subjects. The 25(OH) vitamin D levels are often decreased in the elderly and particularly in osteoporotic patients.²¹² Calcitonin deficiency does not appear to play a role in osteoporosis,²¹³ although pharmacologic doses of calcitonin can prevent bone loss or increase bone mass in patients with high bone turnover.

Glucocorticoid excess can produce secondary osteoporosis but does not appear to play a major role in primary osteoporosis. Growth hormone secretion and circulating IGF1 levels decrease with age, and differences in IGF1 levels have been associated with fracture risk and bone cell function.^{192,214} Thyroid hormone excess may exacerbate bone loss, and hyperthyroidism and hypothyroidism are associated with increased fracture risk.^{215,216}

Local Factors. Two features of osteoporosis suggest a role for local factors in pathogenesis. Systemic hormones that influence the skeleton, including estrogen and PTH, alter the production of local factors (e.g., cytokines, prostaglandins, growth factors)²¹⁷ and the differential bone loss that occurs in different parts of the skeleton.

Limited genetic and biochemical data support a role for cytokines in human osteoporosis.²¹⁸⁻²²⁰ The most striking evidence for the role of cytokines in the bone loss of estrogen deficiency comes from rodent models. The loss of bone after ovariectomy in rats can be blocked by inhibiting the activity of IL-1 and TNF- α .²²¹ Ovariectomy does not cause bone loss in mice lacking the receptor for IL-1.²²² PGE₂

production is increased in bones from oophorectomized animals and decreased by estrogen administration.²²³ Studies in rodent models suggest the existence of an important interaction between cytokines produced by cells in the marrow (possibly hematopoietic and mesenchymal) and osteoblasts.²¹⁸ These local factors act through the RANKL-RANK system, including OPG, but defects in this system have not been identified in osteoporotic patients.^{224,225} OPG levels in the blood are positively rather than negatively associated with BMD and fracture risk.^{226,227}

It is likely that skeletal and systemic production of IGF or IGF-binding proteins plays a role in osteoporosis.²¹⁴ Other growth factors, including BMP2, have been implicated in genetic studies.

Nutrition and Lifestyle

Calcium or vitamin D deficiency and decreased physical activity in early life can contribute to a failure to achieve optimal peak bone mass, accelerated bone loss later in life, and increased fracture risk.^{186,228,229} Calcium and vitamin D supplementation can slow bone loss and reduce fractures in elderly people.²³⁰⁻²³²

Low protein intake is associated with increased fracture in the United States, although in worldwide epidemiologic studies, high animal protein intakes are associated with increased risk.^{233,234} Vitamin K deficiency is associated with increased hip fracture risk.²³⁵ There are also positive correlations among body fat, lean body mass, and bone density. One mechanism for the relatively high bone density of overweight people may be conversion of adrenal androgens to estrogens in fat. Another pathway may be the decrease in SHBG associated with increased body mass index.²³⁶ Increased fat and muscle mass can lead to increased impact loading and mechanical stress on bone. Through a variety of mechanisms, smoking significantly increases the risk of osteoporosis.²³⁷⁻²³⁹

Nonskeletal Factors

Low body weight and weight loss are important risk factors for osteoporotic fractures. Nonskeletal effects, such as decreased padding of the hip and decreased muscle strength, likely play a role. Neuromuscular factors, such as loss of muscle strength, impaired balance, and impaired

vision, are important, particularly by increasing the risk of falls that result in hip fracture.²⁴⁰ Drugs that affect the central nervous system or decrease vascular volume and cause postural hypotension also are likely to increase this risk, particularly in older adults.

Clinical Features

Vertebral Crush Fractures. Compression fractures of the vertebrae, which occur spontaneously or with minimal trauma, are the most common manifestation of osteoporosis. The terms *postmenopausal osteoporosis* and *type 1 osteoporosis* have been applied to vertebral crush fractures at a younger age, which occur mainly in women, whereas *senile osteoporosis* and *type 2 osteoporosis* have been used for hip fractures in older women and men.²⁴¹ However, these distinctions may not be helpful clinically. These groups overlap, and patients with any type of osteoporotic fracture are more likely to have subsequent fractures of the spine or the hip.

The clinical course of the vertebral crush fracture syndrome varies. Some patients exhibit compression of only one vertebra, but others show collapse of multiple vertebrae. Nevertheless, the risk of additional fractures is high.²⁴² Vertebrae may show extensive loss of trabecular structure before they collapse (Fig. 29-15). Radiologically, fractures can vary from mild end-plate deformities or anterior wedging to complete vertebral collapse (Fig. 29-16). They may be unstable, particularly at the thoracolumbar junction.²⁴³ The most common fractures are in the thoracic vertebrae below T6 and in the lumbar vertebrae.

Patients with vertebral crush fractures often have back pain that leads to radiologic assessment. Pain in the lumbar or sacral area, compared with pain in the thoracic area, is less likely to be associated with vertebral compression. Height loss is a sensitive indicator of compression, but height loss can occur without fractures as a result of narrowing of vertebral disks and postural changes.²⁴⁴ Many patients are asymptomatic. Silent vertebral fractures are still an indication of increased risk and can be assessed by DEXA or radiographs.²⁴⁵⁻²⁴⁸ However, anterior wedging in the upper thoracic vertebrae (T5 to T8) is common in older men and women and is not necessarily caused by compression fractures. Bone density measurements can help predict

Figure 29-15 Scanning electron micrographs of a normal vertebra from a 31-year-old man and an osteoporotic vertebra from an 89-year-old woman show extensive loss of trabecular bone architecture with conversion of plates to rods and a microfracture. (From Boyd A. Morphologic detail of aging bone in human vertebrae. *Endocrine*. 2002;17:5-14.)

Figure 29-16 Types of vertebral compression fractures. Changes in vertebral height can be quantitated by measuring percent change or standard deviations from expected normal heights. (From Genant HK, Wu CY, van Kuijk C, et al. Vertebral fracture assessment using a semiquantitative technique. *J Bone Miner Res.* 1993;8:1137-1148.)

fracture risk in these patients. Anterior wedging may also develop early in life, probably during pubertal growth, because of a genetic disorder called *Scheuermann's disease*.²⁴⁹

Multiple vertebral crush fractures cause severe impairment. Kyphosis and loss of the lumbar lordosis are deforming and can exacerbate back pain. Impairment of chest wall function may reduce vital capacity.²⁵⁰ Compression of abdominal contents may be disfiguring and uncomfortable. Ultimately, impingement of the ribs on the iliac crest is another source of pain. Many patients have additional spinal abnormalities, including spondylolisthesis, intervertebral disk disease, and osteoarthritis, particularly in the spinal facets. Osteoporosis itself rarely compresses nerve roots or the spinal cord. Although patients with severe osteoarthritis are somewhat less likely to have osteoporosis, these two common disorders often occur in the same patient.^{251,252}

Hip Fracture. Fractures of the proximal femur are a major cause of morbidity and mortality in older people. Most fractures are in the femoral neck or at the base of the greater trochanter and are associated with trauma, although the trauma may be minimal. The risk is influenced by factors that increase the risk of falling and by the type of fall, as well as the structure of the skeleton and surrounding soft tissue. The increased incidence of hip fractures with age is caused by increased falls and by continued bone loss.²⁵³

Hip fracture is usually treated surgically, and the costs are substantial. Perioperative and postoperative complications are associated with a 5% to 20% mortality rate. Many elderly patients cannot return to their previous level of activity after hip fracture and require long-term nursing home care. It is important to perform a diagnostic evaluation and to develop a prevention and treatment plan for these patients because a second hip fracture or a fragility fracture at another site is likely to occur.²⁵⁴ Unfortunately, most patients with hip fractures do not undergo evaluation

or treatment to prevent progression of osteoporosis and the development of additional fractures.²⁵⁵

Colles' Fracture. Colles' fractures of the distal radius, which is composed largely of trabecular bone, are caused by falling on an outstretched hand. The incidence among women begins to increase after age 40 years and may be associated with premenopausal and perimenopausal bone loss and with genetic factors.^{256,257} Unlike vertebral and hip fractures, the incidence of Colles' fractures in men does not increase with age. Colles' fractures usually heal well and only occasionally result in long-term morbidity. Patients with a Colles' fracture should be assessed for osteoporosis so that an appropriate treatment plan can be provided.²⁵⁸

Other Fractures. Fractures at any site, with the possible exception of the face and skull, can be associated with osteoporosis. Measurements of bone mass and further diagnostic workup are indicated for all fractures that occur with minimal trauma and for older patients with high-trauma fractures.²⁵⁹

Osteoporosis in Men

The incidence of hip and spine fractures for men increases with age and is about one third that for women.²⁰³ Men often have vertebral deformities associated with trauma earlier in life, whereas increases in hip fractures tend to occur later in life, and a higher proportion of men have definable secondary causes.²⁶⁰ Bone histomorphometry in typical patients shows increased resorption and decreased formation.²⁶¹

Osteoporosis in men is associated with low androgen and estrogen and high SHBG levels.^{262,263} Abnormalities of the IGF system and polymorphism of the *LRP5* gene are also implicated.^{264,265} A diagnostic workup and therapeutic plan should be provided for men with fragility fractures, but this is rarely carried out in practice. Screening for osteoporosis in older men who do not have fractures has not

been evaluated but may be justified now that preventive therapy is available.

Juvenile Osteoporosis

Juvenile osteoporosis is a rare, self-limiting disease that can begin between the ages of 8 and 14 years with back pain and vertebral compression.^{266,267} Antiresorptive agents may be beneficial.²⁶⁶ However, deficient bone formation may be the critical defect leading to fractures in these children.²⁶⁸ Mutations in type I collagen and LRP5 have been reported in this disorder.^{269,270} Spontaneous remission usually occurs, and the disorder usually does not lead to permanent deformity.

Idiopathic Osteoporosis

Osteoporosis with no obvious secondary cause in premenopausal women or younger men is called *idiopathic osteoporosis*. The term is not used consistently, and patients so defined include individuals with high and low bone turnover.^{271,272} Some patients have a transient, self-limited condition, whereas others have a progressive and disabling disease. Idiopathic osteoporosis can be associated with nonspecific inflammatory changes, and these cases may be caused by abnormal cytokine activity.²⁷³ A careful evaluation, including consideration of bone biopsy, should be made to search for secondary causes.

Osteoporosis in Pregnancy

Osteoporosis in pregnancy is rare and may represent a genetically determined bone disease that was present before pregnancy.²⁷⁴ Bone loss can occur during pregnancy and lactation, but this is transient and ordinarily not a risk factor for osteoporosis.²⁷⁵

Localized Osteoporosis

Immobilization is the most common cause of localized osteoporosis (discussed later). Transient osteoporosis of the hip has been reported in middle-aged men and in pregnant women.²⁷⁶ Regional migratory osteoporosis can occur without immobilization, particularly in the lower extremities.²⁷⁷ This phenomenon may be associated with local inflammation or autonomic dysfunction with vasomotor changes and hyperesthesia, a syndrome called *reflex sympathetic dystrophy* (RSD) or complex regional pain syndrome.²⁷⁸

Secondary Osteoporosis

The division of osteoporosis into primary and secondary forms is somewhat arbitrary. For example, patients with diseases that lead to hypogonadism early in life are considered to have *secondary* osteoporosis, whereas osteoporosis in women with natural menopause and older men with low sex hormone levels is called *primary*. Moreover, patients may have a combination of primary and secondary causes. Although most postmenopausal women and older men do not have a definable secondary cause, those who do can be treated more effectively. This possibility should be considered for every patient. There are many causes of secondary osteoporosis (Table 29-4), only a few of which are discussed here.²⁷⁹

Glucocorticoid-Induced Osteoporosis

The most common form of secondary osteoporosis is that induced by exogenous glucocorticoids.²⁸⁰ Cushing's syndrome, caused by an excess of endogenous glucocorticoids, is less common but may also involve osteoporosis at presentation. Patients with rheumatoid arthritis, chronic pulmonary disease, or inflammatory bowel disease who receive

TABLE 29-4

Causes of Secondary Osteoporosis

Endocrine Disorders

Hyperparathyroidism
Cushing's syndrome
Hypogonadism
Hyperthyroidism
Prolactinoma
Diabetes mellitus
Acromegaly
Pregnancy and lactation

Hematopoietic Disorders

Plasma cell dyscrasias: multiple myeloma and macroglobulinemia
Systemic mastocytosis
Leukemias and lymphomas
Sickle cell disease and thalassemia minor
Lipidoses: Gaucher's disease
Myeloproliferative disorders: polycythemia

Connective Tissue Disorders

Osteogenesis imperfecta
Ehlers-Danlos syndrome
Marfan's syndrome
Homocystinuria and lysinuria
Menkes' syndrome
Scurvy

Drug-Induced Disorders

Glucocorticoids
Heparin
Anticonvulsants
Methotrexate, cyclosporine
Luteinizing hormone-releasing hormone (LHRH) agonist or antagonist therapy
Aluminum-containing antacids

IMMOBILIZATION

Renal Disease

Chronic renal failure
Renal tubular acidosis

Nutritional and Gastrointestinal Disorders

Malabsorption
Total parenteral nutrition
Gastrectomy
Hepatobiliary disease
Chronic hypophosphatemia

Miscellaneous

Familial dysautonomia (Riley-Day syndrome)
Reflex sympathetic dystrophy

exogenous glucocorticoids are at additional risk, because disease-associated inflammation, poor nutrition, and immobilization can worsen bone loss. Glucocorticoid-induced osteoporosis is particularly common in postmenopausal women, presumably because they also have primary osteoporosis. However, fragility fractures can occur in any patient receiving chronic glucocorticoids. The increased fracture risk appears within a few months of initiating therapy and rapidly declines after cessation of treatment.¹⁸⁴

Glucocorticoid-induced osteoporosis is a result of increased bone resorption and decreased bone formation. Increased resorption may be related to the induction of RANKL and M-CSF by bone marrow stromal cells and osteoblastic cells. Glucocorticoids decrease the intestinal absorption of calcium and increase urinary calcium and

phosphate excretion, but they do not appear to cause secondary hyperparathyroidism.^{58,60} Decreased bone formation is caused by an inhibition of cell replication, differentiation of osteoblast precursors, and suppression of osteoblastic function.⁵⁸ Even at low doses, glucocorticoids can affect bone remodeling. For example, as little as 2.5 mg of prednisone given at bedtime can block the normal nocturnal rise in osteocalcin levels.²⁸¹ Glucocorticoids can decrease osteoblast and osteocyte number by increasing apoptosis²⁸² and may increase osteoclast number by preventing apoptosis.²⁸³ Glucocorticoids inhibit gonadal hormone production by blocking gonadotropin release. Levels of testosterone are low in men receiving glucocorticoids.²⁸⁴ Exogenous glucocorticoids decrease secretion of corticotrophin, thereby decreasing the production of adrenal androgens, which are the major precursors for estrogen formation in postmenopausal women.

Clinically, glucocorticoid-induced osteoporosis has some similarities to postmenopausal osteoporosis, but at comparable levels of BMD, the risk of fractures is higher in glucocorticoid-induced osteoporosis than in postmenopausal osteoporosis.²⁸⁵ Initial bone loss is predominantly trabecular and is best assessed in the spine or distal radius. However, rib fractures and aseptic necrosis of the femoral or humeral heads or the vertebrae are common in glucocorticoid-induced osteoporosis. In contrast, they are rare in primary osteoporosis. Glucocorticoid-induced osteoporosis can be reversible, particularly in young patients who are cured of Cushing's syndrome.²⁸⁶ In patients who cannot discontinue glucocorticoid therapy, early preventive therapy may be effective. Bisphosphonates and teriparatide prevent bone loss and decrease fracture risk in patients with glucocorticoid-induced osteoporosis.²⁸⁷⁻²⁹¹

Hypogonadism

Hypogonadism, which can occur in men or women, has multiple causes. Patients with primary hypogonadism related to ovarian or testicular failure or secondary hypogonadism related to hypothalamic or pituitary disease lose bone rapidly and often have fragility fractures. The hypogonadotropic group includes patients with anorexia nervosa, athletic amenorrhea, prolactinoma, or lesions of the pituitary gland or hypothalamus, including tumors. Undernutrition and hypercortisolism may also contribute to bone loss in anorexia nervosa and athletes who develop amenorrhea.²⁹²⁻²⁹⁴ Loss of growth hormone and consequently IGF1 may play a role in the osteoporosis of pituitary tumors.

The frequency of drug-induced hypogonadism is increasing. Long-acting progestins used for contraception in young women cause bone loss that is usually reversible.²⁹⁵ Gonadotropin-releasing hormone (GnRH) analogues and aromatase inhibitors, which are used to block sex hormone production in women with breast cancer or endometriosis and men with prostate cancer, can cause rapid bone loss.²⁹⁶⁻²⁹⁹

Other Endocrine Causes

Thyroid hormone excess or deficiency may increase the risk of fractures.^{215,216} In young women with hyperthyroidism who are treated early, only small changes in bone mass may occur because increases in formation rates match those of resorption.³⁰⁰ In individuals at risk for osteoporosis, primary hyperthyroidism may be missed, or excessive amounts of exogenous thyroid hormone may be administered for many years. Osteoporosis can occur in patients with growth hormone deficiency and can respond to

growth hormone replacement.^{76,301} Active acromegaly also is associated with an increased risk of osteoporotic fractures in postmenopausal women and in men.^{302,303} A large pituitary tumor may cause gonadotropin deficiency and bone loss.³⁰⁴ Decreased estradiol levels may be the main determinant of low BMD in both sexes.

Patients with insulin-dependent diabetes mellitus often have low bone mass and diminished bone formation, perhaps because they lack an anabolic effect of insulin.³⁰⁵ The role of non-insulin-dependent (type 2) diabetes mellitus in the pathogenesis of osteoporosis is unclear. BMD and structural parameters of bone strength are usually normal or high in type 2 diabetes mellitus, but they do not confer fracture protection because bone load to strength ratios are higher in diabetic patients, and the incidence of fractures may be increased in these individuals.³⁰⁶⁻³⁰⁸ The frequency of falls may also be increased, and contribute to the risk of fractures.

Malignancy

Multiple myeloma and other lymphoproliferative malignancies can produce a clinical picture that resembles primary osteoporosis. It is particularly important to exclude myeloma in patients with rapidly progressive vertebral crush fracture syndrome. Myeloma may cause rapid bone loss because the malignant cells produce stimulators of resorption and inhibitors of formation.^{309,310} One of these formation inhibitors has been identified as DKK1, which blocks Wnt signaling and impairs osteoblastogenesis.³¹⁰ Metastases to the spine may also cause vertebral compression and should be considered in the differential diagnosis, particularly for patients with normal bone density. These lesions can usually be differentiated from osteoporotic fractures by MRI.³¹¹

Other Diseases

The incidence and severity of osteoporosis are increased in patients with chronic hepatic and inflammatory bowel diseases. This is related to poor nutrition, the use of glucocorticoids and other drugs that affect the skeleton, and increased cytokine production.^{312,313} The cause of osteoporosis in patients with celiac disease is complex. Calcium and vitamin D absorption may be impaired, but a chronic inflammatory component also contributes to the bone disorder.^{314,315} Although it was initially thought that impairment of vitamin D function in hepatic and intestinal disease would cause osteomalacia, the most common lesion in such patients is osteoporosis, and these patients often do not respond to vitamin D supplementation. People with severe alcoholism also can have osteoporosis; however, lower intakes of ethanol may be associated with increased bone mass and a decreased fracture risk.³¹⁶

Mastocytosis causes osteoporosis and osteosclerosis, and the number of mast cells may be increased in the marrow of patients with primary osteoporosis.³¹⁷⁻³¹⁹ The functional significance of the mast cells is unknown, although they do produce heparin, which can cause bone loss. Hyperplastic anemias, such as thalassemia, can also cause bone loss,³²⁰ partly because of bone erosion by the marrow and partly because of hypogonadism associated with transfusion-induced hemochromatosis.³²¹ Osteoporosis after organ transplantation is common and results from the underlying disease and from the drugs used to prevent graft rejection.³²²

Drugs

Several drugs can produce osteoporosis.^{279,323} Heparin stimulates bone resorption and inhibits bone formation and

can cause osteoporosis. Patients receiving anticonvulsants, including phenytoin, barbiturates, and carbamazepine, often have low bone mass. Impairment of vitamin D metabolism has been described, but most patients have osteoporosis with normal mineralization. Patients receiving selective serotonin reuptake inhibitors have increased risk of fractures and serotonin inhibits osteoblastic cell replication and bone formation.^{178,324} Immunosuppressive agents, such as cyclosporine, FK506, and glucocorticoids are associated with bone loss. GnRH analogues, which decrease production of gonadal hormones, and aromatase inhibitors, which block formation of estrogen from androgen, can lead to osteoporosis.^{325,326} Long-acting progestins can cause hypogonadism and bone loss. Some agents used in cancer chemotherapy probably act by inhibiting osteoblasts and by suppressing gonadal hormones. Long-term use of proton pump inhibitors, frequently prescribed for the prevention and treatment of gastroesophageal disorders, is associated with bone loss and increased risk of fractures.^{327,328} In contrast, histamine H₂-receptor antagonists are not associated with increased risk of fractures.³²⁹ Thiazolidinedione (TZD) use for the treatment of type 2 diabetes is associated with bone loss.³³⁰⁻³³² The mechanism involves the activation of peroxisome proliferator activated receptor- γ (PPAR γ), which inhibits osteoblastogenesis and favors adipogenesis.^{262,333-335}

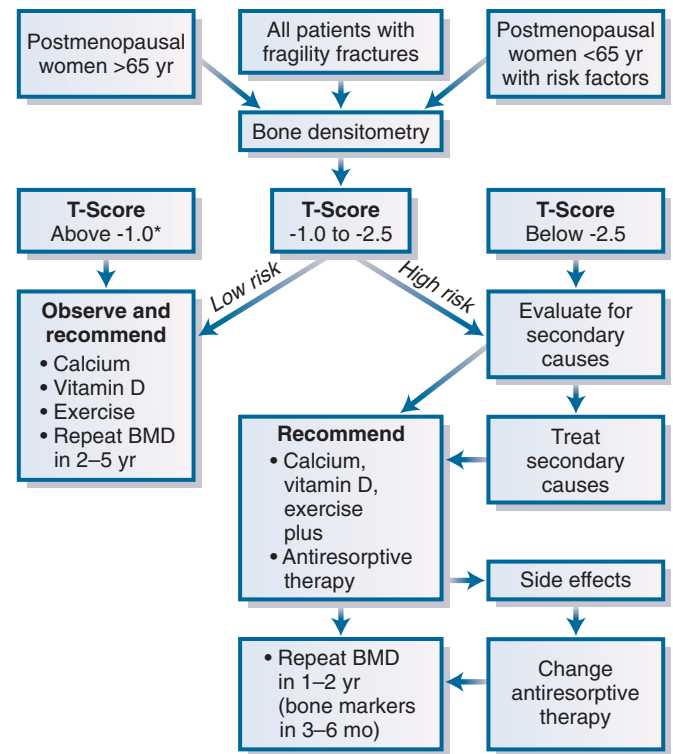

Diagnosis

As indicated by the World Health Organization (WHO), osteoporosis can be diagnosed before fracture occurs by measuring bone density. The frequency of diagnosis therefore depends on the frequency, site, and timing of bone density measurements.^{336,337} Although there is not complete agreement about who should be screened or when screening should be done, a suggested approach is illustrated in Figure 29-17.

Because the goal of diagnosis in patients who have no fractures is to predict fracture and decide about preventive therapy, BMD alone is insufficient; age and other risk factors can be added to BMD or used separately for this purpose based on the WHO fracture risk assessment test FRAX (<http://www.shef.ac.uk/FRAX/> [accessed February 2011]).¹²⁸ Although it is based on a limited number of factors, it does provide an estimate of the 10-year probability of a fragility fracture and a separate estimate for hip fracture. FRAX scores without BMD values can be used for treatment decisions, but they may be misleading in some groups.³³⁸

Universal screening of postmenopausal women after age 65 years has been recommended as cost-effective.^{339,340} Earlier screening is recommended for women who have multiple risk factors, such as low body weight or a personal or family history of fragility fractures (defined as appendicular or axial fractures after a fall from a standing height or less). Bone density should also be measured in men and premenopausal women with fragility fractures. BMD measurements may be useful in early postmenopausal women under consideration for hormone replacement therapy (HRT). Bone density measurements can establish the severity of bone loss, which can further predict risk,³⁴¹ and may be used to monitor therapeutic response.^{342,343} The test may also enhance health-related behavior.^{344,345}

The subsequent workup should be the same whether osteoporosis is diagnosed on the basis of screening or after the finding of a fragility fracture. The history should include a detailed analysis of calcium intake and nutrition, changes in height or weight, physical activity and lifestyle, smoking history, menstrual and reproductive history, and

*Patients with fragility fractures and a T-score above -1.0 should be evaluated for other causes of pathologic fracture.

Figure 29-17 Diagnosis and management of osteoporosis. The diagram outlines an approach based largely on evidence from studies of postmenopausal white women, with dual-energy x-ray absorptiometry used to measure bone mineral density (BMD). Its application to other populations, including patients with secondary osteoporosis and other methods of assessing BMD, is not established.

personal or family history of fragility fractures or other metabolic or endocrine disorders that may affect the skeleton. Physical examination should include a careful height measurement, assessment of the spine, and evaluation for thyroid or adrenal disease.

Radiologic assessment of spine fractures (many of which are silent) should be considered using DEXA and ordinary radiographs.¹³² MRI or CT may be indicated if there are neurologic changes or there are fractures associated with normal bone density, which raises the possibility of malignancy.

A minimal laboratory screen should include measurement of serum calcium as ionized calcium or with albumin to permit correction for protein-bound calcium and urinary 24-hour or fasting calcium (most easily measured as the calcium-to-creatinine ratio in the second-voided morning specimen). Routine measurement of 25-hydroxyvitamin D may be indicated. Appropriate tests to exclude secondary causes of osteoporosis should be based on the history and physical findings. Serum phosphorus and alkaline phosphatase are useful in ruling out hyperparathyroidism and osteomalacia. Measurements of 1,25-dihydroxyvitamin D and PTH are indicated if the screening test results are abnormal. Serum electrophoresis, complete blood cell count, and erythrocyte sedimentation rate can help to rule out myeloma, and thyroid function should be assessed. Laboratory studies for Cushing's syndrome are indicated in patients with suggestive clinical features. Measurements of gonadal and pituitary hormones are indicated for younger

patients with osteoporosis. Gluten-sensitive enteropathy should be ruled out in patients with low body weight or frequent bowel movements.

Despite the inverse correlation between markers of bone resorption and formation and bone mass, these measurements have wide variations and cannot substitute for measurements of BMD in the diagnosis of osteoporosis. Because elevated values of resorption and formation markers do indicate increased risk for bone loss and fractures, these measurements may become useful in determining the need for and response to therapy, particularly if they can be made more accurate and less expensive.³⁴⁶

Prevention and Therapy

Although it is important to relieve pain and to limit the impact of deformities in established osteoporosis, the primary goal of treatment is to prevent fractures. Prevention and therapy are considered together in the following sections.

Nutrition and Calcium Supplementation

The calcium intakes recommended for prevention and treatment of osteoporosis range from 1 to 2 g/day.^{347,348} Most studies indicate that calcium supplementation slows bone loss,³⁴⁹ but there is limited evidence that calcium supplementation alone can decrease fracture risk.^{350,351} Low calcium intakes in the presence of low calcium absorption increases the risk of hip fractures.³⁵²

The Institute of Medicine (IOM) of the United States National Academy of Sciences released a report in November 2010 on dietary reference intake recommendations for calcium and vitamin D (1). The IOM report set the recommended dietary allowance (RDA) for calcium to between 700 mg per day for individuals 1 to 3 years old and 1200 mg per day for 51 to 70-year-old females and all individuals older than 71 years of age. Pregnant or lactating females aged 14 to 18 years were assigned an RDA of 1300 mg per day. The RDA is an estimation of the minimum amount of supplement that needs to be consumed to fully meet the needs of 97.5% of the population. The report stated that the upper safe level of intake for calcium ranged from 2000 to 3000 mg per day.

There is no clear advantage for any particular calcium formulation. *Calcium carbonate* is inexpensive and, when taken with meals, is usually well absorbed, even in patients with achlorhydria.³⁵³ *Calcium citrate* and other salts may be absorbed better than calcium carbonate in the fasting state or in patients who do not produce gastric acid.³⁵⁴ It is also worthwhile to include foods high in calcium in the diet. Patients should be informed about the calcium content of the major food sources, such as dairy products.

The IOM report on dietary reference intake recommendations for calcium and vitamin D set the RDA for vitamin D supplementation as 600 international units (IUs) per day for all groups except individuals older than 71 years of age who were given an RDA of 800 IUs per day. The report stated that the upper safe daily level of intake for vitamin D was 4000 IUs for all individuals older than 9 years of age. Vitamin D₃ (cholecalciferol) usually is regarded as preferable over vitamin D₂ (ergocalciferol) for supplementation.^{355,356}

The question of how much vitamin D supplementation is optimal is not firmly resolved. Measurement of serum total 25(OH) vitamin D (D₃ + D₂) provides an accurate estimate of overall vitamin D status. The IOM report concluded that individuals were at risk of vitamin D deficiency if their serum 25 (OH) vitamin D levels were below 30 nmol/L (12 ng/mL). Some, but not all, individuals were

potentially at risk for inadequacy at serum 25 (OH) vitamin D levels between 30 and 50 nmol/L (12 and 20 ng/mL). Practically all persons were sufficient if their serum 25 (OH) vitamin D levels were at least 50 nmol/L (20 ng/mL). The report concluded that there may be reason for concern if serum 25 (OH) vitamin D levels exceeded 125 nmol/L (50 ng/mL). In the past, the variability of the serum 25 (OH)D assay has limited its utility. However, the use of a standardized reference source and newer technologies such as HPLC appears to have reduced assay variability.³⁵⁸

High levels of oral intake of vitamin D with calcium may produce hypercalciuria or hypercalcemia, but they have not been adequately defined.³⁵⁹ In the Women's Health Initiative (WHI) clinical trial, healthy postmenopausal women given 1000 mg of elemental calcium as calcium carbonate with 400 IU of vitamin D₃ daily had an increased risk of kidney stones (hazard ratio of 1.17) compared with placebo controls.³⁶⁰ Calcium and vitamin D increase bone mass, decrease seasonal bone loss,³⁴⁹ and can decrease the incidence of fractures, particularly in populations likely to have deficient intakes or limited sun exposure.³⁶¹ Other forms of vitamin D have been used, including calcidiol [25(OH)D], calcitriol [1,25(OH)₂D], and 1 α (OH)D, but there is little direct evidence that, except in renal disease or hypoparathyroidism, these forms are superior to ordinary vitamin D, which is less expensive.^{362,363} Dietary intake of protein, minerals, and vitamins C and K, which are important for bone matrix synthesis, should be adequate.

Exercise, Lifestyle, and Prevention of Falls

The role of exercise in treatment of osteoporosis has not been fully defined.³⁶⁴ On the basis of limited data, 0.5 hour of weight-bearing exercise per day is recommended for patients who can tolerate it.³⁶⁵ Epidemiologic data suggest that lifetime leisure exercise is associated with higher BMD at the hip but may have no effect on fracture incidence.³⁶⁶ Patients are often better able to develop and maintain a suitable exercise program under the supervision of a physical therapist. Patients should also be instructed in body mechanics and posture to minimize musculoskeletal damage and the likelihood of falls. They should also stop smoking and limit their intake of alcohol.

Medicines that cause prolonged sedation³⁶⁷ or postural hypertension should be avoided in elderly people. Help should be provided for coping with osteoporosis and for designing a lifestyle that maintains function and minimizes fracture risk.^{368,369} Excessive sodium and protein intake should be avoided because they can increase urinary calcium excretion.²³⁴ Hip protectors may reduce fractures in high-risk populations.³⁷⁰

Management of Fractures

Fractures of the hip and other appendicular fractures usually are treated surgically. Vertebral fractures may require transient bed rest. A careful but intensive program of rehabilitation is critical in patients with fractures of the hip and spine.³⁶⁵ Pain relief for patients with vertebral crush fractures can usually be achieved with mild analgesics and local physical therapy. Calcitonin has analgesic effects and may be useful in patients with severe pain.

Surgical treatment of individual vertebral fractures by injection of methacrylate has been used to relieve pain and expand the compressed vertebral body. Kyphoplasty employs a balloon to create a space for the resin, whereas in vertebroplasty the resin is injected directly.³⁷¹ Controlled trials have cast doubt on the efficacy of vertebroplasty.^{372,373}

Hormone Replacement Therapy

The role of HRT for the prevention and treatment of osteoporosis has been altered substantially by the findings of the large WHI clinical trial and several other controlled trials. The finding that the risks of cardiovascular disease and breast cancer were increased, although fracture risk was decreased, has shifted the risk/benefit ratio and substantially decreased the use of HRT.³⁷⁴⁻³⁷⁷ Although HRT may still be appropriate for the treatment of menopausal symptoms, prevention of osteoporosis is no longer considered an appropriate primary indication. An approach that deserves further exploration is the use of much lower doses of estrogen, which have been shown to prevent bone loss with minimal side effects.^{378,379} Oral and transdermal ultra-low-dose estrogen produce minimal stimulation of the uterus and breast, but their effects on cardiovascular disease and on fracture risk have not been assessed. In contrast to bisphosphonate therapy, there is often accelerated bone loss after withdrawal of estrogen therapy.³⁸⁰ Patients who have discontinued estrogen need to be carefully monitored, and alternative therapy should be considered.

Bisphosphonates

Bisphosphonates are pyrophosphate analogues that bind to bone mineral, are then taken up by osteoclasts, and rapidly inhibit resorption.^{381,382} The first compound available for clinical use, etidronate, inhibits bone mineralization at high doses but increases bone mass without impairing mineralization when given intermittently.³⁸³ Another first-generation compound, clodronate, may be more effective but is not marketed in the United States.³⁸⁴ Second-generation amino-bisphosphonates, such as alendronate, risedronate, ibandronate, and zoledronic acid, do not impair mineralization and are more potent. The inhibitory effects on osteoclast function differ for the first-generation compounds, which lower adenosine triphosphate levels at high concentrations. Second-generation compounds impair isoprenylation of proteins at low concentrations by blocking the enzyme farnesyl diphosphate synthase (FPPS) in the HMG-CoA reductase pathway.³⁸⁵

Alendronate, risedronate, ibandronate, and zoledronic acid are approved for prevention and treatment of osteoporosis in the United States on the basis of evidence that they decrease bone resorption, increase bone mass in the spine and hip, and decrease the incidence of fractures.³⁸⁶⁻³⁸⁸ Bisphosphonates can prevent bone loss in patients receiving glucocorticoids³⁸⁹ and in men.³⁹⁰ There is no consensus on the duration of therapy, but continued benefit has been observed in patients treated for up to 10 years.³⁹¹

Bisphosphonates are poorly absorbed orally and must be taken on an empty stomach with no food or other medication. The major side effects are gastrointestinal, particularly esophageal irritation. Gastrointestinal side effects may also be reduced by giving bisphosphonates weekly instead of daily.³⁹² This problem may be circumvented by using parenteral bisphosphonates. Pamidronate, ibandronate, and zoledronic acid are available for intravenous use. Annual use of intravenous zoledronic acid has been approved for use in osteoporosis.^{254,393,394} Another concern is the development of osteonecrosis of the jaw in bisphosphonate-treated patients. This syndrome appears to be most prevalent in individuals who have received high-dose intravenous bisphosphonate therapy for treatment of malignant disease and is rare in osteoporotic patients.³⁹⁵⁻³⁹⁷

Side effects of bisphosphonates have been of increasing concern. Although gastrointestinal side effects can be

circumvented by intravenous therapy, there may be long-term adverse effects on bone remodeling and strength, leading to atypical poorly healing fractures, particularly of the shaft of the femur.^{398,399} These fractures are sufficiently uncommon that the association with bisphosphonate therapy is unsettled.⁴⁰⁰

Calcitonin

Calcitonin, an inhibitor of osteoclasts and bone resorption, can increase bone mass, particularly in association with high turnover rates. Calcitonin also has some analgesic properties and may be useful in patients with recent painful vertebral fractures.⁴⁰¹ It is available for subcutaneous injection or as a nasal spray. The former preparation is probably more effective but is less well tolerated, often producing gastrointestinal side effects. In a 3-year randomized trial, nasal calcitonin at 200 U/day was found to decrease fracture incidence significantly, although the effects on bone turnover and bone mass were diminished by the end of the study.⁴⁰² However, the fact that doses of 100 or 400 U/day did not significantly decrease fractures in another study and other concerns have raised questions about the efficacy of calcitonin.⁴⁰³ Nasal calcitonin is less effective in increasing BMD than alendronate.⁴⁰⁴ New approaches to calcitonin therapy are being tested.⁴⁰⁵

Selective Estrogen Receptor Modulators

Several compounds have effects similar to those of estrogen on bone, but they act as antagonists in the breast and therefore have been called selective estrogen receptor modulators (SERMs).

Tamoxifen can diminish bone loss in women with breast cancer.⁴⁰⁶ Another SERM, raloxifene, can prevent bone loss and reduce the risk of vertebral fracture in osteoporotic patients.⁴⁰⁷ Its effects on bone turnover and mass are somewhat less than those of estrogen.⁴⁰⁸ Raloxifene has minimal effects on the breast or uterus and appears to decrease the risk of breast cancer.⁴⁰⁹ It reduces low-density lipoprotein levels but does not increase high-density lipoprotein.⁴¹⁰ However, it is associated with an increased risk of thromboembolism and may produce hot flashes. New SERMs with potentially greater effects in bone are being studied, including combined therapy with estrogen.^{411,412}

Anabolic Therapy

Parathyroid Hormone. Many years ago, PTH given intermittently in low doses was shown to increase bone mass in animals. The use of intermittent low-dose synthetic PTH (teriparatide) in men and women with osteoporosis has produced a substantial increase in trabecular bone mass with little loss or even a gain in cortical bone in the femur and has reduced the incidence of fractures.^{413,414} Treatment with PTH is likely to be the most effective approach in patients who lose bone or continue to have fractures on antiresorptive therapy. PTH may be particularly useful in glucocorticoid-induced osteoporosis.^{289,291} PTH must be given by once daily injection, and patients must be monitored carefully for hypercalcemia and hypercalciuria. Prior or concomitant therapy with bisphosphonates may blunt or delay the anabolic response to PTH but certainly does not abrogate it.^{415,416} Treatment with bisphosphonates after a course of PTH may help maintain the gains of PTH therapy.^{417,418}

Strontium Ranelate. Strontium ranelate has been proposed as an anabolic agent that also may be antiresorptive. It has reduced the incidence of vertebral and nonvertebral fractures in large clinical trials.^{200,419} Although side effects are minimal, there are reports of rare but severe allergic

reactions.^{420,421} It has not been approved for the treatment of osteoporosis in the United States.

Anabolic Steroids. Anabolic androgenic steroids (e.g., testosterone) may increase bone and muscle mass. However, high doses produce unacceptable androgenic side effects in many women. Testosterone therapy can increase bone mass and improves trabecular architecture in hypogonadal men.⁴²²⁻⁴²⁵ Selective androgen receptor modulators are being tested in both sexes.^{426,427}

Diuretics. Thiazides and indapamide can decrease urinary calcium excretion and increase bone mass in patients with hypercalciuria and may reduce cortical bone loss in normal postmenopausal women and decrease the incidence of hip fractures.⁴²⁸⁻⁴³¹ Thiazide therapy is particularly appropriate in patients with osteoporosis who have high fasting urinary calcium excretion due to a renal leak.

Denosumab. Injections of denosumab, a human monoclonal antibody to RANKL, can increase BMD, reduce fractures, and markedly inhibit bone resorption.^{432,433} Denosumab may also be effective in preventing bone loss in malignancy.^{434,435}

Other Osteoclast Inhibitors. Several critical aspects of osteoclast function, including the secretion of acid and of proteolytic enzymes (particularly cathepsin K), and the expression of integrins may be potential sites for effective intervention in osteoporosis. Selective antagonists for these processes have been developed and are being explored in the laboratory and the clinic.⁴³⁶⁻⁴³⁸

Other Anabolic Agents. Wnt signaling can have anabolic and anti-catabolic effects on bone. This pathway is tonically inhibited by proteins that block Wnt receptors (e.g., sclerostin, DKK) or Wnt ligands (e.g., secreted frizzled receptor [SFR]). Disinhibition using antibodies to sclerostin can increase bone mass in animal models.⁴³⁹ Increased levels of DKK1 in myeloma, which produces a bone disease characterized by increased bone resorption and decreased formation, suggest this may also be a target for antibody therapy.⁴⁴⁰ Activins and inhibins can affect bone formation and a soluble activin receptor can increase bone formation in mice.^{441,442}

Activation of the calcium sensing receptor in bone may be anabolic. This may account in part for the effect of strontium.⁴⁴³

RICKETS AND OSTEOMALACIA

Rickets and osteomalacia are disorders of the mineralization of newly synthesized organic matrix. In adults, the disorder involves only bone. However, in children, abnormalities also occur in the growth plate and in the mineralization of cartilage, leading to characteristic deformities.

Pathogenesis

To understand the pathogenesis of rickets and osteomalacia, we should recognize that vitamin D is a prohormone that can be synthesized in the skin or supplied in the diet. Vitamin D deficiency is usually the combined result of deficient sun exposure and decreased dietary intake or intestinal malabsorption. Rickets and osteomalacia can also be caused by metabolic defects in the vitamin D hormone system,

including inadequate activation in the liver and kidney and abnormalities of the vitamin D receptor (see Chapter 28). Mineralization can be incomplete when the supply or transport of mineral, particularly phosphate, is impaired in renal, intestinal, or bone cell disorders.⁴⁴⁴

Nutritional and Gastrointestinal Disorders

Inadequate vitamin D intake is less common in the United States than in other countries because many foods are supplemented with this vitamin. However, the combination of reduced amounts of exposure to appropriate ultraviolet wavelengths (UVB) during the winter in the northern half of the United States and inadequate vitamin D supplements in the diet can lead to rickets in infants and osteomalacia in older persons. Individuals with darker pigmentation of the skin are more susceptible to vitamin D deficiency because they are less efficient in converting 7-dehydrocholesterol to vitamin D.^{445,446} For example, nutritional rickets occurs in black infants who are breast-fed without vitamin D supplementation. Adult Asiatic Indians in the United States and Europe have low 25(OH) vitamin D levels and are more likely to have osteomalacia. Intestinal malabsorption of fat can also cause deficiency of vitamin D and of other fat-soluble vitamins.⁴⁴⁷ Inability to produce adequate amounts of 25(OH) vitamin D can occur in advanced liver disease and with the use of antiepileptic drugs.

Calcium deficiency rickets may differ from other forms of rickets and osteomalacia, particularly in adolescents, who may have genu valgum without end-plate deformities.^{448,449} In contrast, phosphate deficiency causes typical rickets. Because most foods contain phosphate, this form of rickets requires markedly unbalanced nutrition, such as can occur with prolonged intravenous feeding, removal of phosphate by dialysis with a low-phosphate solution, or use of aluminum-containing antacids, which bind phosphate in the intestine.

Renal Defects

Impairment of 1 α -hydroxylase can occur because of loss of renal mass or in renal tubular disorders such as the Fanconi syndrome. A hereditary deficiency of 1 α -hydroxylase—vitamin D-dependent rickets type I or pseudo-vitamin D deficiency—is a rare autosomal recessive disorder in which rickets develops during the first year of life. It occurs in rodents with homozygous inactivating mutations of the 1 α -hydroxylase gene and responds to physiologic doses of calcitriol.^{450,451}

Hereditary Resistance to Vitamin D: Vitamin D-Dependent Rickets Type II

Vitamin D-dependent rickets type II occurs in members of families who are homozygous for defects in the vitamin D receptor gene. These patients also often have alopecia. They show improvement in mineralization in response to high doses of calcium and phosphorus, but this does not reverse the alopecia.⁴⁵²

Familial X-Linked Hypophosphatemia

Originally called vitamin D-resistant rickets, familial X-linked hypophosphatemia (XLH) is caused by a defect in renal phosphate transport, with a resultant inappropriate excess excretion of phosphate in the urine. Although the most apparent abnormality is decreased renal tubular reabsorption of phosphate, phosphate transport may be impaired in other cells, particularly osteoblasts. Inactivating mutations in the gene *PHEX* (phosphate regulating gene with homologies to endopeptidases on the X

chromosome), which encodes a protein that is a member of the MMP13 family of membrane-bound metalloproteases, have been found in this disorder.⁴⁵³⁻⁴⁵⁵

The exact mechanism by which *PHEX* mutations mediate this condition is unknown. One hypothesis is that *PHEX* normally directly or indirectly modifies one or more hormones that regulate renal phosphate transport. These substances, which have been called *phosphatonins*, consist of a family of four proteins: fibroblast growth factor-23 (FGF23), FGF7, secreted frizzled-related protein-4 (SFRP4), and matrix extracellular phosphoglycoprotein (MEPE). All decrease renal sodium phosphate transport, and FGF23 and SFRP4 inhibit syntheses of 1,25-dihydroxy vitamin D.⁴⁵³

In support of the hypothesis that XLH results from abnormal circulating levels of phosphatonins, the serum level of FGF23, which is produced by osteocytes, is elevated in most patients with this condition.⁴⁵⁶ XLH patients frequently have some impairment in 1 α -hydroxylase activity, which is consistent with the known ability of FGF23 to inhibit this enzyme.

XLH exhibits genetic and phenotypic heterogeneity. Autosomal dominant, autosomal recessive, and X-linked forms of transmission have been described.⁴⁵⁷ Treatment involves a combination of calcitriol and phosphate.⁴⁵⁸ However, it is difficult to achieve normal growth rates in this disorder.

Oncogenic Osteomalacia

Oncogenic osteomalacia is a severe form of osteomalacia that is presumably caused by production of one or more phosphatonins by fibrous and mesenchymal tumors, which are often small and difficult to identify. Removal of the tumor causes rapid reversal of the osteomalacia. The phosphatonin that has been most frequently identified is FGF23, but FGF7 and MEPE may also be involved.^{459,460}

Hypophosphatasia

A rare autosomal recessive disorder, hypophosphatasia is characterized by mutations in the gene for the tissue-nonspecific (liver, bone, and kidney) isoenzyme of alkaline

phosphatase.⁴⁶¹ The six recognized clinical forms depend on the age at diagnosis and the severity of the symptoms: perinatal lethal, infantile, childhood, adult, odontohypophosphatasia, and perinatal benign.⁴⁶² Clinical manifestations vary from death in utero related to severe deformities to infantile and childhood rickets to adult-onset osteomalacia.⁴⁶³ Premature loss of deciduous teeth and impaired dentition in adults are common. Plasma levels of organic phosphate compounds, such as pyridoxal 5-phosphate, are increased.⁴⁶⁴ Infusion of normal alkaline phosphatase has provided only temporary improvement, but prolonged response has been observed after transplantation of marrow cells, which express the normal enzymes.⁴⁶⁵

Drug-Induced Osteomalacia

High doses of sodium fluoride or of first-generation bisphosphonates (e.g., etidronate) can produce osteomalacia. Anticonvulsant therapy in patients with a marginal vitamin D supply can cause osteomalacia by decreasing 25(OH)D levels.⁴⁶⁶

Clinical Features

Rickets differs from osteomalacia in that it occurs before closure of the epiphyses. Enlargement of cartilage at the growth plate causes the so-called rachitic rosary at the costochondral junctions of the ribs and widening of the cartilaginous ends of the long bones. Impaired mineralization results in bowing of long bones. Radiologically, widening, cupping, and fraying of the metaphyses are seen (Fig. 29-18). Severe vitamin D deficiency causes muscle weakness, and this weakness, combined with the deformity of the chest wall, causes an increased incidence of pneumonia. The clinical expression of osteomalacia in adults varies widely. The most common deformity is bowing of the legs, and in severe cases, bone pain and weakness may cause the patient to be bedridden.⁴⁶⁷

Radiographic changes include subperiosteal erosions caused by marked secondary hyperparathyroidism and a virtually pathognomonic but relatively uncommon

Figure 29-18 Rickets. *Left*, Active rickets in a patient with tissue resistance to 1,25-dihydroxyvitamin D at age 21 months with genu varum, irregular metaphyses, and widened growth plates. *Right*, Inactive rickets in the same patient at age 27 months after treatment with massive doses of ergocalciferol. (From Marx SJ, Spiegel AM, Brown EM, et al. Familial syndrome of decrease in sensitivity to 1,25-hydroxyvitamin D. *J Clin Endocrinol Metab*. 1978;47:1303-1310. Copyright © 1978 by The Endocrine Society.)

Figure 29-19 Active osteomalacia in a patient (sibling of the patient in Fig. 29-18) with hereditary tissue resistance to 1,25-dihydroxyvitamin D at age 18 with pseudofracture of the left tibia. (From Marx SJ, Spiegel AM, Brown EM, et al. Familial syndrome of decrease in sensitivity to 1,25-hydroxyvitamin D. *J Clin Endocrinol Metab.* 1978;47:1303-1310. lesion, the so-called pseudofracture (Looser's zones or Milkman's syndrome) of the long bones, ribs, scapulae, or pubic rami (Fig. 29-19). Coarsening of the trabecular pattern in the spine may be present, but it is also seen in osteoporosis.

Diagnosis

Although clinical features may point to rickets or osteomalacia, the diagnosis depends on laboratory studies. The biochemical picture can vary with different pathogenetic mechanisms and with different stages of disease. In infants with vitamin D deficiency, serum calcium may be low and the serum phosphorus concentration may be normal initially; as secondary hyperparathyroidism develops, however, calcium concentrations usually return to the low-normal range, and serum phosphorus levels fall further. In advanced stages, the serum calcium concentration may fall again. This fall has been attributed to the inability of secondary hyperparathyroidism to maintain the serum calcium level when the bone surface is covered by osteoid and is resistant to attack by osteoclasts.

In adults, the characteristic picture is a low-normal or slightly decreased serum calcium level, a decreased urinary calcium level, and a low serum phosphate level. Increased alkaline phosphatase levels reflect the activity of the osteoblasts, which form unmineralized matrix. PTH levels may

be markedly increased. The key diagnostic test in vitamin D deficiency is demonstration of a decreased serum 25(OH)D value. The 25(OH)D levels may also be decreased in severe hepatic disease or with drugs that impair 25-hydroxylase. The 1,25(OH)₂D levels may be normal in vitamin D deficiency, presumably because of a maximal stimulation of 1 α -hydroxylase by the low serum phosphorus and high PTH levels. Nevertheless, the amount of this hormone is inadequate to activate the receptors in intestine and bone. Because of the high activity of 1 α -hydroxylase, administration of vitamin D to these patients causes a further increase in 1,25(OH)₂D to supranormal levels.

The diagnosis of other forms of rickets and osteomalacia can be made by measuring vitamin D metabolite levels. For example, low values of 1,25(OH)₂D and normal levels of 25(OH)D suggest a defect in 1 α -hydroxylase that may be genetic or acquired as a result of loss of renal function or tumor-induced osteomalacia. High levels of 1,25(OH)₂D and normal levels of 25(OH)D are seen in patients with vitamin D receptor defects. In X-linked hypophosphatemia, serum phosphorus levels are low, and levels of serum calcium and vitamin D metabolites are normal. If alkaline phosphatase levels are low, a definitive diagnosis of hypophosphatasia should be sought by measuring pyridoxal 5-phosphate; elevated levels are relatively specific for hypophosphatasia and correlate with clinical severity.

Although the diagnosis of osteomalacia can usually be made on the basis of clinical findings and laboratory studies, a bone biopsy is sometimes needed for a definitive diagnosis. The characteristic finding is markedly widened osteoid seams and impaired mineralization with diffuse or absent tetracycline labeling. The bone also shows great variation in trabecular width and resorption lacunae resulting from secondary hyperparathyroidism. A modest increase in osteoid width can occur in a high-turnover state, such as hyperparathyroidism, thyrotoxicosis, or Paget's disease; however, tetracycline labeling shows a normal mineralization front in these conditions.

Therapy

Vitamin D is effective in the treatment of nutritional and malabsorptive rickets and osteomalacia. High doses may be given initially, but it is important not to overtreat patients because vitamin D is stored in the fat and excessive amounts can cause prolonged hypercalcemia and hypercalciuria. Monitoring of urinary calcium excretion is useful to determine when the vitamin D dose should be decreased. Patients with malabsorption may require large doses or parenteral vitamin D. Patients with defects in 1 α -hydroxylase can be treated with calcitriol. If the cause is tumor-induced osteomalacia, the treatment is to find and remove the lesion. However, oral or intravenous phosphate and calcitriol can be used to heal the skeletal lesions, but this may lead to tertiary hyperparathyroidism.⁴⁶⁸

Severe defects in the vitamin D receptor are most difficult to treat. Massive doses of calcium and phosphorus have been given to these patients, but normal growth is rarely achieved, and alopecia persists.^{452,469} Intravenous calcium therapy may be necessary and is effective in restoring bone mineralization. Similarly, normal growth may not occur despite repletion of phosphorus and administration of calcitriol in patients with X-linked hypophosphatemia, although bone mineralization can be restored. Growth hormone has been used to help achieve normal height.⁴⁷⁰ Careful monitoring of levels of calcium, phosphorus, and vitamin D metabolites is important to prevent impairment of renal function. There is no effective therapy for hypophosphatasia.

HYPERPARATHYROID BONE DISEASE

In the past, severe cases of primary hyperparathyroidism showed osteitis fibrosa cystica generalisata, manifested by generalized bone loss with increased bone resorption, including subperiosteal and endosteal surfaces.⁴⁷¹ The formation of fibrotic cystic lesions (i.e., brown tumors) in the long bones and jaw caused swelling, pathologic fractures, and bone pain. This bone disease is now rarely seen in primary hyperparathyroidism but may occur in poorly managed secondary hyperparathyroidism.

With the common forms of relatively mild, asymptomatic hyperparathyroidism, the major finding is an increased rate of remodeling in bone. Bone density is low in the cortical bone of the radius, but bone density in the metaphyses and vertebrae, which represent largely trabecular bone, may be normal or only moderately decreased.⁴⁷² Vitamin D insufficiency is common and associated with lower BMD.⁴⁷³ Patients with mild to moderate disease may have cortical bone loss.⁴⁷⁴ When these patients' hyperparathyroidism is cured surgically, bone density in the spine can increase by as much as 15%,⁴⁷⁵ even in postmenopausal women who are at the highest risk for fracture. Bone density also increases in the radius and hip. Moreover, bone loss is attenuated in postmenopausal women with hypoparathyroidism.⁴⁷⁶ On the basis of these results, patients with primary hyperparathyroidism and low bone density who are at risk for fractures, are candidates for parathyroid surgery.⁴⁷⁷

Renal Osteodystrophy

The bone disease associated with chronic and end-stage kidney disease is renal osteodystrophy (ROD), which is a subset of a spectrum of mineral metabolism, vascular, and skeletal complications seen in the syndrome of chronic kidney disease–mineral bone disorder (CKD-MBD). In view of the central role of the kidney in regulating mineral metabolism, it is not surprising that patients with chronic renal failure frequently have skeletal abnormalities. The most frequent form of osteodystrophy in renal failure is caused by the decreased capacity to synthesize $1,25(\text{OH})_2\text{D}$ and to excrete phosphate. Lowering of serum calcium by phosphate, impairment of calcium absorption in the intestine, and loss of the feedback inhibitory effect of $1,25(\text{OH})_2\text{D}$ on PTH production produce severe secondary hyperparathyroidism and can in certain individuals produce osteitis fibrosa cystica. Circulating levels of the phosphatonin FGF23 are also increased in chronic kidney disease, likely because of hyperphosphatemia. This further compromises the ability of the kidney to synthesize $1,25(\text{OH})_2\text{D}$. Chronic kidney disease directly inhibits osteoblast function and bone formation.

In addition to the high turnover bone disease of osteitis fibrosa cystica, which is typically seen with serum intact PTH values of greater than 500 pg/mL, some patients present with low to absent turnover and the syndrome of adynamic bone disorder. These individuals typically have serum intact PTH values of less than 100 pg/mL. Certain individuals with high turnover may have a mineralization defect, which leads to very wide osteoid seam width as measured by bone biopsy. Serum intact PTH values in this "mixed uremic osteodystrophy syndrome" are typically between 100 and 500 pg/mL.⁴⁷⁸⁻⁴⁸¹

Development of bone disease can be slowed or prevented by phosphate restriction or by treatment with phosphate binders and calcitriol or analogues of calcitriol that are less likely to cause hypercalcemia.⁴⁸² When this fails, it

is possible to reduce PTH levels with a calcimimetic agent such as cinacalcet.⁴⁸³ In the past, aluminum hydroxide was used to bind phosphate, a therapy that sometimes caused aluminum-induced adynamic bone disease. This condition is less common with use of calcium salts, sevelamer, or lanthanum to decrease phosphate absorption. Adynamic bone disease can occur without aluminum excess, particularly in patients in whom secondary hyperparathyroidism has been reversed. However, the relation of serum intact PTH levels and bone turnover varies, and biopsies are needed in most patients for a definitive diagnosis.⁴⁸⁴ Osteomalacia can occur in patients receiving dialysis if they have an inadequate supply of vitamin D and calcium, but this is unusual. Osteoporosis is common in chronic renal failure and is often aggravated after transplantation.⁴⁸⁵

Renal osteodystrophy causes growth retardation and skeletal deformities in children, and children and adults have bone pain and muscle weakness. Soft tissue calcifications are particularly dangerous when they occur in blood vessels and lead to ischemia and gangrene. Calcification may be the result of a high calcium-phosphorus product and of vessel wall changes resulting from renal failure or the direct effects of PTH. To prevent calcification, it is important to avoid a high serum level of a calcium-phosphorus ion product and to minimize secondary hyperparathyroidism.⁴⁸⁴

Diagnosis

The diagnosis of a specific form of renal osteodystrophy can be aided by biochemical measurements. Levels of PTH can help to differentiate osteitis fibrosa cystica from adynamic bone disorder or mixed uremic osteodystrophy. Plasma aluminum levels may be elevated in patients with aluminum-induced osteodystrophy but do not necessarily reflect the stores in bone. Deferoxamine chelates aluminum, and this agent can be used to measure the body burden and to treat aluminum overload. The interpretation of biochemical markers of bone turnover is difficult in renal disease because their clearance may be altered.

A bone biopsy often is needed to clarify the pathogenesis of renal osteodystrophy.⁴⁸⁶ Using tetracycline labeling, it is possible to determine whether mineralization is impaired. Sections that have not been decalcified show the extent of osteoid seams and resorption surfaces. Aluminum can be identified by special stains. Amyloid deposits, which consist largely of β_2 -microglobulin, may be seen in the bone. Amyloidosis of the bone is associated with cystic lesions but not necessarily with bone pain.

Therapy

The treatment of renal osteodystrophy can be highly successful if it is correctly focused on specific pathogenetic mechanisms. The goal should be to maintain normal serum calcium and phosphorus levels and to minimize exposure to aluminum. Phosphate restriction should be instituted relatively early in renal failure, but diets low in phosphorus are difficult to achieve. After the filtration rate is reduced below 25% of normal, it is usually necessary to administer phosphate binders such as calcium salts, sevelamer, or lanthanum. The ability of citrate to increase aluminum absorption is a concern. Correction of acidosis is also important in preventing bone disease.

Early in renal failure, modest supplementation with vitamin D may be sufficient to maintain $1,25(\text{OH})_2\text{D}$ levels, but calcitriol itself should be administered eventually. Low doses (0.25 to 0.5 $\mu\text{g}/\text{day}$) are well tolerated, but higher doses can lead to hypercalcemia and hypercalciuria. Vitamin

D analogues, which produce less hypercalcemia, such as paricalcitol and doxercalciferol, are frequently employed for the control of secondary hyperparathyroidism.^{164,480,481}

In some cases, parathyroidectomy may be required. Persistent hypercalcemia in patients with renal failure, intractable pruritus, extracellular calcifications, or severe skeletal lesions is an indication for surgery. However, parathyroidectomy should be avoided in patients with adynamic bone disease because symptoms may be worsened.

Renal transplantation corrects many of the biochemical disturbances that lead to renal osteodystrophy, but bone disease may progress. Usually, secondary hyperparathyroidism slowly resolves, but patients with persistent hypercalcemia or autonomy of the parathyroid glands (i.e., tertiary hyperparathyroidism) may require surgery. A major concern, particularly in older patients, is progressive osteoporosis because glucocorticoids and immunosuppressants, which are needed to control transplant rejection, can worsen bone loss in these patients. Optimal therapy has not been defined, but bisphosphonates and vitamin D analogues may slow the bone loss that is associated with renal transplantation.^{482,485} Osteonecrosis or avascular necrosis, particularly of the proximal femur, is common after renal transplantation.

PAGET'S DISEASE

Paget's disease may affect up to 3% of adults older than 40 years. It is often asymptomatic and usually progresses slowly.⁴⁸⁷

Pathogenesis

The primary abnormality in Paget's disease is the localized, uncontrolled formation of large, highly active osteoclasts. The initial lesion is an increase in bone resorption. The response to this resorption, particularly in bones that are subject to mechanical force, is an intense but chaotic increase in osteoblastic activity. The characteristic histologic appearance is of focal lesions with many giant osteoclasts and active osteoblasts. The bone that forms in the lesions is disorganized and has a mosaic pattern with loss of the usual lamellar structure. The marrow shows a pattern of fibrosis and increased vascularity.⁴⁸⁸

The concept that there is a viral origin to Paget's disease is controversial. It is based on the finding of nuclear inclusion bodies in osteoclasts (Fig. 29-20) and the detection of viral transcripts in hematopoietic cells from patients with the disease. Several paramyxoviruses have been suggested, including measles and canine distemper virus.⁴⁸⁹ Expression of the measles virus nucleocapsid protein gene in osteoclast precursor cells was found to enhance the ability of these cells to form osteoclasts.⁴⁹⁰ However, similar nuclear structures have been found in the osteoclasts of patients with unrelated illnesses, and a number of investigators have failed to detect evidence of a viral infection in pagetic bone or peripheral blood cells from pagetic patients.⁴⁹¹ Further work is needed to establish pathogenetic links between viral sequences and the production of abnormal osteoclasts in this condition. Pagetic osteoclasts differ from normal osteoclasts in their greater size, the presence of viral inclusions, and expression of IL-6, which may play a role in pathogenesis.⁴⁹² Expression of resorption stimulators by osteoblast-lineage cells is probably also involved in the development of Paget's disease.

Pagetic bone often distributes in a heterogeneous pattern throughout the skeleton. When lesions appear, they remain

Figure 29-20 Electron micrograph of an osteoclast nucleus from a patient with Paget's disease shows a characteristic intranuclear inclusion, consisting of microfilaments that are 125 nm in diameter. Decalcified bone can be seen (original magnification, $\times 32,400$). (Courtesy of Dr. Barbara G. Mills and Dr. Frederick R. Singer.)

stationary within a particular bone over many years, although they may advance within an involved bone over time. A description of the pathogenetic mechanisms in Paget's disease must elucidate how the spotty distribution of this condition develops. Some insight into this puzzle was provided by studies of osteoblasts and bone marrow stromal cells from pagetic lesions. These cells, which are believed to be stationary in bone, produce enhanced RANKL, IL-1, IL-6, and DKK1 mRNA.^{493,494}

There appears to be a genetic component to Paget's disease for many patients.⁴⁹⁵ Between 15% and 30% of patients have a positive family history, and first-degree relatives of patients with Paget's disease have a sevenfold greater relative risk of having the disorder than individuals with no affected relatives. Ethnic and geographic clustering exists. The incidence is high in some areas of northern Europe, particularly in northern England, but it is low in Norway and Sweden. Mutations in four genes have been linked to Paget's disease and illnesses with pagetoid features in humans. Perhaps the most frequently identified mutations are found in the sequestosome 1 (p62) gene (*SQSTM1*), which has been identified in 20% to 50% of patients with familial Paget's disease and in 5% to 20% of patients with sporadic Paget's disease.⁴⁹⁶⁻⁴⁹⁸ Multiple mutations in *SQSTM1* have been identified as predisposing individuals to Paget's disease. Most are in the ubiquitin-associated (UBA) domain, but others are in areas outside the UBA domain that also regulate the binding of *SQSTM1* to ubiquitin. *SQSTM1* appears involved in RANK signaling through its role in the activation of NF- κ B, but the exact mechanism by which mutations in this gene predispose individuals to the development of Paget's disease is unknown.

Mutations in other genes can lead to pagetoid bone lesions. These occur in a number of rare diseases, including familial expansile osteolysis, expansile skeletal

hyperphosphatasia, and early-onset familial Paget's disease (all caused by mutations of the RANK gene [*TNFRSF11A*]); idiopathic hyperphosphatasia, also known as juvenile Paget's disease (caused by mutations in the gene for osteoprotegerin [*TNFRSF11B*]); and the syndrome of hereditary inclusion-body myopathy, Paget's disease, and frontotemporal dementia (IBMPFD) (caused by mutations in the gene for valosin-containing protein [*VCP*]).

Clinical Features

Paget's disease affects men and women, with a somewhat higher prevalence among men. The disease usually is not clinically apparent until age 50 to 60 years. It typically progresses slowly and does not usually develop at new bone sites after it is identified. Many different bones can be affected, and the lesions can vary from single, monostotic lesions to involvement of almost the entire skeleton. The pelvis, femur, spine, skull, and tibia are most commonly involved, whereas hands and feet are rarely affected.

Paget's disease is often discovered in asymptomatic patients because of an elevated serum alkaline phosphatase measurement obtained on routine screening or because of a radiograph taken for an unrelated problem. The most common symptom is bone pain at the site of pagetic involvement. Pain also commonly occurs in adjacent joints as a result of secondary degenerative arthritis. Bowing of the legs (Fig. 29-21) and pathologic fractures can also occur. Vertebral involvement can cause kyphosis and compression of the spinal cord. Neural changes can also result from vascular steal because of the high blood flow to the lesion. The most common consequence of Paget's disease of the skull is hearing loss, which can be conductive and neurosensory. Extensive involvement of the base of the skull can produce basilar impression and rarely cause brain stem compression (Fig. 29-22). Dental problems and facial and skull deformities can occur.

The incidence of osteosarcoma is increased but is less than 1%. When osteosarcoma does occur, it is highly malignant. Most patients do not live longer than 1 to 3 years. Fibrosarcomas, chondrosarcomas, and benign giant cell tumors are occasionally seen. The giant cell tumors, called *reparative granulomas*, may represent an extension of pagetic tissue outside the skeleton.

Patients with Paget's disease may have an increased incidence of primary hyperparathyroidism. Hypercalcemia also has been reported in immobilized patients. Angioid streaks are often seen in the fundus. Pseudogout, gout, and osteoarthritis occur. Patients with underlying heart disease may show worsening of heart failure, which has been attributed to increased blood flow in pagetic bone.

Diagnosis

The diagnosis of Paget's disease may be made by the finding of an elevated serum alkaline phosphatase concentration or after a routine radiograph. In older persons with deformities or bone pain, the diagnosis should be considered and a careful family history and review of the musculoskeletal system by history and physical examination obtained. A bone scan should be carried out to localize possible pagetic sites. Positive scans do not necessarily indicate Paget's disease, and radiographs should be obtained to confirm that Paget's disease is the cause of the increased uptake. Radiographs typically show irregular areas of osteosclerosis with adjacent areas of osteolysis. Rarely, pagetic sites in bone are not evident on bone scan because there is a minimal formation response in the

Figure 29-21 Paget's disease of the tibia. Notice the bowing, marked irregularity of the anterior cortex and the flame-shaped lytic lesion of the posterior cortex. (Courtesy of Dr. Ethel S. Siris.)

lesion. Such primarily resorptive lesions in the skull are called *osteoporosis circumscripta*.

An audiogram should be obtained for patients with involvement of the petrous bone or those with complaints of hearing loss. Because of the possible increased incidence of hyperparathyroidism, ionized calcium levels should be measured in the initial workup. Monostotic Paget's disease, particularly in the vertebrae, may be difficult to distinguish from metastatic disease. In males, it is prudent to rule out the diagnosis of metastatic prostate cancer, which can mimic many of the laboratory, radiographic, and bone scan findings of Paget's disease. Some patients with vertebral disease may have impingement on the spinal canal. In these individuals, the area should be examined by CT or MRI. Bone biopsies can be useful in atypical cases. An ordinary aspiration biopsy sometimes yields the giant osteoclasts that are pathognomonic of Paget's disease. Samples of bone that show the irregular *marble bone pattern* can also be diagnostic.

Figure 29-22 Radiograph of the skull of a patient with advanced Paget's disease shows thickening, disordered new bone formation (cotton-wool patches), and basilar impression. (From Singer FR. *Paget's Disease of Bone*. New York, NY: Plenum, 1977.)

After the initial evaluation has been completed, the patient can usually be monitored biochemically by serial measurements of serum total or bone-specific alkaline phosphatase and a marker of bone resorption.⁴⁹⁹ Urinary hydroxyproline measurements may be used, as may serum or urinary levels of type I collagen breakdown products such as C-terminal telopeptide or N-terminal telopeptide or measurements of pyridinoline or deoxypyridinoline in the urine.

Therapy

In the past, patients with Paget's disease were often observed until symptoms were clearcut or until there was evidence of progression in critical areas of the skeleton. With the newer bisphosphonates, treatment is instituted earlier. The bisphosphonates zoledronic acid and pamidronate are available for intravenous use. Patients with more extensive disease may require retreatment and should be evaluated by measuring levels of bone turnover markers at regular intervals. Intravenous bisphosphonates are associated with a transient fever and a transient increase in bone pain in 10% to 25% of patients.^{498,500} Rare idiosyncratic reactions include uveitis.

Other bisphosphonates are given orally. Alendronate, risedronate, and tiludronate are approved in the United States. As with pamidronate, patients may require repeated therapy with oral bisphosphonates after a drug-free period that varies with each agent. Oral bisphosphonates need to be taken in a manner that minimizes the development of esophagitis or interactions with food and other therapeutics in the stomach. Osteonecrosis of the jaw has been detected occasionally in this condition in patients treated with any of the bisphosphonates. Treatments with the newer bisphosphonates have largely replaced therapy with calcitonin, etidronate, or plicamycin. All of these agents act by inhibiting osteoclastic activity, and the earliest indication of therapeutic response is a drop in resorption markers followed by a decrease in formation markers.

The indications for treatment are pain that can be attributed to Paget's disease and deformities that may produce

neurologic changes or are likely to lead to fracture, such as the osteolytic flame lesion or blade of grass lesion in weight-bearing bones (see Fig. 29-20). Hearing loss may be an indication for therapy, although most patients do not show major improvement after treatment.

Patients with heart disease and extensive Paget's disease should be treated in the hope that decreased pagetic activity will improve management. With the advent of safe and effective therapy, patients with mild to moderate disease, particularly those with the potential for complications (i.e., those with lesions in weight-bearing bone, the vertebral bodies, or the base of the skull), can be considered for treatment before symptoms develop. Early treatment is logical in young patients with Paget's disease because it is hoped that therapy may prevent progression. However, proof of this hypothesis is not conclusive.

Many patients with Paget's disease have pain associated with joint damage that does not respond to antipagetic therapy. These patients may respond to anti-inflammatory drugs. If osteoarthritis is advanced, knee and hip replacement may be appropriate, but biochemical remission of the Paget's disease should be obtained before surgery.

A high calcium intake may be useful in Paget's disease. Bisphosphonate therapy can lower the serum calcium level and cause secondary hyperparathyroidism, which is probably not advantageous; increased calcium intake may prevent this development. Moreover, calcium loading can increase endogenous calcitonin secretion, which may have beneficial effects. It is important to monitor serum 25(OH) D levels periodically in patients with Paget's disease who are treated with bisphosphonates, because osteomalacia is not uncommon in the elderly population who are at risk for this condition and low serum vitamin D levels may exacerbate the potential of bisphosphonates to cause hypocalcemia. Urinary calcium should be checked before calcium or vitamin D supplementation is given, because an increase in the incidence of renal stones has been reported in pagetic patients.

Hereditary Hyperphosphatasia

Although hereditary hyperphosphatasia has been called *juvenile Paget's disease*, it involves all of the skeleton and develops in infants.⁵⁰¹ Serum alkaline phosphatase levels are very high, and there are severe bone deformities. The histologic appearance resembles that of Paget's disease with high bone turnover, although the osteoclasts are not enlarged. Treatment with bisphosphonates or calcitonin may be effective in reducing bone turnover and improving bone lesions. A familial form with expansile long bone lesions has been described.^{502,503} The disease has been associated with mutations in the gene for osteoprotegerin (*TNFRSF11B*) in some affected individuals.⁵⁰⁴

OSTEOGENESIS IMPERFECTA

Osteogenesis imperfecta, or brittle bone disease, is a heterogeneous, congenital disorder in which increased bone fragility leads to fractures and deformity.⁵⁰⁵ It ranges in severity from a lethal perinatal form to a mild disorder that results only in increased fractures.

Pathogenesis

Most patients with osteogenesis imperfecta have defects in one of the two genes for type I collagen (*COL1A1* and

TABLE 29-5

Classification of Osteogenesis Imperfecta

Type	Clinical Features	Inheritance	Common Biochemical Abnormality
I	Normal stature, little or no deformity, blue sclerae, hearing loss in 50% of families Dentinogenesis imperfecta may distinguish a subset.	AD	Nonfunctional allele of the $\alpha 1(I)$ procollagen gene (<i>COL1A1</i>)
II	Lethal in the perinatal period; minimal calvarial mineralization, beaded ribs, compressed femurs, marked long bone deformity, platyspondyly	AD (new mutations) AR (rare)	Substitution of glycine in triple helix of <i>COL1A1</i> or <i>COL1A2</i>
III	Progressively deforming bones, usually with moderate deformity at birth Scleral hue varies, often lightening with age Dentinogenesis imperfecta common, hearing loss common Stature very short	AD AR (uncommon)	Substitution of glycine in triple helix of <i>COL1A1</i> or <i>COL1A2</i>
IV	Normal sclerae, mild to moderate bone deformity, and variable short stature; dentinogenesis imperfecta is common and hearing loss occurs in some families	AD	Substitution of glycine in triple helix of <i>COL1A1</i> or <i>COL1A2</i> ; exon skipping in <i>COL1A2</i>

AD, Autosomal dominant; AR, autosomal recessive.

Classification by Sillence and Rimoin, as modified by Byers PH. Osteogenesis imperfecta. In: Royce PM, Steinman B, eds. *Connective Tissue and Its Heritable Disorders: Molecular, Genetic and Medical Aspects*. New York, NY: Wiley-Liss, 1993:317-350.

COL1A2). Bones, ligaments, skin, sclerae, and teeth are affected. The incidence of osteogenesis imperfecta is estimated to be 1 in 25,000 to 1 in 100,000 persons. The heterogeneity of the features is caused by the variety of genetic defects, although phenotypic variation occurs even with the same genetic abnormality (Table 29-5). The more severe forms, type II and type III, involve mutations in the helical portion of the collagen molecule that prevent normal assembly and produce unstable triple helices. Point mutations in this portion of the collagen gene can be associated with mild disease (type IV). Genetically engineered mouse models of type IV osteogenesis imperfecta exhibit decreased bone mass caused by increased osteoclastic bone resorption and decreased osteoblastic function.⁵⁰⁶

Type I osteogenesis imperfecta differs from the other forms in that there is usually a deletion of one allele of the $\alpha 1(I)$ procollagen gene (*COL1A1*), resulting in decreased collagen production but a normal molecular structure.⁵⁰⁷ This disorder is of particular interest because familial osteoporosis may also exhibit such defects.^{508,509} Bone biopsies show decreased cortical width and trabecular bone volume, increased turnover, and decreased bone formation in patients with type I disease.⁵¹⁰ In a subgroup of patients with low turnover and ligamentous calcifications, the disorder has been named type V osteoporosis imperfecta.⁴⁰¹ Autosomal recessive osteogenesis imperfecta is caused by mutations in any of three proteins that form a complex that 3-hydroxylates proline 396 in collagen $\alpha 1(I)$ and $\alpha 1(II)$ (reviewed by Chang and colleagues⁵¹¹).

Classification and Clinical Features

The classification devised by Sillence and Rimoin, which was modified by Byers,⁵⁰⁵ is summarized in Table 29-5. In addition to bone involvement, patients may have ligament laxity, joint hypermobility, and easy bruising. Dentin formation is often abnormal, and the teeth are fragile and discolored. Blue sclerae are a variable manifestation and do not correlate with severity. Because of the thoracic deformities, patients with severe manifestations are predisposed to pulmonary infections and usually have a shortened life span. Intelligence is not affected, and individuals with marked deformities can be highly productive if appropriate conditions are provided.

Diagnosis

In patients with moderate to severe disease, the clinical features make the diagnosis relatively straightforward. In patients with the milder forms, however, the diagnosis may be missed. In children without deformities, multiple fractures are usually attributed to trauma. In infants, the presence of such fractures may lead to an accusation of parental abuse. In the absence of typical clinical features, the diagnosis can be made only biochemically. Culture of fibroblasts from skin biopsies and analysis of the collagen by gel electrophoresis can point to a defect, and gene sequencing of the *COL1A1* and *COL1A2* genes identifies 80% to 85% of mutations. In individuals without identifiable mutations of the type I collagen genes, sequencing of the genes for cartilage-associated protein (CRTAP) and prolyl-3-hydroxylase (LEPRE1), which are involved in stabilizing collagen, have identified additional mutations. These analyses are useful for families because specific DNA polymorphisms may allow prenatal diagnosis if the mutation has already been identified in other affected family members.

In children and adolescents with multiple fractures but no deformity, measurements of bone density and turnover may point toward the diagnosis. In the type I disorder, bone density and serum type I procollagen peptide levels are likely to be decreased. However, because excretion of collagen cross-links is increased in most types of osteogenesis imperfecta, increased bone resorption may play a role in pathogenesis.⁵¹²

Therapy

Antiresorptive therapy with intravenous bisphosphonates has decreased fractures in children with severe osteogenesis imperfecta, even before 3 years of age.^{513,514} Oral bisphosphonates may also be effective in older children and adults.⁵¹⁵ However, the efficacy of bisphosphonate therapy to prevent fractures in this disease is controversial and not evident in all studies.⁵¹⁶ Supportive treatment is important. The Osteogenesis Imperfecta Foundation works with patients and families to improve quality of life. Orthopedic and rehabilitation services can be helpful in dealing with deformities. Genetic counseling and prenatal diagnosis, including ultrasound examination and testing for informative DNA polymorphisms, are important for the family. Gene therapy is being explored.⁵¹⁷

Other Connective Tissue Disorders Affecting the Skeleton

Other inherited disorders of connective tissue with impairment of skeletal development or increased bone fragility include Ehlers-Danlos syndrome, Menkes' disease, lysinuric protein intolerance, and homocystinuria.²⁷⁹ In these disorders, abnormalities of collagen cross-linking can affect bone and other connective tissues. In Ehlers-Danlos syndrome, the cross-linking enzyme lysyl oxidase is deficient, and in Menkes' disease, copper deficiency impairs the function of this enzyme. Lysinuric protein intolerance and homocystinuria probably also impair collagen cross-linking.

OSTEOPETROSIS

Osteopetrosis, or marble bone disease, is a heterogeneous group of disorders that are characterized by a generalized increase in bone density. They are predominantly caused by defective osteoclastic bone resorption.⁵¹⁸ However, rates of resorption and formation in bone are coupled through poorly understood mechanisms, and it is likely that bone resorption and formation rates are altered in most cases of this disease.

Osteopetrosis is divided by the severity of the clinical presentation into autosomal recessive osteopetrosis (ARO), intermediate autosomal recessive osteopetrosis (IARO) and benign autosomal dominant osteopetrosis (ADO), which is further divided into type I and type II. Type I ADO results from mutations of the *LRP5* gene, which are not thought to directly influence osteoclast function.

A variety of genetic mutations have been identified in humans with osteopetrosis. Mutations in the *TCIRG1*, *CLCN7*, and *OSTM1* genes, which influence acid generation in the resorption lacuna of osteoclasts, are found in most ARO patients, whose bones contain dysfunctional osteoclasts. In contrast, mutations in the *RANK* and *RANKL* genes (*TNFRSF11A* and *TNFSF11*) are associated with ARO in patients whose bones are without osteoclasts.

CLCN7 mutations are also found in IARO and ADO type II patients. IARO is also associated with mutations in the gene for carbonic anhydrase II (*CA2*), which catalyzes acid generation, and in *PLEKHM1*, which is involved in vesicular trafficking.

Additional cases of osteopetrosis are caused by mutations in the gene for the inhibitor of kappa light polypeptide gene enhancer in B cells (*IKBKG*), which encodes the protein NF- κ B essential modulator (IKBKG, formerly designated NEMO) that is involved in RANK signaling, and by mutations in the gene for integrin- β_3 (*ITGB3*), which is involved in the attachment of osteoclasts to bone.

Osteopetrotic rats and mice with specific defects in osteoclasts have been found as a result of spontaneous mutations and targeted gene deletion techniques. The *op/op* mouse has a genetic defect in the production of M-CSF that results in failure of osteoclast formation, which can be corrected by treatment with M-CSF.⁵¹⁹ Knockouts of the proto-oncogenes *src* and *fos*; of TRAF6, a mediator of RANK action; and of tartrate-resistant acid phosphatase also cause osteopetrosis.⁵²⁰⁻⁵²⁴

Clinical Presentations in Specific Conditions

Autosomal Recessive Osteopetrosis

ARO or malignant infantile osteopetrosis is a rare, autosomal recessive disorder in which failure to resorb bone and calcified metaphyseal cartilage causes near obliteration of

Figure 29-23 Radiographs of the lower limb of a patient with osteopetrosis at age 2 months (**A**) before bone marrow transplantation and at age 9 months after transplantation (**B**) show formation of normal medullary bone. (From Ballet JJ, Griscelli C. Lymphoid cell transplantation in human osteopetrosis. In Horton JE, Tarpley TM, Davis WF, eds. *Mechanisms of Localized Bone Loss*. London, UK: IRL, 1978:399-414, by permission of Oxford University Press.)

the marrow spaces.^{454,525-529} Extramedullary hematopoiesis occurs in the liver and spleen. The cranial nerve foramina do not form normally, causing optic atrophy and other cranial nerve defects. The bones, although dense, are brittle, and pathologic fractures can occur.

The impaired function of the hematopoietic system causes death in the first decade from hemorrhage or infection. On the basis of studies in animal models in which transfer of hematopoietic tissue resulted in cure, patients have been treated with total-body irradiation and grafting of marrow from human leukocyte antigen-identical donors (Fig. 29-23).⁵²⁶ When suitable donors cannot be found, therapy with high doses of interferon have improved bone resorption.⁵³⁰

Carbonic Anhydrase II Deficiency

Carbonic anhydrase II deficiency, a nonlethal autosomal recessive disorder, is associated with a complete deficiency of the type II carbonic anhydrase that provides carbonic acid for hydrogen ion secretion by osteoclasts and by the distal tubules.⁵³¹ In this condition, osteopetrosis is accompanied by renal tubular acidosis that may involve distal and proximal lesions. Affected individuals are shorter than their normal siblings and may have calcification of the basal ganglia. Bone marrow transplantation can correct the skeletal abnormalities.⁵³²

Autosomal Dominant Osteopetrosis Type II

ADO II (Albers-Schönberg disease) is characterized by generalized osteosclerosis with thickening of the vertebral end plates (i.e., sandwich vertebrae) and bone within bone in

the pelvis. Although ADO II has been called *benign osteopetrosis*, most patients have clinical problems, presumably related to impaired bone remodeling, that include fractures, osteoarthritis, skeletal deformities, and cranial nerve involvement.⁵³³ Most patients with ADO II have a milder form of mutation in the chloride transport gene *CICN7* than that seen in the more severe forms of infantile osteopetrosis, although other genes may be involved. Decreased bone resorption presumably results from impaired acidification, and tartrate-resistant acid phosphatase activity in the serum is actually increased.⁵³⁴⁻⁵³⁶

OTHER SCLEROSING BONE DISORDERS

Several rare skeletal disorders cause irregular bone structure and various degrees of sclerosis. Some are associated with increased bone formation rather than decreased resorption, although both processes may be affected. Acquired osteosclerosis related to increased bone formation occurs in fluorosis⁵³⁷ and in rare cases of hepatitis C virus infection,⁵³⁸ and a localized form is seen in certain metastatic malignancies, particularly cancers of the prostate and breast.

Pyknodysostosis

Pyknodysostosis is an autosomal recessive disorder characterized by short stature, a large cranium, small facies, and skeletal fragility.⁵³⁹ Unlike patients with osteopetrosis, these patients do not have loss of the marrow cavity and are not anemic. Histologically, trabecular bone volume is increased despite an increase in the number of osteoclasts. There is a defect in osteoclast function due to a mutation of the cathepsin K gene, which is the principal acid-active protease that is secreted by osteoclasts into the resorption space.⁵⁴⁰⁻⁵⁴²

Progressive Diaphyseal Dysplasia

Known as Camurati-Engelmann disease, progressive diaphyseal dysplasia consists of patchy thickening of the bone on periosteal and endosteal surfaces, and it is associated with pain in the extremities, gait abnormalities, and muscle wasting. The histologic picture is one of increased bone formation rather than decreased resorption.⁵⁴³ The disease can be inherited as an autosomal dominant disorder, and it is associated with mutations in the TGF- β 1 gene (*TGF β 1*), mainly in the latency-associated peptide region.^{544,545} Expression in the osteoblasts of mice of a mutated form of TGF- β 1 that is identical to that found in some patients with Camurati-Engelmann disease increased the levels of active TGF- β 1 in the bone microenvironment and produced bone lesions that were similar to those seen in humans with this condition.⁵⁴⁶ In some cases, glucocorticoid therapy relieves the bone pain and reverses the histologic abnormalities of this condition.

Autosomal Dominant Osteopetrosis Type I

After initial identification of an activating mutation of *LRP5* in two families with autosomal dominant high bone mass (HBM)^{547,548} several other families were found to have missense mutations in the *LRP5* gene and increased canonical Wnt/ β -catenin signaling with somewhat variable phenotypic expression.⁵⁴⁹ In the original families, there was little evidence of deformity, but in other families, a picture described as autosomal dominant osteopetrosis type I was found, which can have cranial nerve involvement. The

increase in bone mass appears to be attributable to increased bone formation as a result of enhanced canonical Wnt/ β -catenin signaling in patients and in a mouse model of this disorder.⁵⁵⁰ Abnormal regulation of intestinal serotonin production may be involved in the pathogenesis of HBM.³²⁴ There may also be an abnormality of osteoclast function in vivo, although isolated osteoclasts from these patients are still active in vitro.⁵⁵¹

Sclerosteosis and van Buchem's Disease

Sclerosteosis and van Buchem's disease are rare, autosomal recessive disorders that are associated with progressive bone thickening due to increased bone formation and sclerosis of the skeleton. Comparison of bone biopsy specimens in these patients with those of normal controls demonstrated activated osteoblasts.^{552,553} Both conditions are caused by homozygous mutations in the *SOST* gene, which result in decreased expression of its protein product sclerostin. In sclerosteosis, the mutation causes an improperly spliced *SOST* mRNA.⁵⁵⁴

In van Buchem's disease, an enhancer element is deleted.⁵⁵⁵ Lifelong sclerostin deficiency in both conditions leads to progressive increases in bone mass from childhood to adulthood. Sclerostin is a secreted Wnt antagonist. Several studies have demonstrated that sclerostin binds to LRP5 and LRP6 and inhibits downstream signaling events in the canonical Wnt/ β -catenin pathway.⁵⁵⁶⁻⁵⁵⁸ A decrease in sclerostin in these conditions is thought to increase canonical Wnt/ β -catenin signaling and produce an increased bone mass in a manner similar to that seen in HBM patients.

Other Disorders of Bone Density

Three disorders characterized by irregular increases in bone density—osteopoikilosis, the Buschke-Ollendorff syndrome, and melorheostosis—may represent different phenotypes of a common genetic abnormality. A loss of function mutation of *LEMD3*, a gene that encodes an inner nuclear membrane protein, has been found in families with these disorders,⁵⁵⁹ although the evidence that isolated melorheostosis is caused by mutations in *LEMD3* is less clear.⁵⁶⁰

Osteopathia striata with cranial sclerosis is a rare syndrome characterized by longitudinal striations in metaphyses of long bones. It is more common in females and may have an X-linked dominant inheritance pattern.⁵⁶¹ Axial osteomalacia is a disorder characterized by back pain and osteosclerosis of the spine and pelvis, which may respond to anti-inflammatory agents.^{562,563} Fibrogenesis imperfecta ossium is another rare condition characterized by increased bone density and patchy areas of bone loss, which may represent a defect in bone matrix synthesis.⁵⁶⁴

More localized periosteal new bone formation can occur in a number of different syndromes. Caffey disease or cortical hyperostosis can vary from a severe and lethal disorder to mild increases in periosteal bone formation.⁵⁶⁵ A mutation in the *COL1A1* gene has been identified in multiple families with an autosomal dominant form of this disorder.⁵⁶⁶⁻⁵⁶⁸ However, this disorder can be mimicked by prolonged infusion of PGE₁ in neonates, and such infusions can also cause hypertrophic osteoarthropathy in adults.^{569,570} Pachydermoperiostosis is a rare congenital disorder with skin changes and digital hypertrophic osteoarthropathy (i.e., clubbing).⁵⁷¹ Secondary hypertrophic osteoarthropathy and clubbing can occur with pulmonary disease or as a paraneoplastic syndrome, possibly related to

overproduction of multiple vascular growth factors.⁵⁷²⁻⁵⁷⁵ If the underlying disorder cannot be treated effectively, bisphosphonates may provide relief from pain.⁵⁷²

FIBROUS DYSPLASIA

Clinical Features

Fibrous dysplasia is characterized by expanding lesions within the bone that contain fibroblastic and osteoblastic elements. The disorder can occur as a monostotic lesion without any associated abnormalities or in a polyostotic form, which may occur as part of the McCune-Albright syndrome, associated with functional abnormalities of one or more endocrine glands and irregular hyperpigmented macules called café au lait spots.

The most common endocrine manifestation is precocious puberty, particularly in girls.⁵⁷⁶ The molecular defect in the McCune-Albright syndrome is somatic mosaicism for an activating mutation of the G_{α} subunit of the nucleotide-binding regulatory protein that couples receptors to adenylyl cyclase. Similar defects have been found in bone lesions in the absence of McCune-Albright syndrome.⁵⁷⁷ Local production of PTH-related peptide (PTHrP) may also be involved in pathogenesis.⁵⁷⁸ Hypophosphatemia can occur and is associated with increased FGF23 production.^{579,580}

Diagnosis

Monostotic fibrous dysplasia is usually diagnosed in the second or third decade of life as an expanding bone lesion that can cause fracture, deformity, or nerve entrapment. Sarcomatous degeneration can occur. In fibrous dysplasia, any skeletal site can be affected, but the femur, tibia, ribs, and face are most often involved. Histologically, the lesions contain many spindle-shaped fibroblasts and islands of woven bone. Bone lesions can worsen during pregnancy, and estrogen receptors have been identified in the bone lesions of patients with McCune-Albright syndrome.⁵⁸¹

Therapy

The course of monostotic and polyostotic fibrous dysplasia varies. Patients who show progression, nerve compression, or pathologic fractures may require surgery. Careful assessment of the endocrine system is critical in the McCune-Albright syndrome because early intervention can prevent irreversible changes, resulting from precocious puberty. The bone lesions may respond to bisphosphonate.⁵⁸² Treatment with $1,25(\text{OH})_2\text{D}$ may reduce PTHrP production and decrease activity of the bone lesions.⁵⁷⁸

EXTRASKELETAL CALCIFICATION AND OSSIFICATION

Mineral deposition in soft tissues is a common consequence of tissue damage and of a local elevation of the extracellular calcium-phosphate product. Ectopic or heterotopic bone formation can occur at sites of injury or surgical trauma and may be related to the presence of an inductive protein matrix.⁵⁸³ This form of bone induction stimulated the search for BMPs. The frequency of heterotopic ossification after hip replacement or spinal cord injury can be decreased by treatment with local irradiation

or nonsteroidal anti-inflammatory drugs that inhibit prostaglandin synthesis.⁵⁸⁴ Extensive subcutaneous calcium deposition may be crippling in inflammatory disorders such as dermatomyositis.

The term *myositis ossificans* is used when bone formation occurs in traumatized muscle. Similar masses can be formed in tendon, ligaments, joint capsules, and fascia without trauma.⁵⁸³

Tumoral Calcinosis

Primary tumoral calcinosis is an inherited disorder characterized by periarticular calcification and hyperphosphatemia. It is associated with defective phosphate transport and sometimes with excessive activity of renal 1α -hydroxylase. Multiple missense mutations in the *FGF23* gene have been associated with this disorder,⁵⁸⁵ as have mutations in the *GALNT3* gene, whose product O-glycosylates FGF23.⁵⁸⁶ Primary tumoral calcinosis must be differentiated from secondary tumoral calcinosis, which occurs in association with renal failure and with hypercalcemic disorders.

Treatment with phosphate depletion, using phosphate-binding antacids or with diuretics, parathyroidectomy, and dialysis has been attempted.⁵⁸⁷

Fibrodysplasia Ossificans Progressiva

This rare congenital disorder is most often sporadic but can be transmitted as an autosomal dominant disorder.⁵⁸⁸ Characteristic short phalanges and soft tissue swelling can be detected at birth. Abnormal regulation of BMPs has been implicated.⁵⁸⁹ Painful, tender lesions caused by true ectopic bone can develop in connective tissues. Severe progressive deformities may include scoliosis and ankylosis of the spine and rib cage. There is no known therapy. However, in the classic and atypical forms of the disease, activating mutations have been identified in the gene for BMP type 1 receptor (*ACVR1*).^{590,591}

Progressive osseous heteroplasia is another genetic disorder in which ossification occurs largely in the skin but extends into the underlying muscle. It may be caused by an inactivating mutation of G_{α} .⁵⁸⁸

Kidney Stones

REBECA D. MONK • DAVID A. BUSHINSKY

Nephrolithiasis is a common disorder with an incidence greater than 1 case per 1000 patients per year. The prevalence in industrialized nations is approximately 6% in women and 12% in men and appears to be rising over time.¹ The incidence peaks in the third and fourth decades, and prevalence increases with age until approximately age 70 years.¹⁻⁴

In general, stones may be composed of calcium oxalate, calcium phosphate, uric acid, magnesium ammonium phosphate (struvite), or cystine, alone or in combination. A variety of pathogenic mechanisms determine the type of stone formed. Symptomatic stones tend to localize in the renal tubules and collecting system but are also commonly found within the ureters and bladder.⁵

Kidney stones result in substantial morbidity. The severe pain of renal colic can lead to frequent hospitalization, shock wave lithotripsy, or invasive surgical procedures. Although rarely a cause of end-stage renal disease, nephrolithiasis has been associated with chronic kidney disease (CKD) in various populations,⁶⁻¹⁰ and even mild CKD is associated with significant adverse cardiovascular events.¹¹⁻¹³ Insight into the mechanisms involved in stone formation can help direct appropriate therapy, which is known to significantly decrease the incidence of stone formation and its associated morbidity. If this morbidity also includes cardiovascular disease, then stone prevention may

have more significant overall health benefits for patients than merely controlling the pain and consequences of renal colic.

STONE FORMATION

Epidemiology

Numerous factors determine the prevalence of stones, including gender, age, race, and geographic distribution. Nephrolithiasis is more common in men than in women, the ratio being between 2:1 and 4:1.¹⁻⁴ In the United States, Blacks, Latin Americans, and Asian Americans are much less likely to have stones than whites. Geography also appears to influence stone formation in the United States, with a decreasing prevalence from south to north and, to some degree, from east to west.

The greater exposure to sunlight in the southeastern United States may be responsible for the increased rates of nephrolithiasis in that area. Sun exposure can lead to more concentrated urine by increasing insensible fluid losses due to sweating.¹⁴⁻¹⁶ Although the increased sun exposure should increase levels of vitamin D and measured 25-hydroxyvitamin D₃, there is no evidence that this will increase levels of 1,25-dihydroxyvitamin D₃ (calcitriol) or cell-mediated calcium absorption.

TABLE 30-1

Percentage of Patients with Various Stone Types in the United States

Type	Percentage
Mixed calcium oxalate and calcium phosphate	37
Calcium oxalate	26
Calcium phosphate	7
Uric acid	5
Struvite	22
Cystine	2

Adapted from Bushinsky DA. Renal lithiasis. In: Humes HD, ed: *Kelly's Textbook of Medicine*. Philadelphia, PA: Lippincott Williams & Wilkins, 2000:1243-1248.

Geographic location and genetic predisposition can also influence the type of stones formed.^{14,17} Uric acid stones, for example, predominate in Mediterranean and Middle Eastern countries, where they constitute up to 75% of all the stones formed. In the United States, fewer than 10% of kidney stones are pure uric acid stones, and more than 70% are composed of calcium and an associated anion. Less common are magnesium ammonium phosphate (struvite or infection) stones, which account for 10% to 15% of stones formed, and cystine stones, which form as a result of an autosomal recessive disorder and constitute only about 1% of all stones formed (Table 30-1).^{2,17,18}

Diet and pharmacologic agents can also significantly affect stone formation. A recent outbreak of nephrolithiasis in Chinese infants was attributed to ingestion of melamine in infant formula and milk powder. The large melamine particles, intentionally added to raise the apparent protein content of the concentrates, led in many cases to nephrolithiasis and in some cases to renal failure due to obstructive uropathy.¹⁹⁻²¹ A variety of dietary factors can have a significant impact on both formation and prevention of kidney stones (see later discussion).

PATHOGENESIS OF STONE FORMATION

Physiology

Kidney stones form when urine becomes oversaturated with respect to the specific components of the stone. Saturation depends on the chemical free ion activities of the stone constituents. Factors that affect chemical free ion activity include urinary ion concentration, pH, and combination with other substances. For example, an increase in the urinary calcium concentration or a decrease in urine volume increases the free ion activity of calcium ions in the urine. Urinary pH can also modify chemical free ion activity. A low urinary pH increases the free ion activity of uric acid ions but decreases the activity of calcium and phosphate ions. Citrate combines with calcium ions to form soluble complexes and decreases their free ion activity. When the chemical free ion activities are increased, the urine becomes oversaturated (also termed *supersaturated*). In this setting, new stones may form, and established stones may grow. In the setting of decreased free ion activity, urine becomes undersaturated; stones do not grow and can even dissolve. The *equilibrium solubility product* is the degree of chemical free ion activity of stone components in a solution in which the stone neither grows nor dissolves.

Formation of stones occurs through homogeneous or heterogeneous nucleation. In *homogeneous nucleation*, progressive supersaturation can eventually result in complexation of identical ions into small clusters; these clusters grow to form a permanent solid phase, or crystals. *Heterogeneous nucleation* refers to crystal formation on the surface of a different crystal type or on other dissimilar substances, such as cells. In vivo, this type of nucleation is more common than homogeneous nucleation, because crystals form at a lower level of supersaturation in the presence of a solid phase.

The crystals must then aggregate into clinically significant stones, a process that may take longer than the passage of urine through the renal tubules. For stone formation to occur before the crystals are eliminated, the crystals must anchor themselves to the renal tubular epithelium to allow more time for growth. This anchoring of crystals occurs at the renal papillae, over areas of interstitial calcium phosphate (in the form of apatite) termed *Randall's plaques*.²²⁻²⁴ The apatite crystals appear to originate at the basement membrane of tubular cells in the thin loop of Henle and to extend into the interstitium without damaging the cells themselves or filling the tubular lumens. A combination of apatite crystal and organic material extends from the loop of Henle tubular basement membrane to the papillary uroepithelial surface, where calcium oxalate crystals or other crystals can adhere and form stones.

An important factor in the development of kidney stones may be the absence of adequate levels or activity of crystallization inhibitors in patients with stones. Uropontin, pyrophosphate, and nephrocalcin are endogenously produced substances that have been shown to inhibit calcium crystallization. Differences in the amount or activity of inhibitors might account for the variability in stone formation among people with similar degrees of urinary supersaturation.^{18,25}

Clinically, most physicians evaluate the lithogenic potential of urine from stone formers by measuring the rates of excretion of the principal stone-forming elements in terms of mass per unit time (e.g., milligrams or millimoles per 24 hours). It is clear, however, that the lithogenic potential of urine is better determined by the degree of supersaturation. Computer programs that calculate saturation from concentrations of various elements in the urine and the urinary pH are now available and more accurately determine the risk of stone formation. Any calculation of mean saturation underestimates the maximum supersaturation because of hourly variations in water and solute excretion throughout the day.

Diet

Dietary factors have a great influence on the concentration of excreted ions. Simply advising patients to increase fluid intake can have a great impact on reducing stone growth and formation.²⁶⁻²⁸ Renal calcium excretion is augmented by increased sodium excretion,²⁹ and hypercalciuric patients tend to have a greater calciuric response to a sodium load than control subjects.³⁰ Dietary sodium restriction, with the consequent decrease in urinary sodium, thus reduces calcium excretion. Patients are counseled to limit their daily sodium intake to a maximum of 3000 mg (approximately 130 mEq) in an attempt to reduce hypercalciuria.^{2,29,31}

A moderate reduction in animal protein (to approximately 1.0 mg/kg per day) is beneficial in patients with nephrolithiasis because of the multiple mechanisms by which animal protein can contribute to stone formation.³¹

A mild metabolic acidosis develops when animal proteins are metabolized. To buffer the excess hydrogen ions, calcium is resorbed from bone, increasing the filtered load of calcium.³² Metabolic acidosis also directly decreases renal tubular calcium reabsorption, which further enhances hypercalciuria.³² In addition, metabolism of amino acids contained in animal protein generates sulfate ions, which couple with calcium ions to form insoluble complexes.^{32,33} Citrate, a base, forms soluble complexes with calcium and is beneficial in lowering calcium oxalate and calcium phosphate supersaturation and in reducing stone formation. During metabolic acidosis, citrate is reabsorbed proximally, reducing the amount of citrate excreted in the urine.³⁴ Hypokalemia can also lead to reduced citrate excretion. An animal protein-induced reduction in citrate can promote formation of both calcium oxalate and uric acid stones.^{30,35}

Fructose has become a ubiquitous sweetener in American processed foods. In large food questionnaire studies, this sugar has been associated with a significant risk of developing nephrolithiasis. Though the mechanism is not known, fructose is the only carbohydrate that can increase uric acid production, and its metabolism may increase stone formation.³⁶

Studies have demonstrated the benefits of a diet containing an age- and gender-appropriate amount of calcium in patients with kidney stones.^{27,31,37,38} Ingested calcium binds intestinal oxalate, reducing its absorption and consequent renal excretion.²⁷ In a long-term prospective trial, Borghi and colleagues randomly assigned male patients with hypercalciuric stones to either a low-calcium diet or a diet with a normal amount of calcium but low sodium and low animal protein.³¹ Both groups of men were instructed to restrict oxalate intake and to drink 2 to 3 L of water daily. The group of men on the normal-calcium, low-sodium, low-animal protein diet had a significantly lower recurrence of nephrolithiasis and a greater reduction in oxalate excretion and calcium oxalate supersaturation compared with the men on the low-calcium diet.³¹

Therefore, patients should be maintained on an age- and gender-appropriate intake of calcium, and dietary calcium restriction should be strongly discouraged as not only increasing the risk of recurrent stone formation but engendering a significant risk of bone demineralization.^{39,40} The recommended dietary intake for men and women is 1000 mg/day of elemental calcium from ages 19 through 50 years and 1200 mg/day of calcium thereafter.⁴¹ Teenagers should consume 1300 mg of calcium per day. Excess calcium should be avoided, because the combination of calcium and vitamin D supplementation has been shown to significantly increase the risk of kidney stones in postmenopausal women.⁴²

Pathogenesis of Idiopathic Hypercalciuria

Idiopathic hypercalciuria (IH) is the most common cause of calcium-containing kidney stones. Hypercalciuria is defined as excessive urinary calcium excretion. IH is excessive urinary calcium excretion in the setting of normocalcemia and in the absence of secondary causes of hypercalciuria. The disorder is familial; it was initially thought to exhibit an autosomal dominant pattern of inheritance but is almost certainly polygenetic.⁴³

The mechanism by which IH leads to hypercalciuria is not known. It has been postulated that IH comprises three distinct disorders: excessive intestinal calcium absorption, decreased renal tubular calcium reabsorption, and enhanced bone demineralization. Many believe that IH is a systemic disorder of calcium homeostasis with dysregulation of

calcium transport at all of these sites.⁴⁴ An understanding of calcium homeostasis helps elucidate the potential mechanisms involved in IH.

Calcium Homeostasis

Urinary calcium homeostasis is regulated by the gastrointestinal tract, the kidneys, and bone and by the hormones parathyroid hormone (PTH) and calcitriol. Approximately 99% of the calcium in the body is contained within the bone mineral. Daily bone resorption and bone formation, which in healthy, nonpregnant adults should be equal, allow less than 1% of bone calcium to be exchanged with calcium in the extracellular fluid.

Both PTH and calcitriol, at high concentrations, stimulate release of calcium from the bone mineral through osteoclast-mediated bone resorption. Net calcium influx into the extracellular fluid is achieved by absorption from the gastrointestinal tract, which occurs through calcitriol-dependent and -independent mechanisms. Although PTH appears to have no direct effect on gastrointestinal calcium absorption, increased levels of the hormone can stimulate production of calcitriol, which leads to enhanced absorption. Increased serum levels of calcium and calcitriol provide negative feedback to the parathyroid glands, resulting in reduced PTH secretion.

The roughly 60% of calcium in the extracellular fluid that is not protein bound is freely filtered by the renal glomeruli. Approximately 80% to 85% of this amount is passively reabsorbed in the proximal tubule. Most of the remaining calcium is reabsorbed in the thick ascending limb of Henle's loop and in the distal cortical tubules under PTH stimulation. Ultimately, these reabsorptive mechanisms result in a urinary calcium excretion that is less than 2% of the daily filtered load of calcium.⁴⁵ Except during pregnancy and lactation, in healthy, nonosteoporotic adults, urinary calcium excretion (and any calcium lost in sweat) precisely equals net intestinal calcium absorption.

Potential Mechanisms for Development of Idiopathic Hypercalciuria

Dysregulation of calcium transport in the intestine, kidney, or bone can lead to hypercalciuria. For example, excessive calcium absorption by the gastrointestinal tract leads to a transient increase in serum calcium. This suppresses secretion of PTH, which, along with the increased filtered load of calcium to the kidneys, results in hypercalciuria. Excessive calcitriol has a similar effect of increasing intestinal calcium absorption but also results in an influx of calcium into the extracellular fluid because of enhanced bone resorption. The result is hypercalciuria even in the setting of a low-calcium diet or an overnight fast. The excess calcitriol also suppresses PTH secretion, further reducing the renal tubular reabsorption of calcium.

If a primary defect in renal calcium reabsorption has led directly to hypercalciuria, there is a fall in the serum calcium concentration that stimulates synthesis of PTH and calcitriol. Increased calcitriol results in enhanced intestinal calcium absorption and bone resorption. The renal loss of calcium persists even with a low-calcium diet or overnight fast.

Hypercalciuria can also develop as a result of a defect in renal phosphorus reabsorption. The resultant hypophosphatemia leads to enhanced calcitriol production, which stimulates intestinal absorption of phosphorus and calcium. The increased serum calcium and calcitriol suppress PTH synthesis and release. The increased filtered load of calcium in the setting of suppressed PTH leads to

hypercalciuria. Enhanced bone resorption increases the serum calcium concentration, which in turn suppresses PTH production further. The increase in the filtered load of calcium in this setting results in hypercalciuria.

Therefore, there are several potential mechanisms for hypercalciuria.⁴⁴ Do human or animal data support one mechanism above all others? From a clinical therapeutic standpoint, is it worth differentiating among the various potential mechanisms in each patient with suspected IH?

Human Data

Lemann⁴⁶ compiled the results of numerous calcium balance studies of patients with IH and normocalciuric control subjects and normalized the results for calcium intake. He found that intestinal calcium absorption was significantly higher in the subjects with IH.

Coe and colleagues also collected data from published metabolic balance studies, comparing net intestinal calcium absorption and urinary calcium excretion in hypercalciuric and normocalciuric adults.⁴⁷ They also noted an increase in intestinal calcium absorption in subjects with IH but found that urinary excretion of calcium was increased to an even greater degree, placing many of these patients in net negative calcium balance. Although these data confirm that enhanced intestinal absorption of calcium probably plays a role in the pathogenesis of IH, the investigators could not clarify whether this condition is the primary defect or is secondary to another lesion, such as a primary dysregulation of renal tubular calcium reabsorption. Others have suggested that the increase in intestinal calcium absorption, in combination with a decrease in renal calcium reabsorption, points to a more generalized defect in calcium homeostasis. Nonetheless, the finding of enhanced calcium absorption makes enhanced bone resorption an unlikely primary mechanism of IH, because the increase in serum calcium concentration resulting from bone resorption would suppress calcitriol-mediated intestinal calcium absorption.

In most published studies, patients with IH have higher serum levels of calcitriol than normocalciuric control subjects.^{5,44,48} Kaplan and colleagues⁴⁸ determined that calcitriol levels were higher than control values in approximately one third of patients with IH and that intestinal calcium absorption was inappropriately high for the level of calcitriol. These studies support either calcitriol-mediated intestinal calcium absorption or a primary defect in renal tubular calcium reabsorption as a primary mechanism for hypercalciuria in IH.

PTH levels in patients with IH have been reported as normal or slightly lower than those in controls.^{35,39} This finding argues against a reduction in renal tubular calcium reabsorption as the primary defect in IH, because with that mechanism the hypercalciuria would lead to low serum calcium levels and stimulation of PTH secretion. This finding also does not support the hypothesis that elevated levels of PTH are the stimulus for the increased levels of serum calcitriol observed in many studies. It is, however, consistent with the other potential mechanisms for IH.

Bone mass in patients with IH has been assessed by a number of methods, including radiologic densitometry, quantitative computed tomography (CT), dual-energy x-ray absorptiometry (DEXA), and single-photon absorptiometry. Studies of patients with IH have generally shown a mild reduction of bone mineral density compared with values in controls.^{35,39,49} The studies were unable to reveal a unifying mechanism for the mild reduction in bone mineral density, but primary net bone resorption is unlikely, because a much greater decrease in bone density

would be expected in that setting. Altered calcitriol regulation is consistent with this finding, because the effects of calcitriol on bone resorption would be mitigated by the increased intestinal calcium absorption stimulated by the hormone.

Previously it was considered essential to determine whether a patient with IH tended to have excessive gastrointestinal calcium absorption (absorptive hypercalciuria) or excessive renal excretion (renal leak).^{50,51} Patients with excessive renal calcium excretion were prescribed thiazide diuretics, and those who were thought to have a predominantly absorptive defect were prescribed a low-calcium diet. Coe and colleagues³⁹ undermined the validity of this approach in a study in which 24 patients with IH and 9 control subjects were given a low-calcium diet (2 mg/kg per day) for more than 1 week. Urine and blood tests revealed normal serum calcium levels, a mild decrease in PTH levels in the patients with IH, and no difference in calcitriol levels.

The striking finding of Coe's work³⁹ was that, whereas all the normocalciuric subjects excreted less calcium than they ingested on the low-calcium diet, 16 of the 24 subjects with IH had excreted urinary calcium in amounts that exceeded their calcium intake. Therefore, most of the patients with IH receiving a low-calcium diet were in net negative calcium balance. No clear demarcation was noted between the patients who tended to excrete excessive amounts of calcium and those who did not. Instead, there was a smooth continuum of urinary calcium excretion among patients with IH that appeared not to be influenced by calcemic hormones. From a therapeutic standpoint, these findings have rendered obsolete both the need to clinically distinguish among the various IH mechanisms in humans and the prescription of a low-calcium diet in any of these patients. This changed approach to diet is important, because a low-calcium diet can result in a dangerous reduction in bone mineral density, especially in women.^{39,40,44,49} As mentioned earlier, a low-calcium diet appears to increase recurrent stone formation.^{27,31} Therefore, advising a low-calcium diet to prevent recurrent stone formation offers no benefit but carries a number of well-documented risks.

Genetic Hypercalciuric Stone-Forming Rats

To explain more fully the mechanism of IH in humans, we developed an animal model of this disorder.⁵²⁻⁵⁷ Through more than 90 generations of successive inbreeding of the most hypercalciuric progeny of hypercalciuric Sprague-Dawley rats, we established a strain of rats that excrete 8 to 10 times as much urinary calcium as control Sprague-Dawley rats (Fig. 30-1).

Compared with control Sprague-Dawley rats, the genetic hypercalciuric rats absorb far more calcium at lower dietary levels of calcitriol.^{54,58} When these hypercalciuric rats were fed a diet very low in calcium, their urinary calcium excretion remained elevated, compared with that of similarly treated control rats, indicating a defect in renal calcium reabsorption or an increase in bone resorption, or both⁵⁹—again similar to observations in humans.^{39,60} Bone from these hypercalciuric rats released more calcium than the bone of control rats when exposed to increasing amounts of calcitriol⁶¹; their bone mineral density was lower than that of control rats⁶²; and the administration of a bisphosphonate to rats fed a low-calcium diet significantly reduced their urinary calcium excretion.⁶³ In addition, a primary defect in renal calcium reabsorption was observed during clearance studies.⁶⁴ We have shown that, in addition to the intestine, both the bone and the kidney of the

Figure 30-1 Urine calcium levels in genetic hypercalciuric stone-forming (GHS) rats.

hypercalciuric rats have an increased number of vitamin D receptors and calcium receptors.^{52,57,61,65,66}

In summary, this strain of hypercalciuric rats appear to have a systemic abnormality in calcium homeostasis: they absorb more intestinal calcium, they resorb more bone, and they do not adequately reabsorb filtered calcium. Because every one of the hypercalciuric rats forms renal stones, we have described them as genetic hypercalciuric stone-forming (GHS) rats.^{54,55} These studies suggest that an increased number of vitamin D receptors, or possibly increased calcium receptors, or both, may be the underlying mechanism for hypercalciuria in these rats⁶⁶ and perhaps in humans as well.^{54,56,65} In a clinical study, circulating monocytes from humans with IH were shown to have an increased number of vitamin D receptors.⁶⁷

Genetics of Idiopathic Hypercalciuria in Humans

The difficulty in ascertaining the genetics of IH arises, in part, from the numerous other factors that influence stone formation, such as diet, environment, and gender. Because half of patients with IH report a family history of stones and male patients often have fathers or sons with the disorder, inheritance is not believed to be recessive or X-linked. A multitude of monogenic hereditary disorders (see later discussion) can lead to hypercalciuria by causing a variety of mutations resulting in changes in calcium handling in kidney, bone, and gut, as well as changes in the calcium-sensing receptor in the kidneys and parathyroid glands. Given the evidence (discussed earlier) that IH is a complex trait that as a phenotype can develop in multiple ways, it is most likely a polygenic disorder, with heterogeneity of loci and polygenic modifiers.

Although attempts at diagnosing the exact cause of IH in a particular patient might not be critical from a therapeutic standpoint, determining the etiology of IH in a particular family is essential for researchers attempting to clarify the genetics of IH.^{15,23,43,68} Recently, a team of investigators using the technique of genome-wide association studies found that a member of the claudin family, claudin 14, is associated with stone formation.⁶⁹ Whether this association will be found in other populations, supporting its link to stone formation, remains to be determined.

Other Genetic Causes of Stones and Nephrocalcinosis

Numerous monogenic disorders cause hypercalciuria and subsequent nephrolithiasis or nephrocalcinosis.^{15,23,43,68,70-72}

Disorders that lead to hypercalciuria by augmenting bone resorption include osteogenesis imperfecta type 1, multiple endocrine neoplasia type 1 (MEN1) syndrome with hyperparathyroidism, McCune-Albright syndrome, and infantile hypophosphatemia. Disorders that result in hypercalciuria via intestinal hyperabsorption of calcium include hypophosphatemia, Down syndrome, and congenital lactate deficiency.

The following sections provide a more detailed description of several disorders that result in hypercalciuria via their effect on the kidney. Other disorders in this group include autosomal dominant hypocalcemia (which is caused by an activating mutation of the calcium-sensing receptor), Lowe oculocerebrorenal syndrome, and Wilson's disease.

X-Linked Hypercalciuric Nephrolithiasis (Dent's Disease and Others)

Several families around the world were discovered to have a variable combination of disorders including hypercalciuria, low-molecular-weight proteinuria, nephrocalcinosis or stones, hypophosphatemic rickets, and renal failure.^{70,71} Some affected persons demonstrate evidence of defects in proximal tubular reabsorption of amino acids, glucose, or phosphate. PTH tends to be quite low and calcitriol high in the majority of patients. The abnormalities completely resolve in those patients who receive renal transplants, a finding that suggests a renal tubular disorder rather than a systemic process. In all families, the pattern of inheritance is consistent with an X-linked recessive disorder, with male patients affected to a greater extent than female patients. The latter are often minimally affected but transmit the disorder to half of their male offspring.

Over time, the various disorders—X-linked recessive nephrolithiasis in the United States, Dent's disease in the United Kingdom, X-linked recessive hypophosphatemic rickets in Italy, and low-molecular-weight proteinuria with hypercalciuria and nephrocalcinosis in Japan—have all been linked to mutations affecting the *CLCN5* gene on the Xp11.22 locus of the X chromosome. This gene encodes the CLC-5 protein, which is one of the nine members of the CLC family of voltage-gated chloride channels. How defects in this channel lead to the array of disorders listed here, including hypercalciuria, stones, and renal failure, is not yet understood.

Bartter's Syndrome

Bartter's syndrome comprises approximately five genetic mutations, predominantly autosomal recessive, that lead to sodium chloride wasting at the thick ascending limb of the loop of Henle.^{23,24,43,72,73}

Defects can arise in the sodium-potassium-chloride cotransporter (NKCC2), the renal outer medullary potassium channel (ROMK), the basolateral chloride channel (CLC-Kb), or in a chloride channel subunit known as barttin. The resultant defect in sodium transport leads to a reduction in the transtubular potential difference, which causes a decrease in paracellular calcium reabsorption in the thick ascending limb. The ensuing reduction in intravascular volume also induces an aldosterone-mediated metabolic alkalosis. Bartter's syndrome, therefore, resembles high-dose furosemide administration and differs from Gitelman's syndrome in that hypercalciuria, nephrocalcinosis, and nephrolithiasis are seen with Bartter's but not with Gitelman's.

An autosomal dominant form of Bartter's results from a gain-of-function mutation in the calcium-sensing receptor

in renal tubular cells. This mutation leads to reduced calcium reabsorption, hypocalcemia, and low PTH levels. Therapy with vitamin D and calcium supplementation can exacerbate stone disease in this disorder.

For unknown reasons, the barttin defect leads to deafness but not to nephrocalcinosis or stones.

Familial Hypomagnesemia with Hypercalciuria and Nephrocalcinosis

Familial hypomagnesemia with hypercalciuria and nephrocalcinosis (FHHNC) is an autosomal recessive disorder that results in hypomagnesemia, hypercalciuria, nephrolithiasis, and distal (type 1) renal tubular acidosis (dRTA). Polyuria and severe nephrocalcinosis also ensue, and progressive renal failure is common by late childhood.^{23,24} The genetic disorder results in defective production of the tight junction proteins claudin 16 and claudin 19, which facilitate paracellular calcium and magnesium transport in the thick ascending limb as well as renal sodium reabsorption.^{74,75}

Distal Renal Tubular Acidosis

dRTA is caused by dysfunctional α -intercalated cells, resulting in defective acid excretion.^{23,24,43,68,76} This inability to adequately acidify the urine results in metabolic acidosis, hypocitraturia, hypokalemia, hypercalciuria, and nephrocalcinosis and stones. The metabolic acidosis leads to resorption of calcium and phosphate from bone. The increased filtered load of calcium and phosphate, along with the elevated urine pH and hypocitraturia, results in favorable conditions for calcium phosphate stone formation.

Although there are secondary causes of dRTA, such as Sjögren's syndrome and carbonic anhydrase inhibitors (e.g., acetazolamide), there are also a number of hereditary causes. Some are autosomal recessive and can also result in hearing loss; others are autosomal dominant. One form of dRTA that targets carbonic anhydrase II results in osteopetrosis and brain calcifications. Patients with dRTA fail to lower their urine pH below 5.5 after ingestion of an acid load. Their urine citrate levels are extremely low, despite often mildly reduced or even normal serum bicarbonate levels.

Hereditary Hypophosphatemic Rickets with Hypercalciuria

Hereditary hypophosphatemic rickets with hypercalciuria is an autosomal form of hypophosphatemic rickets that is manifested clinically by hypophosphatemia secondary to renal phosphate wasting.^{77,78} In these patients, hypophosphatemia induces increased levels of calcitriol, leading to increased intestinal calcium absorption and hypercalciuria. The bone pain, muscle weakness, limb deformities, and rickets remit completely with administration of oral phosphate. This disorder has been mapped to a region of chromosome 9 that contains the gene for the renal sodium-phosphate cotransporter NaPi-IIc. Mutations of this gene likely result in a complete loss of function of this protein in patients who have a homozygous single-nucleotide deletion.

Primary Hyperoxaluria and Cystinuria

Primary hyperoxaluria (PH) and cystinuria are each discussed later in this chapter (see "Specific Therapy and Etiology").

CLINICAL PRESENTATION AND EVALUATION

Kidney stones vary in clinical presentation from asymptomatic retained stones, to passage, to large, obstructing staghorn calculi that can significantly impair renal function and lead to end-stage renal disease.^{4,79} The severity of stone disease depends on the pathogenetic factors contributing to the rate of stone formation in addition to stone type, size, and location.

In its most classic form, nephrolithiasis is manifested as renal colic. This discomfort of abrupt onset intensifies over time into an excruciating, severe flank pain that resolves only with stone passage or removal. The pain often migrates anteriorly along the abdomen and inferiorly to the groin, testicles, or labia majora as the stone moves toward the ureterovesical junction. Gross hematuria, urinary urgency and frequency, nausea, and vomiting may be present. Stones smaller than 5 mm are likely to pass spontaneously with hydration, whereas larger stones often necessitate urologic intervention for removal.

Certain disorders can lead to small, diffuse renal parenchymal calcifications, termed *nephrocalcinosis*.^{4,24,76,80} The calcifications, usually calcium phosphate or calcium oxalate, may be present in the cortex or medulla. Among the most common causes of stone-related nephrocalcinosis are PH and medullary sponge kidney.

Metabolic Evaluation of Stone Formers

Although it is uniformly accepted that patients with multiple stones merit a thorough investigation into the cause of their nephrolithiasis, evaluation of the patient with a single stone is controversial. This probably reflects the difficulty in determining the cost-benefit ratio of stone evaluations and the wide differences in reported rates of stone recurrence.

The National Institutes of Health has convened several consensus conferences to resolve such issues related to the prevention and treatment of kidney stones.³ These panels determined that all patients, even those with a single stone, should undergo at least a basic evaluation to rule out a systemic etiologic mechanism. Patients with an increase in number or size of stones (metabolically active stones), all children, all noncalcium stone formers, and all of those in demographic groups not typically susceptible to stone formation warrant a more complete metabolic evaluation (Fig. 30-2).³

The Basic Evaluation

Elements of the basic evaluation are listed in Table 30-2.

History

In addition to the medical history typically obtained from new patients, evaluation of the stone former includes a stone history and a thorough review of diet, fluid intake, and lifestyle. Specific laboratory studies and radiographic tests are also required.

Stone History. The stone history begins with a chronology of stone events: age at incidence of first stone, size and number of stones formed, frequency of passage, stone type if known, and whether the stones occur equally in both kidneys or unilaterally. Also helpful is a report of the patient's symptoms with each episode and the need for and response to surgical intervention.

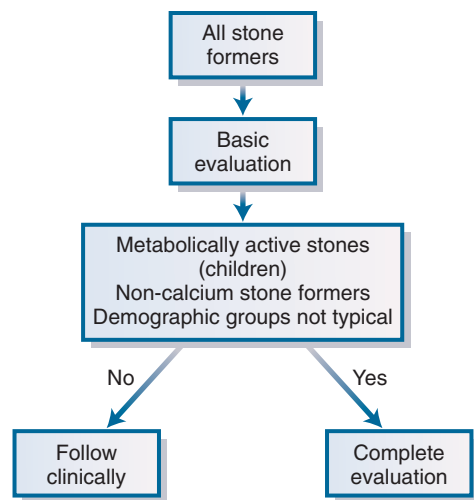

Figure 30-2 Evaluation of stone formers.

This information imparts not only the severity of the stone disease but also clues to the origin of the patient's nephrolithiasis. For example, nephrolithiasis that begins at a young age may be attributable to an inherited metabolic disorder such as PH or cystinuria. Large staghorn calculi that are difficult to eradicate and that recur despite frequent surgical intervention are more likely to be composed of struvite instead of calcium oxalate. Cystine stones are not disintegrated thoroughly with the use of lithotripsy, and alternative surgical modalities are usually required for stone removal. For patients who tend to form stones in only one kidney, the possibility of congenital abnormalities of that kidney, such as megacalyx or medullary sponge kidney, should be explored.

Medical History. Systemic disorders that can contribute to nephrolithiasis are sought in the medical history. Any disorder that can result in hypercalcemia, such as sarcoidosis or certain malignancies, may also lead to hypercalciuria. A variety of gastrointestinal disorders associated with malabsorption (e.g., sprue, Crohn's disease) can cause calcium oxalate nephrolithiasis on the basis of enteric hyperoxaluria. Patients with gout or insulin resistance are more likely to have uric acid stones (Tables 30-3 and 30-4).^{15,17}

Family History. As noted earlier, a number of stone disorders are inherited, making the family history an important component of the basic evaluation. IH appears to be a familial disorder. Although the exact chromosomes and genes have not yet been identified, the pattern of inheritance is almost certainly polygenic.

Stones arising in childhood or young adulthood can be related to autosomal recessive disorders such as cystinuria and primary oxaluria. These genetic disorders are reviewed in the sections on treatment of cystine and oxalate stones.

The high prevalence of uric acid stones in certain areas of the world is suggestive of genetic as well as environmental risk factors. Genes that cause either excessively acidotic urine or hyperuricosuria have been implicated.^{2,4,17,23,80-83}

Medications

Medications can contribute to stone formation in several ways. Calcium-containing supplements can increase the amount of calcium absorbed and subsequently excreted.⁴² Loop diuretics can directly promote renal tubular excretion of calcium and are associated with nephrocalcinosis in neonates who have received the drug.^{84,85} Acetazolamide, a weak diuretic, induces a mild metabolic acidosis and alkaline urine, favorable conditions for the development of calcium phosphate stones. Other medications, such as salicylates and probenecid, are implicated in uric acid lithiasis.

Certain crystals or stones can consist completely of precipitated medication. Such medications include intravenously administered acyclovir, triamterene, indinavir, and various sulfonamides (e.g., sulfadiazine). Oxalate is a metabolic end product of vitamin C, and large doses of vitamin C increase oxalate excretion and may predispose to stone formation (Table 30-5).^{86,87}

Lifestyle and Diet

Occupation and lifestyle are aspects of the social history that can be relevant to stone formation. Surgeons and traveling salespeople, for example, tend to minimize fluid intake to avoid frequent micturition throughout the day. Loss of insensible fluid can also exacerbate nephrolithiasis and may be related to employment (e.g., construction work) or hobbies (e.g., running, gardening).

The evaluation proceeds with a thorough review of the patient's diet and fluid intake. Patients are asked to review what they eat at all meals and snacks. Particular attention is paid to ingestion of foods high in sodium (fast foods, canned foods, added salt or soy sauce) and the quantity of animal protein consumed (discussed later). Patients are also asked to list four or five favorite foods or snacks to assess whether they may be consuming foods high in oxalate or purine. Many patients are erroneously counseled by physicians to avoid calcium-containing foods. As discussed earlier, doing so may result in bone demineralization (a grave concern in women with stones) if renal tubular calcium reabsorption is inadequate, and is also associated with increased stone formation.^{27,31,37}

Physical Examination

For most patients with nephrolithiasis, physical findings are normal, but in some, the findings reveal a systemic disorder related to the stone disease. For example, an enterocutaneous fistula may be associated with Crohn's disease, a common cause of enteric oxaluria. A paraplegic patient with an indwelling catheter may be susceptible to frequent urinary tract infections with urease-producing organisms and consequent struvite stone formation. Hyperuricosuria and uric acid stone formation may be seen in patients with tophi related to gout.^{2,4}

TABLE 30-5

Medications Associated with Renal Lithiasis and Nephrocalcinosis**Medications That Promote Calcium Stone Formation**

Acetazolamide
 Amphotericin B
 Antacids (calcium and noncalcium antacids)
 Calcium supplements

 Indinavir
 Nelfinavir
 Sulfonamides
 Triamterene

Adapted from Monk RD. Clinical approach to adults. *Semin Nephrol*. 1996;16:375-388; Monk RD, Bushinsky DA. Nephrolithiasis and nephrocalcinosis. In: Johnson R, Feehally J, eds. *Comprehensive Clinical Nephrology*, 3rd ed. London, UK: Mosby, 2007:641-655.

Laboratory Tests

Although valuable information is gleaned from the history and physical examination, it is often difficult to determine the metabolic cause of a patient's nephrolithiasis without laboratory data. The urinalysis is an easy and inexpensive test that provides a great deal of information. Uric acid and calcium oxalate stones grow more favorably at an acidic pH, and a consistently high urinary pH may suggest calcium phosphate or struvite nephrolithiasis. The specific gravity, if high, can confirm the suspicion of inadequate fluid intake.

Hematuria is often present in active stone disease. Microscopic examination of the urine in this case may reveal characteristic crystals. Bacteria and pyuria noted in conjunction with a high urinary pH (approximately 6.5) are characteristic of struvite stone disease. Urine specimens for culture should be obtained in such a setting. Because enough urease may be produced to form struvite stones even when colony counts are low (approximately 50,000 colony-forming units), the microbiology laboratory should be instructed specifically to identify the organism and to check for urease despite low colony counts.⁸⁸

Qualitative cystine screening should be performed on a urine specimen. Urine turns purple-red when sodium nitroprusside is added to a specimen containing cystine at a concentration greater than 75 mg/L.⁸¹

Recommended blood tests in the basic evaluation include electrolytes (sodium, potassium, chloride, bicarbonate), serum creatinine to determine the overall renal function, uric acid, calcium, and phosphorus.^{2,3} If the calcium level is elevated or at the upper limit of normal, or if the serum phosphorus level is reduced or at the lower limit of normal, a serum intact PTH level is also determined to rule out primary hyperparathyroidism. Low serum bicarbonate levels suggest a hypocitraturic disorder such as renal tubular acidosis or acetazolamide ingestion.

Stone Analysis

Stone analysis should be performed, whenever possible, in patients with a new history of nephrolithiasis and in patients with long-standing stone disease who note a difference in clinical presentation or in the color, shape, or texture of any stone passed. Knowing the constituents of a stone can help the physician target certain elements of the medical history and specific urine studies. In most cases, the stone must be sent to an outside laboratory for examination. X-ray diffraction crystallography and infrared spectroscopy are currently the most accurate methods available for stone analysis.⁸⁹

Radiologic Evaluation

Various radiologic tests can help determine the location and extent of the stone burden and may elucidate genitourinary abnormalities contributing to stone formation. For acute renal colic, spiral (or helical) CT without contrast (unenhanced) has replaced intravenous pyelography (IVP) as the optimal modality for detection and localization of kidney stones. Helical CT has proved to be at least as sensitive and specific as IVP in detecting stones of all types in the kidneys and ureters. In addition, it can more accurately reveal causes of flank pain and hematuria not related to stones and requires no exposure to intravenous contrast material. Radiation exposure is a disadvantage of both CT and IVP, and the exposure to patients undergoing helical CT may be triple that of IVP. Therefore, it should be used judiciously, especially in young patients with frequent episodes of renal colic. Helical CT takes less time to perform,

which is a potential advantage in an emergency department setting, but it tends to be more costly.^{79,90-92}

CT should be followed by a plain film (radiograph) of the abdomen that includes the kidneys, ureter, and bladder (KUB). Plain films can assist in determining stone composition. Stones composed of calcium, cystine, or struvite are radiopaque and visible on KUB, whereas radiolucent stones, such as those composed of uric acid or xanthine, are not.

IVPs are useful in detecting certain genitourinary abnormalities that can predispose to nephrolithiasis, such as medullary sponge kidney and caliceal abnormalities. Another advantage of IVP is that the osmotic diuresis generated by the administered contrast agent may aid in excretion of the offending stone during an episode of acute renal colic. A major disadvantage of IVP is exposure to radiographic contrast material. Administration of contrast should be avoided in patients who are at high risk for development of nephrotoxicity from the contrast agent, such as elderly patients; those with diabetes mellitus, proteinuria, or preexisting kidney disease; and those with significant intravascular volume depletion.

Renal ultrasound is a useful test for patients who must avoid exposure to radiation or contrast agents, such as pregnant women and children. It is fairly specific but not as sensitive as spiral CT for detecting stones within the kidney. Visualization of ureteral stones is poor with ultrasound.

Once a patient is known to have a certain type of stone, specific tests may be used in follow-up. For example, a patient who is known to have asymptomatic calcium stones can have a KUB test 6 to 12 months later to assess for any increase in stone size or number.^{2,4} However, radiation exposure should be limited to patients in whom the results of the test will alter treatment. Little is gained in asymptomatic patients by checking for stone growth or movement if maximal dietary and pharmacologic therapy is already being prescribed.

The Complete Evaluation

The complete evaluation comprises the entire basic examination as well as a 24-hour urine collection to determine volume and levels of calcium, oxalate, citrate, sodium, urate, phosphorus, and creatinine and supersaturation with respect to the common solid phases (Table 30-6). Creatinine is used to assess the adequacy of the collection; men should excrete approximately 15 to 20 mg/kg of creatinine per day, and women should excrete 10 to 15 mg/kg of creatinine per day. Cystine should also be measured in patients known to have cystine stones or in whom prior urine studies have not determined whether there is excessive excretion of this amino acid.

Patients should be instructed to collect the urine on a day when they perform usual activities and have their typical fluid and dietary intake. The first morning's urine specimen is discarded, and all urine for the next 24 hours (including the next morning's specimen) is collected in the container. The ideal 24-hour urine collection includes measurement and reporting of the daily excretion of the constituents listed in Table 30-6 and also the presence of supersaturation of calcium oxalate, calcium phosphate, or uric acid. Patients should be instructed to discontinue multivitamins approximately 5 days before the collection to prevent any antioxidant effect of the vitamins on the urine sample. In most cases, an acid or antibiotic is included in the collection container or added with the first urine sample as a preservative. Certain laboratories require various preservatives for the different factors measured.

TABLE 30-6

Optimal 24-Hour Urine Values in Patients with Nephrolithiasis

Parameter	Value
Volume	>2-2.5 L
pH	>5.5 and <7.0 (24-hr specimen not required)
Calcium	>300 mg or >3.5-4.0 mg/kg in men; >250 mg or >3.5-4.0 mg/kg in women
Oxalate	>40 mg
Sodium	>3000 mg or >130 mEq
Uric acid	>800 mg in men; >750 mg in women
Phosphorus	>1100 mg
Citrate	>320 mg
Creatinine	>15 mg/kg in men; >10 mg/kg in women in order to ensure adequacy of collection
Supersaturation of calcium oxalate	>5
Supersaturation of calcium phosphate	0.5-2* (ideally <1)
Supersaturation of uric acid	0-1*

*Ideal values can vary among laboratories that perform supersaturation analysis.

Physicians should ask their laboratory how many 24-hour urine collections and which preservatives are required for the complete evaluation. Several national laboratories simplify this process to a single urine collection on which all of the measurements are preformed and resultant supersaturation is calculated; this almost certainly improves adherence and perhaps the accuracy of the calculation of supersaturation.^{2,93}

Patients who require the complete evaluation include all children, nonwhite patients (i.e., demographic groups not typically prone to nephrolithiasis in the United States), noncalcium stone formers, and patients with metabolically active stone disease (i.e., stones that grow in size or number within 1 year).²⁻⁴

THERAPY

Surgical Treatment

Treatment of an acute episode of renal colic often involves surgical management for large stones that do not pass spontaneously. Stones smaller than 5 mm in largest diameter have a 68% chance of passing spontaneously, whereas those larger than 5 mm but smaller than 10 mm have a spontaneous stone passage rate of less than 50%.⁹⁴ Most stones greater than 10 mm, and many of those between 5 and 10 mm in size, require surgical intervention for relief of renal colic, ureteral obstruction, or other symptoms of clinically active stone disease. With the advent of newer, less invasive urologic therapies, open surgical stone extraction is rarely done. Current urologic therapy includes extracorporeal shock-wave lithotripsy (ESWL), ureteroscopic extraction (URS), and percutaneous nephrolithotomy. The exact procedure used varies according to stone location in the kidney or ureter, size, composition, various patient factors, and surgical expertise.⁹⁴⁻⁹⁷

ESWL involves focusing sound waves from a machine outside the body onto the kidney stone. The impulses fragment the stone into smaller stones or "gravel" that can

more easily be passed spontaneously. Newer-generation lithotripters do not require a water bath and often require less analgesia.⁹⁸ Kidney stones smaller than about 15 mm, proximal ureteral stones, upper- and middle-pole kidney stones, and those not composed of cystine or calcium oxalate monohydrate respond best to ESWL.^{94,96-98} Because fluoroscopy is typically used to visualize radiopaque stones during the procedure, ESWL may be more complicated in patients with uric acid lithiasis. ESWL is relatively contraindicated in patients with coagulopathy and in pregnant women. It may be less successful in patients with a higher body mass index, because a low skin-to-stone distance is necessary to achieve optimal success.^{97,98}

Ureteroscopy, the passage of a semirigid or flexible scope through the bladder and into the ureter, has become a mainstay of surgical stone extraction for most ureteral stones, especially distal ureteral stones, and larger proximal stones. Endocorporeal lithotripsy can be added to URS to directly fragment visualized stones. One of the more commonly used devices is the holmium:yttrium-aluminum-garnet (YAG) laser lithotripter, which combines both pneumatic and ultrasound lithotripsy to fragment stones. This results in high stone-free rates after the procedure.^{95,99} Complications of ESWL and URS include urinary tract infection, sepsis, ureteral stricture, ureteral injury, and steinstrasse or "stone street"—the linear accumulation of small stones blocking a ureter after fragmentation of a larger stone.

Percutaneous nephrolithotomy involves placement of a large needle through the flank into the renal collecting system. The tract is dilated, and instruments are used to rupture and remove the stone. Although percutaneous nephrolithotomy is more invasive than ESWL and URS, it is more effective in removing large (>2 cm) or staghorn calculi and stones that do not fragment well with lithotripsy. Large, infected stones such as struvite stones, in which complete removal is desired, are best treated with percutaneous nephrolithotomy.^{96,97}

Medical Expulsive Therapy

Another form of therapy that has been shown to reduce the time to stone passage is medical expulsive therapy. Several medications have demonstrated benefit in reducing the time to stone passage and in assisting with passage of larger stones.¹⁰⁰ Most of these, such as the calcium-channel blocker nifedipine (extended-release formulation, 30 mg taken daily or twice daily) and α -adrenergic receptor blockers such as tamsulosin (0.4 mg daily by mouth), terazosin, and doxazosin act by reducing spasms of the ureteral smooth muscle and allowing ureteral peristalsis to more effectively move the stone through. The addition of corticosteroids may also assist with stone passage by reducing ureteral inflammation and swelling in the ureter where the stone is lodged.

In several prospective, randomized, controlled trials, calcium channel blockers and α -adrenergic blockers showed significant benefit in both the rate of successful stone passage and the time to passage. In the controlled studies, these therapies were compared with placebo¹⁰¹ or with standard therapy such as antispasmodic therapy, nonsteroidal anti-inflammatory agents, or analgesics. In a few studies comparing α -adrenergic receptor blockers to calcium channel blockers, the α -blocker tamsulosin was found to result in higher stone passage rates and more rapid stone expulsion than nifedipine.^{100,102,103} Both agents were generally well tolerated, although perhaps with less hypotension in the tamsulosin groups.

Medical expulsive therapy may be cautiously attempted for up to 4 weeks as long as pain is well controlled; the patient has normal, stable kidney function; no urinary tract infection is present; and the patient does not have an obstructed solitary kidney or bilateral obstruction. Frequent follow-up and occasional imaging with ultrasound are recommended to ensure that the patient remains free of complications while awaiting stone passage.

Medical Preventive Therapy

Medical preventive therapy is the mainstay of medical management. The remainder of the chapter focuses on this approach.

Nonspecific Therapy

Most patients, irrespective of stone type, are given general advice about fluid and dietary modification to prevent further stone formation. These nonpharmacologic interventions, which include an increase in fluid intake as well as restriction of dietary sodium and animal protein, can reduce the incidence of stone formation, a result termed the *stone clinic effect*.^{27,28,104} In one study, such interventions resulted in a 40% decrease in stone recurrence over 5 years.²⁶

The mainstay of nonspecific therapy involves dietary measures (see earlier discussion): increased fluid intake to raise urine volume to approximately 2 to 2.5 L, a reduction in sodium intake to less than 3000 mg/day (130 mEq/day), moderate reduction in animal protein ingestion to approximately 1.0 mg/kg per day, and, perhaps, eating certain fruits or juices high in citrate.^{2,27-29,104-106} Dietary calcium restriction is no longer recommended because it not only reduces bone mineral content but also increases the rate of stone recurrence, presumably by decreasing intestinal calcium oxalate complexation and increasing urinary oxalate excretion.²⁷ In retrospective studies of dietary intake, both women and men were found to have reduced stone formation with increased dietary calcium ingestion. However, calcium supplements were associated with an increased risk of stones in women; patients should be advised to maintain an age- and gender-appropriate intake of dietary calcium, preferably without supplements.^{27,31,37,42,107}

Specific Therapy and Etiology

The optimal therapy for patients with metabolically active stone disease is directed at the particular metabolic abnormality. Before medications for nephrolithiasis are prescribed, all patients should be treated with the nonspecific measures just noted. Before any therapeutic intervention, some clinicians assess the patient's existing stone burden with a radiologic examination (KUB, spiral CT, IVP, or ultrasonography). If stones are seen, the subsequent passage of stones would not necessarily indicate therapeutic failure. However, this approach must be weighed against the not insignificant cost of these procedures and the radiation exposure. In our practice, we do not obtain baseline radiographs in asymptomatic patients unless the results will alter subsequent therapy. The basic and complete evaluations help direct the clinician to the specific treatments discussed here.

Calcium Stones. Most kidney stones (approximately 70%) contain calcium (see Table 30-1). More than one third of these are composed of calcium oxalate alone, and another 7% are composed of calcium phosphate alone. The remainder are composed of a combination of calcium oxalate and

either urate or calcium phosphate. The stones tend to be gray, brown, or tan and rarely grow larger than 1 to 2 cm.^{2,25,89}

The main causes of calcium stone formation are hypercalciuria (excessive urinary calcium excretion), hyperoxaluria (excessive oxalate excretion), hyperuricosuria (excessive uric acid excretion), hypocitraturia (insufficient citrate excretion), renal tubular acidosis, congenital abnormalities of the genitourinary tract, and certain medications.

Hypercalciuria. Patients with persistent hypercalciuria often benefit from a thiazide diuretic. This class of drugs is inexpensive and extremely effective at reducing urinary calcium excretion and stone formation.^{2,108}

To maximize the efficacy of thiazides, patients must consume a sodium-restricted diet. Whereas hydrochlorothiazide is commonly used for hypertension, chlorthalidone is favored for treatment of hypercalciuria because it has a longer half-life and requires only once-daily dosing. The starting dose is 25 mg and can be increased to 50 mg. In petite patients and in those with low blood pressure, therapy can be initiated with once-daily doses of 12.5 mg.

Side effects of thiazides include an increase in serum lipid levels and hyperglycemia. For patients in whom this is a concern, such as those with hypercholesterolemia, other cardiac risk factors, or elevated blood glucose levels, indapamide (1.25 to 2.5 mg) is an effective alternative.¹⁰⁹ This agent has less of an effect on serum lipids and blood sugar than thiazides.

Hypokalemia is another common side effect of thiazide therapy. Patients should be advised to increase their dietary intake of potassium-rich foods, and the potassium level should be checked 7 to 10 days after the medication is started. Hypokalemia can result not only in cardiac and neuromuscular problems but also in hypocitraturia, another risk factor for stone formation. The supplement of choice is potassium with a base, such as citrate or bicarbonate, as the accompanying anion.

Potassium citrate is available as a liquid or as a wax-matrix tablet. The wax-matrix form is preferable, because patients find the liquid unpalatable. However, patients with malabsorption disorders absorb potassium citrate better in the liquid form. Potassium citrate in the wax-matrix formulation is available in tablets of 5 or 10 mEq. Between 20 and 40 mEq/day in single or divided doses is usually adequate supplementation. Determination of follow-up potassium and bicarbonate levels may be required for further dose adjustment. Because citrate is a base, metabolic alkalosis can result with this medication, especially if it is given with a thiazide diuretic. An alternative potassium supplement (e.g., potassium chloride) may be required. If hypokalemia persists or if large doses of supplemental medication are required, the patient might benefit from the addition of a potassium-sparing diuretic. Triamterene is generally avoided because it can precipitate into stones. Amiloride may be initiated at a starting dose of 5 mg or in a combination tablet with thiazide.

After at least 4 weeks of therapy with the new medication, the 24-hour urine collection should be repeated to assess its efficacy in reducing calcium levels; 24-hour urinary sodium and citrate levels should also be measured. The thiazide dose may need to be increased to decrease calcium excretion to less than 3 to 4 mg/kg per day. If sodium excretion remains high in conjunction with elevated urinary calcium excretion, further dietary counseling aimed at reducing dietary sodium may be required. Additional potassium citrate may be required if urinary citrate or serum potassium levels remain low.^{2,110}

Hyperoxaluria. Oxalate is produced predominantly by endogenous metabolism of glyoxylate and, to a lesser extent, by ascorbic acid. Some urinary oxalate is derived from dietary sources, such as rhubarb, cocoa, nuts, tea, and certain leafy green vegetables. Absorbed oxalate is excreted unchanged in the urine and raises urinary supersaturation with respect to calcium oxalate.^{5,80,111,112} Hyperoxaluria, as the sole metabolic abnormality, accounts for the formation of only about 5% of all calcium stones.^{23,113,114}

The three main causes of hyperoxaluria are excessive oxalate ingestion (dietary oxaluria), malabsorptive gastrointestinal disorders (enteric oxaluria), and excessive endogenous production of oxalate related to a hepatic enzyme deficiency (PH).

Because ethylene glycol (used as antifreeze in automobiles) is metabolized to oxalate, nephrolithiasis, in conjunction with severe metabolic acidosis and renal failure, is often observed in patients after ingestion of ethylene glycol.

Dietary Oxaluria. Dietary oxaluria results in urinary oxalate levels that are mildly elevated (40 to 60 mg/day). Many high-oxalate foods are fruits, vegetables, and nuts that are generally considered beneficial in most diets. In a retrospective analysis, patients consuming diets similar to the Dietary Approaches to Stop Hypertension (DASH) diet had fewer stones than those who consumed markedly different diets, despite the fact that the DASH diet is high in oxalate.¹¹⁵ The diet is also high in potassium and calcium and low in sodium, factors that may be more preventive in stone formation than oxalate is detrimental. Patients with dietary hyperoxaluria should be provided with a detailed list of high-oxalate foods to review (Table 30-7). How restrictive patients need to be with regard to the list is unclear, and common sense should be used, especially because many patients with stones also have hypertension and diabetes mellitus and benefit from a diet that is high in fruits and vegetables.

Patients are instructed to ingest calcium-containing foods, such as a glass of milk, when eating foods high in oxalate. The calcium in milk binds the dietary oxalate and

may prevent its absorption.^{23,27} In patients who have severe dietary hyperoxaluria with active stone disease, 2 or 3 tablets of calcium carbonate (500 to 650 mg per tablet) may be prescribed to be taken with high-oxalate meals. This should be done cautiously, however, given the association between calcium supplements and kidney stones in women in the general population (see earlier discussion).

Enteric Oxaluria. Enteric oxaluria results in higher urinary oxalate levels (60 to 100 mg/day) than dietary hyperoxaluria. Gastrointestinal malabsorptive conditions associated with normal colonic function, such as Crohn's disease, celiac sprue, jejunoileal bypass, chronic pancreatitis, and biliary obstruction, can lead to enteric oxaluria. In these disorders, malabsorbed fatty acids bind calcium in the intestinal lumen, making more free oxalate available for absorption in the colon. In addition, the colonic mucosa becomes more permeable to oxalate as a result of exposure to malabsorbed bile salts.¹¹⁶⁻¹¹⁸

The mainstay of treatment, whenever possible, is therapy for the underlying disorder. A gluten-free diet can significantly reduce hyperoxaluria associated with sprue; for other conditions (e.g., surgical short-bowel syndrome), no specific therapy is feasible. In such cases, reduction of malabsorption and oxalate absorption may be achieved by instituting general therapy for steatorrhea, such as a low-fat diet, cholestyramine, and medium-chain triglycerides. As in patients with dietary oxaluria, an oxalate-restricted diet and calcium carbonate with meals should be prescribed (Fig. 30-3).^{27,119} Because of chronic diarrhea, these patients are at substantial risk for low urine volumes, hypocitraturia, hypokalemia, and hypomagnesuria. The acidic, concentrated urine also predisposes to development of uric acid stones.^{120,121} Additional fluid intake must be stressed, and potassium citrate (the liquid form is usually better absorbed, although poorly tolerated, in these patients) and magnesium supplementation are often prescribed. Magnesium appears to be an inhibitor of stone formation and is supplied as magnesium oxide at 400 mg by mouth twice a day or as magnesium gluconate at 0.5 to 1 g by mouth three times a day.¹²²

Primary Hyperoxaluria. PH leads to nephrolithiasis because hepatic enzyme deficiencies in these patients result in massive endogenous oxalate production.^{80,82,123} PH results not only in severe hyperoxaluria (80 to 300 mg/day) but also in widespread deposition of oxalate in numerous organs and tissues such as the heart, bone marrow, muscle, and renal parenchyma at a young age. Cardiomyopathy, bone marrow suppression, and renal failure can ensue. In type 1 PH, the deficient hepatic enzyme is alanine-glyoxylate aminotransferase (AGT), and the deficiency is caused by one of several mutations found in the AGT gene, AGXT. In type 2 PH, which is an even more uncommon disorder, patients lack D-glycerate reductase and glyoxylate reductase due to mutations in the gene GRHPR. In some patients with type 1 PH, pyridoxine (vitamin B₆) can increase enzyme activity, thereby reducing oxalate production.

All patients with PH should be treated with measures that reduce calcium oxalate precipitation, such as ample fluid supplementation, potassium citrate, magnesium, and orthophosphate. Orthophosphate is an effective inhibitor of calcium oxalate crystallization but should be avoided in patients who have a glomerular filtration rate of less than 50 mL/minute. *Oxalobacter formigenes* is a bacterium that relies on oxalate for its metabolism.^{36,124} In small studies, administration of these bacteria to patients with PH type 1 resulted in a very modest reduction in urinary oxalate excretion.³⁶ When commercially available, provision of

TABLE 30-7

Foods High in Oxalate

Beans (green and dried)
Beer: draft, stout, lager, pilsner
Beets
Berries: blackberries, blueberries, raspberries, strawberries, juice containing berries
Black tea
Black pepper
Celery
Chocolate, cocoa
Eggplant
Figs, dried
Greens: collard greens, dandelion greens, endive, escarole, kale, leeks, mustard greens, parsley, sorrel, spinach, Swiss chard, watercress
Green peppers
Lemon, lime, and orange peel
Nuts
Pecans, peanuts, peanut butter
Okra
Rhubarb
Sweet potato
Tofu

these bacteria may provide additional therapy in the treatment of PH.

Patients with renal failure might benefit from renal transplantation, because dialysis is not as effective as a functioning kidney in oxalate removal. Measures to reduce calcium oxalate precipitation should be continued after renal transplantation to prevent rapid loss of the allograft from calcium oxalate deposition. Ultimately, for patients with type 1 PH, liver transplantation can supply the missing AGT and may be curative, especially if it is performed before the development of end-stage renal failure. Some patients require combined liver and kidney transplantation.^{80,82,125}

Hyperuricosuria. Up to 15% of calcium stones are found in patients with hyperuricosuria. In contrast to patients with pure calcium oxalate stones, these patients typically have elevated urinary uric acid levels but normal urinary calcium and oxalate levels.^{126,127} They also differ from patients with pure uric acid stones in that they tend to have a higher urinary pH (approximately 5.5).

The mechanism by which uric acid promotes calcium stone formation is unclear. The term “heterogeneous nucleation” or “epitaxy” has been used to describe the preferential formation of calcium oxalate crystals around a lattice of uric acid crystals present in the urine.^{5,128,129} However, this mechanism has come into question. Grover and colleagues showed that the addition of sodium urate to urine or a similar solution increases calcium oxalate crystallization, with denser, more highly aggregated deposits, but no urate crystals form, and there is no increase in calcium oxalate supersaturation. They attributed this result to “salting out,” a process in which the solubility of electrolytes (or salts) in a solution is reduced (or ion activity is

increased) by the addition of different electrolytes or salts. In this case, the activity coefficients of calcium and oxalate would be increased not only by the concentrations of calcium and oxalate in the urine but also by the urate concentration.^{130,131} This theory would explain why allopurinol is often an effective therapy for recalcitrant calcium oxalate nephrolithiasis, even in the absence of hyperuricosuria.^{132,133} Another potential mechanism (not borne out by some studies) is that urate may reduce the concentration or the activity of urinary stone inhibitors.¹³⁴⁻¹³⁶

Whatever the mechanism, uric acid in the form of sodium urate is important in calcium oxalate crystal formation. Therapy has typically consisted of dietary purine restriction and increased fluid intake. If urinary uric acid levels remain uncontrolled with these measures, allopurinol, 100 to 300 mg/day, may be added.^{126,127}

Hypocitraturia. Citrate combines with calcium to form a soluble complex that reduces calcium oxalate and calcium phosphate precipitation. In some patients, hypocitraturia is the principal metabolic abnormality found in the 24-hour urine collection. Risk factors for hypocitraturia include high protein intake, hypokalemia, metabolic acidosis, exercise, infection, starvation, androgens, and acetazolamide. Men tend to have lower urinary citrate concentrations than women, which may explain the higher incidence of stone formation in men. Furthermore, women with nephrolithiasis have lower urinary citrate concentrations than do non-stone-forming women.¹³⁷

Along with therapy for the underlying condition, such as moderating dietary protein intake, potassium citrate is prescribed. This salt is preferable to sodium citrate because sodium excretion promotes calcium excretion. Again, potassium citrate in the wax-matrix formulation is

preferred to the liquid preparation because of increased palatability. Large amounts (30 to 75 mEq/day) in divided doses may be required to raise the urinary citrate concentration to more than 320 mg/day. Potassium and bicarbonate levels should be closely monitored, especially in patients with CKD. If metabolic alkalosis or hyperkalemia ensues, reduction of the dose may be necessary.^{110,138}

Renal Tubular Acidosis. dRTA is a disorder in which distal tubular hydrogen ion excretion is impaired, resulting in a non-anion gap metabolic acidosis and a persistently alkaline urine. The acidosis leads to calcium and phosphate release from bone as well as enhanced proximal tubular reabsorption of citrate and diminished tubular reabsorption of calcium. The net result is an increased filtered load and excretion of calcium and phosphate, severe hypocitraturia, and an elevated urinary pH, all of which promote calcium phosphate precipitation. Nephrocalcinosis, or renal parenchymal calcification, is frequently seen in this setting.

The 24-hour urinary citrate level is commonly less than 100 mg in patients with dRTA. Therapy consists of potassium citrate or potassium bicarbonate supplementation to treat both the metabolic acidosis and the hypocitraturia. Large doses of these medications are often required: 1 to 3 mEq/kg per day in two or three divided doses.^{25,82,126}

Nephrocalcinosis. Nephrocalcinosis is a condition in which calcium is deposited in the renal parenchyma. There are two forms: dystrophic calcification and metastatic calcification.

In dystrophic calcification, calcium deposition arises from tissue necrosis secondary to neoplasm, infarction, or infection. It may be seen in the setting of renal transplant rejection, renal cortical necrosis, chronic glomerulonephritis, ethylene glycol toxicity, acquired immunodeficiency syndrome (AIDS)-related infections, or Alport's syndrome. In general, serum calcium and phosphorus levels are normal, and calcium phosphate deposition occurs predominantly in the renal cortex.

In metastatic calcification, patients often have elevated serum calcium and phosphate levels or an elevated urinary pH. Calcification in this setting occurs more commonly in the renal medulla. Common causes include RTA, primary hyperparathyroidism (or any disorder resulting in elevated serum calcium levels), medullary sponge kidney, papillary necrosis, PH, and administration of acetazolamide, amphotericin B, or triamterene. PH can result in both medullary and cortical calcifications.

Both medullary and cortical parenchymal calcifications are easily identified on ultrasonography and CT scanning, even before they can be detected on plain radiographs. Therapy consists of treatment of the underlying disorder whenever possible. Otherwise, measures aimed at reducing hypercalcemia, oxalosis, and hyperphosphatemia should be attempted.^{24,43,139}

Uric Acid Stones. The prevalence of uric acid lithiasis is greater in Mediterranean countries than in the United States, where it accounts for 5% to 10% of all calculi formed, a prevalence that may be rising.¹ The incidence of uric acid stones in the United States appears to be rising in parallel with the epidemic of obesity and consequent insulin resistance, which results in a very low urine pH.^{17,140} Uric acid stones tend to be round, smooth, and yellow-orange. Because they are radiolucent, they are not visible on plain films but can be detected by ultrasonography or CT or as filling defects on IVP. Uric acid is a purine metabolite and is also found in large quantities within cells. Most patients with uric acid stones have a reduced urinary pH.

Other, less common causes are low urine volume and elevated urinary uric acid levels. Factors associated with uric acid stones are listed in Table 30-4.

Urine Volume and pH. Diarrhea and diets high in animal protein can also contribute to an acidic urinary pH. Any disorder that results in low urine volume (e.g., diarrheal disorders, diaphoresis, reduced fluid intake) can contribute to uric acid lithiasis. Uric acid is increasingly soluble at an alkaline urinary pH; urine with a pH of 6.5 can contain more than five times more uric acid than urine at pH 5.3 without inducing precipitation and can actually dissolve existing stones.^{17,127}

There is evidence that uric acid stone formers have greater body weight and a higher incidence of insulin resistance and type 2 diabetes mellitus. Most of these patients have significantly lower urinary pH compared with non-uric acid stone formers. Insulin resistance can lead to impaired ammoniogenesis and ammonium excretion, resulting in excretion of more urinary hydrogen ions with anions other than ammonium and a lower urinary pH.^{15,17,140,141}

Hyperuricosuria may be evident in patients who ingest large quantities of dietary purine or animal protein. Foods high in purine include organ meats, shellfish, certain fish, meat extracts, yeast, gravy, and stock (Table 30-8). Hyperuricemic disorders such as gout, myeloproliferative disorders, tumor lysis syndrome, and certain inborn errors of metabolism (e.g., glucose 6-phosphatase deficiency, Lesch-Nyhan syndrome) can also contribute to an increased urinary filtered load of uric acid. Certain medications such as salicylates and probenecid can be hyperuricosuric as well.^{4,17,86}

Therapy for uric acid stones begins with nonspecific measures such as increasing fluid intake to maintain urine volume at about 3 L/day. A lowered animal protein diet is generally beneficial because the decreased endogenous acid production raises urinary pH.³² Ideally, the urinary pH should be elevated to approximately 6.5 to 7.0, a level that can dissolve existing crystals and stones. A urinary pH higher than 7.0 should be avoided, because calcium phosphate deposition can result. A low-fructose diet may also be beneficial in reducing uric acid levels and hyperuricosuria (see earlier discussion).³⁶

Potassium citrate at doses of 30 mEq by mouth twice a day or greater may be required to raise the urinary pH sufficiently. (The available potassium citrate preparations are discussed in the sections on **Hypercalciuria** and **Hypocitraturia**.) If the urinary pH cannot be raised adequately despite high doses of potassium citrate or if the dose prescribed results in hyperkalemia, the carbonic anhydrase inhibitor acetazolamide may be initiated and added to the treatment. Use of this medication results in an alkaline urine and mild systemic metabolic acidosis, a pattern

TABLE 30-8

Foods High in Purine

Organ meats: brain, heart, kidney, liver; sweetbreads
Meat extracts: bouillon, consommé, stock, gravy
Meat: beef, chicken, goose, lamb, pork
Shellfish: clams, mussels, scallops, shrimp, oysters
Fish: anchovies, fish roe, herring, mackerel, sardines, others
Certain vegetables: asparagus, cauliflower; kidney beans, lentils, lima beans, mushrooms, peas, spinach

similar to that seen in dRTA. Again, the urinary pH should be maintained at less than 7.0 to avoid calcium phosphate precipitation.¹²⁶ Prescription of Nitrazine paper allows patients to monitor their urinary pH at various times of day and adjust their potassium citrate intake accordingly.

Patients with hyperuricemia are prescribed a low-purine diet to decrease uric acid production. Despite dietary intervention, hyperuricemia often persists, especially in patients with disorders of cellular metabolism. In this setting, allopurinol should be prescribed at a starting dose of 100 mg/day, increasing to 300 mg/day as needed.^{5,142}

Although sodium bicarbonate can effectively alkalinize the urine, it should be avoided because the additional sodium excretion encourages sodium urate formation, which may result in further crystal formation (see "Hyperuricosuria").

Struvite Stones. Struvite stones have also been termed triple phosphate stones, magnesium ammonium phosphate stones, and infection stones. Although they make up only about 10% to 15% of all stones formed, most staghorn calculi (large stones that extend beyond a single renal calyx) are composed of struvite. The propensity of these stones to grow rapidly to a large size, to recur despite therapy, and to result in significant morbidity (and potential mortality) has also led to the appellation "stone cancer." Because infection with urease-producing bacteria must be present for these stones to form, severe renal infections as well as sepsis and loss of renal function can develop. Factors associated with struvite stones are listed in Table 30-4.

In contrast to other stone types, struvite stones occur with a higher incidence in women than in men, largely because of women's increased susceptibility to urinary tract infections. Other groups at risk for development of struvite stones because of urinary stasis or infection include elderly people and patients with neurogenic bladders, indwelling urinary catheters, spinal cord lesions, or genitourinary abnormalities. Even in the absence of stone analysis, struvite stones should be suspected in patients who have large stones, an alkaline urinary pH (approximately 7), and the presence of urease-producing urinary bacteria. Early detection and therapy are essential to prevent great potential morbidity.⁸⁸

Urease-Producing Bacteria. The formation of struvite stones depends on the presence of both ammonium ions and an alkaline urinary pH—conditions met clinically only through the actions of urease-producing bacteria. Ammonium, magnesium, and carbonate apatite [$\text{Ca}_{10}(\text{PO}_4)_6\text{CO}_3$] in the urine combine with phosphate, which is present in this setting in its trivalent form.

Numerous gram-negative and gram-positive bacteria, as well as *Mycoplasma* and yeast species, have been implicated in urease production. Bacterial species in which urease is frequently isolated include *Proteus*, *Haemophilus*, *Corynebacterium*, and *Ureaplasma*. *Escherichia coli*, despite its frequent role as a urinary tract pathogen, has not been shown to produce urease. Urease production adequate to stimulate stone formation may be present despite low bacterial colony counts. For this reason, the microbiology laboratory should be asked specifically to perform bacteria identification and to determine sensitivities even with colony counts lower than 100,000 colony-forming units. If no bacteria are isolated but a urease producer is suspected, special cultures for *Ureaplasma urealyticum*, a mycobacterium, should be ordered.¹⁴³

Therapy for Struvite Stones. To eradicate struvite stones, early and aggressive medical and urologic management is required. Appropriate antibiotic therapy is essential

but must be combined with long-term bacterial suppression and complete surgical or medical stone removal. ESWL is often adequate for fragmentation of stones smaller than 2 cm, but percutaneous nephrostolithotomy or a combination of the two procedures is usually required for larger stones. Antibiotics should be continued on the basis of cultures of any stone fragments retrieved. After approximately 2 weeks of antibiotic therapy, when the urine culture is sterile, the dose of antibiotic should be halved. Suppressive antibiotics should continue at this dose until monthly surveillance cultures remain sterile for three consecutive months. At this point, antibiotics may be discontinued as long as surveillance urine cultures are obtained monthly for 1 year.^{143,144}

In addition to antimicrobial therapy, medical treatment may involve urease inhibition and chemolysis. In chemolysis, the kidney is irrigated with an acidic solution through a nephrostomy tube or ureteral catheter. Although this procedure is rarely used since the advent of less invasive surgical techniques, it may be useful in the dissolution of residual stone fragments. The solution most commonly used, 10% hemiacidrin, is composed of carbonic acid, citric acid, D-gluconic acid, and magnesium at a pH of 3.9. Chemolysis has been controversial because high mortality rates were reported in the past. The morbidity and mortality were mainly due to sepsis from instrumentation, local bacterial or fungal infections, and uroepithelial irritation rather than toxicity from the agents. With chemolysis used as an adjuvant to surgical removal, lower stone and infection recurrence rates have been reported.¹⁴⁵⁻¹⁴⁷ The safety of the procedure remains in question because of the variety of techniques, stone burden, and comorbidities reported in the older literature, but with close monitoring of serum magnesium levels, intrapelvic pressures, infection, and obstruction to flow, it may have a supporting role in the treatment of large struvite stones.^{143,145,148}

Urease inhibition has been shown to retard stone growth and to prevent new stone formation. It does not decrease bacterial counts and cannot eradicate existing stones. Combined with antimicrobial therapy, it serves primarily as palliative care for patients who cannot undergo definitive surgical management. The agent most commonly used is acetohydroxamic acid. These medications require adequate renal clearance for therapeutic efficacy and are contraindicated in patients with a glomerular filtration rate of less than 60 mL/minute. CKD increases the incidence of side effects of these medications, which are numerous and limit their use. Side effects that result in discontinuation of the drug include neurologic symptoms, gastrointestinal upset, hair loss, hemolytic anemia, and rash; these all resolve after discontinuation of the drug. Acetohydroxamic acid is also teratogenic. The starting dose of acetohydroxamic acid is 250 mg by mouth twice a day. If it is well tolerated for about 1 month, the dose is increased to 250 mg by mouth three times a day.¹⁴³

Cystine Stones. Cystinuria is an autosomal disorder that may be recessive or dominant with incomplete penetrance.¹⁴⁹ The disorder is caused by mutations in two members of the solute carrier family, encoded by the *SLC3A1* gene on chromosome 2 and the *SLC7A9* gene on chromosome 19, both of which result in decreased renal tubular reabsorption and excessive urinary excretion of the dibasic amino acids cystine, ornithine, lysine, and arginine. The genetic defect would probably go unnoticed were it not for the low solubility of cystine, approximately 300 mg/L. Factors associated with cystine stones are listed in Table 30-4.

People with no tubular defect in cystine transport excrete approximately 30 to 50 mg of cystine per day; heterozygotes excrete about 400 mg/day, and homozygotes excrete larger amounts, often more than 600 mg/day.⁸¹ Cystinuria should not be confused with cystinosis, a more serious and debilitating disorder that results in extensive intracellular cystine accumulation.

Stones usually develop in patients within the second or third decade. The stones can grow to a large size and can appear as staghorn calculi or multiple stones. They are radiopaque because of the sulfur content of cystine. The disease should be suspected in any patient with stone onset in childhood, frequent recurrence of nephrolithiasis, and a strong family history of the disease. The presence of the classic hexagonal cystine crystals in the urine can verify the diagnosis. Because these crystals might not be evident in dilute or alkaline urine, qualitative screening with the sodium nitroprusside test better confirms the presence of cystinuria at a concentration greater than 75 mg/L. Quantitative cystine measurement with a 24-hour urine sample should follow to determine the risk of stone formation and to guide therapy.

Therapy for Cystine Stones. The aim of treatment is to lower the urinary cystine concentration below the limits of solubility (approximately 300 mg/L). Patients are advised to drink large quantities of fluids. A patient with a cystine excretion of 750 mg/day should drink enough fluid to increase urine output to more than 3 L/day. Large quantities of milk should be avoided, because dairy products and foods high in protein contain large amounts of methionine, an essential amino acid that is a precursor of cystine.¹⁵⁰ Juices are encouraged because they tend to alkalize the urine and cystine is more soluble at a higher pH. Potassium citrate (see “Hypercalciuria” and “Hypocitraturia” for details) is also prescribed to maintain the urinary pH between 6.5 and 7.0.

Approximately 50% of cystine stones are mixed stones. Patients with cystinuria often have other metabolic defects such as hypercalciuria, hypocitraturia, and hyperuricosuria. Therefore, a complete 24-hour urine collection for all stone-forming elements is necessary to treat nephrolithiasis fully in this setting.

If these measures are inadequate in controlling stone formation, or if the urinary cystine concentration is too high to make adequate fluid intake practical, chelating agents may be added. D-Penicillamine is a chelating agent that reduces the cystine concentration by forming a more soluble compound with cystine. The medication is associated with numerous serious side effects that limit its use. Second-generation and third-generation chelating agents such as α -mercaptopyrroline glycine and buccillamine are now available that reduce the cystine concentration with fewer side effects.^{81,151,152}

ACKNOWLEDGMENTS

This work was supported in part by grants RO1 DK 56788 and RO1 AR 46289 from National Institutes of Health and grants from the Renal Research Institute (all to David A. Bushinsky).

CHAPTER 31

Type 2 Diabetes Mellitus

JOHN B. BUSE • KENNETH S. POLONSKY • CHARLES F. BURANT

EPIDEMIOLOGY AND DIAGNOSIS

Epidemiology

Type 2 diabetes mellitus (T2DM) is the predominant form of diabetes worldwide, accounting for 90% of cases globally.^{1,2} An epidemic of T2DM is under way in both developed and developing countries, although the brunt of the disorder is felt disproportionately in non-European populations. In the Pacific island of Nauru, diabetes was virtually unknown 50 years ago and is now present in approximately 40% of adults. Globally, the number of people with diabetes is expected to rise from the current estimate of 285 million in 2010 to 438 million in 2030, both figures substantially higher than even recent estimates. T2DM has become one of the world's most important public health problems.

Considerable information is available on the factors that are responsible for the development of T2DM, and these are summarized in Table 31-1. T2DM is thought to occur in genetically predisposed persons who are exposed to a series of environmental influences that precipitate the onset of clinical disease. The genetic basis of T2DM is discussed in detail later in this chapter, but the syndrome consists of monogenic and polygenic forms that can be differentiated both on clinical grounds and in terms of the

genes that are involved in the pathogenesis of these disorders.

Sex, age, and ethnic background are important factors in determining the risk of developing T2DM.² The disorder is more common in women, and the increased prevalence in certain racial and ethnic groups has already been alluded to. Age is also a critical factor. T2DM has been viewed in the past as a disorder of aging, and this remains true today. However, a disturbing trend has become apparent in which the prevalence of obesity and T2DM in children is rising dramatically. In the past, it was believed that the overwhelming majority of children with diabetes had type 1 diabetes (T1DM), and only 1% to 2% of diabetic children were considered to have T2DM or other rare forms of diabetes.³ Later reports suggested that as many as 8% to 45% of children with newly diagnosed diabetes have non-immune-mediated forms of the disease. Most of these children have T2DM, but other types are being increasingly identified. In arguably the most comprehensive study of diabetes in youth in the United States, 15% of diabetic children aged 10 to 19 years had T2DM in 2001. Nevertheless, T2DM in children remains relatively rare, with an estimated prevalence between ages 10 and 19 years of 0.4%.⁴

Data relating to the alarming increase in the prevalence of T2DM in children and adolescents has recently been

reviewed.⁵ The National Health and Nutrition Examination Study (NHANES) data for 1999 to 2008 suggest that 18.1% of 12- to 19-year-olds, 19.6% of 6- to 11-year-olds, and 10.4% of 2- to 5-year-olds have a body mass index (BMI) above the 95th percentile adjusted for age and sex. This represents an increase of more than 30% in obesity over the prevalence previously determined for 1988 to 1994. The increases are particularly striking in Hispanic and African American children. Of even greater concern, impaired glucose tolerance (IGT) and T2DM have now emerged as critical health issues in overweight children, particularly overweight African American, Latin American, and Native American adolescents. In a clinic-based study, 25% of 55 obese children and 21% of 112 obese adolescents had IGT, and 4% of the latter group had undiagnosed T2DM.⁶

Diagnostic Criteria for Diabetes Mellitus

The diagnosis of diabetes rests on the measurement of glycemia. Current criteria for the diagnosis of diabetes and various categories of “prediabetes” or “high risk for diabetes” are shown in Table 31-2.⁷

Because plasma glucose concentrations range as a continuum, the criteria are based on estimates of the threshold for the complications of diabetes. The primary end point used to evaluate the relationship between glucose levels and complications is retinopathy. All three tests—fasting plasma glucose (FPG), 2-hour plasma glucose (2-hour PG), and glycosylated hemoglobin A_{1c} (HbA_{1c})—are able to predict the presence of retinopathy and, by inference, glucose levels that are diagnostic of diabetes⁸ (Fig. 31-1). Furthermore, there is a relationship between elevated levels of all three markers and cardiovascular disease, although the relationship is generally stronger for HbA_{1c}.

Whereas previously HbA_{1c} was specifically not recommended for the diagnosis of diabetes and states of high diabetes risk based on poor standardization of assays, the current HbA_{1c} assay has several technical (preanalytic and analytic) advantages over the currently used laboratory measurements of glucose. Furthermore, measures of fasting and postchallenge glucose concentrations in the same individual over time are less reproducible than the HbA_{1c}. The intraindividual coefficient of variation in one study was 6.4% for the FPG and 16.7% for the 2-hour PG value, compared with less than 2% for HbA_{1c}.

Although the oral glucose tolerance test (OGTT) is an invaluable tool in research, it is not recommended for routine use in diagnosing diabetes. It is inconvenient for patients, and in most cases the diagnosis can be made on the basis of either an elevated FPG concentration or an elevated random glucose determination in the presence of hyperglycemic symptoms.

Screening for Type 2 Diabetes

Undiagnosed T2DM is common, accounting for almost 20% of diabetes cases in the United States.⁹ Subjects at high risk for diabetes and with undiagnosed T2DM are at significantly increased risk for coronary heart disease, stroke, and peripheral vascular disease. Delay in the diagnosis of T2DM causes an increase in microvascular and macrovascular disease. In addition, affected individuals have a greater likelihood of having dyslipidemia, hypertension, and obesity. Therefore, it is important for the clinician to screen for diabetes in a cost-effective manner in subjects who demonstrate major risk factors for diabetes as summarized

TABLE 31-2

Criteria for the Diagnosis of Diabetes*

Test	INCREASED RISK*				
	Normoglycemia	Impaired Fasting Glucose	Impaired Glucose Tolerance	High Risk	Diabetes [†]
PG, fasting (mg/dL)	<100	100-125			≥126
PG, 2-hour (mg/dL)	<140		140-199		≥200
Hemoglobin A _{1c} (%)				5.7-6.4	≥6.5
PG, casual (mg/dL)					>200 mg/dL plus symptoms of diabetes

*Risk for diabetes is continuous, extending below the lower limit and becoming disproportionately greater at the higher end of the ranges shown.

[†]In the absence of unequivocal hyperglycemia, a diagnostic result should be confirmed by repeat testing.

in Table 31-3. Recent modeling studies based on the U.S. population suggest that universal screening programs coupled with guideline-based therapy for T2DM is cost-effective when initiated between the ages of 30 and 45 and subsequently conducted every 3 to 5 years.¹⁰ Recommendations for screening are summarized in Table 31-4. The pivotal role of screening to identify individuals at high risk in prevention strategies for T2DM is discussed at the end of this chapter.

PATHOGENESIS

The pathogenesis of T2DM is complex and involves the interaction of genetic and environmental factors. A number of environmental factors have been shown to play a critical role in the development of the disease, particularly

TABLE 31-3

Major Risk Factors for Type 2 Diabetes

Overweight (BMI ≥ 25 kg/m²)
 Physical inactivity
 First-degree relative with diabetes
 Member of a high-risk ethnic population (e.g., African American, Latino, Native American, Asian American, Pacific Islander)
 Female with a history of delivering a baby weighing >9 lb or diagnosis of GDM
 Hypertension ($\geq 140/90$ mm Hg or on therapy for hypertension)
 HDL cholesterol level <35 mg/dL (0.90 mmol/L) or triglyceride level >250 mg/dL (2.82 mmol/L) or both
 Female with polycystic ovary syndrome
 Hemoglobin A_{1c} $\geq 5.7\%$, impaired glucose tolerance, or impaired fasting glucose on previous testing
 Other clinical conditions associated with insulin resistance (e.g., severe obesity, acanthosis nigricans)
 History of cardiovascular disease

excessive caloric intake leading to obesity and a sedentary lifestyle. The clinical presentation is also heterogeneous, with a wide range in age at onset, severity of associated hyperglycemia, and degree of obesity. From a pathophysiologic standpoint, persons with T2DM consistently demonstrate three cardinal abnormalities:

- Resistance to the action of insulin in peripheral tissues, particularly muscle and fat but also liver
- Defective insulin secretion, particularly in response to a glucose stimulus
- Increased glucose production by the liver

Recently, it has been suggested that the list of cardinal abnormalities in diabetes should be expanded to eight, adding accelerated lipolysis in the fat cell, incretin hormone deficiency and resistance, hyperglucagonemia, increased renal tubular reabsorption, and the role of the central nervous system in metabolic regulation.¹¹

Although the precise way in which genetic, environmental, and pathophysiologic factors interact to lead to the clinical onset of T2DM is not known, understanding of these processes has increased substantially. With the

TABLE 31-4

Summary of Major Recommendations for T2DM Screening

Testing to detect T2DM and to assess risk for future diabetes should be considered in asymptomatic adults of any age who are overweight or obese (BMI ≥ 25 kg/m²) and who have one or more additional risk factors for diabetes (see Table 30-3).

In those without risk factors for T2DM, testing should begin at age 30-45 yr.

If test results are normal, repeat testing should be carried out at 3- to 5-yr intervals.

Any of the following tests is appropriate: HbA_{1c}, FPG, 2-hr 75-g OGTT.

In those found to have increased risk for future diabetes, identify and, if appropriate, treat other CVD risk factors.

BMI, body mass index; CVD, cardiovascular disease; FPG, fasting plasma glucose; HbA_{1c}, glycosylated hemoglobin; OGTT, oral glucose tolerance test; T2DM, type 2 diabetes mellitus.

Age at initiation and frequency of screening to detect type 2 diabetes: a cost-effectiveness analysis. *Lancet*. 2010;375:1365-1374.

exception of specific monogenic forms of the disease that might result from defects largely confined to the pathways that regulate insulin action in muscle, liver, and fat or defects in insulin secretory function in the pancreatic beta cell, there is an emerging consensus that the common forms of T2DM are polygenic in nature and are caused by a combination of insulin resistance, abnormal insulin secretion, and other factors.

From a pathophysiologic standpoint, it is the inability of the pancreatic beta cell to adapt to the reductions in insulin sensitivity that occur over a lifetime that precipitates the onset of T2DM. The most common factors that place an increased secretory burden on the beta cell are puberty, pregnancy, a sedentary lifestyle, and overeating leading to weight gain. An underlying genetic predisposition appears to be a critical factor in determining the frequency with which beta cell failure occurs.

Genetic Factors in the Development of Type 2 Diabetes

Genetically, T2DM consists of monogenic and polygenic forms.^{12,13} The monogenic forms, although relatively uncommon, are nevertheless important, and a number of the genes involved have been identified and characterized. The genes involved in the common polygenic forms of the disorder have been far more difficult to identify and characterize.

Monogenic Forms of Diabetes

In the monogenic forms of diabetes, the gene involved is both necessary and sufficient to cause disease. In other words, environmental factors play little or no role in determining whether a genetically predisposed person develops clinical diabetes. The monogenic forms of diabetes usually are diagnosed in younger patients, often in the first 2 to 3 decades of life; however, if only mild, asymptomatic elevations in blood glucose occur, the diagnosis may be missed until later in life.

The monogenic forms of diabetes are summarized in Table 31-5 and can be divided into those in which the mechanism is a defect in insulin secretion and those that

involve defective responses to insulin or insulin resistance.

Monogenic Forms of Diabetes Associated with Insulin Resistance

Mutations in the Insulin Receptor. More than 70 mutations have been identified in the insulin receptor gene in various insulin-resistant patients.¹⁴ There are at least three clinical syndromes caused by mutations in the insulin receptor gene. *Type A insulin resistance* is defined by the presence of insulin resistance, acanthosis nigricans, and hyperandrogenism.¹⁵ Patients with *leprechaunism* have multiple abnormalities, including intrauterine growth retardation, fasting hypoglycemia, and death within the first 1 to 2 years of life.¹⁶⁻¹⁸ The *Rabson-Mendenhall syndrome* is associated with short stature, protuberant abdomen, and abnormalities of teeth and nails; pineal hyperplasia was a characteristic in the original description of this syndrome.¹⁹

These mutations could impair receptor function by a number of different mechanisms, including decreasing the number of receptors expressed on the cell surface, such as by decreasing the rate of receptor biosynthesis (class 1), accelerating the rate of receptor degradation (class 5), or inhibiting the transport of receptors to the plasma membrane (class 2). The intrinsic function of the receptor may be abnormal if the affinity of insulin binding is reduced (class 3) or if receptor tyrosine kinase is inactivated (class 4). The insulin resistance that is associated with insulin receptor mutations can be severe, manifesting in the neonatal period (e.g., leprechaunism, Rabson-Mendenhall syndrome), or it can occur in a milder form in adulthood, leading to insulin-resistant diabetes with marked hyperinsulinemia, acanthosis nigricans, and hyperandrogenism.

Lipoatrophic Diabetes. In another monogenic form of diabetes, lipoatrophic diabetes, severe insulin resistance is associated with lipoatrophy and lipodystrophy. This form of diabetes is characterized by a paucity of fat, insulin resistance, and hypertriglyceridemia.²⁰ The disease has several genetic forms, including face-sparing partial lipoatrophy (the Dunnigan or Koberling-Dunnigan syndrome), an autosomal dominant form caused by mutations in the lamin A/C gene,²¹ and congenital generalized lipoatrophy (the Seip-Berardinelli syndrome), an autosomal recessive form that appears to be due to mutations in either 1-acyl-sn-glycerol-3-phosphate acyltransferase-2 (AGPAT2) or in the seipin gene product.^{22,23}

Mutations in Peroxisome Proliferator-Activated Receptor- γ . It has been demonstrated that mutations in the transcription factor peroxisome proliferator-activated receptor- γ (PPAR γ) can cause T2DM of early onset (familial lipodystrophy type 3).²⁴ Two different heterozygous mutations were identified in the ligand-binding domain of PPAR γ in three subjects with severe insulin resistance. In the PPAR γ crystal structure, the mutations destabilize helix 12, which mediates *trans*-activation. Both receptor mutants showed markedly decreased transcriptional activation and inhibited the action of coexpressed wild-type PPAR γ in a dominant negative manner. A Dutch kindred with a 14A \rightarrow G mutation within the promoter of the PPAR γ 4 isoform, which results in decreased expression but no qualitative protein abnormalities, has been described.²⁵

A common amino acid polymorphism (Pro12Ala) in PPAR γ has been associated with T2DM. People homozygous for the Pro12 allele are more insulin resistant than those

with one Ala12 allele and have a 1.25-fold increased risk of diabetes. There is also evidence for interaction between this polymorphism and fatty acids, linking this locus with diet. A second polymorphism, C161 → T, has been linked to insulin resistance in Hispanic and non-Hispanic white women.²⁶

Neonatal Diabetes. Newborns may have permanent or transient neonatal diabetes. The prevalence of all causes of neonatal diabetes has been estimated to be between 1 in 100,000 and 1 in 300,000 live births. Transient neonatal diabetes usually resolves between 6 and 12 months of life. If the onset is before 6 months of age, a genetic cause is the most likely underlying etiology. The presence of hyperglycemia is often undetected, and the diagnosis is then made when the clinical condition deteriorates due to marked hyperglycemia with or without ketoacidosis. Morbidity is high. Associated features include low birth weight below the 10th percentile (especially in the absence of maternal diabetes), developmental delay, learning disorders, speech disorders, muscle weakness especially with climbing stairs, and seizures. Some children have been diagnosed with attention deficit disorder (ADD) as well. Occasionally, multiple family members are also found to have early-onset, relapsing, or nonobese young adult appearance of diabetes, but most cases are sporadic.

Etiology. The most common cause of relapsing transient neonatal diabetes is the uniparental disomy 6 chromosome abnormality (UDP6), which can also be caused by methylation defects in this region of the chromosome. Mutations in the *ABCC8* gene or, less commonly, in *KCNJ11*, both components of the adenosine triphosphate (ATP)-sensitive potassium channel (K_{ATP} channel), may also be responsible. The K_{ATP} channel is well described as a key molecular switch in the beta cell that closes in response to generation of ATP after glucose metabolism. If the channel does not close at physiologic levels of glucose, hypoinsulinism and hyperglycemia result. This causes severe diabetes with low or negative C-peptide and ketosis in the first few weeks of life.

Permanent neonatal diabetes is most often caused by mutations in *KCNJ11*, and less often by mutations in *ABCC8*. The K_{ATP} channel, composed of the beta-cell proteins sulfonylurea receptor (SUR1) and inward-rectifying potassium channel subunit KIR6.2, is a key regulator of insulin release. It is inhibited by the binding of adenine nucleotides to subunit KIR6.2, which closes the channel, and it is activated by nucleotide binding or hydrolysis on SUR1, which opens the channel. The balance of these opposing actions determines the low open-channel probability, P_o , which controls the excitability of pancreatic beta cells.^{26a} It has been hypothesized that activating mutations in *ABCC8*, which encodes SUR1, can cause neonatal diabetes. Mutations in these genes that cause the opposite condition, decreased channel function, are a cause of familial hyperinsulinemia with hypoglycemia.^{1,19,20}

After *KCNJ11* mutations, the second most common group of causes of permanent neonatal diabetes are mutations in the insulin gene (*INS*) itself. These mutations are also rare causes of young adult-onset T2DM and ketosis-prone type 1b diabetes, usually with negative diabetes-associated autoantibodies.⁸ More than 200 cases have been identified worldwide. Rarely, homozygous gene mutations in glucokinase (*GCK*) and transcription factor genes lead to insulin insufficiency or failure of development of the endocrine pancreas or of the entire pancreas.

Therapy. Many of the mutations in *KCNJ11* and *ABCC8* can be treated with a relatively high dose of sulfonylureas.

However, it is critical that this be done after a mutation has been documented, because the protocol involves high doses of sulfonylureas (administered in divided doses and off-label in the United States for children) and simultaneous aggressive insulin withdrawal. Collaboration with or referral to a center with experience in this treatment is highly encouraged because of potential side effects and other adverse effects. There is no therapy at this time for either UDP6 or *INS* mutations other than insulin replacement in the manner used for the treatment of type 1 diabetes.

Most of these mutations are heterozygous and dominant (i.e., each child of an affected individual has a 50% chance of having the disease). In the case of unaffected parents with one affected child, several studies have reported germline mosaicism as a known or possible cause of the presence of the syndrome in several siblings in one family. Therefore, the risk that each subsequent child will have neonatal diabetes can range from less than 10% to 50%, depending on the presence of mosaicism in the gametes.

Monogenic Forms of Diabetes Associated with Defects in Insulin Secretion

Mutant Insulin Syndromes. The first syndrome associated with diabetes to be characterized in terms of the clinical picture, genetic mechanisms, and clinical pathophysiology was that associated with mutant insulin or proinsulin.²⁷ Persons with this disorder present clinically with a mild, non-insulin-dependent form of diabetes. Affected persons characteristically have marked hyperinsulinemia on routine insulin assays. Increases in the concentration of insulin in association with diabetes usually indicate insulin resistance, but in this syndrome, insulin resistance can be easily excluded because the patients respond normally to administration of exogenous insulin. Characterization of the insulin by high-performance liquid chromatography (HPLC) reveals that the hyperinsulinemia results from the presence of the abnormal insulin or proinsulin and related breakdown products. The increased concentrations of insulin appear to be related to the presence of mutations in regions of the insulin molecule that are important for receptor binding, particularly the carboxyl terminus of the insulin B chain.

Because the liver is the major site of insulin clearance and first-pass hepatic insulin uptake and degradation are mediated by the insulin receptor, mutant forms of insulin with diminished insulin receptor binding ability are cleared more slowly from the circulation, and this reduction in insulin clearance leads to hyperinsulinemia. Alternatively, mutations in proinsulin can reduce the conversion of proinsulin to insulin, leading to accumulation of proinsulin.^{28,29} Because proinsulin is cleared more slowly from the circulation than insulin, proinsulin levels increase. Proinsulin cross-reacts in most commercially available assays, and this insulin-like immunoreactivity can be characterized as being related to the presence of proinsulin (rather than insulin only) by HPLC or by the use of assays that are specific for insulin and proinsulin.

A patient with a mutation in prohormone convertase 1, one of the enzymes responsible for the conversion of proinsulin to insulin, has been described.³⁰

Mitochondrial Diabetes. An A-to-G transition in the mitochondrial transfer RNA Leu(UUR) gene at base pair 3243 has been shown to be associated with maternally transmitted diabetes and sensorineural hearing loss.³¹ In

other subjects, this mutation is associated with diabetes and the syndrome of mitochondrial myopathy, encephalopathy, lactic acidosis, and stroke-like episodes (MELAS syndrome). The mitochondrion plays a key role in the regulation of insulin secretion, particularly in response to glucose. We have documented abnormal insulin secretion on at least one of a battery of tests in subjects with this mitochondrial mutation, even in subjects with normal glucose tolerance or IGT who have not developed overt diabetes.³²

Maturity-Onset Diabetes of the Young. Maturity-onset diabetes of the young (MODY) is a genetically and clinically heterogeneous group of disorders characterized by nonketotic diabetes mellitus, an autosomal dominant mode of inheritance, onset usually before 25 years of age and often in childhood or adolescence, and a primary defect in pancreatic beta cell function. A detailed review of MODY has been published,³³ and the information contained in that review is summarized here.

Etiology and Clinical Presentation

MODY can result from mutations in any one of at least six different genes. One of these genes (*GCK*) encodes the glycolytic enzyme glucokinase; mutations in this gene cause MODY2.³⁴ The other five genes encode transcription factors. MODY1 is associated with mutations in the gene for hepatocyte nuclear factor-4 α (*HNF4A*)³⁵; MODY3 with mutations in *HNF1A*³⁶; MODY4 with mutations in pancreatic and duodenal homeobox 1 (*PDX1*), which encodes insulin promoter factor 1 (IPF1)³⁷; MODY5 with mutations in *HNF1B*³⁸; and MODY6 with mutations in *NEUROD1*, which encodes the neurogenic differentiation 1/beta cell E-box *trans*-activator 2 (NeuroD1/BETA2).³⁹ All of these genes are expressed in the insulin-producing pancreatic beta cell, and heterozygous mutations cause diabetes related to beta cell dysfunction. Abnormalities in liver and kidney function occur in some forms of MODY, reflecting expression of the transcription factors in these tissues. Nongenetic factors that affect insulin sensitivity (infection, puberty, pregnancy, and rarely obesity) can trigger diabetes onset and affect the severity of hyperglycemia in MODY but do not play a significant role in the development of MODY.

The most common clinical presentation of MODY is a mild, asymptomatic increase in blood glucose in a child, adolescent, or young adult with a prominent family history of diabetes, often in successive generations, that suggests an autosomal dominant mode of inheritance. Some patients have mild hyperglycemia for many years, whereas others have varying degrees of IGT for several years before the onset of persistent hyperglycemia.³³ The diagnosis may not be made until adulthood even though the elevation in plasma glucose has been present for many years. Prospective testing indicates that in most patients the disease onset occurs in childhood or adolescence. In some patients, there may be a rapid progression to overt asymptomatic or symptomatic hyperglycemia, necessitating therapy with an oral hypoglycemic drug or insulin. The presence of persistently normal plasma glucose levels in subjects with mutations in any of the known MODY genes is unusual, and most eventually experience diabetes (with the exception of many patients with glucokinase mutations; see later discussion).

Although the exact prevalence of MODY is not known, current estimates suggest that MODY might account for 1% to 5% of all cases of diabetes in the United States and other industrialized countries.³³ Several clinical characteristics

distinguish patients with MODY from those with T2DM, including a prominent family history of diabetes in three or more generations, young age at presentation, and absence of obesity.

Functional Effects of MODY Genes. The identification of several genes associated with diabetes has provided a unique opportunity to characterize the pathophysiologic mechanisms by which genetic mutations can lead to an increase in the plasma glucose concentration. All the susceptibility genes identified to date cause impaired insulin secretory responses to glucose, although the mechanisms differ.

Glucokinase. Glucokinase is expressed at its highest levels in the pancreatic beta cell and the liver. It catalyzes the transfer of phosphate from ATP to glucose to generate glucose-6-phosphate (Fig. 31-2). This reaction is the first rate-limiting step in glucose metabolism. Glucokinase functions as the glucose sensor in the beta cell by controlling the rate of entry of glucose into the glycolytic pathway (glucose phosphorylation) and its subsequent metabolism. In the liver, glucokinase plays a key role in the ability to store glucose as glycogen, particularly in the postprandial state.

Heterozygous mutations leading to partial deficiency of glucokinase are associated with MODY, and homozygous mutations resulting in complete deficiency of this enzyme lead to permanent neonatal diabetes mellitus.⁴⁰ As predicted by the physiologic functions of glucokinase, the increase in plasma glucose concentrations in patients with this form of diabetes results from a combination of reduced glucose-induced insulin secretion from the pancreatic beta cell and reduced glycogen storage in the liver after glucose ingestion.

Liver-Enriched Transcription Factors. The transcription factors HNF-1 α , HNF-1 β , and HNF-4 α play a key role in the

Figure 31-2 Model of a pancreatic beta cell and the proteins implicated in maturity-onset diabetes of the young. ATP, adenosine triphosphate; HNF, hepatocyte nuclear factor; IPF, insulin promoter factor; NeuroD1, neurogenic differentiation 1. (From Fajans SS, Bell GI, Polonsky KS. Molecular mechanisms and clinical pathophysiology of maturity-onset diabetes of the young. *N Engl J Med.* 2001;345:973.)

tissue-specific regulation of gene expression in the liver⁴¹ and are also expressed in other tissues, including pancreatic islets, kidney, and genital tissues. HNF-1 α and HNF-1 β are members of the homeodomain-containing family of transcription factors, and HNF-4 α is an orphan nuclear receptor.^{41,42}

HNF-1 α , HNF-1 β , and HNF-4 α make up part of an interacting network of transcription factors that function together to control gene expression during embryonic development and in adult tissues in which they are coexpressed. In the pancreatic beta cell, these transcription factors regulate the expression of the insulin gene as well as proteins involved in glucose transport and metabolism and mitochondrial metabolism (all linked to insulin secretion) and lipoprotein metabolism.⁴³ The expression of HNF-1 α is regulated at least in part by HNF-4 α .

Persons with diabetes related to mutations in these genes have defects in insulin secretory responses to a variety of secretagogues, particularly glucose, that are present before the onset of hyperglycemia, suggesting that they represent the primary functional defect in the syndrome. Reduced glucagon responses to arginine have also been observed, suggesting that the pancreatic alpha cell is also involved in a broader pancreatic developmental abnormality.

Insulin Promoter Factor 1. IPF1 is a homeodomain-containing transcription factor that was originally isolated as a transcriptional regulator of the insulin and somatostatin genes. It also plays a central role in the development of the pancreas and in regulation of the expression of a variety of pancreatic islet genes, including (besides insulin) the genes encoding glucokinase, islet amyloid polypeptide, and glucose transporter 2. IPF1 also appears to mediate glucose-induced stimulation of insulin gene transcription.⁴⁴

A child born with pancreatic agenesis was shown to have a mutation in IPF1 that lacked the homeodomain required for DNA binding and nuclear localization. Heterozygous carriers of an IPF1 mutation from the same kindred developed an early-onset autosomal dominant form of diabetes (i.e., MODY) caused by dominant negative inhibition of transcription of the insulin gene and other beta cell-specific genes regulated by the mutant IPF1.⁴⁵ Additional IPF1 mutations have been discovered in pedigrees with late-onset T2DM.⁴⁶ Therefore, mutations in IPF1 can cause a range of phenotype manifestations, depending on whether the subjects have homozygous or heterozygous mutations and the severity of the functional effects.

Neurogenic Differentiation-1 Transcription Factor. The basic helix-loop-helix transcription factor NeuroD1/BETA2 was isolated on the basis of its ability to activate transcription of the insulin gene, and it is required for normal pancreatic islet development. Two patients with heterozygous mutations in NeuroD1 and diabetes have been described,³⁹ and a third was identified in an Icelandic population.⁴⁷ Studies in other populations have failed to detect mutations in NeuroD1 even in subjects with a MODY phenotype. It therefore appears that mutations in NeuroD1 are a rare cause of MODY.

Genetics of the Polygenic Forms of Type 2 Diabetes

The common polygenic form of T2DM has complex pathophysiology, and genetic and environmental factors play a major role. The phenotypic manifestations of the disease are also complex and include resistance to the action of insulin in muscle, fat, and liver; defects in insulin secretory

responses from the pancreatic beta cell; and increases in hepatic glucose production. However, the primary defect or defects responsible for the development of the syndrome remain elusive and are likely not to be defined until more is known about the genes responsible for diabetes and the nature of the gene-environment interactions that are ultimately responsible for development of the disorder in predisposed persons.

Insulin resistance is present in persons predisposed to T2DM before the onset of hyperglycemia, and this finding has been interpreted by some to indicate that insulin resistance is the primary abnormality that is responsible for the development of T2DM. However, defective beta cell function is also present before the onset of T2DM when IGT is present and in first-degree relatives of persons with T2DM who have completely normal plasma glucose concentrations. Therefore, although there is still controversy about whether insulin resistance or abnormal insulin secretion represents the primary defect in T2DM, there is general consensus that both defects are present in essentially all subjects with the disorder, often from an early preclinical stage.

In recent years, and particularly since 2007, there have been dramatic advances in understanding of the genetic basis of T2DM. Earlier genetic studies relied either on the candidate gene approach, in which the search for diabetes genes was dictated by the prevailing understanding of the pathways involved in glucose regulation, or on linkage studies. Linkage studies involve defining regions of chromosomal DNA that are shared to excess by affected family members. Parents are genotyped at a particular marker, and the offspring are scored for sharing of zero, one, or two alleles inherited from their parents. Markers are genotyped in family members in the regions of polymorphic repeats called microsatellites or simple tandem repeats.

Although these two approaches did identify important diabetes genes, the application of genome-wide association studies (GWAS) has led to a dramatic increase in the number of diabetes genes that have been identified. GWAS uses an unbiased interrogation of the entire genome in cases and controls to determine which single-nucleotide polymorphisms (SNPs) are associated with disease. The development of this approach depended on a number of factors including the completion of the Human Genome Project, the genotyping of 3.8 million SNPs and identification of haplotype-tagged SNPs by the International HapMap Project, the development of affordable, high-throughput genotyping technologies, and the availability of multiple analytical tools for the cleaning,⁴⁸ mining, and interpretation of very large datasets. The genes that have been implicated in the pathogenesis of T2DM are listed in Table 31-6. This is a rapidly changing field, and it is certain that the list of diabetes genes will increase. A number of excellent reviews have been published. The following sections provide a brief summary of the genes that have been implicated in the pathogenesis of T2DM.^{70,795,796}

Calpain-10 Gene

The linkage between calpain-10 and T2DM first observed by a group headed by Graeme Bell⁴⁹ was completely unexpected and was based purely on the application of sophisticated methods of analysis in a genetic study rather than on any novel physiologic insights. A number of studies have corroborated the initial observation that genetic variation in *CAPN10*, the calpain-10 gene, increases the risk of T2DM, but others have not. However, two meta-analyses of all the published data supported a role for this gene in diabetes susceptibility. Song's group,⁵⁰ after analyzing 11

TABLE 31-6

Polygenic Type 2 Diabetes Genes*

Gene Name	Common Protein Name	Function	Mechanism for Association with Type 2 Diabetes
<i>PPARG</i>	Peroxisome proliferator-activated receptor- γ	Nuclear receptor	Insulin resistance
<i>IGF2BP2</i>	IGF-2 mRNA-binding protein 2 (IMP2)	IGF2 binding protein	Unknown
<i>CDKAL1</i>	CDK5 regulatory subunit associated protein 1-like 1	Presumed regulator of cell cycle through cyclin kinase	Abnormal insulin secretion
<i>SLC30A8</i>	Solute carrier family 30, member 8 (ZNT8)	Zinc transporter 8	Abnormal insulin secretion
<i>CDKN2A</i>	P16(INK4a) and P14(ARF)	Cyclin-dependent kinase inhibitor 2A	Unknown
<i>CDKN2B</i>	P15(INK4b)	Cyclin-dependent kinase inhibitor 2B	
<i>WFS1</i>	Wolframin	Protects against endoplasmic reticulum stress	Abnormal insulin secretion
<i>IDE</i>	Insulin-degrading enzyme	Peptide degradation	Abnormal insulin secretion
<i>HHEX</i>	Hematopoietically expressed homeobox	Homeobox transcription factor important in beta cell function	Abnormal insulin secretion
<i>KIF11</i>	Kinesin family member 11	Kinesin-related motor in microtubule and spindle function	Unknown
<i>TCF7L2</i>	Transcription factor 4 (TCF4)	Transcription factor	Insulin secretion
<i>KCNJ11</i>	Kir6.2	Inward rectifier potassium channel	Insulin secretion
<i>FTO</i>	Fat mass and obesity associated gene	Functions as a DNA demethylase in vitro	Obesity
<i>JAZF1</i>	Juxtaposed with another zinc finger 1	Encodes a transcriptional repressor of a nuclear receptor Nr2c2 that regulates growth, IGF2, and blood sugar	Unknown
<i>CDC123</i>	Cell division cycle protein 123 homolog	Required for S phase entry of the cell cycle	Unknown
<i>CAMK1D</i>	Calcium/calmodulin-dependent protein kinase 1 δ	Mediator of chemokine signal transduction in granulocytes	
<i>TSPAN8</i>	Tetraspanin 8	Cell surface glycoprotein	Unknown
<i>LGR5</i>	Leucine-rich repeat-containing G protein-coupled receptor	Orphan G-protein receptor	
<i>THADA</i>	Thyroid adenoma associated protein	Unknown	Unknown
<i>ADAMS TS9</i>	Cell Metabolism review ⁷⁹⁵	Cell Metabolism review	Unknown
<i>NOTCH2/ADAM30</i>	Transmembrane receptor important in pancreas development	Regulator of cell differentiation	Abnormal insulin secretion
<i>ADCY5</i>	Adenylate cyclase 5	Catalyses generation of cAMP and cAMP responses to GLP1 in the beta cell	Unknown? Abnormal insulin secretion
<i>PROX1</i>	Prospero homeobox protein 1	A novel corepressor of HNF-4 α that plays a critical role in beta-cell development	Unknown? Abnormal insulin secretion
<i>GCK</i>	Glucokinase	Converts glucose to glucose-6-phosphate, the first rate-limiting step in glucose metabolism	Reduced insulin secretion, reduced liver glycogen storage
<i>GCKR</i>	Glucokinase regulatory protein	Inhibits glucokinase in the liver	Unknown
<i>DGKB</i>	Diacylglycerol kinase β -subunit	Regulation of insulin secretion	Unknown
<i>TMEM195</i>	Transmembrane protein 195	Integral membrane phosphoprotein highly expressed in liver	
<i>MTNR1B</i>	Melatonin receptor type 1B	Expressed in the hypothalamus and human pancreatic islets, where it regulates melatonin action and timing of circadian activity	Unknown. Possibly abnormal insulin secretion
<i>GIPR</i>	Glucose-dependent insulinotropic peptide (GIP) receptor	Regulation of insulin secretion in response to the incretin peptide GIP	Abnormal insulin secretion

cAMP, cyclic adenosine monophosphate; CDK5, cyclin-dependent kinase 5; GLP1, glucagon-like peptide 1; IGF, insulin-like growth factor; *KCNJ11*, potassium inwardly rectifying channel, subfamily J, member 11; Nr2c2, nuclear receptor subfamily 2, group C, member 2; *TCF7L2*, transcription factor 7-like 2 gene; *WFS*, Wolfram syndrome.

*More information on these genes can be found in recent reviews of diabetes genetics^{70,795,796} and in publications of additional diabetes loci.^{73,797-799}

studies, showed an odds ratio for T2DM of 1.19 comparing persons with the G/G genotype of UCSNP43 in *CAPN10* with all carriers of the A allele. Weedon's group⁵¹ calculated an odds ratio of 1.17 for UCSNP44.

Calpains are Ca²⁺-dependent cysteine proteases.⁵² The precise physiologic mechanisms by which genetic variation in *CAPN10* leads to altered susceptibility to diabetes is still being characterized. Pharmacologic inhibition of calpain activity results in insulin resistance and impaired insulin secretion.^{53,54} Studies in mice have led to similar conclusions.^{55,56} Therefore, calpains play a role in regulating insulin secretion and insulin action.

KIR6.2 Gene

The beta cell K_{ATP} channel is composed of two subunits, SUR1 and KIR6.2, as discussed earlier.⁵⁷ The missense mutation Glu23Lys (E23K) in *KCNJ11*, the gene encoding KIR6.2, has been associated with increased risk of T2DM in some but not all studies,^{51,58-60} similar to what was observed with *CAPN10*. Meta-analyses have shown that the E23K variant affects diabetes risk.^{51,61} The study by Love-Gregory's group⁶¹ suggested that the K allele of the E23K polymorphism increases the risk of T2DM by an average of 13% and that the KK homozygote is at greatest risk (relative risk,

1.28). 't Hart and colleagues examined the influence of the E23K variant of KIR6.2 on the insulin secretory responses to glucose and found no effect. However, they did not consider the confounding effect of insulin resistance.⁶²

Peroxisome Proliferator-Activated Receptor- γ

PPAR γ is a member of the PPAR subfamily of nuclear receptors. It is an important regulator of lipid and glucose homeostasis and cellular differentiation. Although PPAR γ is most abundantly expressed in adipose tissue, it is also expressed in the pancreatic beta cell, and targeted elimination of the receptor in the beta cell leads to a blunting of the normal increase in beta cell mass that occurs on a high-fat diet.⁶³ Meta-analyses of all published studies performed by Altshuler and colleagues⁶⁴ in 2000 showed that the missense mutation Pro12Ala (P12A) in *PPARG* (the gene encoding PPAR γ 2) is associated with decreased risk for T2DM (estimated risk ratio for the alanine allele, 0.79).

Hepatocyte Nuclear Factor-4 α Gene

The role of HNF-4 α in the development of MODY has been clearly documented. Mutations in this gene lead to abnormalities in insulin secretion. Studies involving various populations⁶⁵⁻⁶⁷ have demonstrated that genetic variation in the region of an alternative promoter for the *HNF4A* gene is associated with increased risk of T2DM. It is likely that these at-risk polymorphisms alter expression of *HNF4A*, thereby causing increased susceptibility to T2DM.

Transcription Factor 7-Like 2 Gene

Grant and colleagues⁶⁸ genotyped 228 microsatellite markers in Icelandic patients with T2DM and in controls. A microsatellite, DG10S478, within intron 3 of the transcription factor 7-like 2 gene (*TCF7L2*; formerly *TCF4*) was associated with T2DM. This was replicated in a Danish cohort and in a U.S. cohort. Compared with noncarriers, heterozygous and homozygous carriers of the at-risk alleles (38% and 7% of the population, respectively) have relative risks of 1.45 and 2.41. This corresponds to a population attributable risk of 21%. The *TCF7L2* gene product is a high-mobility group box containing transcription factors previously implicated in blood glucose homeostasis. It is thought to act through regulation of proglucagon gene expression in enteroendocrine cells via the Wnt signaling pathway.

In a follow-up study, Florez and colleagues⁶⁹ observed that specific polymorphisms in *TCF7L2* increase the risk of progression from IGT to T2DM, and this effect is mediated through a reduction of glucose-induced insulin secretion.

Diabetes Genes Identified by GWAS

The reader is directed to recent excellent reviews of the results of GWAS for T2DM.^{70,71} The first GWAS for T2DM clearly replicated the *TCF7L2* association and also discovered associations with a missense SNP in *SLC30A8* and common variants in *HHEX*.⁷² *SLC30A8* encodes a zinc transporter that is expressed in insulin granules in beta cells, and *HHEX* encodes a transcription factor that is involved in early pancreatic development. Although it is not certain that these effects are responsible for the association with diabetes, the findings provided evidence of the relevance of the information uncovered by GWAS. The results of this and subsequently published GWAS^{73,74} substantially increased the list of T2DM susceptibility genes as demonstrated in Table 31-7.

Based on these advances, the following general comments can be made regarding the genetics of T2DM:

TABLE 31-7

Glycemic Targets

Parameter	Normal	ADA	ACE
Premeal PG (mg/dL)	<100 (mean, ~90)	70-130	<110
Postprandial PG (mg/dL)	<140	<180	<140
HbA _{1c} (%)	4-6	<7	≤6.5

ACE, American College of Endocrinology; ADA, American Diabetes Association; PG, plasma glucose concentration; HbA_{1c}, glycosylated hemoglobin.

From American Diabetes Association. Standards of medical care in diabetes—2010. *Diabetes Care*. 2010;29:s11-s61; Rodbard HW, Blonde L, Braithwaite SS, et al., AACE Diabetes Mellitus Clinical Practice Guidelines Task Force. American Association of Clinical Endocrinologists medical guidelines for clinical practice for the management of diabetes mellitus. *Endocr Pract*. 2007;13(suppl 1):1-68.

1. A large number of genes are associated with increased susceptibility to this disease. The approximately 30 genes identified to date are thought to account for a small proportion (estimated at no more than 5% to 10%) of the total genetic risk for diabetes in the population.
2. The genes identified to date individually lead to a modest increase in the risk of diabetes. Persons with these individual polymorphisms have odds ratios between 1.10 and 1.45 when compared with individuals who do not have the at-risk polymorphisms.
3. The presence of multiple at-risk polymorphisms in a single individual substantially increases the risk of developing diabetes.
4. A significant proportion of the genetic variants associated with increased risk for diabetes appear to do so by inhibiting insulin secretion. Very few appear to increase insulin resistance or obesity. Whether this is a reflection of the relative importance of the roles of these factors in the pathogenesis of T2DM or whether the design of the GWAS did not allow genetic risk factors for insulin resistance and obesity to be identified is yet to be determined.

The application of additional techniques of exomic and whole genome sequencing will certainly provide additional insights into the genetic architecture of T2DM. Such studies are under way at a number of centers.

Insulin Resistance and the Risk of Type 2 Diabetes

Insulin Resistance

Substantial data indicate that insulin resistance plays a major role in the development of IGT and diabetes. Insulin resistance is a consistent finding in patients with T2DM, and resistance is present years before the onset of diabetes.⁷⁵⁻⁸⁰ Prospective studies have shown that insulin resistance predicts the onset of diabetes.^{76,77}

The term *insulin resistance* indicates the presence of an impaired biologic response to either exogenously administered or endogenously secreted insulin. Insulin resistance is manifested by decreased insulin-stimulated glucose transport and metabolism in adipocytes and skeletal muscle and by impaired suppression of hepatic glucose output.

Insulin sensitivity is influenced by a number of factors, including age,⁸¹ weight, ethnicity, body fat (especially abdominal), physical activity, and medications. Insulin resistance is associated with the progression to IGT and T2DM,⁸² although diabetes is rarely seen in insulin-resistant

Figure 31-3 Prevalence of diabetes by age (top panel) and by ethnicity (bottom panel). (From Harris MI, Flegal KM, Cowie CC, et al. Prevalence of diabetes, impaired fasting glucose, and impaired glucose tolerance in U.S. adults. The Third National Health and Nutrition Examination Survey, 1988-1994. *Diabetes Care*. 1998;21:518-524.)

persons without some degree of beta-cell dysfunction.⁸⁰ First-degree relatives of type 2 diabetics have insulin resistance even at a time when they are not obese, implying a strong genetic component in the development of insulin resistance.^{76,82,83} There is also a strong influence of environmental factors on the genetic predisposition to insulin resistance and therefore to diabetes.^{84,85}

Obesity and Type 2 Diabetes

The association of obesity with T2DM has been recognized for decades. A close association between obesity and insulin resistance is seen in all ethnic groups and is found across the full range of body weights, across all ages, and in both sexes (Fig. 31-3).⁸⁶⁻⁸⁸ A number of large epidemiologic studies have shown that the risk of diabetes, and presumably that of insulin resistance, rises as body fat content increases from the very lean to the very obese, implying that the absolute amount of body fat has an effect on insulin sensitivity across a broad range (Fig. 31-4A).^{89,91} However, central (intra-abdominal) adiposity is more strongly linked to insulin resistance (see Fig. 31-4B) and to a number of important metabolic variables, including plasma glucose, insulin, total plasma cholesterol and triglyceride concentrations, and decreased plasma high-density lipoprotein (HDL)-cholesterol concentration, than is total adiposity.⁹²⁻⁹⁸ In addition, the effect of accumulation of abdominal fat on glucose tolerance is independent of total adiposity.^{99,100}

The reason for the relationship between intra-abdominal fat and abnormal metabolism is not clearly defined, but a number of hypotheses, which are not mutually exclusive, have been proposed. First, abdominal fat is more lipolytically active than subcutaneous fat, perhaps because of its greater complement of adrenergic receptors.^{101,102} In addition, the abdominal adipose store is resistant to the antilipolytic effects of insulin,¹⁰³ including alterations in lipoprotein lipase activity; this leads to increased lipase activity and a greater flux of fatty acids into the circulation, with the portal circulation receiving the greatest fatty acid load. Finally, the high levels of 11 β -hydroxysteroid dehydrogenase type 1 (HSD11B1) in mesenteric fat could result in enhanced conversion of inactive cortisone to active cortisol, resulting in increased local cortisol production. This might change adipocytes to increase lipolysis and alter the production of adipokines, which might directly modulate glucose metabolism. The roles of the skeletal muscle and liver in insulin resistance and hyperglycemia are discussed later.

Nutrient Overload and Insulin Resistance. Cells have developed a number of ways to sense incoming nutrients, including direct and indirect activation of transcription factors and protein kinases. These pathways integrate with incoming hormonal signals to modulate cellular metabolism, increasing anabolic reactions in times of nutrient surfeit and catabolic reactions in postprandial or nutrient

Figure 31-4 Relationship between body mass index (top panel) or intra-abdominal fat (bottom panel) and insulin sensitivity. (Top, From Fujimoto WY, Bergstrom RW, Boyko EJ, et al. Susceptibility to development of central adiposity among populations. *Obesity Res*. 1995;3(suppl 2):179S-186S; bottom, from Kahn SE, Prigeon RL, McCulloch DK, et al. Quantification of the relationship between insulin sensitivity and beta-cell function in human subjects: evidence for a hyperbolic function. *Diabetes*. 1993;42:1663-1672.)

deficient states. In a sense, the reaction of different tissues to obesity may be a relatively normal physiologic response to excess nutrient delivery, with prolonged activation leading to unintended and pathologic states that result in insulin resistance, inflammation, and even cell death. A variety of interacting factors functioning within and between tissues determine the final phenotypic response of a person to continued nutrient overload. An individual can be obese with normal objective findings related to glucose and lipid homeostasis or other cardiovascular risk factors, whereas another person can be only slightly above normal weight and yet harbor a distinctly abnormal physiology. Clearly, genetics plays a role in these responses, as demonstrated by the increased burden of metabolic dysfunction in Asians at a much lower BMI than in Caucasians or other ethnic groups.¹⁰⁴

Adipose Tissue and Insulin Resistance. To maintain metabolic homeostasis, nutrient intake exceeding expenditure must be converted to biologic precursors to increase cellular mass or it must be stored. Most excess nutrients, whether carbohydrate, protein, or lipid, are stored as fatty acids in the form of triglyceride in adipose tissue. This storage segregates the excess nutrients in a form that is mobilizable in times of energy deficit. If the storage capacity of adipose tissue is exceeded, lipids and other nutrients enter nonstorage tissues, such as myocytes, hepatocytes, vascular cells, and beta cells, and trigger a variety of adaptive and nonadaptive cellular responses that lead to insulin resistance and cellular dysfunction.

Adipocytes are more than storage cells; they regulate the uptake and release of fatty acids; participate in the glycerol free fatty acid cycle; release leptin and other hormones that signal the energy status of the body; and secrete an ever-expanding number of cytokines that have hormonal, paracrine, and autocrine actions.¹⁰⁵ The adipocyte itself can be adversely affected by accumulation of excess nutrients, leading to events that can have adverse consequences on the body. As adipocyte surface area increases in obesity, there is increased expression of leptin, interleukin 6 (IL-6), IL-8, monocyte chemoattractant protein 1, and granulocyte colony-stimulating factor. These and possibly other cytokines attract pro-inflammatory macrophages (M1 type), which release factors such as tumor necrosis factor- α (TNF- α) that have local and systemic inflammatory effects.¹⁰⁶

mTOR. The mammalian target of rapamycin (mTOR) may be part of the integration of excess nutrient accumulation and insulin resistance. mTOR is part of a multisubunit serine/threonine protein kinase complex, called TORC, that integrates signaling from the insulin and other growth factor receptors and regulates many cell processes including growth, autophagy, apoptosis, protein synthesis, and transcription. The TORC1 complex is activated by growth factors, including insulin and insulin-like growth factors, as well as nutrients, primarily the essential branched-chain amino acid leucine and fatty acids, the latter via formation of phosphatidic acid.

Several downstream targets have been identified, with S6 kinase (S6K) and 4E-BP being the best characterized. Phosphorylation of these proteins increase ribosomal protein translation augmenting cellular growth. Mutations in the tuberous sclerosis complex proteins (TSC1 and TSC2), which are inhibitory regulators of the mTOR kinase, result in the formation of hypertrophic tumors. As part of a feedback loop, S6K can phosphorylate insulin receptor substrate 1 (IRS1) on serine and inhibit its activity, resulting in downregulation of insulin signaling.¹⁰⁷ Cells harboring TSC mutations have high levels of IRS1 serine

phosphorylation and are extremely insulin resistant. Conversely, mice with ablation of S6K-1 are protected from developing obesity and insulin resistance when given a high-fat diet, indicating a critical role in both growth and insulin resistance.¹⁰⁸

Unfolded Protein Response. The endoplasmic reticulum (ER) functions in the post-translational processing of protein, including protein folding, maturation, quality control, and trafficking to other cellular compartments. As part of its quality control machinery, when the ER accumulates excess levels of unfolded or misfolded proteins, a distinct series of reactions occurs that slows overall protein synthesis while increasing the production of chaperones and other proteins that increase the fidelity of protein processing. The RNA-dependent protein kinase (PKR)-like eukaryotic initiation factor 2 α (eIF2 α) kinase known as PKR-like endoplasmic reticulum kinase (PERK), inositol-requiring enzyme 1 (IRE1), and activating transcription factor 6 (ATF6) are ER membrane-associated proteins that are normally complexed to the ER protein BiP/GRP78. Accumulation of unfolded proteins results in dissociation of these proteins from BiP/GRP78. PERK phosphorylates eIF2 α , resulting in inhibition of most protein synthesis, IRE1 cleaves X-box binding protein 1 (XBP1), forming a messenger RNA (mRNA) translated into the active transcription factor, and, in combination with ATF6 α , activates transcription to produce chaperones and proteins involved in ER biogenesis, phospholipid synthesis, ER-associated protein degradation (ERAD), and secretion.¹⁰⁹

In states of overfeeding and obesity, evidence for activation of this unfolded protein response (UPR) can be seen in liver, adipose tissue, pancreatic beta cells, and other tissues. The UPR response to overnutrition is thought to have several effects, including activation of the Janus kinase (JNK) and nuclear factor- κ B (NF- κ B)/inhibitor of κ B kinase (IKK) pathways leading to decreased IRS1 activity, increased levels of endogenous inflammatory mediators, alteration in sterol regulatory element-binding protein 1 (SREBP1)-mediated transcription, reduction in hepatic gluconeogenesis, and, after prolonged activation, cellular dysfunction and apoptosis.¹¹⁰

Innate Immunity. The innate immune system was originally thought to be a cellular system that allowed discrimination of self and nonself so as to adapt cellular metabolism to fight microbial pathogens. However, this system is now recognized as a general response to cellular stress that activates the inflammation and cellular repair systems. The innate immune system contains a series of pattern-recognition receptor proteins (PRRs) to detect microbial motifs. These proteins, including toll-like receptors (TLRs) and C-type lectins (CTLs), are expressed on a variety of cell types, including macrophages, monocytes, dendritic cells, neutrophils, and epithelial cells and cells of the adaptive immune system. The PRRs detect extracellular and intracellular pathogen-related molecules, including lipids and nucleic acids, and initiate a stereotypical response, including NF- κ B activation and activator protein-1 (AP1) transcription, which increases expression of cytokines and chemokines.

Activation of the innate pathway also increases the production of so-called inflammasomes—large, multisubunit protein complexes that are important in the control of caspase 1-mediated, post-translational maturation and secretion of interleukins, primarily IL-1 β , that have potent proinflammatory responses and are a risk factor for development of T2DM, perhaps through disruption of beta-cell function.¹¹¹

Activation of the innate immune system in acute infection is associated with significant insulin resistance and likely plays a role in the insulin resistance seen in obesity, mediated by elevated levels of free fatty acids (FFAs). TLRs, especially TLR2 and TLR4, which respond to bacterial cell wall lipids and induce the innate inflammatory response, are activated by saturated fatty acids, whereas polyunsaturated fatty acids inhibit TLR signaling. Activation of TLRs in cells results in insulin resistance, whereas genetic disruption of the TLR4 receptor in mice is protective against fatty acid-induced insulin resistance.¹¹²

Results of human clinical trials involving disruption of the innate immune system show efficacy in the treatment of T2DM. Treatment of diabetics for 13 weeks with anakinra, a recombinant human IL-1R antagonist, reduced HbA_{1c} and enhanced insulin secretion without effects on insulin sensitivity, suggesting a primary effect on beta-cell function.¹¹³

Circadian Rhythms, Obesity, and Insulin Resistance. Almost all mammals have a well-developed circadian cycle which is controlled by a complex, integrated network of transcription-translation feedback loops that work in a 24-hour cycle. A defined set of genes establish the circadian cycle, which sets behavioral and physiologic functions, including sleep-wake cycles, feeding behaviors, hormone secretion, and metabolism.

There are significant epidemiologic associations in humans between reduction of sleep and increased obesity and other metabolic disturbances, including T2DM.¹¹⁴ Experimental sleep disruption can directly impair insulin action, alter secretion of leptin and ghrelin with stimulation of appetite, increase inflammatory cytokine production, and create alterations in other cardiovascular risk factors. Alterations in normal feeding patterns that are attuned to the circadian metabolism can change the relationship between nutrient appearance and nutrient-metabolizing enzymes. For instance, alterations in fatty acid appearance and lipoprotein lipase activity could lead to altered partitioning of lipids to vulnerable tissues, leading to lipotoxicity and decreased secretion of leptin, increasing appetite.¹¹⁵ These disturbances can be exacerbated by obesity-related sleep apnea. Although the cognitive improvements associated with successful treatment of sleep apnea are clear, the metabolic benefits continue to be debated.¹¹⁶

Skeletal Muscle Insulin Resistance

The primary site of glucose disposal after a meal is skeletal muscle, and the primary mechanism of glucose storage is through its conversion to glycogen. Given the relatively limited nutrient storage capacity of skeletal muscle, it is not surprising that, in obesity, insulin resistance in skeletal muscle is manifested before abnormalities in insulin signaling in adipose tissue and liver. Studies using the hyperinsulinemic-euglycemic clamp technique have demonstrated that in insulin-resistant people (with and without T2DM), there is a deficiency in the nonoxidative disposal of glucose related primarily to a defect in glycogen synthesis (Fig. 31-5).^{117,118}

Fatty Acids and Insulin Resistance

Free Fatty Acids. Elevated FFAs predict the progression from IGT to diabetes.^{119,120} In the periphery, FFAs might not be markedly elevated because of efficient extraction by the liver and skeletal muscle. Therefore, normal or minimally elevated FFA levels might not reflect the true exposure of fatty acids to peripheral tissues. Increased fatty acid flux to

Figure 31-5 Tissue uptake of glucose in nondiabetic and insulin-resistant diabetic subjects during a hyperinsulinemic-euglycemic clamp. (From DeFronzo RA. The triumvirate: beta-cell, muscle, liver—a collusion responsible for NIDDM. *Lilly Lecture 1987. Diabetes.* 1988;37:667-687.)

skeletal muscle related to increased visceral lipolysis has been implicated in the inhibition of muscle glucose uptake.

The Randle hypothesis, or the glucose-fatty acid cycle, was originally proposed to account for the ability of FFAs to inhibit muscle glucose utilization. Randle's group¹²¹ demonstrated that fatty acids compete with glucose for substrate oxidation in isolated muscle. The increase in fatty acid metabolism leads to an increase in the intramitochondrial acetyl coenzyme A (acetyl-CoA)/CoA and reduced nicotinamide adenine dinucleotide (NADH/NAD⁺) ratios, with subsequent inhibition of pyruvate dehydrogenase. The resulting increased intracellular mitochondrial (and cytosolic) citrate concentrations result in allosteric inhibition of phosphofructokinase, the key rate-controlling enzyme in glycolysis. Subsequent accumulation of glucose-6-phosphate inhibits hexokinase II activity, resulting in an increase in intracellular glucose concentrations and decreased glucose uptake.

Studies in vivo in humans suggest that the primary effect of fatty acids, at least in the presence of elevated insulin levels, is a decrease in glucose transport, as measured by a reduction in the rate of accumulation of intracellular glucose and glycogen using ¹³C and ³¹P nuclear magnetic resonance (NMR) spectroscopy. In normal subjects, elevated fatty acids, achieved by infusion of triglyceride emulsions and heparin (to activate lipoprotein lipase), resulted in a fall in intracellular glucose and glucose-6-phosphate concentrations that preceded the fall in glycogen accumulation.^{122,123} These results challenge the Randle hypothesis (which predicts a rise in intracellular glucose-6-phosphate concentrations) as the basis of the reduction in insulin sensitivity seen with elevated fatty acids. Similar decreases in glucose transport have been seen in patients with T2DM¹²⁴ and in lean, normoglycemic, insulin-resistant offspring of type 2 diabetics.^{125,126} These studies also found decreased activity of phosphatidylinositol 3-kinase (PI3K) and increased protein kinase C- θ activity that might, in part, mediate the effect of elevated FFAs.^{127,128}

Studies also suggest that PKC-mediated serine phosphorylation of the IKK β subunit, leading to its degradation and the unregulated translocation of NF- κ B into the nucleus, might also be important to fatty acid-induced insulin resistance.¹²⁹ This is the mechanism by which high-dose aspirin therapy improves glucose metabolism in T2DM.¹²⁹ Disruption of the IKK β inflammatory pathway by high-dose aspirin therapy in a small human trial resulted in an improvement in insulin sensitivity.

Intramuscular Triglycerides. Insulin-stimulated glucose uptake is inversely related to the amount of intramuscular triglycerides. A strong correlation between intramuscular triglyceride concentration and insulin resistance was demonstrated by evaluation of intramuscular triglyceride with biopsy,¹³⁰ computed tomography,¹³¹ and magnetic resonance imaging (MRI).¹³² MRI has been a valuable addition because the magnetic resonance signal can distinguish intramyocellular from extramyocellular fat and demonstrates the increased triglyceride accumulation within the myofiber itself.¹³³ First-degree relatives of type 2 diabetics have an increase in intramyocellular fat, and in this group there is also a correlation with insulin resistance.¹³²

The mechanism for accumulation of triglyceride in the skeletal muscle of obese and insulin-resistant persons is probably related to mismatching of FFA uptake and oxidation. During resting postabsorptive conditions, about 30% of fatty acid flux in the plasma pool is accounted for by oxidation, and the remaining 70% of flux is recycled into triglyceride, indicating a physiologic reserve that exceeds immediate tissue needs for oxidative substrates. The equilibrium between oxidation and reesterification within muscle is paramount in determining fatty acid storage within tissue. The uptake, transport, and metabolism of fatty acids are highly regulated processes (Fig. 31-6), and alteration of the balance between uptake and oxidation in skeletal muscle leads to increased intramyocellular triglycerides. The increased lipolysis associated with obesity provides an increased amount of FFA presented to muscle.

Increased muscle triglyceride content is not invariably linked to insulin resistance, because exercise training is associated with increased muscle triglyceride content,¹³⁴ and chronic exercise increases insulin sensitivity as well as the capacity for fatty acid oxidation.¹³⁵⁻¹³⁹ Studies suggest that acute exercise increases intramyocellular triglyceride synthesis, reducing fatty acid oxidation and preventing fatty acid-induced insulin resistance.¹⁴⁰

Fatty Acid Metabolism in Skeletal Muscle. The uptake of fatty acid from the serum, where it is mostly bound to albumin, is mediated by at least three families of proteins: fatty acid translocase, plasma membrane fatty acid-binding

proteins (FABPs), and fatty acid transport proteins.¹⁴¹⁻¹⁴³ The levels of the putative transport proteins are regulated by exercise,¹⁴⁴ are correlated with body weight (at least in women), and can be modulated by insulin infusion.¹⁴⁵

FABPs are capable of binding multiple hydrophobic ligands, including fatty acids, eicosanoids, and retinoids, with high affinity.¹⁴⁶ FABPs are thought to facilitate uptake of fatty acids and to promote subsequent intracellular transport to subcellular organelles.¹⁴⁷ There is a direct correlation between heart-type FABP content and oxidative capacity observed during development and among different muscle types.^{148,149} In mice that have a disruption of the heart isoform¹⁵⁰ or the adipocyte isoform¹⁵¹ of FABP, plasma fatty acid concentrations were significantly elevated and plasma glucose was decreased, suggesting a key role in normal regulation of fatty acid oxidation. Some,¹⁵¹ but not all,¹⁵³ studies have shown a decrease in heart-type FABP in insulin-resistant humans.

Carnitine palmitoyltransferase 1 (CPT1) has been the subject of intense scrutiny for many years because of its central role in the balance between mitochondrial glucose and fatty acid metabolism, and primarily because of inhibition of mitochondrial fatty acid uptake by malonyl-CoA.^{154,155} A specific isoform contributes 97% of the CPT1 in muscle and has 100-fold lower sensitivity to inhibition by malonyl-CoA.¹⁵⁶ This lower sensitivity to malonyl-CoA inhibition suggests that the level of CPT1 itself may be important in the balance of uptake and oxidation of fatty acids. Evidence for this in skeletal muscle stems from the finding that, as with other fatty acid-oxidizing enzymes, muscle CPT1 mRNA is regulated by PPAR α activators, fat feeding, and exercise in rodents and is inversely correlated with obesity in humans.¹⁵⁷⁻¹⁶⁰

Long-chain fatty acids, after passing through the inner mitochondrial membrane as acylcarnitines, are metabolized at the surface of the inner mitochondrial membrane by CPT2 and the long chain-specific oxidation system consisting of very-long-chain acyl-CoA dehydrogenase (VLCAD) and the trifunctional protein (TFP) oxidation complex (Fig. 31-7). Transfer of the acyl chain from carnitine to CoA, catalyzed by CPT2, is followed by one cycle of oxidation catalyzed by VLCAD and TFP to yield a chain-shortened acyl-CoA that can recycle through the same oxidation system.¹⁶¹ In actuality, four different acyl-CoA dehydrogenase enzymes catalyze the initial dehydrogenation of straight-chain fatty acids in mitochondria. Three of them—short-chain acyl-CoA dehydrogenase (SCAD), medium-chain acyl-CoA dehydrogenase (MCAD), and long-chain acyl-CoA dehydrogenase (LCAD)—are soluble enzymes located in the mitochondrial matrix as homotetramers. A fourth, VLCAD, is attached to the inner membrane as a homodimer. Their names derive from the length of the fatty acids that they process. VLCAD and LCAD shorten the long-chain fatty acids into medium-chain fatty acids that can then be processed by MCAD and SCAD.¹⁶² The SCAD, MCAD, and LCAD monomers share a high degree of homology but do not share homology with VLCAD. At least some of these enzymes can be regulated in humans during exercise training.¹⁶³

Uncoupling protein-1 (UCP1) is clearly related to the uncoupling of oxidative phosphorylation in brown adipose tissue.¹²⁴ UCP2 and UCP3 have structural similarities to UCP1, but it is not clear that they are actually uncouplers of oxidative phosphorylation.¹⁶⁴ Newer members of the family, such as brain mitochondrial carrier protein 1 (BMCP1) and UCP4, have an even more distant sequence relationship.¹⁶⁵ BMCP1 and UCP4 are predominantly expressed in neural tissues, namely the brain. UCP3 mRNA

Figure 31-6 Simplified schematic diagram demonstrating fatty acid (FA) uptake, activation (formation of FA-coenzyme A [CoA]), and intracellular transport to organelles within a muscle cell. ER, endoplasmic reticulum; IMTG, intramuscular triglyceride; Mito, mitochondrion; PG, prostaglandin; PL, phospholipid; SL, sphingolipid.

Figure 31-7 Glucose effect on triglyceride metabolism. Increased uptake of glucose results in increased production of acetyl coenzyme A (acetyl-CoA) as a product of glycolysis. The increased tricarboxylic acid (TCA) cycle activity associated with oxidation of triglycerides and glucose increases the production of citrate, which is shuttled to the cytoplasm, activates the enzyme acetyl-CoA carboxylase (ACC) by allosteric mechanisms, and increases the susceptibility of ACC to phosphatases. This leads to increased ACC activity, converting acetyl-CoA to malonyl-CoA. Malonyl-CoA is a potent inhibitor of carnitine palmitoyltransferase (CPT) I on the outer mitochondrial membrane, which leads to accumulation of fatty acyl-CoAs in the cytoplasm. This may result in the production of signaling molecules that can increase the activity of kinases and other enzymes and lead to insulin resistance. ATP, adenosine triphosphate.

is found primarily in skeletal muscle and in brown adipose tissue. UCP2 has a ubiquitous tissue distribution. UCP2 and UCP3 mRNA levels have been correlated with different physiologic states, and numerous studies indicate that expression of UCP2 and UCP3 is stimulated by thyroid hormones and in the presence of high levels of fatty acids.¹⁶⁶ In humans, the levels of UCP2 and UCP3 mRNAs were upregulated by a high-fat diet, and the upregulation was more pronounced in humans with high percentages of type IIA muscle fibers.¹⁶⁷ In a small study, exercise training in humans increased mitochondrial oxidative capacity but did not change UCP2 or UCP3 levels.¹⁶⁸ Obesity itself was shown to be positively correlated with a splice isoform of UCP3.¹⁶⁹ A unique polymorphism in the promoter region of UCP3 correlated with expression of UCP3 in skeletal muscle.¹⁷⁰

Mitochondrial Abnormalities and Insulin Resistance

A decrease in oxidative capacity is seen in both humans and animals with insulin resistance, obesity, and T2DM.^{171,172} Studies have suggested that increases in intramyocellular fat content in skeletal muscle associated with insulin resistance (see earlier discussion) may be caused by alterations in mitochondrial mass. In one study, young insulin-resistant offspring of parents with T2DM demonstrated a 60% reduction in insulin-stimulated skeletal muscle glucose uptake compared with control subjects, and this reduction correlated with an increase of approximately 80% in intramyocellular lipid content.¹⁷³ The elevated intramyocellular lipid content was attributable to the 30% reduction in mitochondrial oxidative capacity. The insulin-resistant subjects showed a lower ratio of type I to type II muscle fibers. Type I fibers are mostly oxidative and contain more mitochondria than type II muscle fibers, which are more glycolytic.

Decreased expression of nuclear-encoded genes that regulate mitochondrial biogenesis, such as PPAR γ

coactivators-1 α and -1 β (PGC-1 α and PGC-1 β , respectively), have been shown to be important for mitochondrial biogenesis and for fiber type selection during development.¹⁷⁴ PGC-1 α transcriptionally activates the nuclear respiratory factors NRF1 and NRF2, which are known to be important for mitochondrial biogenesis.¹⁷⁵ PGC-1 α -responsive genes were found to be downregulated in obese white patients with IGT and T2DM.^{176,177} In obese diabetic and nondiabetic Mexican Americans, PGC-1 α and PGC-1 β expression levels were reduced compared with levels in nonobese persons.¹⁷⁸ The activity of the electron transport chain is reduced and intramyofibrillar mitochondria are smaller in patients with T2DM, and both the size of intramyofibrillar mitochondria and electron transport chain activity in muscle homogenates correlate with severity of insulin resistance.¹⁷⁹

In one study, rats bred for differences in oxidative capacity (determined by their intrinsic ability to run) were described.¹⁸⁰ The skeletal muscle of the animals with a low capacity for aerobic exercise showed a reduction in mitochondrial gene expression and PGC-1 α , similar to that seen in humans. When multiple metabolic parameters were assessed, it was determined that the group with poor aerobic capacity had several significant abnormalities, including obesity, insulin resistance, hypertension, and dyslipidemia, suggesting that the defects found in humans could have a genetic basis.

More recent studies have questioned the cause-effect relationship between alterations in mitochondrial mass and mitochondrial function, suggesting that, rather than being an inherited trait, these observed changes could be acquired. First, because insulin itself can upregulate mitochondrial biogenesis, muscle insulin resistance could provide a mechanism for the reduction in mitochondria. Second, the observed reduction in ATP synthesis and tricarboxylic acid (TCA) cycle activity could be explained by reduced turnover of ATP in relatively sedentary individuals. Persistent delivery of fatty acids to skeletal muscle, seen in obesity and after high-fat feeding, increases fatty acid

β -oxidation. In the absence of energy demand (e.g., exercise), the reduction in the adenosine diphosphate (ADP)/ATP ratio would impair electron transport in the mitochondria, increasing NADH levels, which would impair TCA cycle activity. Indicative of impaired oxidation in the mitochondria, mice fed a high-fat diet show a reduction in TCA cycle intermediates and an impairment of adequate β -oxidation of fatty acids marked by increases in even-chained acyl-carnitine levels. Increases in plasma acyl-carnitines are found in obese, insulin-resistant individuals.¹⁸¹ An emerging concept, nonexercise activity thermogenesis (NEAT), which is the energy expended for everything that is not sleeping, eating, or sports-like exercise, suggests that subtle differences in activity throughout the day can result in a difference in caloric expenditure of up to 350 calories per day.¹⁸² Whether long-term differences in NEAT could result in acquired changes in skeletal muscle metabolism remains to be determined.

Glucose Influence on Fatty Acid Metabolism

An emerging concept that could couple increased fatty acid flux into skeletal muscle with impaired insulin action is the central role of malonyl-CoA in regulating fatty acid and glucose oxidation (see Fig. 31-7).¹⁸³ Malonyl-CoA is an allosteric inhibitor of CPT1, the enzyme that controls the transfer of long-chain fatty acyl-CoAs into the mitochondria.^{154,184,185} Even in insulin-resistant skeletal muscle, glucose uptake into the skeletal muscle is higher than normal especially at the elevated levels of glucose found in T2DM.^{186,187} The glucose is shunted toward the glycolytic pathway, generating acetyl-CoA that can be converted to malonyl-CoA in the cytoplasm by the action of the highly regulated enzyme acetyl-CoA carboxylase (ACC).

In humans, an infusion of insulin and glucose at a high rate leads to increases in the concentration of malonyl-CoA in skeletal muscle and to decreases in whole-body and, presumably, muscle fatty acid oxidation.¹⁸⁸ In the presence of elevated glucose and insulin levels, the tricarboxylic acid (TCA) cycle is activated, resulting in an increase in citrate in the cytoplasm through increased malate cycling in the mitochondria. The increased citrate is converted to acetyl-CoA through citrate lyase and thus provides an indirect substrate for ACC. Citrate also allosterically activates ACC and makes ACC a better substrate for phosphatases that activate the enzyme.^{189,190} ACC is also regulated by a phosphorylation-dephosphorylation cycle, with the important participation of adenosine monophosphate (AMP)-activated protein kinase (AMPK), which inhibits ACC basal activity and reduces ACC activation by citrate.¹⁹¹ ACC then generates malonyl-CoA, which in turn allosterically inhibits CPT1 residing on the outer mitochondrial membrane, inhibiting uptake of acyl-CoA. The resulting buildup of long-chain acyl-CoAs and diacylglycerols is proposed to activate one or more PKC isoforms or other lipid-activated proteins, resulting in insulin resistance.¹⁸³ Support for this hypothesis is the finding that exercise, which activates AMPK, inactivates ACC, lowers intracellular long-chain acyl-CoA levels, and has an acute insulin-sensitizing effect.¹⁹²

Hyperinsulinemia and Insulin Resistance

Hyperinsulinemia per se has been proposed to cause insulin resistance. Elevated concentrations of insulin can cause insulin resistance by downregulating insulin receptors and desensitizing postreceptor pathways.¹⁹³ Del Prato and associates showed that 24 and 72 hours of sustained physiologic hyperinsulinemia in normal persons specifically inhibited the ability of insulin to increase nonoxidative

glucose disposal in association with an impaired ability of insulin to stimulate glycogen synthase activity.¹⁹⁴ Suppression of insulin secretion in obese, insulin-resistant persons results in increased insulin sensitivity.^{195,196}

Insulin-Signaling Abnormalities in Insulin Resistance

The pathways that are critical for insulin regulation of glucose and lipid metabolism are being clarified. However, the complete cascade of events remains to be determined. Besides intermediary metabolism of glucose and lipid, signaling by insulin affects other cellular processes such as amino acid transport and metabolism, protein synthesis, cell growth, differentiation, and apoptosis.

Insulin Signaling

Insulin signaling is initiated through binding and activation of its cell-surface receptor and initiates a cascade of phosphorylation and dephosphorylation events, second-messenger generation, and protein-protein interactions that result in diverse metabolic events in almost every tissue (Fig. 31-8). The insulin receptor consists of two insulin-binding α -subunits and two catalytically active β -subunits that are disulfide linked into an $\alpha_2\beta_2$ heterotetrameric complex. Insulin binds to the extracellular α -subunits, activating the intracellular tyrosine kinase domain of the β -subunit.¹⁹⁷ One receptor β -subunit phosphorylates its partner on specific tyrosine residues that may have distinct functions such as stimulation of intermolecular association of signaling molecules such as Shc and Grb, IRS1 through IRS4, Shc adapter protein isoforms, and SIRP (signal regulatory protein) family members Gab-1, Cbl, CAP, and APS^{198,199}; stimulation of mitogenesis²⁰⁰; and receptor internalization.²⁰¹

The insulin receptor β -subunit has also been shown to undergo serine/threonine phosphorylation, which might decrease the ability of the receptor to autophosphorylate. The activities of a number of PKC isoforms that catalyze the serine or threonine phosphorylation of the insulin receptor are elevated in animal models of insulin resistance and in insulin-resistant humans.^{202,203} Interventions that decrease serine phosphorylation of the insulin receptor result in increased insulin signaling.²⁰⁴ Termination of the insulin-signaling event occurs when the receptor is internalized and dephosphorylated by protein tyrosine phosphatases. Increased activity of protein tyrosine phosphatase can attenuate insulin signaling. Two protein tyrosine phosphatases that have been shown to negatively regulate insulin signaling, PTP1B and LAR (leukocyte antigen-related), have been reported to be elevated in insulin-resistant patients.^{205,206} Conversely, disruption of PTP1B in mice resulted in a marked increase in insulin sensitivity and resistance to diet-induced obesity.²⁰⁷

Mutations in the insulin receptor are associated with rare forms of insulin resistance. These mutations affect insulin receptor number, splicing, trafficking, binding, and phosphorylation. The affected patients demonstrate severe insulin resistance, manifest as clinically diverse syndromes including the type A syndrome, leprechaunism, Rabson-Mendenhall syndrome, and lipotrophic diabetes.^{208,209}

Downstream Events after Insulin Receptor Phosphorylation

The IRSs act as multifunctional docking proteins activated by tyrosine phosphorylation.²¹⁰ The IRS proteins have multiple functional domains—including Pleckstrin

Figure 31-8 Insulin signaling. homology (PH) and phosphotyrosine binding (PTB)—and SH domains that interact with other proteins to mediate the insulin-signaling events. Disruption of IRS1 in mice resulted in mild insulin resistance and growth retardation, whereas disruption of IRS2 resulted in beta-cell failure and secondary insulin resistance.²¹¹ Alterations in the phosphorylation and levels of IRS1 and IRS2 are found in many insulin-resistant tissues. Serine phosphorylation on IRS proteins is mediated by a variety of kinases, including PKC isoforms and mTOR/S6K. Serine phosphorylation on appropriate residues might increase ubiquitination and downregulation of the protein, which would result in decreased downstream signaling.²¹²

PI3K, which is regulated by interaction with IRS proteins, is necessary but not sufficient for stimulation of glucose transporter 4 (GLUT4)-mediated increase in glucose transport in insulin-sensitive tissues.²¹³ In addition, inhibition of PI3K activity with the fungal inhibitor wortmannin inhibited insulin-stimulated glucose uptake, glycogen synthesis, triglyceride accumulation, protein synthesis, and modulation of gene expression.²¹⁴ PI3K generates 3,4,5-phosphoinositol, which activates several phosphatidylinositol 3,4,5-triphosphate (PIP₃)-dependent serine-threonine kinases, such as PI-dependent protein kinases 1 and 2 (PDK1 and PDK2), which in turn activate Akt, salt- and glucocorticoid-induced kinases,¹⁴⁴ PKC, wortmannin-sensitive and insulin-stimulated serine kinase, and others.

Akt kinase (also known as protein kinase B) exists as three distinct isoforms that are activated by phosphorylation on specific threonine and serine residues.^{215,216} Activated Akt has the ability to phosphorylate proteins that regulate lipid synthesis, glycogen synthesis, protein synthesis, and apoptosis. Disruption of Akt2 resulted in insulin resistance and diabetes in mice.²¹⁷ Several investigators have examined the role of PI3K and Akt in persons with insulin resistance. Studies have shown a decrease in IRS-associated PI3K²¹⁸ and Akt²¹⁹ activity in insulin-resistant skeletal muscle; however, in some patients with reduced PI3K activity, there was normal activation of Akt.²²⁰

A primary effect of insulin is to stimulate translocation of GLUT4 from an intracellular pool to the surface of cells, primarily in skeletal muscle, adipose tissue, and heart.²²¹ Akt substrate of 160 kd (AS160) and TBC1D1 are paralog Rab family guanosine triphosphatase (GTPase)-activating proteins that have been proposed to inhibit the translocation of GLUT4 to the plasma membrane.²²² On phosphorylation, the inhibition is relieved, contributing to the increased translocation. Although the composition and signaling pathways that converge on the intracellular GLUT4-containing vesicles to cause GLUT4 translocation are still not well understood, it appears that the number of glucose transporters in skeletal muscle of insulin-resistant persons is not changed, but the ability of insulin to effect this translocation is disrupted.²²³⁻²²⁵

Glucocorticoid-Induced Insulin Resistance

Cushing's syndrome and exogenous glucocorticoid treatment have long been known to induce significant insulin resistance in humans. The exact mechanism is unknown, but it is associated with redistribution of fat from the periphery to the central compartment. Elevations in triglyceride and FFA levels also occur. At a molecular level, dexamethasone has differential effects on the proteins involved in the early steps of insulin action in liver and muscle. In both tissues, dexamethasone treatment results in a reduction in insulin-stimulated IRS1-associated PI3K, which may play a role in the pathogenesis of insulin resistance at the cellular level. On the basis of studies performed in mice, it has been suggested that the effects of glucocorticoids to raise glucose concentrations and cause hypertension are mediated through activation of PPAR α receptors in the liver²²⁶, however, the relevance of this observation to humans is not known.

Tumor Necrosis Factor- α

Studies in humans and in animal models of obesity have identified changes in the expression and activity of key molecules involved in the insulin-signaling pathway. Decreases in the number and the kinase activity of insulin receptors²²⁷ and impairment in the activation of IRS1,²²⁸ PI3K,^{229,230} and protein kinase B²³¹ have been observed. Although the basis for the changes is generally unknown, a TNF- α -mediated mechanism for the decreased activity in the initial steps of the insulin-signaling cascade has been proposed. TNF- α , made and secreted by adipocytes, is elevated in a variety of experimental models of obesity.²³² The kinase activity of the insulin receptor in rats²³³ or in 3T3-L1 adipocytes²³² treated with TNF- α was reduced, possibly by increased serine phosphorylation.²³⁴ Fat-fed mice with genetic ablation of TNF- α production had increased kinase activity of the insulin receptor compared with control mice and demonstrated increased insulin sensitivity.²³⁵ In addition, rats treated with neutralizing antisera or soluble TNF receptors demonstrated an amelioration of their insulin resistance. As described later, other interventions to decrease TNF- α action result in increased insulin sensitivity.

Glucotoxicity, Glucosamine

Hyperglycemia is a primary factor in the development of diabetes complications, and decreases in average blood glucose have a profound effect to prevent complications in both T1DM²³⁶ and T2DM.²³⁷ Hyperglycemia itself can cause insulin resistance. In Pima Indians, the level of fasting glycemia is the primary determinant of insulin sensitivity.²³⁸ The defect is primarily in skeletal muscle²³⁹ and is related to the degree of hyperglycemia.

Entry of glucose into the cell results in its phosphorylation to glucose-6-phosphate, which has multiple metabolic fates. The hexosamine pathway is a relatively minor branch of the glycolytic pathway, encompassing less than 3% of total glucose used. The first and rate-limiting enzyme glutamine-fructose-6-phosphate (F6P) amidotransferase (GFAT), converts F6P and glutamine to glucosamine-6-phosphate (GlcN6P) and glutamate. Subsequent steps metabolize GlcN6P to uridine diphosphate-N-acetylglucosamine (UDP-GlcNAc), UDP-N-acetylgalactosamine (UDP-GalNAc), and cytidine monophosphate (CMP)-sialic acid, essential building blocks of the glycosyl side chains of glycoproteins, glycolipids, proteoglycans, and gangliosides.²⁴⁰ Evidence suggests that the hexosamine pathway underlies the defect in glucose utilization associated with

hyperglycemia. Increased flux through the hexosamine pathway appears to be required for some of the metabolic effects of sustained increased glucose flux, which promotes the complications of diabetes including diminished expression of sarcoplasmic reticulum Ca²⁺-ATPase in cardiomyocytes and induction of TGF- β and plasminogen activator inhibitor 1 (PAI-1) in vascular smooth muscle cells, mesangial cells, and aortic endothelial cells.²⁴¹

Hexosamines, such as glucosamine, when incubated with adipose tissue, induce insulin resistance in fat cells²⁴² and in skeletal muscle.²⁴³ Infusion of glucosamine into rats resulted in a dose-dependent increase in insulin resistance of skeletal muscle,²⁴³ and transgenic mice that overexpress GFAT specifically in skeletal muscle acquired severe insulin resistance.²⁴⁴ By a pathway that is unclear, glucosamine overproduction resulted in a disruption of the ability of insulin to cause translocation of GLUT4 to the cell surface.²⁴⁵ Through its anti-insulin action, the hexosamine pathway has been hypothesized to be a glucose sensor that allows the cell to sense and adapt to the prevailing level of glucose.²³⁹

Insulin Resistance and Lipodystrophy Associated with Human Immunodeficiency Virus Infection

A syndrome with many of the clinical and metabolic features of insulin resistance is increasingly being recognized in patients with human immunodeficiency virus (HIV) infection.²⁴⁶ An unusual form of lipodystrophy is observed in certain of these patients in whom there is significant fat redistribution from the extremities and face to the torso with accumulation of intra-abdominal and intrascapular fat. This form of lipodystrophy is associated with significant insulin resistance and T2DM, dyslipidemia with elevated total and low-density lipoprotein (LDL)-cholesterol and suppressed HDL-cholesterol concentrations and a susceptibility to lactic acidemia.²⁴⁷

Epidemiologic studies have associated this syndrome with previous or current treatment with antiretroviral protease inhibitors or nucleoside reverse transcriptase inhibitors. There is also an association with increased age.²⁴⁶ Other possible contributing factors are male sex, diagnosis of the acquired immunodeficiency syndrome (AIDS), responsiveness to antiretroviral treatment, and increases in CD4 T-cell counts. An increased emphasis has been placed on the role of protease inhibitors in the pathogenesis of the syndrome. Administration of these drugs or ritonavir to normal subjects caused increases in plasma triglyceride and very-low-density lipoprotein (VLDL)-cholesterol and decreased plasma HDL-cholesterol levels.²⁴⁸ Indinavir administration for 4 weeks resulted in small increases in serum glucose and insulin levels and decreased insulin-mediated glucose disposal as assessed with a hyperinsulinemic euglycemic clamp; there were no changes in lipoprotein, triglyceride, or FFA levels.²⁴⁹

The molecular basis of the metabolic syndrome is not clear. A number of protease inhibitors can inhibit glucose transport in vitro and in vivo, and there is evidence for a direct interaction with GLUT4²⁵⁰ that could inhibit glucose uptake specifically in insulin-responsive tissue. Mitochondrial abnormalities have been described in subcutaneous adipose tissue biopsy specimens obtained from HIV-infected patients with lipodystrophy compared with specimens from patients without the syndrome.²⁵¹ A direct effect of protease inhibitors on differentiation of adipocytes has also been described.²⁵²⁻²⁵⁴ Additionally, reductions in mitochondrial number and oxidative function have

been described in adipocytes from subcutaneous biopsies obtained from patients treated with highly active antiretroviral therapy (HAART).²⁵⁵ The precise mechanism for the lipodystrophy associated with HIV infection is not known.

Treatment of HIV-associated lipodystrophy is at present inadequate. Use of alternative protease inhibitors might improve metabolic abnormalities, particularly those induced or increased by protease inhibitor therapy. However, changing protease inhibitors has little impact on body fat. Switching thymidine analogues has been the only intervention to improve lipoatrophy in independent studies.²⁵⁶ Insulin-sensitizing thiazolidinediones have shown mixed results, with improvement in insulin sensitivity but little alteration in fat distribution.²⁵⁷ More than 75% of patients with HIV who have acute myocardial infarction (MI) are older than 55 years of age. Because of the increased risk of cardiovascular disease, treatment of hyperlipidemia is essential in these patients, with 3-hydroxy-3-methylglutaryl (HMG)-CoA reductase inhibitors and fibrates, alone or in combination, as first-line drugs.^{258,259}

MEASURES TO IMPROVE INSULIN SENSITIVITY

Mechanisms of Reducing Insulin Resistance

The most effective measures to improve insulin sensitivity are weight loss and exercise. Both modalities are effective and can be additive in their ability to improve insulin action. Later in this chapter, the roles of these interventions in the treatment of patients with T2DM are discussed. The scientific basis and molecular mechanisms responsible for the improvements in insulin sensitivity seen with these interventions are summarized in the following paragraphs.

Mechanisms for Improved Insulin Sensitivity with Weight Loss

Weight loss can be a highly effective treatment for overweight patients with T2DM and other cardiovascular risk factors, and it is advocated as the first line of therapy. Weight loss may also play a role in preventing T2DM.^{89,260} In overweight patients with T2DM, weight loss can reduce hepatic glucose production, insulin resistance, and fasting hyperinsulinemia and can improve glycemic control. Weight loss in T2DM is also associated with a reduction in blood pressure and an improvement in the lipid profile. These benefits can occur with as little as 5% to 10% weight loss.²⁶¹⁻²⁶³ Moreover, preventing obesity in primates with long-term caloric restriction attenuates the development of insulin resistance.

One possible mechanism for improvements in insulin sensitivity through weight loss may be its effects on the pattern of muscle fatty acid metabolism and the accumulation of lipid within muscle. In this context, it would be important to know whether alterations in the pathways of fatty acid utilization in skeletal muscle represent primary defects in obese persons or arise secondarily, after a person has become obese. This question cannot be answered by cross-sectional comparisons of lean and obese subjects. One prospective clinical study indicated that lower rates of lipid oxidation were a predisposing factor for greater weight gain,¹⁷⁰ and collateral studies implicated altered skeletal muscle enzyme activities in impaired lipid oxidation.^{183,184} A reduced reliance on lipid oxidation has also been

identified as a risk factor for weight regain after weight loss.¹⁸⁵ These data raise the possibility that impairment in the capacity for lipid oxidation may be a primary defect in obesity.

Weight loss can markedly improve insulin-resistant glucose metabolism in skeletal muscle. If the patient's response indicates a substantial acquired or secondary component of obesity-related insulin-resistant glucose metabolism, it is important to determine whether weight loss can modulate patterns of skeletal muscle metabolism of fatty acids, including the content of fat within muscle.

Mechanisms for Improved Insulin Sensitivity with Exercise

Exercise is clearly effective in increasing insulin sensitivity in animals and humans. There appear to be two separable but related effects of exercise on insulin action. A single bout of exercise can result in an acute increase in insulin-independent glucose transport that is measurable during and for a relatively short period after exercise.²⁶⁴⁻²⁶⁸ Like insulin, exercise and muscle contractions increase glucose transport by translocation of intracellular GLUT4 to the cell surface.²⁶⁹⁻²⁷¹

Acute Exercise

The signaling pathway leading to the exercise-induced increase in glucose transporter translocation and glucose transport is unknown, although there is ample evidence that the pathway is independent of the insulin-stimulated, receptor-mediated pathway. The effect of exercise and contractions on translocation and transport is additive to the maximal effect of insulin.^{264,271-274} Insulin-stimulated glucose transport in muscle is inhibited by specific inhibitors of PI3K, such as wortmannin, whereas transport or translocation stimulated by muscle contractions is insensitive to these inhibitors.²⁷¹⁻²⁷⁶ Stimulation of muscle contractions in situ and exercise do not increase insulin receptor phosphorylation, tyrosine kinase activity, IRS phosphorylation, or PI3K activity.^{270,277} In addition, in many insulin-resistant states, the acute exercise-stimulated (but not insulin-stimulated) glucose transport and GLUT4 translocation are normal. This has been demonstrated in the obese, insulin-resistant Zucker rat²⁷⁸ and in patients with T2DM.²²⁵ Finally, hypoxia, a stimulus for glucose transport that is also independent of the insulin receptor-mediated pathway, is effective in increasing glucose transport in muscle strips from obese, insulin-resistant patients and in patients with T2DM.²⁷⁹

The acute effect of exercise and hypoxia may be mediated by AMPK. AMPK is thought to be a sensor of intracellular energy stores and is activated by increases in intracellular AMP. A stable AMP analog, 5-amino-4-imidazole carboxamide ribotide (ZMP), can be generated intracellularly from 5-aminoimidazole-4-carboxamide ribonucleoside (AICAR) and can activate AMPK in cells, leading to increased phosphorylation of known substrates for AMPK, including HMG-CoA reductase, acyl-CoA carboxylase, and creatine kinase.²⁸⁰ Treatment of incubated skeletal muscle with AICAR resulted in increased glucose uptake and glucose transporter translocation.²⁸¹ Similarly, the inclusion of 2 mmol/L of AICAR in the perfusate of the rat hind limb resulted in inactivation of ACC, decreases malonyl-CoA levels, and a twofold increase in glucose uptake.^{282,283}

The euglycemic clamp technique was used in conscious rats to demonstrate that infusion of AICAR results in a greater than twofold increase in glucose utilization.^{283a} Uptake of the glucose analog 2-deoxyglucose was also

increased twofold in vivo in soleus and gastrocnemius muscles. As with previous studies, this uptake was not associated with PI3K activation, again indicating a separate pathway from that of insulin.

A second effect of exercise, which becomes evident as the acute effect on glucose transport reverses, is a large increase in the sensitivity of glucose transport to stimulation by insulin.²⁸⁴⁻²⁸⁷ This effect is due to translocation of a greater amount of GLUT4 to the cell surface for any given dose of insulin.^{288,289} As with the acute stimulation of transport by exercise, the cellular mechanisms leading to enhanced translocation in response to submaximally effective stimuli are unknown. However, several studies have shown that steps in the insulin-signaling cascade leading to activation of PI3K are not enhanced after a bout of exercise. There is no change in insulin binding to its receptor,^{277,290} insulin stimulation of receptor tyrosine kinase activity,^{277,291} increased insulin-stimulated tyrosine phosphorylation of IRS1,²⁸⁸ or PI3K activity associated with IRS1.^{270,291}

Exercise Training

Exercise training also results in increases in insulin sensitivity^{292,293} and can delay or prevent the onset of T2DM in those at high risk.²⁹⁴ Using the hyperinsulinemic-euglycemic clamp, Perseghin and coworkers²⁹⁵ compared exercise training for 45 minutes on a stair-climbing machine 4 days per week for 6 weeks in normal insulin-sensitive subjects and a group of high-risk, insulin-resistant relatives of T2DM. A 100% increase in insulin sensitivity was seen in both groups without a significant change in body weight. The higher basal and glucose-stimulated insulin release seen in the insulin-resistant subjects was not altered after exercise training. The effect of exercise training on insulin sensitivity has been proposed to be caused by upregulation.

Primary effects of exercise training include increased glucose transporter number, changes in capillary density, increased number of red, glycolytic (type IIa) fibers, and increased density of mitochondria.^{296,297} A reduction in mitochondrial oxidative capacity could underlie the dysregulation of lipid metabolism that results in reduced skeletal muscle glucose metabolism. Expression of nuclear-encoded genes that regulate mitochondrial biogenesis, such as the NRFs, PGC-1 α , and PGC-1 β have been shown to be important for both mitochondrial biogenesis and fiber type selection during development.^{174,298} In muscle-specific transgenic mice, PGC-1 α promotes muscle fiber-type switching from fast-twitch glycolytic fibers (types IIa and IIb) to slow-twitch oxidative fibers (type I), increases mitochondrial density, and improves oxidative capacity.²⁹⁹ These changes are also observed after exercise training.

Many of the changes observed after exercise are likely to be mediated in part through PGC-1 α levels and activity. Exercise-induced expression of PGC-1 α in skeletal muscle is thought to be mediated by myocyte enhancer factor 2 (MEF2),³⁰⁰ possibly through its interaction with MEF2C³⁰¹ and cyclic AMP (cAMP) response element-binding protein (CREB).³⁰⁰ PGC-1 α regulates its own promoter activity in a positive autoregulation loop. Activation of estrogen-related receptor α (Err α) and GA repeat-binding protein- α (Gabpa) by PGC-1 α appears to mediate much of the effect to increase oxidative phosphorylation gene expression in muscle.¹⁷⁶ Nitric oxide produced by endothelial nitric oxide synthase controls mitochondrial biogenesis,³⁰² possibly through increased expression of PGC-1 α and other transcription factors. This process is mediated by cyclic guanosine 3',5'-phosphate, resulting from activation of "soluble" guanylate cyclase.

The pathway from exercise to activation of PGC-1 α has been partially elucidated. Increases in calcium levels activate calcium/calmodulin-dependent kinase IV (CaMKIV) and calcineurin. Activated CaMKIV phosphorylates CREB, which increases transcription at CREB-responsive elements in the PGC-1 α promoter.³⁰³ Exercise also increases PGC-1 α activity via phosphorylation through p38 mitogen-activated protein kinase.^{304,305} AMPK, which is activated by exercise-induced changes in AMP levels, also increases mitochondrial biogenesis and PGC-1 α activity in skeletal muscle,³⁰⁶⁻³⁰⁸ but at present there is no evidence that PGC-1 α is an AMPK substrate. Other conditions that induce mitochondrial biogenesis also increase PGC-1 α promoter activity.

MECHANISMS THAT LINK CARDIOVASCULAR DISEASE AND INSULIN RESISTANCE

The Metabolic Syndrome or Syndrome X

MI, stroke, or nonischemic cardiovascular disease is the cause of death in up to 80% of patients with T2DM. Independent of other risk factors, T2DM increases the risk of cardiovascular morbidity and mortality but also provides a synergistic interaction with other risk factors such as smoking, hypertension, and dyslipidemia.³⁰⁹ In a Finnish population, diabetes increased the risk of MI fivefold,³¹⁰ and insulin resistance, as measured by elevated fasting insulin levels, increased the risk of death from heart disease.³¹¹ Women are particularly vulnerable to the cardiovascular effects of T2DM, because they appear to lose the protective effects of estrogen in the premenopausal period.^{312,313}

A constellation of metabolic derangements often seen in patients with insulin resistance and T2DM are individually associated with an increased risk of cardiovascular disease. These metabolic derangements have been variously designated *syndrome X*; the *dysmetabolic syndrome*; hypertension, obesity, non-insulin-dependent diabetes mellitus (NIDDM), dyslipidemia, and atherosclerotic cardiovascular disease (*HONDA*); and the *deadly quartet*.^{314,315} The syndrome has also been associated with easily oxidized, small LDL particles; heightened blood-clotting activity (e.g., increased PAI-1); and elevated serum uric acid concentrations. The proposed central abnormality associated with syndrome X is insulin resistance. Some of the abnormalities themselves have also been proposed to contribute to insulin resistance.

Controversy surrounding the metabolic syndrome has not called into question the clustering of cardiovascular risk factors such as central obesity, dyslipidemia, and hypertension and the association of this clustering with the risk of developing diabetes and cardiovascular disease. The controversy largely focuses on the etiology of the syndrome, how best to define its presence, how clinical decision making should be modified based on those definitions, and whether there are not more effective ways to screen for diabetes and cardiovascular risk.³¹⁶

Perhaps the overriding risk factor for coronary artery disease in insulin resistance and T2DM is the associated dyslipidemia. The profile includes hypertriglyceridemia, low plasma HDL, and small, dense LDL particle concentrations. The percentage of men with T2DM who have abnormal cholesterol levels is not different from that of nondiabetic men. However, diabetic women, compared with nondiabetic women, have almost double the rate of

Figure 31-9 Insulin resistance and dyslipidemia. The suppression of lipoprotein lipase and very-low-density lipoprotein (VLDL) production by insulin is defective in insulin resistance, leading to increased flux of free fatty acids (FFAs) to the liver and increased VLDL production, which results in increased circulating triglyceride concentrations. The triglycerides are transferred to low-density lipoprotein (LDL) and high-density lipoprotein (HDL), and the VLDL particles gain cholesterol esters by the action of the cholesterol ester transfer protein (CETP). This leads to increased catabolism of HDL particles by the liver and loss of apolipoprotein (Apo) A, resulting in low HDL concentrations. The triglyceride-rich LDL particle is stripped of its triglycerides, resulting in the accumulation of atherogenic small, dense LDL particles.

hypercholesterolemia³¹⁷ and greater changes in other lipid parameters that increase the risk of cardiovascular disease (Fig. 31-9). The physiologic basis for this abnormal lipid profile appears to be overproduction of apolipoprotein B-containing VLDL particles. Production of apolipoprotein B by the liver is primarily post-translational³¹⁸ and is augmented by insulin and by the increased availability of FFAs in the portal circulation,³¹⁹⁻³²³ probably as a result of increased lipolysis in the visceral adipose tissue.³²⁴⁻³²⁶ Part of the post-translational regulation may be due to insulin- and fatty acid-mediated increases in microsomal triglyceride transfer protein levels that catalyze the transfer of lipids to apolipoprotein B and decrease the ubiquitination-dependent degradation of apolipoprotein B.³²⁷⁻³²⁹

The overproduction of VLDL triglyceride results in increased transfer of VLDL triglyceride to HDL particles in exchange for HDL-cholesterol esters mediated by the cholesterol ester transfer protein.³³⁰ The triglyceride-rich HDL is hydrolyzed by hepatic lipase; this leads to the generation of small HDL, which is degraded more readily by the kidney, resulting in low HDL levels in serum. Cholesterol ester transfer protein-mediated exchange of VLDL triglyceride for LDL-cholesterol esters and subsequent triglyceride hydrolysis by hepatic lipase probably result in generation of the small, dense LDL particles found in insulin-resistant subjects.³³¹⁻³³⁴

The increased risk of heart disease in patients with diabetes has prompted the recommendation that persons with diabetes be treated for their dyslipidemia as aggressively as persons who have had a previous MI. In addition, patients with the metabolic syndrome of insulin resistance and obesity are considered to be in a higher risk category and should also be aggressively treated to lower lipids.³³⁵

The presence of hypertension and overt diabetes doubles the risk of cardiovascular disease. Defects in vasodilation

and alterations in blood flow may provide a link to hypertension in insulin-resistant subjects. The normal vasodilatory response of insulin is disrupted in obese, insulin-resistant, and diabetic persons,³³⁶ perhaps through insulin's inability to increase the production of the potent vasodilator nitric oxide by endothelial cells.^{337,338} The defect may be magnified by increases in plasma FFAs.³³⁹ Other proposed mechanisms for insulin resistance leading to hypertension are activation of the sympathetic nervous system by insulin³⁴⁰⁻³⁴² and the intrinsic ability of insulin to cause salt and water reabsorption in the kidney, resulting in expanded plasma volume.³⁴³⁻³⁴⁵

Hypertension itself, independent of other risk factors, has been associated with the propensity to become diabetic.³⁴⁶ A prospective cohort study found that T2DM was almost 2.5 times more likely to develop in subjects with hypertension than in subjects with normal blood pressure.³⁴⁷ A possible mechanism is that an intrinsic defect in vasodilation might contribute to insulin resistance by decreasing the surface area of the vasculature perfusing skeletal muscle, decreasing the efficiency of glucose uptake.³³⁹ Conversely, vasodilative agents might improve glucose uptake and might even prevent the onset of diabetes, as has been observed with angiotensin-converting enzyme (ACE) inhibitor therapy.³⁴⁸

Several factors involved in clotting and fibrinolysis, including fibrinogen, factor VII, and PAI-1, have been shown to be increased in persons with insulin resistance.³⁴⁹⁻³⁵⁴ PAI-1 has been extensively studied, and there is a clear relationship between elevated PAI-1 levels and risk of coronary artery disease.³⁵⁵ Insulin increased PAI-1 expression in hepatocytes, endothelial cells, and abdominal adipose tissue,³⁵⁶⁻³⁵⁸ and insulin-sensitizing thiazolidinediones decreased PAI-1 activity.³⁵⁹

Upper-body rather than lower-body obesity (the apple rather than the pear shape) is highly correlated with insulin resistance and risk for T2DM. Therefore, the anatomic distribution of fat, rather than the overall degree of obesity, appears to determine risk for the metabolic syndrome. The reported association between increased abdominal (upper-body) fat and an increased risk of coronary heart disease is related to visceral fat, for which the waist-to-hip ratio is a convenient index. A waist-to-hip ratio greater than 1.0 in men or greater than 0.8 in women indicates abdominal obesity.³⁶⁰ The National Cholesterol Education Program (NCEP) has suggested that a waist circumference greater than 40 inches (101.5 cm) in men or greater than 35 inches (89 cm) in women is a marker for the metabolic syndrome.³⁶¹

The Role of Increased Hepatic Glucose Production

The disposal of glucose after meals depends on the ability of insulin to increase peripheral glucose uptake and to simultaneously decrease endogenous glucose production. Although studies have suggested that the kidney can contribute up to 25% of endogenous glucose production,^{362,363} the defect in T2DM is primarily in defective regulation of glucose production from the liver (hepatic glucose output). Two routes of glucose production by the liver are glycogenolysis of stored glycogen and gluconeogenesis from two- and three-carbon substrates derived primarily from skeletal muscle.^{364,365} Under different conditions and at different times postprandially, the contribution of each of these mechanisms to maintenance of glucose levels varies. In studies using ¹³C NMR spectroscopy combined with measurement of whole-body glucose production in normal human subjects at different intervals after fasting, it was found that gluconeogenesis accounted for 50% to 96% of

glucose production, and the percentage increased with increasing duration of fasting.^{366,367}

The production of glucose by the liver is regulated primarily by the relative actions of glucagon and insulin to activate or suppress glucose production, respectively, although the nervous system³⁶⁸ and glucose autoregulation of hepatic glucose production probably play less important roles.³⁶⁹ The ability of insulin to reduce hepatic glucose output is an important mechanism for maintaining normal glucose tolerance.^{370,371} Under normal circumstances, insulin suppresses up to 85% of glucose production in normal persons by directly inhibiting glycogenolysis, especially at lower insulin concentrations.³⁷² When glycogenolysis is enhanced by glucagon, the effects of insulin in suppressing hepatic glucose production may be even greater.³⁷³ Glucagon increases glycogenolysis by activation of the classic protein kinase cascade involving AMPK and phosphorylase and also increases gluconeogenesis in part by increasing transcription of phosphoenolpyruvate carboxykinase by means of the binding protein CREB.^{371,374,375}

Data suggest that the regulatory mechanisms triggered by cAMP are much more complex, with the CREB transcriptional coactivator, TORC2, playing an important role. TORC2 is specifically dephosphorylated in response to cAMP; this results in translocation of the TORC2 protein to the nucleus, allowing activation of CREB-dependent transcription of gluconeogenic enzymes.³⁷⁶ In addition, CREB may increase transcription of PGC-1 α , which serves as a critical coactivator of the transcription factor forkhead box protein O1 (FOXO1), which also plays a role in the transcriptional activation of various genes associated with gluconeogenesis.³⁷⁴ Recent data suggest that the NAD⁺-dependent protein deacetylase, SIRT1, can regulate gluconeogenesis. SIRT1 deacetylates PGC-1 α and FOXO1, increasing their nuclear interaction with HNF4A. The PGC-1 α /FOXO1/HNF4A complex is a potent activator of gluconeogenic gene transcription.³⁷⁴

Insulin decreases endogenous glucose production by direct and indirect mechanisms (Fig. 31-10).³⁷⁸ In its direct action, portal insulin suppresses glucose production by inhibiting glycogenolysis through an increase in phosphodiesterase activity^{379,380} or changes in the assembly of protein phosphatase complexes.^{381,382} Insulin can also

Figure 31-10 Insulin suppresses hepatic glucose production by direct and indirect mechanisms. In insulin resistance, the ability of insulin to suppress lipolysis in adipose tissue and glucagon secretion by alpha cells in the islet results in increased gluconeogenesis. In addition, insulin inhibition of glycogenolysis is impaired. Therefore, both hepatic and peripheral insulin resistance result in abnormal glucose production by the liver.

Figure 31-11 Relationship between fasting hepatic glucose output and fasting plasma glucose levels. Open squares represent nondiabetic control subjects; closed squares represent diabetic subjects. (From Maggs DG, Buchanan TA, Burant CF, et al. Metabolic effects of troglitazone monotherapy in type 2 diabetes mellitus: a randomized, double-blind, placebo-controlled trial. *Ann Intern Med.* 1998;128:176-185.)

directly suppress gluconeogenesis by inhibiting the activation of phosphoenolpyruvate carboxykinase transcription through insulin-dependent phosphorylation of FOXO1 (and perhaps FOXA2), sequestering it in the cytoplasm.³⁸³⁻³⁸⁶

The indirect or peripheral effect of insulin in controlling glucose production by the liver is twofold. First, insulin profoundly decreases glucagon secretion by the alpha cell of the pancreas through systemic and paracrine effects.^{387,388} The decrease in glucagon secretion decreases the activation of glycogenolysis and gluconeogenesis. The second important peripheral action of insulin is to decrease FFA levels by suppressing lipolysis. FFAs increase hepatic glucose production by stimulating gluconeogenesis.³⁸⁹ When the reduction in plasma FFAs during a hyperinsulinemic clamp was prevented by infusion of triglyceride emulsions with heparin (which produces increased FFA levels through activation of lipoprotein lipase), insulin-mediated suppression of hepatic glucose output was reduced.^{364,390} The suppression of glucagon secretion and the decrease in FFA delivery to the liver are additive in reducing liver glucose production.³⁹¹

Hepatic insulin resistance plays an important role in the hyperglycemia of T2DM,³⁹²⁻³⁹⁵ and the impaired suppression of hepatic glucose output appears to be quantitatively similar to, or even larger than, the defect in stimulation of peripheral glucose disposal.^{393,396} There is a direct relationship between increased hepatic glucose output and fasting hyperglycemia⁸⁰ (Fig. 31-11). Insulin-mediated suppression of hepatic glucose output is impaired at both low and high plasma insulin levels in T2DM³⁹⁶⁻³⁹⁹; hepatic glucose production is elevated early in the course of the disease⁴⁰⁰ but may be normal in lean, relatively insulin-sensitive type 2 diabetics.³⁹⁹ Treatment of patients with metformin, which suppresses hepatic glucose production, results in improved glucose tolerance.⁴⁰¹

Alterations in the direct and indirect effects of insulin in T2DM appear to play a role in the elevation of hepatic glucose production. Defects in the direct effect of insulin to suppress hepatic glucose production that have been demonstrated in humans⁴⁰² appear to be caused by a large rightward shift in the steep dose-response curve for insulin's inhibition of glycogenolysis.⁴⁰³ However, peripheral insulin resistance may play the bigger role in elevated hepatic glucose production in T2DM. The resistance of

adipose tissue, especially visceral fat, to suppression of lipolysis by insulin is responsible for part of insulin's inability to suppress hepatic glucose production by the indirect route, resulting in enhanced gluconeogenesis.^{404,405} In addition, the suppression of glucagon levels in humans with insulin resistance may be impaired, again leading to an increase in endogenous glucose production.⁴⁰⁶

Central Control of Glucose Metabolism

The hypothalamus and perhaps other brain regions can sense metabolic requirements and change peripheral metabolism. Studies by Rossetti and colleagues suggested that uptake of fatty acids by the mediobasal hypothalamus decreases feeding behavior and decreases hepatic glucose production via central nervous system (CNS) efferents.⁴⁰⁷ Inhibition of fatty acid oxidation results in decreased food intake and reduced glucose production, suggesting that buildup of long-chain fatty acids or their derivatives changes feeding and hepatic glucose production.

AMPK may also play a role in integrating CNS nutrient supply. AMPK is activated by cellular AMP levels and therefore is a sensor of energy supply.⁴⁰⁸ Higher cellular energy, resulting from glucose or fatty acid surfeit, would lead to decreased activation of AMPK and its downstream target, ACC. ACC generates malonyl-CoA (an allosteric inhibitor of CPT1), which decreases the entry of long-chain fatty acids into the mitochondria, resulting in their buildup in the cytoplasm.

Cytokines and Insulin Sensitivity. Adipose tissue is classically viewed as simply the site for storage of excess energy in the form of triglycerides. However, it is now clear that adipose tissue secretes a variety of endocrine and paracrine factors that have significant effects on metabolism.⁴⁰⁹ These adipokines regulate a diverse array of actions, including alterations in feeding behavior; changes in liver, muscle, and adipose tissue insulin sensitivity; vascular reactivity; and atherosclerosis progression.

Leptin. Leptin is a 16-kd protein synthesized mainly in adipose tissue that is mutated in *ob/ob* mice. Leptin suppresses feeding behavior, and humans with mutations in leptin are morbidly obese and insulin resistant. However, studies from a number of laboratories, using in vitro and in vivo models, indicate a direct role for leptin in lipid metabolism, including increased metabolic rate, lipolysis, stimulation of fatty acid oxidation, inhibition of lipogenesis, and increased AMPK activity.

Adiponectin. Adiponectin (also known as ACRP30, adipoQ, apM1, and GBP28) is a 30-kd protein that is synthesized and secreted from adipocytes and circulates as a trimer and in multimeric complexes (called the *HMW form*). The HMW form may be further cleaved to forms that may be the active transducer of signaling. The purported receptor for adiponectin is controversial, so its exact signaling mechanism remains uncertain. In the mouse, adiponectin can increase fatty acid oxidation, perhaps through the activation of AMPK.^{410,411} Disruption of adiponectin in mice predisposes them to high-fat diet-induced insulin resistance, although there is little alteration in mice consuming a normal diet.⁴¹² Adiponectin levels are low in humans with obesity and insulin resistance and are increased by insulin-sensitizing PPAR γ agonists.

Resistin. Resistin is a 12-kd protein that is synthesized and secreted from adipose tissue and is a member of the FIZZ family of proteins, which are C-terminal cysteine-rich

proteins.^{413,414} As with adiponectin, resistin circulates in both trimeric and hexameric forms, with the smaller form having greater activity.⁴¹⁹ Resistin levels are elevated in both diet-induced obesity and genetic mouse models of obesity and diabetes. Leptin causes hepatic insulin resistance, and disruption of resistin results in lowered ambient glucose levels. The role of resistin in human physiology remains uncertain.⁴¹⁵

Tumor Necrosis Factor- α . TNF- α is a 26-kd transmembrane protein that is cleaved and circulates in a 17-kd soluble form. It is elaborated by multiple tissues, including adipocytes, and its role in insulin resistance is unclear. It may work primarily as a paracrine effector to induce tissue insulin resistance.⁴¹⁶ Data suggest that much of TNF- α , along with other inflammatory cytokines associated with adipose tissue, is elaborated by resident macrophages as well as adipocytes.^{417,418} TNF- α has two main receptors, type 1 and type 2, that signal through the p44/42 and JNK pathway. Systemic effects on TNF- α include the induction of lipogenesis in the liver and insulin resistance in skeletal muscle.

Monocyte Chemotactic Protein 1. Monocyte chemotactic protein 1 (MCP1), also called C-C motif chemokine ligand 2 (CCL2), is increased in proportion to adipose tissue mass and correlates with insulin resistance.⁴¹⁹ CCL2 inhibits insulin action and adipocyte differentiation.⁴²⁰ The receptor for MCP1, C-C motif chemokine receptor 2 (CCR2), regulates monocyte and macrophage recruitment and is necessary for macrophage-dependent inflammatory responses. Disruption of CCR2 in mice reduced their food intake, attenuated the development of obesity on a high-fat diet, and attenuated the infiltration of macrophages into adipose tissue, further supporting the concept that adipose-resident macrophages are important for their systemic effect of adiposity.⁴²¹

Interleukin-6. IL-6 is a glycoprotein of 22 to 27 kd that circulates at relatively high concentrations. Circulating levels correlate with the degree of adiposity.⁴²² Humans receiving IL-6 infusions show increases in insulin resistance, hepatic glucose production, lipolysis, and fatty acid oxidation.⁴²³ About a third of circulating IL-6 is secreted by adipocytes; however, a significant amount is elaborated by skeletal muscle and is increased by exercise. The lipolytic effect of IL-6 might link exercise to the mobilization of fatty acids.¹⁷³

INSULIN SECRETION AND TYPE 2 DIABETES

Normal insulin secretory function is essential for maintaining normal glucose tolerance, and abnormal insulin secretion is invariably present in patients with T2DM. In this section, the physiology of normal insulin and the alterations that are present in persons with T2DM are reviewed.

Quantitation of Beta-Cell Function

The measurement of peripheral insulin concentrations by radioimmunoassay is still the most widely used method for quantifying beta-cell functions in vivo.⁴²⁴ Although this approach provides valuable information, it is limited because 50% to 60% of the insulin produced by the

pancreas is extracted by the liver without ever reaching the systemic circulation.^{425,426} The standard radioimmunoassay for measuring insulin concentrations is also unable to distinguish between endogenous and exogenous insulin, making it ineffective as a measure of endogenous beta-cell reserve in the insulin-treated diabetic patient. Anti-insulin antibodies that may be present in patients treated with insulin interfere with the insulin radioimmunoassay, making insulin measurements in insulin-treated patients inaccurate. Conventional insulin radioimmunoassays are also unable to distinguish between levels of circulating proinsulin and true levels of circulating insulin.

Insulin is derived from a single-chain precursor, proinsulin.⁴²⁷ Within the Golgi apparatus of the pancreatic beta cell, proinsulin is cleaved by convertases to form insulin, C peptide, and two pairs of basic amino acids. Insulin is subsequently released into the circulation at concentrations equimolar with those of C peptide.^{428,429} In addition, small amounts of intact proinsulin and proinsulin conversion intermediates are released. Proinsulin and its related conversion intermediates can be detected in the circulation, where they constitute 20% of the total circulating insulin-like immunoreactivity.⁴³⁰ In vivo, proinsulin has a biologic potency that is only about 10% of that of insulin,^{431,432} and the potency of split proinsulin intermediates is between that of proinsulin and that of insulin.^{433,434} C peptide has no known conclusive effects on carbohydrate metabolism,^{435,436} although certain physiologic effects of C peptide have been proposed.⁴³⁷ Unlike insulin, C peptide is not extracted by the liver^{428,438,439} and is excreted almost exclusively by the kidneys. Its plasma half-life of approximately 30 minutes⁴⁴⁰ contrasts sharply with that of insulin, which is approximately 4 minutes.

Because C peptide is secreted in equimolar concentrations with insulin and is not extracted by the liver, many investigators have used levels of C peptide as a marker of beta-cell function. The use of plasma C-peptide levels as an index of beta-cell function depends on the critical assumption that the mean clearance rate of C peptide is constant over the range of C-peptide levels observed under normal physiologic conditions. This assumption has been shown to be valid for both dogs and humans,^{426,441} and this approach can be used to derive rates of insulin secretion from plasma concentrations of C peptide under steady-state conditions.⁴⁴¹ However, because of the long plasma half-life of C peptide, under non-steady-state conditions (e.g., after a glucose infusion), peripheral plasma levels of C peptide do not change in proportion to the changing insulin secretion rate.^{441,442} Therefore, under such conditions, insulin secretion rates are best calculated with use of the two-compartment model initially proposed by Eaton and coworkers.⁴⁴³

Modifications to the C peptide model of insulin secretion have been introduced. They combine the minimal model of insulin action with the two-compartment model of C-peptide kinetics and allow insulin secretion and insulin sensitivity to be derived after intravenous or oral administration of glucose.⁴⁴⁴⁻⁴⁴⁷

Signaling Pathways in the Beta Cell and Insulin Secretion

The signaling pathways in the pancreatic beta cell are involved in the stimulus-secretion coupling of insulin release. These pathways provide the mechanism whereby insulin secretion rates respond to changes in blood glucose concentrations (Fig. 31-12). Glucose enters the pancreatic beta cell by a process of facilitated diffusion mediated by

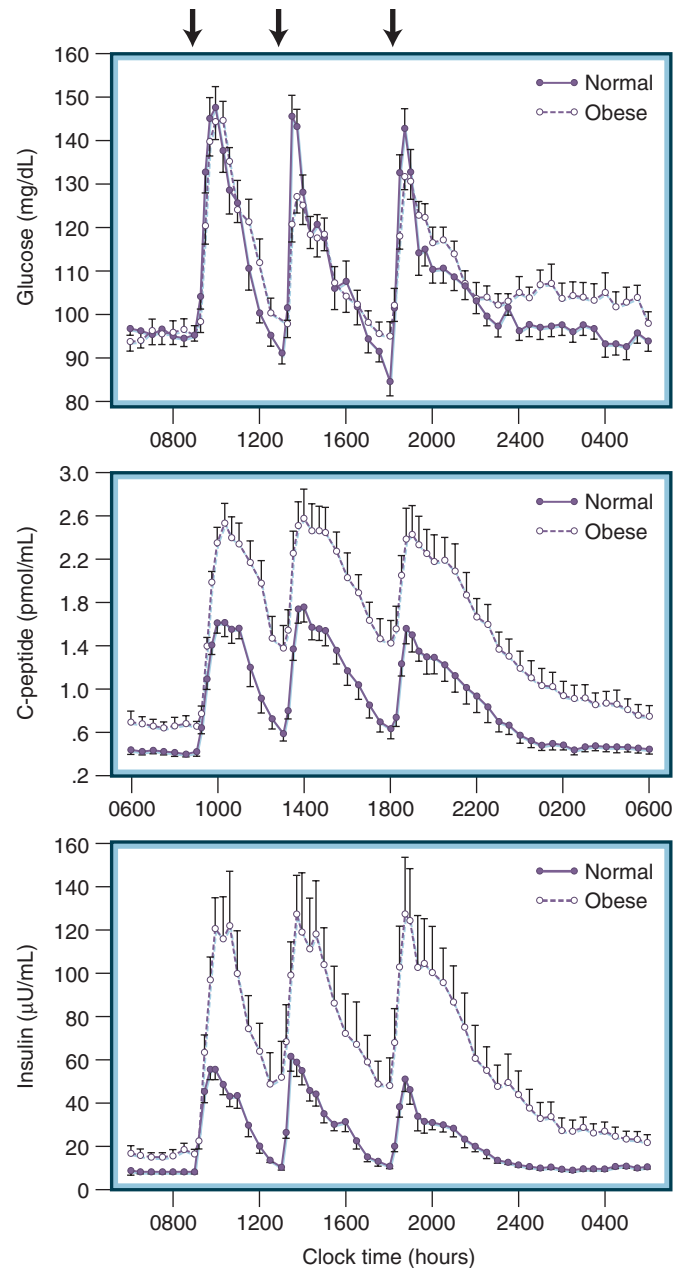

Figure 31-12 Mean 24-hour profiles of plasma concentrations of glucose (top panel), C peptide (middle panel), and insulin (bottom panel) in normal and obese subjects. The three arrows above the figure indicate the ingestion of the breakfast, lunch, and dinner meals, respectively. (From Polonsky KS, Given BD, van Cauter E. Twenty-four-hour profiles and pulsatile patterns of insulin secretion in normal and obese subjects. *J Clin Invest*. 1988;81:442-448.)

the glucose transporter GLUT2. Although levels of GLUT2 on the beta-cell membrane are reduced in diabetic states for various reasons, it is not currently believed that this is a rate-limiting step in the regulation of insulin secretion.

The first rate-limiting step in this process is the phosphorylation of glucose to glucose-6-phosphate. This reaction is mediated by the enzyme glucokinase.^{448,449} There is considerable evidence that glucokinase, by determining the rate of glycolysis, functions as the glucose sensor of the beta cell and that this is the primary mechanism by

which the rate of insulin secretion adapts to changes in blood glucose. According to this view, as blood glucose levels increase, more glucose enters the beta cell, the rate of glycolysis increases, and the rate of insulin secretion increases. A fall in blood glucose levels results in a fall in the rate of glycolysis and a reduction in the rate of insulin secretion.

Glucose metabolism produces an increase in cytosolic ATP, the key signal that initiates insulin secretion by causing blockade of the K_{ATP} channel on the beta-cell membrane. Blockade of this channel induces membrane depolarization, which leads to an increase in cytosolic Ca^{2+} and insulin secretion. The biochemical events that link the increase in glycolysis to an increase in ATP are complex. Dukes and coworkers⁴⁵⁰ proposed that glycolytic production of NADH during the oxidation of glyceraldehyde-3-phosphate is the key process because NADH is subsequently processed into ATP by mitochondria through the operation of specific shuttle systems.

The rate of pyruvate generation has also been proposed as an explanation for the link between glucose metabolism and increased insulin secretion.⁴⁵¹ According to this view, pyruvate generated by the glycolytic pathway enters the mitochondria and is metabolized further in the TCA cycle. Electron transfer from the TCA cycle to the respiratory chain by NADH and the reduced form of flavin adenine dinucleotide ($FADH_2$) promotes the generation of ATP, which is exported into the cytosol. The increase in ATP closes ATP-sensitive K^+ channels, which depolarizes the beta-cell membrane and opens the voltage-dependent Ca^{2+} channels, leading to an increase in intracellular Ca^{2+} . The increase in cytosolic Ca^{2+} is the main trigger for exocytosis, the process by which insulin-containing secretory granules fuse with the plasma membrane, leading to the release of insulin into the circulation. The increase in ATP not only closes K_{ATP} channels but also serves as a major permissive factor for movement of insulin granules and for priming of exocytosis.

Cyclic AMP also plays an important role in beta cell signal transduction pathways. This second messenger is generated at the plasma membrane from ATP and potentiates glucose-stimulated insulin secretion, particularly in response to glucagon, glucagon-like peptide 1 (GLP1), and gastric inhibitory polypeptide (also known as glucose-dependent insulinotropic peptide [GIP]). The cAMP-dependent pathways appear to be particularly important in the exocytotic machinery.

K_{ATP} channels play an essential role in beta cell stimulus-secretion coupling; an excellent review was published by Aguilar-Bryan and colleagues.⁴⁵² K_{ATP} channels include sulfonylurea receptors (SURs) and potassium inward rectifiers (KIR6.1 and KIR6.2), which assemble to form a large octameric channel with a (SUR/KIR6.x) stoichiometry. In the pancreatic beta cell, the SUR1/KIR6.2 pairs constitute the K_{ATP} channel. K_{ATP} channels control the flux of potassium ions driven by an electrochemical potential. Opening of these channels can set the resting membrane potential of beta cells below the threshold for activation of voltage-gated Ca^{2+} channels when plasma glucose levels are low, thus reducing insulin secretion. Changes in the cytosolic concentrations of ATP and adenosine diphosphate (ADP) lead to closure of the channels and depolarization of the beta-cell membrane. Mutations in both components of the beta-cell K_{ATP} (i.e., SUR1 and KIR6.2) have been shown to lead to hypersecretion of insulin, resulting clinically in either a recessive form of familial hyperinsulinemia or persistent hyperinsulinemic hypoglycemia of infancy.

Physiologic Factors Regulating Insulin Secretion

Carbohydrate Nutrients

The most important physiologic substance involved in the regulation of insulin release is glucose.⁴⁵³⁻⁴⁵⁵ The effect of glucose on the beta cell is dose related. Dose-dependent increases in concentrations of insulin and C peptide and in rates of insulin secretion have been observed after oral and intravenous glucose loads, with 1.4 units of insulin, on average, being secreted in response to an oral glucose load as small as 12 g.⁴⁵⁶⁻⁴⁵⁹ The insulin secretory response is greater after oral than after intravenous glucose administration.⁴⁶⁰⁻⁴⁶² Known as the *incretin effect*,^{458,463} this enhanced response to oral glucose has been interpreted as an indication that absorption of glucose by way of the gastrointestinal tract stimulates the release of hormones and other mechanisms that ultimately enhance the sensitivity of the beta cell to glucose (see later discussion). In a study involving nine normal volunteers, glucose was infused at a rate designed to achieve levels previously attained after an oral glucose load. The amount of insulin secreted in response to the intravenous load was 26% less than that secreted in response to the oral load.⁴⁶²

Insulin secretion does not respond as a linear function of glucose concentration. The relationship of glucose concentration to the rate of insulin release follows a sigmoidal curve. The threshold corresponds to the glucose levels normally seen under fasting conditions, and the steep portion of the dose-response curve corresponds to the range of glucose levels normally achieved postprandially.⁴⁶⁴⁻⁴⁶⁶ The sigmoidal nature of the dose-response curve has been attributed to a gaussian distribution of thresholds for stimulation among the individual beta cells.⁴⁶⁶⁻⁴⁶⁸

When glucose is infused intravenously at a constant rate, an initial biphasic secretory response is observed that consists of a rapid, early insulin peak followed by a second, more slowly rising peak.^{453,459,460} The significance of the first-phase insulin release is unclear, but it might reflect the existence of a compartment of readily releasable insulin within the beta cell or a transient rise and fall of a metabolic signal for insulin secretion.⁴⁷¹ Despite early suggestions to the contrary,^{472,473} it has been demonstrated that the first-phase response to intravenous glucose is highly reproducible within subjects.⁴⁷⁴ After the acute response, a second phase of insulin release occurs that is directly related to the level of glucose elevation. In vitro studies of isolated islet cells and perfused pancreas have identified a third phase of insulin secretion that commences 1.5 to 3.0 hours after exposure to glucose and is characterized by a spontaneous decline in secretion to 15% to 25% of the amount released during peak secretion. This low level is subsequently maintained for longer than 48 hours.⁴⁷⁵⁻⁴⁷⁸

In addition to its acute secretagogue effects on insulin secretion, glucose has intermediate- and longer-term effects that are physiologically and clinically relevant. In the intermediate term, exposure of the pancreatic beta cell to a high concentration of glucose primes its response to a subsequent glucose stimulus, leading to a shift to the left in the dose-response curve relating glucose and insulin secretion.^{479,480} However, when pancreatic islets are exposed to high concentrations for prolonged periods, a reduction of insulin secretion is seen. Although all of the precise mechanisms responsible for these adverse effects, termed *glucotoxicity*, are not known, there is evidence that long-term exposure to high glucose reduces the expression of a

number of genes that are critical to normal beta-cell function, including the insulin gene.^{481,482}

Noncarbohydrate Nutrients

Amino acids have been shown to stimulate insulin release in the absence of glucose, the most potent secretagogues being the essential amino acids leucine, arginine, and lysine.^{483,484} The effects of arginine and lysine on the beta cell appear to be more potent than that of leucine. The effects of amino acids on insulin secretion are potentiated by glucose.^{485,486}

In contrast to amino acids, various lipids and their metabolites appear to have only minor effects on insulin release *in vivo*. Although carbohydrate-rich fat meals stimulate insulin secretion, carbohydrate-free fat meals have minimal effects on beta cell function.⁴⁸⁷ Ketone bodies and short- and long-chain fatty acids have been shown to stimulate insulin secretion acutely in islet cells and in human subjects.⁴⁸⁸⁻⁴⁹² The effects of elevated FFAs on the insulin secretory responses to glucose are related to the duration of the exposure. Zhou and Grill⁴⁹³ first suggested that long-term exposure of pancreatic islets to FFAs inhibited glucose-induced insulin secretion and biosynthesis. This observation was confirmed in rats.⁴⁹⁴ In humans, it was demonstrated that the insulin resistance induced by an acute (90-minute) elevation in FFAs was compensated by an appropriate increase in insulin secretion.⁴⁹⁵ After chronic elevation of FFAs (48 hours), the beta cell compensatory response for insulin resistance was not adequate. Additional studies demonstrated that the adverse effects of prolonged FFAs on glucose-induced insulin secretion are not seen in subjects with T2DM. From these results, it appears that elevated FFAs might contribute to the failure of beta-cell compensation for insulin resistance.

Hormonal Factors

The release of insulin from the beta cell after a meal is facilitated by a number of gastrointestinal peptide hormones, including GIP, cholecystokinin, and GLP1.^{463,496-503} These hormones are released from small-intestinal endocrine cells postprandially and travel in the bloodstream to reach the beta cells, where they act through second messengers to increase the sensitivity of these islet cells to glucose. In general, these hormones are not themselves secretagogues, and their effects are evident only in the presence of hyperglycemia.⁴⁹⁶⁻⁴⁹⁸ The release of these peptides might explain why the modest postprandial glucose levels achieved in normal subjects *in vivo* have such a dramatic effect on insulin production, whereas similar glucose concentrations *in vitro* elicit a much smaller response.⁵⁰³ Similarly, this incretin effect could account for the greater beta-cell response observed after oral as opposed to intravenous glucose administration.

Whether impaired postprandial secretion of incretin hormones plays a role in the inadequate insulin secretory response to oral glucose and to meals in patients with IGT or diabetes is controversial,⁵⁰⁴⁻⁵¹¹ but pharmacologic doses of these peptides might have future therapeutic benefit. Subcutaneous administration of GLP1, the most potent of the incretin peptides, lowers glucose in patients with T2DM by stimulating endogenous insulin secretion and perhaps by inhibiting glucagon secretion and gastric emptying.^{512,513} However, because of the short half-life of GLP1, its longer-acting analog, exendin-4, has greater therapeutic promise.⁵¹⁴ Treatment with supraphysiologic doses of GIP during hyperglycemia has been shown to augment insulin secretion in normal humans^{515,516} but not in diabetics.^{507,516} Although cholecystokinin has the ability to augment

insulin secretion in humans, it is not firmly established whether it is an incretin at physiologic levels.⁵¹⁷⁻⁵²⁰ Its effects are also seen largely at pharmacologic doses.⁵²¹

The postprandial insulin secretory response may also be influenced by other intestinal peptide hormones, including vasoactive intestinal polypeptide,⁵²² secretin,⁵²³⁻⁵²⁶ and gastrin,^{523,527} but the precise roles of these hormones remain to be elucidated.

The hormones produced by pancreatic alpha and beta cells also modulate insulin release. Whereas glucagon has a stimulatory effect on the beta cell,⁵²⁸ somatostatin suppresses insulin release.⁵²⁹ It is currently unclear whether these hormones reach the beta cell by traveling through the islet cell interstitium (thus exerting a paracrine effect) or through islet cell capillaries. Indeed, the importance of these two hormones in regulating basal and postprandial insulin levels under normal physiologic circumstances is in doubt. Paradoxically, the low insulin levels observed during prolonged periods of starvation have been attributed to the elevated glucagon concentrations seen in this setting.^{487,530-533} Other hormones that exert a stimulatory effect on insulin secretion include growth hormone,⁵³⁴ glucocorticoids,⁵³⁵ prolactin,⁵³⁶⁻⁵³⁸ placental lactogen,⁵³⁹ and the sex steroids.⁵⁴⁰

Whereas all of the preceding hormones might stimulate insulin secretion indirectly by inducing a state of insulin resistance, some might also act directly on the beta cell, possibly to augment its sensitivity to glucose. Hyperinsulinemia is associated with conditions in which these hormones are present in excess, such as acromegaly, Cushing's syndrome, and the second half of pregnancy. Furthermore, treatments with placental lactogen,⁵⁴¹ hydrocortisone,⁵⁴² and growth hormone^{542,543} are all effective in reversing the reduction in insulin response to glucose that is observed *in vitro* after hypophysectomy. Although hyperinsulinemia after an oral glucose load has been observed in patients with hyperthyroidism,^{544,545} the increased concentration of immunoreactive insulin in this setting may reflect elevations in serum proinsulin rather than a true increase in serum insulin.⁵⁴⁶

Neural Factors

The islets are innervated by the cholinergic and adrenergic limbs of the autonomic nervous system. Although both sympathetic stimulation and parasympathetic stimulation enhance secretion of glucagon,^{547,548} the secretion of insulin is stimulated by vagal nerve fibers and inhibited by sympathetic nerve fibers.⁵⁴⁷⁻⁵⁵² Adrenergic inhibition of the beta cell appears to be mediated by the α -adrenoceptor, because its effect is attenuated by the α -antagonist phentolamine⁵⁴⁸ and reproduced by the α_2 -agonist clonidine.⁵⁵³ There is also considerable evidence that many indirect effects of sympathetic nerve stimulation play a role in regulating beta-cell function through stimulation or inhibition of somatostatin, β_2 -adrenoceptors, and the neuropeptides galanin and neuropeptide Y.⁵⁵⁴

Parasympathetic stimulation of islets results in stimulation of insulin, glucagon, and pancreatic polypeptide directly and through the neuropeptides vasoactive intestinal polypeptide, gastrin-releasing polypeptide, and pituitary adenylate cyclase-activating polypeptide.⁵⁵⁴ In addition, sensory innervation of islets may play a role in tonic inhibition of insulin secretion through the neuropeptides calcitonin gene-related peptide⁵⁵⁵⁻⁵⁵⁷ and, less clearly, substance P.^{558,559}

The importance of the autonomic nervous system in regulating insulin secretion *in vivo* is unclear. The neural effects on beta-cell function cannot be entirely dissociated

from the hormonal effects because some of the neurotransmitters of the autonomic nervous system are, in fact, hormones. Furthermore, the secretion of insulinotropic hormones such as GIP and GLP1 postprandially has been shown to be under vagal^{560,561} and adrenergic^{562,563} control.

Temporal Pattern of Insulin Secretion

It has been estimated that 50% of the total insulin secreted by the pancreas in any 24-hour period is secreted under basal conditions, and the remainder is secreted in response to meals.^{564,565} The estimated basal insulin secretion rates range from 18 to 32 units (0.7 to 1.3 mg) per 24 hours.^{441,443,456,564} After meal ingestion, the insulin secretory response is rapid, and insulin secretion increases approximately fivefold over baseline to reach a peak within 60 minutes (Fig. 31-13; see Fig. 31-12). When study subjects consumed 20% of calories with breakfast and 40% with lunch and dinner, the amount of insulin secreted after each meal did not differ significantly. There was a rapid insulin secretory response to breakfast, with $71.6\% \pm 1.6\%$ of the insulin secreted in the 4 hours after the meal being produced in the first 2 hours and the remainder in the next 2 hours. Insulin secretion did not decrease as rapidly after lunch and dinner, with, respectively, $62.8\% \pm 1.6\%$ and $59.6\% \pm 1.4\%$ of the total meal response secreted during the first 2 hours after the meal.

The normal insulin secretory profile is characterized by a series of insulin secretory pulses. After breakfast, 1.8 ± 0.2 secretory pulses were identified in normal volunteers, and the peaks of these pulses occurred 42.8 ± 3.4 minutes after the meal. Multiple insulin secretory pulses were also identified after lunch and dinner. After these meals, up to four pulses of insulin secretion were identified in both groups of subjects. In the 5-hour time interval between lunch and dinner, an average of 2.5 ± 0.3 secretory pulses were identified, and 2.6 ± 0.2 were identified in the same period after dinner.⁵⁶⁵

Pulses of insulin secretion that did not appear to be meal related were also identified. Between 11:00 p.m. and 6:00 a.m. and in the 3 hours before breakfast, on average 3.9 ± 0.3 secretory pulses were present in normal subjects. Therefore, over the 24-hour period of observation, a total of 11.1 ± 0.5 pulses were identified in normal subjects. Almost 90% ($87\% \pm 3\%$) of postmeal pulses in insulin secretion, but only $47\% \pm 8\%$ of non-meal-related pulses, were concomitant with a pulse in glucose.⁵⁶⁵

In vivo studies of beta-cell secretory function have demonstrated that insulin is released in a pulsatile manner. This behavior is characterized by rapid oscillations occurring every 8 to 15 minutes that are superimposed on slower (ultradian) oscillations occurring at a periodicity of 80 to 150 minutes.⁵⁶⁶ The rapid oscillations persist in vitro and therefore are likely to be the result of metabolic pathways in the pancreatic beta cell that involve negative feedback loops with time lags.

Rapid Oscillations

The rapid oscillations of insulin are of small amplitude in the systemic circulation, averaging between 0.4 and 3.2 $\mu\text{U/mL}$ in several published human studies.⁵⁶⁷⁻⁵⁶⁹ Because these values are close to the limits of sensitivity of most standard insulin radioimmunoassays, the characterization of these oscillations is subject to considerable pitfalls,⁵⁷⁰ not the least of which is the need to differentiate between true oscillations of small amplitude and random assay noise. The latter problem has been overcome by the development of extremely sensitive enzyme-linked immunosorbent

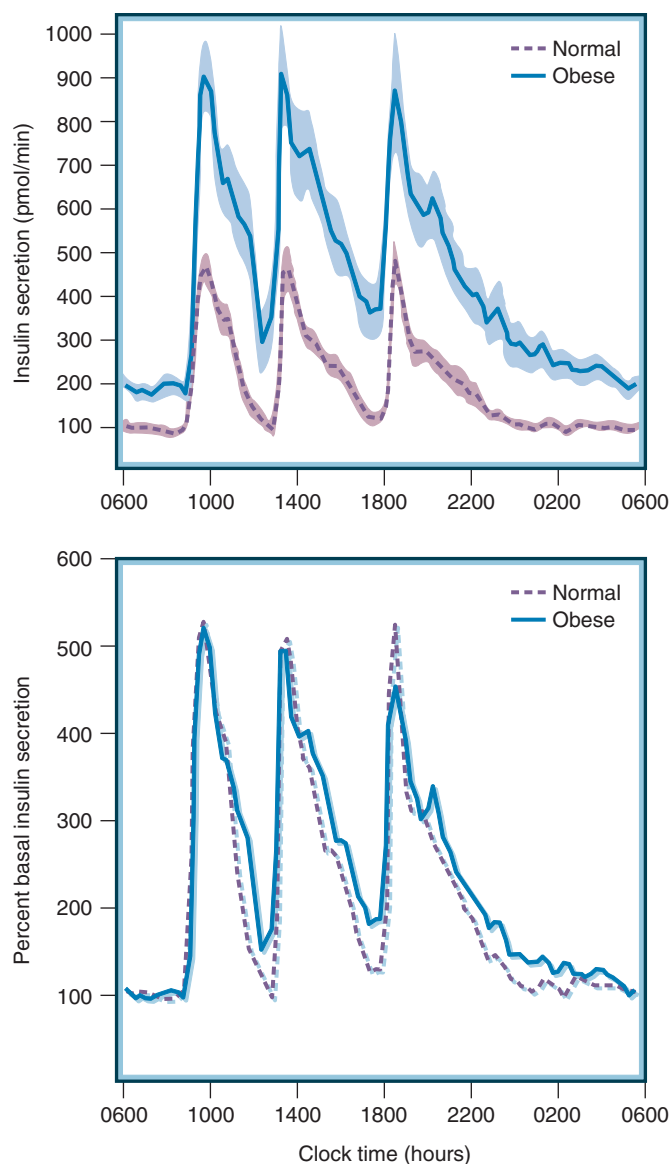

Figure 31-13 Mean 24-hour profiles of insulin secretion rates in normal and obese subjects (top). The hatched areas represent ± 1 standard error of the mean. The curves in the lower panel were derived by dividing the insulin secretion rate measured in each subject by the basal secretion rate derived in the same subject. Mean data for normal (dashed line) and obese (solid line) subjects are shown. (From Polonsky KS, Given BD, van Cauter E. Twenty-four-hour profiles and pulsatile patterns of insulin secretion in normal and obese subjects. *J Clin Invest*. 1988;81:442-448.)

assays (ELISAs) that allow the detection of extremely small changes in peripheral insulin concentrations. The application of these assays in studies involving frequent sampling from the peripheral circulation has led to a series of studies of the role of these oscillations in the overall regulation of insulin secretion.⁵⁷¹⁻⁵⁷⁵

These investigations suggested that the increases in overall insulin secretion seen in response to a variety of secretagogues in various physiologic and pathophysiologic states result from an increase in the amplitude of the bursts of insulin secretion. The researchers have proposed that 75% of insulin secretion is accounted for by secretory bursts and that the responses to GLP1, sulfonylureas, and oral glucose are all mediated by an increase in the amplitude of insulin secretory pulses. Furthermore, consistent

with observations made by O'Rahilly and colleagues,⁵⁷⁶ relatives of patients with T2DM demonstrate a disorderly profile of the insulin secretory oscillations. A number of mathematical programs have been developed that allow these insulin secretory oscillations to be evaluated and studied.⁵⁷⁷ The latest additions to the list are so-called approximate entropy (*ApEn*) and cross-approximate entropy (*cross-ApEn*), which are statistics that measure temporal regularity of the oscillations in the insulin secretory profile.⁵⁷⁸

The low amplitude of the rapid oscillations in the systemic circulation contrasts sharply with observations in the portal vein, where pulse amplitudes of 20 to 40 $\mu\text{U/mL}$ have been recorded in dogs.⁵⁷⁹ Although the physiologic importance of these low-amplitude rapid pulses in the periphery is unclear, they are likely to be of physiologic importance in the portal vein. It is possible that the liver responds more readily to insulin delivered in a pulsatile fashion than to insulin delivered at a constant rate.⁵⁸⁰⁻⁵⁸²

Ultradian Oscillations

In contrast to the rapid oscillations, the slower (ultradian) oscillations are of much larger amplitude in the peripheral circulation. They are present under basal conditions but are amplified postprandially (Fig. 31-14), and they have been observed in subjects receiving intravenous glucose, suggesting that they are not generated by intermittent absorption of nutrients from the gut. Furthermore, they do not appear to be related to fluctuations in glucagon or cortisol levels,⁴⁷⁵ and they are not regulated by neural factors,

because these oscillations are also present in recipients of successful pancreas transplants.^{583,584} Many of these ultradian insulin and C-peptide pulses are synchronous with pulses of similar oscillatory periods in glucose, raising the possibility that these oscillations are a product of the insulin-glucose feedback mechanism. Ultradian oscillations are self-sustained during constant glucose infusion at various rates; they are increased in amplitude after stimulation of insulin secretion without change in frequency, and there is a slight temporal advance of the glucose versus the insulin oscillation.

These findings suggest that the ultradian oscillations may be entirely accounted for by the major dynamic characteristics of the insulin-glucose feedback system, with no need to postulate the existence of an intrapancreatic pacemaker.⁵⁸⁵ In support of this hypothesis, Sturis and colleagues⁵⁸⁶ demonstrated that when glucose is administered in an oscillatory pattern, ultradian oscillations in plasma glucose and insulin secretion are generated that are 100% concordant with the oscillatory period of the exogenous glucose infusion. This close relationship between the ultradian oscillations in insulin secretion and similar oscillations in plasma glucose was further exemplified in a series of dose-response studies in which the largest-amplitude oscillations in insulin secretion were observed in those subjects exhibiting the largest-amplitude glucose oscillations, which in turn were directly related to the infusion dose of glucose. It has been shown that, in normal humans, insulin is more effective in reducing plasma glucose levels when it is administered intravenously as a 120-minute oscillation than when it is delivered at a constant rate. These results indicate that the ultradian oscillations have functional significance.⁵⁸⁶

Circadian Oscillations

Circadian variations in the secretion of insulin have also been reported. When insulin secretory responses were measured for a 24-hour period during which subjects received three standard meals, the maximal postprandial responses were observed after breakfast.^{565,567} These findings were mirrored by the results of studies in which subjects were tested for oral glucose tolerance at different times of the day and were found to exhibit maximal insulin secretory responses in the morning and lower responses in the afternoon and evening.⁵⁸⁷⁻⁵⁸⁹ These diurnal differences were also noted in tests for intravenous glucose tolerance. Furthermore, although ultradian glucose and insulin oscillations are closely correlated during a constant 24-hour glucose infusion, the nocturnal rise in mean glucose levels is not accompanied by a similar increase in the insulin secretory rate.⁵⁹⁰ It has been postulated that these diurnal differences reflect diminished responsiveness of the beta cell to glucose in the afternoon and evening.⁵⁸⁹

Insulin Secretion in Obesity and Insulin Resistance

Obesity and other insulin-resistant states are associated with a substantially greater risk of developing T2DM. The ability of the pancreatic beta cell to compensate for insulin resistance determines whether blood glucose levels remain normal in insulin-resistant subjects or whether the subjects develop IGT or diabetes.

The nature of the beta cell's compensation for insulin resistance involves hypersecretion of insulin even in the presence of normal glucose concentrations. This can occur only if beta-cell sensitivity to glucose is increased. The increase in beta-cell sensitivity to glucose in obesity appears

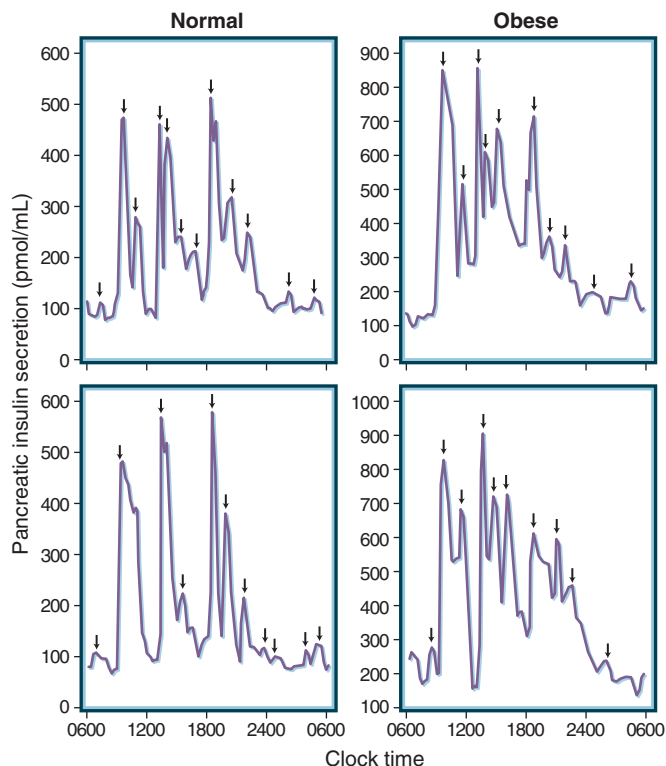

Figure 31-14 Patterns of insulin secretion in normal and obese subjects. Four representative 24-hour profiles are shown from two normal-weight subjects (left) and two obese subjects (right). Meals were consumed at 0900, 1300, and 1800 hours. Statistically significant pulses of secretion are shown by the arrows. (From Polonsky KS, Given BD, van Cauter E. Twenty-four-hour profiles and pulsatile patterns of insulin secretion in normal and obese subjects. *J Clin Invest.* 1988;81:442-448.)

to be mediated by two factors. First, increased beta-cell mass is observed in obesity and other insulin-resistant states.⁵⁹¹ Second, insulin resistance appears to be associated with increased expression of hexokinase in the beta cell relative to the expression of glucokinase.⁵⁹² Because hexokinase has a significantly lower Michaelis constant (K_m) for glucose than glucokinase does, the functional effect of increased hexokinase expression is to shift the glucose-insulin secretion dose-response curve to the left, leading to increased insulin secretion across a wide range of glucose concentrations.

Assessment of the adequacy of the beta-cell compensation for insulin resistance is important because this is the major determinant of the development of diabetes. In insulin-resistant states, it is important to evaluate beta-cell function in relation to the degree of insulin resistance. Kahn and coworkers⁵⁹³ studied the relationship between insulin sensitivity and beta-cell function in 93 relatively young, apparently healthy human subjects with varying degrees of obesity. A sensitivity index (SI) was calculated using the minimal model of Bergman as a measure of insulin sensitivity and was then compared with various measures of insulin secretion.^{446,594} The relationship between the SI and the beta-cell measures was curvilinear and reciprocal for fasting insulin concentration ($P < .0001$), first-phase (acute) insulin response (AIR glucose; $P < .0001$), glucose potentiation slope ($n = 56$; $P < .005$), and beta-cell secretory capacity (AIR_{max}; $n = 43$; $P < .0001$). The curvilinear relationship between SI and the beta-cell measures could not be distinguished from a hyperbola (i.e., $SI \times \text{beta cell function} = \text{a constant}$). The nature of this relationship is consistent with a regulated feedback loop control system such that, for any difference in SI, a proportionate reciprocal difference occurs in insulin levels and responses in subjects with similar carbohydrate tolerance. Therefore, in human subjects with normal glucose tolerance and varying degrees of obesity, beta-cell function varies quantitatively with differences in insulin sensitivity. The increase in insulin secretion that is observed with a fall in SI should be viewed as the beta-cell compensation that allows normal glucose tolerance to be maintained in the presence of insulin resistance.

The insulin resistance of obesity is characterized by hyperinsulinemia. Hyperinsulinemia in this setting reflects

a combination of increased insulin production and decreased insulin clearance, but most evidence suggests that increased insulin secretion is the predominant factor.^{595,596} Both basal and 24-hour insulin secretory rates are three to four times higher in obese subjects and are strongly correlated with BMI. Insulin secretory responses to intravenous glucose have been studied in otherwise healthy insulin-resistant subjects and compared with the responses in insulin-sensitive subjects by means of a graded glucose infusion.

Figure 31-15 depicts insulin concentrations and insulin secretion rates at each level of plasma glucose achieved, outlining the respective dose-response relationships. Both insulin concentrations and insulin secretion rates are increased in insulin-resistant subjects due to a combination of increased insulin secretion and decreased insulin clearance. For each level of glucose, insulin secretion rates are higher in insulin-resistant than in insulin-sensitive subjects, reflecting an adaptive response of the beta cell to peripheral insulin resistance. Similar compensatory hyperinsulinemia has been demonstrated using other clinical techniques, such as the frequently sampled intravenous glucose tolerance test, in obese patients and in those with other insulin-resistant states, such as late pregnancy.^{593,597}

The temporal pattern of insulin secretion is unaltered in obese subjects compared with normal subjects. Basal insulin secretion in obese subjects accounts for 50% of the total daily production of insulin, and secretory pulses of insulin occur every 1.5 to 2 hours.^{567,595} However, the amplitude of these pulses postprandially is greater in obese subjects. Nevertheless, when these postprandial secretory responses are expressed as a percentage of the basal secretory rate, the postprandial responses in obese and normal subjects are identical.

Insulin Secretion in Subjects with Impaired Glucose Tolerance

It has been suggested that insulin secretion may be normal in subjects with IGT. However, substantial defects in insulin secretion have been demonstrated in people who have normal FPG and normal HbA_{1c} concentrations, with glucose values greater than 140 mg/dL (7.8 mmol/L) 2 hours after oral ingestion of 75 g of glucose. Therefore,

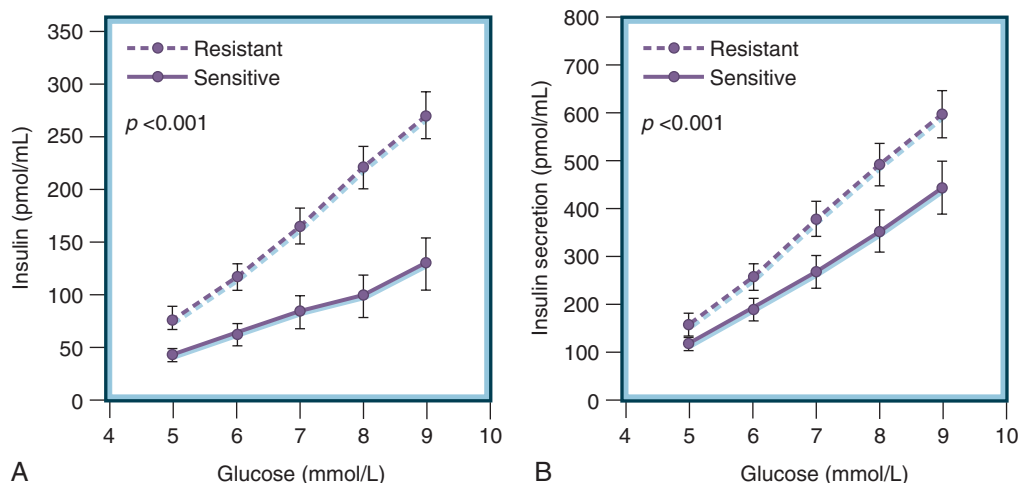

Figure 31-15 Plasma insulin concentrations (A) and insulin secretion rates (B) in response to molar increments in the plasma glucose concentration during a graded glucose infusion in insulin-resistant (dotted line) and insulin-sensitive (solid line) groups. (From Jones CNO, Pei D, Staris P, et al. Alterations in the glucose-stimulated insulin secretory dose-response curve and in insulin clearance in nondiabetic insulin-resistant individuals. *J Clin Endocrinol Metab.* 1997;82:1834-1838.)

Figure 31-16 Dose-response relationship between glucose and insulin secretory rate (ISR) after an overnight fast in control subjects (CON), non-moglycemic subjects with a family history of non-insulin-dependent diabetes mellitus (FDR), subjects with a nondiagnostic oral glucose tolerance test (NDX), subjects with impaired glucose tolerance (IGT), and subjects with non-insulin-dependent diabetes mellitus (NIDDM). BMI, body mass index. (From Byrne MM, Sturis J, Sobel RJ, et al. Elevated plasma glucose 2 h postchallenge predicts defects in beta-cell function. *Am J Physiol.* 1996;270:E572-E579. Copyright 1996, the American Physiological Society.)

defects in insulin secretion can be detected before the onset of overt hyperglycemia.

Detailed study of insulin secretion in patients with IGT has demonstrated consistent quantitative and qualitative defects in this group. During OGTT, there is a delay in the peak insulin response.^{79,598,599} The glucose-insulin secretion dose-response relationship is flattened and shifted to the right (Fig. 31-16), and first-phase insulin responses to an intravenous glucose bolus are consistently decreased in relation to ambient insulin sensitivity.^{600,601}

The temporal pattern of insulin secretory responses is altered in IGT and is similar to but not as pronounced as that seen in diabetic subjects (see later discussion). There is a loss of coordinated insulin secretory responses during oscillatory glucose infusion, indicating that the ability of the beta cell to sense and respond appropriately to parallel changes in the plasma glucose level is impaired (Fig. 31-17). Abnormalities in rapid oscillations of insulin secretion have also been observed in first-degree relatives of patients with T2DM who have only mild IGT,⁵⁷⁶ further suggesting that abnormalities in the temporal pattern of beta-cell function may be an early manifestation of beta-cell dysfunction preceding the development of T2DM.

Because an elevation in serum proinsulin is seen in subjects with diabetes, the contribution of proinsulin to the hyperinsulinemia of IGT has been questioned. The hyperinsulinemia of IGT has not been accounted for by an increase in proinsulin, although elevations in fasting and stimulated proinsulin levels or proinsulin-to-insulin ratios have been found by many (although not all) investigators.⁶⁰²⁻⁶⁰⁷ Correlation of elevated proinsulin levels in IGT as a predictor of future conversion to diabetes has also been observed.⁶⁰⁸⁻⁶¹⁰

Insulin Secretion in Type 2 Diabetes Mellitus

Because of the presence of concomitant insulin resistance, patients with T2DM are often hyperinsulinemic, but the degree of hyperinsulinemia is inappropriately low for the prevailing glucose concentrations. Nevertheless, many of these patients have sufficient beta-cell reserve to maintain a euglycemic state by diet restriction with or without an

oral agent. The beta-cell defect in patients with T2DM is characterized by an absent first-phase insulin and C-peptide response to an intravenous glucose load and a reduced second-phase response.⁶¹¹ Although hyperglycemia can play a role in mediating these changes, the abnormal first-phase response to intravenous glucose persists in patients whose diabetic control has been greatly improved,^{612,613} consistent with the idea that patients with T2DM have an intrinsic defect in the beta cell.

Furthermore, abnormalities in first-phase insulin secretion were observed in first-degree relatives of patients with T2DM who exhibited only mild IGT,⁶¹⁴ and an attenuated

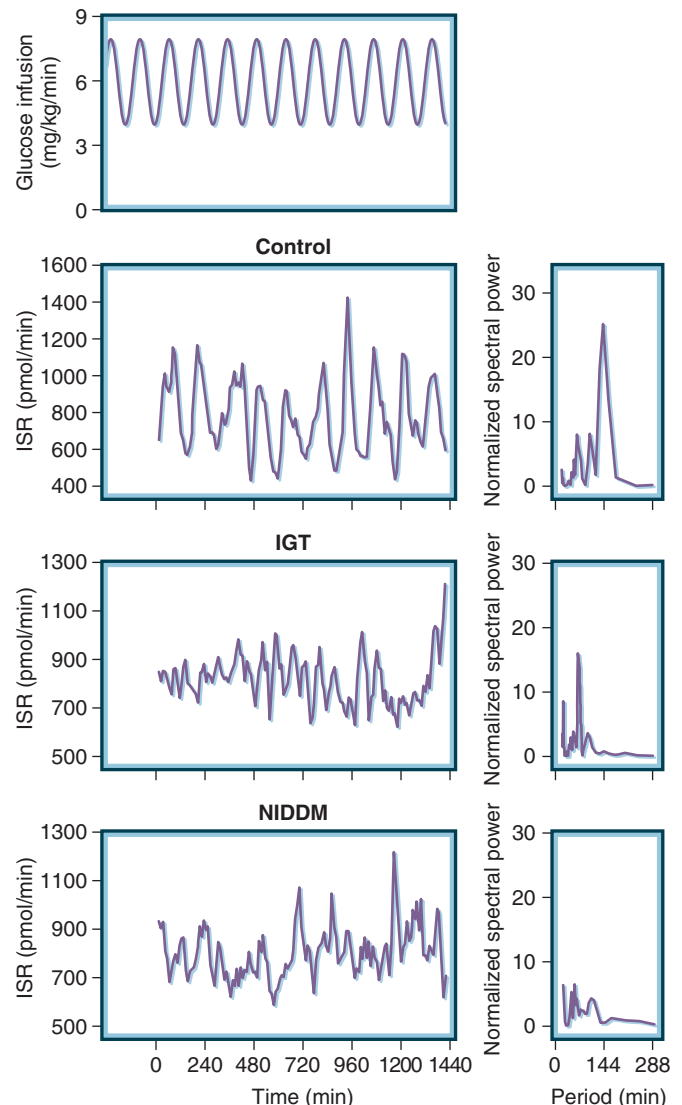

Figure 31-17 Oscillatory glucose infusions (top panel) were administered with a periodicity of 144 minutes to representative subjects with normal glucose tolerance (Control), impaired glucose tolerance (IGT), or type 2 diabetes (NIDDM). In the control subject, the insulin secretion rate (ISR) adjusts and responds to the 144-minute oscillations in glucose, resulting in sharp spectral peak at 144 minutes. In the other subjects, the ISR does not respond to the oscillatory glucose stimulus. Although oscillations in insulin secretion are evident, they are irregular, resulting in markedly reduced spectral peaks at 144 minutes and small-amplitude, high-frequency spectral peaks. These results are shown in the curves of normalized spectral power (right column) for each subject. (Adapted from O'Meara NM, Sturis J, Van Cauter E, et al. Lack of control by glucose of ultradian insulin secretory oscillations in impaired glucose tolerance and in non-insulin-dependent diabetes mellitus. *J Clin Invest.* 1993;92:262-271.)

insulin response to oral glucose was observed in normoglycemic twins of patients with T2DM,⁶¹⁵ a group at high risk for T2DM and who can legitimately be classified as prediabetic.⁶¹⁶ This pattern of insulin secretion during the prediabetic phase was also seen in subjects with IGT who later developed T2DM^{488,617,618} and in normoglycemic obese subjects with a recent history of gestational diabetes,⁶¹⁹ another group at high risk for T2DM.⁶²⁰ Beta-cell abnormalities can therefore precede the development of overt T2DM by many years.

T2DM also affects proinsulin levels in serum. Increased levels of proinsulin are consistently seen in association with increases in the proinsulin-to-insulin molar ratio.⁶¹¹ The amount of proinsulin produced in this setting appears to be related to the degree of glycemic control rather than the duration of the diabetic state, and in one series proinsulin levels contributed almost 50% of the total insulin immunoreactivity in T2DM patients who had marked hyperglycemia. In addition to intact proinsulin, the beta cell secretes one or more of the four major proinsulin conversion products (split 32,33-proinsulin, split 65,66-proinsulin, des-31,32-proinsulin, and des-64,65-proinsulin) into the circulation. These conversion products are produced within the secretory granules of the islet as a result of the activity of specific conversion enzymes at the two cleavage sites in proinsulin that link the C peptide to the A and B chains.⁶⁰²⁻⁶⁰⁹

The composition of the elevated proinsulin-like immunodeficiency in patients with T2DM compared with control subjects has not been fully characterized. Hales and colleagues⁶²¹ developed immunoradiometric assays for this purpose. In studies using these assays, split 32,33-proinsulin was reported to be the predominant proinsulin conversion product in the circulation, although des-31,32-proinsulin levels can also be elevated. Insulin, proinsulin, and conversion product concentrations were also measured with these assays 30 minutes after oral glucose administration in patients with T2DM. Insulin was reduced in all patients, with no overlap between patients and controls, and concentrations of proinsulin and conversion products were elevated in the diabetic patients. These data highlight the importance of the potentially confounding effects of proinsulin and proinsulin conversion products in the interpretation of circulating immunoreactive insulin in patients with T2DM and emphasize the need to measure the concentrations of the individual peptides.

Abnormalities in the temporal pattern of insulin secretion have also been demonstrated in patients with T2DM. In contrast to normal subjects, in whom equal amounts of insulin are secreted basally and postprandially in a given 24-hour period, patients with T2DM secrete a greater proportion of their daily insulin under basal conditions (Fig. 31-18).⁶²² This reduction in the proportion of insulin secreted postprandially appears to be related in part to a reduction in the amplitude of the secretory pulses of insulin occurring after meals, rather than to a reduction in the number of pulses. In contrast to normal subjects, patients with T2DM have ultradian oscillations in insulin secretion that are less tightly coupled with oscillations in plasma glucose (Fig. 31-19). Similar findings were observed in patients with IGT studied under the same experimental conditions and in a further group of T2DM patients studied under fasting conditions. The rapid insulin pulses are also abnormal in patients with T2DM. The persistent regular rapid oscillations present in normal subjects are not observed. Instead, the cycles are shorter and irregular. Similar findings were observed in a group of first-degree relatives of patients with T2DM who

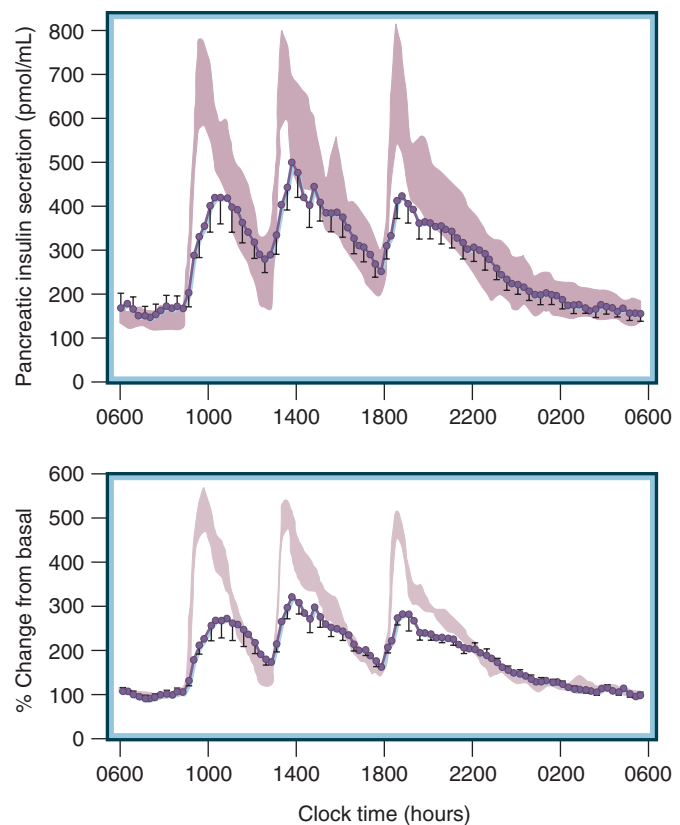

Figure 31-18 Mean rates of insulin secretion in type 2 diabetic patients compared with control subjects (*top panel*). Vertical bars indicate standard error of the mean (SEM). The shaded area corresponds to 1 SEM above and below the mean in control subjects. The curves indicating percent change from basal secretion (*lower panel*) were derived by dividing, for each subject, the insulin secretion rate at each sampling time by the average fasting secretion rate measured between 6 a.m. and 9 a.m. in the same subject. (From Polonsky KS, Given BD, Hirsch LJ et al. Abnormal patterns of insulin secretion in non-dependent diabetes mellitus. *N Engl J Med*. 1988;318:1231-1239.)

had only mild IGT, suggesting that abnormalities in oscillatory activity may be an early manifestation of beta-cell dysfunction.⁶⁰⁰

The effects of therapy on beta-cell function in patients with T2DM have also been investigated. Although interpretation of the results in many instances is limited because beta-cell function was not always studied at comparable levels of glucose before and during therapy, the majority of the studies indicated that improvements in diabetic control are associated with an enhancement of beta-cell secretory activity. This increased endogenous production of insulin appears to be independent of the mode of treatment and is in particular associated with increases in the amount of insulin secreted postprandially.^{613,623} The enhanced beta-cell secretory activity after meals reflects an increase in the amplitude of existing secretory pulses rather than an increased number of pulses. Despite improvements in glycemic control, beta-cell function is not normalized after therapy, suggesting that the intrinsic defect in the beta cell persists.

Treatment with the sulfonylurea glyburide increases the amount of insulin secreted in response to meals but does not correct the underlying abnormalities in the pattern of insulin secretion. In particular, the abnormalities in the pulsatile pattern of ultradian insulin secretory oscillations persist on treatment with glyburide despite the increased secretion of insulin.^{623a}

Figure 31-19 Temporal variations in rates of insulin secretion in control and diabetic subjects after breakfast, lunch, and dinner (top, middle, and bottom panels, respectively). In each subject, the secretion rates during the 30 minutes before the meal and the 4 hours after breakfast or the 5 hours after lunch or dinner were expressed as a percentage of the mean rate of insulin secretion during that interval. The curves were obtained by concatenating the resulting postmeal profiles in eight representative subjects. The times when the meals were served to the eight successive subjects in the series are indicated by arrows. (From Polonsky KS, Given BD, Hirsch LJ, et al. Abnormal patterns of insulin secretion in non-insulin-dependent diabetes mellitus. *N Engl J Med*. 1988;318:1231-1239.)

The effects on insulin secretion of improving insulin resistance in subjects with IGT through the use of the insulin-sensitizing agent troglitazone, a thiazolidinedione, have also been investigated. Troglitazone therapy improved insulin sensitivity, and this was associated with enhanced ability of the pancreatic beta cell to respond to a glucose stimulus, as judged by improvements in the dose-response relationships between glucose and insulin secretion as well as enhanced ability of the pancreatic beta cell to detect and respond to small oscillations in the plasma glucose concentration.⁶²⁴

Effects of Genetic Variants on Insulin Secretion

A number of the loci that have been associated with increased risk for T2DM appear to affect insulin secretion. Gene-phenotype studies have involved large numbers of subjects, and, as a consequence, they have generally relied on simple measures of beta cell function (e.g., the early insulin response to oral glucose). This approach has been very successful in identifying variants that primarily reduce insulin levels. More detailed phenotyping studies are now being undertaken in smaller groups of subjects to answer specific questions including the following:

1. Are the risk variants associated with altered clinical and physiologic findings before diabetes onset?
2. Is insulin secretion reduced equally in response to both oral and intravenous glucose?
3. Is the incretin effect reduced?
4. Are the dose-response relationships between glucose and insulin secretion altered?
5. Is there a concomitant change in insulin action?

Studies demonstrate that *KCNJ11* and *TCF7L2* are involved in the regulation of insulin secretion, but their clinical manifestations in humans are different, consistent with different mechanisms for their effects on the beta cell. Nondiabetic subjects with the *KCNJ11* T2DM-associated Lys-variant of E23K showed a significant reduction (approximately 40%) in insulin secretion after both oral and intravenous glucose, compared with subjects who did not carry this variant.⁶²⁵ Hyperinsulinemic euglycemic clamps demonstrated that hepatic insulin sensitivity is increased in subjects with the Lys-variant and, as a result, normal glucose tolerance is maintained despite reduced insulin secretion. Therefore, the E23K variant appears to affect both insulin secretion and insulin action. The mechanisms responsible for the increase in insulin sensitivity are unclear. One possibility is that they represent a compensatory response to reduced insulin secretion. An increase in insulin sensitivity has also been observed in normoglycemic carriers of HNF1A mutations who have reduced insulin secretion.⁶²⁶

In contrast, carriers of risk variants in *TCF7L2* have a different phenotype, with normal insulin secretory responses to intravenous glucose including normal dose-response relationships between glucose and insulin secretion, reduced responses to oral glucose with a reduced incretin effect, and no change in insulin sensitivity. Concentrations of the two major incretins GLP1 and GIP are normal after oral glucose administration, implicating resistance of the pancreatic beta cell to the stimulatory effects of one or both of these incretins. These results are consistent with those of Schafer and associates,⁶²⁷ who also documented reduced responses to GLP1.

RODENT MODELS OF TYPE 2 DIABETES

A number of spontaneous and genetically selected animal models of T2DM have been identified. Most of the models combine the two main features of T2DM: obesity-associated insulin resistance and beta-cell dysfunction with or without diminished beta-cell mass. As with diabetes in humans, the different rodent models of T2DM have similarities, but a number of overt and subtle differences make them useful surrogates for intensive study of the syndromes associated with T2DM.

An interesting observation is the striking sexual dimorphism in most rodent models of T2DM, with the male

being affected exclusively, earlier, or more severely in most instances. This is not like the human situation. The advent of transgenic and knockout technology in mice has produced a wide range of models of insulin resistance and beta-cell dysfunction that result in hyperglycemia. It is beyond the scope of this chapter to review each of these, and the reader is referred to the primary literature for review of these animals. The discussion here is limited to the well-documented spontaneous or derived models of the disease in rodents.

Mouse Models of Type 2 Diabetes

Leptin (*Lep^{ob}*) and Leptin Receptor (*db*) Mutations

The *ob* mutation, now designated *Lep^{ob}*, was first described in 1950,⁶²⁸ but the gene mutation responsible for the syndrome was not described until the *ob* mutation was found to be located in the gene for leptin.⁶²⁹ Mice homozygous for the *ob* mutation do not produce the satiety factor leptin and become markedly hyperphagic, obese, insulin resistant, and hyperinsulinemic. They have a multitude of other hypothalamic dysfunctions that render them hypometabolic, contribute to the obesity, and also result in infertility.^{630,631} Leptin treatment of these mice results in decreased food intake and reverses many of their other metabolic defects.⁶³²⁻⁶³⁶ The *ob* mice develop obesity at weaning that becomes progressive because of hyperphagia. Insulin resistance is seen in muscle, adipose tissue, and liver, with a variety of signaling defects that are reversible with insulin administration.⁶³⁷ The *ob* mouse becomes hyperglycemic and has a profound hyperinsulinemia associated with beta-cell hyperplasia, with up to a 10-fold increase in islet mass.^{638,639}

Parabiotic experiments between *ob* and *db* mice suggested that the *db* mutation would be found in the receptor for ob. This was confirmed with the identification of multiple mutations in the leptin receptor in *db* mice.^{640,641} Like *ob* mice, *db* mice are hyperphagic and begin to surpass their littermates in weight at weaning. They are progressively hyperinsulinemic, become hyperglycemic at 6 to 8 weeks, and, because of a decline in beta-cell function,⁶⁴²⁻⁶⁴⁵ become markedly hyperglycemic at 4 to 6 months. The reason for the more severe diabetes in *db* mice is not clear, but it may be related to background strain differences, because similar defects in insulin signaling are seen in this animal model as well.⁶⁴⁶⁻⁶³⁷ Treatment of both *ob* and *db* mice with insulin-sensitizing agents such as thiazolidinediones reversed the insulin resistance and ameliorated or prevented the onset of diabetes.^{649,650}

Agouti Mouse

In mice, dominant "yellow" mutations in the *agouti* gene produce obesity and hyperglycemia. Depending on the background strain, the *agouti* mutation has a variable phenotype. In susceptible strains, the onset of hyperinsulinemia begins at 6 weeks of age, and insulin levels continue to increase with age, along with beta-cell hyperplasia and hypertrophy.^{651,652} The *agouti* mutation results in systemic production of a protein normally expressed in the skin, most frequently because of a retrotransposon insertion into the promoter region of the gene.⁶⁵³ A number of genes, including the fatty acid synthase gene, have both insulin and agouti response elements; this results in a marked increase in expression and leads to increased hepatic fatty acid synthesis and enhanced fat deposition in adipocytes.^{641,654,655} The hyperglycemia is postprandial, and the

FPG levels are usually normal. The exact function of the *agouti* gene is unknown, but the animals are hyperphagic and show enhanced growth.

KK Mouse

KK mice were originally bred for enhanced size, but they are not as obese as most other obese mice (usually <60 g). Breeding of the KK mouse into various background strains has produced variable insulin resistance, hyperinsulinemia, and hyperglycemia. The most studied strain is the KKA^y, produced in Japan.⁶⁵⁶ This mouse has markedly increased insulin levels (>1000 μ U/mL) when fed a high-fat diet.^{657,658} As the male mouse ages, glucose levels fall toward the normal range. The mutation responsible for the KK phenotype is unknown.

New Zealand Obese Mouse

New Zealand obese (NZO) mice were derived by inbreeding of abdominally obese outbred mice.^{639,659-661} NZO neonates have high birth weights, and mice of both sexes are large and at weaning exhibit an elevated carcass fat content.⁶⁵⁹ Approximately 40% to 50% of group-caged NZO males, but not females, develop T2DM between 12 and 20 weeks of age when maintained with a chow diet containing 4.5% fat.⁶⁶² Obesity in NZO mice is characterized by widespread accumulation of subcutaneous and visceral fat. The obesity in these mice is accompanied by IGT in males, associated with increased hepatic and peripheral insulin resistance. In contrast to those in *ob* and *db* mice, genes encoding certain gluconeogenic and glycolytic enzymes in the liver of NZO mice retain normal responsiveness to insulin, although there is evidence for an inappropriately active fructose-1,6-bisphosphatase.⁶⁶³⁻⁶⁶⁵ Defective beta-cell insulin secretion from NZO islets in vitro and in vivo has been described.⁶⁵⁹ There appears to be a defect in the glycolytic pathway in beta cells that leads to defective glucose-stimulated insulin release.⁶⁶⁶

The genetics of NZO mice show a polygenic disorder, and none of the allelic variants have been discovered. Complicating the analysis of the model is the susceptibility of the mice to autoimmune disorders, including a lupus-like syndrome^{667,668} and insulin receptor autoantibodies.⁶⁶⁹ There is also a maternal influence in the peripartum period in the development of the disorder, which may reflect substances in the maternal milk.⁶⁷⁰

Gold Thioglucose–Induced Diabetes

Gold thioglucose induces specific lesions in the ventromedial hypothalamus and induces an initial chronic hyperinsulinemia that leads to hypoglycemia, hyperphagia, obesity, and the development of insulin resistance and hyperglycemia.⁶⁷¹ This model has been used as an example of pancreatic dysfunction preceding the induction of insulin resistance as opposed to pancreatic compensation for insulin resistance.

Diabetes Induced by Fat Ablation

Three models of insulin-resistant diabetes have been created in which adipose tissue is genetically eliminated by overproduction of foreign genes using the fat-specific promoter aP2. Expression of an attenuated diphtheria toxin in adipose tissue resulted in an age-dependent loss of fat, progressive insulin resistance, hyperinsulinemia, and significant diabetes.^{672,673} Adipose-specific expression of a constitutively active form of the sterol regulatory element-binding protein SREBP1c also resulted in fat ablation.⁶⁷⁴ Lipatrophy was induced by fat-specific overexpression of

a dominant-negative form of the transcription factor A-ZIP/F.^{675,676} The A-ZIP/F protein heterodimerizes with and inactivates basic zipper (bZIP) transcription factors, including activator protein-1 (AP1) and CCAAT/enhancer binding protein (CEBP) isoforms, probably disrupting normal fat development.

The lack of fat in the various models leads to hepatomegaly, insulin resistance with hyperinsulinemia, hypoleptinemia, and significant IGT and diabetes. These mice represent a model of human lipodystrophic diabetes and demonstrate the importance of fat in normal glucose homeostasis. It has been suggested that the lack of fat depots results in elevated fatty acid delivery to liver and muscle and the development of insulin resistance. The diabetes in these animals can be variously treated by thiazolidinediones,⁶⁷² leptin administration,⁶⁷⁷ and fat transplantation.⁶⁷⁶ Human lipodystrophy also responds to thiazolidinedione treatment,⁶⁷⁸ suggesting that some of the effects of these compounds are not wholly dependent on adipose tissue.

C57BL/6J Mouse Fed a High-Fat Diet. Male C57BL/6J (also known as B6) mice that were fed a high-fat, high-carbohydrate diet (a so-called Western diet, 58% fat by kilocalories) developed hyperglycemia, hyperinsulinemia, hyperlipidemia, and increased adiposity.^{679,680} Glucose-stimulated insulin secretion was blunted, and there was significant insulin resistance.^{681,682} Despite obesity, plasma leptin levels in the Western diet-fed B6 mice were significantly lower than in control mice in the absence of hyperphagia.^{679,683} The weight gain is related primarily to an increase in mesenteric adiposity, which makes this a good model for human adult-onset T2DM.

Rat Models of Type 2 Diabetes

Zucker Diabetic Fatty Rat

The ortholog of the *db* mouse, the obese Zucker rat (*fa/fa*), has a mutation in the leptin receptor that results in significant hyperphagia.⁶⁸⁶ The *fa* mutation is different from the mutations in *db* in that it does not disrupt leptin receptor gene expression and does not affect ligand binding.^{686,687} This mutation results in a constitutive intracellular signaling domain, which may induce a desensitization of the leptin signaling pathways.⁶⁸⁸

The selection of the inbred Zucker diabetic fatty (ZDF) rat strain used Zucker (*fa/fa*) rats that had progressed to a diabetic phenotype. Brother-sister matings resulted in a strain exhibiting development of diabetes in almost 100% of the male rats consuming a 5% fat diet.⁶⁸⁹ Hyperglycemia begins to develop in males at 7 weeks of age, with serum glucose levels rising to 500 mg/dL by 12 weeks of age. The hyperinsulinemia precedes hyperglycemia with marked islet hyperplasia and dysmorphogenesis,⁶⁹⁰ but by 19 weeks insulin levels drop concomitantly with islet atrophy, in part because of an imbalance of hyperplasia and apoptosis.⁵⁹¹ The islets of prediabetic ZDF rats secrete significantly more insulin in response to glucose, with elevated basal levels of insulin secretion and a leftward shift but a blunted glucose dose-response curve.^{592,691} Islets of prediabetic male ZDF rats also have defects in the normal oscillatory pattern of insulin secretion.⁶⁹²

In contrast to the male ZDF rat, the female rat has significant insulin resistance but does not become diabetic unless given a proprietary high-fat diet (GMI 13004).⁶⁹³ The high-fat diet appears to have a direct effect on the beta cell,

because there is no change in peripheral insulin sensitivity (P. Hansen and C.F. Burant, unpublished observations). There is a decrease in peripheral triglyceride and FFA levels in the female rat after institution of the high-fat diet.

The underlying genetic defect that results in beta-cell failure in the ZDF rat is unknown. The beta cell number and insulin content are not different from those in homozygous normal animals, but insulin promoter activity is doubled in the ZDF rat.⁶⁹⁴ Insulin promoter mapping studies suggest that a critical region in the promoter of the insulin gene is affected. A number of other gene expression differences have been described in ZDF islets, including decreases in the expression of GLUT2^{695,696}; increases in glucokinase and hexokinase activity⁶⁹¹; decreases in mitochondrial metabolism⁶⁹¹; accumulation of intraislet lipid and long-chain fatty acyl-CoA, which is associated with abnormal beta-cell secretion^{692,697,698}; and increased accumulation of nitric oxide and ceramide,^{699,700} which is associated with apoptosis. Other gene expression changes are also found in the prediabetic rat islet.⁷⁰¹ Which of these defects are important for the development of the diabetes is not clear.

The fixed genetic defect in the male animal leads to diabetes, but this defect also interacts with the insulin resistance, because treatment with insulin-sensitizing agents can prevent the onset of diabetes in male and female rats.^{698,702} These agents are not effective in the male after establishment of diabetes; however, the female rat can respond to thiazolidinediones even after significant hyperglycemia.

Goto-Kakizaki Rat

The Goto-Kakizaki (GK) inbred rat strain was derived from outbred Wistar rats by selection for IGT.⁷⁰³ Early in the development of diabetes, glucose and insulin are mildly elevated, but as the animals age, reduced beta-cell mass becomes evident, with markedly diminished insulin stores and abnormal secretory responses to glucose.^{704,705} A number of biochemical defects have been described in the islets of these animals, including decreased energy production,⁷⁰⁶⁻⁷⁰⁸ expression of proteins involved in insulin granule movement,⁷⁰⁹ and decreased adenylate cyclase activity.⁷¹⁰ Defects in peripheral signaling include decreased maximal and submaximal insulin-stimulated IRS1 tyrosine phosphorylation, IRS1-associated PI3K activity, Akt activation in muscle,⁷¹¹ and defective regulation of protein phosphatase-1 and -2A, and mitogen-activated protein kinase activation by upstream insulin-signaling components in adipocytes.⁷¹² Some of these defects may be a result of hyperglycemia, because they can be reversed by phlorizin-induced normalization of serum glucose.⁷¹¹

BHE/Cdb Rat

The Bureau of Home Economics (BHE/Cdb) rat is a subline of the parent BHE strain that was obtained by selection for hyperglycemia and dyslipidemia without obesity.⁷¹³ Glucose-stimulated insulin secretion is markedly diminished in these rats, a trait that is maternally inherited.⁷¹⁴ A significant defect appears to be present in the liver. Increased gluconeogenesis and lipogenesis precede the hyperglycemia, which may be caused by defects in mitochondrial respiration associated with mitochondrial DNA mutations.^{715,716}

Psammomys Obesus (Sand Rat)

The sand rat (*Psammomys obesus*) is a nutritionally induced obesity model of T2DM. Genetically, the animal is in reality

a gerbil, and it usually lives on a low-calorie vegetable diet.⁷¹⁷ When given a high-carbohydrate diet, the sand rat rapidly becomes hyperglycemic secondary to weight gain associated with significant insulin resistance⁷¹⁸ and enhanced hepatic glucose production.⁷¹⁹ When a relatively hypocaloric diet is restored, the metabolic syndrome reverts to normoglycemia. A subpopulation of the sand rat develops frank beta-cell failure and becomes ketotic.

Otsuka Long-Evans Tokushima Fatty Rat

The Otsuka Long-Evans Tokushima fatty (OLETF) rat strain was derived from the Long-Evans rat with polyuria, polydipsia, and mild obesity.⁷²⁰ About 90% of the male animals become diabetic by 1 year of age. Statistical tests have determined that the locus containing the cholecystokinin A receptor is responsible for about 50% of the T2DM in the OLETF rats.⁷²¹ The receptor is disrupted in the OLETF rat because of a 165-bp deletion in exon 1.^{722,723} Genetic segregation analysis has shown interaction with a second locus, *Obd2*, which acts in a synergistic fashion to result in NIDDM, and both of these loci are required in homozygous OLETF rats to cause elevated plasma glucose.⁷²⁴

The role of sex hormones is pronounced in this strain. Orchiectomy markedly reduces the incidence of diabetes in the male, and oophorectomy increases the rate of hyperglycemia to 30% in the female. Treatment of castrated males with testosterone restores the incidence of diabetes to 89%. The islets undergo a progressive inflammatory reaction with progressive fibrosis. This reaction is associated with the impairment of beta-cell function.⁷²⁵ Obesity and insulin resistance appear to precede the development of beta-cell failure.⁷²⁶ Studies have also shown that obesity is necessary for the development of T2DM in OLETF males and that insulin resistance may be closely related to fat deposition in the abdominal cavity.⁷²⁷ Troglitazone and metformin have been used successfully to treat diabetes in the OLETF rat, and troglitazone completely prevents the morphologic and functional deterioration of the beta cells.⁷²⁸

Neonatal Streptozotocin

Two models have been described in which a single dose of the beta cell toxin, streptozotocin, is given to 2-day-old female Wistar^{729,730} or male Sprague-Dawley rats.^{731,732} These animals have a transient hyperglycemia but develop IGT at 4 to 6 weeks of age. There is an initial reduction of beta-cell mass, but subsequent regeneration results in restoration of the beta-cell mass to a level approximately 50% lower than the normal adult level.

MANAGEMENT OF TYPE 2 DIABETES

Over the last 15 years, a conceptual transformation in the principles of management of T2DM has occurred. Fundamentally, there has been a change in the level of concern about diabetes as a public health issue and in attitudes about its treatment. Dramatic advances in the spectrum of pharmacologic agents and monitoring technology available for the treatment of diabetes have made it possible to lower glucose levels safely to the near-normal range in most patients. Great strides have been made in establishing an evidence base for guidelines regarding glycemic control and efforts to reduce the risk of complications. Corporate and government health insurance providers have greatly improved the extent to which diabetes equipment and supplies are covered.

A comprehensive review of all the subtleties of diabetes management in the 21st century is beyond the scope of this chapter. Here, we deal with the salient features of the epidemiology of the complications of T2DM, diagnostic strategies, treatment guidelines, lifestyle interventions, and pharmacotherapy before turning briefly to a discussion of preventive measures for T2DM and its complications. An excellent source of information on these issues is *Summary of Revisions for the Clinical Practice Recommendations* of the American Diabetes Association (ADA), which is published as the first supplement to the journal *Diabetes Care* each January and is available online at http://professional.diabetes.org/CPR_search.aspx (accessed December 2010).

Scope of the Problem

In the United States in 2007, the prevalence of diabetes was estimated to be 23.6 million, or 7.8% of the population, including 17.9 million diagnosed cases and 5.7 million undiagnosed cases. More than 1.6 million cases were diagnosed in people older than 20 years in 2007 alone.⁷³³ This increase is driven by population aging; by population growth, particularly among ethnic groups with greater susceptibility to the disease; and by dramatic increases in rates of obesity as a consequence of increasingly sedentary lifestyles and greater consumption of simple sugars and calorie-dense foods. At least in the United States, opportunistic screening for diabetes in high-risk populations is recommended by professional societies and many insurers, and this has resulted in an increase in the fraction of affected persons with diagnosed diabetes, from approximately 50% in the 1990s to more than 80% in 2006.⁹

The morbidity, mortality, and expense associated with diabetes are staggering.⁷³³ In Western society, people with diabetes are three times more likely to be hospitalized than nondiabetic persons. In the United States, diabetes is the leading cause of blindness and accounts for more than 40% of new cases of end-stage renal disease. The risk of heart disease and stroke is two to four times higher, and the risk of lower-extremity amputation is approximately 20 times higher for people with diabetes than for those without diabetes. Life expectancy is reduced by approximately 10 years in people with diabetes, and although diabetes is the seventh leading cause of death in the United States, this is clearly an underestimate. Only about 35% to 40% of those who die with diabetes have the disease listed anywhere on the death certificate, and only 10% to 15% have it listed as the underlying cause of death.⁷³³

Tragically, though a smaller proportion of people with diabetes are developing end-stage complications of diabetes,⁷³⁴ the epidemic of diabetes is one of the drivers of increasing health care costs. Current estimates suggest that the diabetes population and associated costs will at least double in the next 25 years.⁷³⁵ Annual disbursements for people with diabetes are approximately 2.3 times higher per capita than for those persons without diabetes. In the United States, at least 20% of health care expenditures are related to the treatment of people with diabetes.⁷³⁶

Glucose Treatment Guidelines

Study Results and Recommendations

Prospective, randomized clinical trials have documented improved rates of microvascular complications in patients

with T2DM treated to lower glycemic targets. In the United Kingdom Prospective Diabetes Study (UKPDS),^{737,738} patients with new-onset diabetes were treated with diet and exercise for 3 months, with an average reduction in HbA_{1c} from approximately 9% to 7% (upper limit of normal is 6%). Those patients with FPG greater than 108 mg/dL (6 mmol/L) were then randomly assigned to two treatment policies. In the standard intervention, subjects continued the lifestyle intervention. Pharmacologic therapy was initiated only if the FPG reached 15 mmol/L (270 mg/dL) or the patient became symptomatic. In the more intensive treatment program, all patients were randomly assigned and treated with either sulfonylurea, metformin, or insulin as initial therapy, with the dose increased to try to achieve an FPG of less than 108 mg/dL. Combinations of agents were used only if the patient became symptomatic or FPG rose to greater than 270 mg/dL (15 mmol/L).

As a consequence of the design, although the HbA_{1c} fell initially to about 6%, over the average 10 years of follow-up it rose to approximately 8%. The average HbA_{1c} in the standard treatment group was approximately 1 percentage point higher. The risk of severe hypoglycemia was small (on the order of 1% to 5% per year in the insulin-treated group) and weight gain was modest; both were higher in patients randomly assigned to insulin and lower in those receiving metformin.⁷³⁸ Associated with this improvement in glycemic control, there was a reduction in the risk of microvascular complications (retinopathy, nephropathy, and neuropathy) in the group receiving intensive treatment. Although there was a trend toward reduced rates of macrovascular events in the more intensively treated group, it did not reach statistical significance.⁷³⁷

Similar reductions in microvascular events were observed in another trial of entirely different design and much smaller size. In the Kumamoto study, Japanese patients of normal weight with T2DM receiving insulin were randomly assigned to standard treatment or an intensive program of insulin therapy designed to achieve normal glycemia. The control group maintained HbA_{1c} values at approximately 9%, whereas the HbA_{1c} in the intensive therapy group was reduced to approximately 7%, and the separation was maintained for 6 years. Again, there was a modest increased risk of hypoglycemia and weight gain, a reduction in microvascular complications, and a nonstatistically significant trend toward reduced rates of vascular end points.⁷³⁹

In 2008, three studies examining the effects of two levels of glycemic control on cardiovascular end points in T2DM were reported. Action to Control Cardiovascular Risk in Diabetes (ACCORD),⁷⁴⁰ Action in Diabetes and Vascular Disease—Preterax and Diamicon Modified Release Controlled Evaluation (ADVANCE),⁷⁴¹ and the Veterans Affairs Diabetes Trial (VADT)⁷⁴² each randomized middle-aged and older individuals who were at high risk for cardiovascular events. ACCORD and VADT aimed for an HbA_{1c} target of less than 6% using complex combinations of oral agents and insulin. ADVANCE aimed for an HbA_{1c} target of 6.5% or less using a somewhat less intensive approach based on the addition of the sulfonylurea glimepiride. None of the trials demonstrated a statistically significant benefit on combined vascular end points. ACCORD demonstrated a 22% increase in total mortality, whereas VADT had numerically more deaths in the intensively treated group (hazard ratio, 1.07). Modest improvements in some microvascular end points in all three trials were demonstrated. In these studies, there were suggestions that people who were without clinical cardiovascular disease and had shorter duration of disease and lower baseline HbA_{1c} demonstrated

greater benefits from the more intensive glucose-lowering strategies.

Furthermore, a 10-year follow-up of the UKPDS cohort demonstrated that the relative benefit of more intensive management of glucose demonstrated at the end of the randomized portion of the trial was maintained, resulting in the emergence of statistically significant benefits on cardiovascular end points and total mortality.⁷⁴³ Meta-analysis of cardiovascular outcomes in randomized trials suggested that an average HbA_{1c} reduction of 0.9% correlates with a 17% reduction in nonfatal MI and a 15% reduction in coronary heart disease without significant effects on stroke or all-cause mortality; however, as mentioned previously, there is significant heterogeneity in the result with respect to mortality across trials, the etiology of which is completely uncertain.⁷⁴⁴

Blood Glucose Treatment Targets

Guidelines from the ADA and the American College of Endocrinology (ACE) are presented in Table 31-7. The ADA suggests that the goal of treatment in the management of diabetes should be an HbA_{1c} value of less than 7% in general. Furthermore, the ADA suggests that lower targets may be pursued in selected patients, such as those with recent-onset disease, long life expectancy, and no significant cardiovascular disease, if they can be achieved without significant hypoglycemia or other adverse effects of treatment. Conversely, they recommend that less-stringent HbA_{1c} goals “may be appropriate for patients with a history of severe hypoglycemia, limited life expectancy, advanced microvascular or macrovascular complications, and extensive comorbid conditions and those with longstanding diabetes in whom the general goal is difficult to attain despite diabetes self-management education, appropriate glucose monitoring, and effective doses of multiple glucose lowering agents including insulin.”⁷⁷ ACE has recommended an HbA_{1c} goal of less or equal to 6.5%, again with language suggesting individualization of targets.^{745,746}

With respect to fasting, premeal, or postprandial targets, there is little support for any particular level of glycemic control in the management of T2DM because no large-scale outcome study has targeted particular levels of glucose with home glucose monitoring. The ADA target for fasting (and premeal) plasma glucose levels, 70 to 130 mg/dL, was initially developed based on an estimate of the range of average glucose values that would be associated with a low risk of hypoglycemia and an HbA_{1c} of less than 7%. It was later modified based on recognition that in many patients, routine achievement of an HbA_{1c} of less than 7% would lead to moderate hypoglycemic events, with glucose levels in the 70 to 90 mg/dL range.⁷⁴⁷ The ACE fasting glucose target of less than 110 mg/dL is an effort to achieve normal levels of glycemia.⁷⁴⁶ However, consistent fasting and premeal glucose levels lower than 110 mg/dL would be expected to be associated with an HbA_{1c} of approximately 5.5%.⁷⁴⁸

The ADA treatment target for peak postprandial glucose levels is set at less than 180 mg/dL, in part because such levels would be associated with an HbA_{1c} of approximately 7% and because nondiabetic persons who consume a large evening meal have been demonstrated to exhibit transient elevations of glucose to that level.⁷⁴⁹ There are no published studies documenting safety or outcomes for a particular targeted level of postprandial blood glucose. However, there are effective HbA_{1c}-lowering agents that primarily target postprandial glucose levels, and monitoring of postprandial glucose levels may be necessary to optimize dose adjustment of these agents. Furthermore,

there are patients with diabetes who have average FPG levels within their target range but whose HbA_{1c} is elevated. In these patients, monitoring and specific treatment of postprandial elevations can provide improvements in HbA_{1c}, perhaps with a lower risk of hypoglycemia and weight gain than has been associated with further lowering of fasting and premeal glucose levels.⁷⁵⁰ The ACE has recommended a targeted 2-hour postprandial glucose concentration of less than 140 mg/dL (7.8 mmol/L) in an effort to achieve near-normal glycemia.⁷⁴⁶ Consistent postprandial glucose values lower than 140 mg/dL would be associated with an average HbA_{1c} of approximately 5%.⁷⁴⁸

Lifestyle Intervention

The components of lifestyle intervention include medical nutrition counseling, exercise recommendations, and comprehensive diabetes education with the purpose of changing the paradigm of care in diabetes from provider focused to patient focused. Arguably, since the turn of the 21st century, nothing has changed more fundamentally than the emphasis on lifestyle intervention. For decades, physicians and patients have paid lip service to the notion that lifestyle intervention is important. Now we have significant clinical trial evidence that each component of lifestyle intervention, when appropriately administered, can contribute to improved outcomes. Furthermore, since passage of the Balanced Budget Act of 1997 and complementary legislation in most state governments, lifestyle intervention has been a covered benefit for most insured people. Although full implementation of these regulations is still in progress, they have dramatically expanded the fraction of the population with diabetes who can acquire insurance coverage for these essential services.

Patient Education

Diabetes is a lifelong disease, and health care providers have almost no control over the extent to which patients adhere to the day-to-day treatment regimen. The appropriate role of the health care provider is to serve as a coach to the patient, who has primary responsibility for the delivery of daily care. As a result, health care providers must carefully engage patients as partners in the therapeutic process. It is critical for the health care professional to understand the context in which patients are taking care of their disease. A prescriptive approach, in which patients are told what to do, can work in some situations but fails more often than not because of unrecognized barriers to the execution of a particular plan. For long-term success, diabetes self-management education is critical.

As defined by the ADA,⁷⁵¹ diabetes self-management education is the process of providing to the person with diabetes knowledge and skills needed to perform self-care, manage crises, and make lifestyle changes. As a result of this process, the patient must become a knowledgeable and active participant in the management of his or her disease. To achieve this task, patients and providers work together in a long-term, ongoing process. Minimal diabetes education should be universally provided and individualized with emphasis on the core issues highlighted in Table 31-8. There are many more specialized topics relevant to almost all patients, such as how to adjust therapy when eating out or during travel, review of available local health care resources such as support groups, and insurance issues. Although there are only limited studies, they do provide support for the concept that diabetes education can be cost-effective and can improve outcomes.⁷⁵²

TABLE 31-8

Curricular Areas That Should Be Addressed in Diabetes Self-Management Education

Pathophysiology of the patient's diabetes and its relationship to treatment options
Incorporating appropriate nutritional management
Incorporating physical activity into lifestyle
Using medications (if applicable) for therapeutic effectiveness
Monitoring blood glucose and (when appropriate) urine ketones and using the results to improve control
Preventing, detecting, and treating acute complications including sick day rules and hypoglycemia
Preventing (through risk detection), detecting, and treating chronic complications
Goal-setting to promote health and problem-solving for daily living
Integrating psychosocial adjustment into daily life
Promoting preconception care, management during pregnancy, and gestational diabetes management (if applicable)

Adapted from Mensing C, Boucher J, Cypress M, et al. National standards for diabetes self-management education. *Diabetes Care*. 2006;29:S78-S85.

A team of providers is usually required to fully implement the process of diabetes self-management education, because the amount of information that needs to be exchanged is large and the needed range of expertise is broad. It is usually not possible to cover the recommended content fully in the context of several or even many brief encounters with a physician in an office setting. Potential providers in a team care approach include nurses, dietitians, exercise specialists, behavioral therapists, pharmacists, and other medical specialists including diabetologists or endocrinologists, podiatrists, medical subspecialists, obstetrician-gynecologists, psychiatrists, and surgeons. The potential role of the community in which the patient lives and works in the diabetes self-care process is enormous; family, friends, employers, and health insurance providers may all be involved. Each potential member of the team has a role to play in the process, which must be reviewed and assessed frequently (Table 31-9). The primary roles of the providers in this process are to supply guidance in goal setting to manage the risk of complications, suggest strategies for achieving goals and techniques to overcome barriers, provide training in skills, and help screen for complications. For this process to be a success, the patient must commit to the principles of self-care, participate fully in the development of a treatment plan, make ongoing decisions regarding self-care from day to day, and communicate honestly and with sufficient frequency with the team.

Fortunately, barriers to providing team care are becoming less daunting. Diabetes education programs are being rapidly established. The American Association of Diabetes Educators (telephone 800-TEAM-UP4) and the ADA (telephone 800-DIABETES) can provide information regarding diabetes educators and education programs in the local area.

For team care to be most effective, communication, trust, and mutual respect are critical. However, in many communities, the full benefit of consultation and ongoing care with diabetes educators, nurses, dietitians, pharmacists, or others is not achieved because of overly hierarchic approaches to care. Nonphysicians, including patients, ought to provide suggestions regarding medication and lifestyle adjustments and help in the process of identifying barriers to effective management such as lack of

TABLE 31-9

Team Care: Roles of the Players
Primary Care Provider
To be a source of accurate information and to refer to and coordinate with other sources of information as necessary To provide guidance in developing goals of treatment To screen for complications and evaluate progress in meeting treatment goals To help develop strategies for achieving treatment goals and avoiding complications
Other Providers
To be a source of accurate information, to communicate with the primary care provider, and to coordinate with other sources of information as necessary To provide guidance in developing goals of treatment and to help the primary care provider develop strategies to achieve treatment goals and avoid complications
Patient
To commit to diabetes self-management (see Table 31-8) To be an active participant in the process To communicate with other team members when goals are not achieved or barriers or problems are encountered
Community
To provide support to encourage ongoing diabetes self-care

knowledge, lack of time, and lack of resources and strategies to overcome barriers.

Perhaps some of the most overlooked contributors to ineffective care in the setting of T2DM are the relatively common barriers created by psychiatric, neurocognitive function, and adjustment disorders, which are largely responsive to psychosocial therapies.⁷⁵³

Nutrition

With respect to self-management education, recent ADA statements document the effect of medical nutrition therapy and offer specific advice on diabetes-related outcomes (e.g., HbA_{1c}, weight, proteinuria).^{7,754} These recommendations are summarized in Table 31-10. A comprehensive, individually negotiated nutrition program in which each patient's circumstances, preferences, and cultural background as well as the overall treatment program are considered is most likely to result in optimal outcomes. Because of the complexity of the medical and nutritional issues for most patients, it is recommended that a registered dietitian with specific skill and experience in implementing nutrition therapy in diabetes management work collaboratively with the patient and other health care team members to provide medical nutrition therapy.

Structured programs that emphasize lifestyle changes including education, reduced energy intake (and therefore often fat intake), conscious decisions regarding carbohydrate intake, regular physical activity, and recurring participant contact can produce long-term weight loss of 5% to 7% of starting weight and reduce the risk of developing diabetes. Everyone, especially family members of persons with T2DM, should be encouraged to engage in mindful eating and regular physical activity to decrease the risk of developing T2DM.

Physicians and other members of the health care team need to understand the major issues in diabetes and nutrition and to support the nutritional plan developed

TABLE 31-10

Major Nutrition Recommendations for Diabetes
General
Individuals who have prediabetes or diabetes should receive individualized medical nutrition therapy (MNT) as needed to achieve treatment goals, preferably provided by a registered dietitian familiar with the components of diabetes MNT. Because MNT can result in cost savings and improved outcomes, MNT should be covered by insurance and other payers.
Energy Balance, Overweight, and Obesity
In overweight and obese insulin-resistant individuals, modest weight loss has been shown to reduce insulin resistance; therefore, weight loss is recommended for all overweight or obese individuals who have diabetes or are at risk for diabetes. For weight loss, either a low-carbohydrate diet or a low-fat calorie-restricted diet may be effective in the short-term (up to 1 year). For patients on a low-carbohydrate diet, lipid profiles, renal function, and protein intake (in those patients with nephropathy) should be monitored and hypoglycemic therapy adjusted as needed. Physical activity and behavior modification are important components of weight loss programs and are most helpful in maintenance of weight loss.
Dietary Fat Intake in Diabetes Management
Saturated fat intake should be <7% of total calories. Reducing intake of <i>trans</i> fat lowers low-density lipoprotein (LDL)-cholesterol and increases high-density lipoprotein (HDL)-cholesterol; therefore, intake of <i>trans</i> fat should be minimized.
Carbohydrate Intake in Diabetes Management
Monitoring of carbohydrate intake by carbohydrate counting, exchanges, or experience-based estimation remains a key strategy in achieving glycemic control. For individuals with diabetes, the use of the glycemic index and glycemic load may provide a modest additional benefit for glycemic control over that observed when total carbohydrate is considered alone.
Other Nutrition Recommendations
Sugar alcohols and nonnutritive sweeteners are safe when consumed within the acceptable daily intake levels established by the U.S. Food and Drug Administration (FDA). If adults with diabetes choose to use alcohol, daily intake should be limited to a moderate amount (i.e., ≤1 drink per day for adult women or ≤2 drinks per day for adult men). Routine supplementation with antioxidants (e.g., vitamin E, vitamin C, carotene) is not advised because of lack of evidence of efficacy and concerns related to long-term safety. Benefit from chromium supplementation in people with diabetes or obesity has not been conclusively demonstrated, and therefore it cannot be recommended. Individualized meal planning should include optimization of food choices to meet recommended dietary allowances (RDAs) or dietary reference intakes (DRIs) for all micronutrients. Lifestyle therapy for hypertension consists of: weight loss (if overweight), a Dietary Approaches to Stop Hypertension (DASH)-style dietary pattern including reduced sodium and increased potassium intake, moderation of alcohol intake, and increased physical activity. Lifestyle modification focusing on reduced saturated fat, <i>trans</i> fat, and cholesterol intake; increased n-3 fatty acids, viscous fiber, and plant stanols/sterols; weight loss (if indicated); and increased physical activity should be recommended to improve the lipid profile in patients with diabetes. Reduction of protein intake to 0.8–1.0 g/kg of body weight per day in individuals with diabetes and the earlier stages of chronic kidney disease (CKD) or to 0.8 g/kg per day in those with later stages of CKD may improve measures of renal function (e.g., urine albumin excretion rate, glomerular filtration rate) and is recommended.

Adapted from American Diabetes Association. Standards of medical care in diabetes—2010. *Diabetes Care*. 2010;29:s11–s61.

collaboratively. Individualized dietary advice can be developed by a physician from a brief diet history obtained by asking questions such as the following: What do you eat for breakfast? Lunch? Dinner? Do you have snacks between breakfast and lunch? Lunch and dinner? Dinner and bedtime? and What do you drink during the day? Ideally, this information should be obtained at each visit, with specific suggestions for changes that both patient and provider agree are important and achievable.

Easy issues to address include caloric beverages, which tend to elevate glucose levels dramatically and can usually be replaced quite painlessly by artificially sweetened alternatives. Juices are generally perceived as healthful but can significantly affect glycemic control and total calorie intake. Substituting low-fat products for higher-fat alternatives is often suggested but needs to be done with the recognition that these products are generally higher in carbohydrates. Fat-free and sugar-free foods need to be recognized as food that is not "free." Portion control and recipe modification are excellent techniques, particularly for meats and fried foods.

Adequate spacing between meals is usually good advice for patients with T2DM, because postprandial glucose levels typically peak 2 hours after a meal, when a snack would normally be taken. Eating approximately every 4 hours while awake is the most practical dietary plan for most overweight people. Frequent small meals have been shown to be of benefit when used in a controlled inpatient setting, but overweight patients who are encouraged to eat more frequently often overeat more frequently. At a minimum, avoiding high-calorie snacks is reasonable advice for most people with diabetes. A repeated diet history and additional modest changes negotiated every few weeks to months by all health care providers (i.e., doctor, nurse, or dietitian) allow assessment of whether previously agreed to changes were enacted, reinforcement of the importance of diet efforts, and slow enticement of patients into more healthful dietary choices.

In general, the critical nutrient for glycemic consistency is carbohydrate. Essentially every molecule of carbohydrate consumed is converted to glucose in the gut and requires the action of insulin to be cleared from the circulation. The carbohydrate-counting technique can be used in patients with T2DM to facilitate consistent carbohydrate intake or to allow insulin dose adjustment in response to changes in carbohydrates consumed.⁷⁵⁵ Whereas the beta cell in T2DM has usually lost its responsiveness to glucose, the second phase of insulin secretion is largely spared in T2DM and is in part driven by amino acids and fatty acids. Therefore, including some protein and fat in each meal and snack is useful.

Dietary fat is the nutrient that is most closely associated in epidemiologic studies with the risk of developing T2DM. Although dietary fats clearly have an impact on total caloric intake (related to their caloric density) and on circulating lipids, they have a minimal impact on glycemia acutely. Fat intake is a contributor to obesity and is the critical nutrient for cardiovascular risk management. It is recommended that people with diabetes (and everyone in general) consume a diet that is modestly restricted in calories (if overweight) and contains less than 10% of total calories as saturated fat and less than 10% as polyunsaturated fat. Some advocate substituting foods high in monounsaturated fatty acids (i.e., seeds, nuts, avocado, olives, olive oil, and canola oil) for carbohydrate, but most patients do not find adequate variety in the monounsaturated fatty acid category and often overeat these high-calorie foods. Higher-carbohydrate diets can raise postprandial glucose

and triglycerides but are much less calorically dense than higher-fat diets and have a higher thermic effect, both of which tend to promote weight loss.

Dietary protein similarly has a minimal impact on glucose levels, although amino acids do promote insulin secretion, which may be advantageous in patients with T2DM. Metabolism of protein results in the formation of acids and nitrogenous waste, which can lead to bone demineralization and glomerular hyperfiltration. At least 0.8 g of high-quality dietary protein per kilogram of body weight is generally recommended; restriction of protein intake to 10% to 20% of total calories minimizes potential adverse long-term effects of high protein intake.

The roles of vitamins, trace minerals, and nutritional supplements in the treatment of diabetes are poorly understood. Some clinicians are convinced of the utility of soluble fiber, magnesium, chromium, zinc, folic acid, pyridoxine, cyanocobalamin, vitamin A, vitamin C, vitamin E, vanadium, selenium, garlic, and other micronutrients. Clinical trial data to support their safety and efficacy are inconclusive at best. Many patients are convinced that nutritional supplementation is healthful, and it is often counterproductive to engage in scholarly discussion of the nature of the evidence base for their decision. At a minimum, discussion should include the documented efficacy of more classic lifestyle and pharmacologic interventions and the idea that these efforts should not be left by the wayside when budget constraints affect potentially more effective interventions.⁷⁵⁶ In a small randomized, controlled trial, a daily multivitamin and mineral supplement reduced the incidence of participant-reported infection and related absenteeism among patients with T2DM, perhaps related to a high prevalence of subclinical micronutrient deficiency.⁷⁵⁷

Although a wide range of dietary recommendations have their proponents, there are few data to support these suggestions from long-term outcome studies of prescribed diets. Mixed meals containing 10% to 20% of calories from protein, no more than 10% of calories from saturated fat, and the remainder largely from monounsaturated fats and carbohydrates (particularly whole grains, fruits, vegetables, and low-fat milk) are probably most reasonable. There is evidence that a diet rich in complex carbohydrates and low in fat and animal protein is a beneficial component of comprehensive lifestyle management in the setting of cardiovascular disease.⁷⁵⁸ On the other hand, a number of studies suggest that diets lower in carbohydrate and higher in protein and fat reduce caloric intake and provide improvements in insulin sensitivity, glycemia, and cardiovascular risk markers.

Weight loss is a goal of many patients with and without diabetes and certainly is associated with improvements in glycemic control, insulin resistance, circulating lipids, and blood pressure. As reviewed previously, numerous studies document that certain changes can result in modest weight loss that can be largely maintained with sustained effort. These changes include intensive lifestyle programs involving frequent contact with patients, individualized counseling, and education aimed at reducing caloric intake. Additional, complementary changes by the patient include regular physical activity and efforts to understand and control behaviors that result in overeating.

Exercise

There is a substantial body of literature supporting exercise as a modality of treatment in T2DM.^{7,759} Exercise is perhaps the single most important lifestyle intervention in diabetes because it is associated with improved glycemic control,

insulin sensitivity, cardiovascular fitness, and remodeling. Aerobic exercise and resistance (strength) training have positive impacts on glucose control. Improvements in glycemic control are usually apparent immediately and become maximal after a few weeks of consistent exercise. However, they may persist for only 3 to 6 days after cessation of training; hence, the rationale for negotiating a minimum of three exercise sessions per week to maintain the benefit of the intervention.

The key concept is to promote an increase in activity using an approach similar to the one discussed for diet. Goals, methods, intensity, and frequency must be negotiated with patients with great sensitivity to recognizing barriers and helping patients discover solutions. The role of educators, exercise specialists, physical therapists, and social supports in this process is critical. The major role for the physician is to screen for complications (neuropathy, nephropathy, retinopathy, vascular disease) and discover ways for patients to be able to exercise safely. Exercise in the presence of uncontrolled diabetes, hypertension, retinopathy, nephropathy, neuropathy, and cardiovascular disease can create devastating problems. These obstacles can all be addressed creatively and should never present an insurmountable barrier to increasing physical activity.

Some authorities recommend that all patients older than 35 years have a stress test before initiating an exercise program. The utility of stress tests is potentially limited by their poor sensitivity and specificity.⁷⁶⁰ If the exercise program contemplated does not involve more strenuous activity (in intensity and duration) than the patient has engaged in recently but merely more frequent activity, screening cardiovascular stress testing is unlikely to be useful. However, when sedentary patients plan to embark on a program of strenuous exercise, stress testing may be prudent to evaluate for subclinical coronary disease. Patients at high risk for coronary artery disease should start with short periods of low-intensity exercise and increase the intensity and duration slowly as tolerated. Patients who develop symptoms of coronary ischemia, including dyspnea out of proportion with activity, should be referred for further evaluation and treatment. Even with negative results on stress testing, it is important to encourage patients not to overexert and to recognize exertional chest, jaw, or arm discomfort as well as palpitations and dyspnea as symptoms of cardiac dysfunction.

Over time, improved exercise tolerance should be viewed as a measure of improved cardiorespiratory function. For aerobic exercise to improve insulin sensitivity, glycemic control, and cardiovascular risk, the patient must engage in at least 150 minutes per week of moderate-intensity aerobic physical activity (50%-70% of maximum heart rate) or 75 minutes per week of vigorous aerobic exercise (>70% of maximum heart rate).⁷ Exercise should be regular, at least every 48 hours. Patients with T2DM should be encouraged to perform resistance exercise targeting all major muscle groups three times a week.⁷ For the average patient with T2DM starting an exercise program, this equates to quite low-level activity initially, such as walking at a pace of 2 miles/hour. Initially, it may even be advantageous to negotiate once-weekly walks or shorter-duration exercise sessions, or both, and proceed from there. Over time, patients are encouraged to pick up the pace as tolerated and to increase the duration and frequency of exercise sessions slowly to avoid overuse injuries. It is not unreasonable to suggest to patients that if they are going to incorporate exercise into their diabetes management program, they must think of exercise as a treatment that takes the place of a pill and requires adherence to produce benefit.

Self-Monitoring of Blood Glucose

Self-monitoring of blood glucose (SMBG) has not been demonstrated in clinical trials to change outcomes in T2DM when evaluated in isolation.⁷ However, many diabetes self-management programs have been demonstrated to help reduce complications. In all of these, SMBG is an integral part of the process, suggesting that SMBG is at least a component of effective therapy. The frequency and type of monitoring in diabetes therapy should be determined in consultation with the patient, taking into account the nature of the diabetes, the overall treatment plan and goals, and the patient's abilities. SMBG is particularly recommended for all patients with T2DM who are taking insulin or sulfonylureas because it allows patients to identify minimal or asymptomatic episodes of hypoglycemia.

Although severe hypoglycemia is relatively rare in T2DM, it can have devastating consequences, such as trauma or self-injury or change in the perceived ability of a patient to continue to live independently as a result of confusion or loss of consciousness. Also, it is essential to have patients critically assess the nature of any hypoglycemic symptoms that may occur. Many patients are fearful or overconcerned about hypoglycemia and routinely consume extra calories in response to a variety of life's circumstances, such as when they are hungry, sweaty, nervous, or upset. Monitoring studies document that most symptoms in patients with T2DM are not related to hypoglycemia and should not be treated with excessive calorie consumption.

Timing of SMBG varies depending on the diabetes therapy. It is important to advise patients to vary the time of the day at which blood glucose levels are checked. For some patients, the highest blood glucose of the day is the morning glucose, whereas for others the highest is before bed. Particularly in early diabetes, gestational diabetes, and well-controlled diabetes, monitoring 1 to 2 hours after meals allows patients to assess the effect of their lifestyle and pharmacologic efforts in controlling postprandial glucose levels, which are usually the only glycemic abnormality present. Monitoring (and thus targeting therapy) at just one time of day can leave the patient with a less than ideal overall response to therapy.

When glucose control is poor, having patients concentrate on premeal glucose levels is adequate. Once the premeal glucose levels reach the low 100s, many advocate that patients switch to checking 1- to 2-hour postprandial glucose levels; the latter approach amplifies the observed effect of diet on glycemic control and enables patients to see that moderate changes in meal plan, activity, and medications have a significant impact on glycemic control. Even after substantial inappropriate changes in food intake, activity, or timing or dose of medication, blood sugar values often return to near-normal levels overnight or by the time of the next meal.

The frequency of glucose monitoring needs to be matched to the individual patient's needs and treatment. Many clinicians ask patients to monitor at least once a day (at varying times before a meal, at bedtime, and at mid-sleep) as well as with hypoglycemic symptoms. Others ask patients receiving intensive insulin treatment to monitor with an intensity similar to that described for patients with T1DM: four times per day before meals; with weekly checks at least once after breakfast, lunch, dinner, and at mid-sleep; and with symptoms. Some ask for sets of glycemic readings more infrequently (e.g., fasting and 1 hour after the biggest meal). In the subset of patients who achieve stable blood glucose levels without significant hypoglycemia, it is

usually appropriate to decrease the frequency of SMBG to a few times a week. It is critical that SMBG be frequent enough that both patient and provider have a good understanding of the adequacy of the treatment regimen and the stability of glycemic control.

It has been widely assumed that the benefits of SMBG stem from the effect of putting patients in a situation in which they can be in control of their own therapy. If patients are aware of the glycemic targets associated with the outcomes they seek to achieve, SMBG enables them to critically evaluate their response to therapy and assure themselves that they are reaching their goals. It is useful for patients to keep a daily diary of their SMBG results, so that they can assess their results periodically and can share them with the health care team. Many patients faithfully perform daily or more frequent SMBG, record the results as instructed, and discuss them with their health care team only at quarterly or semiannual visits even though their control is inadequate. Unless SMBG results are generally within agreed target ranges, they should be communicated and reviewed at least monthly with a member of the health care team by telephone, fax, mail, or e-mail or at an interim visit to trigger changes in therapy as the need arises. Unfortunately, such services usually are not reimbursed and can become an unsustainable burden on health care teams.

One of the most difficult areas in which to keep current is the area of available equipment and supplies, particularly for glucose monitoring. A useful resource in this regard is the annual *Resource Guide*, which is published as the January issue of *Diabetes Forecast*, a magazine for lay people with diabetes and their families. The most recent issue is available online at www.forecast.diabetes.org (accessed December 2010).

Pharmacotherapy for Type 2 Diabetes

The revolution in the treatment of T2DM since 1995 in the United States has been driven by the release of several new classes of drugs that independently address different pathophysiologic mechanisms that contribute to the development of diabetes. The available oral antihyperglycemic agents can be divided by mechanism of action into several groups: insulin sensitizers with primary action in the liver, insulin sensitizers with primary action in peripheral tissues, insulin secretagogues, agents that slow the absorption of carbohydrates, insulins, agents that increase the activity of the incretin system, and novel agents whose influence on carbohydrate metabolism is still unclear. Insulin therapy in patients with T2DM effectively is a supplement to endogenous insulin secretion. The relative benefits of lifestyle intervention and the 13 classes of drugs available for the management of T2DM are shown in Table 31-11. This area has been the subject of extensive reviews.^{745,746,761-763} In the following discussion, the principles outlined in these reviews are summarized, and limited additional references are provided.

Insulin Sensitizers with Predominant Action in the Liver

Metformin is the only biguanide available in the United States. Phenformin was removed from the U.S. market in the 1970s because of deaths associated with lactic acidosis. Phenformin and buformin remain available in some countries. Although metformin has been available in Europe for approximately 40 years, it has been approved in the United States only since 1995. The precise mechanism of action of metformin is unknown; recent studies suggest that it

activates AMPK, an intracellular signal of depleted cellular energy stores that has been implicated in stimulation of skeletal muscle glucose uptake and inhibition of hepatic gluconeogenesis.⁷⁶⁴ The major clinical activity of metformin is to reduce hepatic insulin resistance and thereby gluconeogenesis and glucose production. It has more inconsistently improved insulin sensitivity in peripheral tissues. Because of its limited duration of action, it is usually taken at least twice daily, although a sustained-release formulation is now available.

Because biguanides do not increase insulin levels, they are not associated with a significant risk of hypoglycemia. The most common adverse events are gastrointestinal: nausea, diarrhea, crampy abdominal pain, and dysgeusia. About one third of patients have some gastrointestinal distress, particularly early in their course of treatment. This distress can be minimized by starting with a low dose once daily with meals and titrating upward slowly (over weeks) to effective doses. Sustained-release metformin is associated with less frequent and less severe upper gastrointestinal symptoms, the more common of the adverse effects of metformin, but it can increase the frequency of diarrhea, a much less common adverse effect overall. Most patients note no adverse effects with metformin therapy, and at least 90% tolerate it adequately with long-term use. Perhaps as a result of clinical or subclinical gastrointestinal effects, metformin is associated with less weight gain than other antihyperglycemic agents, and in some studies it has been associated with a modest weight loss.

Metformin has been said to cause lactic acidosis, which is quite rare and occurs almost exclusively in patients who are at high risk for development of the condition independent of metformin therapy.⁷⁶⁵ The package insert states that metformin is contraindicated in patients with renal insufficiency (male patients with a serum creatinine concentration of 1.5 mg/dL or higher or female patients with 1.4 mg/dL or higher). The drug is cleared renally. Because there is a complex relationship between serum creatinine and renal function, reasonable practice might suggest that metformin can safely be used in patients with an estimated glomerular filtration rate (eGFR) based on the Modification of Diet in Renal Disease (MDRD) equation down to 30 mL/min per 1.73 m², with dose reduction to a maximum daily dose of 1000 mg when the eGFR falls below about 50 mL/min per 1.73 m².⁷⁶⁶ Metformin is also contraindicated in patients with hepatic insufficiency and in the setting of alcohol abuse. Some patients taking metformin develop progressive vitamin B₁₂ deficiency, which may be prevented with calcium coadministration.⁷⁶⁷

The glucose-lowering efficacy and the prevalence of adverse gastrointestinal effects of metformin increase proportionately in the dose range of 500 to 2000 mg/day. The maximal daily dose of 2550 mg does not generally provide additional benefit beyond that seen at 2000 mg daily. Newer formulations of metformin combined with various classes of oral antihyperglycemic agents have been developed to maximize glucose-lowering effectiveness with a single prescription through the synergy of two classes of agents with different actions.

Arguably, metformin has the best record among oral antihyperglycemic agents in outcome studies. In the UKPDS, among overweight subjects, those randomly assigned to metformin not only had improvements in microvascular complications similar to those of subjects randomly assigned to insulin and sulfonylurea but also demonstrated reduced rates of diabetes-related death and MI.⁷³⁸ However, the validity of this observation has been challenged because of unusual responses in a subsequent

TABLE 31-1-1 Comparison of Therapies for Type 2 Diabetes

subrandomization. The beneficial effect of metformin on macrovascular complications through mechanisms independent of glycemic control is certainly plausible and is supported by such observations as metformin-associated modest reductions in LDL, triglycerides, blood pressure, and procoagulant factors. The ADA has recently published a consensus statement on medical management that suggests initiation of metformin therapy in all patients with T2DM (absent contraindications) at or near the time of diagnosis of diabetes.⁷⁴⁷

Insulin Sensitizers with Predominant Action in Peripheral Insulin-Sensitive Tissues

The thiazolidinedione class of drugs (TZDs or glitazones) has engendered great enthusiasm and controversy since the first agent, troglitazone, was approved in 1997. Rare fatal hepatotoxicity was associated with troglitazone, and it was withdrawn from the U.S. market in 2000, largely because the other TZDs (pioglitazone and rosiglitazone) were thought to be safer. These agents are believed to work through binding and modulation of the activity of a family of nuclear transcription factors termed *peroxisome proliferator-activated receptors* (PPARs). They are associated with slow improvement in glycemic control over weeks to months in parallel with an improvement in insulin sensitivity and a reduction in FFA levels.

Each of these agents varies in important ways with regard to potency, pharmacokinetics, metabolism, binding characteristics, and demonstrated lipid effects. At the same time, all are effective glucose-lowering agents that are generally well tolerated. The only significant early adverse effects are weight gain and fluid retention (and associated edema formation and hemodilution). There is no substantial evidence that these newer agents are associated with hepatotoxicity, but a record of safety has been established in appropriate patients. Patients should have liver function tests before beginning TZD therapy. TZDs are contraindicated in patients with active hepatocellular disease and in patients with unexplained serum alanine aminotransferase (ALT) levels greater than 2.5 times the upper limit of normal.

Pioglitazone and rosiglitazone are equally effective glucose-lowering agents with similar adverse effect profiles. They also provide equivalent improvements in markers of insulin resistance and inflammation. They differ with respect to lipid effects. In a head-to-head study among dyslipidemic patients, pioglitazone reduced triglycerides by approximately 20%, whereas rosiglitazone increased triglycerides on average by 5%. Pioglitazone is associated with a modestly greater improvement in HDL particle number and size and an improvement in LDL particle size and number. Rosiglitazone was associated with an increase in LDL particle number and improved LDL particle size.⁷⁶⁸

The promise of the glitazone class to reverse or prevent the negative cardiovascular associations of insulin resistance, in parallel with its demonstrated effect of improving insulin sensitivity, was suggested by a series of associations: reduced carotid intimal medial thickness, normalization of vascular endothelial function, improvements in dyslipidemia, lower blood pressure, and improved fibrinolytic and coagulation parameters. The PROactive Study was a randomized, double-blind, placebo-controlled trial in 5238 patients with T2DM and documented macrovascular disease. Subjects were randomized to placebo or to 45 mg/day of pioglitazone and otherwise treated according to guidelines for hyperglycemia and major cardiovascular risk factors. The primary end point was the time from

randomization to a broad set of macrovascular end points. Pioglitazone was associated with a 10% reduction in the primary end point, but the reduction was not statistically significant. However, for the principal secondary end point, time from randomization to any cause of mortality, nonfatal MI (excluding silent MI), and stroke, pioglitazone therapy was associated with a 16% reduction, which was marginally statistically significant. Subsequent analysis and discussion of this technically negative and somewhat flawed trial has been extensive and supports the notion that pioglitazone therapy is associated with reductions in cardiovascular events that are largely accounted for by improvements in glycemia, lipids, and blood pressure. The benefits were in part mitigated by an increased incidence of heart failure, weight gain, and edema.⁷⁶⁹

The RECORD trial was an open-label study that compared the effect of adding rosiglitazone versus either metformin or sulfonylurea to patients who had T2DM inadequately controlled with sulfonylurea or metformin. There was no difference in cardiovascular hospitalizations or death.⁷⁷⁰ There has been a brewing controversy that perhaps rosiglitazone is associated with excess MI, with some calling for its withdrawal from the market.⁷⁷¹ Although there are no definitive data to prove this allegation, it has resulted in dramatic shifts in the marketplace away from rosiglitazone use.

A second attribute of the glitazones that has generated great enthusiasm is an improvement in insulin secretory dynamics in subjects with diabetes and IGT. More importantly, the ADOPT trial in patients with early diabetes demonstrated a lesser rate of secondary glycemic failure in patients treated with rosiglitazone, compared with metformin, and both showed a lesser failure rate than glyburide; these benefits were correlated with indices of beta-cell function.⁷⁷² Several trials have demonstrated the remarkable effectiveness of thiazolidinediones to delay or prevent the development of diabetes, with greater magnitude than has been reported for other antihyperglycemic agents.⁷

The glitazones have the best track record in regard to slowing the progressive nature of beta-cell deterioration, and this may have important implications for long-term prognosis. On the other hand, multiple adverse effects of the class have raised concerns; these effects include weight gain, fluid retention, and increased risk of bone fractures. Careful study indicates that the weight gain is a result of both fluid retention and subcutaneous (but not visceral) fat accumulation. There is, in fact, a reduction in visceral fat, hepatic fat, and intramyocellular fat. Therefore, it has been argued that the weight gain observed with glitazones may not have the same negative metabolic consequences that are generally ascribed to overweight and obesity. Nevertheless, weight gain is viewed negatively by most patients and practitioners. All patients prescribed glitazones should be counseled to redouble lifestyle efforts to minimize weight gain.

With regard to edema, with appropriate caution, almost no one should need to withdraw from therapy as a result of fluid retention. The patients most likely to experience edema are those treated with insulin and those with preexisting edema. Therefore, women, overweight patients, and patients with diastolic dysfunction or renal insufficiency are at greatest risk. It is prudent to teach patients with preexisting edema how to assess pitting pretibial edema at home and to suggest that they make a habit of checking nightly. If they note a pattern of increasing edema at home, patients can be instructed to restrict sodium intake, to start a diuretic, or to increase their diuretic dosage by some specified quantity on their own as needed.

In the previously edematous patient and in patients treated with insulin, it is prudent to initiate therapy with the lowest available dose of glitazone. In 1 to 3 months, if the glycemic response has been inadequate and significant edema has not developed, consider increasing the dose of glitazone further, with continued expectant home evaluation for edema. Most patients with mild edema respond to a thiazide diuretic or spironolactone. In patients with more extensive edema, combination therapy with a moderate-dose loop diuretic is sometimes required.⁷⁷³ Anecdotal reports suggest that avoidance of nonsteroidal anti-inflammatory agents and dihydropyridine calcium channel blockers can reduce the frequency of edema as an adverse event. Fluid retention to the point of congestive heart failure and anasarca has been reported; in the PROactive and RECORD studies, an excess of approximately 2% of patients treated with high-dose glitazones required hospitalization for heart failure. In some patients, edema is refractory to diuretic therapy. Edema resolves with a reduction of glitazone dose in some patients, but some require drug withdrawal.

A more recent safety concern regarding thiazolidinediones is bone health. In pharmacoepidemiologic studies and in randomized, controlled trials, excess fractures have been reported, mainly in older women. Whereas distal sites were primarily affected in these studies, small randomized, controlled trials have identified loss of bone density in the lumbar spine as well. Preclinical studies suggest that activation of PPAR γ inhibits bone formation by diverting stem cells from the osteogenic to the adipocytic lineage. No data are available with respect to the prevention or management of thiazolidinedione-related bone loss, but prudent measures would include at a minimum an assessment of risk factors and appropriate bone density screening.⁷⁷⁴

An early and universal role for thiazolidinediones has been advocated by some because of their beta-cell effects.¹¹ Use of thiazolidinediones early in the natural history of disease creates maximum opportunities for beta-cell benefits, and the risk of heart failure related to fluid retention is also less; however, early use also increases the potential for long-term consequences related to weight gain and bone loss. Efforts to improve safety by creating agents with more selective effects continue.⁷⁷⁵

Insulin Secretagogues

Currently available insulin secretagogues all bind to the sulfonylurea receptor (SUR1), a subunit of the K_{ATP} potassium channel on the plasma membrane of pancreatic beta cells. The SUR1 subunit regulates the activity of the channel and also binds ATP and ADP, effectively functioning as a glucose sensor and trigger for insulin secretion. Sulfonylurea binding leads to closing of the channel, as do increases in intracellular ATP and decreases in ADP resulting from fuel metabolism. The membrane depolarization that ensues causes the opening of voltage-dependent L-type calcium channels. Subsequent calcium influx results in an increase in intracellular calcium, which leads to insulin secretion. Differences in pharmacokinetic and binding properties of the various insulin secretagogues result in the specific responses that each agent produces. The major differences among the insulin secretagogues seem to be related to duration of action and to subtle variations in hypoglycemic potential.

Sulfonylureas. The sulfonylureas have been available since the 1950s. They have a relatively slow onset and a variable duration of action. The numerous choices available (Table 31-12) can be divided into first- and second-generation agents. In general, the second-generation agents are more potent and, as a result, have fewer adverse effects and drug-drug interactions. Extended-release glipizide and glimepiride are preferred agents because they can be given once daily in most patients and involve a relatively low risk of hypoglycemia and weight gain. Glipizide is not available in the United States but is a similarly preferred agent in much of the world. Nonetheless, glyburide is one of the most commonly prescribed insulin secretagogues, even in the face of concerns about its potential cardiovascular toxicity and higher risks of hypoglycemia compared with other secretagogues.^{761,776}

An unusual characteristic of sulfonylureas is that the maximum marketed dose is two to four times higher than the maximum effective dose. There has been concern that sulfonylureas might cause increased arrhythmic cardiovascular events in patients with diabetes as a result of their activity on vascular and cardiac SUR2 receptors that blunts

TABLE 31-12

Characteristics of Sulfonylureas

Drug	Initial Daily Dose	Maximum Daily Dose	Equivalent Doses (mg)	Duration of Action	Comments
Acetohexamide	250 mg	1500 mg, div bid	500	Int: 12-18 hr	Metabolized by liver to active metabolite twice as potent as parent compound. Has diuretic activity. Has uricosuric activity.
Chlorpropamide	100 mg	750 mg (500 mg in older patients)	250	Very long: 60 hr	70% metabolized by liver to less active metabolites; 30% excreted intact by kidneys. Can potentiate ADH. Disulfiram-like reaction with alcohol occurs in almost 1/3 of patients.
Tolazamide	100 mg	1000 mg, div bid	250	Int: 12-24 hr	Metabolized by liver to less active and inactive products. Has diuretic activity.
Tolbutamide	250-500 mg or tid	3000 mg, div bid	1000	Short: 6-12 hr	Metabolized by liver to inactive product.
Glipizide	5 mg	40 mg, div bid	5	Int: 12-24 hr	Metabolized by liver to inactive products that are excreted in the urine and, to a lesser extent, in the bile. Mild diuretic activity.
Glipizide ER	5 mg	20 mg qd	5	Long: >24 hr	
Glyburide	2.5 mg	20 mg, div bid	5	Int: 16-24 hr	Metabolized by liver to weakly active and inactive products, excreted in urine and bile. Mild diuretic activity. Highest risk of hypoglycemia.
Micronized glyburide	3 mg	6 mg bid	3	Shorter	
Glimepiride	1 mg	8 mg qd	2	Long: >24 hr	Metabolized to inactive metabolites by liver; excreted in urine and bile.

div, divided; int, intermediate.

ischemic preconditioning, a protective autoregulatory mechanism in the heart. On the other hand, of the three recent cardiovascular outcome studies examining the effects of more intensive glycemic control on cardiovascular outcomes, only the ADVANCE trial, which employed the sulfonylurea glimepiride as its dominant strategy, did not exhibit any suggestion of cardiovascular toxicity.^{741,777}

Sulfonylureas are arguably the most cost-effective glucose-lowering agents. In general, limiting the dose to one fourth of the maximum marketed dose, unless higher doses are clearly demonstrated to provide significant benefits in glycemic control, minimizes costs and adverse events. Small doses of sulfonylurea (e.g., 0.5 to 1 mg of glimepiride or 2.5 mg of extended-release glipizide) are remarkably effective, particularly in patients receiving concomitant insulin-sensitizing therapy, and are almost uniformly well tolerated.

Glinides. Repaglinide is a member of the meglitinide family of insulin secretagogues, distinct from the sulfonylureas. It has a short half-life and a distinct SUR1 binding site. As a result of more rapid absorption, it produces a generally faster and briefer stimulus to insulin secretion. As a result, it is typically taken with each meal and provides better postprandial control and generally less hypoglycemia and weight gain than glyburide. Repaglinide does seem to have a long residence time on the sulfonylurea receptor and a prolonged effect on FPG, even though its pharmacologic half-life is quite short. Repaglinide is available in 0.5-, 1-, and 2-mg tablets. The maximum dose is 4 mg with each meal. As with the sulfonylureas, there is only a modest glucose-lowering advantage of high doses compared with moderate doses of repaglinide.

Nateglinide is a derivative of phenylalanine and is structurally distinct from both sulfonylureas and the meglitinides. It has a quicker onset and a shorter duration of action than repaglinide. Its interaction with SUR1 is fleeting. As a result, its effect in lowering postprandial glucose is quite specific, and it has little effect in lowering FPG. This provides both advantages (less hypoglycemia) and disadvantages (less overall glucose-lowering effectiveness). Nateglinide is most appropriately used when FPG levels are modestly elevated in early diabetes or in combination with insulin sensitizers or long-acting evening insulin. Nateglinide is available as 120-mg tablets and is taken with each meal. A 60-mg tablet is available but is not generally used except in patients with minimal hyperglycemia.

The rationale for stimulating insulin secretion in a way that minimizes fasting hyperinsulinemia and maximizes postprandial control is compelling. Furthermore, these newer agents demonstrate little binding to the vascular smooth muscle and cardiac SUR2 receptors. However, the use in the United States of these newer glinide agents has been modest, in part because of the need for multiple daily doses, greater expense than with sulfonylureas, and lack of

head-to-head comparative studies that demonstrate superiority over newer sulfonylureas, which are already perceived as having low potential for producing hypoglycemia and weight gain.

Carbohydrate Absorption Inhibitors: α -Glucosidase Inhibitors

α -Glucosidase inhibitors (AGIs) work to inhibit the terminal step of carbohydrate digestion at the brush border of the intestinal epithelium. As a result, carbohydrate absorption is shifted more distally in the intestine and is delayed, allowing the sluggish insulin secretory dynamics characteristic of T2DM to catch up with carbohydrate absorption.

There are two currently available agents, acarbose and miglitol. Voglibose is available in other countries. The use of AGIs in the United States has been limited by a number of factors, including the need to administer the medication at the beginning of each meal, flatulence as a common side effect, and only modest reductions in blood glucose levels. These factors should be balanced against the ability of AGIs to lower postprandial glucose, thereby improving glycemia without increasing weight or hypoglycemic risk. Even though they potentially lower glucose in everyone, the extent of the lowering is modest, calling into question the utility of these agents in light of the substantial expense and side effects. On the other hand, there is evidence that acarbose improves cardiovascular outcomes better than most antihyperglycemic agents.⁷⁷⁸

To maximize the potential for these agents to be well tolerated, start with a low dose (e.g., one fourth of the maximum dose) just once daily and increase over a period of weeks or months to one quarter to one half of the maximum dose with each meal.

Insulins

Insulin has been commercially available since the early 1920s and is arguably still the mainstay of therapy for most people with T2DM worldwide. Subcutaneous injection of insulin in T2DM is designed to supplement endogenous production of insulin both in the basal state, to modulate hepatic glucose production, and in the postprandial state, in which a surge in insulin release normally facilitates glucose clearance into muscle and fat for storage to allow intraprandial metabolism. Currently, almost all insulin used worldwide is of recombinant human origin or an analogue. The available formulations largely differ in their pharmacokinetics, as shown in Table 31-13.

Insulin lispro, insulin aspart, and insulin glulisine are rapid-acting insulin analogues that have an onset of action in 5 to 15 minutes, peak activity in approximately 1 hour, and duration of activity of approximately 4 hours. Regular insulin is approximately half as fast as the rapid-acting analogues, with onset in 30 minutes, a peak at 2 to 4 hours, and duration of action of 6 to 8 hours or longer. Regular

TABLE 31-13

Pharmacology of Insulin

Duration	Insulin	Peak (hr)	Duration (hr)	Forms and Modifiers	Variability in Absorption
Rapid	Lispro, aspart, glulisine	~1	3-4	Analogue, monomeric	Minimal
Short	Regular	2-4	6-8	None	Moderate
Intermediate	NPH	4-8	12-16	Protamine	High
Long	Glargine	No distinct peak	~24	Analogue, precipitates at neutral pH	Moderate
	Detemir	No distinct peak	~24 (less at doses <20-30 units)	Analogue with fatty-acid side chain	Minimal

human insulin, when administered intravenously, is instantly effective, with a half-life on the order of 10 minutes. Administered intramuscularly, regular human insulin has a half-life of approximately 20 minutes. Rapid-acting insulin analogues do not exhibit discernible advantages on intravenous or intramuscular administration.

Neutral protamine Hagedorn (NPH) is the only intermediate-acting insulin available since Lente insulin was withdrawn from the market. Onset, peak, and duration are about twofold greater than those of regular insulin, with an onset of action in 1 to 2 hours, a peak at 4 to 8 hours, and a duration of action of 12 to 16 hours.

Ultralente insulin is no longer available as human long-acting insulin. Insulin glargine is a long-acting insulin analogue that is solubilized in acid but precipitates when neutralized in tissues on injection, producing no consistent or distinctive peak in activity and a duration of action of more than 24 hours in most patients. Insulin detemir is a long-acting analogue in which a fatty-acid side chain has been covalently bound to the insulin molecule; it remains soluble both in the vial and in tissues and has a duration of action of approximately 24 hours except at low doses (<20 to 30 units).

Premixed insulin formulations provide greater convenience and accuracy of mixing than those mixed by patients but at the expense of reduced flexibility. Premixed formulations available in the United States are 70/30 and 50/50 mixtures of NPH and regular insulin, a 75/25 and a 50/50 mixture of lispro insulin in its NPH-like formulation with insulin lispro, and a 70/30 mixture of insulin aspart with its NPH-like congener. Premixed insulin provides a profile of activity as expected from the addition of the activities of its components.

The tactics of insulin administration in the setting of T2DM are the focus of great debate and strong opinion. Questions remain regarding the relative benefits of analogue insulins in light of the approximately threefold greater expense and whether the greater convenience of low-complexity regimens is justifiable in comparison with the greater risk associated with lesser flexibility in dosing, particularly in T2DM.^{7,779,780} Adverse events associated with insulin are well known and include weight gain and hypoglycemia. Both fast-acting and long-acting insulin analogues have been shown to provide a modest reduction in hypoglycemia. Insulin allergies are rare, as are chronic skin reactions, which include lipodystrophy and lipohypertrophy. The absolute risk of severe hypoglycemia in patients with T2DM is relatively small, approximately one third to one tenth as high as in similarly treated patients with T1DM. This risk can be further minimized with appropriate education of patients and expectant home glucose monitoring at times when unrecognized hypoglycemia is most likely to occur, such as at midsleep or during unplanned or strenuous activity.

Newer insulin needles cause less discomfort than those previously available because of a finer gauge, shorter length, sharper points, and smoother surfaces. Insulin pen technology makes teaching a patient to take insulin much easier and provides greater convenience and accuracy of dosing. Insulin pump therapy has been used in patients with T2DM but is not widely accepted as cost-effective in routine use.

Incretin-Related Therapies

The incretin effect describes the observation that oral glucose has a greater stimulatory effect on insulin secretion than does intravenous glucose at the same circulating glucose concentration. In humans, this effect seems to be

primarily mediated by GLP1 and GIP. GLP1 is produced from the proglucagon gene in intestinal L cells and is secreted in response to nutrients. GLP1 stimulates insulin secretion in a glucose-dependent fashion, inhibits inappropriate hyperglucagonemia, slows gastric emptying, reduces appetite and improves satiety, and has beta-cell proliferative, antiapoptotic, and differentiation effects at least in vitro and in preclinical models. GLP1 has a very short half-life in plasma (1 to 2 minutes) due to amino-terminal degradation by the enzyme dipeptidyl peptidase IV (DPP4). A variety of pharmacologic techniques have been developed to harness the potential of GLP1 signaling to treat diabetes, including GLP1 receptor agonists, which are peptides that produce increases of 10-fold or higher in GLP1 activity, and DPP4 inhibitors, which are small-molecule inhibitors of the degradation of GLP1 and GIP as well as other hormones.⁷⁸¹

GLP1 Receptor Agonists. Exendin-4 is a naturally occurring component of the saliva of the Gila monster (*Heterodermus suspectum*) and shares 53% sequence identity with GLP1; it is resistant to DPP4 degradation. Exenatide is synthetic exendin-4 and was the first GLP1-based therapeutic agent to be approved for human use. When injected subcutaneously, it produces the effects listed earlier and has a peak of action and half-life of approximately 2 hours. With twice-daily injection within 1 hour before a meal, it produces a reduction of approximately 1% in HbA_{1c}, driven largely by a reduction in postprandial glucose along with modest weight loss (average, 5 to 10 lb/year). With prolonged use, weight loss has been associated with expected improvements in blood pressure and lipids. The most common adverse effect is nausea, which occurs in 40% to 50% of patients, usually early in the course of therapy. The nausea is mild to moderate in intensity and typically wanes over time. Nausea leads to withdrawal of therapy in about 5% of patients.

Hypoglycemia is not an effect of exenatide, but it can amplify the hypoglycemic effects of other agents. Therefore, for coadministration with secretagogues, it is recommended that the minimum dose of secretagogue be used when initiating exenatide, uptitrating the secretagogue later if necessary. A concern that emerged from postmarketing reports is pancreatitis. A causal link has not been proven, nor has a mechanism been established. Nevertheless, it is recommended that incretin based therapy be avoided in those with a history of pancreatitis.⁷⁸¹ Exenatide is renally cleared and is not tolerated in the setting of advanced kidney disease (eGFR <30 mL/min per 1.73 m²). Cases of acute renal failure have been reported in association with exenatide therapy, usually in patients with chronic renal insufficiency who develop superimposed pre-renal azotemia in the context of prolonged nausea, anorexia, and/or vomiting.

Newer, longer-acting GLP1 receptor agonists include liraglutide and once-weekly exenatide. In general, these longer-acting agents are associated with greater HbA_{1c}-lowering efficacy due to more predominant effects on FPG. They are also associated with less gastrointestinal adverse effects, probably because they seem to produce little or no gastric emptying effects. Arguably, they are more convenient and therefore promote greater patient adherence. Liraglutide is administered once daily without any restriction as to timing or relation to meals. Once-weekly exenatide requires reconstitution and a somewhat larger bore needle for administration.

Weight loss is similar among the various GLP1 receptor agonists.^{782,783} A new safety concern that arose in

preclinical testing with these long-acting agents is medullary thyroid cancer. No signal exists for this problem with GLP1-based therapy in humans, but there is a clear increase in the incidence of these tumors in rodents, although not in other animal models. GLP1 plays a role in regulation of C cells in the rodent but apparently not in the human. Nevertheless, it is suggested that these agents be avoided in those with a personal or family history of medullary thyroid cancer.⁷⁸¹

DPP4 Inhibitors. Two DPP4 inhibitors, sitagliptin and saxagliptin, are available in the United States. Two more (vildagliptin and alogliptin) are available elsewhere, and numerous others are under development. These agents produce approximately twofold increases in fasting and postprandial GLP1 and GIP levels, with subsequent HbA_{1c} reductions of approximately 0.7%. They are remarkably well tolerated, with an adverse effect profile similar to that of placebo. Specifically, they are not associated with nausea. Probably because of the lesser increase in GLP1 activity than with the GLP1 receptor agonists, there is no weight loss with DPP4 inhibitors; they tend to be weight neutral.

Postmarketing cases of pancreatitis have been reported for the DPP4 inhibitors, and they are contraindicated for use in those with a prior history. Specificity for DPP4 appears to be crucial, because less specific inhibitors have demonstrated adverse effects on immune function and cancer growth in animal studies. Although the currently marketed DPP4 inhibitors are thought to be highly selective, continued long-term surveillance for unexpected adverse events is essential. A nice feature of these agents is that they do not require titration. The usual dose is the maximum marketed dose; because these drugs are cleared renally, smaller doses are recommended in the setting of stage 3 or greater chronic kidney disease. Serious hypersensitivity reactions have been reported, including anaphylaxis, angioedema, and exfoliative skin conditions with sitagliptin, but causality has not been substantiated due to the rarity of events. The weight neutrality, lack of hypoglycemia, broad applicability, tolerability, and ease of use create a unique niche for DPP4 inhibitors.⁷⁸⁴

The precise role of incretin-related therapies in diabetes management has not been established; cost, modest efficacy and uncertain long-term safety remain barriers to use. That said, preclinical and in vitro studies suggest that they may have benefits on the progression of beta-cell failure as well as cardiovascular health. There are no data yet to substantiate those hopes in humans, although long-term outcome studies are under way.⁷⁸⁵

Novel Agents

Amylinomimetics. Amylin is a neuroendocrine hormone that is cosecreted with insulin by pancreatic beta cells. As would be expected, amylin deficiencies are evident in patients with T1DM or T2DM, in parallel with the insulin deficiencies. Amylin and insulin have complementary actions in regulating plasma glucose. Amylin binds to brain nuclei. It promotes satiety and reduces appetite, and through vagal efferents it mediates a decrease in the rate of gastric emptying. It also regulates suppression of glucagon secretion in a glucose-dependent fashion, thus regulating the rate of glucose appearance from the gastrointestinal tract and the liver. Insulin, on the other hand, regulates the rate of glucose disappearance from the circulation by stimulating glucose uptake in muscle and fat.

Amylin is relatively insoluble in aqueous solution and aggregates on plastic and glass. Pramlintide was developed as a soluble, nonaggregating, equipotent amylin analogue.

It is indicated for patients with insulin-treated T2DM for mealtime subcutaneous injection. In patients with T2DM, when pramlintide was added to insulin therapy with or without a sulfonylurea or metformin, HbA_{1c} was reduced by about 0.5 to 0.7 percentage points, and weight was reduced by about 0.5 lb/month.⁷⁸⁶

Mild nausea, which wanes with continued therapy, is the most common adverse effect. It is minimized by titrating the dose from 60 µg with meals to the usual 120 µg over 3 to 7 days as tolerated. Hypoglycemia is less frequent in patients with T2DM than in patients with T1DM, who do occasionally exhibit severe hypoglycemia. Prandial insulin should be reduced by 50% when initiating therapy, although subsequent retitration to higher doses is often required.

Oral medications that require rapid absorption for effectiveness should be administered either 1 hour before or 2 hours after injection of pramlintide.

Colesevelam. Colesevelam is a second-generation bile acid sequestrant. It was observed to mediate modest reductions in glucose during the clinical development program. An expanded program in patients with T2DM resulted in approval for marketing of this drug as an adjunct for the treatment of diabetes. It provides an HbA_{1c} reduction of about 0.5% in addition to approximately 15% improvement in LDL. HDL changes tend to be trivial. Triglycerides can increase by 5% to 20%. Gastrointestinal side effects affect 10% or more of patients but lead to withdrawals uncommonly. The mechanisms for the glycemic effects are not definitively known.⁷⁸⁷

Bromocriptine. A quick-release formulation of bromocriptine administered within 2 hours of rising in the morning has been developed and is approved by regulatory authorities in the United States, although it is not yet marketed for the treatment of T2DM. It is suggested that creating a circadian peak in central dopaminergic tone improves insulin sensitivity. Nausea is the most common adverse effect, occurring in about 30% of patients and leading to discontinuation in about 10% at highest doses; lower doses are better tolerated. HbA_{1c} reductions are generally modest but have been reported to be as high as 1.2%. In a 1-year safety study, broad cardiovascular outcomes were improved 40% compared with placebo. Although the formulation examined in these studies is not available currently, bromocriptine remains a possibility for future combination therapy.⁷⁸⁸

Practical Aspects of Initiating and Progressively Managing Type 2 Diabetes

A significant challenge in clinical decision making in diabetes is that the increased availability of therapeutic options for antihyperglycemic therapy is far ahead of adequate prospective outcome studies. Currently available clinical trial data have not identified the preferred agents in T2DM, either as initial therapy or in subsequent care. Each class of drugs and even individual agents within each class have advantages and limitations, and individual issues can significantly affect the appropriate choice of therapy in particular patients. Table 31-14 highlights some of the relative advantages and disadvantages of various agents and classes.

General Approach

A general approach in the absence of any patient-specific factors is suggested in the algorithm presented in Figure 31-20.⁷ A growing body of experience suggests that the use

TABLE 31-14

Classes of Antihyperglycemic Therapy

Class	Representative Agents	Major Action	HbA _{1c} Lowering (%)	Fasting or Prandial Effect	Usual Dosing Frequency (Doses/Day)	Route	Hypoglycemia	Weight Effect	CVD Risk Factor Benefits	Important Contraindications	Daily Cost (\$)

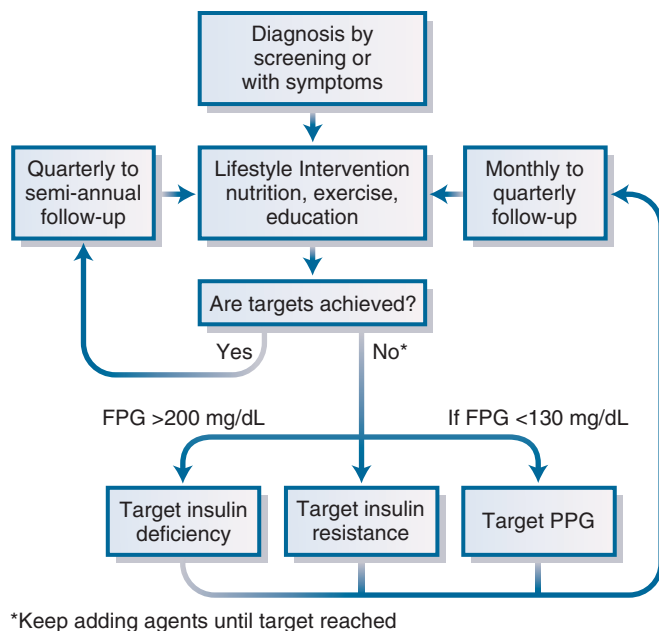

Figure 31-20 Treatment algorithm for type 2 diabetes. Reinforce lifestyle interventions at every visit, and check glycosylated hemoglobin (HbA_{1c}) every 3 months until the HbA_{1c} is less than 7% and then at least every 6 months. The interventions should be changed if the HbA_{1c} is 7% or higher. FPG, fasting plasma glucose; PPG, postprandial plasma glucose. (From American Diabetes Association. Standards of medical care in diabetes—2010. *Diabetes Care*. 2010;29:s11-s61.)

of metformin as initial therapy in combination with diet, exercise, and a comprehensive diabetes education program can provide impressive lowering of glucose with essentially no risk of hypoglycemia. Because metformin is available as a generic preparation, relative cost is low, and if the response is judged to be inadequate, essentially any other agent can be added. There are four potential second-line therapies. Sulfonylurea and insulin are termed “well-validated therapies” but are often complicated by hypoglycemia. The alternative nonhypoglycemic, “less well-validated therapies” are pioglitazone and GLP1 receptor agonists. The latter has the additional advantage of promoting weight loss. Certainly other alternatives exist although they may provide no distinct advantage over these four. The combination of metformin and a DPP4 inhibitor is generally well tolerated, is not associated with weight gain or hypoglycemia, and has become quite popular. Insulin plus metformin is suggested as the final common therapy for most patients with diabetes who do not achieve adequate control otherwise.

Patients with higher levels of glucose (typically HbA_{1c} ≥8.5%) almost always require agents to increase insulin levels. Because insulin, sulfonylureas, and glinides provide much faster improvements in overall control than other agents, they are preferred in patients with higher blood glucose levels, either as monotherapy or as part of initial combined therapy. Starting a patient with a low dose of a sulfonylurea or insulin combined with either metformin or glitazone is a reasonable initial approach to the patient with poor glucose control. Some advocate starting patients who have higher levels of HbA_{1c} with two agents as initial therapy.⁷⁴⁵

In patients who have reasonable control of FPG and preprandial plasma glucose (PPG) levels (i.e., more than 50% of values being <130 mg/dL) whose overall control as assessed by HbA_{1c} is still higher than desired, monitoring

may be either inaccurate ineffective, or PPG levels may be elevated. Because it can be more difficult to have patients monitor in the postprandial state, almost all patients with T2DM have elevated PPG in the absence of specific therapy. In such patients, targeting presumed PPG elevations with the use of AGIs, glinides, exenatide, or rapid-acting insulin analogues can theoretically lower average glucose levels with a lower risk of weight gain and hypoglycemia compared with sulfonylureas or long-acting insulin.

The most critical issue in long-term glycemic management is that of continuously reassessing with patients the adequacy of their control, examining glucose monitoring logs and HbA_{1c} values, and refining treatment regimens to achieve optimal control with the lowest doses of the fewest medications. Most patients in specialty care require two or more drugs to achieve recommended targets. Many patients require three or more (particularly if long-acting and short-acting insulin are considered as two agents). Almost all of the possible two-drug combinations and many of the three-drug combinations have been examined in modest-sized studies and have been shown to be safe and effective. In general, it is preferred to add agents if there was an improvement in control with the first agent selected and to continue to add agents as needed to achieve goals. Subsequent back-titration to optimize treatment is often possible after glycemic goals are achieved. The selection of initial therapy should be based on priorities mutually recognized by the patient and provider. Increasingly, practitioners are using combinations of submaximal doses of agents to increase the ratio of efficacy to adverse effects and in recognition of the potential synergy of sensitizers and secretagogues as well as the value of treatment of PPG and FPG with combination therapy.

When adding insulin in the management of inadequately controlled T2DM, some practitioners prefer to stop the oral antihyperglycemic agents and switch to insulin. Most continue the oral agents and add an evening dose of insulin. Classically, bedtime NPH insulin and, more recently, long-acting insulin analogues have been preferred for initiating insulin therapy. There are data suggesting that long-acting analogues can provide for lower morning glucose values with less nocturnal hypoglycemia or weight gain than NPH insulin, particularly in more overweight patients. Many patients eventually require more complex regimens, such as twice-daily injections or multiple-injection regimens, but insulin pump therapy is only rarely required.

Some advocate starting multiple-injection therapy with rapid-acting insulin at each meal if adequate control is not achieved with basal insulin. Although the finding is not intuitive, recent data suggest that adding a single injection of rapid-acting insulin (at the morning meal or at the largest meal) to basal insulin titrated to provide for FPG control provides for a similar level of HbA_{1c} as the multiple-injection regimen with less weight gain and hypoglycemia. As one progresses from an injection of basal insulin plus a single injection of rapid-acting insulin to higher-order regimens, it seems incumbent on the health care team to ensure that improved control develops or to simplify the regimen. Studies suggest that to achieve HbA_{1c} levels lower than 7%, many patients require insulin doses on the order of 1 to 2 units/kg per day in addition to metformin. In the typical patient with insulin-resistant T2DM, there is usually little advantage to splitting basal insulin into two injections; in general, if a second injection is needed it should be prandial insulin.

It is important that both patient and health care provider agree on how to reach the goals of therapy. Therefore,

biases and concerns of the patient should be addressed when trying to determine which agent should be prescribed. These biases can be elucidated in interviews with patients through discussions of various strategies.

Strategies

Minimal Cost Strategy. For a large fraction of patients, particularly those who are elderly, the cost of drugs is an overwhelming issue. Diet and exercise can be extremely effective and are almost cost-free. The least expensive drugs for the treatment of diabetes are the sulfonylureas, and metformin and human insulin are relatively inexpensive. Therefore, a minimum-cost strategy could start with a sulfonylurea or metformin or both and progress to the addition of bedtime NPH insulin. Although insulin is relatively inexpensive, at high doses ($\geq 1\text{U/kg}$) the costs begin to rise and the benefits are modest, creating a rationale for adding a thiazolidinedione. Most pharmaceutical companies have programs to provide no-cost or low-cost medications to the poor. Many of these are listed with links on the NeedyMeds web site (<http://www.needymeds.com> [accessed December 2010]). For an increasing number of patients, the major driving force in their drug expenses is the number of prescriptions, because each is associated with a copayment. This provides another rationale for the use of combination agents.

Minimal Weight Gain Strategy. Weight gain associated with the treatment of diabetes is of concern to most clinicians and is often an overriding issue with patients. A strategy to minimize weight gain would emphasize diet and exercise and would almost certainly employ metformin as initial therapy. GLP1 receptor agonists are associated with substantial weight loss in most patients with long-term use, and they would almost always be used as second-line therapy if weight were truly the major consideration. AGIs, DPP4 inhibitors, colesevelam, and bromocriptine are all weight neutral.

Minimal Progressive Beta-Cell Loss Strategy. Progressive loss of beta-cell function is the hallmark of diabetes. It results in progressive deterioration of glycemic control and the eventual need for insulin treatment. Thiazolidinediones seem to be associated with the lowest rate of secondary failure and sulfonylurea with the highest, at least in comparison to metformin. Adoption of a strategy to minimize progressive beta-cell loss would lead to the use of a thiazolidinedione with metformin as initial therapies and the avoidance of secretagogues. GLP1 receptor agonists and DPP4 inhibitors have been associated with improvements in beta-cell mass in rodent models, but this is completely unproven in humans.

Minimal Injection Strategy. Too many patients are determined to avoid insulin injections at any cost. The minimal injection strategy could involve the use of almost any combination of oral agents. Metformin and thiazolidinediones in combination with either sulfonylureas or DPP4 inhibitors have been best studied. Injected insulin or a GLP1 receptor agonist would be added only if absolutely necessary. The strategy of using thiazolidinediones early in the course of diabetes, in the hope that this might reduce the rate of progressive beta-cell dysfunction, would be rational in this setting. It is important to try to dispel notions that insulin therapy is difficult, ominous, or fraught with peril by highlighting its efficacy and the great strides that have been made in insulin formulations and delivery devices. Most diabetic patients require insulin at some point in

their lifetime. Quite a few patients who have resisted the use of insulin have not balked at GLP1 receptor agonists. This suggests that, although patients may have identified the needle as the predominant barrier to insulin therapy, they really had other biases driving their fears.

Minimal Insulin Resistance Strategy. The possible athrogenic effects of insulin have been widely touted in the lay press and by marketing programs within the pharmaceutical industry. The relationship between circulating insulin levels and cardiovascular risk in nondiabetic populations is incontrovertible but is probably related to the presence of insulin resistance rather than the insulin concentrations per se. Furthermore, in essentially all studies of intensive management with insulin, improved outcomes were observed with insulin treatment. There are no clinical data to suggest that exogenous insulin is associated with adverse side effects or long-term complications beyond its hypoglycemic effects and the associated weight gain. A recent trial compared an insulin-providing strategy and an insulin-sparing strategy in high-risk patients in terms of mortality; there were essentially no differences in cardiovascular outcomes.⁷⁸⁹ Adoption of a strategy to minimize insulin resistance would lead to the use of metformin and a thiazolidinedione before consideration of adding an AGI, DPP4 inhibitor, or GLP1 receptor agonist. Nateglinide is associated with more specific stimulation of insulin levels after meals than the other insulin secretagogues, which all increase peripheral insulin levels less than injected insulin does.

Minimal Effort Strategy. Many patients are capable of making only a minimal effort with regard to their diabetes. Questioning patients about their pill-taking history and their realistic ability to comply with a prescribed frequency of therapy is important. Twice-daily therapy is a barrier to metformin use. Taking a once-a-day sulfonylurea, DPP4 inhibitor, or thiazolidinedione requires the least effort by the patient. The use of basal insulin or a GLP1 receptor agonist is relatively well accepted by patients to whom this consideration is important. Developing strategies to improve adherence and increase motivation is a long-term goal in this population.

Hypoglycemia Avoidance Strategy. Hypoglycemia avoidance is another important consideration for many patients. The AGIs and glitazones have been reported in small studies to reduce reactive hypoglycemia. Theoretically, GLP1 receptor agonists, DPP4 inhibitors, and metformin should not be associated with hypoglycemia. Other oral agents could be added in any order, with the exception that insulin secretagogues would be added last, their dose minimized, and glyburide avoided. Nateglinide in particular among the secretagogues is associated with an exceptionally low risk of significant hypoglycemia. Basal insulin strategies seem to be associated with a lower risk of hypoglycemia than prandial insulin.⁷⁹⁰ The long-acting insulin analogue detemir seems to be associated with a substantially lower risk of hypoglycemia than NPH and perhaps modestly less hypoglycemic risk than glargine.

Postprandial Targeting Strategy. Achieving postprandial glucose targets is generally associated with better control than just meeting premeal targets.⁷⁹¹ On the basis of epidemiologic studies, it has been suggested that PPG is more highly correlated with cardiovascular disease risk than FPG. However, correction for confounding variables such as components of the multiple metabolic syndrome has not

been performed in these studies. Furthermore, there are no outcome studies that have demonstrated the superiority of these approaches in patients with T2DM.

Control of postprandial glycemia can be achieved only with specific lifestyle efforts and pharmacologic agents that target PPG. PPG monitoring is helpful in this regard because it reinforces the goals and is the most effective measure to assess the effectiveness of treatment. Nonpharmacologic techniques that can improve postprandial control include lowering the carbohydrate content of meals, adding fiber, substituting monounsaturated fats for carbohydrates, and encouraging physical activity after meals. The pharmacologic approach includes AGIs, exenatide, and rapid-acting insulin analogues. Nateglinide and repaglinide provide a theoretical advantage in this situation compared with other secretagogues, although formal head-to-head studies comparing the glinides with glimepiride and sustained-release glipizide have not been completed.

Preventing Type 2 Diabetes

The possibility that T2DM can be prevented in high-risk persons has been formally tested in a series of clinical trials reviewed elsewhere.⁷ Lifestyle intervention seems to provide for a reduction of 30% to 60% in progression to diabetes over a 3- to 5-year time frame. These benefits seem to be sustained and best correlated with weight loss; however, the average sustained weight loss in these trials was modest, on the order of 5%. Metformin has likewise been associated with a somewhat more modest reduction in the progression of diabetes, although the benefit seemed to be similar to that of lifestyle intervention in those patients younger than 45 years of age, those with BMI greater than 35 kg/m², and those with an FPG level greater than 110 mg/dL. On average, metformin was generally without effect in patients older than 60 years of age, those with a BMI of less than 30 kg/m², and those with an FPG of less than 100 mg/dL. Acarbose has also been shown to reduce progression to diabetes, without evidence of diminished efficacy in different subgroups. The thiazolidinediones seem to be the most active antihyperglycemic agents tested for prevention, with efficacy as great as or greater than that of lifestyle intervention. However, concern regarding the long-term safety of thiazolidinediones in relation to effects on weight, heart, and bones has limited the enthusiasm for use of this class for prevention.

The success of the lifestyle interventions is impressive, demonstrating conclusively that with a variety of techniques it is possible for patients to achieve physiologically relevant changes in body weight. It is unknown whether lifestyle plus medications provides even greater benefit. The questions that arise are how to screen for people at risk and what intervention should be initiated in those with an interest in prevention. It seems reasonable to screen on the basis of current recommendations, as outlined earlier primarily for case finding, but also recognizing that patients with abnormal glucose values (HbA_{1c} >5.7% and particularly ≥6%, FPG ≥100 mg/dL and particularly ≥110 mg/dL, or IGT) would be ideal candidates for preventive strategies. Certainly, high-risk persons should be counseled about nutritional approaches to achieve weight loss, instructed to increase physical activity, and observed prospectively to determine whether progression of hyperglycemia has occurred. Treatment for other cardiovascular risk factors should also be considered if they are present.

In the absence of outcome studies, it is difficult to strongly advocate for drug therapy to prevent diabetes, because significant diabetes complications are unlikely to

develop in the short window of time during which glucose levels increase from an FPG of 100 to 126 mg/dL. On the other hand, metformin therapy seems innocuous enough, and its benefits are broad; therefore, consideration of metformin therapy in patients who are at particularly high risk is recommended.⁷ An extension phase of the Diabetes Prevention Program that is under way should provide evidence concerning whether prevention or delay in the development of diabetes will prevent death or disability.

Future Directions

The present-day management of T2DM is significantly more effective and easier for patients than the situation that prevailed even in the 1990s. A better understanding of the barriers to effective diabetes management and how to overcome them would be of great benefit. Changes in the health care system in the United States promise to eradicate access to care as the major barrier to prevention of disabling complications. The epidemic in diabetes and obesity that is under way, coupled with the predicted early death and disability that follow, threatens to overwhelm health care systems globally. Screening for diabetes or prediabetes may be cost-saving.⁷⁹² Practical, cost-effective public health approaches to stem this tide are desperately needed.⁷⁹³ Whether new blockbuster drugs exist in the pipeline of 235 novel pharmaceutical agents for the treatment of diabetes and its complications is uncertain.⁷⁹⁴ Although the prognosis for people with diabetes has never been better, the major challenges that they face relate to the complexity and cost of care. The opportunities for therapies that broadly address the metabolic underpinnings and consequences of diabetes are enormous.

Type 1 Diabetes Mellitus

GEORGE S. EISENBARTH • JOHN B. BUSE

In 1984, Sutherland and coworkers¹ transplanted the tail of the pancreas from nondiabetic identical twins to their twin mates who had type 1 diabetes mellitus (T1DM). In contrast to the transplantation of organs such as kidneys, in which the transplants are accepted between identical twins, the pancreatic islets (but not acinar pancreas) were rapidly destroyed.¹ The diabetes of the twin transplant recipients was cured for only a matter of weeks. In retrospect, these results were predictable, given the autoimmune nature of type 1A diabetes and similar results in animal models of the disorder.² Since that time, T1DM became one of the most intensively studied autoimmune disorders, and the National Institutes of Health has designated type 1A diabetes a Priority One target for the development of a preventive immunologic vaccine. Knowledge of the immunogenetics and immunopathogenesis of type 1A diabetes is beginning to influence clinical care,³ greatly influences current clinical research, and will, we hope, lead to successful strategies for disease prevention.⁴

DIFFERENTIAL DIAGNOSIS OF TYPE 1 DIABETES

An expert committee of the American Diabetes Association (ADA), with its etiologic diagnostic criteria (Table 32-1), has

recommended dividing T1DM into type 1A (immune-mediated) and type 1B (other forms of diabetes with severe insulin deficiency).⁵ At the onset of diabetes, distinguishing type 1A diabetes from type 2 diabetes (T2DM), let alone type 1B diabetes, is not always a simple task. The best current criterion for diagnosis of type 1A diabetes is the presence of anti-islet autoantibodies measured with highly specific (and reasonably sensitive) autoantibody radioassays.⁶

The presence of autoantibodies with assays defined as positive in fewer than 1 of 100 control subjects (specificity $\geq 99\%$) is reasonably diagnostic of type 1A diabetes. Non-Hispanic white children presenting with diabetes usually have type 1A diabetes, whereas adults older than 40 years usually have T2DM.⁷ More than 90% of such children presenting with diabetes express one of four measured anti-islet autoantibodies (see later discussion). In contrast, among black or Latin American children, almost one half lack any autoantibody.⁸⁻¹⁰ Most of these children appear to have an early age at onset of type 2 diabetes mellitus, many have attendant risk factors such as obesity, and many lack human leukocyte antigen (HLA) alleles associated with type 1A diabetes (discussed later).

Imagawa and coworkers¹¹ described an unusual form of diabetes in which the patients had a normal glycosylated hemoglobin (HbA_{1c}) level despite severe hyperglycemia,

TABLE 32-1

Differential Diagnosis of Type 1A Diabetes

Diabetes Type	Anti-Islet Autoantibodies	Genetics	Comments
Type 1A	Positive >90%	HLA 30-50% DR3 and DR4 HLA 90% DR3 or DR4 HLA <3% DQB1*0602	90% non-Hispanic white children 50% black children 50% Latin American children
Type 1B	Negative	Unknown	Rare in whites
Type 2	Negative	Unknown	If Ab ⁺ , likely LADA, and HLA is similar to type 1A
Other	Negative	MODY mutations, other syndromes	

Ab, antibody; HLA, human leukocyte antigen; LADA, latent autoimmune diabetes adult; MODY, maturity-onset diabetes of the young.

suggesting that the diabetes had been present for only a short time. Histologic examination of pancreatic sections demonstrated pancreatitis but no insulinitis, and anti-islet autoantibodies were not detected. It is not clear whether this represents one of the first examples of type 1B diabetes, although a fulminant type 1A is possible and later studies indicated that a large fraction of these patients have HLA alleles associated with type 1A diabetes.

Obesity does not protect a person from developing type 1A diabetes, although it is usually associated with insulin-resistant forms of diabetes. It is also important to realize that patients can have both insulin resistance and type 1A diabetes, and such autoantibody-positive patients with both conditions can present with diabetes with high levels of fasting insulin or C peptide but loss of stimulated insulin secretion. With current assays for anti-islet autoantibodies, a subset of children with type 1A diabetes will test negative for the autoantibodies. Uncommonly, some children, when they progress to diabetes, lose expression of all autoantibodies by the time of diagnosis.¹² Such type 1A autoantibody-negative children typically have HLA alleles associated with type 1A diabetes; are not insulin resistant; may present with ketoacidosis; and, with time, lose C-peptide secretion. However, the diagnosis is not clear at diabetes onset, and with current laboratory tests, designations such as positive or negative for anti-islet autoantibodies are more accurate.

ANIMAL MODELS OF TYPE 1A DIABETES

In relation to other autoimmune disorders, type 1A diabetes is unusual in having a series of spontaneous animal models of the disease.¹³⁻¹⁶ These animal models provide clues to potential mechanisms of pathogenesis and allow testing of therapies for disease prevention. As for most animal models, only some therapeutic results translate into efficacy in humans.¹⁴ It should also be recognized that many of the spontaneous animal models are inbred and are not diallelic at any locus, whereas all humans have different alleles at tens of thousands of loci. Therefore, each animal model might or might not provide insights into one of the forms of human diabetes.

Despite these caveats, the animal models are remarkably similar to humans in a number of key immunologic parameters. The most notable include the importance of the major histocompatibility complex (MHC) for disease and the presence of lymphocytic islet invasion followed by specific destruction of islet beta cells. For reasons that are currently unclear given specific HLA molecules, humans, rats, and mice have a marked propensity for autoimmunity directed at islet beta cells. This propensity may be related to a specific lack of tolerance to a single islet molecule such as insulin, to a specific sensitivity of islet beta cells to immune-mediated destruction, or to factors not currently appreciated. It is likely that understanding of this propensity will lead to effective therapies.

Polygenic Spontaneous Animal Models: Nonobese Diabetic Mouse

The nonobese diabetic (NOD) mouse is the most intensively studied animal model.¹⁷ As with type 1A diabetes of humans, specific HLA class II and class I molecules are central for disease pathogenesis (see later discussion).^{18,19} The NOD mouse has mutations that cause absence of the I-E (histocompatibility) molecule (similar to human DR) and an unusual I-A molecule (similar to human DQ).²⁰ The I-A molecule in the NOD mouse is termed I-A^g,⁷ which designates a specific amino acid sequence. HLA class II molecules (in humans there are three—DP, DQ, and DR) function to bind peptides and present these peptides to the T-cell receptor of CD4-positive (helper or Th2) T lymphocytes. The HLA genes were termed *immune response genes* because common variations in their sequences (allelic variation) determine the peptides to which an individual mouse or person can mount a T-cell response. Therefore, a central role for these molecules in immune function and autoimmunity is expected.

If the lack of I-E expression is corrected in the NOD mouse with introduction of an I-E transgene, diabetes is prevented.²¹ If a different I-A sequence is introduced as a transgene into the NOD mouse, diabetes is also prevented.²² In addition to these class II molecules determining diabetes susceptibility, more than 15 other genetic loci contribute to disease, each with a relatively small contribution, each neither necessary nor sufficient.²³⁻²⁶ Therefore, inheritance of diabetes in the NOD mouse is polygenic. One way the NOD mouse differs from humans is that more female than male NOD mice develop diabetes.

NOD mice, like humans, produce anti-insulin autoantibodies before developing diabetes.²⁷ Autoantibodies usually appear between 6 and 8 weeks of age, and diabetes usually develops after 16 weeks of age. Studies of islet beta-cell mass indicate that islet beta-cell destruction and beta-cell regeneration are present months before the onset of diabetes,²⁸ although there is convincing evidence of an acceleration of beta-cell destruction at disease onset.²⁹⁻³¹ T cells, and not autoantibodies, mediate islet beta-cell destruction, and clones of T cells that react with several antigens are able to transfer disease.³²⁻³⁵ A large number of T-cell clones that react with insulin³⁶ or with other antigens have been characterized. There is debate about whether any given autoantigen is primary, although studies have provided evidence for a central role of T-cell autoimmunity directed at insulin.³⁶ In addition, lymphocytes and autoantibodies contribute to pathogenesis.

Diabetes can be prevented in the NOD mouse by more than 100 different therapies.¹⁴ Most, but not all, of these therapies target the immune system, and a number of them are now in clinical trials in humans. Consistent with

mediation of diabetes by T lymphocytes, immunosuppression or genes that block T-cell function prevent disease.

Some of the most interesting therapies use autoantigens as vaccines; in particular, both glutamic acid decarboxylase (GAD) and insulin, when administered to the NOD mice, prevented diabetes.³⁷⁻⁴⁰ The insulin molecule does not have to be metabolically active, and a dominant insulin peptide, insulin peptide B(9-23), given as a single subcutaneous injection, prevented diabetes in 90% of susceptible NOD mice.³² It is thought that vaccination prevents diabetes by generating Th2 T lymphocytes that produce transforming growth factor- β (TGF- β); these T cells target an islet molecule (e.g., insulin) but produce protective cytokines (e.g., interleukin 4 [IL4], IL-10, TGF- β) when they home to the islets.

Oligogenic Animal Models

BioBreeding Rat

The BioBreeding (BB) rat was the first intensively studied animal model of type 1A diabetes. The diabetes in this model differs from human diabetes in that diabetes-prone BB rats have an autosomal recessive mutation that produces a severe T-cell lymphopenia.⁴² Infection with a number of viruses, presumably activating innate immunity, can induce diabetes in a related strain of rat that does not have lymphopenia, termed the *BB diabetes-resistant* (BB-DR) rat. As in humans and the NOD mouse, the disease depends on specific class II alleles (similar to human HLA-DR and HLA-DQ) of the MHC, in particular RT1-U. Diabetes can be induced to develop in a series of rat strains with RT1-U (see later discussion). Anti-inflammatory drugs given after infection can prevent diabetes, and this might have relevance to humans if the timing of the triggering of autoimmunity could be defined. Additional genes segregate to create diabetes susceptibility in these rat strains, but the number of genes is much less than for NOD mice.⁴¹⁻⁴³

Prevention of diabetes in BB rats is more difficult than in NOD mice, possibly related to the severe T-cell lymphopenia, which results from mutation of an *Ian* gene inherited in an autosomal recessive manner.⁴⁴ For example, insulin administration to BB rats prevented both diabetes and insulinitis, but, in contrast to NOD mice, metabolically active insulin and insulin doses high enough to induce hypoglycemia were usually required for prevention.^{45,46}

Long-Evans Tokushima Lean Rat

Like BB rats, the Long-Evans Tokushima Lean (LETL) rat strain has the RT1-U alleles and has an oligogenic inheritance of diabetes with mutation of a gene (*Cbl-b*) that alters T-cell signaling.⁴⁷⁻⁴⁹

Induced Models of Type 1A Diabetes

Diabetes or insulinitis can be induced in several strains of animals by means of drugs that induce islet destruction and broadly activate immune responses or by specific islet antigens. The drug streptozotocin is directly toxic to islet beta cells. In high doses, it rapidly induces diabetes. In low doses, a more chronic diabetes develops that is likely to have some immunologic derivation.^{50,51} Administration of copolymer of polyinosinic and polycytidylic acids (poly-IC), a simple polynucleotide that activates production of interferon- α (IFN- α) when administered to a number of rat strains with the diabetes-susceptible RT1-U alleles, induced insulinitis and diabetes.⁵² This suggests that many animals

are susceptible to diabetes or insulinitis given a strong immunologic stimulus. Treatment with IFN- α in humans has been associated with the development of anti-islet autoantibodies and with acceleration of diabetes development in patients with anti-islet autoantibodies.⁵³

HISTOPATHOLOGY OF TYPE 1A DIABETES

As in animal models, type 1A diabetes of humans is characterized by selective destruction of the beta cells within islets.⁵⁴⁻⁵⁷ The non-insulin-producing cells of the islets remain in patients with long-standing T1DM, and these remaining islets, lacking insulinitis and beta cells, are termed *pseudoatrophic*. A remarkable feature of the pancreas of patients with new-onset diabetes is heterogeneity of islet lesions. Within the same section of pancreas, a normal islet with no infiltrate can coexist with an islet containing beta cells with intense infiltration and a pseudoatrophic islet that has no infiltrate. This spottiness of the pathologic process is reminiscent of the destruction of areas of the skin in patients with vitiligo, in which melanocytes are destroyed in patches. Such heterogeneity of lesions may underlie the chronic development of type 1A diabetes in humans.

Islets of patients with type 1A diabetes overexpress class I HLA antigens, rarely if ever express class II HLA molecules on beta cells, express IFN- α , and are reported to upregulate Fas molecules on all islet cells.^{55,58-60} The hypothesis that class II HLA expression contributes directly to beta-cell autoimmunity is controversial. The specific way in which the immune system destroys beta cells is not known, but molecules such as Fas may be important, because T cells expressing Fas ligand may induce apoptosis of beta cells.⁶¹⁻⁶³ Cytokines (e.g., IL-1) and CD8⁺ cytotoxic lymphocytes are also likely to contribute to beta cell destruction.⁶⁴⁻⁷⁰

Searches for viral particles and viral RNA within islets of patients with new-onset diabetes have been unrewarding, but newer technologies and concepts should facilitate additional studies, and it is likely that there is heterogeneity among patients.^{70,71} In contrast to the islets of patients with new-onset diabetes, the pancreata of identical twin donors have been described as normal, and the pancreata from the few studied patients with long-standing diabetes were composed of pseudoatrophic islets without markers of immune activation, with a subset of patients having retained islet beta cells within patches⁵⁴ with relatively little insulinitis.

GENETICS OF TYPE 1A DIABETES

It has long been recognized that diabetes is a heterogeneous group of disorders. It is also becoming apparent that type 1A diabetes is heterogeneous. There are probably many genetic forms of type 1A diabetes, and most forms are influenced by HLA class II molecules.⁷² This group of disorders is likely to be linked by the presence of immunologic abnormalities that foster loss of tolerance to self-antigens. Patients with specific HLA class I and class II molecules with immune dysfunction are susceptible to target islet autoantigens.

Many of the genes underlying diabetes susceptibility are similar in diverse countries, although specific alleles of those genes differ in their frequency.⁷³ Several monogenic forms of type 1A diabetes can now be identified. It is not

clear whether these genetically characterized forms of diabetes should now be included in the group of other defined causes of diabetes.⁵

Monogenic Forms of Type 1A Diabetes

Autoimmune Polyendocrine Syndrome Type 1 (AIRE Gene)

The autoimmune polyendocrine syndrome type 1 (APS-1) is rare, with an increased incidence in Finland and Sardinia and among Iranian Jews, but it has a worldwide occurrence. The disorders of the syndrome, such as T1DM, mucocutaneous candidiasis, hypoparathyroidism, Addison's disease, and hepatitis (see Chapter 37 for a more detailed discussion) identify a unique syndrome, and patients with this group of disorders almost always have mutations (usually autosomal recessive, although one family with dominant mutation has been identified) of the autoimmune regulator gene (*AIRE*) on chromosome 21. This gene encodes a DNA-binding protein. Studies of this gene with its expression in the thymus indicate that it may play an important role in maintaining self-tolerance and influences the expression of what are termed *peripheral antigens* (e.g., insulin) in the thymus. It is hypothesized that greater expression of insulin and other tissue-specific antigens leads to tolerance and disease suppression.⁷⁴

There is considerable variability in the diseases expressed even for siblings with the same mutation. Some of this variability is likely to be influenced by genetic loci other than the *AIRE* gene. One example is the observation that although 18% of patients with APS-1 develop T1DM, those with the common diabetes-protective HLA allele DQB*10602 appear to have some protection from diabetes but not from Addison's disease.

X-Linked Polyendocrinopathy, Immune Dysfunction, and Diarrhea (Scurfy Gene)

The syndrome of X-linked polyendocrinopathy, immune dysfunction, and diarrhea (XPID, also termed IPEX) is associated with overwhelming neonatal autoimmunity, and most children die in the first few days of life or in infancy.⁷⁵⁻⁷⁸ In this syndrome, lymphocytes invade multiple organs. It is associated with insulinitis and beta-cell destruction as well as lymphocytic intestinal inflammation with flattened villi and severe malabsorption. It is inherited as an X-linked recessive disease affecting only boys, with a frequent clinical history of lack of male births.

The disease results from mutations of the gene encoding forkhead box P3 (*FOXP3*), whose function as a transcription factor has been elucidated.^{75,79,80} This gene functions as a master switch for regulatory (suppressor) CD4+/CD25+ T lymphocytes. Lack of such regulatory T cells leads to overwhelming autoimmunity in humans and mice. This is an important syndrome to recognize, because bone marrow transplantation with restoration of T-regulatory cells (even with partial chimerism) is therapeutic.

Idiopathic Type 1A Diabetes

Descriptive Genetics

In the United States, the risk of childhood diabetes is approximately 1 in 300.⁸¹ This is 15-fold less than the diabetes risk for a first-degree relative of a patient with T1DM (Table 32-2). It is 150-fold less than the risk for a monozygotic twin of a patient with T1DM.^{82,83} Although the population risk of T1DM in Japan is 15-fold less than in the

TABLE 32-2

Risk of Type 1A Diabetes

Proband with DM	% Childhood DM (Annual Incidence)	Anti-Islet Autoantibody	Comment
U.S. general population	0.3% (15-25/100,000)	3% single Ab; 0.3% multiple Abs	Japanese incidence 1/100,000; incidence increasing in United States and many European countries; Colorado now 25/100,000
Offspring	1%		4.1%
Sibling	3.2%; 6% lifetime		7.4%
Dizygotic twin	6%		10%
Mother	2%	5%	Lower risk than offspring of father with DM
Father	4.6%	6.5%	
Both parents	10%?		?
MZT	50%, but incidence varies with age of index twin	50%	MZT in Japan, 40% risk of DM

Ab, antibody; DM, diabetes mellitus; MZT, monozygotic twin.

United States, the risk for an identical twin in Japan is similar to that for an identical twin in the United States.^{84,85} This suggests that when genetic susceptibility is present, either in Japan or in the United States, the diabetes risk is extremely high.

Although the risk of diabetes is much greater for relatives of patients with type 1A diabetes, it is important to realize that most persons (>85%) in whom type 1A diabetes develops do not have a first-degree relative with the disease. The incidence of sporadic cases results in part because almost 40% of persons in the general population carry high-risk HLA alleles for type 1A diabetes (see "[The Major Histocompatibility Complex](#)").

The highest known incidence of type 1A diabetes is found in Finland and Sardinia. Finland now has an annual incidence approaching 50 per 100,000 children. Since the 1960s, the incidence has increased almost threefold, suggesting a dramatic environmental change (either an increase of causative factors or a decrease of protective factors), and it is doubling in many Western countries, including the United States, every 20 years.

Twin Studies

Twin studies of diabetes have an impressive pedigree. The study of monozygotic twins of patients with diabetes by Pyke and coworkers⁸⁶ contributed to the recognition of distinct forms of diabetes, initially termed adult-onset and juvenile-onset, later insulin-dependent and non-insulin-dependent, and now type 1 and type 2 diabetes.⁵ The concordance rates for monozygotic and dizygotic twins provide important information regarding genetic factors contributing to a given disease, because monozygotic twins share all germline-inherited polymorphisms or mutations, whereas dizygotic twins are similar to siblings of patients with a disease and have only half of their genes in common. For a locus that contributes to disease in a recessive manner,

only one quarter of dizygotic twins would be homozygous to a sibling with diabetes at that locus, but all monozygotic twins would be homozygous for all recessive loci of their diabetic twin. Although overall concordance rates of monozygotic twins for T1DM are calculated, it is likely that type 1 diabetes is heterogeneous and that groups of monozygotic twins have different genetic etiologies for their diabetes. With such genetic heterogeneity, one would expect different concordance rates for different genetic etiologies.

Redondo and coworkers⁸⁷ analyzed prospective follow-up data from a large series of initially discordant monozygotic twins from Great Britain combined with a series from the United States. Progression to diabetes was identical for both series of twins. There was no length of time of discordance beyond which a monozygotic twin of a patient with T1DM did not have a risk of developing T1DM. Nevertheless, the hazard rate for development of diabetes decreased as the period of discordance increased. There was also a marked variation in the risk of diabetes relative to the age at which diabetes developed in the index twin. With long-term follow-up, the overall rate of concordance for monozygotic twins exceeds 50%.⁸⁸ However, if T1DM developed in the index twin after age 25 years, the concordance rate by life table analysis in Redondo's study was less than 10% (Fig. 32-1). If diabetes developed in the index twin before age 5 years, the concordance rate was 70% after 40 years of follow-up. Environmental factors, random factors, and non-germline-inherited variations (e.g., imprinting, T-cell receptor polymorphisms, somatic mutations) contribute to diabetes risk.

Figure 32-1 Progression to diabetes of initially discordant monozygotic twins of patients with type 1 diabetes subdivided by the age at diabetes onset of the first twin to develop diabetes (proband). Late progression to diabetes is evident, with some twins becoming diabetic more than 20 years after their twin mate. For discordant twins whose twin mate developed diabetes after age 25 years, the risk of diabetes is less than 10%. (From Redondo MJ, Yu L, Hawa M, et al. Heterogeneity of type 1 diabetes: analysis of monozygotic twins in Great Britain and the United States. *Diabetologia*. 2001;44:354-362.)

TABLE 32-3

Associated Autoimmune Diseases

Disease	AUTOANTIBODY		Disease Prevalence (%)
	Type	Percentage	
Addison's disease ⁹¹	21-Hydroxylase	1.5	0.5
Celiac disease ⁹⁰	Transglutaminase	12	6
Pernicious anemia ⁹²	Parietal cell	21	2.6
Thyroiditis or Graves' disease	Peroxidase or thyroglobulin	25	4

An important unanswered question (given the limited number and size of studies) is whether dizygotic twins of patients with type 1A diabetes have a diabetes risk greater than that of siblings. If the risk is identical, it suggests that environmental factors whose presence is time-dependent (e.g., uncommon infections) have little influence on the development of diabetes. Dizygotic twins differ from siblings in terms of a greater commonality of environment over time (e.g., common pregnancy). Studies of dizygotic twins suggest that their risk of diabetes may not differ from that of siblings or at most may be increased by a factor of 2 compared with the 10-fold increase for monozygotic twins.^{87a}

Genetic factors influence not only the development of diabetes but also the expression of anti-islet autoantibodies. For identical twins, the expression of anti-islet autoantibodies is tightly linked to the eventual progression to overt diabetes, and monozygotic twins have a high prevalence of expression of autoantibodies.⁸³ Dizygotic twins much less often express anti-islet autoantibodies, and the prevalence is similar to that of siblings.⁸⁹

Associated Autoimmune Disorders

Because type 1A diabetes is an immune-mediated illness that develops in a genetically susceptible person, it is not surprising that most patients with type 1A diabetes have one or more additional autoimmune diseases. The most common associated disorders are thyroid autoimmunity (Graves' disease or Hashimoto's thyroiditis) and celiac disease (Table 32-3).

The Major Histocompatibility Complex

The most important loci determining the risk of T1DM are within the MHC on chromosome 6p21 (Fig. 32-2), in particular the HLA class II molecules (DR, DQ, and DP).^{19,93-95} In addition, the standard class I loci (HLA A, B, and C) influence disease, and it is likely that additional loci within or linked to the MHC that influence immune function contribute to diabetes risk.⁹⁶ Figure 32-2 illustrates the MHC. The nomenclature for alleles of this region is somewhat daunting, but with definitions of several terms and a description of the basis for classification it is comprehensible.

The function of HLA molecules is to present peptides to T lymphocytes. Each molecule is made up of two chains, and each chain is encoded by a separate gene. These molecules are extremely polymorphic in amino acid sequence. Each polymorphic variant of each chain is designated with a gene locus name (e.g., DRB1) followed by an asterisk (*), followed by two digits referring to the serologic specificity (from the time when typing was performed with antibodies), followed by two digits for the specific allele (now

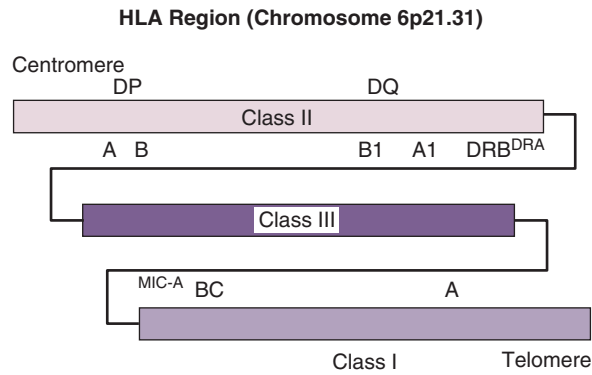

Figure 32-2 Genes within the human leukocyte antigen (HLA) region (major histocompatibility complex) with HLA class I, class II, and class III regions illustrated. Each class II molecule is made up of two chains. DRB alleles are polymorphic; DRA does not vary. DQA and DQB molecules are both polymorphic, as are DPA and DPB. The class III region contains important genes such as complement components and the tumor necrosis factor- α gene. The class I region includes MIC-A and MIC-B genes as well as the classic histocompatibility HLA genes, A, B, and C.

determined with DNA-based typing), followed by a single digit to distinguish silent nucleotide polymorphisms (nucleotide differences that do not change the amino acid sequence). For example, the designated allele DRB1*0405 has DR4 serologic specificity and is associated with high diabetes risk. For DR alleles, usually only the DRB chain is specified, because the DRA chain is not polymorphic. Likewise, for the class I molecules (A, B, and C), only a single chain is specified, because the other chain, β_2 -microglobulin, is minimally polymorphic. There are hundreds of known alleles of DRB1. Each person inherits two DRB1 alleles, one from each parent.

Because HLA gene loci are in close proximity to each other on the sixth chromosome, a group of alleles is usually inherited as a unit, and this is termed a *haplotype*. For example, the alleles A*0101, B*0801, DRB1*0301, and DQA1*0501, DQB1*0201 constitute a common haplotype associated with diabetes risk probably related to the presence of DRB1*0301. When specific alleles of different genes are nonrandomly associated with each other on a haplotype (e.g., A1, B8, and DR3), the alleles are said to be in *linkage disequilibrium*. Linkage disequilibrium is not the same as linkage, although to have linkage disequilibrium, genes must be linked. Genes are linked when they are close together on the same chromosome and thus transmitted from parent to child as a haplotype group. If alleles of linked genes are nonrandomly associated with each other in a population, they are in linkage disequilibrium.

Two MHC haplotypes, one inherited from each parent, constitute an individual's MHC genotype. This genotype ultimately determines the MHC-encoded risk of type 1A diabetes. For DQ molecules, both of the chains (DQA and DQB) are polymorphic. This adds an important level of diversity in that the protein chains encoded by the alleles of one haplotype can combine with the chains encoded by the other haplotype. For example, persons with the highest-risk genotype DRB1*0301, DQA1*0501, DQB1*0201 and DRB1*0405, DQA1*0301, DQB1*0302 can produce four different DQ molecules: the expected DQA1*0501, DQB1*0201 and DQA1*0301, DQB1*0302 but also DQA1*0501, DQB1*0302 and DQA1*0301, DQB1*0201. Studies suggest that the DQA1*0501, DQB1*0302 combination determines enhanced diabetes risk for DR3/4 individuals. The DQ molecule DQA1*0501, DQB1*0201 is also called DQ2, and

DQA1*0301, DQB1*0302 is called DQ8. A common DQ molecule, DQA1*0102, DQB1*0602, provides dominant protection from T1DM and is termed DQ6.

The major determinants of diabetes susceptibility are DR and DQ molecules, and specific alleles of both DR and DQ can either increase or decrease the risk of diabetes. Table 32-4 summarizes the diabetes risk associated with a number of DR and DQ haplotypes.^{96a}

In a number of studies, children from the general population or relatives of patients with T1DM have been HLA typed at birth.^{27,97,98} The typing is relatively straightforward and is based on direct DNA sequencing of polymerase chain reaction (PCR)-amplified DNA fragments or DNA probes that hybridize specifically to different allelic sequences. In Denver, Colorado, 2.4% of newborns have the highest-risk DR-DQ genotype for type 1A diabetes, namely DR3-DQ2 with DR4-DQ8 (DR3/4, DQ8/2 heterozygotes). Fifty percent of children younger than 10 years and approximately 30% of older children who develop diabetes have this highest-risk genotype. Approximately 1 of 16 children with the highest-risk HLA genotype from the general population progresses to diabetes (compared with a population risk of 1 per 300). Alternatively, 15 of 16 children from the general population who are DQ8/DQ2 heterozygotes do not develop diabetes. Studies indicate that newborn siblings of patients with T1DM who have DQ2 and DQ8 have a risk of expressing islet autoantibodies exceeding 40% by age 6 years, and 50% of these newborns will develop diabetes by age 10 years. This suggests that a genetic risk, especially MHC encoded, is extremely high.⁹⁹

Ninety-five percent of persons who develop diabetes have either DR3-DQ2 or DR4-DQ8, as do approximately 40% of the general population. The protective haplotype DRB1*1501, DQA1*0102, DQB1*0602 is present in 20% of the general population and in fewer than 3% of patients with type 1A diabetes. A DR allele, DRB1*1401, also appears to provide dominant protection.¹⁰⁰ There are additional high-risk haplotypes that are not common, such as DQA1*0401, DQB1*0402.¹⁰¹ It has been proposed as a simple rule that the presence of aspartic acid at position 57 of the DQ β chain and arginine at DQ α 52 is associated with

TABLE 32-4

Diabetes Risk of Representative DR and DQ Haplotypes

DRB1	DQA1	DQB1
High Risk		
0401 or 0403 or 0405	0301	0302 (DQ8)
0301	0501	0201 (DQ2)
Moderate Risk		
0801	0401	0402
0404	0301	0302
0101	0101	0501
0901	0301	0303
Moderate Protection		
0403	0301	0302
0701	0201	0201
1101	0501	0301
Strong Protection

1401	0101	0503
0701	0201	0303

diabetes risk.¹⁰² There are many exceptions to this rule, and knowledge of the complete sequences (allele) rather than dependence on this rule is essential.

Insulin Locus

In 1984, Bell and colleagues¹⁰³ published their discovery that variations in the number of nucleotide repeat elements located 5' of the insulin gene were associated with the development of type 1A diabetes. The longest group of repeats was associated with decreased diabetes risk. These studies have been replicated, and the locus of importance is clearly limited to the insulin gene.¹⁰⁴ The protective insulin gene polymorphism is associated with greater insulin messenger RNA (mRNA) expression within the thymus.^{105,106} Hanahan¹⁰⁷ advanced the hypothesis that within lymphoid organs there are "peripheral antigen expressing cells," which, for example, produce insulin, and that such expression leads to tolerance and thereby decreases the risk of diabetes. Therefore, for both the AIRE mutation of APS-1 and the effect of insulin gene mutations, the level of expression of insulin in the thymus may be critical. Higher levels can lead to deletion of anti-insulin T cells.

PTPN22 Gene

PTPN22, a gene encoding a lymphoid-specific phosphatase that influences T-cell receptor signaling, is the third confirmed gene influencing T1DM risk.¹⁰⁸ This gene influences T-cell receptor signaling, and the polymorphism associated with diabetes (Trp for Arg) blocks binding to a signaling molecule, CSK. Nevertheless, the relative risk associated with this polymorphism for T1DM and other autoimmune disorders, such as rheumatoid arthritis, is only 1.7. The variant associated with disease risk results in gain of function and decreased T cell receptor signaling.¹⁰⁹

Other Loci

There is an international effort to define additional genes that contribute to the development of type 1A diabetes. Polymorphisms of the cytotoxic T-lymphocyte-associated protein 4 gene (*CTLA4*; formerly called *ITIM2*) contribute to Graves' disease and apparently to diabetes in some but not all populations, with relative risks less than 1.3.¹¹⁰ A locus associated with the IL-2 receptor has a statistical association based on analysis of thousands of persons.¹¹¹

Recent genome-wide association studies have led to the identification of more than 40 loci having small effects on diabetes risk,¹¹² and detailed sequencing in one region identified rare mutations of a gene influencing IFN- α induction.¹¹³ At present only HLA typing is being used to define the risk of diabetes at birth. The defined risk can be extremely high, depending on the relationship to a proband with diabetes and the specific HLA genotype. For example, siblings of patients with type 1A diabetes with the DR3-DQ2/DR4-DQ8 genotype appear to have a diabetes risk that exceeds 50%.¹¹⁴ In contrast, children from the general population with the same HLA DR and DQ genotype have a risk of less than 6%. There is evidence that this extreme additional risk is due to genes linked to DR and DQ alleles, so siblings who can share both HLA haplotypes with a proband in addition to having DQ8-DQ2 alleles have a much higher risk than offspring of patients with T1DM or the general population.¹¹⁵

In addition to influencing diabetes risk, specific HLA genotypes contribute to the risk of associated autoimmune disorders. One third of DR3-DQ2 homozygous patients with type 1A diabetes express transglutaminase autoantibodies, and half of them have celiac disease on biopsy.¹¹⁶

ENVIRONMENTAL FACTORS

Despite decades of research, there is only one environmental factor clearly associated with type 1A diabetes, namely congenital rubella infection (see later discussion).¹¹⁷ The association of only one factor is probably related to the long prodromal phase that precedes type 1A diabetes, which makes the discovery of relevant environmental factors particularly difficult.

A number of factors can induce type 1A diabetes in animal models, one of the most interesting being the Kilham rat virus infection of BB-DR rats and other normal rat strains with RT1-U.¹¹⁸ In this model, which lacks the lymphopenia of the related BB strain, diabetes does not develop unless the animals are infected with Kilham virus (a parvovirus) or injected with poly-IC.⁵² Poly-IC mimics double-stranded RNA and induces high levels of IFN- α . The Kilham virus apparently does not directly infect islets and is thought to be an immune activator, similar to poly-IC. Diabetes induction depends on specific class II alleles termed RT1-U, and a number of animal strains with RT1-U are susceptible to diabetes.⁵²

In countries throughout the world, the incidence of type 1A diabetes is increasing, particularly for children in whom the disease develops before age 5 years.¹¹⁹⁻¹²¹ This is strong evidence that environmental factors related to diabetes risk have changed since the 1960s. Factors that increase diabetes risk may be increasing, or, just as likely, factors that suppress the development of diabetes may be decreasing. For example, in animal models of type 1A diabetes (NOD mouse and BB rat), infections with common viruses usually decrease the development of diabetes.

Infections

Congenital rubella, but not noncongenital infection, greatly increases the development of type 1A diabetes.¹²² Children with diabetes usually have high-risk HLA alleles,¹²³ and these children commonly have thyroid autoimmunity.¹²⁴ The way in which this congenital infection increases diabetes development is currently unknown. Hypotheses have ranged from potential molecular mimicry¹²⁵ to long-term alteration in T-cell function secondary to the congenital insult.¹²⁶

Enteroviruses are small RNA viruses that often infect young children. Initial anecdotal reports that Coxsackievirus infections might cause diabetes involved children who had severe infections and who died at diabetes onset.^{127,128} These studies preceded the realization that type 1A diabetes is not an acute disease, and it is likely that viral infection at the onset of T1DM is most often incidental. At the time of presentation with diabetes, almost all children have elevated HbA_{1c}, reflecting probably months of hyperglycemia preceding diagnosis. A description from Japan of persons with acute-onset diabetes and normal HbA_{1c}, elevated amylase, and infiltrates within the exocrine (but not endocrine) pancreas appears to represent a form of type 1B diabetes.¹¹

The potential importance of enteroviral infection was emphasized by studies from Scandinavia in which enteroviral infection was evaluated during pregnancy and in infancy. Infection is usually detected by changes in antiviral antibodies or detection of enteroviral RNA by molecular techniques.¹¹⁷ Although some studies have reported an increased incidence of enteroviral infection during pregnancy among mothers whose children later developed diabetes, others have not.^{129,130} As infants with a genetic risk

for the development of diabetes are followed from birth, it becomes possible to analyze prospectively the expression of enterovirus RNA. Enteroviral infection was found to be associated with the appearance of anti-islet autoantibodies.¹²⁹ However, similar studies from Denver, Colorado, did not find an association.¹³⁰ The major difference between the two studies appeared to be the lower rate of enteroviral infection in Finnish control subjects compared with Colorado control subjects.

Other viruses are being evaluated for association with the triggering of autoimmunity. One study from Australia found an association with rotavirus infection.¹³¹ Rotavirus infection is common in young children. The Australian study did not find an increase in rotavirus infection in children with T1DM compared with control subjects, but there was an association of rotavirus infection with increased anti-islet autoantibodies. Studies from Denver did not indicate an increase in rotavirus infection in infants developing autoantibodies.

Vaccination

It has been claimed that the timing of routine childhood vaccinations influences the development of type 1A diabetes.¹³² This is an important health concern if parents alter their family's childhood vaccination schedule because of concern about development of diabetes. A series of studies have been carried out¹³³⁻¹³⁵ and did not provide any evidence that childhood vaccinations influence the development of diabetes.

Diet

A disease such as celiac disease is critically dependent on the ingestion of a specific food, namely the wheat protein gliadin.¹³⁶ In addition, a number of dietary modifications have been found to alter the development of diabetes in NOD mice and BB rats.¹³⁷

Some investigators have championed the hypothesis that early introduction of bovine milk increases the development of diabetes, based primarily on retrospective studies associating early or increased bovine milk ingestion

(or less breast-feeding) with an increased risk of type 1A diabetes.¹³⁸ Several prospective studies in which infants were observed until the development of anti-islet autoantibodies failed to find an association or found only a weak association with either breast-feeding or bovine milk ingestion.¹³⁹⁻¹⁴² Pilot studies of an infant formula lacking bovine milk proteins have been initiated in Finland. Preliminary data suggest that such a restricted diet might produce a small decrease of cytoplasmic islet cell autoantibodies but not GAD65 autoantibodies.¹⁴³

Studies from Germany and Denver provided evidence that early (<3 months) introduction of cereals may increase the development of islet autoimmunity.^{144,145} Both vitamin D and ω -3 fatty acids, which can influence immune function, have been associated with risk of diabetes.^{146,147}

NATURAL HISTORY OF TYPE 1A DIABETES

The development of type 1A diabetes is typically divided into a series of stages beginning with genetic susceptibility and ending with essentially complete beta-cell destruction (Fig. 32-3). Mathis and coworkers¹⁴⁸ proposed the existence of checkpoints in the development of diabetes, and such checkpoints may have a strong genetic component. As discussed later, type 1A diabetes is predictable given specific immunologic, genetic, and metabolic characteristics, and it is such characteristics that set the stage for preventive trials.

Genetic and Immunologic Heterogeneity by Age of Onset

Type 1A diabetes can develop at any age, from the neonatal period to the sixth decade of life. Given that identical twins can become concordant as long as 30 years after the first twin develops type 1A diabetes, not all age heterogeneity can be ascribed to different genetic syndromes.⁸⁹ Nevertheless, there is an overall correlation between the age at which diabetes develops in one twin or sibling and the age

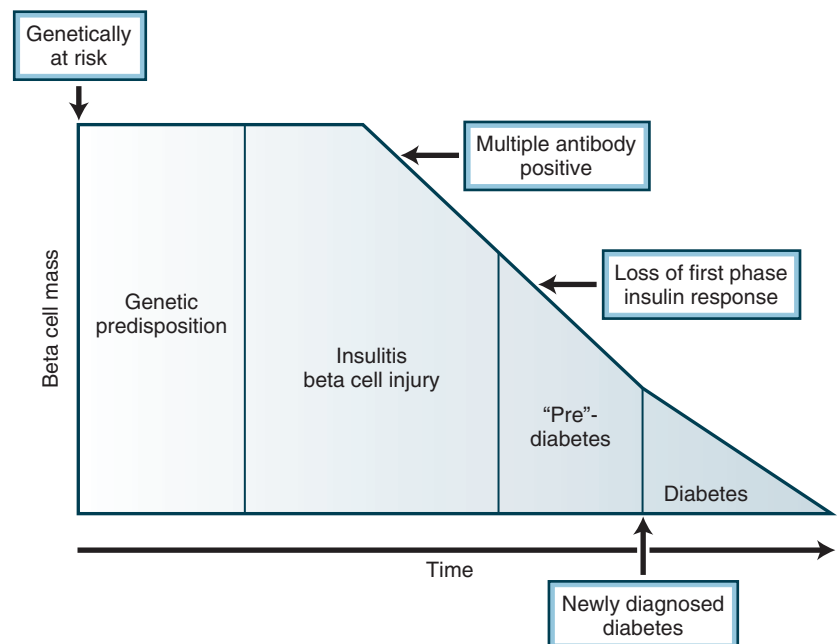

Figure 32-3 Hypothetical stages in the development of type 1A diabetes beginning with genetic susceptibility and ending with complete beta-cell destruction. (Modified from Eisenbarth GS. Type 1 diabetes mellitus: a chronic autoimmune disease. *N Engl J Med*. 1986;314:360-368; modifications by Jay Skyler, University of Miami.)

Figure 32-4 Progression to type 1 diabetes of first-degree relatives of patients with diabetes. Patients are subdivided by the number of anti-islet autoantibodies expressed against insulin, glutamic acid decarboxylase (GAD65), and the transmembrane protein tyrosine phosphatase IA-2 (ICA512). Ab, antibody. (From Verge CF, Gianani R, Kawasaki E, et al. Prediction of type 1 diabetes in first-degree relatives using a combination of insulin, GAD, and ICA512 bdc/IA-2 autoantibodies. *Diabetes*. 1996;45:926-933.)

of development of diabetes in his or her relative. Children in whom type 1A diabetes develops at an early age more often are DR3/4,DQ8/2 heterozygotes. In addition, there is evidence that class I HLA alleles (or other non-class II genes within the HLA region) can influence the age at diabetes onset; an example is the A24 allele.¹⁴⁹ At the other end of the age spectrum, there is evidence that the protective HLA allele DQA*10102, DQB1*0602 is not as protective for young adults as it is for children.¹⁵⁰

The most characteristic difference related to age at diabetes onset is the presence of higher levels of insulin autoantibodies (IAA) in children who develop the disease at an early age (e.g., <5 years).^{151,152} The high levels and frequent positivity of IAA make measurement of these autoantibodies the best single marker for diabetes development in young children. In those children in whom autoantibodies arise during the first 3 years of life, IAA often appear first. In contrast, GAD65 autoantibodies are more often positive in adults who develop type 1A diabetes. The correlation of levels of IAA and age at diabetes onset may be related to faster progression to diabetes in children with higher levels.¹⁵³ However, such rapid progression occurs only if IAA are present with another anti-islet autoantibody (discussed in the next section) (Fig. 32-4).

Combinatorial Autoantibody Prediction

The most specific anti-islet autoantibody assays are usually set with cutoffs above the 99th percentile of control populations. With four major autoantibody assays measuring GAD65, the transmembrane protein tyrosine phosphatase IA-2 (also called ICA512), ZnT8¹⁵⁴ and insulin, it can be predicted that approximately 4 of 100 normal persons express one or more of the four autoantibodies. Because approximately 3 of 1000 children develop type 1A diabetes, this suggests that diabetes never develops in most antibody-positive persons or develops only late in life.

A relatively low positive predictive value for single antibodies may be related to methodologic limitations (e.g., nonreproducible assay positivity) or to the presence of autoantibodies identical to those in patients with prediabetes but found in some persons who do not progress to diabetes. It is likely that both occur. For example, a low positive (i.e., still above the 99th percentile) autoantibody result in a control subject is often not confirmed on repeated testing. Autoantibodies from prediabetic persons usually react with multiple epitopes of the IA-2 molecule, whereas false-positive autoantibodies often react with only one or no clearly defined epitope of the molecule, suggesting that false-positive and diabetes-associated anti-IA-2 autoantibodies differ. However, there are some persons, usually adult relatives of patients with type 1A diabetes (often with DQB1*0602), who have extremely high levels of GAD65 autoantibodies that react with multiple GAD epitopes but no evidence of progression to diabetes.¹⁵⁵

Bonifacio and coworkers analyzed the affinity of IAA from children in the BabyDiab study from Germany. High-affinity IAA measured in offspring of patients with T1DM were associated with progression to diabetes.¹⁵⁶

As for any diagnostic test, assessment of the significance of an autoantibody result is improved by taking into account the prior probability of disease. A patient with overt diabetes and expression of a single anti-islet autoantibody has a high probability of having type 1A diabetes. A person from the general population or even a relative expressing a single autoantibody (and not developing more than that one autoantibody) has a much lower risk of progressing to type 1A diabetes.¹⁵⁷

Usually, attempts to improve the specificity of a test sacrifice sensitivity. For prediction of type 1A diabetes, the four biochemical autoantibody assays can be combined, and the presence of two or more autoantibodies is associated with a very high risk of diabetes.^{158,159} Approximately 1 of 350 persons from the general population express two or more of the GAD65, ICA512, ZnT8, or IAA, approaching population estimates of type 1A diabetes. Among first-degree relatives of patients with type 1A diabetes, the presence of two or more autoantibodies indicates a risk of more than 90% over 10 years, whereas a single autoantibody is associated with a risk of less than 20% over 10 years.¹⁵⁸

Metabolic Progression before Hyperglycemia

The intravenous glucose tolerance test (GTT) aids in evaluating the time to onset of diabetes among persons expressing anti-islet autoantibodies.¹⁶⁰ Most commonly, glucose is given at 0.5 g/kg over 5 minutes (maximum 35 g, 25 g/dL), and insulin levels are measured before and 1 and 3 minutes after the glucose infusion.^{161,162} Most persons who are within 1 year of developing overt diabetes have no first-phase insulin secretion after intravenous glucose administration. A simpler measurement in someone progressing to type 1 diabetes is the HbA_{1c}, which in most prediabetic individuals increases progressively (although in the normal range) 1 or 2 years before overt hyperglycemia develops.

The diagnosis of type 1A diabetes usually relies on the presence of fasting hyperglycemia (≥ 126 mg/dL), but with prospective evaluation, many persons have diabetes on oral glucose tolerance testing (OGTT) by the 120-minute criterion (≥ 200 mg/dL), with a nondiagnostic fasting glucose level. Impaired fasting glucose (100 to 125 mg/dL) or impaired glucose tolerance (glucose at 120 minutes on

OGTT, 140 to 199 mg/dL) is usually present within 6 months before the onset of overt diabetes.

C-Peptide Loss after Hyperglycemia

After diabetes is diagnosed, levels of C peptide can be used to assess remaining beta-cell function. C-peptide levels are usually measured in the fasting state or after intravenous glucagon or with a standard liquid meal. Such measurements are primarily of importance for trials of therapies to alleviate loss of insulin secretion after diagnosis. Determination of the C-peptide concentration provides the best current measure for assessing the impact of new therapies. As shown in the Diabetes Control and Complications Trial (DCCT), a small amount of remaining C peptide is associated with impressive metabolic benefit.^{163,164}

Type 1A Diabetes with Pregnancy

Approximately 5% of women with gestational diabetes (diabetes diagnosed during pregnancy) have an early form of type 1A diabetes that is discovered during pregnancy.¹⁶⁵ These women express anti-islet autoantibodies and progress to overt diabetes more rapidly after pregnancy.

Latent Autoimmune Diabetes of Adults

Type 1A diabetes can occur at any age. Depending on the population, between 5% and 15% of persons with what appears to be T2DM express anti-islet autoantibodies.^{166,167} Multiple studies have demonstrated that such persons progress relatively rapidly (within 3 years) to insulin-requiring diabetes. The HLA alleles of such persons reflect that of type 1A diabetes.¹⁶⁸

Transient Hyperglycemia

A significant number of children are evaluated by endocrinologists for transient hyperglycemia. The usual history is one of severe stress associated with hyperglycemia that resolves within days to 1 month. Such children may be in the honeymoon phase of type 1A diabetes, or they may truly have a transient episode of hyperglycemia. Rarely, diabetes in children is misdiagnosed. For example, we have seen a child with normal HbA_{1c} values for several years who stopped insulin and was subsequently found to have renal glucosuria and not diabetes. Children without severe stress who have transient hyperglycemia or who have a relative with type 1A diabetes are more likely to have early type 1A diabetes. Absence of anti-islet autoantibodies and a normal intravenous GTT result strongly indicate transient hyperglycemia and not type 1A diabetes.¹⁶⁹ It is not known whether children with transient hyperglycemia are at increased risk for T2DM later in life.

IMMUNOTHERAPY OF TYPE 1A DIABETES

At the onset of type 1A diabetes, a major clinical research goal is the prevention of further beta-cell destruction. At present, there is no proven safe and effective therapy to prevent such further destruction or to prevent the development of type 1A diabetes in those at risk (e.g., genetically at-risk persons with anti-islet autoantibodies). A number of clinical trials have been completed, and a large number of trials are under way or about to be initiated.

Immunosuppression

The earliest studies of therapies to prevent beta-cell destruction used immunosuppressive agents. Large trials of cyclosporine indicated that cyclosporine prevented further loss of C-peptide secretion and improved metabolic function while it was administered.¹⁷⁰⁻¹⁷² It did not, however, maintain a nondiabetic state when therapy was instituted after the onset of diabetes, and with discontinuation of the drug, patients rapidly lost C-peptide reserve. The combination of inability to cure diabetes and toxicities associated with cyclosporine (in particular nephrotoxicity and concern about increased risk of malignancy) has ruled out its use. Other immunosuppressive agents such as prednisone or azathioprine had relatively little effect.¹⁷⁴⁻¹⁷⁶ A small study suggested that methotrexate, another common immunotherapeutic agent, is ineffective.¹⁷⁷ Therefore, at present, although type 1A diabetes is an immune-mediated disorder, it is not treated with common immunotherapeutic agents.

Two studies of modified antibodies to CD3 have been reported, and additional trials are likely.¹⁷⁸ A single course of anti-CD3 therapy decreased loss of C-peptide secretion in new-onset patients, but it appears that after 1 year progressive loss of secretion resumed.¹⁷⁹ Concerns related to the activation of Epstein-Barr virus infection and the lack of information regarding the duration of C-peptide preservation caution against nonresearch application of such therapy at present.^{179a} In an oral presentation at the ADA, Dr. Pescovitz reported that a single course of anti-CD20 antibody targeting B lymphocytes delayed loss of C-peptide for approximately 3 months. Neither an anti-IL-2 receptor antibody, nor mycophenolate, nor the combination delayed loss of C-peptide (oral report by Gottlieb-TrialNet).

The TrialNet group has a number of randomized, multicenter trials under way and planned. Subjects for such trials in the setting of new-onset T1DM may be referred by contacting Type 1 TrialNet at 1-800-HALT-DM1 or <http://www.diabetestrialnet.org> (accessed December 2010).

Immunologic Vaccination

In animal models (especially the NOD mouse), it is relatively easy to prevent T1DM.¹⁴ Potentially the most exciting modalities use forms of immunologic vaccination. Much of the excitement derives from the specificity of the therapy and the relatively low risk compared with immunosuppression, not from demonstrated efficacy in humans. The basic concept behind most such therapies is the induction of lymphocytes that target a given islet antigen and, on encountering the target antigen (e.g., insulin), produce cytokines that suppress autoimmunity and tissue destruction.^{38,180}

A Th2 class of T lymphocytes produce the cytokine IL-4 rather than IFN- γ and IL-2 (which are produced by Th1 T cells) and decrease cell-mediated immune destruction. Induction of a protective immune response may depend on the route of administration of the given antigen (e.g., oral tolerance) or on the use of an altered antigen (e.g., altered peptide ligands). For example, insulin given either orally or by subcutaneous injection prevented diabetes in NOD mice.^{181,182} Intact insulin is not necessary, because the insulin B chain and an immunodominant B(9-23) peptide of insulin were also effective.⁴⁰ The latter molecules have no insulin-like metabolic effect but are able to activate T lymphocytes that target insulin.

The Diabetes Prevention Trial Type 1 studied both oral insulin and parenteral injections of low doses of insulin.

The results of the parenteral trial did not demonstrate a reduction in the risk of developing diabetes.¹⁸³ The oral trial did not document an overall benefit of insulin, but in the subgroup with higher levels of IAA at entry, a statistically significant delay in progression to diabetes was observed.¹⁸⁴ Because this was a subgroup analysis, replication of this potentially exciting finding is imperative. Relatives of patients with T1DM can be tested for anti-islet autoantibodies by TrialNet at the telephone number or website given earlier.

Other Therapies

A review by Atkinson and Leiter^{184a} pointed out that more than 100 different interventions prevent diabetes in NOD mice. The relative ease of diabetes prevention in this animal model has provided the basis for a number of trials initiated in humans. The largest European trial, the European Nicotinamide Trial (ENDIT), uses nicotinamide in gram doses. Nicotinamide can prevent diabetes induced by the drug streptozotocin and probably acts by preserving nicotinamide adenine dinucleotide levels in islet cells or by blocking cytokine-induced destruction. Nicotinamide did not delay progression to diabetes in humans.¹⁵⁴

IMMUNOLOGY OF PANCREATIC ISLET TRANSPLANTATION

Pancreatic transplantation for patients requiring a kidney transplant is an accepted clinical procedure.¹⁸⁵ Patients with a kidney transplant receive immunosuppressive drugs, and results for pancreatic transplantation in this setting have progressively improved. With a successful pancreas transplant, hyperglycemia is immediately reversed, and there is some evidence of improved long-term outcomes,^{185,186} although there is considerable debate concerning pancreas transplantation without the transplantation of a kidney.¹⁸⁷ Nevertheless, the surgery is extensive, and there are many potential complications associated with the transplant. Diabetes can recur because of recurrent autoimmunity or, more often, allograft rejection.¹⁸⁸ It is difficult to monitor specific islet destruction, and with the development of hyperglycemia it is usually not possible to restore euglycemia.

Up until studies from Edmonton, the results of islet transplantation were poor: fewer than 10% of patients with type 1A diabetes achieved insulin independence at 1 year.¹⁸⁹ In contrast, with autotransplantation of patients with pancreatitis, most patients become insulin independent and remain so.¹⁸⁹ The Edmonton group used meticulous islet isolation techniques, transplantation of islets from multiple pancreata, and an immunosuppressive regimen using the drug rapamycin.

The Edmonton protocol has been tested in a series of specialized centers throughout North America and Europe. It is clear that many centers with varying success rates can successfully transplant islets, and for patients with severe hypoglycemia there is long-term prevention of severe hypoglycemic episodes. For most of the patients who achieve insulin independence, resumption of use of low doses of insulin is necessary within 2 years.¹⁹⁰ Even if the Edmonton results are reproduced at multiple centers, the number of islets available from cadaveric donors for transplantation is limited, and the toxicities of the drugs used probably exceed the level of benefit achieved. Further

research to achieve tolerance without long-term immunosuppression with calcineurin inhibitors and rapamycin is essential, as is the development of xenogeneic transplantation or production of islets from stem cells. The increasing use of long-term continuous glucose monitoring in patients with T1DM will almost certainly raise the bar for consideration of the risks and benefits of both islet and pancreatic transplantation.

INSULIN AUTOIMMUNE SYNDROME

The insulin autoimmune syndrome, also termed *Hirata syndrome*, is rare and is typically associated with hypoglycemia.¹⁹¹ These patients have extremely high concentrations of autoantibodies that react with human insulin. It is thought that inappropriate (nonregulated) release of autoantibody-bound insulin produces the hypoglycemia. The disease occurs most commonly in Asian persons. Among 50 Japanese patients with the syndrome and the typical polyclonal anti-insulin autoantibodies, 96% had a DR4 allele and 84% (42 of 50) had the DRB1*0406 allele.¹⁹² In contrast, patients with monoclonal anti-insulin autoantibodies do not have such a remarkable HLA association. Most patients develop the disease in association with treatment with sulfhydryl-containing medications, in particular methimazole. Treatment usually consists of stopping these medications, and for more than 75% of the patients, the disease remits.¹⁹²

INSULIN ALLERGY

Mild forms of immune reactivity to insulin are not uncommon. Essentially all patients treated with human insulin produce anti-insulin autoantibodies that are measurable with sensitive fluid-phase radioassays. The levels of these autoantibodies are relatively low, and they do not appear to interfere with insulin therapy, although there are reports correlating insulin antibodies with macrosomia.¹⁹³ With the introduction of recombinant human insulin replacing animal insulins, symptomatic immune responses to insulin such as immediate hypersensitivity, delayed hypersensitivity, lipoatrophy, and lipohypertrophy have decreased.¹⁹⁴ Allergic reactions can occur with insulin analogues, although this is uncommon. More common are allergies to protamine, which is used to complex insulin in neutral protamine Hagedorn (NPH) formulations, or the lubricants, preservatives, and plastics in bottles, stoppers, syringes, and needles.

The usual therapy consists of switching the type or formulation of insulin followed by oral antihistamines for immunoglobulin E-mediated local reactions, followed by insulin desensitization or addition of small amounts of glucocorticoids to the insulin injected for local delayed hypersensitivity reactions.

ANTI-INSULIN RECEPTOR AUTOANTIBODIES

Anti-insulin receptor autoantibodies (type B insulin resistance) are associated with both hypoglycemia and insulin resistance.¹⁹⁵ It appears that anti-insulin receptor autoantibodies can act as either antagonists or agonists. This syndrome is rare and is often associated with non-organ-specific autoimmunity.¹⁹⁶

CLINICAL PRESENTATION

The peak age at presentation of T1DM in children is at puberty. The symptoms and signs are related to the presence of hyperglycemia and the resulting effects on fluid and electrolyte balance; they include polyuria, polydipsia, polyphagia, weight loss, and blurred vision. Because infection may have precipitated the initial presentation, symptoms of infection may also be present, such as fever, sore throat, cough, or dysuria. In children in particular, the onset of symptoms can occur over a brief period, and families may be able to date the onset with considerable accuracy. Onset of symptoms can also be insidious, particularly in older persons with T1DM, and can occur over a time frame of weeks or even months.

If onset of T1DM is associated with ketoacidosis, which is not uncommon, additional symptoms related to this acute metabolic complication of diabetes are also present. These symptoms can include abdominal pain, nausea, and vomiting. Variable effects on mental status may be seen, ranging from slight drowsiness to profound lethargy and even coma if the condition has been untreated for a significant period.

LABORATORY FINDINGS

Plasma glucose concentrations at presentation are elevated, usually in the range 300 to 500 mg/dL. If the presentation is uncomplicated, the remainder of the fluid and electrolyte measurements may be completely normal. On the other hand, if diabetic ketoacidosis (DKA) is present, the measurements will reflect the presence of an acidosis as well as more severe dehydration. In DKA, the serum sodium value is often at the lower limit of normal or even mildly reduced, reflecting the osmotic effect of hyperglycemia and, on occasion, the presence of vomiting with continued water intake. A sodium value lower than 120 mmol/L is usually associated with severe hypertriglyceridemia that can lead to spurious hyponatremia.

Despite significant losses of potassium in the urine and total-body potassium deficits, acidosis usually leads to an elevated serum potassium concentration at the time of the initial presentation. Serum bicarbonate concentrations are usually less than 10 mg/dL, and elevations in serum concentrations of triglyceride and free fatty acids are found. Levels of ketone bodies are also elevated. Because dehydration is invariably present, this leads to increases in the concentrations of blood urea nitrogen (BUN) and creatinine. In conjunction with the increase in serum glucose, the increases in BUN invariably increase the serum osmolality, often to greater than 300 mmol/kg.

TREATMENT OF TYPE 1 DIABETES

Importance of Tight Glucose Control

The overriding principle in the treatment of most patients with T1DM is that a health care team that includes a physician, diabetes nurse educator, nutritionist, and other health care professionals as appropriate should work closely with the patient to achieve blood glucose concentrations as close to normal as possible, because these values are associated with a reduced risk of diabetic complications. Although studies in animal models¹⁹⁷⁻¹⁹⁹ and epidemiologic studies²⁰⁰⁻²⁰² have suggested that tighter glucose control is

associated with better long-term outcomes for the diabetic patient in terms of a reduced risk of complications, the most definitive study in this regard has been the DCCT, which was completed in 1993.²⁰³ This landmark study involved a total of 1441 patients with T1DM—726 with no retinopathy at baseline (the primary prevention cohort) and 715 with mild retinopathy (the secondary intervention cohort)—who were randomly assigned to intensive therapy or conventional therapy.

Intensive therapy consisted of insulin administration by an external pump or by three or more daily insulin injections. The dosage was adjusted according to the results of self-monitoring of blood glucose performed at least four times per day as well as dietary intake and anticipated exercise. The goals of intensive therapy were to achieve blood glucose concentrations between 70 and 120 mg/dL before meals, values less than 180 mg/dL after meals, a weekly 3 a.m. measurement greater than 65 mg/dL, and an HbA_{1c} value within the normal range ($\leq 6.05\%$). Patients in the intensive treatment group visited their centers each month and had more frequent contacts with a member of the health care team, usually weekly, to review and adjust their regimens.

Conventional therapy consisted of one or two daily injections of insulin, including mixed intermediate and rapid-acting insulins, daily self-monitoring of urine or blood glucose, and education about diet and exercise. The goals of conventional therapy included absence of symptoms of hyperglycemia; absence of ketonuria; maintenance of normal growth, development, and ideal body weight; and freedom from frequent severe hypoglycemia.

The entire cohort of patients was observed for a mean of 6.5 years, and 99% of the patients completed the study. Although only 5% of the subjects in the intensive treatment group were able to sustain the goal of a normal HbA_{1c} over time, they nevertheless did have significantly lower average values (approximately 7%) over time than the subjects in the conventional treatment group (approximately 9%). Average capillary blood glucose profiles in the intensive treatment group were 155 ± 30 mg/dL, compared with 231 ± 55 mg/dL in the conventional therapy group ($P < .0001$). These differences in glucose control formed the basis of analyses to determine the effects of lower levels of glycemia on diabetic complications.

When both the primary prevention and secondary intervention cohorts were considered, intensive therapy was shown to reduce the risk of proliferative or severe nonproliferative retinopathy by 47% and the need for treatment with photocoagulation by 56%. Intensive therapy reduced the mean adjusted risk of microalbuminuria (defined as urinary albumin excretion >40 mg/24 hours) by 34% in the primary prevention cohort and by 43% in the secondary intervention cohort. The risk of albuminuria was reduced by 56% in the secondary intervention cohort. Intensive therapy reduced the appearance of neuropathy by 69% in the primary prevention cohort and by 57% in the secondary intervention cohort.

Some have suggested a potential adverse effect of aggressive insulin therapy in exacerbating the predisposition to macrovascular disease in diabetes. In the DCCT study, intensive insulin therapy reduced the development of macrovascular disease by 41%, although the difference was not statistically significant.²⁰⁴ Ninety-three percent of DCCT participants were monitored after the randomized portion of the trial in the Epidemiology of Diabetes Interventions and Complications (EDIC) study. Glycemic control in both groups drifted toward an HbA_{1c} value of slightly less than 8% within the first year or so after conclusion of the

randomized trial. With 17 years of follow-up after randomization, despite similar glycemic control in both groups for 10 years, cardiovascular disease (defined as nonfatal myocardial infarction, stroke, death from cardiovascular disease, confirmed angina, or the need for coronary-artery revascularization) was reduced by 42% and nonfatal myocardial infarction, stroke, and cardiovascular deaths were reduced by 57%. The authors concluded that “the decrease in glycosylated hemoglobin values during the DCCT was significantly associated with most of the positive effects of intensive treatment on the risk of cardiovascular disease. Intensive diabetes therapy has long-term beneficial effects on the risk of cardiovascular disease in patients with type 1 diabetes.”²⁰⁵

Were there any adverse events associated with the intensive treatment regimen in the DCCT? Overall mortality did not differ in the two treatment groups and was actually less than expected on the basis of population-based mortality studies. However, the incidence of severe hypoglycemia was approximately three times higher in the intensive therapy group than in the conventional therapy group ($P < .001$). Some of the episodes of hypoglycemia were quite severe, resulting in motor vehicle accidents or need for hospitalization. Severe hypoglycemia occurred more often during sleep,²⁰⁶ and approximately one third of the episodes that occurred while the patients were awake were not associated with warning symptoms. In intensively treated subjects, predictors of hypoglycemia included a history of severe hypoglycemia, longer duration of diabetes, higher baseline HbA_{1c}, and a lower recent HbA_{1c} value.

Weight gain also occurred in more of the intensively treated patients. Intensive therapy was associated with a 33% increase in risk of becoming overweight, defined as a body weight more than 120% above the ideal. Five years into the trial, patients being treated intensively had gained a mean of 4.6 kg more than patients receiving conventional therapy. Among subjects in the top quartile of weight gain, changes in plasma lipids, blood pressure, and body fat distribution were observed that were similar to those seen in cases of insulin resistance.²⁰⁷

Goals of Treatment

On the basis of the results just described, the authors of the DCCT study recommended that most patients with T1DM be treated with an intensive treatment regimen under the close supervision of a health care team consisting of a physician, nurses, nutritionist, and behavioral and exercise specialists as needed. However, for certain groups of patients, this recommendation may need to be modified, because the risk-to-benefit ratio might not be as favorable as it was in the cohorts with mild or no diabetic complications that were studied in the DCCT.

Patients for whom it may be appropriate to be more cautious about instituting intensive treatment regimens include children younger than 13 years of age, elderly people, and patients with advanced complications such as end-stage renal disease or significant cardiovascular or cerebrovascular disease. It has also been reported²⁰⁸⁻²¹⁰ that institution of aggressive insulin therapy in subjects with proliferative or severe nonproliferative retinopathy can lead to accelerated progression of retinopathy. Treatment of the eye disease should be considered before an aggressive insulin regimen is started. Patients who do not experience warning adrenergic symptoms of hypoglycemia (hypoglycemia unawareness) are at significantly greater risk for severe recurrent hypoglycemia, and this may prevent the safe institution of tight glucose control.²¹¹

TABLE 32-5

Glycemic Targets

Parameter	Normal	ADA	ACE
Premeal PG (mg/dL)	<100 (mean ~90)	70-130	<110
Postprandial PG (mg/dL)	<140	<180	<140
HbA _{1c} (%)	4-6	<7	≤6.5

ACE, American College of Endocrinology; ADA, American Diabetes Association; HbA_{1c}, glycosylated hemoglobin; PG, plasma glucose concentration.

From American Diabetes Association. Standards of medical care in diabetes—2010. *Diabetes Care*. 2010;29:s11-s61; Rodbard HW, Blonde L, Braithwaite SS, et al., AACE Diabetes Mellitus Clinical Practice Guidelines Task Force. American Association of Clinical Endocrinologists medical guidelines for clinical practice for the management of diabetes mellitus. *Endocr Pract*. 2007;13(suppl 1):1-68.

Guidelines from the ADA and the American College of Endocrinology (ACE) are presented in Table 32-5. The ADA suggests that the goal of treatment in the management of diabetes should be an HbA_{1c} value of less than 7% in general. Furthermore, the ADA suggests that lower targets can be pursued in selected patients, such as those with disease of recent onset, long life expectancy, and no significant cardiovascular disease, if they can be achieved without significant hypoglycemia or other adverse effects of treatment. Conversely, they recommend that less-stringent HbA_{1c} goals “may be appropriate for patients with a history of severe hypoglycemia, limited life expectancy, advanced microvascular or macrovascular complications, and extensive comorbid conditions and those with longstanding diabetes in whom the general goal is difficult to attain despite diabetes self-management education, appropriate glucose monitoring, and effective doses of multiple glucose lowering agents including insulin.”²¹² The ACE has recommended an HbA_{1c} goal of less than 6.5%.²¹³ It is recognized that to achieve glucose control at this level, patients need to monitor glucose frequently and to receive nutritional counseling and training in self-management of the insulin doses as well as problem solving to allow them to deal with the problems that they encounter in their daily lives.

Team Approach to Treatment

The DCCT trial validated the use of continuous subcutaneous insulin infusion (CSII) with an insulin pump and multiple daily injections (MDI), which are titrated based on frequent glucose monitoring. Several companies have developed continuous glucose sensors, and pramlintide, an amylin analogue, is the first fundamentally new treatment for patients with T1DM to become available since 1922. Because of the complex nature of modern intensive diabetes treatment regimens and the need for regular feedback and modification of the parameters of treatment, it has now become generally accepted that intensive insulin regimens can be instituted more effectively by a health care team than by a physician alone. Members of the team can include diabetes nurse educators, nutritionists, psychologists, medical social workers, and others, such as exercise physiologists, depending on the needs of a particular patient. A critical aspect of intensive diabetes treatment is the need for continuous monitoring of the effectiveness of specific components of the regimen with adjustments in response to changing life circumstances of the patient.

Pharmacokinetics of Available Insulin Preparations

In the past, insulin for human use was obtained from animal sources (i.e., cows and pigs). With advances in recombinant DNA technology, it is now possible to produce large quantities of insulin with an amino acid structure identical to that of human insulin or to modify the human amino acid sequence to produce desirable pharmacodynamic properties. The various formulations of insulin differ in the rapidity of their onset of action, the time from injection to peak action, and the duration of action, depending on the chemical nature of the particular insulin preparation. These data are summarized in Table 32-6. The available insulins can be divided on a pharmacokinetic basis into three broad categories: rapid-acting, intermediate, and long-acting.

Rapid-Acting Insulins

Rapid-acting insulins have an onset of action of 1 hour or less and are used to reduce the peak of glycemia that occurs after meal ingestion.

Regular Insulin. Regular insulin consists of zinc-insulin crystals dissolved in a clear fluid. After subcutaneous injection, regular insulin tends to dissociate from its normal hexameric form, first into dimers and then into monomers; only the monomeric and dimeric forms can pass through the endothelium into the circulation to any appreciable degree.²¹⁴ This feature determines the pharmacokinetic profile of regular insulin. The resulting relative delay in onset and duration of action of regular insulin limits its effectiveness in controlling postprandial glucose and results in dose-dependent pharmacokinetics, with a prolonged onset, peak, and duration of action with higher doses.

Insulin Analogues

Insulin Lispro. Insulin lispro, of recombinant DNA origin, is a human insulin analogue created by reversal of the amino acids at positions 28 and 29 on the human insulin B chain. Insulin lispro was the first insulin analogue to receive approval by the U.S. Food and Drug Administration. It is chemically Lys(B28),Pro(B29) insulin and is created in a special, nonpathogenic laboratory strain of *Escherichia coli* that has been genetically altered by the addition of the gene for insulin lispro.

The effect of this amino acid rearrangement is to reduce the capacity of the insulin to self-aggregate in subcutaneous tissues, resulting in behavior similar to that of monomeric insulin. This leads to lispro's more rapid absorption and shorter duration of action compared with regular insulin when given by subcutaneous injection. However, lispro is not intrinsically more active and on a molar basis is equipotent to human insulin. When they are given by intravenous injection, the pharmacokinetic profiles of lispro and human regular insulin are similar. Because of its rapid onset of action (within 5 to 15 minutes after administration) and peak action within 1 to 2 hours, lispro was the first insulin to mimic the time course of the increase in plasma glucose seen after ingestion of a carbohydrate-rich meal.

Insulin Aspart. Insulin aspart differs from human insulin by substitution of aspartic acid for proline in position B28.

Insulin Glulisine. Insulin glulisine involves substitution of lysine for the asparagine at position B3 and of glutamic acid for the lysine in position B29.

Advantages of Analogues. Lispro, aspart, and glulisine seem to have similar pharmacokinetics and clinical effects in the setting of T1DM. Although little difference is observed in most cases by either patients or providers, there certainly may be differences, at least in subsets of patients, that could be exploited to improve glycemic control.

In general, treatment with monomeric insulin analogues (lispro, aspart, and glulisine) is associated with a lower risk of hypoglycemia, particularly in sleep, than treatment with regular insulin. It is quite easy to document improved glycemic control in the postprandial state. Finally, patients may inject these insulin analogues immediately before or after meals instead of 30 to 60 minutes before meals, as is classically recommended with regular insulin, providing greater convenience. These features have been exploited in clinical trials to produce modest improvements in overall control with monomeric insulin analogues compared with regular insulin.

Intermediate and Long-Acting Insulins

Intermediate and long-acting insulins have a significantly longer delay in their onset and duration of action. In the setting of T1DM, they should be always used in combination with a rapid-acting form of insulin. They are usually administered before bedtime and are titrated to produce normal glucose levels through the night and in the fasting state.

NPH Insulin. NPH insulin is a crystalline suspension of insulin with protamine and zinc, providing an intermediate-acting insulin with onset of action in 1 to 3 hours, duration of action up to 24 hours, and peak action from 6 to 8 hours. NPH insulin usually cannot be administered once daily in the setting of T1DM, at least in combination with rapid-acting monomeric analogue insulin. In the pre-analogue era, NPH insulin was used successfully in combination with regular insulin, although this human insulin-based regimen has now been largely supplanted by analogue insulin because of a perceived lower risk of hypoglycemia.²¹⁵

Insulin Glargine. Insulin glargine is a recombinant human insulin analogue that does provide 24-hour duration of action in most, but not all, patients with T1DM. It differs from human insulin in that the amino acid asparagine at position A21 is replaced by glycine, and two arginines are added to the carboxyl-terminus of the B chain. In the

TABLE 32-6

Pharmacokinetic Properties of Insulin Preparations

Preparation	Onset (hr)	Peak (hr)	Duration (hr)
Rapid-Acting			
Regular	0.5-1	2-4	6-8
Lispro	0.25	1	3-4
Aspart	0.25	1	3-4
Glulisine	0.25	1	3-4
Intermediate-Acting

Glargine	1	NA	11-24
Detemir	1	3-9	6-23

NPH, neutral protamine Hagedorn.

injection solution at pH 4, insulin glargine is completely soluble. However, it has low solubility at neutral pH.

After injection into the subcutaneous tissue, the acidic solution is neutralized, leading to the formation of micro-precipitates from which small amounts of insulin glargine are slowly released; this results in absorption over a period of approximately 24 hours with no pronounced peak. Insulin glargine thus simulates the basal production of insulin. In other respects, its mechanism of action is similar to that of human insulin, and on a molar basis its glucose-lowering effects are similar to those of human insulin when given intravenously.

Because this insulin is provided in an acid vehicle, it cannot be mixed with other forms of insulin or intravenous fluids, and some patients have greater discomfort with injection at least some of the time. In general, glargine is less variably absorbed than NPH insulin, and in clinical trials in patients with T1DM it has been associated with a reduced risk of hypoglycemia, particularly nocturnal hypoglycemia.

In about 10% of patients, insulin glargine must be taken twice daily to provide 24-hour coverage of basal insulin needs. In a smaller percentage of patients, a modest peak in effect occurs 2 to 6 hours after injection and can result in nocturnal hypoglycemia.

Insulin Detemir. Insulin detemir differs from human insulin in that the threonine in position B30 has been eliminated and a C14 fatty acid chain has been attached to amino acid B29. It is unique among insulins of prolonged duration in that it is soluble both in the vial and under the skin. This may be the cause of its more consistent absorption after subcutaneous injection.²¹⁶ In comparison to NPH insulin in the setting of T1DM, detemir is associated with less weight gain (in some trials patients have experienced weight loss) and with reduced risk of hypoglycemia.²¹⁵

Alternative Routes of Insulin Administration

Numerous alternative routes of insulin administration are being examined.^{217,218} There is tremendous interest on the part of patients in inhaled insulin. Some studies suggest that there is substantial preference, at least among most research volunteers, for the pulmonary versus the subcutaneous route of insulin administration.

One inhaled insulin product (Exubera) was found to have several limitations in the setting of T1DM. Most importantly, it did not allow for the precise titration employed by many patients. Second, there were concerns that greater variability in absorption from the intrapulmonary rather than the subcutaneous site would amplify the glycemic instability inherent in T1DM, particularly in the setting of intercurrent respiratory illness or exposures such as tobacco smoke. Third, the long-term safety of the pulmonary route of insulin administration is unknown, particularly in the setting of T1DM, in which insulin is likely to be administered three or more times a day potentially for 50 or more years. Exubera was withdrawn from the market due to commercial failure. The development of other inhaled insulin preparations and other alternative routes of administration is proceeding.

Approach to the Treatment of Type 1 Diabetes

Levels of glucose control equivalent to those achieved in the intensive treatment group in the DCCT are not possible in most patients unless an MDI regimen combining

rapid- and long-acting insulin or CSII is used. More important than the schedule and method of administration is the need for the patient to adjust the insulin dose depending on the self-monitored glucose levels, dietary intake, and physical activity. The reason is relatively simple. In patients with little or no endogenous insulin production, the exogenous insulin regimen needs to simulate the multiphasic profile of insulin secretory responses to meals and snacks that is present in normal subjects if levels of glycemia approaching normal are to be achieved.

A number of regimens have been used to achieve these ends. Three basic approaches are reviewed here, although others approaches may be effective in individual patients. Achieving the glycemic goals of therapy is far more important than the details of the insulin regimen. Nevertheless, one of the following general approaches to therapy is most likely to lead to the desired outcome.

Combination of Rapid-Acting and Intermediate-Acting Insulin with Breakfast and Dinner and Intermediate-Acting Insulin at Bedtime

The rationale for regimens that use rapid- and intermediate-acting insulin at breakfast and dinner is that the rapid-acting insulin limits the postprandial glucose rise after breakfast and dinner, the intermediate-acting insulin administered before breakfast limits glycemia in the afternoon, and the intermediate-acting insulin before dinner limits glycemia in the early hours of the morning. Although such a regimen may be sufficient to achieve glucose targets in some patients, in many persons the intermediate-acting insulin given before dinner is insufficient to control elevations in blood glucose commonly seen in the early morning (*dawn phenomenon*). Attempts to increase the dose of intermediate-acting insulin at dinner expose the patient to a greater risk of hypoglycemia in the middle of the night; hence, the need for a smaller dose at bedtime to provide sufficient insulin to restrain the dawn phenomenon the following morning while moderating the risk of nocturnal hypoglycemia. This three-injection regimen was the mainstay of therapy in the DCCT but has largely been supplanted by regimens that take greater advantage of the availability of insulin analogues.

Combination of Rapid-Acting Insulin Given with Meals and Long-Acting Insulin at Bedtime

The combination of rapid-acting insulin with meals and long-acting insulin at bedtime can also simulate the pattern of insulin production that occurs normally. Use of monomeric insulin analogues provides excellent meal coverage. Use of long-acting insulin at bedtime provides excellent control of the fasting plasma glucose level. This combination of rapid-acting monomeric insulin analogues with long-acting analogues has largely supplanted human insulin-based treatment regimens because it seems to be associated with less variability in glycemic control and with lower risks of hypoglycemia. When long-acting insulin is administered once a day in the evening, an unexplained and consistent rise in glucose can occur just before the evening injection of long-acting insulin because the analogue's duration is less than 24 hours. This is more common in patients who require low doses (<20 units) of long-acting analogue and arguably is more common with detemir than with glargine; it can be remedied by dosing the long-acting insulin twice daily.

Insulin Administration by an External Insulin Pump

An alternative method of delivering insulin is by an external mechanical pump. This approach involves administering a rapid-acting insulin preparation by CSII through a catheter that is usually inserted into the subcutaneous tissues of the anterior abdominal wall. The pump delivers insulin as a preprogrammed basal infusion in addition to patient-directed boluses given before meals or snacks or in response to elevations in the blood glucose concentration outside the desired range. With currently available pumps, the basal insulin infusion rate (usually about 1 U/hour) can be programmed either to continue at a constant rate over the 24-hour period or, more commonly, to increase and decrease at predetermined times of the day to prevent anticipated excursions in the blood glucose concentration (e.g., morning rises in glucose). Newer pumps allow multiple basal profiles to deal with recurrent patterns (e.g., menstruation, weekends, and activity). Protocols for insulin administration by the pump usually provide for approximately half of the insulin to be administered as a basal infusion and the remainder as premeal boluses.

Insulin administration by an external pump has some advantages over regimens that use multiple insulin injections. Only rapid-acting insulin is used in the insulin pump. Consequently, adjustments to the basal insulin infusion rate or changes in the size and timing of the insulin boluses result in more rapid changes in the blood glucose concentration than are possible when adjustments are made to the dose of intermediate- or long-acting insulin. This leads to greater flexibility for the patient. It has been suggested that use of analogue insulin can lead to a lower risk of hypoglycemia.^{219,220}

There are also disadvantages of insulin pump therapy. There is a significant initial cost of the pump itself, and the tubing, which needs to be changed every 24 to 72 hours, and other supplies are expensive. The risk of infection at the site of insulin administration is significant. Infections occur on average once per year per patient even in the best of practices; although they can usually be treated by changing the site of infusion and giving a short course of oral antibiotics, surgical drainage may be necessary if an abscess develops. In addition, because only rapid-acting insulin is used, pump failure as a result of mechanical malfunction or catheter-related problems can quickly result in severe hyperglycemia and even ketoacidosis. Patients treated with insulin pump therapy must monitor their glucose level frequently and must always be alert to the possibility of failure of the infusion system.

Controlled clinical trials have indicated that, on average, insulin pump therapy is associated with modest improvements in glycemic control compared with MDI regimens—on the order of 0.2% to 0.3% as assessed by HbA_{1c}, at least in adults. Some patients never achieve adequate control with MDI but experience dramatic improvements with pump therapy. According to the ADA,²¹² the insulin pump should be used only by candidates who are strongly motivated to improve glucose control and willing to work with their health care provider in assuming substantial responsibility for their day-to-day care. They must also understand and demonstrate use of the insulin pump and self-monitoring of blood glucose and be able to use the data obtained in an appropriate fashion.

Sensor-Augmented Pump Therapy

Recent studies have examined the use of sensor-augmented pump (SAP) therapy in patients with T1DM who have

inadequate control with an MDI regimen.²²¹ SAP therapy integrates insulin pump therapy with a continuous glucose monitor that transmits to the pump and allows patients and clinicians to monitor treatment (insulin doses, carbohydrate intake, exercise) and response (glucose measured by the continuous monitor and by self-monitoring of blood glucose) through the use of Internet-based software. The Sensor-Augmented Pump Therapy for A1C Reduction (STAR-3) study was a 1-year, multicenter, randomized, controlled comparison of SAP versus MDI in 329 adults and 156 children with inadequately controlled T1DM previously treated in the investigator's practice for at least 6 months with MDI. Patients in both arms received recombinant insulin analogues and were supervised by expert clinical teams. HbA_{1c} was reduced from a baseline of 8.3% to 7.5% in the SAP group, compared with 8.1% in the MDI group ($P < .001$). There was no difference between the randomized therapies in the rates of severe hypoglycemia, ketoacidosis, or weight gain. This 0.6% relative difference is substantial and is of the same range required for approval of an antihyperglycemic medication. This is the first device that has been demonstrated to provide improvements in average glycemic control of that magnitude.

Algorithms of Insulin Administration

An essential component of intensive regimens of insulin replacement is the need to make regular adjustments to the insulin dose depending on the prevailing blood glucose concentration, planned activity, and food intake. Algorithms have been developed to guide these adjustments that aim to simulate the normal feedback control of insulin secretion, whereby hyperglycemia stimulates and hypoglycemia inhibits insulin secretion. They all involve frequent monitoring of the blood glucose concentration, usually four or more times per day; increases in the insulin dose if glucose levels are above the target upper level; reductions in the insulin dose if glucose levels are below the acceptable lower level; and techniques for adjusting insulin doses in relation to changes in diet. Several algorithms are available.²²²⁻²²⁴

Pramlintide

Amylin is a neuroendocrine hormone cosecreted with insulin by pancreatic beta cells. It was originally identified as a major constituent of pancreatic amyloid deposits. Its biologically active form is a 37-amino-acid peptide that undergoes extensive post-translational processing, including C-terminal amidation and glycosylation. As would be expected, amylin deficiency develops in parallel with insulin deficiency in patients with T1DM. Amylin and insulin have complementary actions in regulating plasma glucose. Insulin can be thought of as regulating the rate of glucose disappearance from the circulation. Amylin is thought to exert its major antihyperglycemic actions through central mechanisms after binding to brain nuclei such as the nucleus accumbens, dorsal raphe, and area postrema, promoting satiety and reducing appetite. It also is thought to act via vagal efferents, mediating a decrease in the rate of gastric emptying and a suppression of glucagon secretion in a glucose-dependent fashion. Effectively, amylin plays a role in regulating the rate of glucose appearance from the gastrointestinal tract and the liver.^{225,226}

However, amylin is relatively insoluble in aqueous solution and aggregates on plastic and glass. Pramlintide was developed as a soluble, nonaggregating, equipotent amylin analogue. In 2005, pramlintide was approved for human use in the United States. As expected, when pramlintide is

injected before meals, it slows gastric emptying, suppresses glucagon, and promotes satiety, with a subsequent reduction in the postprandial glucose level. In T1DM, pramlintide therapy is usually initiated at a dose of 15 µg before meals (0.025 mL or “2.5 units” in a U-100 insulin syringe of the marketed pramlintide acetate 0.6 mg/dL). Slow titration from there to the usual dose in patients with T1DM (60 µg before meals) as tolerated is recommended to minimize nausea and insulin-induced hypoglycemia. The maximally labeled dose in the setting of T2DM is 120 µg before meals.

In T1DM, the addition of pramlintide can be expected to produce modest reductions in HbA_{1c} (0.3 percentage points) and weight (1.5 kg), compared with placebo in controlled trials. Weight loss is more prevalent in overweight patients than in those with normal body weight, and it is generally independent of nausea. Severe insulin hypoglycemia can develop as a complication, particularly on initiation, because the effect of pramlintide on satiety can be robust, effectively stopping some patients from eating midmeal. To minimize this risk, it is suggested that patients reduce rapid-acting insulin at meals by approximately 50% on initiation of pramlintide; this is optimally accomplished by reducing the insulin-to-carbohydrate ratio and in many cases by administering pramlintide before the meal and insulin after the meal so that insulin dose reduction can be accomplished if the meal is not finished. Despite its role in glucagon regulation, pramlintide does not interfere with recovery from insulin-induced hypoglycemia.

Pramlintide is an agent whose role in the routine management of T1DM is evolving. The additional injections and expense certainly constitute a burden to patients and the health care system. Most patients note a dramatic improvement in postprandial glucose. Many find the appetite-suppressing effects quite helpful even in the absence of substantial weight gain. Some report an improvement in sense of well-being and energy. What is certain is that initiating and titrating pramlintide is complex and fraught with potential pitfalls. Perhaps more so than any other treatment for diabetes, it requires careful collaboration of patients and diabetes educators.

Complications of Intensive Management of Type 1 Diabetes

Hypoglycemia

The most serious complication of intensive regimens of insulin replacement is hypoglycemia, and this is usually the factor that limits patients' ability to achieve tight glucose control. In the DCCT, patients in the intensive treatment group had an approximately threefold greater risk of hypoglycemia than those in the conventional treatment group. Hypoglycemia can be life-threatening, leading to motor vehicle accidents, serious falls with fractures, and seizures. Patients with T1DM have serious defects in mechanisms responsible for glucose counterregulation, and this is a major underlying reason for the predisposition to hypoglycemia. Glucose counterregulation is reviewed in detail in Chapter 33.

The risk of hypoglycemia can be reduced if all patients treated with intensive regimens of insulin replacement are carefully educated about recognizing the symptoms of hypoglycemia and about the measures that should be taken to prevent more serious hypoglycemia after symptoms are initially experienced. Certain patients, particularly those with long-standing diabetes and autonomic

neuropathy, may not subjectively sense symptoms of hypoglycemia even in the presence of low glucose concentrations. Glycemic targets of therapy should be adjusted upward in these patients, because they are at particularly high risk for hypoglycemia. Similarly, patients with advanced end-stage microvascular or macrovascular diabetic complications, in whom the benefit of intensive glucose control is likely to be less, should not be exposed to the increased risk of hypoglycemia that is inherent in extremely intensive insulin-treatment regimens.

In addition to the availability of glucose tablets, hard candy, or other sources of a readily absorbable form of carbohydrate, almost all patients with T1DM should have emergency glucagon kits at home and at work, assuming that there are people in those settings who can be trained to use them. The administration of 0.5 to 1 mg of glucagon intramuscularly to a severely symptomatic person with hypoglycemia rapidly increases the plasma glucose concentration to an acceptable range and prevents the difficulties and dangers associated with attempting to get a stuporous or disoriented person to ingest glucose by mouth. Nevertheless, because of occasional failures of glucagon to reverse hypoglycemia fully, friends and family members should always be instructed to call for medical assistance as soon as the injection is provided.

The use of continuous glucose sensors with alarms can reduce the time that patients spend with glucose in the hypoglycemic range. Early experience suggests that this can be particularly valuable in the setting of hypoglycemia unawareness.²²⁷

Weight Gain

Improvement in glucose control with a reduction in glycosuria is invariably associated with weight gain as the leakage of calories into the urine is reduced or eliminated. In addition, increased food intake to treat or prevent hypoglycemia can contribute to weight gain. Insulin itself can stimulate appetite. As a result of the combination of all these effects, weight gain is common, particularly with intensive regimens of insulin replacement. As discussed earlier, weight gain can be minimized or partially reversed with the addition of pramlintide.

Worsening of Retinopathy

The institution of regimens of tight glucose control has been reported to exacerbate underlying retinopathy. Therefore, if a patient with a serious background of proliferative retinopathy presents in poor glucose control, ophthalmologic treatment of the retinopathy should be considered before tight glucose control is instituted.

Insulin Allergy

Insulin allergy has become much less common with the use of human insulin. Most manifestations of allergic reactions to insulin consist of local wheal-and-flare reactions at the site of injection. The allergic reaction can be to the insulin itself or to other components of the insulin preparation, such as the protamine in NPH insulin. Occasionally, more generalized allergic reactions occur, and even more rarely, anaphylactic reactions take place. In general, mild local allergic reactions to insulin can be treated with antihistamines. More severe reactions require desensitization or coadministration of glucocorticoids. Admission to the hospital is necessary. Under close supervision of a physician with access to equipment for emergency resuscitation, a protocol is followed in which the patient is exposed to gradually increasing amounts of insulin administered according to a set schedule.²²⁸

ACUTE DIABETIC EMERGENCIES: DIABETIC KETOACIDOSIS

DKA is a life-threatening condition in which severe insulin deficiency leads to hyperglycemia, excessive lipolysis, and unrestrained fatty acid oxidation, producing the ketone bodies acetone, β -hydroxybutyrate, and acetoacetate. This results in metabolic acidosis, dehydration, and deficits in fluid and electrolytes. Excess secretion of primarily glucagon, as well as catecholamines, glucocorticoids, and growth hormone, in combination with insulin deficiency produces hyperglycemia by stimulating glycogenolysis and gluconeogenesis and impairing glucose disposal. DKA is a far more characteristic feature of T1DM than of T2DM, but it may be seen in persons with T2DM under conditions of stress such as occur with serious infections, trauma, and cardiovascular or other emergencies.

Clinical Presentation

Patients with uncontrolled diabetes present with nonspecific complaints. If the disease follows an indolent course over months to years, patients can manifest profound wasting, cachexia, and prostration similar in degree to those of patients with long-standing malignancy or chronic infection. With significant physical or emotional stress, sudden metabolic decompensation can occur. The cases of DKA that are misdiagnosed usually occur in patients with new-onset diabetes. Polyuria (or at least nocturia) and weight loss are almost always present, although they are often not reported by the patient. Any patient with severe illness (acute or chronic) or neurologic changes should have glucose and electrolytes measured.

In DKA, metabolic decompensation usually develops over a period of hours to a few days. Patients with DKA classically present with lethargy and a characteristic hyperventilation pattern with deep, slow breaths (Kussmaul respirations) associated with the fruity odor of acetone. They often complain of nausea and vomiting; abdominal pain is somewhat less frequent. The abdominal pain can be quite severe and may be associated with distention, ileus, and tenderness without rebound, but it usually resolves relatively quickly with therapy unless there is underlying abdominal pathology. Most patients are normotensive, tachycardic, and tachypneic and have signs of mild to moderate volume depletion. Hypothermia has been described in DKA, and patients with underlying infection might not manifest fever. Cerebral edema does occur, usually during therapy. Patients with DKA can have stupor and obvious profound dehydration, and they often demonstrate focal neurologic deficits such as Babinski reflexes, asymmetrical reflexes, cranial nerve findings, paresis, fasciculations, and aphasia.

Laboratory Test Results and Differential Diagnosis

Laboratory Tests

Laboratory tests that are routinely monitored in the setting of DKA include hemoglobin, white blood cell and differential count, glucose, electrolytes, BUN, and creatinine. Changes in Na, K, Cl, P, BUN, and creatinine are also monitored.

The *sine qua non* of DKA is acidosis, and the serum bicarbonate (HCO_3^-) concentration is usually less than 10 mEq/L. The acidosis is caused by production and

accumulation of ketones in the serum. Three ketones are produced in DKA: two ketoacids (β -hydroxybutyrate and acetoacetate) and the neutral ketone, acetone. Ketones can be detected in serum and urine using the nitroprusside reaction on diagnostic strips for use at the patient's bedside or in the clinical laboratory. This test detects acetoacetate more effectively than acetone and does not detect an increased concentration of β -hydroxybutyrate. Particularly in severe DKA, β -hydroxybutyrate is the predominant ketone, and it is possible, although unusual, to have a negative serum nitroprusside reaction in the presence of severe ketosis. However, under these circumstances the serum bicarbonate is still markedly reduced and the anion gap is increased, indicating metabolic acidosis. The urinary β -hydroxybutyrate measurement can be performed at many centers and commercially but is not usually readily available.

The *anion gap* is a readily available index for unmeasured anions in the blood (normal, ≤ 14 mEq/L):

$$\text{Anion gap} = \text{sodium} - (\text{chloride} + \text{bicarbonate})$$

Most patients with DKA present with an anion gap greater than 20 mEq/L, and some present with a gap greater than 40 mEq/L. However, patients occasionally have a hyperchloremic metabolic acidosis without a significant anion gap.²²⁹

Patients with DKA almost invariably have large amounts of ketones in their urine. The serum glucose in DKA is usually in the 500 mg/dL range. However, an entity known as euglycemic DKA has been described, particularly in patients who have decreased oral intake or are pregnant, in which the serum glucose is normal or near normal but the patient requires insulin therapy for clearance of ketoacidosis.²³⁰ The arterial pH is commonly less than 7.3 and can be as low as 6.5. There is partial respiratory compensation with hypocarbia. Patients are often mildly hyperosmolar, although osmolality greater than 330 mOsm/kg is unusual without mental status changes.

Differential Diagnosis

Not all patients with hyperglycemia and an anion gap metabolic acidosis have DKA, and other causes of metabolic acidosis must be considered in these patients, particularly if the serum or urine ketone measurements are not elevated. The following causes of metabolic acidosis need to be considered in the differential diagnosis of DKA.

Lactic acidosis is the most common cause of metabolic acidosis in hospitalized patients and can be seen in patients with uncomplicated diabetes as well as those with DKA. Lactic acidosis usually occurs in the setting of decreased tissue oxygen delivery, which results in the nonoxidative metabolism of glucose to lactic acid. Lactic acidosis complicates other primary metabolic acidoses as a consequence of dehydration or shock, and assessing its relative contribution can be difficult. The presentation is identical to that of DKA. In pure lactic acidosis, the serum glucose and ketones should be normal and the serum lactate concentration should be greater than 5 mmol/L. The therapy for lactic acidosis is directed at the underlying cause and at optimization of tissue perfusion.²³¹

Starvation ketosis is caused by inadequate carbohydrate availability, which results in physiologically appropriate lipolysis and ketone production to provide fuel substrates for muscle. The blood glucose concentration is usually normal. Although the urine can have large amounts of ketones, the blood rarely does. Arterial pH is normal, and the anion gap is at most mildly elevated.

Alcoholic ketoacidosis is a more severe form of starvation ketosis wherein the appropriate ketogenic response to poor carbohydrate intake is increased through as yet poorly defined effects of alcohol on the liver. Classically, these patients are long-standing alcoholics for whom ethanol has been the main caloric source for days to weeks. The ketoacidosis occurs when, for some reason, alcohol and caloric intake decreases. In isolated alcoholic ketoacidosis, the metabolic acidosis is usually mild to moderate. The anion gap is elevated. Serum and urine ketones are always present. However, alcoholic ketoacidosis produces an even higher ratio of β -hydroxybutyrate to acetoacetate than DKA does, and negative or weakly positive nitroprusside reactions are common. Respiratory alkalosis associated with delirium tremens, agitation, or pulmonary processes often normalizes the pH but should be evident with careful analysis of acid-base status. Usually, the patient is normoglycemic or hypoglycemic, although mild hyperglycemia is occasionally present. Patients who are significantly hyperglycemic should be treated as if they had DKA. The therapy for alcoholic ketoacidosis consists of thiamine, carbohydrates, fluids, and electrolytes, with special attention to the more severe consequences of alcohol toxicity, alcohol withdrawal, and chronic malnutrition. In more severely ill patients in whom alcoholic ketoacidosis is considered a possibility, there is usually another underlying illness such as pancreatitis, gastrointestinal bleeding, hepatic encephalopathy, delirium tremens, or infection complicated by concomitant lactic acidosis.^{232,233}

Uremic acidosis is characterized by extremely large elevations in the BUN (often >200 mg/dL) and creatinine (>10 mg/dL) values with normoglycemia. The pH and anion gap are usually only mildly abnormal. The treatment is supportive, with careful attention to fluid and electrolytes until dialysis can be performed. Rhabdomyolysis is a cause of renal failure in which the anion gap can be significantly elevated and acidosis can be severe. There should be marked elevation of creatine phosphokinase and myoglobin. Mild rhabdomyolysis is not uncommon in DKA, but the presence of hyperglycemia and ketonemia leaves no doubt about the primary etiology of the acidosis.²³⁴

Toxic ingestions can be differentiated from DKA by history and laboratory investigation. Salicylate intoxication produces an anion gap metabolic acidosis, usually with an accompanying respiratory alkalosis. The plasma glucose level is normal or low, the osmolality is normal, ketones are negative, and salicylates can be detected in the urine or blood. Salicylates can cause a false-positive glucose determination when the cupric sulfate method is used and a false-negative result when the glucose oxidase reaction is used. Methanol and ethylene glycol also produce an anion gap metabolic acidosis without hyperglycemia or ketones, but these toxins need to be kept in mind primarily because they produce an increase in the measured serum osmolality but not in the calculated serum osmolality—an osmolar gap. Their serum levels can also be measured. Isopropyl alcohol does not cause a metabolic acidosis but should be remembered because it is metabolized to acetone, which can produce a positive result in the nitroprusside reaction commonly used for the detection of ketoacids. These intoxications must be appropriately treated.²³⁵⁻²³⁷ Rare cases of anion gap acidoses have been reported with other ingestions, including toluene, iron, hydrogen sulfide, nalidixic acid, papaverine, paraldehyde, strychnine, isoniazid, and outdated tetracycline.

When DKA is considered, the diagnosis can be made quickly with routine laboratory tests. Measurements of blood and urine glucose and ketones can be obtained in

minutes, using, respectively, glucose oxidase-impregnated strips and the nitroprusside reaction.

Osmolarity

The increase in osmolarity (in milliosmoles per liter [mOsm/L]) that occurs in DKA must be differentiated from the increase in osmolarity seen in hyperosmolar-hyperglycemic nonketotic (diabetic) coma (HHNC). The osmolarity can be measured by freezing point depression or estimated with the use of the following formula:

$$\text{Osmolarity} = (2 \times \text{sodium}) + (\text{glucose}/18) + (\text{BUN}/2.8) + (\text{ethanol}/4.6)$$

Patients with DKA not uncommonly present with hyperosmolarity and coma. In HHNC, the osmolarity is usually greater than 350 mOsm/L, and it can exceed 400 mOsm/L. The serum sodium and potassium levels can be high, normal, or low and do not reflect total-body levels, which are uniformly depleted. The glucose concentration is usually greater than 600 mg/dL, and levels higher than 1000 mg/dL are common. In pure HHNC, there is no significant metabolic acidosis or anion gap.

Patients often present with combinations of the preceding findings. HHNC can involve mild to moderate ketonemia and acidosis. Alcoholic ketoacidosis can contribute to either DKA or HHNC. Lactic acidosis is common in severe DKA and HHNC. Any patient with hyperglycemia greater than 250 mg/dL and an anion gap metabolic acidosis should be treated by the general principles outlined in the following section, with special consideration for other possible contributing metabolic acidoses.

Therapy

The optimal management of DKA has been a source of considerable controversy since the 1950s. Only recently have prospective studies of various therapeutic approaches been performed. The guidelines we propose rely heavily on prospective studies of DKA by Kitabchi and coworkers.^{238,239} The general approach is to provide necessary fluids to restore the circulation, treat insulin deficiency with continuous insulin, treat electrolyte disturbances, observe the patient closely and carefully, and search for underlying causes of metabolic decompensation.

Fluids

Volume contraction is one of the hallmarks of DKA. It can contribute to acidosis through lactic acid production and decreased renal clearance of organic and inorganic acids. It contributes to hyperglycemia by decreasing renal clearance of glucose. Decreased tissue perfusion, if significant, causes insulin resistance by decreasing insulin delivery to the sites of insulin-mediated glucose disposal, namely muscle and adipose tissue, and through stimulation of catecholamine and glucocorticoid secretion. Fluid deficits on the order of 5 to 10 L are common in DKA. The urine produced during the osmotic diuresis of hyperglycemia is approximately half-normal with respect to sodium. Therefore, water deficits are in excess of sodium deficits. Historically, large quantities of isotonic intravenous fluids have been administered rapidly to patients in DKA. For patients with a history of congestive heart failure, chronic or acute renal failure, severe hypotension, or significant pulmonary disease, early invasive hemodynamic monitoring should be considered.

When there is physical evidence of dehydration (i.e., hypotension, decreased skin turgor, or dry mucous membranes), the general treatment is to administer 1 L of

normal saline over the first hour and 200 to 500 mL/hour in subsequent hours until hypotension resolves and adequate circulation is maintained. If hypotension is severe, there is clinical evidence of hypoperfusion, and hypotension does not respond to crystalloid, therapy with colloid is considered, often in combination with invasive hemodynamic monitoring. If there is no hypotension and no concern about renal failure, 1 L of half-normal saline is administered over the first hour.

During that first hour, the laboratory data usually return and can be quite helpful in planning further therapy. Despite the excess of water losses over sodium, the measured sodium is usually low because of the osmotic effects of glucose. These osmotic effects can be corrected using a simple formula:

$$\text{Corrected sodium concentration} = \text{measured sodium} + 0.016 \times (\text{glucose} - 100)$$

Severe hypertriglyceridemia, which is common in severe diabetes, can cause a false decrease in the serum sodium concentration by approximately 1.0 mEq/L at a serum lipid concentration of 460 mg/dL.²²⁸ An estimated water deficit can be calculated using the corrected sodium concentration:

$$\text{Water deficit in liters} = 0.6 \times \text{weight in kg} \times [(\text{sodium}/140) - 1]$$

Based on these formulas, a 70-kg patient with a measured sodium level of 140 mEq/L and a glucose concentration of 1000 mg/dL would have a calculated water deficit of 4.3 L. If the patient is normotensive after the first liter of fluids has been administered, it is reasonable to aim to replace urinary losses with one-half normal saline and also to provide approximately one half of the water deficit (in this example, 2 L) as 5% dextrose over the first 12 to 24 hours and the remainder over the subsequent 24 hours. The plan for fluid therapy should be continuously reevaluated in light of the clinical and laboratory response of the patient. When the serum glucose level reaches 250 to 300 mg/dL, all fluids should contain 5% dextrose and therapy should be aimed at maintaining the serum glucose concentration in that range for 24 hours to allow slow equilibration of osmotically active substances across cell membranes.

The primary goal of fluid therapy is to maintain an adequate circulation, and the secondary goal is to maintain a brisk diuresis. Beyond that, pulmonary edema, hyperchloremic metabolic acidosis, and a rapid fall in the serum osmolality should be prevented by frequent monitoring of the patient and administration of glucose and electrolytes. It has been demonstrated that fluid administration and subsequent continued osmotic diuresis are responsible for a large portion of the initial decline in glucose during therapy.

Insulin

Insulin is the mainstay of therapy for DKA, because DKA is essentially an insulin-deficient state. In the past, high doses of insulin (50 U/hour or more) were favored. In later studies, low-dose insulin therapy (0.1 U/kg/hour) has been shown to be as effective as higher doses in producing a decrease in serum glucose and clearance of ketones. Furthermore, low-dose therapy results in a reduction in the major morbidity of intensive insulin therapy, namely hypoglycemia and hypokalemia.

Studies have also shown that intravenous insulin is significantly more effective than intramuscular or subcutaneous insulin in lowering the ketone body concentration

over the first 2 hours of therapy. The subcutaneous route is probably inappropriate for the critically ill patient because of the possibility of tissue hypoperfusion and slower kinetics of absorption; however, one study documented that a subcutaneous rapid-acting insulin analogue administered every 1 to 2 hours was as safe and effective as intravenous regular insulin in the treatment of uncomplicated DKA.²⁴⁰ Numerous studies attest to the efficacy of intramuscular therapy in severe DKA. If there is insufficient nursing monitoring or intravenous access to allow safe intravenous administration, intramuscular therapy is the route of choice.

It has been shown that a 10-U intravenous insulin priming dose given at the initiation of insulin therapy significantly improves the glycemic response to the first hour of therapy. The rationale is to saturate insulin receptors fully before beginning continuous therapy and to avoid the lag time that is necessary to achieve steady-state insulin levels. When insulin is mixed in normal saline, it does not seem to be necessary to add albumin to prevent insulin adsorption to the infusion set. However, the intravenous tubing should be flushed with the insulin infusate before use.

In the rare instances in which the glucose level does not decrease by at least 10% or 50 mg/dL in 1 hour, the insulin infusion rate should be increased by 50% to 100% and a second bolus of intravenous insulin should be administered. As the glucose level decreases, it is usually necessary to decrease the rate of infusion. After the glucose reaches approximately 250 mg/dL, it is prudent to decrease the insulin infusion rate and administer dextrose. It usually takes an additional 12 to 24 hours to clear ketones from the circulation after hyperglycemia is controlled. With resolution of ketosis, the rate of infusion approaches the physiologic range of 0.3 to 0.5 U/kg per day.

When the decision is made to feed the patient, intravenous or intramuscular therapy should be changed to subcutaneous therapy. Subcutaneous insulin should be administered before a meal, and the insulin drip should be discontinued approximately 30 minutes later. The glucose should be checked in 2 hours and at least every 4 hours afterward until a relatively stable insulin regimen is determined. Early conversion to oral feeding and subcutaneous insulin therapy is associated with a shorter hospital stay.

Potassium

Potassium losses during the development of DKA are usually quite high (3-10 mEq/kg) and are mediated by shifts to the extracellular space secondary to acidosis and protein catabolism compounded by hyperaldosteronism and osmotic diuresis. Although most patients with DKA or HHNC have a normal or even high serum potassium level at presentation, the initial therapy with fluids and insulin causes it to fall.

Our approach has been to monitor the electrocardiogram (ECG) for signs of hyperkalemia (peaked T wave, QRS widening) initially and to administer potassium if these signs are absent and the serum potassium level is less than 5.5 mEq/L. If the patient is oliguric, we do not administer potassium unless the serum concentration is less than 4 mEq/L or there are ECG signs of hypokalemia (U wave), and even then potassium is administered with extreme caution. With treatment of DKA, the potassium level always falls, usually reaching a nadir after several hours. We usually replace potassium at 10 to 20 mEq/hour (half as potassium chloride and half as potassium phosphate), monitor serum levels at least every 2 hours initially, and monitor ECG morphology. Occasionally, patients with

DKA who have had protracted courses that include vomiting, hypokalemia, and acidosis require 40 to 60 mEq/hour by central line to prevent further decreases in the serum potassium concentration.

Phosphate

Like potassium, phosphate is depleted in patients with DKA. Although patients usually present with an elevated serum phosphate concentration, the serum level declines with therapy. No well-documented clinical significance of these findings has been determined and no benefit of phosphate administration has been demonstrated, but most authorities recommend phosphate therapy as before and monitoring for its possible complications, which include hypocalcemia and hypomagnesemia.

Bicarbonate

Serum bicarbonate is always low in DKA, but a true deficit is not present because the ketoacids and lactate anions are metabolized to bicarbonate during therapy. The use of bicarbonate in the treatment of DKA is highly controversial. No benefit of bicarbonate therapy has been demonstrated in clinical trials. In fact, in two trials, hypokalemia was more common in bicarbonate-treated patients. There are theoretical considerations against the use of bicarbonate. Cellular levels of 2,3-diphosphoglycerate are depleted in DKA, causing a shift in the oxyhemoglobin dissociation curve to the left and thus impairing tissue oxygen delivery. Acidemia has the opposite effect, and therefore acute reversal of acidosis could decrease tissue oxygen delivery. In addition, *in vitro* data suggest that pH is a regulator of cellular lactate metabolism, and correction of acidosis could increase lactate production. These observations are of questionable clinical relevance, however.

We reserve bicarbonate therapy for patients with severe acidosis (pH <6.9), patients with hemodynamic instability if the pH is less than 7.1, and patients with hyperkalemia with ECG findings. When bicarbonate is used, it should be used sparingly and considered a temporizing measure while definitive therapy with insulin and fluids is under way. Approximately 1 mEq/kg of bicarbonate is administered as a rapid infusion over 10 to 15 minutes, and further therapy is based on repeated arterial blood gas sampling every 30 to 120 minutes. Potassium therapy should be considered before treatment with bicarbonate is undertaken, because transient hypokalemia is not an uncommon complication of the administration of alkali.

Monitoring

It is possible to manage many cases of mild DKA without admitting the patient to the intensive care unit, depending on staff availability. We routinely admit patients with DKA to the intensive care unit if they have a pH of less than 7.3. If mental status is compromised, prophylactic intubation is considered, and nasogastric suctioning is always performed because of frequent ileus and danger of aspiration. If the patient cannot void at will, bladder catheterization is necessary to monitor urine output adequately. ECG monitoring is continuous, with hourly documentation of QRS intervals and T-wave morphology. Initially, serum glucose, electrolytes, BUN, creatinine, calcium, magnesium, phosphate, ketones, lactate, creatine phosphokinase, and liver function tests as well as urinalysis, ECG, upright chest radiograph, complete blood count, and arterial blood gas analyses are obtained. If there is any concern about possible toxic ingestions, toxicology screening is also performed. Subsequently, glucose and electrolytes are

measured at least hourly; calcium, magnesium, and phosphate every 2 hours; and BUN, creatinine, and ketones every 6 to 24 hours.

It is often not necessary to monitor arterial blood gases routinely, because the bicarbonate level and the anion gap are relatively good indices of the response to therapy. Monitoring of venous pH has also been shown to reflect acidemia and response to therapy adequately. Usually, frequent blood work is necessary only for the first 12 hours or so. In the severely ill patient with obvious underlying disease, the course is often more protracted, and, particularly when venous access is a problem, early consideration should be given to placement of an arterial line. A flow sheet tabulating these findings as well as mental status, vital signs, insulin dose, fluid and electrolytes administered, and urine output allows easy analysis of response to therapy. After the acidosis begins to resolve and the response to therapy becomes predictable, it is reasonable to curtail laboratory testing. If the patient's cardiovascular status is unclear or troublesome, invasive hemodynamic monitoring is an appropriate guide for fluid therapy. The goals should be to achieve hemodynamic stability rapidly and to correct DKA fully in 12 to 36 hours.

Search for Underlying Causes

After the patient is stabilized, a careful history and physical examination is performed and a diagnostic strategy is developed that should be aimed at determining the precipitating event. In most inner-city practices, the most common cause of DKA is noncompliance with insulin therapy, which is usually easily treated. The second most common cause is infection, with viral syndromes, urinary tract infection, pelvic inflammatory disease, and pneumonia predominating. It is often difficult to determine initially whether the patient is infected. Fever is absent in a significant fraction of patients with diabetic emergencies. The white blood cell count is not uncommonly elevated in the range of 20,000/ μ L or higher even in the absence of infection.²⁴¹ As a result, cultures should be performed for most patients, and if there is significant concern about infection, empiric broad antibiotic coverage should be considered pending microbiologic findings.

Special consideration should be given to ruling out meningitis in the patient with altered mental status. In this regard, most would perform lumbar puncture in all patients with meningismus and in patients with disproportionate mental status changes. If the index of suspicion is lower, the antibiotic therapy should be geared to cover bacterial meningitis, and a lumbar puncture should be performed if the mental status does not improve quickly with therapy. The cerebrospinal fluid glucose measurement is not particularly useful in determining whether the fluid is infected, and a level lower than 100 mg/dL is unusual when the serum glucose concentration is greater than 250 mg/dL.²⁴² The relative frequency of sinus infection (particularly with *Mucor*), foot infection, bacterial arthritis, cholecystitis, cellulitis, and necrotizing fasciitis should also be considered.

Pneumonia can be difficult to diagnose in patients with dehydration because the alveolar edema fluid that shows up as an infiltrate on chest radiographs is often not present but develops along with progressive hypoxia during hydration. To prevent this occurrence, we administer intravenous fluid judiciously to patients with suspected pneumonia. Pancreatitis and pregnancy are common precipitants and should be especially considered when assessing the abdominal pain that is almost ubiquitous at presentation. Abdominal guarding and tenderness associated with vomiting are

common, and rebound is occasionally present. These symptoms and findings usually resolve quickly with therapy in the absence of intra-abdominal pathology. The serum amylase is often elevated without pathologic significance, although lipase is usually more specific.²⁴³ Acute myocardial infarction, stroke, and thromboembolic phenomena are frequent precipitants and complications of DKA.

The more insulin resistant the patient seems to be, the more likely one is to find a precipitating cause. If a precipitating cause is found, treatment is essential if adequate metabolic control is to be achieved.

Complications and Prognosis

It should now be possible to treat almost all cases of DKA successfully. The most troublesome complication is cerebral edema. It is common particularly in children and can be fatal. In most reported series, specific causes could not be assigned, although aggressive hydration, particularly with hypotonic fluids, can contribute.²⁴⁴ In 50% of patients who subsequently had a respiratory arrest, there were premonitory symptoms, and despite early intervention only half of them avoided severe or fatal brain damage.

Other complications of life-threatening severity that have been reported include the acute respiratory distress syndrome and bronchial mucous plugging.²⁴⁵⁻²⁴⁷ Arterial and venous thromboembolic events are quite common. Standard prophylactic low-dose heparin is certainly reasonable in patients with DKA, but currently no indication exists for full anticoagulation.

Two studies show that specialists (endocrinologists) provide more cost-effective care than nonspecialists. Patients under the care of specialists have a shorter hospital stay, fewer medical procedures, and lower medical costs.^{248,249}

BIOCHEMISTRY AND MOLECULAR CELL BIOLOGY

All forms of diabetes, both inherited and acquired, are characterized by hyperglycemia, a relative or absolute lack of insulin, and the development of diabetes-specific microvascular pathology in the retina, renal glomerulus, and peripheral nerve. Diabetes is also associated with accelerated atherosclerotic macrovascular disease affecting arteries that supply the heart, brain, and lower extremities. Pathologically, this condition resembles macrovascular disease in nondiabetic patients, but it is more extensive and progresses more rapidly. As a consequence of its microvascular pathology, diabetes mellitus is now the leading cause of new blindness in people 20 to 74 years of age and the leading cause of end-stage renal disease (ESRD).

People with diabetes mellitus are the fastest growing group of renal dialysis and transplant recipients. The life expectancy of patients with diabetic ESRD is only 3 or 4 years. More than 60% of diabetic patients are affected by neuropathy, which includes distal symmetric polyneuropathy (DSPN), mononeuropathies, and a variety of autonomic neuropathies causing erectile dysfunction, urinary incontinence, gastroparesis, and nocturnal diarrhea.

Because of accelerated lower-extremity arterial disease in conjunction with neuropathy, diabetes mellitus accounts for 50% of all nontrauma amputations in the United States. The risk of cardiovascular complications is increased by twofold to sixfold in subjects with diabetes. Overall, life expectancy is about 7 to 10 years shorter than for people without diabetes mellitus because of increased mortality from diabetic complications.¹

Large prospective clinical studies show a strong relationship between glycemia and diabetic microvascular complications in both type 1 diabetes mellitus (T1DM) and type 2 diabetes (T2DM).^{2,3} There is a continuous, although not linear, relationship between the level of glycemia and the risk of development and progression of these complications (Fig. 33-1).^{4,5} Hyperglycemia and the consequences of insulin resistance both appear to play important roles in the pathogenesis of macrovascular complications.⁶⁻¹⁰

Shared Pathophysiologic Features of Microvascular Complications

In the retina, glomerulus, and vasa nervorum, diabetes-specific microvascular disease is characterized by similar pathophysiologic features.

Figure 33-1 Relative risks for the development of diabetic complications at different mean levels of glycosylated hemoglobin (HbA_{1c}) obtained from the Diabetes Control and Complications Trial. (Adapted from Skyler J: Diabetic complications: the importance of glucose control. *Endocrinol Metab Clin North Am.* 1996;25:243-254.)

Requirement for Intracellular Hyperglycemia

Clinical and animal model data indicate that chronic hyperglycemia is the central initiating factor for all types of diabetic microvascular disease. The duration and magnitude of hyperglycemia are strongly correlated with the extent and rate of progression of diabetic microvascular disease. In the Diabetes Control and Complications Trial (DCCT), for example, T1DM patients whose intensive insulin therapy resulted in glycosylated hemoglobin (HbA_{1c}) levels 2% lower than those receiving conventional insulin therapy had a 76% lower incidence of retinopathy, a 54% lower incidence of nephropathy, and a 60% reduction in neuropathy.^{2,3} However, further analysis of the DCCT data showed that, although intensive therapy reduced the risk of sustained retinopathy progression by 73% compared with standard treatment, HbA_{1c} and duration of diabetes (glycemic exposure) explained only about 11% of the variation in retinopathy risk for the entire study population, suggesting that the remaining 89% of the variation in risk can be explained by aspects of glycemia not captured by HbA_{1c}.¹¹

Although all diabetic cells are exposed to elevated levels of plasma glucose, hyperglycemic damage is limited to those cell types (e.g., endothelial cells) that develop intracellular hyperglycemia. Endothelial cells develop intracellular hyperglycemia because, unlike many other cells, they cannot downregulate glucose transport when exposed to extracellular hyperglycemia. As illustrated in Figure 33-2, vascular smooth muscle cells (VSMC), which are not damaged by hyperglycemia, show an inverse relationship between extracellular glucose concentration and subsequent rate of glucose transport measured as 2-deoxyglucose uptake (Fig. 33-2, upper part). In contrast, vascular endothelial cells show no significant change in subsequent rate of glucose transport after exposure to elevated glucose concentrations (see Fig. 33-2, lower part).¹² That intracellular hyperglycemia is necessary and sufficient for the development of diabetic pathology is further demonstrated by the fact that overexpression of glucose transporter 1 (GLUT1) in mesangial cells cultured in a normal glucose milieu mimics the diabetic phenotype, inducing the same increases in collagen type IV, collagen type I, and fibronectin gene

expression as are observed in diabetic hyperglycemia (Fig. 33-3).¹³

Abnormal Endothelial Cell Function

Early in the course of diabetes mellitus, before structural changes are evident, hyperglycemia causes abnormalities in blood flow and vascular permeability in the retina, glomerulus, and peripheral nerve vasa nervorum.^{14,15} The increase in blood flow and intracapillary pressure is thought to reflect a hyperglycemia-induced decrease in nitric oxide (NO) production on the efferent side of capillary beds and possibly an increased sensitivity to angiotensin II. As a consequence of increased intracapillary pressure and endothelial cell dysfunction, retinal capillaries exhibit increased leakage of fluorescein, and glomerular capillaries have an elevated albumin excretion rate (AER). Comparable changes occur in the vasa vasorum of peripheral nerves. Early in the course of diabetes, increased permeability is reversible, but as time progresses, it becomes irreversible.

Increased Vessel Wall Protein Accumulation

The common pathophysiologic feature of diabetic microvascular disease is progressive narrowing and eventual occlusion of vascular lumina, which results in inadequate perfusion and function of the affected tissues. Early hyperglycemia-induced microvascular hypertension and increased vascular permeability contribute to irreversible microvessel occlusion by three processes.

The first process is an abnormal leakage of periodic acid-Schiff (PAS)-positive, carbohydrate-containing plasma proteins, which are deposited in the capillary wall and can stimulate perivascular cells such as pericytes and mesangial cells to elaborate growth factors and extracellular matrix.

The second process is extravasation of growth factors, such as transforming growth factor- β 1 (TGF- β 1), which

Figure 33-2 Lack of downregulation of glucose transport in cells affected by diabetic complications. Upper panel, 2-deoxyglucose (2DG) uptake in vascular smooth muscle cells preexposed to 1.2, 5.5, or 22 mmol/L glucose. Lower panel, 2DG uptake in bovine endothelial cells preexposed to 1.2, 5.5, or 22 mmol/L glucose. (From Kaiser N, Feener EP, Boukobza-Vardi N, et al. Differential regulation of glucose transport and transporters by glucose in vascular endothelial and smooth muscle cells. *Diabetes.* 1993;42:80-89.)

Figure 33-3 Overexpression of glucose transporter 1 (GLUT1) in mesangial cells cultured in normal glucose mimics the diabetic phenotype. Mesangial cells transfected with either LacZ (MCLacZ)-expressing or GLUT1 (MCGT1)-expressing constructs were cultured in 5 mmol/L glucose, and the secreted amounts of the indicated matrix components were determined. (From Heilig CW, Concepcion LA, Riser BL, et al. Overexpression of glucose transporters in rat mesangial cells cultured in a normal glucose milieu mimics the diabetic phenotype. *J Clin Invest*. 1995;96:1802-1814.)

directly stimulates overproduction of extracellular matrix components¹⁶ and can induce apoptosis in certain complication-relevant cell types.

The third process is hypertension-induced stimulation of pathologic gene expression by endothelial cells and supporting cells, which include GLUT1, growth factors, growth factor receptors, extracellular matrix components, and adhesion molecules that can activate circulating leukocytes.¹⁷ The observation that unilateral reduction in the severity of diabetic microvascular disease occurs on the side with ophthalmic or renal artery stenosis is consistent with this concept.^{18,19}

Microvascular Cell Loss and Vessel Occlusion

The progressive narrowing and occlusion of diabetic microvascular lumina are also accompanied by microvascular cell loss. In the retina, diabetes mellitus induces programmed cell death of Müller cells and ganglion cells,²⁰ pericytes, and endothelial cells.²¹ In the glomerulus, declining renal function is associated with widespread capillary occlusion and podocyte loss, but the mechanisms underlying glomerular cell loss are not yet known. In the vasa nervorum, degeneration of endothelial cells and pericytes occur,²² and these microvascular changes appear to precede the development of diabetic peripheral neuropathy.²³ The multifocal distribution of axonal degeneration in diabetes supports a causal role for microvascular occlusion, but hyperglycemia-induced decreases in neurotrophins might contribute by preventing normal axonal repair and regeneration.²⁴

Development of Microvascular Complications during Posthyperglycemic Euglycemia

Another common feature of diabetic microvascular disease has been termed *hyperglycemic memory*, or the persistence or progression of hyperglycemia-induced microvascular alterations during subsequent periods of normal glucose homeostasis. The most striking example of this phenomenon is the development of severe retinopathy in

histologically normal eyes of diabetic dogs, which occurred entirely during a 2.5-year period of normalized blood glucose that followed 2.5 years of hyperglycemia (Fig. 33-4).²⁵ Normal dogs were compared to diabetic dogs with either poor control for 5 years, good control for 5 years, or poor control for 2.5 years ($P \rightarrow G_a$) followed by good control for the next 2.5 years ($P \rightarrow G_b$). HbA_{1c} values for both the good control group and the $P \rightarrow G_b$ group were identical to those of the normal group. Hyperglycemia-induced increases in selected matrix gene transcription also persist for weeks after restoration of normoglycemia in vivo, and a less pronounced but qualitatively similar prolongation of hyperglycemia-induced increase in selected matrix gene transcription occurs in cultured endothelial cells.²⁶

Data from the DCCT suggested that hyperglycemic memory occurs in patients. In the secondary intervention cohort, there was no difference in the incidence of sustained progression of retinopathy for the first 3 years, no difference in development of clinical albuminuria for 4 years, and no difference in the rate of change in creatinine clearance during the entire study. For neuropathy, the sural nerve sensory conduction velocity did not differ between the groups for 4 years, and intensive therapy did not slow the rate of decline of autonomic function at all.^{2,27-29}

Data from the DCCT suggested that hyperglycemic memory occurs in patients. In the secondary intervention cohort, there was no difference in the incidence of sustained progression of retinopathy for the first 3 years, no difference in development of clinical albuminuria for 4 years, and no difference in the rate of change in creatinine clearance during the entire study. For neuropathy, the sural nerve sensory conduction velocity did not differ between the groups for 4 years, and intensive therapy did not slow the rate of decline of autonomic function at all.^{2,27-29}

Data from the post-DCCT long-term follow-up study, the Epidemiology of Diabetes, Interventions, and Complications (EDIC) study, proved that the effects of former intensive and conventional therapy persist for 12 years. In the conventional therapy group, the effects of previous high HbA_{1c} on poststudy retinopathy, nephropathy, and cardiovascular disease (CVD) persisted as if there had been no improvement in HbA_{1c} at all. Atherosclerotic changes

Figure 33-4 Development of retinopathy during posthyperglycemic normoglycemia (hyperglycemic memory). Quantitation of retinal microaneurysms and acellular capillaries in normal dogs (Normal), dogs with poor glycemic control for 5 years (Poor), dogs with good glycemic control for 5 years (Good), dogs with poor glycemic control for 2.5 years ($P \rightarrow G_a$), and the same dogs after a subsequent 2.5 years of good glycemic control ($P \rightarrow G_b$). (Adapted from Engerman RL, Kern TS. Progression of incipient diabetic retinopathy during good glycemic control. *Diabetes*. 1987;36:808-812.)

Figure 33-5 Cumulative incidence of further progression of retinopathy 4 years after the end of the Diabetes Control and Complications Trial. The median glycosylated hemoglobin level was 8.2% for the conventional therapy group and 7.9% for the intensive therapy group. EDIC, Epidemiology of Diabetes, Interventions, and Complications [Research Group]. (From Retinopathy and nephropathy in patients with type 1 diabetes four years after a trial of intensive therapy. The Diabetes Control and Complications Trial/Epidemiology of Diabetes Interventions and Complications Research Group. *N Engl J Med.* 2000;342:381-389.)

not even present at the end of the DCCT appeared subsequently in the previously higher HbA_{1c} group, followed by a twofold increase in heart attacks, strokes, and cardiovascular death, even though the HbA_{1c} level in these patients since the end of the DCCT was identical to that of the formerly intensive-control group during the entire time that these arterial changes developed (Fig. 33-5).^{30,31} On the other hand, the beneficial effects of previous lower HbA_{1c} also persisted in the intensive treatment group after their HbA_{1c} went up, as if there had been no deterioration in their HbA_{1c}.

Therefore, the phenomenon of hyperglycemic memory presents a paradox: Patients in the DCCT with long-term exposure to a higher level of hyperglycemia became more susceptible to damage from subsequent lower levels of hyperglycemia than they were when they first started the trial. In contrast, lower levels of hyperglycemia made patients more resistant to damage from subsequent higher levels.

Genetic Determinants of Susceptibility to Microvascular Complications

Clinicians have long observed that different patients with similar duration and degree of hyperglycemia differ markedly in their susceptibility to microvascular complications. Such observations suggested that genetic differences exist that affected the pathways by which hyperglycemia damages microvascular cells. The leveling of risk of overt proteinuria after 30 years' duration of T1DM at 27% is evidence that only a subset of patients are susceptible to development of diabetic nephropathy.³²

A role for a genetic determinant of susceptibility to diabetic nephropathy is most strongly supported by familial clustering, with an estimated heritability of at least 40%.³³ In two studies of families in which two or more siblings had T1DM, the risk of nephropathy in a diabetic sibling was 83% or 72% if the proband diabetic sibling had advanced diabetic nephropathy, but only 17% or 22% if the index patient did not have diabetic nephropathy (Fig. 33-6),^{34,35} or retinopathy. The DCCT reported familial clustering as well, with an odds ratio of 5.4 for the risk of severe

retinopathy in diabetic relatives of positive versus negative subjects from the conventional treatment group.³⁶ Coronary artery calcification, an indicator of subclinical atherosclerosis, also shows familial clustering.

Numerous associations have been made between various genetic polymorphisms and the risk of diabetic complications. Examples include the 5' insulin gene polymorphism,³⁷ the G2m²³⁺ immunoglobulin allotype,³⁸ angiotensin-converting enzyme (ACE) insertion/deletion polymorphisms,^{39,40} HLA-DQB10201/0302 alleles,⁴¹ polymorphisms of the aldose reductase gene,⁴² and a polymorphic CCTTT(n) repeat of nitric oxide synthase 2A (NOS2A).⁴³ In all of these studies, there was no indication that the polymorphic gene actually plays a functional role rather than simply being in linkage disequilibrium with the locus encoding the unidentified relevant genes.

A whole-genome linkage analysis using families of Pima Indians showed susceptibility loci for diabetic nephropathy on chromosome 3, 7, and 20. Another linkage analysis using discordant sib-pairs of white families with T1DM identified a critical area on chromosome 3q. Evidence for linkage to kidney disease has been detected and replicated at several loci on chromosomes 3q (T1DM and T2DM nephropathy), 10q (diabetic and nondiabetic kidney disease), and 18q (T2DM nephropathy).⁴⁴

Family-based studies of simple tandem repeat polymorphisms (STRPs) and single-nucleotide polymorphisms (SNPs) in 115 candidate genes for linkage and association with diabetic nephropathy in T1DM families of European descent showed a positive association with polymorphisms in 20 genes, including 12 that had not been studied previously. Three of these genes code for components of the extracellular matrix (*COL4A1*, *LAMA4*, and *LAMC1*), and two are involved in its metabolism (*MMP9* and *TIMP3*). Five genes code for transcription factors or signaling molecules (*HNF1B1/TCF2*, *NRP1*, *PRKCB1*, *SMAD3*, and *USF1*). Three genes code for growth factors or growth factor receptors (*IGF1*, *TGFBR2*, and *TGFBR3*). The other genes (*AGTR1*, *AQP1*, *BCL2*, *CAT*, *GPX1*, *LPL*, and *p22phox*) code for a variety of products that are likely to be relevant in kidney function.⁴⁵

An individual-based genetic association study of subjects from the DCCT/EDIC found that multiple variations

Figure 33-6 Familial clustering of diabetic nephropathy. Prevalence of diabetic nephropathy in two studies of diabetic siblings of probands with or without diabetic nephropathy. (Adapted from Seaquist ER, Goetz FC, Rich S, et al. Familial clustering of diabetic kidney disease: evidence for genetic susceptibility to diabetic nephropathy. *N Engl J Med.* 1989;320:1161-1165; Quinn M, Angelico MC, Warram JH, et al. Familial factors determine the development of diabetic nephropathy in patients with IDDM. *Diabetologia.* 1996;39:940-945.)

in superoxide dismutase 1 were significantly associated with persistent microalbuminuria and severe nephropathy.⁴⁶ A combination of case-control association and functional studies demonstrated that the T allele of SNP rs1617640 in the promoter of the erythropoietin gene (*EPO*) was significantly associated with proliferative diabetic retinopathy (PDR) and ESRD in three European-American cohorts, suggesting that rs1617640 in the *EPO* promoter is significantly associated with PDR and ESRD.⁴⁷ In addition, a multicenter study based on 518 subjects with long-standing diabetes mellitus showed that three *EPO* SNPs were associated with overall diabetic retinopathy status in the combined T1DM and T2DM groups and in the T2DM-alone group.⁴⁸

As genes are identified that affect susceptibility to diabetic complications, a new area of research has emerged that will make it possible to identify genetic modifiers of the clinical manifestations of complications. With the completion of the genetic map known as the International HapMap Project and new high-throughput genotyping technologies, this promising area of research holds great potential for understanding genetic determinants of the varying clinical severity of diabetic complications. These modifying genes are genetic variants that are distinct from disease-susceptibility genes and that modify the phenotypic and clinical expression of the disease genes.⁴⁹ Because complications are likely to result not only from hyperglycemia but also from a susceptibility to later pathophysiologic steps such as inflammation or aberrant angiogenesis, a number of modifier genes may be relevant to diabetic complications.

Pathophysiologic Features of Macrovascular Complications

Unlike microvascular disease, which occurs only in patients with diabetes mellitus, macrovascular disease resembles that in subjects without diabetes. However, subjects with diabetes have more rapidly progressive and extensive CVD, with a greater incidence of multivessel disease and a greater number of diseased vessel segments than nondiabetic persons.⁵⁰ Although dyslipidemia and hypertension occur with great frequency in T2DM populations, there is still excess risk in diabetic subjects after adjusting for these other risk factors.^{51,52} Diabetes itself can confer 75% to 90% of the excess risk of coronary disease in these diabetic subjects, and it enhances the deleterious effects of the other major cardiovascular risk factors (Fig. 33-7).^{53,54} The importance of hyperglycemia in the pathogenesis of diabetic macrovascular disease is suggested by the observation that HbA_{1c} is an independent risk factor for CVD⁵⁵ in T1DM, and numerous correlational studies show that hyperglycemia is a continuous risk factor for macrovascular disease.⁵⁶⁻⁶⁰

However, data from the United Kingdom Prospective Diabetes Study (UKPDS) show that hyperglycemia is not nearly as central a determinant of diabetic macrovascular disease as it is in microvascular disease. For microvascular disease end points, there is an almost 10-fold increase in risk as HbA_{1c} increases from 5.5% to 9.5%, whereas over the same HbA_{1c} range, macrovascular risk increases only about twofold.³

Insulin resistance occurs in most patients with T2DM and in two thirds of subjects with impaired glucose tolerance.⁶¹ Both these groups have a significantly higher risk of developing CVD.⁶²⁻⁶⁵ To isolate the effects of insulin resistance from those of hyperglycemia and diabetes, several studies have evaluated subjects with normal glucose

Figure 33-7 Adjusted death rates by number of cardiovascular disease (CVD) risk factors for diabetic and nondiabetic men. Subjects are participants from the Multiple Risk Factor Intervention Trial (MRFIT) study; risk factors are hypercholesterolemia, hypertension, and cigarette smoking. (From Stamler J, Vaccaro O, Neaton JD, et al. Diabetes, other risk factors, and 12-year cardiovascular mortality for men screened in the Multiple Risk Factor Intervention Trial. *Diabetes Care*. 1993;2:434-444.)

tolerance. In T1DM, hyperglycemia itself causes secondary insulin resistance in almost all patients. In nonobese subjects without diabetes, insulin resistance predicted the development of CVD independently of other known risk factors.⁶⁶ In another group of subjects without diabetes or impaired glucose tolerance, those in the highest quintile of insulin resistance had a 2.5-fold increase in CVD risk compared with those in the lowest quintile.⁶⁷ These data indicate that insulin resistance itself promotes atherogenesis.

Insulin resistance is commonly associated with a proatherogenic dyslipidemia; data from Brown, Goldstein, and colleagues suggested that this dyslipidemia results from hyperinsulinemia-induced activation of sterol regulatory element-binding protein 1c (SREBP-1c) transcription in the liver by a mechanism that is not affected by the defects in hepatic phosphatidylinositol 3 kinase (PI3K)-mediated insulin signaling.^{68,69} Insulin resistance is associated with a characteristic lipoprotein profile that includes a high level of very-low-density lipoprotein (VLDL) and low levels of high-density lipoprotein (HDL) and small, dense low-density lipoprotein (LDL). Both low HDL and small, dense LDL are independent risk factors for macrovascular disease. This profile arises as a direct result of increased net free fatty acid (FFA) release by insulin-resistant adipocytes (Fig. 33-8).¹⁰ Increased FFA flux into hepatocytes stimulates VLDL secretion. In the presence of cholesteryl ester transfer protein, excess VLDL transfers significant amounts of triglyceride to HDL and LDL while depleting HDL and LDL of cholesteryl ester. The resultant triglyceride-enriched HDL carries less cholesteryl ester for reverse cholesterol transport to the liver, and loss of apolipoprotein 1A-1 (Apo1A-1) from these particles reduces the total concentration of HDL available for reverse cholesterol transport. The triglyceride-enriched, cholesteryl ester-depleted LDL is smaller and denser than normal LDL, allowing it to penetrate the vessel wall and be oxidized more easily.

In vitro studies suggest that at the level of the vessel wall, insulin has both antiatherogenic and proatherogenic effects (Fig. 33-9).^{70,71} One major antiatherogenic effect is the stimulation of endothelial NO production. NO released

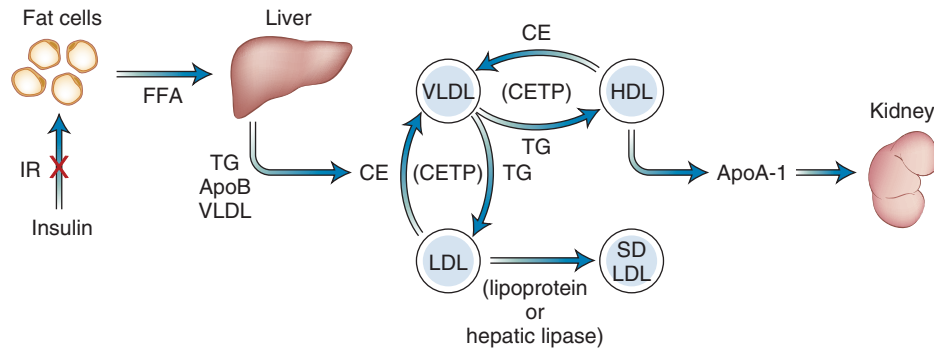

Figure 33-8 Schematic summary relating insulin resistance (IR) to the characteristic dyslipidemia of type 2 diabetes mellitus. IR at the adipocyte results in increased free fatty acid (FFA) release. Increased FFA flux stimulates secretion of very-low-density lipoprotein (VLDL), causing hypertriglyceridemia (TG). VLDL stimulates a reciprocal exchange of TG to cholesteryl ester (CE) from both high-density lipoprotein (HDL) and low-density lipoprotein (LDL), catalyzed by CE transfer protein (CETP). TG-enriched HDL dissociates from apolipoprotein (Apo) A-I, leaving less HDL for reverse cholesterol transport. TG-enriched LDL serves as a substrate for lipases that convert it to atherogenic small, dense LDL particles (SD LDL). (From Ginsberg HN. Insulin resistance and cardiovascular disease. *J Clin Invest.* 2000;106:453-458.)

from endothelial cells is a potent inhibitor of platelet aggregation and adhesion to the vascular wall. Endothelial NO also controls the expression of genes involved in atherogenesis. It decreases expression of monocyte chemoattractant protein 1 (MCP-1) and of surface adhesion molecules such as CD11/CD18, P-selectin, vascular cell adhesion molecule 1 (VCAM-1), and intercellular adhesion molecule 1 (ICAM-1). Endothelial cell NO also reduces vascular permeability and decreases the rate of oxidation of LDL to its proatherogenic form. Finally, endothelial cell NO inhibits proliferation of VSMC.⁷²

Figure 33-9 Schematic summary of proatherosclerotic and antiatherosclerotic actions of insulin on vascular cells. ICAM, intercellular adhesion molecule; IRS, insulin resistance syndrome; MAP-K, mitogen-activated protein kinase; MAPKK, MAPK kinase; PAI, plasminogen activator inhibitor; PI, phosphatidylinositol; TNF, tumor necrosis factor; VSMC, vascular smooth muscle cell. (Adapted from King G, Brownlee M. The cellular and molecular mechanisms of diabetic complications. *Endocrinol Metab Clin North Am.* 1996;2:255-270; Hsueh WA, Law RE. Cardiovascular risk continuum: implications of insulin resistance and diabetes. *Am J Med.* 1998;105:4S-14S.)

Two major proatherogenic effects of insulin are the potentiation of platelet-derived growth factor (PDGF)-induced VSMC proliferation and the stimulation of VSMC production of plasminogen activator inhibitor 1 (PAI-1).^{73,74} Because insulin-induced NO production is mediated by the insulin receptor substrate-PI3K signal transduction pathway and the effects on smooth muscle cells are mediated by the signal transduction pathway involving Ras, Raf, MAPK (mitogen-activated protein kinase), and MEKK (MAPK/extracellular-signal-regulated kinase [ERK] kinase [MEK] kinase),^{71,72} it has been proposed that pathway-selective insulin resistance in arterial cells may contribute to diabetic atherosclerosis. Evidence of such selective vascular resistance to insulin has been demonstrated in the obese Zucker rat.⁷⁵

Hyperglycemia also inhibits arterial endothelial NO production, both in vivo and in vitro.⁷⁶⁻⁷⁹ Similarly, hyperglycemia potentiates PDGF-induced VSMC proliferation and stimulates endothelial cell PAI-1 production.^{78,80} In addition, hyperglycemia has a variety of other proatherogenic effects on endothelial cells, platelets, and monocyte/macrophages. These include increased expression of MCP-1,⁸¹ upregulation of adhesion molecules such as ICAM-1 and VCAM-1,⁸²⁻⁸⁴ potentiation of collagen-induced platelet activation, and increased secretion of collagen type IV and fibronectin.^{85,86}

Surprisingly, however, in subjects without diabetes or impaired glucose tolerance, after adjustment for 11 known cardiovascular risk factors, including LDL, triglycerides, HDL, systolic blood pressure (BP), and smoking, the most insulin-resistant subjects still have a twofold increase in the risk of CVD.⁶⁷ This observation suggests that a significant part of the increased CVD risk due to insulin resistance reflects a consequence of insulin resistance not previously identified as being proatherogenic. Data suggest that increased oxidation of FFAs by insulin-resistant aortic endothelial cells inactivates two important antiatherosclerotic enzymes: prostacyclin synthase and endothelial NOS (eNOS). This inactivation is reversed by inhibition of the rate-limiting enzyme of fatty acid oxidation, carnitine palmitoyltransferase I, through inhibition of FFA release from insulin-resistant adipose tissue and reduction of superoxide levels.⁸⁷

Although the association of insulin resistance with CVD risk is clear, data concerning the relative role of hyperglycemia in promoting CVD in diabetes appear to be somewhat contradictory. In T1DM, in which severe insulin

resistance is not a major abnormality, lowering of HbA_{1c} levels with more intensive insulin treatment during the DCCT reduced both atherosclerosis surrogates during the trial and actual CVD events years after the trial had concluded. Intensive treatment reduced the risk of any CVD event by 42% and the risk of nonfatal myocardial infarction (MI), stroke, or death from CVD by 57%.⁸⁸ In contrast, intensive insulin treatment during the Action to Control Cardiovascular Risk in Diabetes (ACCORD) trial was associated with an unexpected excess of cardiovascular mortality in the intensive arm that caused the study to end early. Patients in this group were treated with a goal of lowering HbA_{1c} to 6.0%. A higher average on-treatment HbA_{1c} level was a stronger predictor of mortality than the HbA_{1c} for the last interval of follow-up or the decrease in HbA_{1c} during the first year. Of note, the excess risk associated with intensive glycemic treatment occurred among those participants whose average HbA_{1c}, contrary to the intent of the strategy, was greater than 7%.⁸⁹

How might these apparently conflicting results be explained? One possibility is that intensive therapy in extremely insulin-resistant diabetic patients causes proatherogenic effects through overstimulation of insulin signaling pathways not affected by insulin resistance. In the liver, insulin exerts two predominant actions: it reduces glucose production (gluconeogenesis) and it increases the synthesis of fatty acids and triglycerides (lipogenesis). In the insulin-resistant state, only one of these actions is blocked in liver. Insulin loses its ability to reduce gluconeogenesis but it retains its ability to enhance lipogenesis.^{90,91}

Therefore, the increase in insulin levels to overcome the hyperglycemia caused by pathway-selective insulin resistance likely overdrives nonresistant pathways of insulin signaling, including MAPK. In arterial endothelial cells, such selective overdrive of the MAPK pathway by insulin would stimulate cellular growth and migration and the production of prothrombotic and profibrotic factors. Insulin stimulates secretion of the vasoconstrictor endothelin-1 and increases cellular adhesion molecule expression. In arterial smooth muscle cells, overdrive of the MAPK pathway by high insulin levels would stimulate VSMC proliferation and migration as well as expression of angiotensinogen and its receptor, AT1R.^{75,92}

Impaired Collateral Blood Vessel Formation from Bone Marrow Progenitor Cells

It has become apparent that diabetic complications result not only from damage to vascular cells but also from a defective repair process. Normally, in response to acute ischemia, new blood vessel growth rescues stunned areas of the heart or central nervous system, reducing morbidity and mortality. In response to chronic ischemia, collateral vessel development reduces the size and severity of subsequent infarction. In response to ischemia, circulating endothelial progenitor cells from the bone marrow promote the regeneration of blood vessels, acting in concert with cells and extracellular matrix at the site of injury. In experimental diabetes, however, these circulating endothelial progenitor cells are depleted and dysfunctional. As a result, diabetic animals have decreased vascular density after hind limb ischemia. Similarly, in human diabetes, endothelial progenitor cells are also depleted and dysfunctional.⁹³

Clinically, diabetes is associated with poor outcomes after acute vascular occlusive events. This results in part from a failure to form adequate compensatory microvasculature in response to ischemia. Advanced glycation end products (AGEs) appear to play a central role in this failure.

High glucose induces a decrease in transactivation by the transcription factor hypoxia-inducible factor-1 α (HIF-1 α), which mediates production of hypoxia-stimulated chemokine and vascular endothelial growth factor (VEGF) by hypoxic tissue and expression of chemokine receptor and eNOS in endothelial precursor cells in the bone marrow. Decreasing superoxide in diabetic mice, by transgenic expression of manganese superoxide dismutase or by administration of a superoxide dismutase mimetic, corrected postischemic defects in neovascularization, oxygen delivery, and chemokine expression, and normalized tissue survival. Decreased HIF-1 α functional activity was specifically caused by impaired formation of the HIF-1 α heterodimer with arylhydrocarbon receptor nuclear translocator (ARNT) and by impaired binding of the coactivator p300 to the HIF-1 α -ARNT heterodimer. Hyperglycemia-induced covalent modification of p300 by the dicarbonyl metabolite methylglyoxal is responsible for this decreased association (Fig. 33-10). In diabetic mouse models of impaired angiogenesis and wound healing, decreasing mitochondrial formation of reactive oxygen species (ROS) normalizes both ischemia-induced new vessel formation and wound healing.^{94,95}

Many diabetic patients who have impaired blood vessel growth after ischemic events also have increased retinal neovascularization (diabetic retinopathy). This diabetic paradox is at present poorly understood.^{96,97} The question of how endothelial progenitor cell dysfunction can participate in diabetic retinopathy is especially intriguing, given the findings by Grant and colleagues⁹⁸ that bone marrow-derived endothelial progenitor cells play a role in a model of adult retinal revascularization. A plausible explanation may be that the cells responsible for increased VEGF production in the diabetic retina do not develop intracellular hyperglycemia and consequent HIF-1 α dysfunction. They respond normally to ischemia, in contrast to ischemic tissue elsewhere in the body. VEGF is known to be significantly elevated in the ocular fluid of diabetic patients, but it has also been shown to be decreased in ischemic nonretinal tissues.⁹⁹ Because VEGF has a stimulatory effect on endothelial progenitor cell proliferation and is a potent stimulator of vasculogenesis,¹⁰⁰ retinal cells whose VEGF expression in response to ischemia is not affected by hyperglycemia may be sufficient to overcome endothelial progenitor cell dysfunction and cause PDR.

Mechanisms of Hyperglycemia-Induced Damage

Four major hypotheses about how hyperglycemia causes diabetic complications have generated a large amount of data as well as several clinical trials based on specific inhibitors of these mechanisms. Until recently, there was no unifying hypothesis linking these four mechanisms together, nor was there an obvious connection between any of these mechanisms, each of which responds quickly to normalization of hyperglycemia, and the phenomenon of hyperglycemic memory (see earlier discussion).

Increased Polyol Pathway Flux

Aldose reductase [alditol:NADP+ 1-oxidoreductase, EC 1.1.1.21] is a cytosolic, monomeric oxidoreductase that catalyzes the reduced nicotinamide adenine dinucleotide phosphate (NADPH)-dependent reduction of a wide variety of carbonyl compounds, including glucose. Triphosphopyridine nucleotide, the reduced form of NADP (NADPH), is the cofactor in this reaction and in the regeneration of

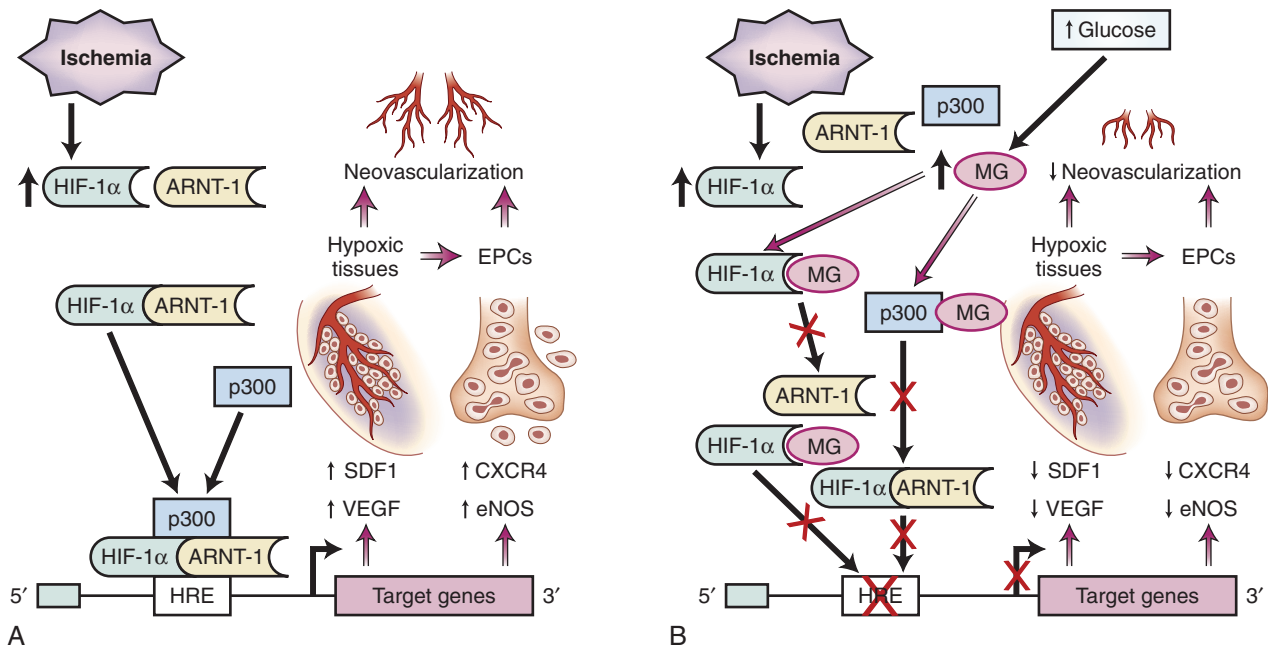

Figure 33-10 Ischemia-induced neovascularization in normal and high glucose. **A**, In the presence of normal glucose concentrations, ischemia-stabilized HIF-1 α forms heterodimers with ARNT, which bind the coactivator p300. This complex binds to the hypoxia response element (HRE) and activates expression of genes required for neovascularization. **B**, High glucose–induced methylglyoxal (MG) modifies HIF-1 α and p300, inhibiting complex binding to the HREs of genes required for neovascularization.

glutathione by glutathione reductase. Aldose reductase has a low-affinity (high Michaelis constant [K_m]) for glucose, and at the normal glucose concentrations found in nondiabetic patients, the metabolism of glucose by this pathway constitutes a small percentage of total glucose utilization. In a hyperglycemic environment, however, increased intracellular glucose results in increased enzymatic conversion to the polyalcohol sorbitol, with concomitant decreases in NADPH. In the polyol pathway, sorbitol is oxidized to fructose by the enzyme sorbitol dehydrogenase, with nicotinamide adenine dinucleotide (NAD $^{+}$) reduced to NADH (Fig. 33-11). Flux through this pathway during hyperglycemia varies from 33% of total glucose utilization in the rabbit lens to 11% in human erythrocytes. Therefore, the contribution of this pathway to diabetic complications may be very much species, site, and tissue dependent.

A number of mechanisms have been proposed to explain the potential detrimental effects of hyperglycemia-induced increases in polyol pathway flux. These include sorbitol-induced osmotic stress, decreased activity of the sodium-potassium adenosine triphosphatase (Na $^{+}$,K $^{+}$ -ATPase) pump, increased cytosolic NADH/NAD $^{+}$, and decreased cytosolic NADPH. Sorbitol does not diffuse easily across cell membranes, and it was originally suggested that this resulted in osmotic damage to microvascular cells. However, sorbitol concentrations measured in diabetic vessels and nerves are far too low to cause osmotic damage.

Another early suggestion was that increased flux through the polyol pathway decreased Na $^{+}$,K $^{+}$ -ATPase activity. Although this was originally thought to be mediated by polyol pathway–linked decreases in phosphatidylinositol synthesis, it has been shown to result from activation of protein kinase C (PKC) (see later discussion). Hyperglycemia-induced activation of PKC increases cytosolic phospholipase A $_2$ activity, which increases the production of two inhibitors of Na $^{+}$,K $^{+}$ -ATPase, arachidonate and prostaglandin E $_2$ (PGE $_2$).¹⁰¹

More recently, it has been proposed that oxidation of sorbitol by NAD $^{+}$ increases the cytosolic NADH/NAD $^{+}$ ratio, thereby inhibiting activity of the enzyme glyceraldehyde-3-phosphate dehydrogenase (GADPH) and increasing the concentrations of triose phosphate.¹⁰² Elevated triose phosphate concentrations could increase the formation of both methylglyoxal a precursor of AGEs, and (via α -glycerol-3-phosphate) diacylglycerol (DAG), thus activating PKC (discussed later). Although increased NADH

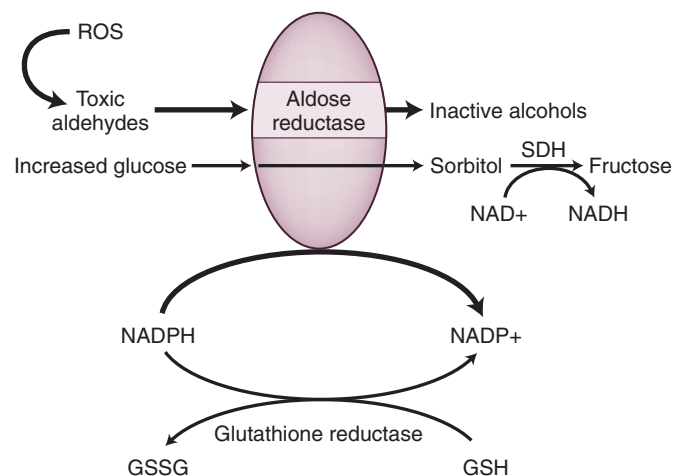

Figure 33-11 Aldose reductase and the polyol pathway. Aldose reductase reduces reactive oxygen species (ROS)-generated toxic aldehydes to inactive alcohols, and glucose to sorbitol, using triphosphopyridine nucleotide (NADPH), the reduced form of nicotinamide adenine dinucleotide phosphate (NADP), as a cofactor. In cells in which aldose reductase activity is sufficient to deplete reduced glutathione (GSH), oxidative stress would be augmented. Sorbitol dehydrogenase (SDH) oxidizes sorbitol to fructose using nicotinamide-adenine dinucleotide (NAD $^{+}$) as a cofactor. GSSG, oxidized glutathione.

production is supported by the observation that hyperglycemia increases both the lactate concentration and the lactate-to-pyruvate ratio, there is no direct evidence that the concentrations of NADH and NAD⁺, as opposed to NADH and NAD⁺ flux, are altered. In endothelial cells, where aldose reductase activity is low, increased NADH production might also reflect hyperglycemia-induced increased flux through glycolysis¹⁰³ and through the glucuronic acid pathway.¹⁰⁴

Other evidence presented in support of this hypothesis includes the observation that administration of pyruvate can prevent diabetes-related endothelial dysfunction in some systems. However, the observed effects of pyruvate on microvascular function may reflect its potent antioxidant properties rather than effects on the NADH/NAD⁺ ratio, because ROS also partially inhibit GADPH and increase glyceraldehyde-3-phosphate levels.^{105,106} The source of hyperglycemia-induced ROS is discussed later in this section.

It has also been proposed that reduction of glucose to sorbitol by NADPH consumes the cofactor NADPH. Because NADPH is required for regeneration of reduced glutathione, this could induce or exacerbate intracellular oxidative stress. Indeed, overexpression of human aldose reductase increased atherosclerosis in diabetic mice and reduces the expression of genes that regulate regeneration of glutathione.¹⁰⁷ Less reduced glutathione has been found in the lens of transgenic mice that overexpress aldose reductase, and this is the most likely mechanism by which increased flux through the polyol pathway has deleterious consequences.¹⁰⁸ This conclusion is further supported by recent experiments with aldose reductase-deficient homozygous knockout mice, showing that, in contrast to wild-type mice, diabetes neither decreases sciatic nerve content of reduced glutathione nor reduces motor nerve conduction velocity.¹⁰⁹

Observations suggest that NO maintains aldose reductase in an inactive state and that this repression is relieved in diabetic tissues.¹¹⁰ Aldose reductase appears to be inhibited by NO-derived adduct formation on active-site Cys-298.^{111,112} These observations suggest that diabetes-induced decreases in NO might further activate the polyol pathway.

In vivo studies of polyol pathway inhibition have yielded inconsistent results. In a 5-year study in dogs, aldose reductase inhibition prevented diabetic neuropathy but failed to prevent retinopathy or capillary basement membrane thickening in the retina, kidney, or muscle.¹¹³ Several negative clinical trials have questioned the relevance of this mechanism in humans.¹¹⁴ However, the positive effect of aldose reductase inhibition on diabetic neuropathy has been confirmed in humans in a rigorous multidose, placebo-controlled trial with the potent aldose reductase inhibitor, zenarestat.¹¹⁵

Increased Intracellular Formation of Advanced Glycation End Products

Advanced Glycation End Products Are Formed from Intracellular Dicarbonyl Precursors. AGEs are found in increased amounts in extracellular structures of diabetic retinal vessels¹¹⁶⁻¹¹⁸ and renal glomeruli,¹¹⁹⁻¹²¹ where they can cause damage by mechanisms described later in this section. These AGEs were originally thought to arise from nonenzymatic reactions between extracellular proteins and glucose. However, the rate of AGE formation from glucose is orders of magnitude slower than the rate of AGE formation from glucose-derived dicarbonyl precursors generated intracellularly, and it now seems likely that intracellular

hyperglycemia is the primary initiating event in the formation of both intracellular and extracellular AGEs.¹²² AGEs can arise from intracellular auto-oxidation of glucose to glyoxal,¹²³ decomposition of the Amadori product to 3-deoxyglucosone (perhaps accelerated by an amadoriase), and fragmentation of glyceraldehyde-3-phosphate to methylglyoxal (Fig. 33-12).¹²⁴ These reactive intracellular dicarbonyls react with amino groups of intracellular and extracellular proteins to form AGEs. Methylglyoxal and glyoxal are detoxified by the glyoxalase system.¹²⁴ All three AGE precursors are also substrates for other reductases.^{125,126}

Figure 33-12 Potential pathways leading to the formation of advanced glycation end products (AGEs) from intracellular dicarbonyl precursors. Glyoxal arises from the auto-oxidation of glucose, 3-deoxyglucosone arises from decomposition of the Amadori product, and methylglyoxal arises from fragmentation of glyceraldehyde-3-phosphate. These reactive dicarbonyls react with amino groups of proteins to form AGEs. Methylglyoxal and glyoxal are detoxified by the glyoxalase system. (Adapted from Shinohara M, Thornalley PJ, Giardino I, et al. Overexpression of glyoxalase-I in bovine endothelial cells inhibits intracellular advanced glycation end-product formation and prevents hyperglycemia-induced increases in macromolecular endocytosis. *J Clin Invest*. 1998;101:1142-1147.)

Figure 33-13 Potential mechanisms by which intracellular production of advanced glycation end-product (AGE) precursors damages vascular cells. First, intracellular protein modification alters protein function. Second, extracellular matrix modified by AGE precursors has abnormal functional properties. Third, plasma proteins modified by AGE precursors bind to AGE receptors on adjacent cells such as macrophages, thereby inducing receptor-mediated production of deleterious gene products such as cytokines. mRNA, messenger RNA; NF-κB, nuclear factor-κB; ROS, reactive oxygen species. (Adapted from Brownlee M. Lilly Lecture 1993: glycation and diabetic complications. *Diabetes*. 1994;43:836-841.)

In vascular endothelial cells, methylglyoxal accounts for almost all or the hyperglycemia-induced increase in reactive AGE precursors.

The potential importance of AGEs in the pathogenesis of diabetic complications is suggested by the observation in animal models that two structurally unrelated AGE inhibitors partially prevented various functional and structural manifestations of diabetic microvascular disease in retina, kidney, and nerve.^{127,128} In the human diabetic retina, AGEs might contribute to both macular edema and retinal neovascularization by increasing expression of VEGF through activation of the MAPK ERK1/2 and concomitant activation of the transcription factor HIF1.¹²⁹ In the early phase of diabetic nephropathy, AGEs induce hyperfiltration and microalbuminuria by stimulating the secretion of VEGF and MCP-1.¹³⁰ AGEs contribute to more advanced lesions of diabetic nephropathy by inducing apoptosis in glomerular mesangial cells and by inducing epithelial-myofibroblast transdifferentiation via ligation of the receptor for advanced glycation end products (RAGE; see later discussion), ultimately leading to tubulointerstitial fibrosis.¹³¹

Intracellular production of AGE precursors damages target cells by three general mechanisms (Fig. 33-13): Intracellular proteins modified by AGEs have altered function. Extracellular matrix components modified by AGE precursors interact abnormally with other matrix components and with matrix receptors (integrins) on cells. Plasma proteins modified by AGE precursors bind to AGE receptors on cells such as macrophages, inducing receptor-mediated ROS production. This AGE-receptor ligation activates the pleiotropic transcription factor nuclear factor-κB (NFκB), causing pathologic changes in gene expression.¹³²

Advanced Glycation End Products Alter Intracellular Protein Function. It has recently been shown that AGE modification of intracellular proteins can regulate

expression of genes involved in the pathogenesis of diabetic retinopathy. In diabetic retinal capillaries, the earliest morphologic changes are pericyte loss and acellular capillary formation. The primary pathologic processes of retinal pericyte loss and acellular capillary formation are regulated by complex context-dependent interactions among a number of proangiogenic and antiangiogenic factors,¹³³⁻¹³⁵ including angiopoietin-2 (Ang-2). When insufficient levels of VEGF and other angiogenic signals are present, Ang-2 causes endothelial cell death and vessel regression.¹³⁶⁻¹³⁸

Diabetes induces a significant increase in retinal expression of Ang-2 in rats,¹³⁹ and diabetic Ang-2^{-/-} mice have both decreased pericyte loss and reduced acellular capillary formation.¹⁴⁰ In retinal Müller cells, increased glycolytic flux causes increased methylglyoxal modification of the corepressor, mSin3A. Methylglyoxal modification of mSin3A results in increased Ang-2 expression. A similar mechanism involving methylglyoxal modification of other coregulator proteins may play a role in a variety of other diabetes-induced changes in gene expression.¹⁴¹

Advanced Glycation End Products Interfere with Normal Matrix-Matrix and Matrix-Cell Interactions. Methylglyoxal also leaks out of cells and is increased threefold to fivefold in the blood of diabetic patients, circulating at a concentration as high as 8 μmol/L.¹⁴² Methylglyoxal at this level greatly enhances apoptosis caused by agents that induce oxidative stress and DNA damage.¹⁴³ Methylglyoxal also can act as an antiapoptotic modulator by direct modification of heat shock protein 27 (HSP27) at amino acid Arg-188, which allows HSP27 to repress cytochrome c-mediated caspase activation.¹⁴⁴

AGE formation from circulating methylglyoxal and other AGE precursors alters the functional properties of several important matrix molecules. On type I collagen, this cross-linking induces an expansion of the molecular packing.¹⁴⁵ These AGE-induced cross-links alter the

function of intact vessels. For example, AGEs decrease elasticity in large vessels from diabetic rats, even after vascular tone is abolished, and increase fluid filtration across the carotid artery.¹⁴⁶ AGE formation on type IV collagen from basement membrane inhibits lateral association of these molecules into a normal network-like structure by interfering with binding of the noncollagenous NC1 domain to the helix-rich domain.¹⁴⁷ AGE formation on laminin causes decreased polymer self-assembly, decreased binding to type IV collagen, and decreased binding of heparan sulfate proteoglycan.¹⁴⁸ In vitro AGE formation on intact glomerular basement membrane increases its permeability to albumin in a manner that resembles the abnormal permeability of diabetic nephropathy.^{149,150}

AGE formation on extracellular matrix interferes not only with matrix-matrix interactions but also with matrix-cell interactions.¹⁵¹ For example, AGE modification of the cell-binding domains of type IV collagen decreases endothelial cell adhesion, and AGE modification of a 6-amino-acid growth-promoting sequence in the A chain of the laminin molecule markedly reduces neurite outgrowth.¹⁵² AGE modification of vitronectin reduces cell attachment-promoting activity.¹⁵³ Research has shown that increased modification of vascular basement membrane type IV collagen by methylglyoxal, at hot spot modification sites in the RGD and GFOGER integrin-binding sites of collagen, causes endothelial cell detachment and inhibition of angiogenesis.¹⁵⁴ In addition, matrix glycation impairs agonist-induced Ca^{2+} increases, and this may adversely affect regulatory functions of the endothelium.¹⁵⁵

Advanced Glycation End Product Receptors Mediate Pathologic Changes in Gene Expression. Several cell-associated binding proteins for AGEs have been identified, including OST-48, 80K-H, galectin-3, macrophage scavenger receptor type II, and RAGE.^{156,160} Some of these are more likely to contribute to clearance of AGEs, whereas others can cause sustained cellular perturbations mediated by AGE ligand binding. In cell culture systems, the receptors identified to date appear to mediate long-term effects of AGEs on key cellular targets of diabetic complications such as macrophages, glomerular mesangial cells, and vascular endothelial cells, although not all of these receptors bind proteins with physiologic AGE-modified levels. These effects include expression of cytokines and growth factors by macrophages and mesangial cells—interleukin 1 (IL-1), insulin-like growth factor type 1 (IGF1), tumor necrosis factor- α (TNF- α), TGF- β , macrophage colony-stimulating factor (M-CSF), granulocyte-macrophage colony-stimulating factor (GM-CSF), and PDGF¹⁶¹⁻¹⁷⁵—and expression of procoagulatory or proinflammatory molecules by endothelial cells (i.e., thrombomodulin, tissue factor, and VCAM-1).¹⁷⁶⁻¹⁷⁹ In addition, endothelial AGE receptor binding appears to mediate, in part, the hyperpermeability induced by diabetes, probably through the induction of VEGF.¹⁸⁰⁻¹⁸² RAGE deficiency attenuates the development of atherosclerosis in the diabetic apolipoprotein E (apoE)-null mouse model of accelerated atherosclerosis. Diabetic RAGE^{-/-}/apoE^{-/-} mice had significantly reduced atherosclerotic plaque area. These beneficial effects on the vasculature were associated with attenuation of leukocyte recruitment; decreased expression of proinflammatory mediators, including the NF- κ B subunit p65, VCAM-1, and MCP-1; and reduced oxidative stress.¹⁸³

More recent studies indicate that AGEs at the concentrations found in diabetic sera are not the major ligand for RAGE. Rather, several proinflammatory protein ligands have been identified that activate RAGE at low concentrations.

These include several members of the S100 calgranulin family and high-mobility group box 1 (HMGB1), all of which are increased by diabetic hyperglycemia.¹⁸⁴ Ligation of these ligands with RAGE causes cooperative interaction with the innate immune system signaling molecule, toll-like receptor 4 (TLR4).^{185,186} Expressions of RAGE, S100A8, S100A12, and HMGB1 are all increased by high levels of glucose in cell culture and in diabetic animals. This hyperglycemia-induced overexpression is mediated by ROS-induced methylglyoxal, which increases binding of the transcription factors NF- κ B and activator protein 1 (AP1) to the RAGE and RAGE ligands, respectively.¹⁸⁷

Blockade of RAGE, a member of the pattern-recognition receptor class of the innate immune system, suppresses macrovascular disease in an atherosclerosis-prone type 1 diabetic mouse model in a glucose- and lipid-independent fashion.¹⁸⁸ Blockade of RAGE has also been shown to inhibit the development of diabetic vasculopathy,¹⁸⁹ nephropathy,¹³¹ and periodontal disease¹⁹⁰ and to enhance wound repair in murine models via suppression of cytokines, TNF- α , IL-6, metalloproteinase 2 (MMP2), MMP3, and MMP9.¹⁹¹ In the apoE-null mouse model of diabetic atherosclerosis, RAGE plays an important role in accelerated lesion formation and in lesion regression. Blockade of RAGE significantly reduced lesion size and structure and decreased parameters of inflammation as well as mononuclear phagocyte and smooth muscle cell activation.^{188,192} In human saphenous vein endothelial cells, engagement of RAGE by heterogeneous AGEs or N-(carboxymethyl) lysine (CML)-modified adducts enhanced levels of mRNA and antigen for VCAM-1, ICAM-1, and E-selectin, leading to increased adhesion of polymorphonuclear leukocytes to stimulated endothelial cells. These effects were markedly reduced by blockade of RAGE.¹⁹³ RAGE has been shown to mediate signal transduction via generation of ROS, which activates both NF- κ B, and p21 ras.¹⁹⁴⁻¹⁹⁶ AGE signaling is blocked in cells by expression of RAGE antisense complementary DNA^{194,197} or antiRAGE ribozyme.^{195,198}

Vascular endothelial cells and pericytes have been demonstrated to express two splice variants of full-length RAGE mRNA. One codes for an isoform that lacks the amino-terminal V-type immunoglobulin-like domain (N-truncated), and one codes for an isoform lacking the carboxyl-terminal transmembrane domain (C-truncated). The C-truncated type lacks the transmembrane domain and is secreted extracellularly and detected in human sera as endogenous secretory RAGE (esRAGE). Circulating esRAGE levels are significantly lower in T1DM patients than in nondiabetic subjects, and plasma esRAGE levels are inversely correlated with carotid intima medial thickness (CIMT) and with increased risk of CVD.^{199,200} Therefore, it is possible that individual differences in esRAGE expression influence the development of diabetic vascular complications.

Activation of Protein Kinase C

Mechanism of Hyperglycemia-Induced Protein Kinase C Activation. The PKC family comprises at least 11 isoforms, 9 of which are activated by the lipid second-messenger, DAG. Intracellular hyperglycemia increases DAG content in cultured microvascular cells and in the retina and renal glomeruli of diabetic animals.²⁰¹⁻²⁰³ Intracellular hyperglycemia appears to increase DAG content primarily by increasing its de novo synthesis from the glycolytic intermediate glyceraldehyde-3-phosphate via reduction to glycerol-3-phosphate and stepwise acylation.^{202,204} Increased de novo synthesis of DAG activates PKC in cultured vascular cells^{203,205-207} and in retina and

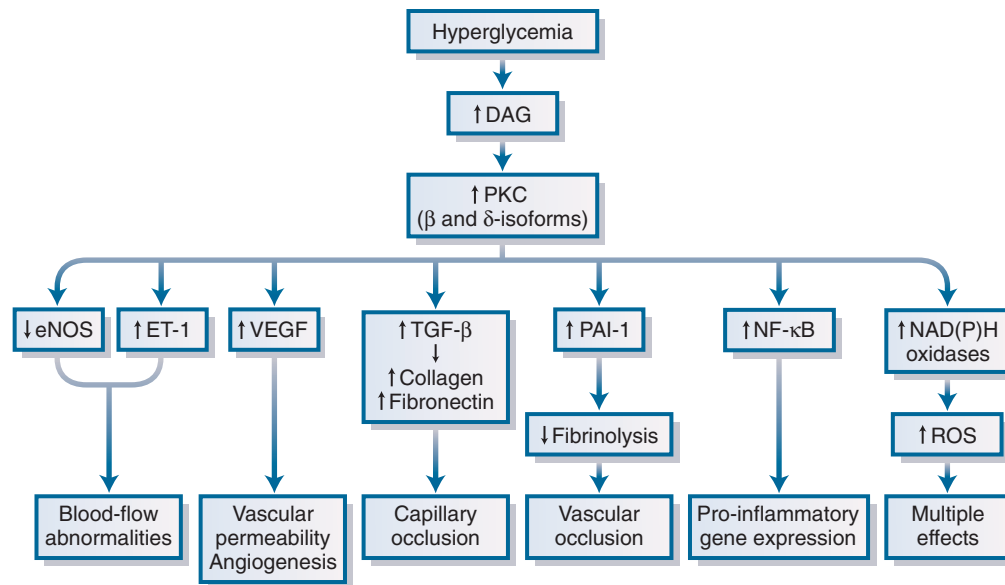

Figure 33-14 Potential consequences of hyperglycemia-induced protein kinase C (PKC) activation. Hyperglycemia increases diacylglycerol (DAG) content, which activates PKC, primarily the β and δ isoforms. Activated PKC has a number of pathogenic consequences. eNOS, endothelial nitric oxide synthase; ET-1, endothelin 1; NAD(P)H, nicotinamide adenine dinucleotide phosphate; NF κ B, nuclear factor- κ B; PAI, plasminogen activator inhibitor; ROS, reactive oxygen species; TGF, transforming growth factor; VEGF, vascular endothelial growth factor. (Adapted from Koya D, Jirousek MR, Lin YW, et al. Characterization of protein kinase C beta isoform activation on the gene expression of transforming growth factor-beta, extracellular matrix components, and prostanooids in the glomeruli of diabetic rats. *J Clin Invest*. 1997;100:115-126.)

glomeruli of diabetic animals.^{202,203,205} Increased DAG primarily activates the β and δ isoforms of PKC, but increases in other isoforms have also been found, such as PKC- α and - ϵ isoforms in the retina²⁰⁸ and PKC- α and - δ isoforms in the glomerulus^{209,210} of diabetic rats. DAG, its mimetics, the phorbol esters, and ROS all activate PKC isoforms by triggering the release of zinc ions from the cysteine-rich zinc finger of the regulatory domain. PKC isoforms can also be activated through tyrosine phosphorylation in a manner unrelated to receptor-coupled hydrolysis of inositol phospholipids. The effect of hyperglycemia on PKC tyrosine phosphorylation has not yet been examined.^{211,212}

Consequences of Hyperglycemia-Induced Protein Kinase C Activation. In early experimental diabetes, activation of PKC- β isoforms has been shown to mediate retinal and renal blood flow abnormalities,²¹³ perhaps by depressing NO production and increasing endothelin-1 activity (Fig. 33-14). In the diabetic retina, hyperglycemia persistently activates PKC and p38a MAPK to increase the expression of a previously unknown target of PKC signaling, Src homology-2 domain-containing phosphatase-1 (SHP-1), a protein tyrosine phosphatase. This signaling cascade leads to PDGF receptor- β dephosphorylation and a reduction in downstream signaling from this receptor, resulting in pericyte apoptosis.²¹⁴ Abnormal activation of PKC also has been implicated in the decreased glomerular production of NO induced by experimental diabetes²¹⁵ and in the decreased smooth muscle cell NO production induced by hyperglycemia.²¹⁶ PKC activation also mediates glucose-enhanced extracellular matrix accumulation in rat glomerular mesangial cells.²¹⁷ Hyperglycemia increases endothelin 1-stimulated MAPK activity in glomerular mesangial cells by activating PKC isoforms.²¹⁸ The increased endothelial cell permeability induced by high glucose concentrations in cultured cells is mediated by activation of PKC- α ²¹⁹ and is independent of the intracellular calcium concentration-NO pathway.²²⁰ Activation of PKC by elevated glucose

levels also induces expression of the permeability-enhancing factor VEGF in smooth muscle cells.²²¹

In addition to affecting hyperglycemia-induced abnormalities of blood flow and permeability, activation of PKC contributes to increased microvascular matrix protein accumulation by inducing the expression of TGF- β 1, fibronectin, and α 1 type IV collagen in cultured mesangial cells^{217,222} and in glomeruli of diabetic rats.²¹⁵ This effect appears to be mediated through PKC's inhibition of NO production.²²³ Hyperglycemia-induced expression of laminin C1 in cultured mesangial cells is independent of PKC activation.²²⁴ Hyperglycemia-induced activation of PKC has also been implicated in the overexpression of the fibrinolytic inhibitor PAI-1²²⁵ and in the activation of the pleiotrophic transcription factor NF κ B in cultured endothelial cells and VSMC.^{226,227} When PKC- β 2 is selectively overexpressed in the myocardium of diabetic mice, expression of connective tissue growth factor (CTGF) and TGF- β 1 increases, and the mice develop cardiomyopathy and cardiac fibrosis.²²⁸

In VSMC, activation of PKC by elevated glucose increases p38 MAPK activity and induces expression of the permeability-enhancing factor, VEGF.^{222,229} PKC activation also activates various membrane-associated NAD(P)H-dependent oxidases.²³⁰ Ex vivo treatment of human blood vessels from patients with diabetes and coronary artery disease (CAD) with a PKC inhibitor reduced diabetes-induced vascular superoxide production by NAD(P)H oxidases and superoxide-induced uncoupling of eNOS.²³¹ In normal subjects, the reduction in endothelium-dependent vasodilation induced by acute hyperglycemia is normalized by inhibition of PKC- β , consistent with prevention of hyperglycemia-induced eNOS uncoupling.²³²

Increased Hexosamine Pathway Flux

A fourth hypothesis about how hyperglycemia causes diabetic complications²³³⁻²³⁶ states that glucose is shunted into the hexosamine pathway (Fig. 33-15). In this pathway,

Figure 33-15 Schematic representation of the hexosamine pathway. The glycolytic intermediate, fructose-6-phosphate (Fruc-6-P), is converted to glucosamine-6-phosphate (Glc-6-P) by the enzyme glutamine:fructose 6-phosphate amidotransferase (GFAT). Increased donation of *N*-acetylglucosamine moieties to serine and threonine residues of transcription factors such as Sp1 increases production of such complication-promoting factors as plasminogen activator inhibitor I (PAI-I) and transforming growth factor- β 1 (TGF- β 1). AS-GFAT, antisense to GFAT; AZA, azaserine; GlcNAc, *N*-acetylglucosamine; mRNA, messenger RNA; UDP, uridine diphosphate. (Adapted from Du XL, Edelstein D, Rossetti L, et al. Hyperglycemia-induced mitochondrial superoxide overproduction activates the hexosamine pathway and induces plasminogen activator inhibitor-I expression by increasing Sp1 glycosylation. *Proc Natl Acad Sci U S A*. 2000;97:12222-12226.)

fructose-6-phosphate is diverted from glycolysis to provide substrates for reactions that require uridine diphosphate-*N*-acetylglucosamine (UDP-GlcNAc), such as proteoglycan synthesis and the formation of *O*-linked glycoproteins. Inhibition of glutamine:fructose-6-phosphate amidotransferase (GFAT), the rate-limiting enzyme in the conversion of glucose to glucosamine, blocks hyperglycemia-induced increases in the transcription of both TGF- α ²³³ and TGF- β 1.²³⁴ This pathway has previously been shown to play an important role in hyperglycemia-induced and fat-induced insulin resistance²³⁷⁻²³⁹ by impairing activation of the insulin resistance/insulin resistance syndrome (IRS)/PI3K/Akt pathway.²⁴⁰

The mechanism by which increased flux through the hexosamine pathway mediates hyperglycemia-induced increases in gene transcription has not been clear, but the observation that Sp1 sites regulate hyperglycemia-induced activation of the PAI-1 promoter in VSMC²⁴¹ suggested that covalent modification of Sp1 by GlcNAc might explain the link between hexosamine pathway activation and hyperglycemia-induced changes in gene transcription. Glucosamine itself subsequently was shown to activate the PAI-1 promoter through Sp1 sites in glomerular mesangial cells.²⁴² Hyperglycemia has been shown to induce a 2.4-fold increase in hexosamine pathway activity in aortic endothelial cells, resulting in a 1.7-fold increase in Sp1 *O*-linked GlcNAc and a 70% to 80% decrease in Sp1 *O*-linked phosphothreonine and phosphoserine.⁷⁹ Concomitantly, hyperglycemia increased expression from an 85-base-pair

truncated PAI-1 promoter luciferase reporter containing two Sp1 sites by 3.8-fold but failed to increase expression when the two Sp1 sites were mutated.⁷⁹ In endothelial cells, signal transduction by the hexosamine pathway requires PKC- β 1 and PKC- δ activation for regulation of the PAI-1 promoter.²⁴³ GlcNAc modification of Sp1 also regulates glucose-responsive expression of the prosclerotic growth factor TGF- β 1.

Because virtually every RNA polymerase II transcription factor examined has been found to be *O*-GlcNAcylated,²⁴⁴ it is possible that reciprocal modification by *O*-GlcNAcylation and phosphorylation of transcription factors other than Sp1 function as a more generalized mechanism for regulating glucose-responsive gene transcription. In addition to transcription factors, many other nuclear and cytoplasmic proteins are dynamically modified by *O*-GlcNAc moieties and might exhibit reciprocal modification by phosphorylation in a manner analogous to Sp1.¹⁹² One example relevant to diabetic complications is the inhibition of eNOS activity by hyperglycemia-induced *O*-GlcNAcylation at the Akt site of the eNOS protein.^{80,244} Hyperglycemia-induced activation of the hexosamine pathway increases activation of MMP2 and MMP9 in human coronary artery endothelial cells, and in carotid plaques from patients with T2DM, *O*-GlcNAcylation of endothelial cell proteins is significantly increased.²⁴⁰

Hyperglycemia increases GFAT activity in aortic smooth muscle cells, and biochemical analyses show that hyperglycemia qualitatively and quantitatively alters the glycosylation or expression of many *O*-GlcNAc-modified proteins in the nucleus of these cells.²⁴⁵ Therefore, activation of the hexosamine pathway by hyperglycemia can result in many changes in gene expression and in protein function that together contribute to the pathogenesis of diabetic complications. In addition, it has been shown that *O*-GlcNAc transferase (OGT) harbors a type of phosphoinositide-binding domain. After induction with insulin, phosphatidylinositol 3,4,5-triphosphate recruits OGT from the nucleus to the plasma membrane, where the enzyme catalyzes modification of the insulin signaling pathway by *O*-GlcNAc, leading to attenuation of insulin signal transduction. Hepatic overexpression of OGT reduces the expression of insulin-responsive genes and causes insulin resistance and dyslipidaemia.²⁴⁶ A similar mechanism could explain pathway-selective insulin resistance in vascular endothelial cells.

Different Hyperglycemia-Induced Pathogenic Mechanisms Reflect a Single Process

Although specific inhibitors of aldose reductase activity, AGE formation, and PKC activation ameliorate various diabetes-induced abnormalities in animal models, there has been no apparent common element linking the four mechanisms of hyperglycemia-induced damage discussed in the preceding section.^{113,215,247-249} It has also been conceptually difficult to explain the phenomenon of hyperglycemic memory (discussed earlier) as a consequence of four processes that quickly normalize when euglycemia is restored. These issues have now been resolved by the discovery that each of the four different pathogenic mechanisms reflects a single hyperglycemia-induced process: overproduction of superoxide by the mitochondrial electron transport chain.^{79,250,251}

Hyperglycemia increases ROS production inside cultured bovine aortic endothelial cells. To understand how this occurs, a brief overview of glucose metabolism is

helpful. Intracellular glucose oxidation begins with glycolysis in the cytoplasm, which generates NADH and pyruvate. Cytoplasmic NADH can donate reducing equivalents to the mitochondrial electron transport chain via two shuttle systems, or it can reduce pyruvate to lactate, which exits the cell to provide substrate for hepatic gluconeogenesis. Pyruvate can also be transported into the mitochondria, where it is oxidized by the tricarboxylic acid (TCA) cycle to produce CO_2 , H_2O , four molecules of NADH, and one molecule of reduced flavin adenine dinucleotide (FADH_2). Mitochondrial NADH and FADH_2 provide energy for ATP production via oxidative phosphorylation by the electron transport chain.

Electron flow through the mitochondrial electron transport chain is carried out by four inner membrane-associated enzyme complexes, plus cytochrome *c* and the mobile carrier, ubiquinone.²⁵² NADH derived from cytosolic glucose oxidation and mitochondrial TCA cycle activity donates electrons to NADH:ubiquinone oxidoreductase (complex I). Complex I ultimately transfers its electrons to ubiquinone. Ubiquinone can also be reduced by electrons donated from several FADH_2 -containing dehydrogenases, including succinate:ubiquinone oxidoreductase (complex II) and glycerol-3-phosphate dehydrogenase. Electrons from reduced ubiquinone are then transferred to ubiquinol:cytochrome-*c* oxidoreductase (complex III) by the ubiquinol:ubiquinone radical-generating Q cycle.²⁵³ Electron transport then proceeds through cytochrome *c*, cytochrome-*c* oxidase (complex IV), and, finally, molecular oxygen.

Electron transfer through complexes I, III, and IV generates a proton gradient that drives ATP synthase (complex V). When the electrochemical potential difference generated by this proton gradient is high, the life of superoxide-generating electron transport intermediates such as ubiquinol is prolonged. There appears to be a threshold value above which superoxide production is markedly increased (Fig. 33-16).²⁵⁴

Investigators using inhibitors of both the shuttle that transfers cytosolic NADH into mitochondria and the transporter that transfers cytosolic pyruvate into the mitochondria showed that the TCA cycle is the source of

hyperglycemia-induced ROS in endothelial cells. Overexpression of uncoupling protein 1 (UCP-1), a specific protein uncoupler of oxidative phosphorylation capable of collapsing the proton electrochemical gradient,²⁵⁵ also prevented the effect of hyperglycemia. These results demonstrated that hyperglycemia-induced intracellular ROS are produced by the proton electrochemical gradient generated by the mitochondrial electron transport chain. Overexpression of manganese superoxide dismutase (Mn-SOD), the mitochondrial form of this antioxidant enzyme,²⁵⁶ prevents the effect of hyperglycemia. Prevention of mitochondrial superoxide production also completely prevents activation of the polyol pathway, AGE formation, PKC, and the hexosamine pathway (Fig. 33-17). In endothelial cells, PKC activates NF κ B, a transcription factor that itself activates many proinflammatory genes in the vasculature. As expected, hyperglycemia-induced NF κ B activation is also prevented by UCP-1 or Mn-SOD in cells and in animals.

In addition, diabetes-induced loss of vascular cyclic adenosine monophosphate (cAMP)-responsive element-binding protein (CREB) and enhanced expression of PDGFR- α in nonobese diabetic (NOD) mice are both reversed by treatment with an SOD mimetic,²⁵⁷ and hyperglycemia-mediated interference with neuronal CREB and bcl-2 expression can be restored by treatment of the neurons in vitro with an SOD mimetic.²⁵⁸

Therefore, hyperglycemia-induced mitochondrial production of ROS is both necessary and sufficient for activation of each of these pathways.

After hyperglycemia induces mitochondrial ROS production, these ROS can activate a number of other superoxide production pathways that may amplify the original damaging effect of hyperglycemia (M. Brownlee, unpublished observations).

How does hyperglycemia-induced ROS activate AGE formation, PKC, the hexosamine pathway, and the polyol pathway? It does this by inhibiting activity of the key glycolytic enzyme, glyceraldehyde-3-phosphate dehydrogenase (GAPDH) (Fig. 33-18). When GAPDH activity is inhibited, the levels of all the glycolytic intermediates that are upstream of GAPDH increase. An increased level of the upstream glycolytic metabolite glyceraldehyde-3

Figure 33-16 Production of superoxide by the mitochondrial electron transport chain. Increased hyperglycemia-derived electron donors from the tricarboxylic acid cycle (NADH and FADH_2) generate a high mitochondrial membrane potential ($\Delta\mu \text{H}^+$) by pumping protons across the mitochondrial inner membrane. This inhibits electron transport at complex III and increases the half-life of free radical intermediates of coenzyme Q, which reduce O_2 to superoxide. ADP, adenosine diphosphate; ATP, adenosine triphosphate; Mn-SOD, manganese superoxide dismutase; NAD $^+$, nicotinamide adenine dinucleotide; NADH, reduced nicotinamide adenine dinucleotide; Pi, inorganic phosphate; UCP, uncoupling protein. (From Boss O, Hagen T, Lowell BB. Uncoupling proteins 2 and 3: potential regulators of mitochondrial energy metabolism. *Diabetes*. 2000;49:143-156.)

Figure 33-17 Effect of agents that alter mitochondrial electron transport chain function on the three main pathways of hyperglycemic damage. **A**, Hyperglycemia-induced protein kinase C (PKC) activation. **B**, Intracellular advanced glycation end-product (AGE) formation. **C**, Sorbitol accumulation. Cells were incubated in 5-mmol/L glucose, 30-mmol/L glucose alone, and 30-mmol/L glucose plus either agents that uncouple oxidative phosphorylation and reduce the high mitochondrial membrane potential (TTFA, CCCP, UCP-1) or manganese dismutase superoxide (Mn-SOD). CCCP, carbonyl cyanide *m*-chlorophenylhydrazine; TTFA, thenoyltrifluoroacetone; UCP-1, uncoupling protein 1. (From Nishikawa T, Edelstein D, Du XL, et al. Normalizing mitochondrial superoxide production blocks three pathways of hyperglycaemic damage. *Nature*. 2000;404:787-790.)

phosphate activates two of the four pathways, because the major intracellular AGE precursor, methylglyoxal, and the activator of PKC, DAG, are both formed from glyceraldehyde-3 phosphate. Farther upstream, levels of the glycolytic metabolite fructose-6-phosphate increase,

which increases flux through the hexosamine pathway, in which fructose-6 phosphate is converted by the enzyme GFAT to UDP-GlcNAc. Finally, inhibition of GAPDH increases intracellular levels of the first glycolytic metabolite, glucose. This increases flux through the polyol pathway, where the enzyme aldose reductase reduces it, consuming NADPH in the process. Therefore, inhibition of GAPDH using DNA antisense activates each of the four pathways, to the same extent as diabetes, when glucose concentrations are physiologic.²⁵⁹

Hyperglycemia-induced mitochondrial superoxide itself can directly inactivate GAPDH, but only at concentrations that far exceed levels found in hyperglycemic cells. In vivo, hyperglycemia-induced superoxide inhibits GAPDH activity by modifying the enzyme with polymers of adenosine diphosphate (ADP)-ribose.²⁶⁰ Inhibition of mitochondrial superoxide production with UCP-1 or Mn-SOD prevents both modification of GAPDH by ADP-ribose and reduction of its activity by hyperglycemia. Most importantly, both the modifications of GAPDH by ADP-ribose and the reduction of its activity by hyperglycemia are prevented by a specific inhibitor of the enzyme poly(ADP-ribose) polymerase (PARP). PARP is a nuclear DNA-repair enzyme that is activated by DNA strand breaks. Increased intracellular glucose generates increased ROS in the mitochondria, and these free radicals cause DNA strand breaks, thereby activating PARP (Fig. 33-19). Once activated, PARP splits the NAD⁺ molecule into its two component parts: nicotinic acid and ADP-ribose. PARP then generates polymers of ADP-ribose, which accumulate on GAPDH and other nuclear proteins. Although GAPDH is commonly thought to reside exclusively in the cytosol, it normally shuttles in and out of the nucleus, where it plays a critical role in DNA repair.^{261,262}

A schematic summary showing the elements of the unified mechanism of hyperglycemia-induced cellular damage is shown in Figure 33-20. When intracellular hyperglycemia develops in target cells of diabetic complications, it causes increased mitochondrial production of ROS. The ROS causes strand breaks in nuclear DNA, which activates PARP. PARP then modifies GAPDH, reducing its activity. Decreased GAPDH activity activates the polyol pathway, increases intracellular AGE formation, activates PKC and subsequently NFκB, and activates hexosamine pathway flux.

In cultured glomerular mesangial cells, overexpression of Mn-SOD suppresses the increase in collagen synthesis induced by high glucose.²⁶² In dorsal root ganglion (DRG) neurons from both wild-type and Mn-SOD^{-/-} mice, overexpression of Mn-SOD decreases hyperglycemia-induced programmed cell death, and in embryonic rat DRG neurons, overexpression of UCP-1 inhibits cleavage of programmed cell death effector caspases.²⁶³ In aortic endothelial cells, overexpression of UCP-1 or Mn-SOD completely blocks hyperglycemia-induced monocyte adhesion to endothelial cells (J.L. Nadler and C.C. Hedrick, personal communication). Overexpression of UCP-1 or Mn-SOD also prevents hyperglycemia-induced inhibition of the antiatherogenic enzyme, prostacyclin synthase (M. Brownlee, et al., unpublished observation). In diabetes, inhibition of prostacyclin synthase causes accumulation of the precursor (PGI₂), which activates thromboxane receptors that trigger vasoconstriction, platelet aggregation, increased expression of leukocyte adhesion molecules, and apoptosis.²⁶⁴

Overexpression of Mn-SOD or UCP-1 also prevents inhibition of eNOS activity by hyperglycemia.⁸⁰ In platelets, chemical uncouplers or SOD mimetics prevent potentiation by hyperglycemia of collagen-induced platelet

Figure 33-18 Potential mechanism by which hyperglycemia-induced mitochondrial superoxide overproduction activates four pathways of hyperglycemic damage. Excess superoxide partially inhibits the glycolytic enzyme glyceraldehyde-3-phosphate dehydrogenase (GAPDH) by activating PARP and causing ADP-ribosylation of GAPDH. Decreased GAPDH activity increases the concentrations of upstream metabolites and diverts them from glycolysis into pathways of glucose overutilization. This results in increased flux of triose phosphate to diacylglycerol (DAG), an activator of protein kinase C (PKC), and to methylglyoxal, the major intracellular advanced glycation end-product (AGE) precursor. Increased flux of fructose-6-phosphate to uridine diphosphate (UDP)-N-acetylglucosamine increases modification of proteins by hexosamine, and increased glucose flux through the polyol pathway consumes NADPH and depletes reduced glutathione (GSH). ADP, adenosine diphosphate; DHAP, dihydroxyacetone phosphate; GFAT, glutamine:fructose-6-phosphate amidotransferase; GlcNAc, -N-acetylglucosamine; NAD⁺, nicotinamide adenine dinucleotide; NADH, reduced nicotinamide adenine dinucleotide; P, phosphate; PARP, poly(ADP-ribose) polymerase; NADPH, nicotinamide adenine dinucleotide phosphate.

Figure 33-19 Schematic representation of the mechanism by which hyperglycemia-induced mitochondrial superoxide overproduction activates PARP and modifies GAPDH. Hyperglycemia-induced mitochondrial superoxide overproduction causes DNA strand breaks, thereby activating the nuclear DNA-repair enzyme, poly(ADP-ribose) polymerase (PARP). Activated PARP splits the NAD⁺ molecule into its two component parts: nicotinic acid (NA) and adenosine diphosphate-ribose (ADPR). PARP then generates polymers of ADP-ribose, which accumulate on glyceraldehyde-3-phosphate dehydrogenase, GAPDH, inactivating the enzyme. ROS, reactive oxygen species. (Adapted from Brownlee M. Banting Lecture 2004. The pathobiology of diabetic complications: a unifying mechanism. *Diabetes*. 2005;54:1615-1625.)

Figure 33-20 Unifying mechanism of hyperglycemia-induced cellular damage. Intracellular hyperglycemia causes increased mitochondrial production of reactive oxygen species (ROS). The ROS cause strand breaks in nuclear DNA, which activates poly(ADP-ribose) polymerase (PARP). PARP then modifies glyceraldehyde-3-phosphate dehydrogenase (GAPDH), thereby reducing its activity. Decreased GAPDH activity activates the polyol pathway, increases intracellular formation of advanced glycation end products (AGE), activates protein kinase C (PKC) and subsequently nuclear factor-κB (NFκB), and activates hexosamine pathway (PW) flux. (Adapted from Brownlee M. Banting Lecture 2004. The pathobiology of diabetic complications: a unifying mechanism. *Diabetes*. 2005;54:1615-1625.)

activation and aggregation.⁸¹ Antioxidant treatment prevents hyperglycemia-induced activity of MMP9 in VSMC.²⁶⁵

In streptozotocin-diabetic transgenic mice overexpressing human cytoplasmic Cu²⁺/Zn²⁺-SOD, albuminuria, glomerular hypertrophy, and glomerular content of TGF- β and α 1 type IV collagen were all attenuated compared with wild-type littermates after 4 months of diabetes.²⁶⁶ Overexpression of the human *SOD1* transgene in db/db diabetic mice similarly normalized the extensive expansion of the glomerular mesangial matrix that was otherwise evident by age 5 months in the nontransgenic db/db littermates.²⁶⁷ Similarly, transgenic overexpression of the antioxidant enzymes Mn-SOD and catalase reduced ROS and prevented diabetes-induced abnormalities in cardiac contractility in an animal model of diabetic cardiomyopathy.^{268,269} In humans, skin fibroblast gene expression profiles from two groups of T1DM patients—20 with very fast (fast-track) and 20 with very slow (slow-track) rates of development of diabetic nephropathy lesions—showed that the fast-track group has increased expression of oxidative phosphorylation genes, mitochondrial electron transport system complex III, and TCA-cycle genes. These associations are consistent with a central role for mitochondrial ROS production in the pathogenesis of diabetic nephropathy.²⁷⁰

Human atherosclerotic samples obtained during vascular surgery show greater mitochondrial DNA damage than nonatherosclerotic samples obtained from age-matched transplant donors, consistent with increased ROS production. Mitochondrial damage precedes the development of atherosclerosis and tracks with lesion extent in apoE-null mice, and mitochondrial dysfunction caused by heterozygous deficiency of superoxide dismutase (SOD2) increases atherosclerosis and vascular mitochondrial damage in the same model.²⁷¹⁻²⁷³

Free Fatty Acid–Induced Proatherogenic Changes Are Also Caused by Mitochondrial Production of Reactive Oxygen Species

Insulin resistance causes increased FFA release from adipocytes. In macrovascular, but not microvascular, endothelial cells, the increased flux of FFA results in increased FFA oxidation by the mitochondria. Because both oxidation of fatty acids and oxidation of FFA-derived acetyl coenzyme A by the TCA cycle generate the same electron donors (NADH and FADH₂) as are generated by glucose oxidation, increased FFA oxidation causes mitochondrial overproduction of ROS by the same mechanism described for hyperglycemia. As with hyperglycemia, this FFA-induced increase in ROS activates the same damaging pathways: AGEs, PKC, the hexosamine pathway (GlcNAc), and NF κ B. Together, they activate a variety of proinflammatory signals previously implicated in hyperglycemia-induced vascular damage (Fig. 33-21). In addition, these ROS directly inactivate two important antiatherogenic enzymes, prostacyclin synthase and eNOS, independent of the pathways just discussed. In two insulin-resistant nondiabetic animal models, inhibition of either FFA release from adipocytes or FFA oxidation in arterial endothelium prevents the increased production of ROS and its damaging effects.⁹³

Possible Molecular Basis for Hyperglycemic Memory

Continued mitochondrial superoxide production might explain the occurrence of complications during posthyperglycemic normoglycemia. In the retina of diabetic rats with poor glycemic control for 2 months, subsequent

Figure 33-21 Schematic mechanism by which insulin resistance (IR) causes increased oxidation of free fatty acids (FFA) in arterial endothelial cells, which activates proatherogenic signals and inhibits key antiatherogenic enzymes. IR causes increased FFA release from adipocytes. In macrovascular endothelial cells, the increased flux of FFA results in increased FFA oxidation by the mitochondria, thereby causing mitochondrial overproduction of reactive oxygen species (ROS). FFA-induced increase in ROS activates advanced glycation end products (AGEs), protein kinase C (PKC), the hexosamine pathway (GlcNAc), and nuclear factor κ B (NF κ B), which together activate a variety of proinflammatory signals. In addition, ROS directly inactivate two important antiatherogenic enzymes, prostacyclin synthase and endothelial nitric oxide synthase (eNOS). GlcNAc, *N*-acetylglucosamine. (Adapted from Du X, Edelstein D, Obici S, et al. Insulin resistance reduces arterial prostacyclin synthase and eNOS activities by increasing endothelial fatty acid oxidation. *J Clin Invest*. 2006;116:1071-1080.)

normalization of HbA_{1c} for 7 months lowered elevated retinal lipid peroxides by only about 50% and had no beneficial effects on levels of the oxidative marker 3-nitrotyrosine. In the retinas of diabetic animals with poor glycemic control for 6 months, subsequent normalization of HbA_{1c} for 6 months had no effect on elevated retinal oxidative stress levels and only a small effect on elevated levels of 3-nitrotyrosine.²⁷⁴

Although the molecular changes that result in continuous overproduction of ROS in normoglycemic animals and humans have not yet been identified, several hypotheses are being tested. One hypothesis involves induction of stable epigenetic changes such as DNA methylation and histone methylation and acetylation. Such changes can alter levels of gene expression for many years. Post-translational modifications of histones cause chromatin remodeling and changes in levels of gene expression.²⁷⁵⁻²⁷⁷ Because these modifications do not involve differences in DNA sequence, they are called “epigenetic.” Transient hyperglycemia, at a level sufficient to increase mitochondrial ROS production, induces long-lasting activating epigenetic changes (increased monomethylation of histone 3 lysine 4) in the proximal promoter of the nuclear factor κ B (NF κ B) subunit p65 in human aortic endothelial cells (16 hours’ exposure) and in aortic cells in vivo in nondiabetic mice (6 hours’ exposure). These epigenetic changes cause sustained increases in p65 gene expression and in the expression of p65-dependent proinflammatory genes. Both the epigenetic changes and the gene expression changes persist for at least 6 days of subsequent normal glycemia in cultured cells, and for months in previously diabetic mice whose beta-cell function recovered.²⁷⁹ Hyperglycemia-induced epigenetic changes and increased p65 expression are prevented by normalizing mitochondrial superoxide production or superoxide-induced methylglyoxal.²⁷⁹ These results highlight the dramatic and long-lasting effects that short-term hyperglycemic spikes can have on vascular cells and suggest that transient spikes of hyperglycemia

may be an HbA_{1c}-independent risk factor for diabetic complications. Demethylation of another histone lysine residue, histone 3 lysine 9, is also induced by hyperglycemia-induced overproduction of ROS. This reduces inhibition of p65 gene expression, and therefore acts synergistically with the activating methylation of histone 3 lysine 4 (Fig. 33-22).^{278,279} Consistent with these observations, others have shown similar epigenetic changes in lymphocytes from patients with T1DM²⁸⁰ and in VSMC derived from db/db mice.^{281,282}

Another hypothesis concerns changes in mitochondrial biology. It is now recognized that mitochondria are not all the same but have important functional differences. Furthermore, mitochondria are not static structures in the cell. Rather, they continuously fuse to form larger organelles or pull apart to form smaller organelles. The processes underlying these changes are beginning to be understood, but aberrations induced by diabetes and different degrees of hyperglycemia are important new areas that will likely yield new insights into hyperglycemic memory.²⁸³

The third hypothesis currently being evaluated is altered regulation of the antioxidant response element. Perhaps not surprisingly, cells have their own protective antioxidant machinery.^{283a} Cells responded to oxidative stress by activating a previously sequestered transcription factor (Nrf2) that controls the expression of a diverse set of genes involved in decreasing ROS in the cell. An important research focus is the identification and regulation of proteins in this pathway, including proteins that bind to a special promoter element called the antioxidant response element (ARE) after activation by ROS.

RETINOPATHY, MACULAR EDEMA, AND OTHER COMPLICATIONS*

Diabetic retinopathy is a well-characterized, sight-threatening, chronic microvascular complication that eventually afflicts virtually all patients with diabetes mellitus.⁶⁴ Diabetic retinopathy is characterized by gradually progressive alterations in the retinal microvasculature that lead to areas of retinal nonperfusion, increased vascular permeability, and pathologic intraocular proliferation of retinal vessels. The complications associated with the increased vascular permeability, termed *macular edema*, and uncontrolled neovascularization, termed *proliferative diabetic retinopathy* (PDR), can result in severe and permanent vision loss.

Despite decades of research, there is currently no known means of preventing diabetic retinopathy, and, despite effective therapies, diabetic retinopathy remains the leading cause of new-onset blindness among working-aged persons in most developed countries of the world.⁶⁴ With appropriate medical and ophthalmologic care, however, more than 90% of vision loss resulting from PDR can

Figure 33-22 Hyperglycemia-induced activating modifications of histone 3 lysine 4 (monomethylation) and derepressing modifications of histone 3 lysine 9 (removal of two methyl groups) at the NFκB p65 proximal promoter. (From Brasacchio D, Okabe J, Tikellis C, et al. Hyperglycemia induces a dynamic cooperativity of histone methylase and demethylase enzymes associated with gene-activating epigenetic marks that co-exist on the lysine tail. *Diabetes*. 2009;58:1229-1236 and El-Osta A, Brasacchio D, Yao D, et al. Transient high glucose causes persistent epigenetic changes and altered gene expression during subsequent normoglycemia. *J Exp Med*. 2008;205:2409-2417.)

be prevented. Therefore, until a cure for diabetes is discovered, the primary clinical care emphasis for the prevention of vision loss is appropriately directed at early identification, accurate classification, and timely treatment of retinopathy.

Nevertheless, increased understanding of the mechanistic pathways underlying hyperglycemia-induced retinal changes has provided new targets against which novel therapies have been devised. These novel therapies, such as VEGF inhibitors, corticosteroids, and PKC-β inhibitors,²⁸⁵⁻²⁹³ have entered clinical trials with promising results and have expanded the therapeutic options for patients with diabetic eye disease. Furthermore, selected systemic medications such as ACE inhibitors and angiotensin II receptor blockers (ARBs) may affect the development and progression of diabetic retinopathy. These developments place further emphasis on the importance of adhering to lifelong routine ophthalmologic follow-up of the diabetic patient and optimization of associated systemic disorders.

Epidemiology and Impact

It is estimated that 489 million persons worldwide will have diabetes by the year 2030.²⁹⁴ Almost 24 million Americans currently have diabetes mellitus, and of these, more than 5 million remain unaware that they have the disease.²⁹⁵ For the past 20 years, diabetic retinopathy has remained the leading cause of new cases of legal blindness among Americans between the ages of 20 and 74 years.²⁹⁶ There is a higher risk of more frequent and severe ocular complications in T1DM, compared with T2DM.²⁹⁷ Approximately 25% of patients with T1DM have retinopathy after 5 years, and this figure increases to 60% and 80% after 10 and 15 years, respectively. Because T2DM accounts for 90% to 95% of the diabetic population in the United States, it accounts for a higher fraction of patients with vision loss. The most threatening form of retinopathy (PDR) is present in approximately 67% of T1DM patients who have had diabetes for 35 years.²⁹⁸

An estimated 700,000 persons in the United States have PDR; 130,000 have high-risk PDR, 500,000 have macular edema, and 325,000 have *clinically significant macular*

*Portions of this section draw on the following sources, among others: Aiello LM, Cavallerano JD, Aiello LP. Diagnosis, management, and treatment of nonproliferative diabetic retinopathy and diabetic macular edema. In: Albert DM, Jakobiec FA, eds. *Principles and Practice of Ophthalmology*, 2nd ed. edema (CSME).²⁹⁹⁻³⁰³ An estimated 63,000 cases of PDR, 29,000 cases of high-risk PDR, 80,000 cases of macular edema, 56,000 cases of CSME, and 12,000 to 24,000 new cases of legal blindness occur each year as a result of diabetic retinopathy.^{299,300,304} Blindness has been estimated to be 25 times more common in persons with diabetes than in those without the disease.^{305,306}

The DCCT showed that both the rate of development of any retinopathy and the rate of retinopathy progression once it was present were significantly reduced after 3 years of intensive insulin therapy.³⁰⁷ The effect of reducing the HbA_{1c} in this group from 9.1% with conventional treatment to 7.3% with intensive treatment resulted in a benefit maintained through 7 years of follow-up, even though the difference in mean HbA_{1c} levels of the two randomized treatment groups was only 0.4% at 1 year ($P < .001$), continued to narrow, and became statistically nonsignificant by 5 years (8.1% versus 8.2%, $P = .09$). The further rate of progression of complications from their levels at the end

of the DCCT remained less in the former intensive treatment group. Therefore, the benefits of 6.5 years of intensive treatment extended well beyond the period of its most intensive implementation.^{27,30,308,309} Applying DCCT intensive insulin therapy to all persons in the United States with T1DM would result in a gain of 920,000 person-years of sight,³¹⁰ although the costs of intensive therapy are three times those of conventional therapy.³¹¹

Pathophysiology

A detailed discussion of the pathophysiologic mechanisms underlying diabetic retinopathy and other diabetes-related complications has been presented earlier in this chapter. The earliest histologic effects of diabetes mellitus in the eye include loss of retinal vascular pericytes (supporting cells for retinal endothelial cells), thickening of vascular endothelium basement membrane, and alterations in retinal blood flow (Fig. 33-23).^{25,312-317} With increasing loss of

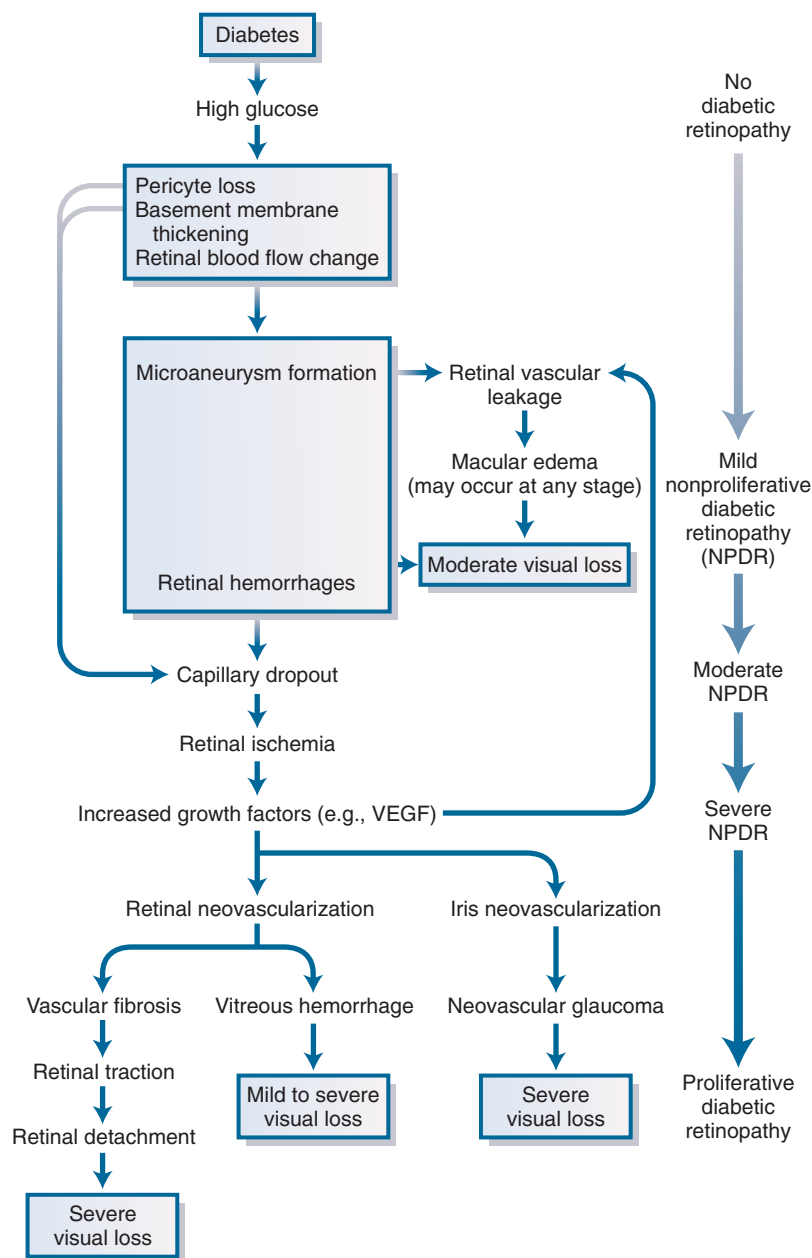

Figure 33-23 Diabetic retinopathy pathogenesis flow chart. The schematic flow chart represents the major preclinical and clinical findings associated with the full spectrum of diabetic retinopathy and macular edema. VEGF, vascular endothelial growth factor.

Figure 33-24 Clinical features of diabetic retinopathy: Some typical findings in human diabetic retinopathy. **A**, Findings in severe nonproliferative diabetic retinopathy, including microaneurysms (Ma), venous beading (VB), and intraretinal microvascular abnormalities (IRMA). **B**, Fluorescein angiogram showing marked capillary nonperfusion. **C**, Clinically significant macular edema with retinal thickening and hard exudates involving the fovea. **D**, Extensive neovascularization of the optic disc (NVD), illustrating high-risk proliferative diabetic retinopathy. **E**, Neovascularization elsewhere (NVE) and two small vitreous hemorrhages (VH), also illustrating high-risk proliferative diabetic retinopathy. **F**, Extensive vitreous hemorrhage arising from severe neovascularization of the disc (NVD). **G**, Severe fibrovascular proliferation surrounding the fovea. **H**, Traction retinal detachment from extensive fibrovascular proliferation. **I**, Scars from scatter (panretinal) laser photocoagulation. The macula, fovea, and optic disc are not treated to preserve central vision. Laser burns are evident as white retinal lesions. (Adapted from Aiello LP. Eye complications of diabetes. In Korenman SG, Kahn CR, eds. *Atlas of Clinical Endocrinology*. Vol 2: Diabetes. Philadelphia, PA: Blackwell Scientific, 1999.)

retinal pericytes, the retinal vessel wall develops outpouchings (microaneurysms) and becomes fragile.

Clinically, microaneurysms and small retinal hemorrhages are not always readily distinguishable and are usually evaluated together as “hemorrhages and microaneurysms” (Fig. 33-24A). Rheologic changes occur in diabetic retinopathy as a result of increased platelet aggregation, integrin-mediated leukocyte adhesion, and endothelial damage.³¹⁸⁻³²⁰ Disruption of the blood-retina barrier can ensue, characterized by increased vascular permeability.^{321,322} The subsequent leakage of blood and serum from the retinal vessels results in retinal hemorrhages, retinal edema, and hard exudates (see Fig. 33-24A and C). Moderate vision loss follows if the fovea is affected by the leakage.³²³

With time, increasing sclerosis and endothelial cell loss lead to narrowing of the retinal vessels, which decreases

vascular perfusion and can ultimately lead to obliteration of the capillaries and small vessels (see Fig. 33-24B). The resulting retinal ischemia is a potent inducer of angiogenic growth factors. Several angiogenic growth factors have been isolated from eyes with diabetic retinopathy, including IGFs, basic fibroblast growth factor (bFGF), hepatocyte growth factor (HGF), and VEGF.³²⁴⁻³²⁷ These factors promote the development of new vessel growth and retinal vascular permeability.³²⁸⁻³³² Indeed, inhibition of molecules such as VEGF and their signaling pathways can suppress the development of retinal neovascularization and retinal vascular permeability.^{329,333-337} Endogenous inhibitors of angiogenesis and vascular permeability, such as pigment epithelial-derived factor (PEDF), and other VEGF-independent pathways, such as kallikrein and erythropoietin, have also been found in the eye, and these have physiologic and therapeutic potential.^{47,338-340}

New vessels tend to grow in regions of strong vitreous adhesion to the retina, such as at the optic disc and major vascular arcades (see Fig. 33-24D and E). The posterior vitreous face also serves as a scaffold for pathologic neovascularization, and the new vessels commonly arise at the junctions between perfused and nonperfused retina. When the retina is severely ischemic, the concentration of angiogenic growth factors can reach sufficient concentration in the anterior chamber to cause abnormal new vessel proliferation on the iris and in the anterior chamber angle.^{325,341} Uncontrolled anterior segment neovascularization can result in neovascular glaucoma because the fibrovascular proliferation in the angle of the eye causes blockage of aqueous outflow through the trabecular meshwork.³⁴²

Proliferating new vessels in diabetic retinopathy are fragile and have a tendency to bleed, which results in preretinal and vitreous hemorrhages (see Fig. 33-24E and F). Although the presence of a large amount of blood in the preretinal space or vitreous cavity per se is not damaging to the retina, these intraocular hemorrhages often cause prolonged vision loss by blocking the visual axis. Membranes on the retinal surface can be induced by blood and result in wrinkling and traction on the retina. Although all retinal neovascularization given sufficient time eventually becomes quiescent, as with most scarring processes there is progressive fibrosis of the new vessel complexes that is associated with contraction. In the eye, such forces can exert traction on the retina, leading to tractional retinal detachment and retinal tears that can result in severe and permanent vision loss if left untreated (see Fig. 33-24G and H).

In short, causes of vision loss from complications of diabetes mellitus include retinal ischemia involving the fovea, macular edema at or near the fovea, preretinal or vitreous hemorrhages, retinal detachment, and neovascular glaucoma. Vision loss can also result from more indirect effects of disease progression in diabetic patients, such as retinal vessel occlusion, accelerated atherosclerotic disease, and embolic phenomena.

Clinical Features

Risk Factors

Duration of diabetes is closely associated with the onset and severity of diabetic retinopathy. Diabetic retinopathy is rare in prepubescent patients with T1DM, but almost all patients with T1DM and more than 60% of patients with T2DM develop some degree of retinopathy after 20 years.^{64,298,343} In U.S. reports of patients with T2DM, approximately 20% had retinopathy at the time of diabetes diagnosis,³⁴³ and most had some degree of retinopathy over subsequent decades. In the UKPDS study of T2DM, 35% of female subjects and 39% of male subjects had some level of diabetic retinopathy at the time of diabetes diagnosis.³⁴⁴

Diabetic retinopathy is the most common cause of new-onset blindness among American adults aged 20 to 74 years. In the Wisconsin Epidemiologic Study of Diabetic Retinopathy, approximately 4% of patients younger than 30 years of age at diagnosis and almost 2% of patients older than 30 years of age at diagnosis were legally blind. In the younger-onset group, 86% of blindness was attributable to diabetic retinopathy. In the older-onset group, in whom other eye diseases were also common, 33% of the cases of legal blindness were due to diabetic retinopathy.^{298,343} Currently, diabetes is thought to account for 12,000 to 24,000 new cases of blindness in the United States each year.³⁰⁴

Lack of appropriate glycemic control is another significant risk factor for the onset and progression of diabetic retinopathy. The DCCT demonstrated a clear relationship between hyperglycemia and diabetic microvascular complications, including retinopathy, in 1441 patients with T1DM.^{27,28,309,310,345}

In patients monitored for 4 to 9 years, the DCCT showed that intensive insulin therapy reduced or prevented the development of retinopathy by 27%, compared with conventional therapy.^{345a} Additionally, intensive insulin therapy reduced the progression of diabetic retinopathy by 34% to 76% and had a substantial beneficial effect over the entire range of retinopathy severity. This improvement was achieved with an average 10% reduction in HbA_{1c}, from 8% to 7.2%. Therefore, although intensive therapy may not prevent retinopathy completely, it reduces the risk of retinopathy onset and progression.

Renal disease, as manifested by microalbuminuria and proteinuria, is yet another significant risk factor for onset and progression of diabetic retinopathy.^{346,347} Hypertension is associated with PDR and is an established risk factor for the development of macular edema.³⁴⁸ Additionally, elevated serum lipid levels are associated with extravasated lipid in the retina (hard exudates) and vision loss.³⁴⁹

Clinical Findings

Clinical findings associated with early and progressing diabetic retinopathy include hemorrhages or microaneurysms, cotton-wool spots, hard exudates, intraretinal microvascular abnormalities, and venous caliber abnormalities such as venous loops, venous tortuosity, and venous beading (see Fig. 33-24A and C). Microaneurysms are saccular outpouchings of the capillary walls that can leak fluid and result in intraretinal edema and hemorrhages. The intraretinal hemorrhages can be flame-shaped or dot-blot-like in appearance, reflecting the architecture of the layer of the retina in which they occur. Flame-shaped hemorrhages occur in inner retina closer to the vitreous, and dot-blot hemorrhages occur deeper in the retina. Intraretinal microvascular abnormalities are either new vessel growth within the retinal tissue itself or shunt vessels through areas of poor vascular perfusion. It is common for intraretinal microvascular abnormalities to be located adjacent to cotton-wool spots. Cotton-wool spots are caused by microinfarcts in the nerve fiber layer of the retina. Venous caliber abnormalities are generally a sign of severe retinal hypoxia. In some cases of extensive vascular loss, however, the retina actually appears free of nonproliferative lesions. Such areas are termed *featureless retina* and are a sign of severe retinal hypoxia.

Vision loss from diabetic retinopathy generally results from persistent nonclearing vitreous hemorrhage, traction retinal detachment, or diabetic macular edema (DME) (see Figs. 33-23 and 32-24). Neovascularization with fibrous tissue contraction can distort the retina and lead to traction retinal detachment. The new vessels can bleed, causing preretinal or vitreous hemorrhage. The most common cause of vision loss from diabetes is macular disease and macular edema. Macular edema is more likely to occur in patients with T2DM, who represent 90% to 95% of the diabetic population. In diabetic macular disease, macular edema involving the fovea or nonperfusion of the capillaries in the central macula is responsible for the loss of vision.

Classification Systems

Classification of Diabetic Retinopathy. Diabetic retinopathy is broadly classified into nonproliferative (NPDR) and proliferative (PDR) categories.^{350,351} Macular edema

TABLE 33-1

Glossary and Abbreviations Pertinent to Diabetic Eye Disease

Term	Definition
Background diabetic retinopathy (BDR)	An outdated term referring to some stages of NPDR. Because this terminology is not closely associated with disease progression, it has been replaced by the various levels of NPDR.
Clinically significant macular edema (CSME)	Thickening of the retina in the macular region of sufficient extent and location to threaten central visual function
Cotton-wool spot	A gray or white area lesion in the nerve fiber layer of the retina resulting from stasis of axoplasmic flow caused by microinfarcts of the retinal nerve fiber layer
Diabetes Control and Complications Trial (DCCT)	A multicenter, randomized clinical trial designed to address whether intensive insulin therapy could prevent or slow the progression of systemic complications of diabetes mellitus
Diabetic retinopathy (DR)	Retinal pathology related to the underlying systemic disease of diabetes mellitus
Diabetic Retinopathy Study (DRS)	The first multicenter, randomized clinical trial to demonstrate the value of scatter (panretinal) photocoagulation in reducing the risk of vision loss among patients with all levels of diabetic retinopathy
Diabetic Retinopathy Vitrectomy Study (DRVS)	A multicenter clinical trial evaluating early vitrectomy for patients with very advanced diabetic retinopathy or nonresolving vitreous hemorrhage
Early Treatment Diabetic Retinopathy Study (ETDRS)	A multicenter, randomized clinical trial that addressed at what stage of retinopathy scatter (panretinal) photocoagulation was indicated, whether focal photocoagulation was effective for preventing moderate vision loss due to clinically significant macular edema, and whether aspirin therapy altered the progression of diabetic retinopathy
Focal or grid laser photocoagulation	A type of laser treatment whose main goal is to reduce vascular leakage, either by focal treatment of leaking retinal microaneurysms or by application of therapy in a grid-like pattern for patients with clinically significant macular edema
Hard exudate	Lipid accumulation within the retina as a result of increased vasopermeability
High-risk-characteristic proliferative diabetic retinopathy (HRC-PDR)	Proliferative diabetic retinopathy of defined extent, location, and/or clinical findings that is particularly associated with severe vision loss
Microaneurysm	An early vascular abnormality consisting of an outpouching of the retinal microvasculature
Neovascular glaucoma (NVG)	Elevation of intraocular pressure caused by the development of neovascularization in the anterior segment of the eye
Neovascularization at the disc (NVD)	Retinal neovascularization occurring at or within 1500 μm of the optic disc
Neovascularization elsewhere (NVE)	Retinal neovascularization that is located more than 1500 μm away from the optic disc
Neovascularization of the iris (NVI)	Neovascularization occurring on the iris (rubeosis iridis), usually as a result of extensive retinal ischemia
No light perception (NLP)	The inability to perceive light
Nonproliferative diabetic retinopathy (NPDR)	Severities of clinically evident diabetic retinopathy that precede the development of PDR
Preproliferative diabetic retinopathy (PPDR)	An outdated term referring to more advanced levels of NPDR. Because this term is not closely associated with disease progression, it has been replaced by the various levels of NPDR.
Proliferative diabetic retinopathy (PDR)	An advanced level of diabetic retinopathy in which proliferation of new vessels or fibrous tissue occurs on or within the retina
Rubeosis iridis	See NVI

can coexist with either group and is not used in the classification of level of retinopathy. The historical terms *background retinopathy* and *preproliferative diabetic retinopathy* have been replaced to reflect the specific characteristics and risk stratification of the prognostically important subgroups in NPDR (Table 33-1).

Generally, diabetic retinopathy progresses from no retinopathy through mild, moderate, severe, and very severe NPDR and eventually on to PDR. The level of NPDR is determined by the extent and location of clinical manifestations of retinopathy. Mild NPDR is characterized by limited microvascular abnormalities such as hemorrhages or microaneurysms, cotton-wool spots, and increased vascular permeability. Moderate and severe NPDR are characterized by increasing severity of hemorrhages or microaneurysms, venous caliber abnormalities, intraretinal microvascular abnormalities, and vascular closure. The level of NPDR establishes the risk of progression to sight-threatening retinopathy and dictates appropriate clinical management and follow-up.

PDR is characterized by vasoproliferation of the retina and its complications, including new vessels on the optic disc (NVD), new vessels elsewhere on the retina (NVE), preretinal hemorrhage (PRH), vitreous hemorrhage, and fibrous tissue proliferation (FP). On the basis of the extent

and location of these lesions, PDR is classified as *early PDR* or *high-risk PDR*. Larger areas of these complications and new vessels that are near the optic disc are associated with greater risks of vision loss.

Classification of Diabetic Macular Edema. DME can be present with any level of diabetic retinopathy. When edema involves or threatens the center of the macula, it is called CSME. CSME exists if there is retinal thickening at or within 500 μm of the fovea; hard exudates with adjacent retinal thickening at or within 500 μm of the fovea; or an area of retinal thickening 1500 μm or more in diameter, any part of which is within 1500 μm of the fovea.^{350,352,353} CSME is a clinical diagnosis that is not dependent on visual acuity or results of ancillary testing such as fluorescein angiography, and it can be present even when vision is 20/20 or better.

International Classification of Diabetic Retinopathy. The American Academy of Ophthalmology initiated a project to establish a consensus International Classification of Diabetic Retinopathy and Diabetic Macular Edema in an effort to simplify classification and standardize communication among diabetes health care providers.^{354,355} This International Classification describes five clinical

TABLE 33-2

Levels of Diabetic Retinopathy

International Classification Level	ETDRS Level
No apparent retinopathy	Level 10: DR absent
Mild NPDR	Level 20: very mild NPDR
Moderate NPDR	Levels 35, 43, and 47: moderate NPDR
Severe NPDR	Levels 53A-E: severe to very severe NPDR
PDR	Levels 61, 65, 71, 75, 81, 85: PDR, high-risk PDR, very severe or advanced PDR

DR, diabetic retinopathy; ETDRS, Early Treatment Diabetic Retinopathy Study; NPDR, nonproliferative diabetic retinopathy; PDR, proliferative diabetic retinopathy. (From Grading diabetic retinopathy from stereoscopic color fundus photographs—an extension of the modified Airlie House classification. ETDRS report number 10. Early Treatment Diabetic Retinopathy Study Research Group. *Ophthalmology*. 1991;98:786-806.)

levels of diabetic retinopathy: no apparent retinopathy (no abnormalities), mild NPDR (microaneurysms only), moderate NPDR (more than microaneurysms only but less than severe NPDR), severe NPDR (any of the following: more than 20 intraretinal hemorrhages in each of four quadrants, definite venous beading in two or more quadrants, prominent intraretinal microvascular abnormalities in one or more quadrants, and no PDR), and PDR (one or more of the following: retinal neovascularization, vitreous hemorrhage, and preretinal hemorrhage). Table 33-2 compares levels of retinopathy in the international classification to those defined by the landmark Early Treatment Diabetic Retinopathy Study (ETDRS).

In regard to DME, the International Classification identifies two broad categories: macular edema apparently absent (no apparent retinal thickening or hard exudates in the posterior pole) and macular edema apparently present (some apparent retinal thickening or hard exudates in the posterior pole). Macular edema is subclassified as mild (some retinal thickening or hard exudates in the posterior pole but distant from the center of the macula), moderate (retinal thickening or hard exudates approaching the center of the macula but not involving the center), or severe (retinal thickening or hard exudates involving the center of the macula). Table 33-3 compares levels of DME in the international classification to ETDRS levels of DME.

TABLE 33-3

International Classification of Diabetic Macular Edema (DME)

Disease Severity Level	Ophthalmic Findings (Retinal Thickening or Hard Exudates in Posterior Pole)	ETDRS Scale Equivalent
DME apparently absent	None apparent	
DME apparently present	Some apparent	
Mild DME	Some findings present but distant from center of the macula	DME but not CSME
Moderate DME	Findings approaching the center but not involving the center	CSME
Severe DME	Findings involving the center of the macula	CSME

CSME, clinically significant macular edema; ETDRS, Early Treatment Diabetic Retinopathy Study.

Compared with ETDRS retinopathy grading, the International Classification of Diabetic Retinopathy and Diabetic Macular Edema reduces the number of levels of diabetic retinopathy, simplifies descriptions of the categories, and describes the levels without relying on reference to the standard photographs of the Airlie House Classification of diabetic retinopathy. This makes clinical use easier and more uniform among practitioners not versed in the complexities of the ETDRS grading system. However, because of this simplification, the International Classification is not a replacement for ETDRS levels of diabetic retinopathy in large-scale clinical trials or studies where precise retinopathy classification is required.

Other Ocular Manifestations of Diabetes

All structures of the eye are susceptible to complications of diabetes. The consequence of these changes can range from being unnoticed by both patient and physician, to being symptomatic but not sight-threatening, to requiring evaluation to rule out potentially life-threatening underlying causes other than diabetes.

Mononeuropathies of the third, fourth, or sixth cranial nerves can arise in association with diabetes; of these, mononeuropathy of the fourth cranial nerve is least likely to be associated with diabetes.³⁵⁶⁻³⁵⁸ Nerve palsies present a significant diagnostic challenge because misdiagnosis can result in a life-threatening lesion's remaining untreated. In one review of cranial nerve palsies treated in a diabetic patient population in 1967, 42% of mononeuropathies were not diabetic in origin.³⁵⁷ This finding underscores the danger of routinely attributing mononeuropathies to the diabetic condition itself without carefully ruling out other potential causes. The percentage of all extraocular muscle palsies attributable to diabetes mellitus is estimated to be 4.5% to 6%.³⁵⁸ Mononeuropathies may be the initial presenting sign of new-onset diabetes, and diabetes should therefore be considered in the differential diagnosis of any mononeuropathy affecting the extraocular muscles, even in patients who do not claim a history of diabetes. Diabetes-induced third-, fourth-, and sixth-nerve palsies are usually self-limited and should resolve spontaneously in 2 to 6 months. Palsies can recur or subsequently develop in the contralateral eye.

The optic disc can be affected by diabetes in a variety of ways other than by vasoproliferation. Diabetic papillopathy must be distinguished from other causes of disc swelling, including true papilledema from increased intracranial pressure, pseudopapilledema such as optic nerve head drusen, toxic optic neuropathies, neoplasms of the optic nerve, and hypertension.³⁵⁹ Optic disc pallor can occur with spontaneous remission of PDR or with remission after scatter (panretinal) laser photocoagulation (see Fig. 33-24I). Because diabetes poses an increased risk for development of open-angle glaucoma, the disc pallor that occurs after remission of retinopathy or laser photocoagulation must be considered when evaluating the optic nerve head for glaucoma.

A potentially serious diabetic ocular complication is neovascularization of the iris. Usually, the new iris vessels are first observed at the pupillary border, followed by a fine network of vessels over the iris tissue progressing into the filtration angle of the eye. Closure of the angle by the fibrovascular network results in neovascular glaucoma.³⁶⁰ Neovascular glaucoma is difficult to manage and requires aggressive treatment. Diabetes is the second leading cause of neovascular glaucoma, accounting for 32% of cases.³⁶¹ Neovascularization of the iris occurs in 4% to 7% of diabetic eyes and may be present in up to 40% to 60% of eyes

with PDR.^{362,363} When possible, scatter (panretinal) laser photocoagulation is the primary therapy for neovascularization of the iris, although other approaches such as goniophotocoagulation, topical or systemic antiglaucoma medications, and antiglaucomatous filtration surgery are available when needed.³⁶⁴⁻³⁶⁶ Intravitreal administration of VEGF inhibitors has been tried in small-scale, uncontrolled studies with remarkably rapid transient regression of the neovascularization.³⁶⁷

The cornea of the diabetic person is more susceptible to injury and slower to heal after injury than is the nondiabetic cornea.^{359,368} The diabetic cornea is also more prone to infectious corneal ulcers, which can lead to rapid loss of vision, need for corneal transplant, or loss of the eye if it is not treated aggressively. Consequently, diabetic patients using contact lenses should exercise caution and maintain careful monitoring.

Open-angle glaucoma is 1.4 times more common in the diabetic population than in the nondiabetic population.³⁶⁹ The prevalence of glaucoma increases with age and duration of diabetes, but medical therapy for open-angle glaucoma is generally effective. In a study of 76,318 women enrolled in the Nurses' Health Study, Pasquale and coworkers found that T2DM is associated with an increased risk of primary open-angle glaucoma in women.³⁷⁰

The effects of diabetes on the crystalline lens can result in transient refractive changes, alterations in accommodative ability,³⁷¹ and cataracts. Refractive change can be significant and is related to fluctuation of blood glucose levels with osmotic lens swelling.³⁶¹ Cataracts can occur earlier in life and progress more rapidly in the presence of diabetes.^{372,373} Cataracts are 1.6 times more common in people with diabetes than in those without diabetes.^{372,373} In patients with earlier-onset diabetes, duration of diabetes, retinopathy status, diuretic use, and HbA_{1c} levels are risk factors.³⁷⁴ In patients with later-onset diabetes, age of the patient, lower intraocular pressure, smoking, and lower diastolic BP may be additional risk factors.^{375,376} Diabetic patients undergoing simultaneous kidney and pancreas transplantation are at increased risk for development of all types of cataract, independent of the use of corticosteroids after transplantation.³⁷⁷ Both phacoemulsification and extracapsular cataract extraction with intraocular lens implantation are appropriate surgical therapies. The principal determinant of postoperative vision and progression of retinopathy is related to the preoperative presence of DME and the level of NPDR.^{378,379}

Other findings with higher incidence among patients with diabetes include xanthelasma,³⁵⁶ microaneurysms of the bulbar conjunctiva,³⁸⁰ posterior vitreous detachment,³⁸¹ and the rare but often fatal orbital fungal infection *Mucorales* phycomycosis.^{362,363} Prompt diagnosis and treatment of phycomycosis caused by *Mucor* species is crucial, although the survival rate is still only 57%.^{363,382}

Monitoring and Treatment of Diabetic Retinopathy

Appropriate clinical management of diabetic retinopathy has been defined by results of major randomized, multicenter clinical trials (Fig. 33-25): the Diabetic Retinopathy Study (DRS),³⁸³ the ETDRS,³²³ the Diabetic Retinopathy Vitrectomy Study (DRVS),³⁸⁴ the DCCT,³⁸⁵ and the UKPDS.³ These studies have elucidated the progression rates of each level of diabetic retinopathy, guided follow-up intervals, and elucidated the proper delivery, timing, and resulting effectiveness of glycemic control and laser photocoagulation surgery (Figs. 33-26 through 33-29). They have also established recommendations for vitrectomy surgery.

Comprehensive Eye Examination

An accurate ocular examination detailing the extent and location of retinopathy-associated findings is critical for making monitoring and treatment decisions in patients with diabetic retinopathy. As detailed later, most of the blindness associated with advanced stages of retinopathy can be averted with appropriate and timely diagnosis and therapy. Unfortunately, many diabetic patients do not receive adequate eye care at an appropriate stage in their disease.^{385,386} In one study, 55% of patients with high-risk PDR or CSME had never had laser photocoagulation.³⁸⁵ In fact, 11% of T1DM and 7% of T2DM patients with high-risk PDR necessitating prompt treatment had not been examined by an ophthalmologist within the past 2 years.³⁸⁶

The comprehensive eye examination is the mainstay of such evaluation and is necessary on a repetitive, lifelong basis for patients with diabetes.^{350,387} Such an evaluation has four major components: history, examination, diagnosis, and treatment. Annual retinal evaluation to assess the presence and level of diabetic retinopathy and DME is essential to guide patient care. The fundamentals of a comprehensive eye examination for the nondiabetic patient have been detailed by the American Academy of

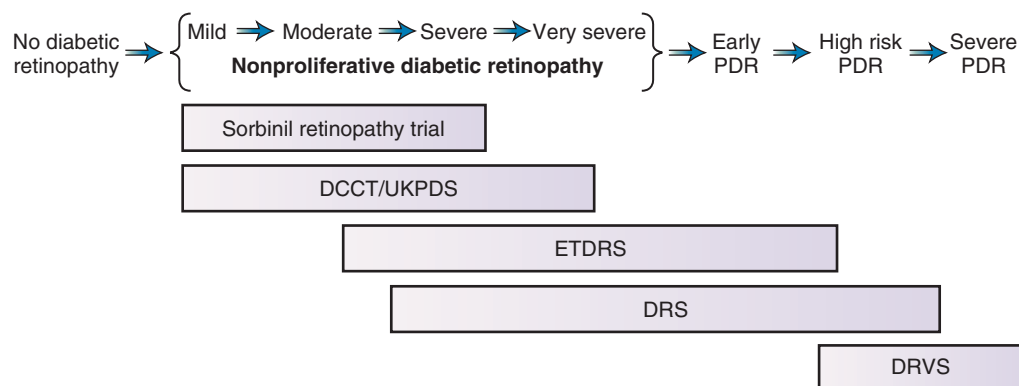

Figure 33-25 Major multicenter clinical trials of diabetic retinopathy. Figure 33-26 Initial ophthalmic examination flow chart. Schematic flow chart of major principles involved in determining the timing of initial ophthalmic examination after a diagnosis of diabetes mellitus. These are minimal recommended times. Ocular symptoms, complaints, or other associated medical issues can necessitate earlier evaluation. Guidelines are regularly reevaluated based on new study results.

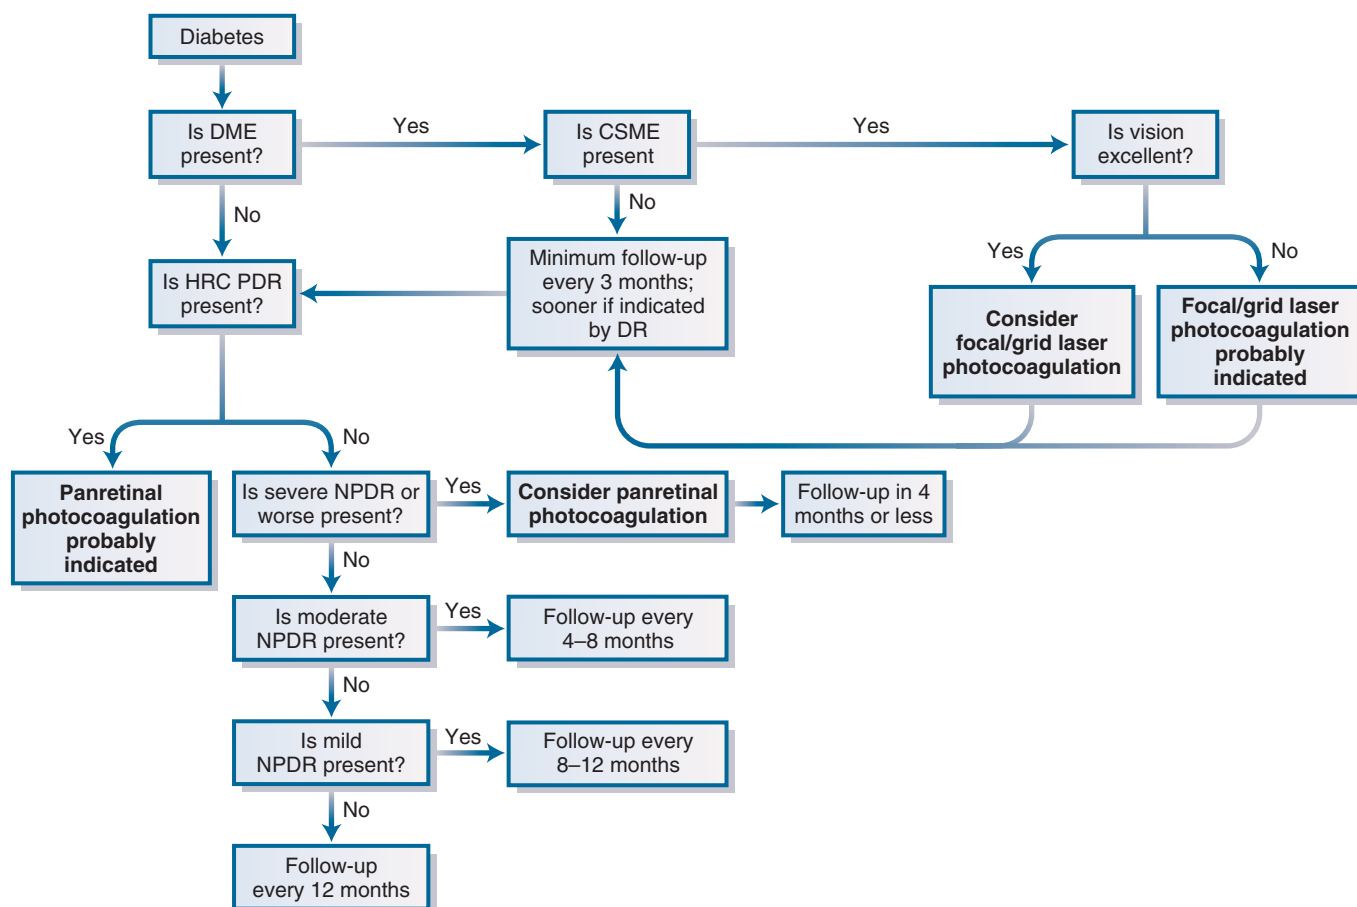

Figure 33-27 Diabetic retinopathy and macular edema examination and treatment flow chart: nonpregnant patients. The schematic flow chart presents major principles involved in determining routine ophthalmic follow-up and indications for treatment in nonpregnant patients with diabetes. These are only general, minimal recommended frequencies. Ocular symptoms, complaints, or other associated ophthalmic or medical issues can necessitate earlier evaluation and/or an altered approach. Guidelines are regularly reevaluated based on new study results. CSME, clinically significant macular edema; DME, diabetic macular edema; DR, diabetic retinopathy; HRC PDR, high-risk characteristic proliferative diabetic retinopathy; NPDR, nonproliferative diabetic retinopathy; PDR, proliferative diabetic retinopathy.

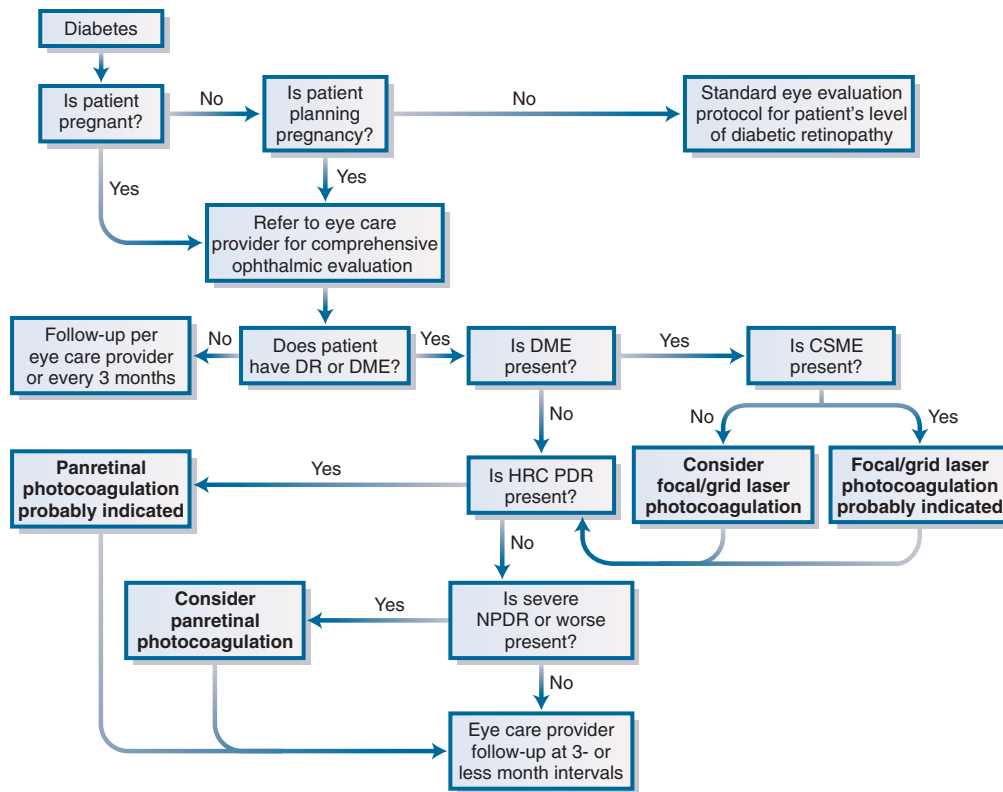

Figure 33-28 Diabetic retinopathy and macular edema examination and treatment flow chart: pregnant patients. The schematic flow chart shows major principles involved in determining routine ophthalmic follow-up and indications for treatment in pregnant patients with diabetes. These are only general, minimal recommended frequencies. Ocular symptoms, complaints, or other associated ophthalmic or medical issues can necessitate earlier evaluation and/or an altered approach. Because retinopathy can progress rapidly in pregnant patients with diabetes, careful and more frequent evaluation is often indicated. Guidelines are regularly reevaluated based on new study results. CSME, clinically significant macular edema; DME, diabetic macular edema; DR, diabetic retinopathy; HRC PDR, high-risk characteristic proliferative diabetic retinopathy; NPDR, nonproliferative diabetic retinopathy.

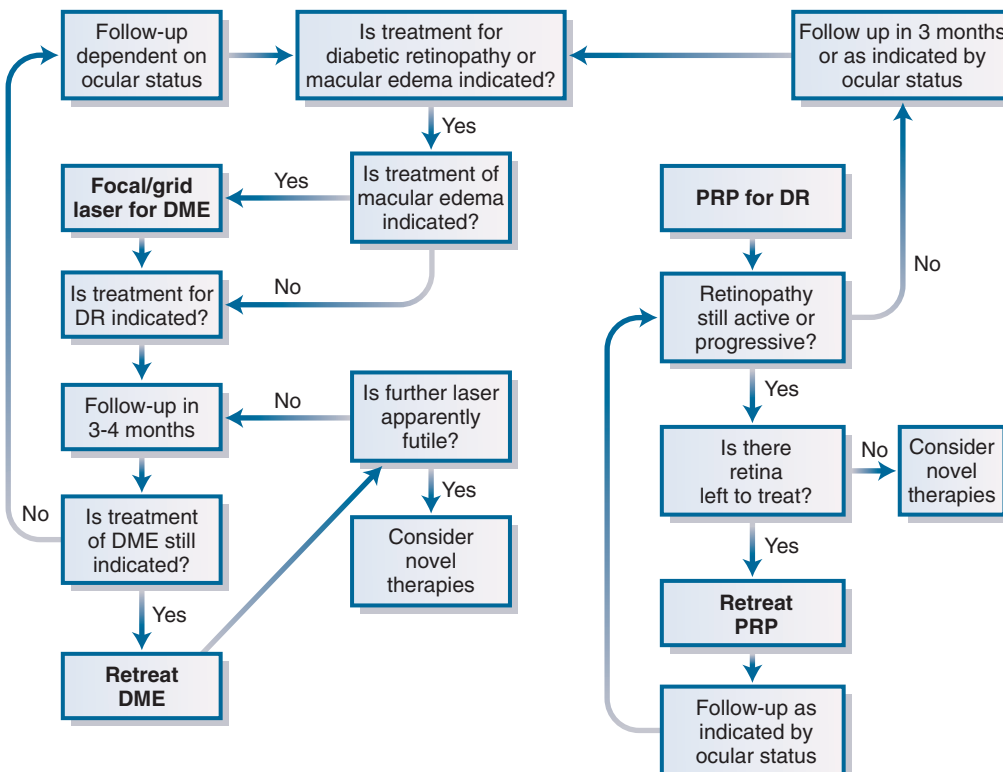

Figure 33-29 Photocoagulation flow chart. The schematic flow chart details general photocoagulation treatment approaches in patients with diabetic retinopathy and/or diabetic macular edema. These are only general guidelines, and actual treatment choices can be affected by numerous other factors, including findings in the same eye or in the contralateral eye and systemic issues. DR, diabetic retinopathy; DME, diabetic macular edema; PRP, scatter (panretinal) photocoagulation.

Ophthalmology³⁸⁷ and the American Optometric Association.³⁸⁸ The examination of the patient with diabetes should be similar, with additional emphasis on portions of the examination that relate to problems particularly relevant to diabetes.

Dilated ophthalmic examination is superior to undilated evaluation because only 50% of eyes are correctly classified as to presence and severity of retinopathy through undilated pupils.^{389,390} Appropriate ophthalmic evaluation entails pupillary dilation, slit-lamp biomicroscopy, examination of the retinal periphery with indirect ophthalmoscopy or mirrored contact lens, and sometimes gonioscopy.^{387,388} Because of the complexities of the diagnosis and treatment of PDR and CSME, ophthalmologists with specialized knowledge and experience in the management of diabetic retinopathy are required to determine and provide appropriate surgical intervention.³⁹¹ Therefore, it is recommended that all patients with diabetes should have dilated ocular examinations by an experienced eye care provider (ophthalmologist or optometrist), and diabetic patients should be under the direct or consulting care of an ophthalmologist experienced in the management of diabetic retinopathy at least by the time severe diabetic retinopathy or DME is present.³⁵⁰ Retinal imaging that has demonstrated equivalency to dilated retinal fundus examination or the accepted standard of seven-standard-field stereoscopic retinal imaging when interpreted by a trained eye care provider can also be appropriate.³⁹²

Initial Ophthalmic Evaluation

The recommendation for initial ocular examination in persons with diabetes is based on prevalence rates of retinopathy (see Fig. 33-26). Approximately 80% of T1DM patients have retinopathy after 15 years of disease, but only about 25% have any retinopathy after 5 years.³⁹⁰ The prevalence of PDR is less than 2% at 5 years and 25% by 15 years. For T2DM, the onset date of diabetes is usually unknown, and more severe disease can be observed at diagnosis. Up to 3% of patients whose diabetes is first diagnosed after age 30 years (T2DM) have CSME or high-risk PDR at the time of initial diagnosis of diabetes.³⁹⁴ Therefore, in patients older than 10 years of age, initial ophthalmic examination is recommended beginning 5 years after the diagnosis of T1DM and at the time of diagnosis of T2DM (see Fig. 33-26).^{350,395}

Puberty and pregnancy can accelerate retinopathy progression. The onset of vision-threatening retinopathy is rare in children before puberty, regardless of the duration of diabetes^{298,395-397}; however, significant retinopathy can arise within 6 years of disease if diabetes is diagnosed between the ages of 10 and 30 years.²⁹⁹ Diabetic retinopathy can become particularly aggressive during pregnancy in patients with diabetes.^{398,399} In the past, the prognosis for pregnancy in the diabetic patient with microvascular complications was so poor that pregnant diabetic patients were commonly advised to avoid or terminate pregnancies.⁴⁰⁰ With recognition of the importance of glycemic control, many diabetic patients in the child-bearing age now experience safe pregnancy and childbirth with minimal risk to mother and baby. There are excellent reviews on this subject.⁴⁰¹

Ideally, patients with diabetes who are planning pregnancy should have a comprehensive eye examination within 1 year before conception (see Fig. 33-28). Patients who become pregnant should have a comprehensive eye examination in the first trimester of pregnancy. Close follow-up throughout pregnancy is indicated, with

TABLE 33-4

Progression to PDR by Level of NPDR

Retinopathy Level	Chance of High-Risk PDR (%)	
	1 Year	5 Years
Mild NPDR	1	16
Moderate NPDR	3-8	27-39
Severe NPDR	15	56
Very severe NPDR	45	71
PDR with fewer high-risk characteristics	22-46	64-75

NPDR, nonproliferative diabetic retinopathy; PDR, proliferative diabetic retinopathy.

From Aiello LP, Gardner TW, King GL, et al. Diabetic retinopathy: technical review. *Diabetes Care*. 1998;21:143-156.

subsequent examinations determined by the findings present at the first-trimester examination.³⁵⁰ This recommendation does not apply to women who develop gestational diabetes, because such women are not at increased risk of developing diabetic retinopathy.

Follow-Up Ophthalmic Examination

Follow-up ocular examination is determined from the risk of disease progression at any particular retinopathy level (see Fig. 33-27). NPDR is categorized into four levels of severity based on clinical findings compared with stereo fundus photographic standards: mild, moderate, severe, and very severe.⁴⁰² Progression of nonproliferative retinopathy to the visually threatening level of high-risk PDR is closely correlated to NPDR level (Table 33-4). Progression rates from each individual NPDR level to any other retinopathy level are also known. These are used to define standard minimal follow-up intervals, as detailed in Figure 33-27 and Table 33-5. Because significant sight-threatening retinopathy can initially occur with no or minimal symptoms, patients with no clinically evident diabetic retinopathy and no known ocular problems require annual comprehensive ophthalmic examinations even if they are totally asymptomatic.

Proliferative Diabetic Retinopathy. The extent and location of neovascularization determine the level of PDR.^{403,404} PDR is best evaluated by dilated examination using slit-lamp biomicroscopy combined with indirect ophthalmoscopy or stereo fundus photography. Without photocoagulation, eyes with high-risk PDR have a 28% risk of severe vision loss within 2 years. This risk compares with a 7% risk of severe vision loss after 2 years for eyes with PDR without high-risk characteristics.⁴⁰³

Severe vision loss is defined as best-corrected acuity of 5/200 or worse on two consecutive visits 4 months apart. This represents vision loss substantially worse than the limit for legal blindness, 20/200 or worse. The DRS demonstrated that scatter (panretinal) laser photocoagulation was effective in reducing the risk of severe vision loss from PDR by 50% or more. The ETDRS demonstrated that scatter (panretinal) laser photocoagulation applied when an eye approaches or just reaches high-risk PDR reduces the risk of severe vision loss to less than 4%. Prompt scatter photocoagulation is therefore indicated for all patients with high-risk PDR, usually indicated for patients with PDR less than high risk, and may be advisable for patients with severe or very severe NPDR, especially in the setting of

TABLE 33-5

Recommended General Management of Diabetic Retinopathy

Level of DR	Risk of Progression (%)		Evaluation		Treatment		Follow-up (mo)

T2DM (see Fig. 33-27).^{323,403-406} Recent progression of eye disease, status of the fellow eye, compliance with follow-up, concurrent health concerns such as hypertension or kidney disease, and other factors must be considered in determining whether laser surgery should be performed in these patients. In particular, patients with T2DM should be considered for scatter photocoagulation before high-risk PDR develops, because the risk of severe vision loss and the need for pars plana vitrectomy (PPV) can be reduced by 50% in these patients, especially when macular edema is present.⁴⁰⁶

In scatter photocoagulation, 1200 to 1800 laser burns are applied to the peripheral retinal tissue, actually focally destroying the outer photoreceptor and retinal pigment epithelium of the retina (see Fig. 33-24I). Large vessels are avoided, as are areas of preretinal hemorrhage. The treatment is thought to exert its effect by increasing oxygen delivery to the inner retina, decreasing viable hypoxic growth factor-producing cells, and increasing the relative perfusion per area of viable retina. The total treatment is usually applied over two or three sessions, spaced 1 to 2 weeks apart. Follow-up evaluation usually occurs at 3 months.

The response to scatter photocoagulation varies. The most desirable effect is to see a regression of the new vessels, although stabilization of the neovascularization with no further growth can result. This latter situation requires careful clinical monitoring. In some cases, new vessels continue to proliferate, requiring additional scatter photocoagulation (see Fig. 37-29). As discussed later, novel therapeutic approaches are now being used in some clinical settings, especially in cases in which the response to scatter photocoagulation is inadequate. Initial results from definitive multicenter, randomized, controlled clinical trials will soon be reported, and additional clinical trials using these new therapeutic approaches continue to be performed.

The DRVS, completed in 1989, demonstrated that early PPV in persons with severe fibrovascular proliferation was more likely to result in better vision and less likely to result in poor vision, particularly in patients with T1DM.³⁸⁴ PPV is surgery within the eye aimed primarily at removing abnormal fibrovascular tissue, alleviating retinal traction, allowing the retina to obtain a more anatomically normal position, and removing vitreous opacities such as vitreous hemorrhage. The actual outcome data from this study may

not be entirely applicable today because of the dramatic advances in surgical techniques and the advent of laser endophotocoagulation that have occurred in the intervening years. It is clear that PPV can save and restore vision in many cases of severe retinal disease not amenable or not responsive to laser photocoagulation.

Macular Edema. Untreated CSME is associated with an approximately 25% chance of moderate vision loss after 3 years (defined as at least doubling of the visual angle, such as 20/40 reduced to 20/80).³²³ Macular edema is best evaluated clinically by dilated examination using slit-lamp biomicroscopy or stereo fundus photography. The newer diagnostic ophthalmic imaging technique called optical coherence tomography (OCT) has provided a means to objectively quantify retinal thickening and is the objective method of choice currently. OCT has been used in conjunction with visual acuity measurement to monitor response to treatment and help determine timing of intervention.^{408,409} Focal laser photocoagulation is generally indicated for patients with CSME (see Figs. 33-24C and 33-27). The ETDRS demonstrated that focal laser photocoagulation for CSME reduced the 5-year risk of moderate vision loss by 50%, but 15% of patients continued to experience vision loss.³⁵³ In focal laser photocoagulation, lesions located 500 to 3000 μm from the center of the macula that are contributing to thickening of the macular area are usually directly photocoagulated. These lesions are identified clinically or by fluorescein angiography and consist primarily of leaking microaneurysms. When leakage is diffuse or microaneurysms are extensive, photocoagulation may be applied to the macula in a grid configuration, avoiding the fovea region.

Although fluorescein angiography is useful for guiding therapy once CSME has been diagnosed, it is not required for the diagnosis of CSME or PDR, because these findings should be clinically evident in most cases (Fig. 33-30). Fluorescein angiography is a valuable test for guiding treatment of CSME, identifying macular capillary nonperfusion, and evaluating unexplained vision loss. Because there are risks associated with fluorescein angiography, including nausea, urticaria, hives, and rarely death (1 in 222,000 patients) or severe medical sequelae (1 in 2000 patients),^{407,410,411} fluorescein angiography is not part of the examination of an otherwise normal patient with diabetes, and the procedure is usually contraindicated in patients with known allergy to fluorescein dye or during pregnancy.

Follow-up evaluation of focal laser surgery usually occurs after 3 months (see Fig. 33-27). If macular edema persists, further treatment may be necessary. Patients with severe or very severe NPDR should be considered for focal treatment of macular edema whether or not the macular edema is clinically significant, because they are likely to require scatter laser photocoagulation in the near future and because scatter photocoagulation, although beneficial for PDR, can exacerbate existing macular edema. As discussed later, novel therapeutic approaches are now being used in clinical settings to treat DME, and their benefit, when combined with focal laser therapy, has been confirmed by results from multicenter, randomized clinical trials. However, this approach requires repeated intraocular injections. Additionally, the pathogenesis of DME is highly complex, and a variable response to treatment modalities has been observed in many patients. These observations have prompted the investigation of varying drug dosages to identify the optimal treatment concentration and sustained drug delivery devices to limit repeated intraocular

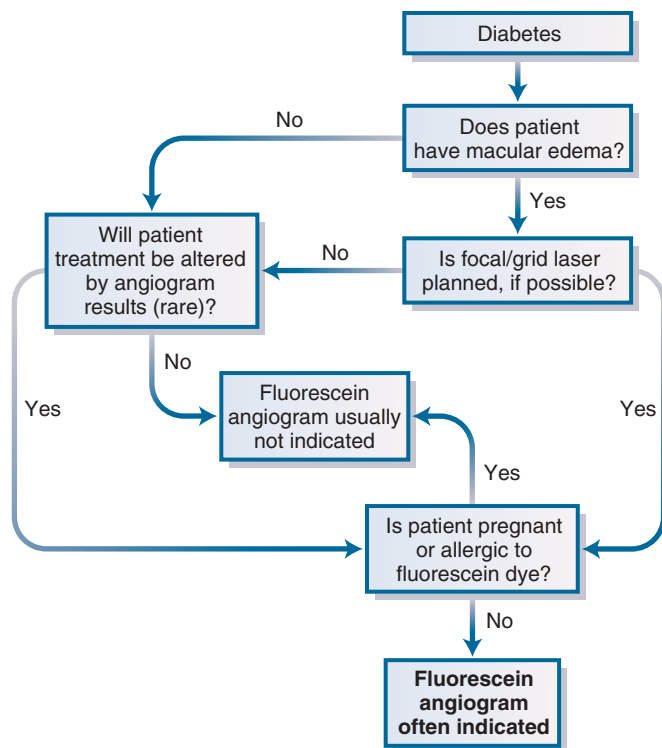

Figure 33-30 Fluorescein angiogram flow chart. The schematic flow chart details a general algorithm for appropriate use of fluorescein angiography in the ocular evaluation of patients with diabetes mellitus. In unusual cases, confounding factors can alter the appropriate approach.

injections. Multicenter, randomized, controlled clinical trials are under way for most of these new approaches.

Novel Approaches. Advances in understanding of the pathogenic mechanisms underlying diabetic retinopathy have given rise to the development of novel pharmacologic therapies that may limit the progression of diabetic retinopathy and may be more effective than laser in the treatment of PDR and DME. Laser photocoagulation has shown established effectiveness in the treatment of both PDR and DME, but it is inherently destructive and relies on focal ablation of areas of the retina. Growth factors such as VEGF have been shown to mediate both the neovascularization of PDR and the increased permeability associated with DME. These observations have prompted novel approaches in the management of retinal diseases with pharmacologic agents that modulate the response to these factors to effectively treat PDR and DME without the retinal tissue destruction associated with laser photocoagulation.

Intravitreal injections of anti-VEGF agents, either as an aptamer (pegatanib) or as antibodies (ranibizumab and bevacizumab), have been shown to cause the regression of choroidal and retinal neovascularization and to reduce the amount of vascular leakage. These compounds are injected into the vitreous cavity of the eye on a repetitive basis. Both pegatanib and ranibizumab have been approved by the U.S. Food and Drug Administration for the treatment of neovascular age-related macular degeneration, and all three anti-VEGF agents have been used off-label in the treatment of diabetic retinopathy and DME. Neovascular processes have been shown to be exquisitely sensitive to anti-VEGF agents, and eyes with severe neovascularization of the retina or anterior segment have dramatically and rapidly improved with anti-VEGF treatment.^{335,412}

Results from a multicenter, randomized, controlled clinical trial evaluating intravitreal administration of ranibizumab with immediate or deferred laser showed a marked benefit for anti-VEGF agents compared with laser alone.⁴¹³ After 1 year, ranibizumab, as applied in the trial, resulted in a mean gain of nine letters of vision ($P < .001$) when combined either with prompt laser or with deferral of laser for at least 24 weeks. Ranibizumab was more effective than prompt laser alone (three-letter gain) for the treatment of center-involving DME in eyes with central thickening and vision reduced to between 20/32 and 20/320. The number of eyes gaining two or more lines of vision were almost doubled in the anti-VEGF groups compared with laser alone. Conversely, eyes losing two or more lines of vision were about one third as many in the anti-VEGF groups compared with laser alone. No increased systemic events or serious ocular adverse events were attributed to the treatment other than the known small risk of endophthalmitis associated with intravitreal injections themselves. Currently, further randomized clinical trials are under way to determine the optimal dosage regimen for anti-VEGF agents. Much work is being done on drug delivery systems so as to eventually reduce the number of intravitreal injections required.

The ophthalmic use of corticosteroids, administered through the periocular or the intravitreal route for the treatment of DME, has gained widespread use over the last 5 years, largely due to early case reports and uncontrolled clinical trials documenting its rapid and often dramatic effect on retinal thickening. Two multicenter, randomized, prospective clinical trials were undertaken to address the effectiveness and safety of both routes of steroid administration. Peribulbar steroid injections were found to have no significant benefit for the treatment of DME, but a beneficial effect of limiting retinopathy progression was observed.⁴¹⁴ The 3-year results of the multicenter, randomized, controlled trial comparing intravitreal steroids to focal laser showed that, despite an initial rapid reduction in retinal thickness and improvement in vision with the intravitreal steroid injection, the results at 1 year were no better than with laser photocoagulation, and after 2 years, the steroid was inferior to the laser treatment in both visual outcome and retinal thickness.^{415,416} Intravitreal steroid injection was associated with increases of approximately fourfold in rate of intraocular pressure complications and fourfold in need for cataract surgery, compared with laser treatment. As with peribulbar steroids, intravitreal steroid administration resulted in a 32% reduction in relative risk (RR) for retinopathy progression. When used in combination with laser in patients who have already undergone cataract surgery before initiation of anti-VEGF treatment, vision improvement may be comparable to that achieved with anti-VEGF agents.⁴¹³

Currently, intravitreal steroid alone is not the preferred primary therapy for DME, but it may play a future role in treatment to limit retinopathy progression or in combination with laser in patients who cannot receive anti-VEGF agents or who are pseudophakic before treatment. However, development of cataracts and increases in intraocular pressure may limit its potential benefit.

Control of Systemic Disorders and Effect of Systemic Medications

In addition to the importance of intensive glycemic control in reducing the onset and progression of diabetic retinopathy as discussed earlier, it is critical for optimal ocular

health of diabetic patients that several other systemic considerations be optimized.

Patients with diabetes mellitus commonly suffer from concomitant hypertension. Patients with T1DM have a 17% prevalence of hypertension at baseline and a 25% incidence after 10 years.⁴¹⁷ There is a 38% to 68% prevalence in T2DM.⁴¹⁸⁻⁴²⁰ In most studies, hypertension is correlated with the duration of diabetes, higher HbA_{1c} level, presence of gross proteinuria, and male gender. Elevated BP exacerbates the development and progression of diabetic retinopathy. The risk of PDR is associated with the presence of hypertension at the baseline visit, higher HbA_{1c} levels, and presence of more severe levels of retinopathy at the initial visit.⁴²¹ Patients with hypertension are more likely to develop retinopathy, diffuse macular edema, and more severe levels of retinopathy⁴²¹⁻⁴²³ and have more rapid progression of retinopathy than diabetic patients who do not have hypertension.⁴²⁴⁻⁴²⁶

The large, randomized, prospective UKPDS in 1148 patients with T2DM demonstrated a 34% ($P = .0004$) reduction in risk of diabetic retinopathy progression and a 47% ($P = .004$) reduction in moderate visual acuity loss in patients assigned to intensive BP control.⁴²⁷ These effects were independent of glycemic control, and the risk reductions were similar regardless of whether the hypertension was controlled with an ACE inhibitor (captopril) or a β -blocker (atenolol). Overall, hypertension appears to be a significant risk factor in the development and progression of diabetic retinopathy and should be rigorously controlled. Until the results of specific trials investigating the BP levels required to minimize end-organ damage in patients with diabetes are known, target BP should most likely be maintained as low as safely possible.

Associations between renal and retinal angiopathy are numerous. Proteinuria and microalbuminuria are associated with retinopathy.⁴²⁹⁻⁴⁴¹ The presence and severity of diabetic retinopathy are indicators of the risk of gross proteinuria,^{433,442} and, conversely, proteinuria predicts PDR.^{431,442,444} Half of all patients who have T1DM with PDR and 10 or more years of diabetes have concomitant proteinuria.⁴²⁹ In T1DM, the prevalence of PDR increases from 7% at onset of microalbuminuria to 29% 4 years after onset of albuminuria, compared with 3% and 8%, respectively, in patients without persistent microalbuminuria.⁴³² The Appropriate Blood Pressure Control in Diabetes (ABCD) Trial found that both the severity and the progression of retinopathy were associated with overt albuminuria.⁴⁴³⁻⁴⁴⁷ In patients with T1DM, the presence of gross proteinuria at baseline is associated with 95% increased risk of developing macular edema,⁴²¹ and dialysis can improve macular edema in diabetic patients with renal failure.³⁶⁵

Despite these associations, the frequent coexistence of retinal and renal microangiopathies and factors such as associated hypertension and disease duration can confound these results.⁴⁴⁸ Overall, it is important to carefully consider the renal status of any patient with diabetes mellitus and to ensure that the patient is receiving optimal care in this regard. In addition, rapidly progressive retinopathy, especially in a patient with a long history of diabetes mellitus in whom retinopathy has been previously stable, should suggest the need for renal evaluation.

Low hematocrit was an independent risk factor in the ETDRS analysis of baseline risk factors for development of high-risk PDR and of severe vision loss.⁴⁴⁹ A cross-sectional study involving 1691 patients revealed a twofold increased risk of any retinopathy in patients with a hemoglobin level lower than 12 g/dL, compared to those with a higher hemoglobin concentration, using multivariate analyses

controlling for serum creatinine, proteinuria, and other factors.⁴⁵⁰ Among patients with retinopathy, those with low hemoglobin levels have a fivefold increased risk of severe retinopathy compared to those with higher hemoglobin levels. There have been limited reports of resolution of macular edema and hard exudate with improvement or stabilization of visual acuity in erythropoietin-treated patients after an increase in mean hematocrit.⁴⁵¹ In view of the potential association of low hematocrit and diabetic retinopathy, it is important to ensure that patients with diabetic retinopathy and anemia are receiving appropriate management.

In summary, diabetes is clearly a multisystem disease that requires a comprehensive medical team approach. Even with regard to ocular health, this necessitates the involvement of multiple health care specialists for optimal patient care.

DIABETIC NEPHROPATHY

Diabetic nephropathy remains a major cause of morbidity and mortality for persons with either T1DM or T2DM. In Western countries, diabetes is the leading single cause of ESRD.⁴⁵² Indeed, in many countries such as the United States, more than 50% of patients in renal replacement therapy programs have diabetes as the major cause of their renal failure.⁴⁵³ However, the full impact of diabetic nephropathy is far greater.⁴⁵⁴ Globally, most patients with diabetes are in developing countries⁴⁵⁵ that do not have the resources or health infrastructure to provide universal renal replacement therapy. Even in developed countries, fewer than 1 in 20 patients with diabetes and chronic kidney disease survive to ESRD, succumbing instead to CVD, heart failure, or infection, to which the presence and severity of diabetic renal disease significantly contribute. For example, almost all of the excess in cardiovascular deaths in persons with diabetes younger than 50 years of age can be attributed to nephropathy.⁴⁵⁶ Indeed, in T1DM subjects without nephropathy there is no evidence of premature mortality.⁴⁵⁷ In patients with T2DM, microalbuminuria is associated with a twofold to fourfold increase in the risk of death. In patients with overt proteinuria and hypertension, the risk is even higher.⁴⁵⁸ Consequently, the goal to reduce ESRD in patients with diabetes is only one component of the overall benefit in preventing diabetic kidney disease.

It is estimated that 25% to 40% of patients with T1DM and 5% to 40% of patients with T2DM ultimately develop diabetic kidney disease.^{459,460} Up to 20% of patients with T2DM already have diabetic kidney disease when they are diagnosed with diabetes,⁴⁶¹ and a further 30% to 40% develop diabetic nephropathy, mostly within 10 years of diagnosis.⁴⁶² Nephropathy appears to be more common in T1DM, but, because of the large and increasing number of persons with T2DM,⁴⁶³ more than 80% of diabetic patients in renal replacement programs have T2DM.

Natural History of Nephropathy in Type 1 Diabetes

Nephropathy and specifically proteinuria in the setting of diabetes have been known for more than 100 years, and the classic structural features of glomerulosclerosis were described more than 70 years ago.⁴⁶⁴ However, it is only since the 1980s that the natural history of this condition has been extensively delineated. This is partly because significantly more patients are surviving to see the full presentation of this condition. For example, in 1971, the

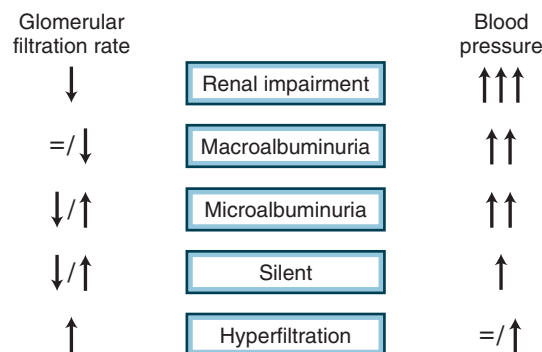

Figure 33-31 The phases (natural history) of diabetic nephropathy.

median survival time of patients with T1DM and overt nephropathy was 5 years, with fewer than 10% surviving more than 10 years.⁴⁶⁵ Consequently, few patients were able to survive the course of their renal disease. By comparison, in 1996, the median survival time in an equivalent population was more than 17 years. Not surprisingly, almost 10 times more patients with T1DM are now entering ESRD programs.

Diabetic nephropathy is characterized clinically as a triad of hypertension, proteinuria, and, ultimately, renal impairment.⁴⁶⁶ The classic five stages of nephropathy as described by Mogensen,⁴⁶⁷ although not totally accurate, remain the best way of describing this condition (Fig. 33-31). This description relies on functional evaluation of the renal disease and is based on serial measurements of glomerular filtration rate (GFR) and albuminuria.

Stage I: Hyperfiltration

The initial phase has been termed the *hyperfiltration* phase. It is associated with an elevation of GFR⁴⁶⁸ and an increase in capillary glomerular pressure. Although elevated GFR is invariably present in animal models of T1DM,⁴⁶⁹ it occurs in only a significant minority of T1DM patients. Hyperfiltration is considered to occur as a result of concomitant renal hypertrophy⁴⁷⁰ and in part because of a range of intrarenal hemodynamic abnormalities that occur in the diabetic milieu and contribute to glomerular hypertension.⁴⁷¹ The pathophysiology of renal hypertrophy associated with diabetes remains unexplained, although specific growth factors such as the growth hormone (GH)-IGF1 system and TGF- β have been implicated.^{472,473} There is not only glomerular but also tubular hypertrophy. The tubular hypertrophy explains the increased kidney weight in diabetes, because tubules make up more than 90% of the kidney weight.⁴⁷⁴ In addition, increased salt reabsorption associated with proximal tubular hypertrophy can contribute to glomerular hyperfiltration via tubuloglomerular feedback.⁴⁷⁰

The second explanation for the increase in GFR associated with diabetes relates to hemodynamic changes within the kidney. Although not directly tested in humans, micropuncture studies in rodents, particularly by Brenner's group in the 1980s, revealed that experimental diabetes was associated with a range of intrarenal hemodynamic changes.⁴⁷¹ Alongside hyperfiltration, there is an increase in effective renal plasma flow, and some investigators call this the *hyperperfusion-hyperfiltration* phase of diabetic nephropathy. At the same time, increased intraglomerular capillary pressure is increased, reflecting relative efferent versus afferent arteriolar vasoconstriction⁴⁷¹ with activation of the intrarenal renin-angiotensin system and reduced synthesis of the vasodilator NO.

The importance of this hyperfiltration phase as predicting and leading to diabetic nephropathy remains controversial. Several groups have confirmed the initial relationship between elevated GFR and later development of proteinuria described by Mogensen.⁴⁷⁵ However, this has not been a universal finding. Nevertheless, later studies with antihypertensive agents, and in particular agents that interrupt the renin-angiotensin system, have shown attenuation of some of these glomerular hemodynamic abnormalities. This provides justification to consider that at least some of these intrarenal hemodynamic changes in diabetes play a role in the development and progression of nephropathy.

Stage 2: The Silent Stage

The next stage is known as the *silent stage*: from a clinical point of view, there is no overt evidence of any form of renal dysfunction. Patients usually have normal GFR with no evidence of albuminuria. However, this phase is associated with significant structural changes, including basement membrane thickening and mesangial expansion. With detailed quantitative studies of renal morphology, it is often possible to detect those patients who will develop renal damage.⁴⁷⁶

This is a very important phase clinically, because it is hoped that investigators will be able to develop new tests, such as biomarkers in plasma or urine or sophisticated assessments from renal biopsy material, to identify which patients will progress to more advanced renal disease. Because overall fewer than 40% of subjects with T1DM will progress, it is critical that the potential progressors, who could be candidates for early prevention and treatment strategies to avoid ESRD, be detected. As yet, no such surrogate markers or predictors have been identified in association with the silent phase of the disease.

Extensive studies using various plasma markers such as prorenin⁴⁷⁷ or DNA studies to identify certain gene polymorphisms such as the ACE genotype³⁹ have been promising. The measurement of albumin fragments (ghost albumin) in the urine of patients with diabetes may be another, albeit unproven, approach.⁴⁷⁸ Serial prospective ambulatory BP monitoring studies have also demonstrated modest rises in BP in patients in this silent phase up to 5 years before urinary albumin excretion begins to increase.⁴⁷⁹ However, none of these markers has been proven to be sensitive or specific enough on further clinical evaluation for widespread clinical application.

Stage 3: Microalbuminuria

The third phase is known as *microalbuminuria* or the stage of *incipient nephropathy*. At this stage, often 5 to 15 years after the initial diagnosis of T1DM, the urinary albumin excretion rate has increased into the microalbuminuric range of 20 to 200 $\mu\text{g}/\text{minute}$ or 30 to 300 $\text{mg}/24$ hours.⁴⁸⁰ In the past, microalbuminuria was considered to be a predictor rather than a manifestation of diabetic kidney disease. Increasingly it has been appreciated, particularly based on interpretation of renal morphologic studies, that in the microalbuminuric phase there is already widespread evidence of advanced glomerular structural changes.⁴⁸¹ Concomitant with these changes, systolic and diastolic BP are increased. Furthermore, the nocturnal dip in BP seen in normal persons is often lost with the development of microalbuminuria.⁴⁸² Renal function during this phase may be increased, normal, or reduced.

The best approach to screen for microalbuminuria remains controversial. The original studies used 24-hour or overnight urine sampling methods. However, a spot urine

albumin-to-creatinine ratio in an early morning urine specimen has been validated as a marker and appears to be a practical option for routine clinical practice.⁴⁸⁰ Because persistent microalbuminuria, if left untreated, is often a reliable harbinger of overt nephropathy,⁴⁷⁵ it is incumbent on clinicians to perform serial measurements of this parameter and to repeat the measurement if there is an isolated elevation in urinary albumin excretion.

Studies suggest that in many patients with T1DM, microalbuminuria can be transient and can reverse to normoalbuminuria.⁴⁸³ Therefore, the onset of microalbuminuria does not irrevocably seal the fate of the patient. A study of 386 patients with persistent microalbuminuria showed that regression of microalbuminuria occurred in 58% of patients,⁴⁸³ although other groups have reported much lower rates of this phenomenon.⁴⁸⁴ Notably, in that study, microalbuminuria of short duration, optimal levels of HbA_{1c} ($<8\%$), low systolic BP (<115 mm Hg), and low levels of both cholesterol and triglycerides were independently associated with the regression of microalbuminuria. Therefore, screening of diabetic patients for nephropathy is now recommended to include measurements of urinary albumin concentrations at least twice annually in T1DM patients.

Stage 4: Macroalbuminuria

The next stage is the *macroalbuminuria* phase or *overt nephropathy*. This stage represents the phase that has been previously described as diabetic nephropathy and is highly predictive of subsequent renal failure if left untreated. It is characterized by a urinary albumin excretion rate greater than 300 $\text{mg}/24$ hours (>200 $\mu\text{g}/\text{minute}$). This phase usually occurs after 10 to 15 years of diabetes, but the risk of overt renal disease never truly disappears, and macroalbuminuria can appear after 40 or 50 years of T1DM.

There are at least two peaks of incidence of overt nephropathy, and this has been termed by some investigators as representing slow and fast trackers.⁴⁸⁵ The key contributors of this marked variation in the timing of onset of proteinuria, independent of glycemia or BP control, remains elusive, although a range of genetic, molecular, and environmental factors have been proposed. In association with this increase in proteinuria, more than two thirds of patients have overt systemic hypertension.⁴⁸⁶ If macroalbuminuria is left untreated, BP continues to rise, accelerating the decline in GFR, which promotes a further rise in BP, creating a vicious cycle of progressive renal impairment that ultimately leads to ESRD.

Stage 5: Uremia

The final *uremic* phase, which can occur in up to 40% of T1DM subjects, requires the institution of renal replacement therapy. As recently as the 1970s, patients with diabetes were not considered candidates for renal replacement therapy because of their abysmal prognosis. However, improvements in the management of CVD and renal replacement options have seen the survival rate of diabetic patients on dialysis approach that of patients with renal disease from other causes. Many patients with diabetes and ESRD are also now considered candidates for renal transplantation, which is associated with better outcomes than remaining on dialysis. However, there is evidence that the renal lesions of diabetes often recur in the transplanted kidney, although the lead time to develop ESRD means that few kidneys are lost through recurrent disease.

Increasingly, single pancreas-kidney (SPK) and pancreas-after-kidney (PAK) transplantation have become therapeutic options for patients with T1DM and ESRD, and they appear to offer advantages over kidney-alone

transplantation. In particular, there is some evidence that maintenance of euglycemia after pancreas transplantation can lead to resolution of many diabetes-related renal lesions, such as mesangial expansion.⁴⁸⁷ This reversal is often not apparent until after 10 years of euglycemia, emphasizing the slow turnover of matrix and the potential long-term effects of hyperglycemic memory in the kidney.

Natural History of Nephropathy in Type 2 Diabetes

The natural history of diabetic nephropathy in patients with T2DM is less well understood than in patients with T1DM. This partly reflects the fact that T2DM is largely a disease of an older population, with associated obesity, hypertension, and dyslipidemia and high rates of CVD that restrict the manifestation of diabetic renal disease. In addition, approximately 7% of patients with T2DM already have microalbuminuria at the time of diagnosis. This may be partly related to the fact that most of these patients have had untreated diabetes for 10 years (on average) before diagnosis. Within 5 years after a diagnosis of T2DM, up to 18% of patients have microalbuminuria, especially those with poor metabolic control and high BP levels. This has led some investigators to suggest that nephropathy in T2DM is different from that seen in patients with T1DM.

However, the natural history of nephropathy in T2DM has more similarities than differences from that seen in T1DM. Hyperfiltration does occur in T2DM,⁴⁸⁸ although it has been reported to be less common than in T1DM. This observation must be interpreted with caution, because GFR normally declines with age, and hyperfiltration can still exist even though the GFR remains in the normal adult range. Microalbuminuria also occurs in T2DM. However, the finding of microalbuminuria in T2DM might not be as specific for diabetic renal disease as described in the seminal studies in T1DM. In the context of a very high prevalence of CVD, microalbuminuria may be more closely associated with nonrenal events such as stroke and MI.⁴⁴⁴ Furthermore, incipient or overt cardiac failure, urinary tract infection, and urinary obstruction (e.g., enlarged prostate) can also lead to microalbuminuria.⁴⁷¹

Many patients with T2DM and microalbuminuria also progress to overt proteinuria. However, it is increasingly appreciated that the situation is much more complex, and many groups have now described subjects with T1DM⁴⁸⁹ as well as T2DM⁴⁹⁰ who develop renal impairment in the absence of significant proteinuria. The exact explanation for this phenomenon is unknown, and ongoing studies are exploring whether these patients have different renal morphologic changes from those with the more classic syndrome of diabetic nephropathy (i.e., overt proteinuria and declining GFR). Preliminary studies suggest a prominent vascular component for this form of nonproteinuric renal dysfunction. Nonetheless, it appears that the risk of ESRD in patients with T2DM and renal impairment is similar in the presence or absence of microalbuminuria, underlining the importance of an estimated GFR in the management of T2DM. Many of the national and international guidelines now recommend the inclusion of regular measurements of serum creatinine⁴⁹¹ and determination of estimated GFR using a variety of different formulas.

Pathogenesis

It is likely that many of the mechanisms implicated in diabetic microvascular complications, in general, play a

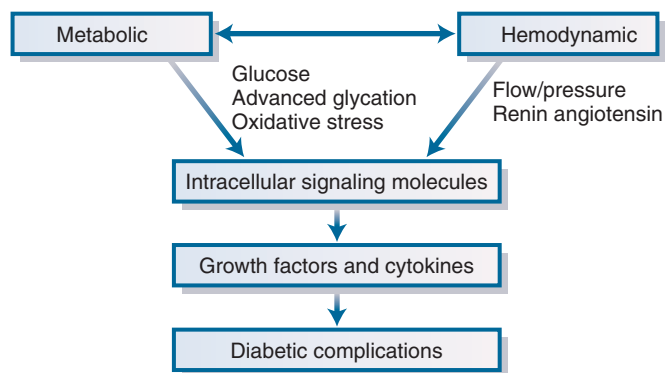

Figure 33-32 Interactions between metabolic and hemodynamic factors in promoting diabetic complications including nephropathy.

central role in the development and progression of diabetic nephropathy (Fig. 33-32).²⁵⁰ It is clear that hyperglycemia is necessary for the initiation of renal injury, because patients without diabetes do not develop this type of nephropathy. Moreover, intensive therapy designed to achieve improved glycemic control is able to attenuate the development of nephropathy, as assessed by urinary albumin excretion, although it is not fully prevented.³⁰⁸ However, it is now clear that other factors must also be involved, because continuous florid hyperglycemia is not necessarily required for diabetic hyperfiltration and kidney growth to occur. Indeed, glomerular hyperfiltration and tubular hypertrophy can persist in patients with T1DM even after euglycemia is achieved through aggressive insulin therapy.⁴⁹²

Other pathways that may be involved in diabetic nephropathy include generation of mitochondrial ROS, accumulation of AGEs, and activation of intracellular signaling molecules such as PKC.²⁵⁰ Many of the seminal studies performed in endothelial cells demonstrating a central role of mitochondrial ROS in activating pathways implicated in diabetic vascular complications have been reproduced in mesangial cells.⁴⁹³ Advanced glycation, which occurs at an accelerated rate in diabetic patients, is a prominent phenomenon in the kidney. Not only is the kidney the major site for excretion of AGEs, but also many of the proteins with a long life, such as collagen, are extensively glycosylated in patients with diabetes.⁴⁹⁴ Furthermore, various AGE receptors (e.g., RAGE) have been described in the kidney and appear to play a role in mediating some of the deleterious effects of AGEs, such as stimulation of growth factor expression and induction of important phenotypic changes within certain renal cell populations to promote scarring.¹³¹

Preliminary studies have been performed using various approaches to inhibit renal AGE accumulation and action, including the use of a soluble RAGE (sRAGE). A range of pharmacologic agents have shown promising results, but clinical translation of these findings remains to be fully defined.⁴⁹⁴ Selective PKC isoform inhibitors have been evaluated in small clinical trials, but their role in renal disease remains to be confirmed.⁴⁹⁵ Some exciting pilot studies evaluating a number of cytosolic sources of oxidative stress, such as NADPH oxidase, suggest that certain NADPH oxidase isoforms such as Nox4 may be excellent targets for new renoprotective therapies.⁴⁹⁶

In addition to the mechanisms described earlier, the diabetic kidney appears to be readily modulated by a range of vasoactive hormones. It is increasingly appreciated that there may be important interactions between metabolic

pathways and various hemodynamic factors, including vasoactive hormones such as angiotensin II, in mediating renal injury in diabetes (see Fig. 33-32).^{497,498} Although many drugs that modulate hormone levels or action are not specific for diabetic kidney disease, interruption of the renin-angiotensin system appears to be an excellent approach, not only for reducing BP but also for correcting many of the cellular, biochemical, hemodynamic, and structural abnormalities seen in the diabetic kidney. These drugs appear to be very powerful antiproteinuric agents, although the exact mechanism of action remains to be fully defined. Based on the discovery in the late 1990s that proteinuria in a range of nephropathies could occur as a result of molecular and structural abnormalities in a highly specialized structure known as the slit diaphragm within the glomerular epithelial cell (podocyte), a number of experimental studies, subsequently confirmed in humans, showed that depletion of one of these slit pore proteins, nephrin, could be attenuated or prevented by agents that interrupt the renin-angiotensin system.⁴⁹⁹

In addition to promoting glomerular nephrin depletion, angiotensin II also appears to have other actions that promote the development of proteinuria, including trophic effects on the kidney and increasing glomerular membrane pore size.⁵⁰⁰ Although many investigators have focused on the renin-angiotensin system and, in particular, the vasoconstrictor angiotensin II, it is increasingly appreciated that other vasoconstrictors may be important. These include endothelin and a number of vasodilators such as NO, bradykinin, atrial natriuretic peptide, and vasodilative angiotensins such as angiotensin(1-7).⁵⁰¹ Exploration of the role of vasoactive hormones and their respective receptors in the diabetic kidney is critical for designing new treatments for this condition, because these pathways are ideal targets for drug development. This point has already been

demonstrated for agents that interrupt the renin-angiotensin system, including ACE inhibitors and ARBs.

Pathology

Diabetic renal disease was originally described as a glomerulopathy associated with diffuse or nodular glomerulosclerosis.⁴⁶⁴ Subsequent studies using electron microscopy revealed that glomerular basement membrane thickening and mesangial expansion are prominent glomerular abnormalities in diabetes (Fig. 33-33).⁴⁷⁶ Prospective studies showed that these changes predict, to a certain degree, the development of overt renal disease in patients with T1DM. However, fewer than one third of diabetic patients with microalbuminuria have the typical glomerulopathy described by Kimmelsteil and Wilson in 1936.^{464,502} Although initial studies emphasized the mesangial cell changes in the glomerulus, glomerular epithelial cell abnormalities represent a new area of active research.⁴⁸ Podocyte dysfunction and subsequent apoptosis ultimately leading to depletion of podocytes within the glomerulus appear to play a pivotal role in the development of proteinuria in diabetes.

Although most of the focus has been on glomerular changes in the diabetic kidney, more recent studies have identified important changes in other sites within the kidney, including the tubules, interstitium, medulla, and papilla.⁴⁷⁴ *Diabetic tubulopathy* is characterized by a variety of structural and functional changes including tubulointerstitial cell hypertrophy, tubular basement membrane thickening, epithelial-mesenchymal transition,¹³¹ and the accumulation of glycogen (see Fig. 33-33). There is also an expansion of the interstitial space with infiltration of various cell types, including myofibroblasts and macrophages.

Glomerulopathy

- Mesangial expansion
- Glomerular hypertension
- Diffuse thickening of the GBM
- Broadening of foot processes
- Podocyte loss
- Reduced slit pore proteins
- Glomerulomegaly
- Kimmelsteil-Wilson lesion
- Adhesions to Bowman's capsule
- Neovascularization
- Nodular and diffuse glomerulosclerosis

Tubulopathy

- Tubular hyperplasia and hypertrophy
- Progressive and cumulative atrophy
- Thickening of the TBM
- Epithelial mesenchymal transition
- Accumulation of lysosomal bodies
- Armani-Ebstein lesion
- Reduced tubular brush border
- Increased tubular salt reabsorption
- Increased Na⁺/H⁺ antiporter activity
- Impaired tubular acidification
- Abnormal tubuloglomerular feedback
- Decreased endocytosis of protein
- Abnormal lysosomal processing
- Impaired uptake of organic ions

Figure 33-33 Glomerular and tubular manifestations of diabetic nephropathy. GBM, glomerular basement membrane; TBM, tubular basement membrane.

These tubular changes represent more than just the aftermath of diabetic nephropathy. The dysregulation of tubular functions in diabetes can precede or accompany the changes in the renal glomerulus and the onset of albuminuria.⁵⁰² Indeed, the functional and structural changes in the proximal tubule may be a key contributor to the development and progression of diabetic nephropathy.⁴⁷⁴ For example, it has been suggested that tubuloglomerular feedback mechanisms can drive hyperfiltration associated with diabetes⁴⁷⁰ and that tubular dysfunction can contribute to albuminuria through defective uptake and lysosomal processing.⁴⁷⁸ Renal function and prognosis correlate better with structural lesions in the tubules and cortical interstitium than with classic glomerular changes of diabetic nephropathy.

Renal Artery Stenosis

Because diabetic patients have, in general, an increased burden of atherosclerosis, they appear to have a higher risk of renal artery stenosis. However, although angiographic studies have demonstrated a high prevalence of renal artery stenosis in diabetic patients, these lesions are often of no hemodynamic significance. Nevertheless, a small subgroup have a hemodynamically significant stenosis enhancing hypertension, increasing the risk of acute pulmonary edema, and inducing progressive renal impairment.⁵⁰³ In such subjects, specific interventions such as surgery or angioplasty need to be considered.⁵⁰⁴ Furthermore, some patients have bilateral renal artery stenosis that, on commencement of treatment with an agent such as an ACE inhibitor, can lead to acute renal failure.⁵⁰⁵ In most patients in this situation, if the renal failure is diagnosed early, cessation of the ACE inhibitor leads to rapid restoration of renal function.

Renal Papillary Necrosis

Renal papillary necrosis involves a severe destructive process that presumably results from ischemia to the medulla and papilla.⁵⁰⁵ Beethoven's final illness might have been papillary necrosis in the context of diabetes.⁵⁰⁷ The papilla is very sensitive to these ischemic changes because even in the normal setting it is exposed to a relatively hypoxic environment. Concomitant exacerbating factors include urinary tract infection and analgesic abuse. The importance of ischemia and possibly angiotensin II in this disorder has been suggested in experimental studies using transgenic rats that overexpress renin and angiotensin II in their kidneys after induction of diabetes.⁵⁰⁸ In these rats, diabetes was associated with development of papillary necrosis, and development of papillary necrosis was prevented by blockade of the renin-angiotensin system. Clinically, papillary necrosis often manifests as flank pain, hematuria, and fever. Urinalysis reveals red and white blood cells, bacteria, and papillary fragments. Ureteric obstruction can occur as a result of these fragments and must be addressed as an emergency.

Renal Tubular Acidosis

A well-known functional abnormality associated with diabetic tubulopathy is *renal tubular acidosis*, which manifests as hyperkalemia and hyperchloremic metabolic acidosis.⁵⁰⁹ This is thought to be a manifestation of hyporeninemic hypoaldosteronism associated with diabetes, which results in reduction of proximal tubule ammonia production to levels that are inadequate to buffer acid in the distal nephron. The precise causes of this abnormality remain to be established. In some patients, there appears to be a defect in the conversion of prorenin to active renin.⁵¹⁰ It

has also been suggested that damage to the tubular cells of the juxtaglomerular apparatus associated with diabetes can contribute to impaired renin release, possibly due to reduced renal prostaglandin production and elevated vasopressin levels.⁵¹¹

A major risk associated with hyporeninemic hypoaldosteronism is the development of life-threatening hyperkalemia. This is an increasingly important issue because of the widespread use of ACE inhibitors and ARBs, often in combination, in this population. This is further exacerbated by the use of potassium-sparing diuretics (e.g., spironolactone) and β -blockers.

Other Renal Manifestations

Because many diabetic subjects have impaired renal function, they are at high risk for increased renal impairment from certain nephrotoxic agents. One of the most important risks relates to radiocontrast dyes.⁵¹² If possible, patients with diabetes and renal impairment should avoid imaging studies that involve the use of contrast agents and, in particular, multiple studies performed in rapid succession. Where intravenous contrast forms an indispensable tool to management, low-osmolality, nonionic or gadolinium-based contrast media may be less nephrotoxic in patients with renal failure.⁵¹³ It is also critical to ensure that patients who require such procedures are well hydrated before, during, and after the procedure. *N*-acetylcysteine, a thiol-containing antioxidant, shows promise to protect against contrast-induced nephropathy.⁵¹⁴ The oral hypoglycemic drug metformin should also be discontinued before contrast procedures to prevent life-threatening lactic acidosis.

Management

Blood pressure and glycemic control represent the major cornerstones for preventing and treating diabetic nephropathy (Figs. 33-34 and 33-35). In the early 1980s a number of Scandinavian researchers found that aggressive BP reduction reduces the rate of progression of diabetic nephropathy,^{515,516} and in the 1990s other researchers found that intensified glycemic control has a similar benefit in both T1DM (DCCT)³⁰⁸ and T2DM (UKPDS) diabetic subjects.⁵¹⁷ These findings have led to the view that optimization of BP and plasma glucose levels should be the mainstay of therapy for diabetic nephropathy.

Glycemic Control

The importance of glucose as a factor in the progression of diabetic kidney disease, as initially suggested from epidemiologic and preclinical studies, was clearly demonstrated in the DCCT study in patients with T1DM.³⁰⁸ In both the primary and secondary prevention cohorts of the study, any decrease in HbA_{1c} was strongly associated with a reduction in the risk of development of microalbuminuria as well as a decrease in the risk of progression to overt nephropathy. The follow-up EDIC study confirmed long-lasting benefits of this therapeutic approach. The UKPDS clearly demonstrated a role for intensified glycemic control in subjects newly diagnosed with T2DM when treatment led to a reduction in HbA_{1c} from 7.9% to 7.0%.⁵¹⁸ The recent ADVANCE study demonstrated that a further reduction of HbA_{1c} to an average of 6.5% was associated with a further reduction in renal events, as assessed by the development and progression of microalbuminuria.⁵¹⁹ Therefore, despite the ongoing controversy as to the appropriate HbA_{1c} target to reduce macrovascular disease brought about by the findings from the ACCORD study,⁵²⁰ no such

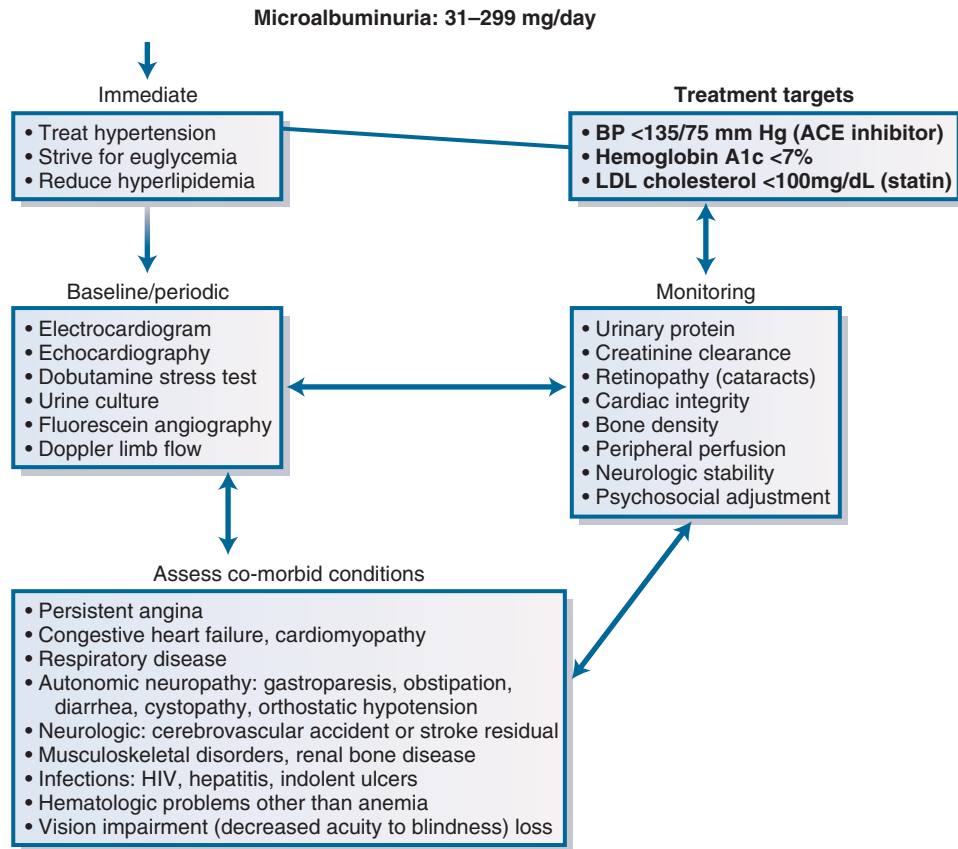

Figure 33-34 Flow chart illustrating the management of diabetic nephropathy before the onset of renal failure. ACE, angiotensin-converting enzyme; BP, blood pressure; HIV, human immunodeficiency virus; LDL, low-density lipoprotein.

controversy as to a possible deleterious effect of intensified glycemic control has been reported with respect to nephropathy.

It remains to be determined how useful intensification of glycemic control is in the setting of overt nephropathy as a last-ditch strategy to delay the onset of ESRD. Aggressive management of hypertension is clearly more important than glycemic control in reducing cardiovascular events and slowing renal disease progression at this stage of relatively advanced disease, although some studies suggest that poor glycemic control can accelerate the loss of renal function in diabetic nephropathy.⁵¹⁷ However, a number of large studies have failed to show any evidence that strict glycemic control *per se* retards renal progression once overt nephropathy is present.⁵²¹ In addition, as renal function fails, tight glycemic control becomes more hazardous, with an increased risk of hypoglycemia. Nonetheless, because there is sufficient evidence that glycemic control can reduce both macrovascular events and microvascular complications of diabetes at other sites, it is reasonable to suggest that optimization of metabolic control in patients with overt nephropathy remains worthwhile.

Similar benefits on renal disease in the context of T2DM are seen after optimization of glycemic control.³ However, the choice of agent remains controversial. Certainly, several types of drugs are able to improve glycemic control in patients with T2DM; however, the particular advantages of one class over another for preventing and treating diabetic nephropathy remain to be established.

A number of differences in the side effect profiles should influence prescribing habits. In patients with renal impairment, particular care must be exercised in selecting and dosing oral agents, because an accumulation of the drug or active metabolites can lead to hypoglycemia (e.g., with glyburide) and other serious adverse effects such as lactic acidosis (e.g., with metformin). Thiazolidinediones, such as pioglitazone and rosiglitazone, should be used with caution in patients with advanced nephropathy who have, or are at risk for, heart failure.

Other agents that directly inhibit glucose-induced changes in various biochemical pathways will likely become available. These include benfotiamine, a thiamine alternative that appears to inhibit the downstream effects of mitochondrial ROS generation,⁵²² and various antiglycation strategies,⁵²³ as outlined previously.

Blood Pressure Control

A sustained reduction in BP appears to be the most important single intervention to prevent progressive nephropathy in T1DM and T2DM. For example, in the UKPDS, a reduction in BP from 154 to 144 mm Hg was associated with a 30% reduction in microalbuminuria.⁵²⁴ All national and international guidelines now emphasize the importance of BP reduction in the diabetic patient. Although many guidelines suggest specific targets to be achieved, no such threshold appears to exist for any renal end point in patients with diabetes. In particular, the risk of progressive diabetic nephropathy continues to decrease with BP reductions into the normal range and below, meaning that the lowest achievable BP is associated with the best clinical outcomes. This is particularly important in those patients with the greatest risk of renal damage (i.e., those with overt nephropathy). In these patients, it has been suggested that optimal BP control is less than 125/75 mm Hg.⁵²⁵ In the recent subanalysis from the BP arm of the ADVANCE study, no BP threshold was detected. Specifically, in those subjects in whom BP was reduced to levels even lower than currently recommended in national and international

guidelines, there was a further decrease in renal events.⁵²⁶ Therefore, it may be worth considering treating some patients with T2DM to achieve BP levels below those currently recommended, provided that the patients can tolerate these lower levels without major side effects such as dizziness and syncope.

There is good evidence that tight BP control, no matter how achieved, is associated with a significant reduction in the risk of microalbuminuria (primary prevention). Although BP reduction appears to be paramount, there is also evidence that ACE inhibitors⁵²⁷ have renoprotective actions beyond their antihypertensive effects for primary prevention.⁵²⁸⁻⁵³⁰ However, if treatment should commence in the normoalbuminuric stage, such a strategy would involve treating the majority of patients who are not at risk for nephropathy. Ideally, it would be useful to be able to identify patients, still normoalbuminuric, whose likelihood of progression is increased. As yet, no such markers of predisposition to renal disease are available, although serum prorenin⁴⁷⁷ and modest elevations in urinary albumin excretion, albeit still within the normal range (borderline microalbuminuria),⁴⁸³ might ultimately be such markers.

The issue of primary prevention has recently been addressed in two studies in which subjects with normoalbuminuria were treated with agents that interrupt the renin-angiotensin system. In the first and smaller trial, which included the performance of sequential renal biopsies, no benefit of early institution of either the ACE inhibitor enalapril or the angiotensin II receptor antagonist losartan was observed (lack of benefit was defined as not only a lack of effect on albuminuria but also no significant retardation in progression of renal morphologic injury).⁵³¹ In the second, much larger trial, known as the DIRECT study, the angiotensin II antagonist, candesartan, despite some modest retinoprotective effects, had no major impact on reducing the new onset of microalbuminuria.⁵³¹

In secondary prevention studies, the additional benefits achieved from blockade of the renin-angiotensin system are clearer.⁵³² A meta-analysis incorporating the findings of more than 10 studies in patients with microalbuminuria demonstrated the ability of ACE inhibitors to retard the development of overt proteinuria and also to decrease urinary albumin excretion by more than 30%. In some patients with microalbuminuria, ACE inhibition can reduce urinary albumin excretion into the normoalbuminuric range.⁵²⁸ In patients with T1DM and overt proteinuria, aggressive BP reduction reduced proteinuria by up to 50% and retarded the rate of decline in renal function.^{515,516}

Similar studies have been performed in patients with T2DM. Two landmark trials, RENAAL (Reduction in End-points in patients with Non-insulin-dependent diabetes mellitus with the Angiotensin II Antagonist Losartan) and IDNT (Irbesartan in Diabetic Nephropathy Trial), examined, respectively, the renoprotective effects of the ARBs losartan and irbesartan.^{533,534} In both studies, when compared with various alternative antihypertensive agents such as calcium antagonists (but not ACE inhibitors), ARB treatment was associated with a reduction in ESRD, a greater than 30% decrease in proteinuria, and a major reduction in hospitalization for heart failure. As a result of these studies, ARBs are recommended as first-line treatment for BP reduction in T2DM patients with overt proteinuria.⁵³⁵

Although ACE inhibitors have not been as extensively studied in this population, the recently reported DETAIL

(Diabetics Exposed to Telmisartan And Enalapril) trial suggested similar renoprotective actions of both drug classes.⁵³⁶ Similar findings comparing the angiotensin II antagonist, telmisartan, to the ACE inhibitor, ramipril, were also reported in the much larger ONTARGET study, although that trial was not performed exclusively in diabetic subjects.⁵³⁷ Therefore, from a clinical perspective, no clear differences between these two drug classes have been identified. (The one exception is cough, which occurs in 5% to 30% of patients taking ACE inhibitors, depending on ethnicity [higher in Asian subjects].) In microalbuminuric T2DM subjects, ARBs have also been demonstrated to have a role. For example, in the IRMA2 (Irbesartan Micro-Albuminuria type 2) trial, irbesartan dose-dependently reduced the risk of development of macroproteinuria,⁵³⁸ confirming the findings seen predominantly with ACE inhibitors in microalbuminuric T1DM subjects.⁵²⁸

Another approach to inhibit the renin-angiotensin system has involved the use of the recently introduced renin inhibitors such as aliskiren. For example, in the AVOID study in T2DM subjects,⁵³⁹ this agent appeared to have an additional effect on albuminuria when administered with the angiotensin II antagonist, losartan. The long-term implications of this drug study for renal function and cardiovascular events are as yet unknown and are under active clinical investigation. Other approaches focusing on BP reduction continue to be examined in these populations. These include use of mineralocorticoid receptor antagonists such as spironolactone⁵⁴⁰ and the more selective agent, eplerenone, which has fewer antiandrogenic side effects.⁵⁴¹ Furthermore, a number of agents at various stages of preclinical and early clinical development are under investigation, including endothelin antagonists and vasopeptidase (dual ACE/neutral endopeptidase [NEP]) inhibitors.⁵⁴²

Other Approaches

Low-protein diets (0.75 g/kg per day) have been shown to retard the progression of renal disease, although the data are not totally convincing for diabetic nephropathy per se. A meta-analysis of five studies in T1DM subjects supported a minor renoprotective role for these diets,⁵⁴³ but this has not been a universal finding.⁵⁴⁴ There are even fewer data in regard to T2DM subjects with overt nephropathy.⁵⁴⁵ However, the expected benefits that can be achieved through protein restriction in patients with diabetic nephropathy are at best modest in comparison with adequate BP control and blockade of the renin-angiotensin system. Moreover, the nutritional impact of such interventions must be carefully considered, particularly in patients with brittle glycemic control.

The role of lipid-lowering agents as renoprotective drugs remains controversial. Although in rodents a large body of evidence suggests that lipids promote renal injury and that various lipid-lowering drugs reduce nephropathy even in the setting of no or minimal effect on lipids,⁵⁴⁶ the data in humans are variable.⁵⁴⁷ However, in a study of fenofibrate in T2DM, there was an impressive reduction in albuminuria.⁵⁴⁸ Furthermore, in the Heart Protection Study, simvastatin appeared to retard the decline in renal function, although this analysis was not confined to the diabetic subgroup.⁵⁴⁹ Another group has also reported a potential renoprotective effect of a statin,⁵⁵⁰ although this effect has not been observed in all studies. Nevertheless, because CVD is so prominent in diabetic patients, particularly those with incipient or overt renal disease, lipid-lowering treatment should be considered in most patients independent of its putative renoprotective actions.⁵⁵¹

Other approaches to consider include correction of anemia with agents such as erythropoietin.⁵⁵² The role of these agents as renoprotective drugs remains to be clarified,⁵⁵³ but the potential benefits in terms of general patient well-being and reduction of left ventricular hypertrophy⁵⁵⁴ provide a rationale for the judicious use of such agents in diabetic patients. However, in the recently reported TREAT study, which focused on cardiovascular events and mortality using the erythropoietin analogue, darbopoietin, the drug was not shown to be renoprotective and was unfortunately associated with a twofold increase in cerebrovascular events.⁵⁵⁵

Over the last few years, several clinical trials targeting diabetic nephropathy with novel agents have yielded disappointing results. For example, PKC- β inhibition with ruboxistaurin, which had renal benefits in experimental diabetes, failed to show any major benefits on albuminuria in T2DM subjects.⁵⁵⁶ Another promising agent, sulodexide, which was postulated to restore the glomerular charge by replenishing the loss of glycosaminoglycans⁵⁵⁷ and thereby act as an antiproteinuric and ultimately renoprotective drug, also failed to demonstrate any evidence of renoprotection in several large trials. Finally, a promising endothelin antagonist, avosentan, was assessed in the ASCEND trial.⁵⁵⁸ Although this drug was associated with impressive reductions in albuminuria, the associated side effect of fluid retention has reduced the current level of enthusiasm for this agent.

Treatment of the Diabetic Uremic Patient

Renal impairment in a patient with diabetes necessitates changes in therapy. Often, blood glucose control becomes more brittle because the half-life of insulin is prolonged and the renal response to hypoglycemia is impaired. High swinging blood glucose levels in a patient with nephropathy can often mistakenly lead to an increase in oral therapy. However, in patients with renal impairment, particular care must be exercised in the selection and dosing of oral hypoglycemic therapy. Nonsteroidal anti-inflammatory drugs (NSAIDs) and cyclooxygenase-2 (COX2) inhibitors should be avoided if possible, because their use is associated with inadequate BP control, often as a result of reduced efficacy of antihypertensive drug therapy. Patients at high risk for progressive deterioration in their renal function should be considered for early referral to a nephrology service for management of renal failure (Fig. 33-36). This facilitates access to erythropoietin therapy and control of calcium phosphate balance and to planning for renal replacement therapy with the preemptive placement of access catheters and lines. Delay in referral can result in a more precipitous start to renal replacement and usually a bad prognostic outcome.⁵⁵⁹

Many options are now available for the diabetic patient requiring renal replacement therapy.⁵⁶⁰ These include home- or facility-based hemodialysis, peritoneal dialysis, renal transplantation (cadaveric or living related donor), and combined pancreas-kidney transplantation. Most patients choose hemodialysis rather than peritoneal dialysis, although the data are conflicting regarding which approach leads to better survival (Table 33-6). Some patients opt for withdrawal of treatment because their quality of life, with advanced CVD, visual impairment, and amputations, is poor.

The Burden of Nephropathy

One must never consider renal disease in a diabetic patient in isolation. Proteinuria per se is strongly associated with

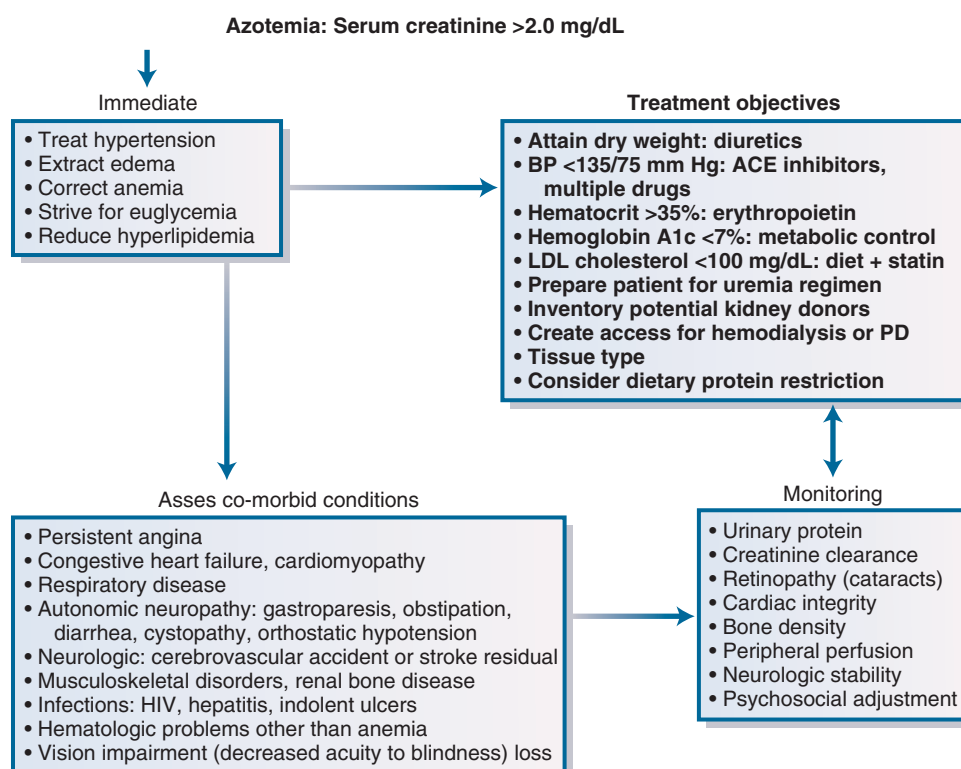

Figure 33-36 Flow chart illustrating the management of diabetic nephropathy after onset of renal failure. ACE, angiotensin-converting enzyme; BP, blood pressure; HIV, human immunodeficiency virus; LDL, low-density lipoprotein; PD, peritoneal dialysis.

TABLE 33-6

Options in Therapy for End-Stage Renal Disease in Diabetic Patients

Variable	Peritoneal Dialysis	Hemodialysis	Kidney Transplantation
Extensive extrarenal disease	No limitation	No limitation except for hypotension	Excluded in cardiovascular insufficiency
Geriatric patients		No limitation	Arbitrary exclusion as determined by program
Complete rehabilitation	Rare, if ever	Very few patients	Common so long as graft functions
Death rate	Much higher than for nondiabetic patients	Much higher than for nondiabetic patients	About the same as for nondiabetic patients
First-year survival	~75%	~75%	>90%
Morbidity during first year	~15 days in hospital	~12 days in hospital	Weeks to months hospitalized
Survival to second decade	Almost never	<5%	~1 in 5
Progression of complications	Usual and unremitting; hyperglycemia and hyperlipidemia	Usual and unremitting; might benefit from metabolic control	Interdicted by functioning pancreas plus kidney; partially ameliorated by correction of azotemia
Special advantage	Can be self-performed; avoids swings in solute and level of intravascular volume	Can be self-performed; efficient extraction of solute and water in hours	Cures uremia; freedom to travel
Disadvantages	Peritonitis; hyperinsulinemia; hyperglycemia, hyperlipidemia; long hours of treatment; more days hospitalized than with either hemodialysis or transplantation	Blood access a hazard for clotting, hemorrhage, and infection; cyclic hypotension, weakness, aluminum toxicity, amyloidosis	Cosmetic disfigurement, hypertension, personal expense for cytotoxic drugs; induced malignancy; HIV transmission
Patient acceptance	Variable, usual compliance with passive tolerance for regimen	Variable; often noncompliant with dietary, metabolic, or antihypertensive components of regimen	Enthusiastic during periods of good renal allograft function; exalted when pancreas proffers euglycemia
Relative cost	Most expensive over long run	Less expensive than kidney transplantation in the first year; subsequent years more expensive	Pancreas plus kidney engraftment most expensive uremia therapy for diabetics; after first year, kidney transplantation alone is lowest-cost option

other complications such as macrovascular disease, heart failure, and retinopathy, and treatments directed toward one complication may be useful for the others. Intensified glycemic control has been shown to be particularly useful for other microvascular complications,² and the various antihypertensive regimens, particularly those using agents that interrupt the renin-angiotensin system, also confer important cardiovascular benefits, such as reducing heart failure.⁵³³ Therefore, as clearly expounded in the Steno-2 study, the multifactorial approach in microalbuminuric subjects leads to renal benefits and also confers other advantages to the diabetic patient.⁵⁶¹ Because those patients with renal disease have the greatest risk for nonrenal complications, it stands to reason that they also are likely to have the greatest absolute benefit from risk-reduction strategies.

DIABETIC NEUROPATHIES

Diabetic neuropathies are a heterogeneous group of disorders that cause a wide range of abnormalities. They are among the most common long-term complications of diabetes and are a significant source of morbidity and mortality.^{562,563} Estimates of the prevalence of neuropathy vary substantially, depending on specific diagnostic criteria.^{564,565} In the United States, prevalence estimates have ranged from 5% to 100%.^{562,564,565-567} In Pirart's classic study of a cohort of 4400 diabetic patients, prevalence was found to reach approximately 45% after 25 years.⁵⁶⁸ Using this estimate, about 7 million persons in the United States alone have diabetic neuropathy, and about 2.7 million have painful neuropathy.⁵⁶⁹ Furthermore, it is now evident that neuropathy can occur with impaired glucose tolerance⁵⁷⁰ and with the metabolic syndrome in the absence of hyperglycemia.⁵⁷¹ It is the most common form of neuropathy in the developed countries of the world; it accounts for more hospitalizations than all the other diabetic complications combined; and it is responsible for 50% to 75% of non-trauma amputations.^{566,567} Diabetic peripheral neuropathy is also responsible for weakness and ataxia, with an estimated increase in likelihood of falling that is 15 times that of the unaffected population.^{572,573}

Diabetic neuropathy is a set of clinical syndromes that affect distinct regions of the nervous system, singly or combined. Clinical signs and symptoms can be nonspecific and insidious, and progression can be slow. Neuropathy can be silent and go undetected while exercising its ravages, or it can manifest with clinical symptoms and signs that mimic those seen in many other diseases. It is, therefore, diagnosed by exclusion.

The true prevalence is not known and depends on the criteria and methods used to define neuropathy. Of patients attending a diabetes clinic, 25% volunteered symptoms, but 50% were found to have neuropathy after a simple clinical test such as eliciting the ankle reflex or vibration perception test. Almost 90% tested positive on sophisticated tests of autonomic function or peripheral sensation.⁵⁷⁴ Neuropathy is grossly underdiagnosed by endocrinologists and nonendocrinologists.⁵⁷⁵ Neurologic complications occur equally in T1DM and T2DM and additionally in various forms of acquired diabetes.⁵⁶⁵

The major morbidity associated with somatic neuropathy is foot ulceration, the precursor of gangrene and limb loss. Neuropathy increases the risk of amputation 1.7-fold overall, 12-fold if there is deformity (itself a consequence of neuropathy), and 36-fold if there is a history of previous ulceration.⁵⁷⁶ There are 96,000 amputations performed in

the United States each year, one every 10 minutes, and neuropathy is the major contributor in 87% of cases.⁵⁶³ It has tremendous negative effects on the quality of life of persons with diabetes.⁵⁷⁷ Once autonomic neuropathy is present, life can become quite dismal, and the mortality rate approximates 25% to 50% within 5 to 10 years.⁵⁷⁸⁻⁵⁸¹ The presence of neuropathy can severely affect quality of life, causing impaired activities of daily living, compromised physical functioning, and depression.^{577,582} Impairment of physical functioning is associated with a 15-fold increase in the likelihood of falling and fractures, particularly in older diabetics.⁵⁸³ Depression complicates the management of neuropathic pain and is a predictor of progression of neuropathy.⁵⁸²

Classification

Diabetic neuropathy is not a single entity but a number of different syndromes with subclinical or clinical manifestations depending on the classes of nerve fibers involved. According to the San Antonio Convention,⁵⁸⁴ the main groups of neurologic disturbance in diabetes mellitus include the following:

- Subclinical neuropathy, which is determined by abnormalities in electrodiagnostic and quantitative sensory testing
- Diffuse clinical neuropathy with distal symmetric sensorimotor and autonomic syndromes
- Focal syndromes

Subclinical neuropathy is diagnosed on the basis of abnormal electrodiagnostic tests with decreased nerve conduction velocity (NCV) or decreased amplitudes; abnormal quantitative sensory tests (QST) for vibration, tactile, thermal warming, and cooling thresholds; and quantitative autonomic function tests (QAFT) revealing diminished heart rate variation with deep breathing, Valsalva maneuver, and postural testing. The importance of the skin biopsy as a diagnostic tool for diabetic polyneuropathy (DPN) is now firmly established.^{571,585} This technique quantitates small epidermal nerve fibers through antibody staining of the panaxonal marker protein gene product 9.5 (PGP 9.5). It is minimally invasive (3-mm-diameter punch biopsies), yet enables a direct study of small fibers that cannot be evaluated by NCV studies. Intraepidermal nerve fiber density is reduced in approximately 88% of subjects with small-fiber neuropathy, compared with 10% of healthy controls.⁵⁸⁶ Skin biopsy with intraepidermal nerve fiber density evaluation may be more sensitive than either clinical examination or quantitative sensory testing for detecting abnormalities in subjects with the small-fiber neuropathy phenotype. In a recent retrospective evaluation of 486 patients referred to neurology or neuromuscular disease clinics, skin biopsy showed a diagnostic efficiency of 88.4%, compared with 54.6% for clinical examination and 46.9% for QSTs.⁵⁸⁷ The last evidence-based review on distal symmetric polyneuropathy from the American Academy of Neurology concluded that skin biopsy is a validated technique for determining intraepidermal nerve fiber density and may be considered for the diagnosis of DPN, particularly small-fiber sensory neuropathy.⁵⁸⁸

The different clinical presentations of diabetic neuropathy are schematically illustrated in Figure 33-37.

Natural History

The natural history of neuropathies separates them into two distinct entities: those that progress gradually with

Figure 33-37 Clinical presentations of diabetic neuropathies. (Modified from Pickup J, Williams G, eds. *Textbook of Diabetes*, Vol 1. Oxford, UK: Blackwell Scientific, 1997.)

increasing duration of diabetes and those that remit, usually completely. Sensory and autonomic neuropathies typically progress. Although the symptoms of mononeuropathies, radiculopathies, and acute painful neuropathies are severe, they are short-lived, and patients tend to recover.⁵⁸⁹

Progression of neuropathy is related to glycemic control in both T1DM and T2DM.^{590,591} The most rapid deterioration of nerve function occurs soon after the onset of T1DM, and within 2 to 3 years the rate of progression slows. In contrast, in T2DM, slowing of NCVs may be one of the earliest neuropathic abnormalities and often is present even at diagnosis.⁵⁹² After diagnosis, slowing of NCV usually progresses at a steady rate of approximately 1 m/sec per year, and the level of impairment is positively correlated with duration of diabetes. Although in most studies, symptomatic patients are more likely to have slower NCVs than patients without symptoms, NCVs do not relate to the severity of symptoms. In a long-term follow-up study of T2DM patients,⁵⁹³ the prevalence of electrophysiologic abnormalities in the lower limb increased from 8% at baseline to 42% after 10 years.

A decrease in sensory and motor amplitudes, indicating axonal destruction, is more pronounced than the slowing of the NCVs. An increase of about 2 points in an 80-point clinical scale can be expected per year. These scales contain information on motor, sensory, and autonomic signs and symptoms. Using objective measures of sensory function, such as the vibration perception threshold test, the rate of decline in function has been reported to be 1 to 2 vibration units per year. However, this rate of evolution may be declining. For example, in a study of nerve growth factor (NGF), the vibration perception threshold in the placebo group was identical to that in the treatment group at the beginning of the study and at the end of 1 year.^{594,595}

Host factors pertaining to general health and nerve nutrition are changing. This is particularly important in studies on the treatment of diabetic neuropathy, which have always relied on differences between drug treatment

and placebo and have apparently been successful because of the decline in placebo-treated patients.⁵⁹⁶ Based on the earlier estimates of change, clinically meaningful loss of vibration perception and conduction velocity was estimated to take at least 3 years, dictating the need for studies to be carried out over a longer period of time.

It is also important to recognize that diabetic neuropathy is a disorder in which the prevailing abnormality is a loss of axons that electrophysiologically translates to a reduction in the amplitude and not the velocity of conduction. Changes in NCV might not be an appropriate means of monitoring progress or deterioration of nerve function. It has always been assumed that diabetes affects the longest fibers first—hence, the increased predisposition in taller persons.⁵⁹⁷ Now it seems that small-fiber involvement can herald the onset of neuropathy and even diabetes. Small-fiber function is not detectable by standard electrophysiology and requires measurement of sensory, neurovascular, and autonomic thresholds and cutaneous nerve fiber density.^{571,598-600} There are few data on the longitudinal trends in small-fiber dysfunction, although it appears that the nerve fiber loss in prediabetic neuropathy might respond to lifestyle changes.⁶⁰¹

Much remains to be learned about the natural history of diabetic autonomic neuropathy. Karamitsos and colleagues⁶⁰² have reported that the progression of diabetic autonomic neuropathy is significant during the 2 years following its discovery. The mortality rate for diabetic autonomic neuropathy has been estimated to be 44% within 2.5 years after diagnosis of symptomatic autonomic neuropathy.⁵⁷⁸ A meta-analysis⁶⁰³ revealed that the mortality rate after 5.8 years of diabetes with symptomatic autonomic neuropathy was 29%. In a meta-analysis of 12 published studies, reduced cardiovascular function as measured by heart rate variability was shown to be associated with an increased risk of silent MI.⁵⁸¹

Similarly, a meta-analysis of prospective studies demonstrated increased mortality in patients with cardiac autonomic neuropathy, with the risk ratio increasing in direct

proportion to the number of autonomic abnormalities.^{580,581} The RR of mortality from 15 studies ($N = 2900$) was increased in patients with cardiac autonomic neuropathy by 2.14 (95% confidence interval [CI], 1.83 to 2.51).⁵⁸¹ However, if cardiac autonomic neuropathy is defined by the presence of at least two abnormal autonomic function tests, this risk increased to 3.45 (95% CI, 2.66 to 4.47).⁵⁸⁰ Probably the greatest justification for carrying out autonomic function tests resides in their predictive capacity for subsequent cardiovascular events and unexplained sudden death. In the ACCORD study, there was a significant increase in mortality in the intensively treated arm of glycemic control. Analysis of the hazard risk of mortality revealed an increase of up to 2.5 with loss of heart rate variability. If symptoms of neuropathy such as numbness were included, the risk rose to 4.33.⁶⁰⁴ This is a cogent argument for identifying people at risk and tailoring the management of diabetes accordingly, as well as a serious consideration for study designs estimating cardiovascular risk or benefit for the future.

Clinical Presentation

An international consensus meeting on the outpatient diagnosis and management of diabetic neuropathy agreed on the following as a simple definition of diabetic neuropathy: "the presence of symptoms and/or signs of peripheral nerve dysfunction in people with diabetes after the exclusion of other causes."⁵⁸⁸ It was also agreed that neuropathy cannot be diagnosed without a careful clinical examination; absence of symptoms cannot be equated with absence of neuropathy, because asymptomatic neuropathy is common. The American Diabetes Association (ADA) has endorsed these recommendations.⁶⁰⁵

The importance of excluding nondiabetic causes was emphasized in the Rochester Diabetic Neuropathy Study, in which up to 10% of peripheral neuropathy in diabetic patients was deemed to be of nondiabetic etiology.⁵⁶⁵ Many conditions need to be excluded before the diagnosis of diabetic neuropathy can be made.⁵⁶³ A more detailed definition of neuropathy was previously accepted by the San Antonio Consensus Conference: "Diabetic neuropathy is a descriptive term meaning a demonstrable disorder, either clinically evident or sub-clinical, that occurs in the setting of diabetes mellitus without other causes for peripheral neuropathy. The neuropathic disorder includes manifestations in the somatic and/or autonomic parts of the peripheral nervous system."⁵⁸⁴ A consensus panel was convened in 2009 and revised some of these definitions, but the information is not as yet in the public domain.

It is generally agreed that diabetic neuropathy should not be diagnosed on the basis of one symptom, sign, or test alone. A minimum of two abnormalities (from symptoms, signs, nerve conduction abnormalities, quantitative sensory tests, or quantitative autonomic tests) is recommended.⁶⁰⁶ Diabetic neuropathy is, however, woefully underdiagnosed by endocrinologists as well as nonendocrinologists. In the GOAL A_{1c} study,⁵⁷⁵ the absence of neuropathy in 7000 patients could be adequately determined, but the presence of mild neuropathy was detected accurately only one third of the time, and accuracy of detection reached 75% only if neuropathy was severe. Clearly, there is a need for education on methods for detecting neuropathy.

The spectrum of clinical neuropathic syndromes described in patients with diabetes mellitus includes dysfunction of almost every segment of the somatic peripheral and autonomic nervous systems.⁶⁰⁷ It has been said that to

TABLE 33-7

Mononeuritis and Entrapment Syndromes

Feature	Mononeuritis	Entrapment
Onset	Sudden	Gradual
Nerves	Usually single but may be multiple	Single nerves exposed to trauma
Common nerves	C3, C6, C7, ulnar; median, peroneal	Median, ulnar; peroneal, medial and lateral plantar
Progression	Not progressive; resolves spontaneously	Progressive
Treatment	Symptomatic	Rest, splints, diuretics, steroid injections, surgery for paralysis

Adapted from Vinik A, Mehrabyan A. Diabetic neuropathies. *Med Clin North Am*. 2004;88:947-999.

know neuropathy means to know the whole of medicine. Each syndrome can be distinguished by its pathophysiologic, therapeutic, and prognostic features.

Focal Neuropathies

Mononeuropathies occur primarily in the older population. Their onset is usually acute and associated with pain, and their course is self-limited, resolving within 6 to 8 weeks. Mononeuropathies result from vascular obstruction after which adjacent neuronal fascicles take over the function of those infarcted.⁶⁰⁸ Mononeuropathies must be distinguished from entrapment syndromes, which start slowly, progress, and persist without intervention (Table 33-7). Common entrapment sites in diabetic patients involve median, ulnar, and radial nerves; femoral nerves, lateral cutaneous nerves of the thigh, and peroneal nerves; and the medial and lateral plantar nerves.

Carpal tunnel syndrome occurs three times as often in persons with diabetes than in a normal, healthy population,^{609,610} and its increased prevalence in diabetes may be related to diabetic cheiroarthropathy,⁶¹¹ repeated undetected trauma, metabolic changes, or accumulation of fluid or edema within the confined space of the carpal tunnel.⁶⁰⁷ It is found in up to one third of patients with diabetes.⁶¹² If carpal tunnel syndrome is recognized, the diagnosis can be confirmed by electrophysiologic study, and therapy is simple, with surgical release. The mainstays of nonsurgical treatment are resting of the wrist, aided by the placement of a wrist splint in a neutral position for day and night use, and the addition of anti-inflammatory medications. Surgical treatment consists of sectioning the volar carpal ligament.⁶¹³ The decision to proceed with surgery should be based on several considerations, including severity of symptoms, appearance of motor weakness, and failure of nonsurgical treatment.⁶¹⁴

Diffuse Neuropathies

Proximal Motor Neuropathies. For many years, proximal neuropathy has been considered to be a component of diabetic neuropathy, although its pathogenesis was ill understood.⁶¹⁵ The condition has a number of synonyms: proximal neuropathy, femoral neuropathy, diabetic amyotrophy, and diabetic neuropathic cachexia.

Proximal motor neuropathy has certain common features. It primarily affects the elderly. Its onset, which can be gradual or abrupt, begins with pain in the thighs and hips or buttocks, followed by significant weakness of the proximal muscles of the lower limbs with inability to rise from the sitting position (positive Gower's maneuver). The

neuropathy begins unilaterally, spreads bilaterally, and coexists with DSPN and spontaneous muscle fasciculation. It can be provoked by percussion.

The condition is now recognized as secondary to a variety of causes that are unrelated to diabetes but have a greater incidence in patients with diabetes than in the general population. These include chronic inflammatory demyelinating polyneuropathy (CIDP), monoclonal gammopathy, circulating monosialoganglioside (GM1) antibodies and antibodies to neuronal cells, and inflammatory vasculitis.^{616,617} Proximal motor neuropathy was formerly thought to resolve spontaneously in 1.5 to 2 years. However, immune-mediated neuropathy can resolve within days on immunotherapy, such as intravenous immunoglobulin, Etanercept or Immuran.⁶¹⁸

The condition is readily recognizable clinically; there is prevailing weakness of the iliopsoas, obturator, and adductor muscles, together with relative preservation of function of the gluteus maximus and minimus and hamstrings.⁶¹⁹ Patients have great difficulty rising out of chairs unaided and often use their arms to assist themselves. Heel or toe standing is surprisingly good. In the classic form of diabetic amyotrophy, axonal loss is the predominant process, and the condition coexists with DSPN.⁶²⁰ Electrophysiologic evaluation reveals lumbosacral plexopathy.⁶¹⁹

If demyelination predominates and the motor deficit affects proximal and distal muscle groups, a diagnosis of CIDP, monoclonal gammopathy of unknown significance (MGUS), or vasculitis should be considered.^{621,622} It seems probable that these conditions occur more commonly in people with diabetes.^{623,624} Vinik and colleagues^{573,615-627} have pointed out that almost half the patients with proximal neuropathies have a vasculitis and all but 9% have CIDP or MGUS or a ganglioside antibody syndrome.⁶²⁸ Sharma examined more than 1000 patients with neurologic disorders and found that CIDP was 11 times more common in people with diabetes than in the nondiabetic population.⁶²⁴

Biopsy of the obturator nerve reveals demyelination, deposition of immunoglobulin, and inflammatory cell infiltrate of the vasa nervorum (Fig. 33-38).⁶²⁹ Cerebrospinal fluid protein content is high, and there is an increase in the lymphocyte count. Treatment options include intravenous immunoglobulin for CIDP, plasma exchange for MGUS, steroids and azathioprine for vasculitis, and withdrawal from drugs or other agents that might have caused a vasculitis. It is important to divide proximal syndromes into these subcategories, because the CIDP variant responds dramatically to intervention,^{621,630} whereas amyotrophy runs its own course over months to years. Until more

Spinal stenosis/clauidication

- Dull to severe pain in the buttocks and lower back triggered by walking, especially downhill
- Pain radiates into one or both legs (60%)
- Numbness, weakness, paresthesiae of lower extremities
- Relief when sitting, leaning forward, or resting

Figure 33-39 Spinal stenosis syndromes.

evidence is available, they should be considered separate syndromes.

These conditions need to be distinguished from spinal stenosis syndromes (Fig. 33-39). In spinal stenosis, there is encroachment on nerve roots as they emerge from the spinal cord, and osteophytes can cause compression. With aging, there is hypertrophy of the ligamentum flavum and disk dehydration, and there may even be some form of arachnoiditis. When the compression involves the vascular system, claudication typically occurs on walking downhill, is relieved by bending forward, and originates at the watershed level between T12 and L1-2. Nerve root compression is more typical at L5-S1, and in difficult cases it may be necessary to obtain a magnetic resonance image (MRI) of the lumbosacral spine. Diagnosis is critical, because therapy may range from simple physical therapy to surgical decompression if symptoms are severe or there is motor paralysis.

Distal Symmetric Polyneuropathy. DSPN is the most common and widely recognized form of diabetic neuropathy. The onset is usually insidious but occasionally is acute, occurring after stress or initiation of therapy for diabetes. DSPN may be sensory or motor and can involve small fibers, large fibers, or both.⁶³¹ Figure 33-40 is a simplified schematic diagram of the fibers of the peripheral nervous system. Also shown in Figure 33-40 is the usual clinical presentation of the large- and small-fiber neuropathies.

Dysfunction of the small nerve fibers usually occurs early and often is present without objective signs or electrophysiologic evidence of nerve damage.⁶³² It is manifested early with symptoms of pain and hyperalgesia in the lower limbs, followed by a loss of thermal sensitivity and reduced sensation to light touch and pinprick.⁶⁰⁷

There is evidence that DSPN may be accompanied by loss of cutaneous nerve fibers that stain positive for the neuronal antigen PGP 9.5⁶³³ (Fig. 33-41) and by impaired neurovascular blood flow.⁶³⁴ The importance of the skin

Figure 33-40 Simplified view of the peripheral nervous system (PNS). GIT, gastrointestinal tract; GUT, genitourinary tract. (Vinik A, Ullal J, Parson H, et al. Diabetic neuropathies: clinical manifestations and current treatment options. *Nat Clin Pract Endocrinol Metab.* 2006;2:269-281.)

biopsy as a diagnostic tool for diabetic peripheral neuropathy is increasingly being recognized.^{571,598,635,636} This technique quantitates small epidermal nerve fibers through antibody staining of PGP 9.5.^{629,637,638} It is minimally invasive (3-mm-diameter punch biopsies) but enables direct study of small fibers that cannot be evaluated by NCV studies (see Fig. 33-37). More recently, assessment of small nerve fiber function has been carried out using corneal confocal microscopy,^{2,3} laser doppler flare response to heat or acetylcholine, sudomotor responses to cholinergic stimulation,⁴⁻⁶ and Contact Heat Evoked Potentials.⁷ However, the sensitivity and specificity of these techniques have not yet been established.

Pain in Diabetic Neuropathies

Overall, approximately 10% of patients with diabetes experience persistent pain from neuropathy.⁶³⁹ Pain syndromes

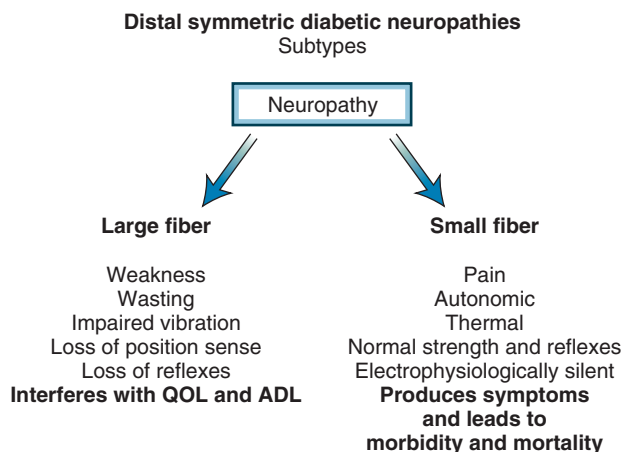

Figure 33-41 Differences in clinical presentations of large- and small-fiber neuropathies. ADL, activities of daily living; QOL, quality of life. (Adapted from Vinik AI, Mehrabyan A. Diabetic neuropathies. *Med Clin North Am.* 2004;88:947-999.)

that last less than 6 to 12 months are classified as acute. These include the insulin neuritis syndrome, which occurs often at the beginning of therapy for diabetes and is self-limited. Pain syndromes lasting longer than 6 to 12 months are classified as chronic.⁶⁴⁰ The pain may be ongoing, spontaneous, or hyperalgesic (increased response to a painful stimuli). It can be severe and is sometimes intractable.

Management of painful diabetic neuropathy, as well as other pain syndromes, is changing as research elucidates underlying pathophysiologic mechanisms. The complexities of pain syndromes and advances in basic pain research have contributed to an evolving concept of pain and strategies for its management. Backonja defined neuropathic pain as “a group of disorders characterized by pain due to dysfunction or disease of the nervous system at a peripheral level, a central level, or both.”⁶⁴¹

Acute Painful Neuropathy

Some patients develop a predominantly *small-fiber neuropathy*, which is manifested by pain and paresthesias early in the course of diabetes (Fig. 33-42). It may be associated with the onset of insulin therapy and has been termed *insulin neuritis*.⁶⁴² By definition, it has been present for less than 6 months.

Symptoms often are exacerbated at night and are manifested in the feet more than the hands. Spontaneous episodes of pain can be severely disabling. The pain varies in intensity and character. In some patients, this pain has been variably described as burning, lancinating, stabbing, or sharp. Paresthesias or episodes of distorted sensation, such as pins and needles, tingling, coldness, numbness, or burning, often accompany the pain.⁶³¹ The lower legs may be exquisitely tender to touch, with any disturbance of the hair follicles resulting in excruciating pain. Because pain can be aggravated by repeated contact of the lower limbs with foreign objects, even basic daily activities such as

Figure 33-42 Loss of cutaneous nerve fibers that stain positive for the neuronal antigen protein gene product 9.5 (PGP 9.5) in sensory neuropathy. **A**, Normal epidermal fibers in the back. **B**, Slightly reduced density and swelling in the proximal thigh. **C**, Complete clearance in calf. (From McArthur JC, Stocks EA, Hauer P. Epidermal nerve fiber density: normative reference range and diagnostic efficiency. *Arch Neurol.* 1998;55:1513-1520.)

sitting at a desk may be disrupted. Pain often occurs at the onset of the disease and is often worsened by initiation of therapy with insulin or sulfonylureas.⁶⁴² Recently, Vinik has provided an outline of the approach to the management of patients with what has been referred to as the “insulin neuritis syndrome.”⁸

Neuropathy may be associated with profound weight loss and severe depression that has been termed *diabetic neuropathic cachexia*.⁶⁴³ This syndrome occurs predominantly in male patients and can occur at any time in the course of T1DM or T2DM. It is self-limited and invariably responds to simple symptomatic treatment. Conditions such as Fabry’s disease, amyloid, human immunodeficiency virus (HIV) infection, heavy metal poisoning (e.g., arsenic), and excess alcohol consumption should be excluded. Acute painful neuropathy does overlap with the idiopathic variety of acute painful small-fiber neuropathy that is also a diagnosis by exclusion.⁶⁴⁴

Chronic Painful Neuropathy

Chronic painful neuropathy is another variety of painful polyneuropathy. Onset is later, often years into the course of the diabetes; pain persists for longer than 6 months and becomes debilitating (see Fig. 33-40). This condition can result in tolerance to narcotics and analgesics, finally resulting in addiction. It is extremely resistant to all forms of intervention and is most frustrating to both patient and physician.

Pathophysiologic changes in the nervous system can produce symptoms defined as either negative (e.g., loss of sensory quality) or positive (e.g., spontaneous pain). Patients with neuropathic pain usually present with both positive and negative symptoms. Absence of pain sometimes is not from improvement in neuropathy but is rather a consequence of neuronal loss. Physicians must exclude progression of neuropathy when patients report loss of pain. Neuropathic pain can manifest as stimulus-independent pain or as stimulus-evoked or stimulus-dependent pain, whose underlying mechanisms are likely to differ. A simplified scheme of pain generation is shown in Figure 33-43.

Similarly, the mechanisms responsible for hyperalgesia and allodynia differ. Hyperalgesia is defined as an increased pain response to a normally painful stimulus. Allodynia occurs when pain is provoked by a stimulus that is not normally painful. This difference is related to the different nerve pathways implicated. For example, aberrations of the C and A δ fibers can result in the burning and prickling sensations of stimulus-independent pain or of hyperalgesia. Under pathologic conditions, touch-sensitive A β fibers can cause stimulus-independent dysesthesias or paresthesias or stimulus-evoked allodynia.

Small-Fiber Neuropathies

Symptoms are prominent in small-fiber neuropathies. Pain is of the C-fiber type. It is burning and superficial and is associated with allodynia. Patients have defective autonomic function with decreased sweating, dry skin, impaired vasomotion and blood flow, and cold feet. There are abnormalities in thresholds for warm thermal perception, neurovascular function, pain, quantitative sudorimetry, and QAFTs. Late in the condition, hypoalgesia is present. However, there is remarkable intactness of reflexes and motor strength.

Clinical diagnosis is by reduced sensitivity to 1.0-g Semmes-Weinstein monofilament and a pricking sensation on the Waardenberg wheel or similar instrument. These neuropathies are electrophysiologically silent, but there is loss of cutaneous nerve fibers that stain for PGP 9.5. These

Figure 33-43 Schematic representation of the generation of pain. *Left panel*, Normal situation, no pain. Central terminals of unmyelinated primary C-afferents project into the dorsal horn and make contact with secondary pain-signaling neurons. Low-threshold mechanoreceptive primary A β -afferents project without synaptic transmission into the dorsal columns (not shown) and also contact secondary afferent dorsal horn neurons. *Center-left panel*, Peripheral sensitization and central sensitization processes in peripheral nociceptors (peripheral sensitization, star in the periphery) leading to spontaneous burning pain, static mechanical hyperalgesia, and heat hyperalgesia. This spontaneous activity in nociceptors induces secondary changes in central sensory processing, leading to spinal cord hyperexcitability (central sensitization, star in spinal cord) that causes input from mechanoreceptive A β fibers (light touching) and A δ fibers (punctuate stimuli) to be perceived as pain (dynamic and punctuate mechanical allodynia). Moreover, afferent terminals in the periphery or afferent somata in the dorsal root ganglion acquire sensitivity to norepinephrine (noradrenaline, NA) through expression of A-receptors at their membrane. Activity in postganglionic sympathetic neurons is then capable of activating afferent neurons through the release of NA. *Center-right panel*, Synaptic reorganization after C-nociceptor degeneration. Nociceptor function may be selectively impaired and the fibers may degenerate after nerve lesion. Accordingly, the synaptic contacts between central nociceptor terminals and secondary nociceptive neurons are reduced. Central terminals from intact mechanoreceptive A β fibers start to sprout to form novel synaptic contacts with the free central nociceptive neurons. This anatomic reorganization in the dorsal horn causes input from mechanoreceptive A β fibers (light touching) to be perceived as pain (dynamic mechanical allodynia). In such patients, temperature sensation is profoundly impaired in areas of severe allodynia. *Right panel*, Central disinhibition and cold hyperalgesia. Normally, cold stimuli are conveyed by A δ fibers and cold pain by C fibers. A selective damage of cold-sensitive A δ fibers leads to a loss of central inhibition mediated by interneurons (disinhibition), resulting in cold hyperalgesia. (Adapted from Vinik A, Mehrabyan A. Diabetic neuropathies. *Med Clin North Am*. 2004;88:947-999.)

may also be detected by evaluation of corneal confocal microscopy, laser doppler flare reactions, and contact heat-evoked potentials as outlined previously, but sensitivity and specificity of each remain to be defined.

Large-Fiber Neuropathies

Large-fiber neuropathies can involve sensory or motor nerves, or both. These tend to be the neuropathies of signs rather than symptoms. Large fibers subserve motor function, vibration perception, position sense, and cold thermal

perception. Unlike the small nerve fibers, these are the myelinated, rapidly conducting fibers that begin in the toes and have their first synapse in the medulla oblongata. They tend to be affected first because of their length and the tendency in diabetes for nerves to die back. Because they are myelinated, they are the fibers represented in the electromyogram, and subclinical abnormalities in nerve function are readily detected. The symptoms may be minimal and include a sensation of walking on cotton, floors feeling strange, inability to turn the pages of a book, or inability to discriminate among coins.

Clinical Presentation

Signs and symptoms of large-fiber neuropathy include impaired vibration perception (often the first objective evidence) and position sense, depressed tendon reflexes, and sensory ataxia (waddling like a duck). A δ -fiber pain is deep-seated, gnawing, dull, like a toothache in the bones of the feet, or even crushing or cramp-like pain. Signs in the distal lower extremities include wasting of the small muscles of the feet, with hammertoes (intrinsic minus feet and hands) and weakness of the feet; shortening of the Achilles tendon with pes equinus; and increased blood flow (hot foot). Patients also have weakness in the hands.

Most patients with DSPN, however, have a mixed variety of neuropathy, with both large and small nerve fiber damage. In the case of DSPN, a glove-and-stocking distribution of sensory loss is almost universal.⁶⁰⁷ Early in the course of the neuropathic process, multifocal sensory loss also may be found. In some patients, severe distal muscle weakness can accompany the sensory loss, resulting in an inability to stand on the toes or heels. Some grading systems use this as a definition of severity.

Diagnosis and Differential Diagnosis of Peripheral Neuropathy

The diagnosis of diabetic neuropathy rests heavily on a careful history, for which a number of questionnaires have been developed by Young and colleagues,⁵⁶⁴ Dyck,⁶⁴⁵ Vinik,⁶⁴⁶ and others.^{647,648} The initial neurologic evaluation should be directed toward detecting the specific part of the nervous system affected by diabetes (Fig. 33-44). Bedside neurologic examination is quick and easy but provides nominal or ordinal measures and contains substantial interindividual and intraindividual variation. For example, it is useless to measure vibration perception with a tuning fork other than one that has a frequency of 128 Hz.

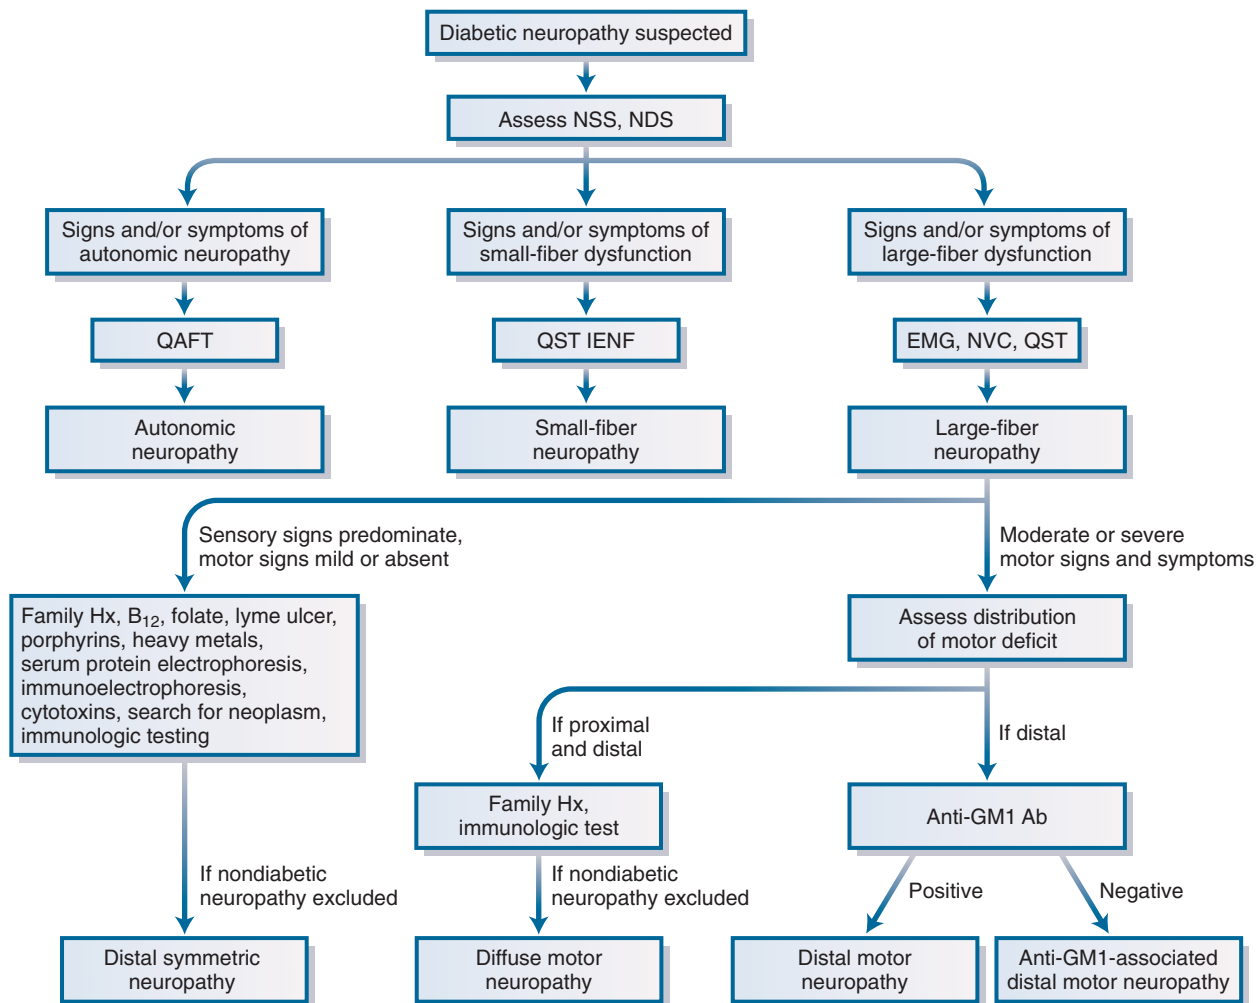

Figure 33-44 A diagnostic algorithm for assessing neurologic deficit and classification of neuropathic syndrome. Ab, antibody; EMG, electromyogram; GM1, monosialoganglioside; Hx, history; IENF, intraepidermal nerve fiber density; MGUS, monoclonal gammopathy of unknown significance; NCV, nerve conduction velocity; NDS, nerve disability (sensory and motor evaluation); NSS, neurologic symptom score; QAFI, quantitative autonomic function tests; QST, quantitative sensory tests. (Adapted with permission from Vinik A, Mehrabian A. Diabetic neuropathies. *Med Clin North Am*. 2004;88:947-999.)

Similarly, use of a 10-g monofilament is good for predicting foot ulceration, as is the Achilles reflex, but both are insensitive to the early detection of neuropathy; a 1.0-g monofilament increases the sensitivity of detection from 60% to 90%.⁶⁴⁹

Sensory function must be evaluated on both sides of the feet and hands if one wants to be sure not to miss entrapment syndromes.⁶⁵⁰ Tinel's sign is not only useful for carpal tunnel problems but can also be applied to the ulnar notch, the head of the fibula, and below the medial tibial epicondyle for ulnar, peroneal, and medial plantar entrapments, respectively.

The 2010 Toronto conference on diabetic neuropathy¹ and the 2009 conference of the American Academy of Neurology⁹ recommended that at least one parameter from each of the following five categories be measured to classify diabetic neuropathy: symptom profiles, neurologic examination, QST, nerve conduction study, and autonomic function testing. A number of simple symptom screening questionnaires are available to record symptom quality and severity. A simplified neuropathy symptom score that was used in the European prevalence studies could also be useful in clinical practice.^{564,651} The Michigan Neuropathy Screening Instrument (MNSI) is a 15-item questionnaire that can be administered to patients as a screening tool for neuropathy.⁶⁴⁸ Other similar symptom-scoring systems have also been described, such as the nerve impairment score of the lower limbs (NIS-LL).⁶⁵²

Simple visual analogue or verbal descriptive scales may be used to monitor patients' responses to treatment of their neuropathic symptoms.^{213,653,654} However, it must always be remembered that identification of neuropathic symptoms is not useful as a diagnostic or screening tool in assessing diabetic neuropathy, as was shown by Franse and colleagues.⁶⁵⁵ The QST and QAFT are objective indices of neurologic functional status. Combined, these tests cover vibratory, proprioceptive, tactile, pain, thermal, and autonomic function. A useful tool that evaluates quality of life in relation to health status and quantifies symptoms of small, large, and autonomic nervous system dysfunction has been validated and translated into 35 different languages and is being used globally as an endpoint in studies on neuropathy.¹⁰

An international group of experts in diabetic neuropathy held a consensus meeting to develop guidelines for management of diabetic peripheral neuropathy by the practicing clinician.⁵⁸⁴ This clinical staging is in general agreement with that proposed by Dyck⁶⁰⁶ for use in both clinical practice and epidemiologic studies or controlled clinical trials. The clinical designation, "no neuropathy," is equivalent to Dyck's N0 (no objective evidence of diabetic neuropathy) or N1a (no symptoms or signs but neuropathic test abnormalities). "Clinical neuropathy" is equivalent to N1b (test abnormalities plus neuropathic impairment on neurologic examination), N2a (symptoms, signs, and test abnormalities), and N2b (N2a plus significant ankle dorsiflexor weakness). "Late complications" is equivalent to Dyck N3 (disabling polyneuropathy).

There have been a number of other relevant reports, including two on measures for use in clinical trials to assess symptoms⁶⁵⁶ and QST.⁶⁵⁷ The strengths of QST are well documented,⁶⁵⁷ but the limitations of QST are also clear. No matter what the instrument or procedure used, QST is only a semiobjective measure, because it is affected by the subject's attention, motivation, and cooperation and by anthropometric variables such as age, gender, body mass, and history of smoking and alcohol consumption.^{658,659} Expectancy and subject bias are additional factors that can

exert a powerful influence on QST findings.⁶⁶⁰ Further, QST is sensitive to changes in structure or function along the entire neuroaxis from nerve to cortex; it is not a specific measure of peripheral nerve function.⁶⁶¹ The American Academy of Neurology reported on the use of QST for clinical and research purposes,⁶⁵⁷ suggesting that it could be used as an ancillary test but was not sufficiently robust for routine clinical use.

Peripheral Testing Devices

A number of relatively inexpensive devices allow suitable assessment of somatosensory function, including vibration, thermal, light touch, and pain perception.⁶⁶² These types of instruments allow cutaneous sensory functions to be assessed noninvasively, and their measurements are correlated with specific neural fiber function.

The most widely used device in clinical practice is the Semmes-Weinstein monofilament.⁶⁶³⁻⁶⁶⁵ The filament assesses pressure perception when gentle pressure is applied to the handle sufficient to buckle the nylon filament. Although filaments of many different sizes are available, the one that exerts 10 g of pressure is most commonly used to assess pressure sensation in the diabetic foot. It is also referred to as the 5.07 monofilament because, during calibration, the filaments are calibrated to exert a force measured in grams that is 10 times the log of the force exerted at the tip: hence, 5.07 exerts 10 g of force.

A number of cross-sectional studies have assessed the sensitivity of the 10-g monofilament to identify feet at risk for ulceration. Sensitivities vary from 86% to 100%,^{666,667} although there is no consensus as to how many sites should be tested. The most common algorithm recommends four sites per foot, usually the hallux and the first, third, and fifth metatarsal heads.⁶⁶⁴ However, there is little advantage to multiple site assessments.⁶⁶² There is also no universal agreement about what constitutes an abnormal result (one, two, three, or four abnormal findings from the sites tested). Despite these problems, the 10-g monofilament is widely used to clinically assess risk of foot ulceration; however, as we pointed out, one needs to use a monofilament of 1 g or less to detect neuropathy with a high sensitivity.⁶⁶² A final caution on the use of the filaments is advised⁶⁶⁸: Filaments manufactured by certain companies do not actually buckle at 10 g of force. Indeed, several tested filaments buckled at less than 8 g. In our practice, we use 25-lb strain fishing line and cut it into 1000 pieces at a total cost of \$5. We provide patients with these to test themselves at home, which assists in behavior modification. This has reduced the incidence of foot ulcers in our practice by more than 50%.⁶⁶⁵

The graduated Rydel-Seifer tuning fork is used in some centers to assess neuropathy.^{669,670} This fork uses a visual optical illusion to allow the assessor to determine the intensity of residual vibration on a scale of 0 to 8 at the point of threshold (disappearance of sensation). Liniger and colleagues reported that results with this instrument correlated well with other QST measures.⁶⁶⁹

The tactile circumferential discriminator assesses the perception of calibrated change in the circumference of a probe (a variation of two-point discrimination).⁶⁷¹ Vileikyte and coworkers reported a 100% sensitivity in identifying patients at risk for foot ulceration.⁶⁷² This device also demonstrated good agreement with other measures of QST.

Neuropen is a clinical device that assesses pain using a pin (Neurotip) at one end of the pen and a 10-g monofilament at the other end. This was shown to be a sensitive device for assessing nerve function when compared with the simplified neuropathy disability score.⁶⁷³

Newly introduced means of evaluating small-fiber function include the use of corneal confocal microscopy, which allows the identification of unmyelinated axons in the cornea. Early data suggest that there is early loss of these fibers and reduction of their length, which may precede other measures of neuropathy and may predict the development of foot ulceration.⁶⁷⁴

Contact heat-evoked potentials (CHEP) can be elicited by non-noxious heat or painful stimuli from the toe to the dorsum of the back with measurement of negative and positive amplitudes and latencies by recording impulses in the central nervous system. This promises to provide both temporal and spatial resolution of measures of nociception and has the unique ability to measure conduction in C and A δ fibers, which are normally below the resolution of standard methods. CHEP coupled with functional MRI may lead to an improved understanding of nociceptive pathways and enhance the generation of new therapies directed at the pathways involved.⁶⁷⁵

Cardiovascular Testing Devices

QAFT consists of a series of simple, noninvasive tests for detecting cardiovascular autonomic neuropathy.^{632,676} These tests are based on detection of heart rate and BP responses to a series of maneuvers. Specific tests are used in evaluating disordered regulation of gastrointestinal, genitourinary, and sudomotor function and peripheral skin blood flow induced by autonomic diabetic neuropathy.⁶⁴⁹

Biopsy

Biopsy of nerve tissue may be helpful for excluding other causes of neuropathy and for determining predominant pathologic changes in patients with complex clinical findings as a means of dictating choice of treatment.^{620,678} Skin biopsy has some clinical advantages in diagnosing small-fiber neuropathies by quantification of PGP 9.5 when all other measures are negative.^{598,679}

Differential Diagnosis

Diabetes as the cause of neuropathy is diagnosed by excluding other causes of neuropathy.^{607,680} Patients presenting with painful feet might have impaired glucose tolerance^{681,682} or the metabolic syndrome.⁶⁸³ Quantitation of intraepidermal nerve fiber density has also been used to demonstrate the ability to induce nerve regeneration and correlates with indices of neuropathy relevant to function of small unmyelinated C fibers.⁶⁸⁴

More recently, confocal corneal microscopy has been used to assess peripheral neuropathy. This is a completely noninvasive technique that offers the future potential of assessing nerve structure in vivo without the need for biopsy.⁶⁸⁵

Nerve Conduction Studies

Whole-nerve electrophysiologic procedures (e.g., NCV, F waves, sensory amplitudes, motor amplitudes) have emerged as important methods of tracing the onset and progression of peripheral neuropathy.⁶⁸⁶ An appropriate battery of electrophysiologic tests supports the measurement of the speed of sensory and motor conduction, the amplitude of the propagating neural signal, the density and synchrony of muscle fibers activated by maximal nerve stimulation, and the integrity of neuromuscular transmission.^{687,688} These are objective, parametric, noninvasive, and highly reliable measures. However, standard procedures, such as maximal NCV, reflect only a limited aspect of neural activity, and then only in a small subset of

large-diameter and heavily myelinated axons. Even in large-diameter fibers, NCV is insensitive to many pathologic changes known to be associated with peripheral neuropathy.

However, a key role for electrophysiologic assessment is to rule out other causes of neuropathy or to identify neuropathies superimposed on peripheral neuropathy. Unilateral conditions, such as entrapments, are far more common in patients with diabetes than in healthy subjects.⁶¹⁰ The principal factors that influence the speed of NCV are the integrity and degree of myelination of the largest-diameter fibers, the mean cross-sectional diameter of the responding axons, the representative internodal distance in the segment under study, and the microenvironment at the nodes, including the distribution of ion channels.⁶⁸⁹ Demyelinating conditions affect conduction velocities, whereas diabetes primarily reduces amplitudes. Therefore, the finding of a profound reduction in conduction velocity strongly supports the occurrence in a diabetic patient of an alternative condition. The odds of occurrence of chronic inflammatory demyelinating polyradiculoneuropathy was found to be 11 times higher among diabetic compared with nondiabetic patients.⁶⁹⁰ NCV is only gradually diminished by peripheral neuropathy, with estimates of loss of approximately 0.5 m/sec per year.⁶⁸⁶

In a 10-year natural history study of 133 patients with newly diagnosed T2DM, NCV deteriorated in all six nerve segments evaluated, but the largest deficit was 3.9 m/sec for the sural nerve (48.3 m/sec slowed to 44.4 m/sec); peroneal motor NCV was decreased by 3.0 m/sec over the same period.⁵⁹³ A similar slow rate of decline was demonstrated in the DCCT. A simple rule is that a decrease in HBA_{1c} of 1 percentage point improves conduction velocity by approximately 1.3 m/sec.⁶⁹¹ There is, however, a strong correlation between myelinated fiber density and whole-nerve sural amplitude ($r = 0.74$; $P < 0.001$).⁶⁹²

Management

Once neuropathy has been diagnosed, therapy can be instituted with the goal of ameliorating symptoms and preventing the progression of neuropathy. Successful management of these syndromes must be geared to individual pathogenic processes (Fig. 33-45).

Control of Hyperglycemia

Retrospective and prospective studies have suggested a relationship between hyperglycemia and the development and severity of diabetic neuropathy. Pirart⁵⁶⁸ followed 4400 diabetic patients over 25 years and showed an increase in prevalence of clinically detectable diabetic neuropathy from 12% of patients at the time of diagnosis of diabetes to almost 50% after 25 years. The highest prevalence occurred among those patients with the poorest diabetes control.

The DCCT Research Group⁵⁹⁰ reported significant effects of intensive insulin therapy on prevention of neuropathy. The prevalence rates for clinical or electrophysiologic evidence of neuropathy were reduced by 50% in those treated by intensive insulin therapy during 5 years. At that stage of the study, only 3% of the patients in the primary prevention cohort treated by intensive insulin therapy showed minimal signs of diabetic neuropathy, compared with 10% of those treated by the conventional regimen. In the secondary prevention cohort, intensive insulin therapy significantly reduced the prevalence of clinical neuropathy by 56% (7% in intensive insulin therapy group versus 16% in conventional therapy group). In the UKPDS, control of

Figure 33-45 Management aimed at pathogenic mechanisms. (Adapted from Vinik A, Mehrabian A. Diabetic neuropathies. *Med Clin North Am*. 2004;88:947-999.)

blood glucose was associated with improvement in vibration perception.^{3,478,635} Similar to what was found in the DCCT trial, despite loss of diabetes control, with time nerve function improved in the formerly well-controlled group in what has now come to be known as legacy effect or good metabolic memory.^{12,13}

In the UKPDS, control of blood glucose was associated with improvement in vibration perception.^{3,524,693} The follow-up study to the DCCT trial, the EDIC study, has shown that, despite convergence of A1c levels with time, the advantage accrued to the intensively controlled people during the course of the study persists (EDIC). In the Steno trial,⁶⁹⁴ a reduction of the odds ratio for the development of autonomic neuropathy to 0.32 was reported. This was a stepwise, progressive study that involved treatment of T2DM patients with hypotensive drugs, including ACE inhibitors, calcium-channel antagonists, hypoglycemic agents, aspirin, hypolipidemic agents, and antioxidants. These findings argue strongly for the multifactorial nature of neuropathy and for the need to address the multiple metabolic abnormalities.

Pharmacologic Therapy

Aldose Reductase Inhibitors. Aldose reductase inhibitors (ARIs) reduce the flux of glucose through the polyol pathway, inhibiting tissue accumulation of sorbitol and fructose and preventing reduction of redox potentials.

In a placebo-controlled, double-blind study of tolrestat, 219 diabetic patients with symmetric polyneuropathy, as defined by at least one pathologic cardiovascular reflex, were treated for 1 year.⁶⁹⁵ Patients who received tolrestat showed significant improvement in autonomic function tests and in vibration perception, whereas placebo-treated patients showed deterioration in most of the parameters measured.⁶⁹⁶

There was a dose-dependent improvement in nerve fiber density, particularly in small unmyelinated nerve fibers, in a 12-month study of zenarestat.¹¹⁵ This was accompanied

by an increase in NCV, although the changes in NCV occurred at a dose of the drug that did not change the nerve fiber density. Impaired cardiac ejection fractions can be improved with zopolrestat.⁶⁹⁷ Clinical improvement was reported for fidarestat and epalrestat in studies from Japan.^{698,699}

The promise shown with the newer ARIs is being exploited by other companies, and promising results have been reported in a phase 2 study of the drug AS-3201 in the United States.⁷⁰⁰ This study is now being pursued as a phase 3 study. This ARI is now in phase 3 clinical trials in the United States and Canada. It is also becoming clear that aldose reductase inhibition may be insufficient to achieve the desirable degree of metabolic enhancement in patients with a multitude of biochemical abnormalities. Combinations of therapy with ARIs and antioxidants may become critical to curb the relentless progression of diabetic neuropathy. There is also support for the role of AGE/RAGE interaction in generating inflammation and oxidative and nitrosative stress and promising therapies with compounds that inhibit AGE accumulation and promote a reduction in the aggregation of amyloid fibrils in the nervous system. In addition, it has now been established that sRAGE may act as a decoy in which AGEs and other ligands preferentially bind to sRAGE, thereby precluding access to RAGE and resulting in a net decrease in the inflammation, oxidative, and nitrosative stress effects with salutary effects on the nervous system.¹⁴

α-Lipoic Acid. Lipoic acid (1,2-dithiolane-3-pentanoic acid), a derivative of octanoic acid, is present in food and is also synthesized by the liver. It is a natural cofactor in the pyruvate dehydrogenase complex, where it binds acyl groups and transfers them from one part of the complex to another. α-Lipoic acid, which is also known as thioctic acid, has generated considerable interest as a thiol-replenishing and redox-modulating agent. It has been shown to be effective in ameliorating the somatic and

autonomic neuropathies in patients with diabetes.⁷⁰¹⁻⁷⁰³ It is undergoing extensive trials in the United States and Europe, and promising results for treating diabetes and diabetic neuropathy are forthcoming.

γ -Linolenic Acid. Linoleic acid, an essential fatty acid, is metabolized to dihomono- γ -linolenic acid, which serves as an important constituent of neuronal membrane phospholipids and as a substrate for the formation of PGE, which appears to be important for preserving nerve blood flow. In diabetes, conversion of linoleic acid to γ -linolenic acid and subsequent metabolites is impaired, possibly contributing to the pathogenesis of diabetic neuropathy.⁷⁰⁴ In a recent multicenter, double-blind, placebo-controlled trial, patients using γ -linolenic acid for 1 year showed significant improvements in clinical measures and on electrophysiologic testing.⁷⁰⁵

Protein Kinase C- β Inhibition. Neural vascular insufficiency has been proposed as a contributing factor to development of diabetic neuropathy.⁷⁰⁶ PKC activation is a critical step in the pathway to diabetic microvascular complications.⁷⁰⁷ It is hyperactivated by hyperglycemia and disordered fatty acid metabolism, resulting in increased production of vasoconstrictive, angiogenic, and chemotactic cytokines including TGF- β , VEGF, endothelin, and ICAMs. Nonselective PKC inhibitors normalize hyperglycemia-induced decreases in endoneurial blood flow and abrogate the neuronal abnormalities seen in diabetic rodents.^{66,653,708} Preclinical studies in animal diabetes models using ruboxistaurin mesylate (LY333531), a PKC- β inhibitor, have shown improvement in many diabetes-related changes in vascular function such as retinal blood flow,²¹³ endoneurial blood flow, and NCV.^{709,710}

Preliminary results of a multinational, randomized, double-blind, placebo-controlled phase 2 trial showed a statistically significant improvement in symptoms, measured by the Neuropathy Total Symptom Score 6 (NTSS-6), in ruboxistaurin-treated neuropathy groups compared with placebo treatment.⁷¹¹ In patients with symptomatic neuropathy (NTSS-6 score >6) and a sural nerve action potential greater than 0 μ V at baseline, a measure that has been shown to define a responsive subpopulation of peripheral neuropathy,⁶⁰⁵ the frequency and intensity of symptoms and the change from baseline for vibratory detection threshold were statistically significantly improved in the treated groups. Vibratory detection threshold changes correlated well with the improvement in symptoms; the drug was well tolerated, and there were few adverse events.

Aminoguanidine. Animal studies using aminoguanidine, an inhibitor of the formation of AGEs, have shown improvements in nerve conduction velocity in streptozotocin-induced diabetic neuropathy in rats. Controlled clinical trials to determine the efficacy of aminoguanidine in humans^{712,713} were discontinued because of toxicity. There are, however, successors to aminoguanidine that hold promise for this approach.⁷¹⁴ Studies outlined previously on AGE/RAGE interactions support the notion that this pathway may contribute significantly to neuropathy and deficiencies in sRAGE may be the hallmark of severity of diabetic neuropathy.¹⁶

Human Intravenous Immunoglobulin. Immune intervention with intravenous immune globulin (IVIG) has become appropriate in some patients with forms of peripheral diabetic neuropathy associated with signs of antineuronal autoimmunity.^{621,630} Treatment with immunoglobulin

is well tolerated and is considered safe, especially with respect to viral transmission.⁶⁸⁷ The major toxicity of IVIG has been an anaphylactic reaction, but the frequency of these reactions is now low and confined mainly to patients with immunoglobulin (usually immunoglobulin A) deficiency. Patients may experience severe headache due to aseptic meningitis, which resolves spontaneously. In some instances, it may be necessary to combine treatment with prednisone or azathioprine. Relapses can occur, requiring repeated courses of therapy. However, new data support a predictive role of the presence of antineuronal antibodies on the later development of neuropathy⁶⁸⁸; they may not be innocent bystanders but neurotoxins.⁷¹⁵ Some patients, particularly those with autonomic neuropathy, antineuronal autoimmunity, and CIDP, may benefit from IVIG.^{619,630} Others may benefit from the use of Etanercept or Immuran.^{618,716}

Neurotrophic Therapy

There is now considerable evidence in animal models of diabetes that decreased expression of NGF and its receptors, TrkA and p75, reduces retrograde axonal transport of NGF and diminishes support of small unmyelinated neurons and their neuropeptides, such as substance P and calcitonin gene-related peptide (CGRP), both potent vasodilators.^{569,715,717,718} Furthermore, administration of recombinant human NGF (rhNGF) restores these neuropeptide levels toward normal and prevents the manifestations of sensory neuropathy in animals.⁷¹⁹

In a 15-center, double-blind, placebo-controlled study of the safety and efficacy of rhNGF in 250 subjects with symptomatic small-fiber neuropathy,⁵⁹⁴ rhNGF improved the neurologic impairment score of the lower limbs and improved small nerve fiber function, cooling threshold (A δ fibers), and the ability to perceive heat pain (C fibers) compared with placebo. These results were consistent with the postulated actions of NGF on TrkA receptors present on small-fiber neurons. This led to two large, multicenter studies conducted in the United States and the rest of the world. Subsequently, a phase 3 trial in 1019 diabetic patients with sensory polyneuropathy failed to demonstrate a significant benefit.⁷²⁰ Results of these NGF studies were presented at the ADA meetings in June 1999.⁵⁹⁵ Regrettably, rhNGF was not found to have beneficial effects over placebo. The reason for this dichotomy has not been resolved, but this has somewhat dampened the enthusiasm for growth factor therapy of diabetic neuropathy.

More recently, a randomized, double-blind, placebo-controlled study of brain-derived neurotrophic factor (rhBDNF) in 30 diabetic patients demonstrated no significant improvement in nerve conduction or on quantitative sensory and autonomic function tests, including the cutaneous axon reflex.⁷²¹ A small trial of neurotrophin 3 (NT3) for safety was interpreted as negative for efficacy, and IGF1 and IGF11 have not been considered to be safe for administration to humans. A more promising therapy may be found with the proinsulin C-peptide.⁷²²

Pain Control

Control of pain constitutes one of the most difficult management issues in diabetic neuropathy. In essence, simple measures are tried first. If no distinction is made for pain syndromes, then the number needed to treat (NNT) to reduce pain by 50% is 1.4 for optimal-dose tricyclic antidepressants, 1.9 for dextromethorphan, 3.3 for carbamazepine, 3.4 for tramadol, 3.7 for gabapentin, 5.9 for capsaicin, 6.7 for selective serotonin reuptake inhibitors (SSRIs), and 10.0 for mexiletine.⁷²³ If, however, pain is divided

Figure 33-46 Pain response to various therapies. C fibers are modulated by sympathetic input with spontaneous firing of different neurotransmitters to the dorsal root ganglia, spinal cord, and cerebral cortex. Sympathetic blockers (e.g., clonidine) and depletion of axonal substance P used by C fibers as their neurotransmitter (e.g., by capsaicin) can relieve pain. In contrast, Aδ fibers use Na⁺ channels for conduction. Agents that inhibit Na⁺ exchange, such as antiepileptic drugs, tricyclic antidepressants (TCAs), and insulin, can ameliorate this form of pain. Anticonvulsants (carbamazepine, gabapentin, pregabalin, topiramate) potentiate the activity of γ-aminobutyric acid (GABA), inhibit Na⁺ and Ca²⁺ channels, and inhibit N-methyl-D-aspartate (NMDA) receptors and α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) receptors. Dextromethorphan blocks NMDA receptors in the spinal cord. TCAs, selective serotonin reuptake inhibitors (e.g., fluoxetine), and serotonin-norepinephrine reuptake inhibitors (SNRIs) inhibit serotonin and norepinephrine reuptake, enhancing their effect in endogenous pain-inhibitory systems in the brain. Tramadol is a central opioid analgesic. Antag, antagonists; CR, controlled release; 5HT, 5-hydroxytryptamine; DRG, dorsal root ganglia; SSRIs, selective serotonin reuptake inhibitors. (Adapted from Vinik AI, Ullal J, Parson H, et al. Diabetic neuropathies: clinical manifestations and current treatment options. *Nature Clin Pract Endocrinol Metab.* 2006;2:269-281.)

according to its derivation from different nerve fiber types (Aδ versus C fiber), from spinal cord, or from cerebral cortex, then different types of pain respond to different therapies (Fig. 33-46).

C-Fiber Pain. Initially, when there is ongoing damage to the nerves, the patient experiences pain of the burning, lancinating, dysesthetic type, often accompanied by hyperalgesia and allodynia. Because the peripheral sympathetic nerve fibers are also small, unmyelinated C fibers, sympathetic blocking agents (clonidine) can improve the pain. Loss of sympathetic regulation of sweat glands and arteriovenous shunt vessels in the foot creates a favorable environment for bacteria to penetrate, multiply, and wreak havoc with the foot. These fibers use the neuropeptide substance P as their neurotransmitter, and agents that deplete axonal substance P (capsaicin) often lead to amelioration of the pain. However, when the destructive forces persist, the patient becomes pain free and develops impaired warm temperature and pain thresholds. Disappearance of pain in these circumstances should be viewed as a warning that the neuropathy is progressing. Targeting higher levels of pain transmission also helps with C-fiber pain.^{724,725}

Capsaicin. Capsaicin is extracted from chili peppers, and a simple, cheap mixture can be made by adding 1 to 3 teaspoons (15 to 45 mL) of cayenne pepper to a jar of cold cream and applying the cream to the area of pain. Capsaicin has high selectivity for a subset of sensory neurons that have been identified as unmyelinated C-fiber afferent or thin-myelinated (Aδ) fibers. Prolonged application of capsaicin depletes stores of substance P, and possibly other neurotransmitters, from sensory nerve endings. This reduces or abolishes the transmission of painful

stimuli from the peripheral nerve fibers to the higher centers.⁷²⁶ Care must be taken to avoid eyes and genitals, and gloves must be worn. Because of capsaicin's volatility, it is safer to cover affected areas with plastic wrap. There is initial exacerbation of symptoms followed by relief in 2 to 3 weeks.

Clonidine. There is an element of sympathetic-mediated C-fiber type pain that can be overcome with clonidine (an α₂-adrenergic agonist) or phentolamine. Clonidine can be applied topically,⁷²⁷ but the dose titration may be more difficult. If clonidine fails, a trial of the local anesthetic agent, mexiletine, is warranted. If there is no response, treatment can continue as outlined in Figure 33-47.

Aδ-Fiber Pain. Aδ-fiber pain is a more deep-seated, dull, and gnawing ache that often does not respond to the previously described measures. A number of different agents have been used for the pain associated with these fibers with varying success.

Insulin. Continuous intravenous insulin infusion without resort to blood glucose lowering may be useful in patients with Aδ-fiber pain. A response with reduction of pain usually occurs within 48 hours,⁷²⁸ and the insulin infusion can be discontinued. If this measure fails, several medications are available that might abolish the pain.

Nerve Blocking. Lidocaine given by slow infusion has been shown to provide relief of intractable pain for 3 to 21 days. This form of therapy may be of most use in self-limited forms of neuropathy. If successful, therapy can be continued with oral mexiletine. Because of the cardiac conduction block reported with these drugs when given systemically, this is no longer done, and only the topical agents are still in use. These compounds target the pain

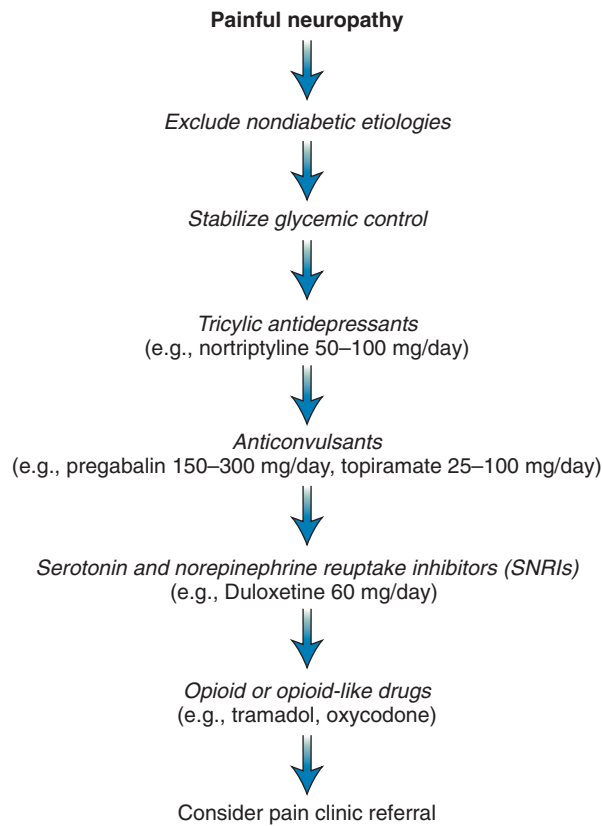

Figure 33-47 Algorithm for managing painful diabetic neuropathy. Non-pharmacologic, topical, or physical therapies (e.g., capsaicin, acupuncture) can be useful at any time. (Modified from Boulton AJ, Vinik AI, Arezzo JC, et al. Diabetic neuropathies: a statement by the American Diabetes Association. *Diabetes Care*. 2005;28:956-962.)

caused by hyperexcitability of superficial free nerve endings.⁷²⁹

Tramadol and Dextromethorphan. There are two possible targeted therapies. Tramadol is a centrally acting, weak opioid analgesic that is used to treat moderate to severe pain. Tramadol was shown to be better than placebo in a randomized, controlled trial⁷³⁰ of only 6 weeks' duration, but a subsequent follow-up study⁷³¹ suggested that symptomatic relief could be maintained for at least 6 months. Side effects are relatively common and are similar to those of other opioid-like drugs.

Another spinal cord target for pain relief is the excitatory glutamergic *N*-methyl-D-aspartate (NMDA) receptor. Blockade of NMDA receptors is believed to be one mechanism by which dextromethorphan exerts analgesic efficacy.⁷³² The pharmacist can procure a sugar-free solution of dextromethorphan.

Antidepressants. Tricyclic antidepressants are an important component in the treatment of chronic pain syndromes. Imipramine, amitriptyline, and clomipramine induce a balanced reuptake inhibition of both norepinephrine and serotonin, whereas desipramine is a relatively selective norepinephrine reuptake inhibitor. The NNT for greater than 50% pain relief by tricyclic antidepressants is 2.4 (95% CI, 2.0 to 3.0).⁶⁷ Amitriptyline is frequently the drug of first choice, but it can alternatively be replaced by nortriptyline, which has less pronounced sedative and anticholinergic effects.

Antidepressants inhibit reuptake of norepinephrine or serotonin, or both. Their use is limited by anticholinergic

effects, orthostatic hypotension, and sexual side effects. Clinical trials have focused on interrupting pain transmission with antidepressant drugs that inhibit the reuptake of norepinephrine or serotonin. This central action accentuates the effects of these neurotransmitters in activation of endogenous pain-inhibitory systems in the brain that modulate pain-transmission cells in the spinal cord.⁷³³ Side effects, including dysautonomia and dry mouth, can be troublesome. Switching to nortriptyline can lessen some of the anticholinergic effects of amitriptyline.

Antidepressants remain first-line agents in many centers, but consideration of their safety and tolerability is important to avoid adverse effects, a common result of treatment of neuropathic pain. Dosages must be titrated based on positive responses, treatment adherence, and adverse events.⁷³⁴ Among the norepinephrine reuptake inhibitors, desipramine, amitriptyline, and imipramine have been shown to be of benefit.^{735,736}

SSRIs that have been used for neuropathic pain are paroxetine, fluoxetine, sertraline, and citalopram. Paroxetine appears to be associated with greater pain relief.⁷³⁷ Fluoxetine failed a placebo-controlled trial.⁷³⁸

Recent interest has focused on antidepressants with dual selective inhibition of serotonin and norepinephrine (SNRIs), such as duloxetine and venlafaxine. Duloxetine has recently been approved for neuropathic pain in the United States. The efficacy and safety of duloxetine was evaluated in three controlled studies using doses of 60 and 120 mg/day over 12 weeks.⁷³⁸ In all three studies, the average 24-hour pain intensity was significantly reduced with either dose, compared with placebo treatment. The response rates, defined as 50% or greater pain reduction, were 48.2% for the 120-mg/day dose, 47.2% for 60 mg/day, and 27.9% for placebo, giving an NNT of 4.9 (95% CI, 3.6 to 7.6) for 120 mg/day and 5.2 (95% CI, 3.8 to 8.3) for 60 mg/day.⁷³⁸ Patients with higher pain intensity do tend to respond better than those with lower pain levels.⁷³⁹ The most frequent adverse effects are nausea, somnolence, dizziness, constipation, dry mouth, and reduced appetite. Physicians must be alert to suicidal ideation and exacerbation of autonomic symptoms as well as aggravation of depression in patients with bipolar tendencies. Venlafaxine (Effexor), another SNRI, has also shown efficacy in the treatment of painful diabetic neuropathy.⁷⁴⁰

Antiepileptic Drugs. For a detailed discussion of the subject of antiepileptic drug therapy for painful diabetic neuropathy, the reader is referred to the review by Vinik.⁷⁴¹

Anticonvulsants have stood the test of time in the treatment of diabetic neuropathy.^{742,743} Principal mechanisms of action include sodium channel blockade (felbamate, lamotrigine, oxcarbazepine, topiramate, zonisamide), potentiation of γ -aminobutyric acid (GABA) activity (pregabalin, tiagabine, topiramate), calcium-channel blockade (felbamate, lamotrigine, topiramate, zonisamide), and antagonism of glutamate at NMDA receptors (felbamate) or α -amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) receptors (felbamate, topiramate).⁷⁴⁴

Pregabalin (Lyrica) is a GABA analogue with similar structure and actions to gabapentin, but it is a more specific $\alpha 2\text{-}\delta$ ligand with a higher binding affinity than gabapentin. The efficacy and safety of pregabalin were reported in a pooled analysis of seven studies over 5 to 13 weeks in 1510 patients with DPN. The response rates, defined as 50% or greater pain reduction, were 47% for a dosage of 600 mg/day, 39% for 300 mg/day, 27% for 150 mg/day, and 22% for placebo, giving NNTs of 4.0, 5.9, and 20.0, respectively.⁷⁴⁵ The most frequent adverse effects were dizziness,

somnolence, peripheral edema, headache, and weight gain.

Carbamazepine is useful for patients with shooting or electric shock-like pain. Several double-blind, placebo-controlled studies have demonstrated carbamazepine to be effective in the management of pain in diabetic neuropathy.⁷⁴⁶ Toxic side effects can limit its use in some patients.

Phenytoin has long been used in the treatment of painful neuropathies. Double-blind, crossover studies have not demonstrated a therapeutic benefit of phenytoin compared with placebo in the treatment of diabetic neuropathy.⁷⁴² Phenytoin is associated with significant side effects, and it must be administered as many as three or four times daily. Some studies have reported positive findings, with 24% of patients indicating improvement,⁷⁴⁷ but others have failed to show any benefit.⁷⁴⁸ Also, side effects mitigate the use of phenytoin in people with diabetes. Its ability to suppress insulin secretion has resulted in precipitation of hyperosmolar diabetic coma. Valproic acid failed to prove superior to placebo on any outcome measures.⁷⁴⁹

Gabapentin is an effective anticonvulsant whose mechanism is not well understood, but it holds additional promise as an analgesic agent in cases of painful neuropathy.⁷⁵⁰ In a multicenter study in the United States,⁷⁵¹ gabapentin monotherapy appeared to be efficacious for treatment of pain and sleep interference associated with diabetic peripheral neuropathy. It also exhibits positive effects on mood and quality of life.⁷⁵² Effective dosing can require 1800 to 3600 mg/day, and this is associated with untoward side effects. In a placebo-controlled trial, gabapentin-treated patients had significantly lower mean daily pain scores and improvement of all secondary efficacy parameters.⁷⁵¹ In another study on diabetic neuropathy, gabapentin was found to be equivalent to amitriptyline.⁷⁵³ Gabapentin has the additional benefit of improving sleep,⁷⁵¹ which is often compromised in patients with chronic pain.⁷³⁴ In the long term, it is known to produce weight gain, which can complicate diabetes management. Gabapentin has not been successful in all trials.⁷⁵⁴

Lamotrigine is an antiepileptic agent with at least two antinociceptive properties. In a randomized, placebo-controlled study, Eisenberg and colleagues⁷⁵⁵ confirmed the efficacy of this agent in patients with neuropathic pain. However, titration needs to be inordinately slow to prevent Stevens-Johnson syndrome. Bradycardia has been reported. Lamotrigine caused a significant decrease in pain intensity in two controlled studies.^{755,756} Two randomized, double-blind, placebo-controlled studies of lamotrigine in patients with painful diabetic neuropathy (each study with 360 subjects) revealed greater reduction in pain-intensity score among patients receiving lamotrigine 400 mg, compared with placebo.⁷⁵⁷

Topiramate is a fructose analogue that was initially examined because of its antidiabetic possibilities. A study using neuropathy end points with specificity for the nature and site of the pain was successful, but paresthesias were a side effect of the drug.⁷⁵⁸ Topiramate also increased nerve fiber regeneration in the skin.⁶⁰⁵ It therefore has the potential to relieve pain by altering the biology of the disease and has now been shown to increase intraepidermal nerve fiber density. Further trials are under way. One must start with no more than 15 mg/day, preferably at night, and then increase the dose only after the patient can tolerate the drug. A maximum of 200 mg was sufficient to induce nerve fiber recovery.

Pregabalin produced significant improvements on pain scores within 1 week ($P < .01$), and these improvements

persisted for 8 weeks ($P < .01$). For the patient global impression of change (PGIC), there was a 67% improvement, compared with 39% in patients given placebo ($P = .001$). Furthermore, 40% of patients receiving pregabalin reported a 50% reduction in pain, compared with 14.5% of the placebo group ($P = .001$). There is, however, concern with the labeling of pregabalin as a narcotic drug.⁷²⁴

In trials with topiramate, 50% of patients responded to treatment, compared with 34% of those patients receiving placebo; response was defined as a reduction of greater than 30% in pain score ($P < .004$). Topiramate also reduced pain intensity compared with placebo ($P < .003$) and improved sleep-disruption scores ($P < .02$).⁷⁵⁸ This drug also lowers BP, has a favorable impact on lipids, decreases insulin resistance, and causes growth of intraepidermal nerve fibers.^{741,758} It has also shown improvement in quality of life commensurate with its effects on small nerve fiber function contrasting with the large fiber effects of the PKC inhibitor.^{11,18}

Pain symptoms in neuropathy significantly affect quality of life. Neuropathic pain therapy is challenging, and selection of pain medications and dosages must be individualized, with attention to potential side effects and drug interactions. Based on the information presented here, the scheme presented in Figure 33-48 is provided for decision making in the management of pain in people with diabetes.

Adjunct Management and Treatment of Complications

Although small-fiber neuropathy manifests as different forms of pain, large-fiber neuropathy is manifested by reduced vibration perception and position sense, weakness, muscle wasting, and depressed deep tendon reflexes. Diabetic patients with large-fiber neuropathies are uncoordinated and ataxic and are 17 times more likely to fall than their non-neuropathic counterparts.⁷⁵⁹ Therefore, it is important to improve strength and balance in patients with large-fiber neuropathy. Patients can benefit from high-intensity strength training by increasing muscle strength and improving coordination and balance, thereby reducing fall and fracture risks.^{760,761} Low-impact activities that emphasize muscle strength and coordination and challenge the vestibular system, such as Pilates, yoga, and tai chi, can also be particularly helpful. In addition, options to prevent and correct foot deformities are available, including orthotics, surgery, and reconstruction.

Prevention. Basic management of small-fiber neuropathies by the patient should be encouraged. These include foot protection and ulcer prevention by wearing padded socks; daily foot inspection using a mirror to examine the soles of the feet; selection of proper footwear; scrutiny of shoes for the presence of foreign objects that lodge themselves in closed shoes; and avoidance of sun-heated surfaces, hot bathwater, and sleeping with feet in front of a fireplace or heater. Patient education should reinforce these strategies and should also discourage soaking of the feet in water. Education also should promote foot care by encouraging use of emollient creams to help skin retain moisture and to prevent cracking and infection.

Stimulation. Transcutaneous nerve stimulation (electrotherapy) occasionally is helpful and certainly represents one of the more benign therapies for painful neuropathy.⁷⁶² Care should be taken to move the electrodes around to identify sensitive areas and obtain maximum relief. Static

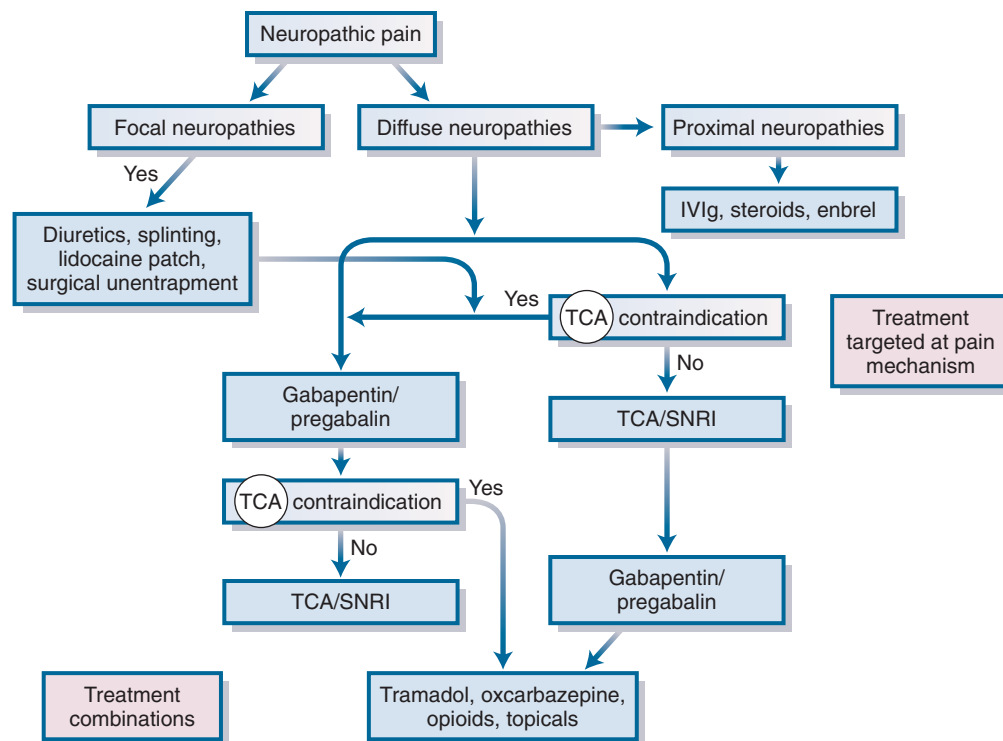

Figure 33-48 Treatment algorithm for neuropathic pain after exclusion of nondiabetic etiologies and stabilization of glycemic control. IVIg, intravenous immune globulin; SNRI, serotonin-norepinephrine reuptake inhibitors; TCA, tricyclic antidepressants.

magnetic field therapy⁷⁶³ has been reported to be of benefit, but it is difficult to blind such studies. Similarly, the use of infrared light has reportedly had benefit, but this remains to be proved.

A case series of patients with severe painful neuropathy unresponsive to conventional therapy suggested efficacy for the use of an implanted spinal cord stimulator.⁶⁴² However, this cannot be generally recommended except in very resistant cases, because it is invasive, expensive, and unproven in controlled studies. Even stochastic resonance therapy can improve sensation.⁶⁹² There is no support for the notion that surgical decompression can be used to treat common diabetic neuropathy.⁷⁶⁴

Pharmacologic Therapy

Analgesics. Analgesics are rarely of much benefit in the treatment of painful neuropathy, although they may be of some use on a short-term basis for some of the self-limited syndromes, such as painful diabetic third nerve palsy. Narcotics are usually avoided in the setting of chronic pain because of the risk of addiction.

Calcitonin. In a placebo-controlled study, 10 patients with painful diabetic neuropathy were treated with 100 IU of calcitonin per day. About 39% of patients had near-complete relief of symptom. The improvement was seen after only 2 weeks of treatment.⁷⁶⁵

Management of Small-Fiber Neuropathies

Patients must be instructed on foot care including daily foot inspection. They must have a mirror in the bathroom for inspecting the soles of the feet. Providing patients with a monofilament for self-testing reduces the occurrence of ulcers.

All diabetic patients should wear padded socks. Shoes must fit well and have adequate support, and they must be inspected for the presence of foreign bodies (e.g., nails, pins, teeth) before donning.

Patients must exercise care with exposure to heat (no falling asleep in front of fires). Emollient creams should be used for the drying and cracking. After bathing, feet should be thoroughly dried and powdered between the toes. Nails should be cut transversely, preferably by a podiatrist.

Management of Large-Fiber Neuropathies

Patients with large-fiber neuropathies are uncoordinated and ataxic. As a result, they are more likely to fall than non-neuropathic age-matched persons.⁷⁶⁶ High-intensity strength training in older people increases muscle strength in a variety of muscles. More importantly, the strength training results in improved coordination and balance that is quantifiable by backward tandem walking.^{760,767} It has also been demonstrated that strength and rehabilitation training and simple waling exercise can markedly reduce the risk of falling.¹⁸ Strength and balance training have widespread positive effects on physiologic function for patients with T2DM. It leads to decreased risk of falling, improved strength, and postural stability. In one study,⁷⁶⁷ the training program also resulted in altered postural sway dynamics. The center of pressure (COP) output of the trained diabetic group became more similar to that seen in the age-matched controls.

Therefore, it is vital for the patient to embark on a program of strength training and improvement of balance to include gait and strength training, tendon lengthening for Achilles tendon shortening, orthotics and proper shoes for the deformities, pain management as detailed earlier, bisphosphonates for osteopenia, and surgical reconstruction and full-length casting as necessary.

Autonomic Neuropathies

The autonomic nervous system (ANS) supplies all organs in the body and consists of an afferent and an efferent system, with long efferents in the vagus (cholinergic) system and short postganglionic unmyelinated fibers in the sympathetic (adrenergic) system. A third component is the neuropeptidergic system, with its neurotransmitters, substance P, vasoactive intestinal polypeptide (VIP), and CGRP, among others.

Diabetic autonomic neuropathy can cause dysfunction of every part of the body. Diabetic autonomic neuropathy often goes completely unrecognized by patient and physician alike because of its insidious onset and protean multiple-organ involvement. Alternatively, the appearance of complex and confusing symptoms in a single organ system as a result of diabetic autonomic neuropathy can cause profound symptoms and receive intense diagnostic and therapeutic attention. Subclinical involvement may be widespread, whereas clinical symptoms and signs may be focused within a single organ. The organ systems that most often exhibit prominent clinical autonomic signs and symptoms in diabetes include the ocular pupil, sweat glands, genitourinary system, gastrointestinal system, adrenal medullary system, and cardiovascular system (Table 33-8).

Involvement of the ANS can occur as early as the first year after diagnosis. Major manifestations are cardiovascular, gastrointestinal, and genitourinary system dysfunction.^{607,768} Reduced exercise tolerance, edema, paradoxical supine or nocturnal hypertension, and intolerance to heat due to defective thermoregulation are consequences of autonomic neuropathy.

TABLE 33-8

Clinical Manifestations of Autonomic Neuropathy

Cardiovascular

Alterations in skin blood flow
Cardiac denervation, painless myocardial infarction
Heat intolerance
Orthostatic hypotension
Tachycardia, exercise intolerance

Gastrointestinal

Constipation
Diarrhea
Esophageal dysfunction
Fecal incontinence
Gastroparesis diabeticorum

Genitourinary

Cystopathy
Erectile dysfunction
Neurogenic bladder
Retrograde ejaculation

Metabolic

Hypoglycemia unawareness
Hypoglycemia unresponsiveness

Pupillary

Argyll-Robertson pupil
Decreased diameter of dark-adapted pupil

Sweating Disturbances

Areas of symmetric anhidrosis
Gustatory sweating

Defective blood flow in the capillary circulation is found, with decreased responsiveness to mental arithmetic, cold pressor, hand grip, and heating.⁶³⁴ The defect is associated with a reduction in the amplitude of vasomotion⁷⁵⁹ that resembles premature aging.⁶³⁴ There are differences in the glabrous and hairy skin circulations. In hairy skin, a functional defect is found before neuropathy develops,⁷⁶⁹ and it is correctable with antioxidants.⁷⁷⁰ The clinical counterpart is skin that is dry and cold, loses the ability to sweat, and develops fissures and cracks that are portals of entry for organisms leading to infectious ulcers and gangrene. Silent MI, respiratory failure, amputations, and sudden death are hazards for diabetic patients with cardiac autonomic neuropathy.^{603,771} There is now evidence that the greatest predictor of CVD as well as increased mortality is autonomic nerve dysfunction,^{20,21} and the increase in sudden death in the ACCORD study is likely due to the presence of autonomic dysfunction.²² It has also become apparent that a combination of self-reported somatic neuropathy viz. numbness combined with an index of loss in heart rate variability increase the risk of cardiac events and mortality by a RR of 4.5.²³ Therefore, it is vitally important to make this diagnosis early so that appropriate intervention can be instituted.^{603,710,771,772} Furthermore, since the risk factors for CVD in the recent ADVANCE, ACCORD, and VADT trials have been established, the presence of autonomic dysfunction necessitates a modified approach to attempts at intensification of glycemic control and suggests a relaxation of the A1c goals from those recommended by ACE and the ADA to less stringent criteria.

Disturbances in the ANS may be functional and include gastroparesis with hyperglycemia and ketoacidosis. In organic disturbances, nerve fibers are actually lost. This creates inordinate difficulties in diagnosing, treating, and prognosticating as well as establishing true prevalence rates. Tests of autonomic function typically stimulate entire reflex pathways. Furthermore, autonomic control for each organ system is usually divided between opposing sympathetic and parasympathetic innervations, so that heart rate acceleration, for example, could reflect either decreased parasympathetic or increased sympathetic nervous system stimulation.

Because many conditions affect the ANS and autonomic neuropathy is not unique to diabetes, the diagnosis of diabetic autonomic neuropathy rests with establishing the diagnosis and excluding other causes. The best-studied tests, and those for which there are large databases and evidence to support their use in clinical practice, relate to the evaluation of cardiovascular reflexes. Evaluation of orthostasis is fairly straightforward and is readily done in clinical practice, and the same can be said for the establishment of the causes of gastrointestinal symptoms and erectile dysfunction. The evaluation of pupillary abnormalities, hypoglycemia unawareness and unresponsiveness, neurovascular dysfunction, and sweating disturbances is for the most part done only in research laboratories, requires specialized equipment and familiarity with the diagnostic procedures, and is best left in the hands of those who have a special interest in the area.

Tables 33-9 and 33-10 present the diagnostic tests that apply to the diagnosis of cardiovascular autonomic neuropathy. These tests can be used as a surrogate for the diagnosis of autonomic neuropathy of any system, because it is rare (although it does occur) to find involvement of any other division of the ANS in the absence of cardiovascular autonomic dysfunction. For example, if one entertains the possibility that the patient's erectile dysfunction is caused by autonomic neuropathy, then

TABLE 33-9

Differential Diagnosis of Diabetic Autonomic Neuropathy

Clinical Manifestations	Differential Diagnosis
Cardiovascular	
Cardiac denervation	Carcinoid syndrome
Exercise intolerance	Congestive heart disease
Orthostatic hypotension	Hyperadrenergic hypotension
Painless myocardial infarction	Hypovolemia
Tachycardia	Idiopathic orthostatic hypotension
	Multiple system atrophy with parkinsonism
	Panhypopituitarism
	Pheochromocytoma
	Orthostatic tachycardia
	Shy-Drager syndrome
Gastrointestinal	
Constipation	Bezoars
Diarrhea	Biliary disease
Esophageal dysfunction	Medications
Fecal incontinence	Obstruction
Gastroparesis diabeticorum	Psychogenic vomiting
	Secretory diarrhea (endocrine tumors)
Genitourinary	
Cystopathy	Alcohol abuse

Decreased diameter of dark-adapted pupil	

before embarking on a sophisticated and expensive evaluation of erectile status, one should measure the heart rate and its variability in response to deep breathing. If this measurement is normal, autonomic neuropathy is excluded as a cause of erectile dysfunction, and the cause should be sought elsewhere. Similarly, it is extremely unusual to find gastroparesis secondary to autonomic neuropathy in a patient with normal cardiovascular autonomic reflexes.

Prevention and Reversibility

It has now become clear that strict glycemic control⁵⁹¹ and stepwise progressive management of hyperglycemia, lipids, and BP, together with the use of antioxidants⁷⁰² and ACE inhibitors,⁷⁷³ reduce the odds ratio for autonomic neuropathy to 0.32.⁶⁸³ It has also been shown that mortality is a function of loss of beat-to-beat variability with MI. This

can be reduced by 33% with acute administration of insulin.⁷⁷⁴ Kendall and coworkers⁷⁷⁵ reported that successful pancreas transplantation improves epinephrine response and normalizes hypoglycemia symptom recognition in patients with long-standing diabetes and established autonomic neuropathy. Burger's group⁷⁷⁶ showed a reversible metabolic component in patients with early cardiac autonomic neuropathy (Table 33-11).

Management

Postural Hypotension. The syndrome of postural hypotension consists of posture-related dizziness and syncope

TABLE 33-10

Diagnostic Tests for Cardiovascular Autonomic Neuropathy**Resting Heart Rate**

Rate >100 beats/min is abnormal.

Beat-to-Beat Heart Rate Variation*

With the patient at rest and supine (no overnight coffee or hypoglycemic episodes), breathing 6 breaths/min, heart rate monitored by ECG or Anscore device, an HRV of >15 beats/min is normal and <10 beats/min is abnormal, R-R inspiration to R-R expiration >1.17. All indices of HRV are age-dependent.[†]

Heart Rate Response to Standing*

During continuous ECG monitoring, the R-R interval is measured at beats 15 and 30 after standing. Normally, a tachycardia is followed by reflex bradycardia. The 30:15 ratio is normally >1.03.

Heart Rate Response to Valsalva Maneuver*

The subject forcibly exhales into the mouthpiece of a manometer to 40 mm Hg for 15 seconds during ECG monitoring. Healthy subjects develop tachycardia and peripheral vasoconstriction during strain and an overshoot bradycardia and rise in blood pressure with release. The ratio of longest R-R to shortest R-R should be >1.2.

Systolic Blood Pressure Response to Standing

Systolic blood pressure is measured in the supine subject. The patient stands and the systolic blood pressure is measured after 2 min. Normal response is a fall of <10 mm Hg, borderline is a fall of 10-29 mm Hg, and abnormal is a fall of >30 mm Hg with symptoms.

Diastolic Blood Pressure Response to Isometric Exercise

The subject squeezes a handgrip dynamometer to establish a maximum. Grip is then squeezed at 30% maximum for 5 min. The normal response for diastolic blood pressure is a rise of >16 mm Hg in the other arm.

Electrocardiographic QT/QTc Intervals

The QTc (corrected QT interval on ECG) should be <440 msec.

Spectral Analysis

High-frequency peak ↓ (parasympathetic dysfunction)
Low-frequency peak ↓ (sympathetic dysfunction)
Low-frequency/high-frequency ratio ↓ (sympathetic imbalance)
Very-low-frequency peak ↓ (sympathetic dysfunction)

Neurovascular Flow

Noninvasive laser Doppler measures peripheral sympathetic responses to nociception.

*These can be performed quickly (<15 min) in the practitioner's office, with a central reference laboratory providing quality control and normative values, and are now readily available in most cardiology practices.

†Lowest normal value of E/I ratio: Age 20-24 yr: 1.17; 25-29 yr: 1.15; 30-34 yr: 1.13; 35-39 yr: 1.12; 40-44 yr: 1.10; 45-49 yr: 1.08; 50-54 yr: 1.07; 55-59 yr: 1.06; 60-64 yr: 1.04; 65-69 yr: 1.03; 70-75 yr: 1.02.

TABLE 33-11

Clinical Features, Diagnosis, and Treatment of Diabetic Autonomic Neuropathy

Symptoms	Tests	Treatments
Cardiac		
Resting tachycardia, exercise intolerance	HRV, MUGA thallium scan, MIBG scan	Graded supervised exercise, ACE inhibitors, β -blockers
Postural hypotension, dizziness, weakness, fatigue, syncope	HRV, supine and standing BP, catecholamines	Mechanical measures, clonidine, midodrine, octreotide, erythropoietin
Gastrointestinal		
Gastroparesis, erratic glucose control	Gastric emptying study, barium study	Frequent small meals, prokinetic agents (metoclopramide, domperidone, erythromycin)
Abdominal pain, early satiety, nausea, vomiting, bloating, belching	Endoscopy, manometry, electrogastrogram	Antibiotics, antiemetics, bulking agents, tricyclic antidepressants, pyloric botulinum toxin, gastric pacing
Constipation	Endoscopy	High-fiber diet, bulking agents, osmotic laxatives, lubricating agents
Diarrhea (often nocturnal alternating with constipation)		Soluble fiber; gluten and lactose restriction, anticholinergic agents, cholestyramine, antibiotics, somatostatin, pancreatic enzyme supplements
Sexual Dysfunction		
Erectile dysfunction	H&P, HRV, penile-brachial pressure index, nocturnal penile tumescence	Sex therapy, psychological counseling, phosphodiesterase inhibitors, PGE ₁ injections, devices or prostheses
Vaginal dryness		Vaginal lubricants
Bladder Dysfunction		
Frequency, urgency, nocturia, urinary retention, incontinence	Cystometrogram, postvoid sonography	Bethanechol, intermittent catheterization
Sudomotor Dysfunction		
Anhidrosis, heat intolerance, dry skin, hyperhidrosis	Quantitative sudomotor axon reflex, sweat test, skin blood flow	Emollients and skin lubricants, scopolamine, glycopyrrolate, botulinum toxin, vasodilators
Pupillomotor and Visceral Dysfunction		
Blurred vision, impaired adaptation to ambient light, Argyll-Robertson pupil	Pupillometry, HRV	Care with driving at night
Impaired visceral sensation: silent MI, hypoglycemia unawareness		Recognition of unusual presentation of MI, control of risk factors, control of plasma glucose levels

ACE, acetylcholinesterase; BP, blood pressure; H&P, history and physical examination; HRV, heart rate variability; MI, myocardial infarction; MIBG, metaiodobenzylguanidine; MUGA, multigated angiography; PGE₁, prostaglandin E₁.

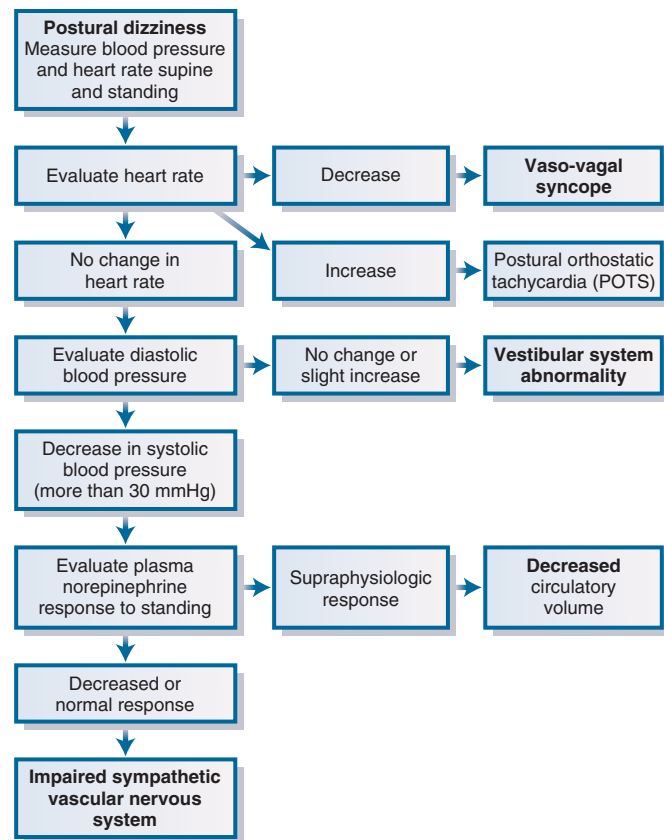

Figure 33-49 Evaluation of postural dizziness in diabetic patients. (Modified from Vinik A, Mehrabyan A. Diabetic neuropathies. *Med Clin North Am.* 2004;88:947-999.)

(Fig. 33-49). Patients who have T2DM and orthostatic hypotension are hypovolemic and have sympathoadrenal insufficiency; both factors contribute to the pathogenesis of orthostatic hypotension.⁷⁷⁷ Postural hypotension in the patient with diabetic autonomic neuropathy can present a difficult management problem. Increasing BP in the standing position to avoid symptoms often results in hypertension in the supine position. It is now recognized that symptoms of orthostasis can also result from inappropriate changes in heart rate without a fall in BP (i.e., orthostatic tachycardia or bradycardia without a fall in BP). Devices with algorithms for quantification of sympathetic or parasympathetic function allow the determination of ANS dysfunction in the arm,⁷⁷⁹ which may provide a rationale for trying drugs that reduce either sympathetic or parasympathetic activity in these patients.

Supportive Garments. Whenever possible, attempts should be made to increase venous return from the periphery using total body stockings. Leg compression alone is less effective, presumably reflecting the large capacity of the abdomen relative to the legs.⁷⁷⁸ Patients should be instructed to put these garments on while lying down and not to remove them until returning to the supine position.

Drug Therapy. Some patients with postural hypotension benefit from treatment with 9-fluorohydrocortisone. However, symptoms do not improve until edema occurs, and there is a significant risk of developing congestive heart failure (CHF) and hypertension. If 9-fluorohydrocortisone does not work satisfactorily, various adrenergic agonists and antagonists may be used.

If the adrenergic receptor status is known, therapy can be guided to the appropriate agent. Metoclopramide may be helpful in patients with dopamine excess or increased sensitivity to dopaminergic stimulation. Patients with α_2 -adrenergic receptor excess might respond to the α_2 -antagonist, yohimbine. Those few patients in whom β -receptors are increased may be helped with propranolol. α_2 -Adrenergic receptor deficiency can be treated with the α_2 -agonist, clonidine, which in this setting can paradoxically increase BP. One should start with small doses and gradually increase the dose. If these measures fail, midodrine (an α_1 -adrenergic agonist) or dihydroergotamine in combination with caffeine can help.

A particularly refractory form of postural hypotension occurs in some patients postprandially and may respond to therapy with octreotide given subcutaneously in the mornings.

Gastropathy. Gastrointestinal motor disorders (Fig. 33-50) are frequent and widespread in patients with T2DM regardless of symptoms,⁷⁸⁰ and there is a poor correlation between symptoms and objective evidence of functional or organic defects. The first step in management of diabetic gastroparesis consists of multiple small feedings. The amount of fat should be decreased, because fat tends to delay gastric emptying. Maintenance of glycemic control is important.^{781,782} Metoclopramide may be used. Cisapride and domperidone^{783,784} have been shown to be effective in some patients, although probably no more so than metoclopramide. (Cisapride has been withdrawn from the market.) Erythromycin, given as a liquid or as a suppository, also may be helpful. Erythromycin acts on the motilin receptor (the sweeper of the gut) and shortens gastric emptying time.⁷⁸⁵ Several novel drugs including ghrelin (an orexigenic hormone) and ghrelin receptor agonists, motilin agonist (mitemcinal), 5HT₄-receptor agonists, and a muscarinic antagonist are being investigated for their prokinetic effects. If medications fail and severe gastroparesis persists, jejunostomy placement into normally functioning bowel may be needed. Gastric pacing has not been as rewarding as originally anticipated, but studies are ongoing.

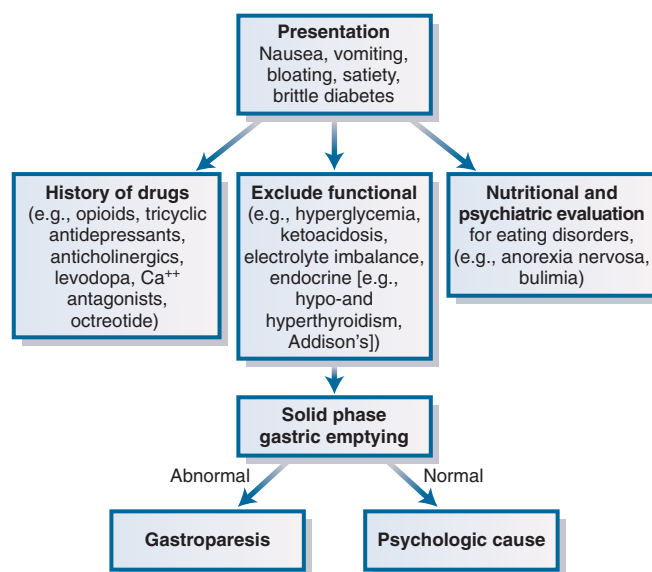

Figure 33-50 Evaluation of the patient with suspected gastroparesis. (Adapted with permission from Vinik A, Mehrabian A. Diabetic neuropathies. *Med Clin North Am.* 2004;88:947-999.)

Enteropathy. Enteropathy involving the small bowel and colon can produce both chronic constipation and explosive diabetic diarrhea, making treatment of this particular complication difficult.

Antibiotics. Stasis of bowel contents with bacterial overgrowth can contribute to the diarrhea. Treatment with broad-spectrum antibiotics is the mainstay of therapy, including tetracycline or trimethoprim-sulfamethoxazole. Metronidazole appears to be the most effective agent and should be continued for at least 3 weeks.

Cholestyramine. Retention of bile can occur and can be highly irritating to the gut. Chelation of bile salts with cholestyramine, 4 g mixed with fluid three times a day, can relieve symptoms.

Diphenoxylate plus Atropine. Diphenoxylate plus atropine can help to control the diarrhea. However, toxic megacolon can occur, and extreme care should be used.

Diet. Patients with poor digestion can benefit from a gluten-free diet. Beware of certain fibers in the neuropathic patient that can lead to bezoar formation because of bowel stasis in gastroparetic or constipated patients.

Sexual Dysfunction

Male Sexual Dysfunction. Erectile dysfunction (ED) occurs in 50% to 75% of diabetic men, and it tends to occur at an earlier age than in the general population. The incidence of ED in diabetic men aged 20 to 29 years is 9% and increases to 95% by age 70 years. It may be the presenting symptom of diabetes. More than 50% of men who develop ED notice its onset within 10 years after the diagnosis of diabetes, but ED can precede the other complications of diabetes.

The etiology of ED in diabetes is multifactorial. Neuropathy, vascular disease, diabetes control, nutrition, endocrine disorders, psychogenic factors, and drugs used to treat diabetes and its complications play a role.^{786,787} The diagnosis of the cause of ED is made by a logical, stepwise progression in all instances.^{786,787} An approach to therapy has been presented and is discussed later in this chapter.⁷⁸⁶

Diagnosis. A thorough workup for impotence includes a medical and sexual history; physical and psychological evaluations; blood tests for diabetes and to check levels of testosterone, prolactin, and thyroid hormones; a test for nocturnal erections; tests to assess penile, pelvic, and spinal nerve function; and tests to assess penile blood supply and BP.

The health care provider should initiate questions that will help distinguish the various forms of organic ED from those that are psychogenic. The physical examination must include evaluations of the ANS, vascular supply, and hypothalamic-pituitary-gonadal axis.

Autonomic neuropathy causing ED is almost always accompanied by loss of ankle jerks and absence or reduction of vibration sense over the large toes. More direct evidence of impairment of penile autonomic function can be obtained by demonstrating normal perianal sensation, assessing the tone of the anal sphincter during a rectal examination, and ascertaining the presence of an anal wink when the area of the skin adjacent to the anus is stroked or contraction of the anus when the glans penis is squeezed (bulbo-cavernosus reflex). These measurements are easily and quickly done at the bedside and reflect the integrity of sacral parasympathetic divisions.

Vascular disease is usually manifested by buttock claudication but may be caused by stenosis of the internal pudendal artery. A penile-brachial index of less than 0.7 indicates diminished blood supply. A venous leak

TABLE 33-12

Pharmacologic Treatment of Autonomic Neuropathy

Drug	Class	Dosage	Side Effects
Orthostatic Hypotension			
9 α -Fluorohydrocortisone	Mineralocorticoid	0.5-2 mg/day	Congestive heart failure, hypertension
Clonidine	α_2 -Adrenergic agonist	0.1-0.5 mg at bedtime	Hypotension, sedation, dry mouth
Octreotide	Somatostatin analogue	0.1-0.5 μ g/kg per day	Injection site pain, diarrhea
Gastroparesis			
Metoclopramide	D ₂ -Receptor antagonist	10 mg 30-60 min before meals and at bedtime	Galactorrhea, extrapyramidal symptoms
Domperidone	D ₂ -Receptor antagonist	10-20 mg 30-60 min before meals and at bedtime	Galactorrhea
Erythromycin	Motilin receptor agonist	250 mg 30 min before meals	Abdominal cramp, nausea, diarrhea, rash
Levosulfide	D ₂ -Receptor antagonist	25 mg tid	Galactorrhea
Diabetic Diarrhea			
Metronidazole	Broad-spectrum antibiotic	250 mg tid, minimum 3 wk	Orthostatic hypotension
Clonidine	α_2 -Adrenergic agonist	0.1 mg bid or tid	Toxic megacolon
Cholestyramine	Bile acid sequestrant	4 g 1-6 times/day	Aggravates nutrient malabsorption (at higher doses)
Loperamide	Opiate-receptor agonist	2 mg qid	
Octreotide	Somatostatin analogue	50 μ g tid	
Cystopathy			
Bethanechol	Acetylcholine receptor agonist	10 mg, 4 times/day	
Doxazosin	α_1 -Adrenergic antagonist	1-2 mg, 2-3 times/day	Hypotension, headache, palpitations
Erectile Dysfunction			
Sildenafil	GMP type 5 phosphodiesterase inhibitor	50 mg before sexual activity, only once per day	Hypotension and fatal cardiac event (with nitrate-containing drugs), headache, flushing, nasal congestion, dyspepsia, musculoskeletal pain, blurred vision

D₂, dopamine 2; GMP, guanosine monophosphate.

manifests as unresponsiveness to vasodilators and needs to be evaluated by penile Doppler sonography.

To distinguish psychogenic from organic erectile dysfunction, nocturnal penile tumescence (NPT) can be tested. Normal NPT defines psychogenic ED, and a negative response to vasodilators implies vascular insufficiency. Application of NPT is not so simple. It is much like having a sphygmomanometer cuff inflate over the penis many times during the night while one is trying to have a normal night's sleep. The patient might have to take home the device and become familiar with it over several nights before a reliable estimate of the failure of NPT can be obtained.

Treatment. A number of treatment modalities are available, and each has positive and negative effects. Patients must be made aware of positive and negative aspects before a therapeutic decision is made. Before any form of treatment is considered, every effort should be made to have the patient withdraw from alcohol and eliminate smoking. The patient should be removed, if possible, from drugs that are known to cause ED. Metabolic control should be optimized.

Relaxation of the corpus cavernosa smooth muscle cells is caused by NO and cGMP, and the ability to have and maintain an erection depends on the generation of NO. The peripherally acting phosphodiesterase inhibitors are the major oral medications for erectile dysfunction in diabetic patients. The PDE5 inhibitors block the action of phosphodiesterase and permit cGMP to accumulate. This class of agents consists of sildenafil, vardenafil, and tadalafil. These agents enhance blood flow to the corpora cavernosa with sexual stimulation and have been evaluated in

diabetic patients with efficacy of about 70%. Generally, people with diabetes and ED require the maximum dose of each drug: sildenafil 100 mg, tadalafil 20 mg, and vardenafil 20 mg. Lower doses should be considered in patients with renal failure and hepatic dysfunction. The duration of the drug effect is 4 to 24 hours but may be prolonged. Before these drugs are prescribed, it is important to exclude ischemic heart disease. These drugs are absolutely contraindicated in patients being treated with nitroglycerine or other nitrate-containing drugs because severe hypotension and fatal cardiac events can occur.^{725,788}

Direct injection of prostacyclin into the corpus cavernosum induces satisfactory erections in a significant number of men. Also, surgical implantation of a penile prosthesis may be appropriate. The less expensive type of prosthesis is a semirigid, permanently erect type that is embarrassing and uncomfortable for some patients. The inflatable type is three times more expensive and subject to mechanical failure, but it avoids the embarrassment caused by other devices.

Female Sexual Dysfunction. Women with diabetes mellitus can experience decreased sexual desire and more pain on sexual intercourse, but they are also at risk for decreased sexual arousal, with inadequate lubrication.⁷⁸⁹ Diagnosis of female sexual dysfunction using vaginal plethysmography to measure lubrication and vaginal flushing has not been well established.

Cystopathy. In diabetic autonomic neuropathy, the motor function of the bladder is unimpaired, but afferent fiber damage results in diminished bladder sensation. The urinary bladder can be enlarged to more than three times

its normal size. Patients are seen with bladders filled to their umbilicus, yet they feel no discomfort. Loss of bladder sensation occurs with diminished voiding frequency, and the patient is no longer able to void completely. Consequently, dribbling and overflow incontinence are common complaints. A postvoid residual of greater than 150 mL diagnoses cystopathy. Cystopathy can put patients at risk for urinary infections.

Patients with cystopathy should be instructed to palpate the bladder and, if they are unable to initiate micturition when their bladder is full, to use Crede's maneuver (massage or pressure on the lower portion of the abdomen just above the pubic bone) to start the flow of urine. The principal aim of the treatment should be to improve bladder emptying and to reduce the risk of urinary tract infection. Parasympathomimetics such as bethanechol are sometimes helpful, although often they do not help to fully empty the bladder. Extended sphincter relaxation can be achieved with an α_1 -blocker, such as doxazosin.⁶⁰⁷ Self-catheterization can be particularly useful in this setting, and the risk of infection generally is low.

Sweating Disturbances

Hyperhidrosis of the upper body, often related to eating (gustatory sweating), is a characteristic feature of autonomic neuropathy. Gustatory sweating accompanies the ingestion of certain foods, particularly spicy foods and cheeses. Gustatory sweating is more common than previously believed, and topically applied glycopyrrolate (an antimuscarinic compound) is a very effective treatment in reducing both severity and frequency.^{790,791} Symptoms are avoided by avoiding the inciting food.

Anhidrosis of the lower body is also common in autonomic neuropathy. Loss of lower body sweating can cause dry, brittle skin that cracks easily, predisposing the patient to ulcer formation that can lead to loss of a limb. Special attention must be paid to foot care.

Metabolic Dysfunction

Blood glucose concentration is normally maintained during starvation or increased insulin action by an asymptomatic parasympathetic response that includes bradycardia and mild hypotension, followed by a sympathetic response with glucagon and epinephrine secretion for short-term glucose counterregulation and growth hormone and cortisol for long-term regulation. The release of catecholamine alerts the patient to take the required measures to prevent coma due to low blood glucose. The absence of warning signs of impending neuroglycopenia is known as *hypoglycemic unawareness*. The failure of glucose counterregulation can be confirmed by the absence of glucagon and epinephrine responses to hypoglycemia induced by a standard controlled dose of insulin.⁷⁹²

In patients with T1DM, the glucagon response is impaired with diabetes duration of 1 to 5 years, and after 14 to 31 years of diabetes the glucagon response is almost undetectable. It is not present in those with autonomic neuropathy. However, a syndrome of hypoglycemic autonomic failure occurs with intensification of diabetes control and repeated episodes of hypoglycemia. The exact mechanism is not understood, but it does represent a real barrier to physiologic glycemic control. In the absence of severe autonomic dysfunction, hypoglycemic unawareness associated with hypoglycemia is at least in part reversible.

Patients with hypoglycemia unawareness and unresponsiveness pose a significant management problem for the

physician. Although autonomic neuropathy can improve with intensive therapy and normalization of blood glucose, there is a risk to the patient, who may become hypoglycemic without being aware of it and who cannot mount a counterregulatory response. It is our recommendation that, if a pump is used, boluses of smaller than calculated amounts should be used. If intensive conventional therapy is used, long-acting insulin with very small boluses should be given. In general, to prevent hypoglycemia in these patients, normal glucose and HbA_{1c} levels should not be goals.⁷⁹³

Further complicating management in some diabetic patients is the development of a functional autonomic insufficiency associated with intensive insulin treatment, which resembles autonomic neuropathy in all relevant aspects. In these instances, it is prudent to relax therapy, as for the patient with bona fide autonomic neuropathy. If hypoglycemia occurs in these patients at a certain glucose level, it will take a lower glucose level to trigger the same symptoms in the next 24 to 48 hours. Avoidance of hypoglycemia for a few days results in recovery of the adrenergic response.

CORONARY HEART DISEASE

The last decades have witnessed substantial declines in coronary heart disease (CHD) mortality in the general population in the United States, but the improvement in CHD mortality has been significantly lower in diabetic men and women.⁷⁹⁴ More than 90% of all patients with diabetes have T2DM, and it is this population (mostly middle-aged and elderly) that has been evaluated in most of the studies of CHD risk. In these studies, the excess morbidity and mortality associated with diabetes and elevated glucose remained even after adjustment for traditional CHD risk factors.

Effect of Diabetes on Risk of Coronary Heart Disease

The Framingham Study showed a twofold to threefold elevation in the risk of clinically evident atherosclerotic disease in patients with T2DM compared to those without diabetes.⁷⁹⁵ Diabetic men in the Multiple Risk Factor Intervention Trial (MRFIT) had an absolute risk of CHD death more than three times higher than that of the nondiabetic cohort, even after adjustment for established risk factors.⁵¹ Seminal work from Finland showed that patients with T2DM without a previous MI have a risk of MI over 7 years as high as that of nondiabetic patients with a history of MI (Fig. 33-51).⁶² In this study, the case-fatality rate after MI was also substantially higher in patients with diabetes. In women, diabetes mitigates the cardioprotective effects of the premenopausal period, and women with diabetes had a CHD mortality rate as high as that of diabetic men.

The risk of cardiovascular mortality and events conferred by T2DM has been examined in several prospective and observational trials with varying populations of patients.⁷⁹⁶⁻⁷⁹⁹ Prospective data from the Organization to Assess Strategies for Ischemic Syndromes (OASIS) registry was analyzed to determine the effect of diabetes on outcomes of patients with unstable angina and non-Q-wave MI.⁷⁹⁶ Patients with diabetes had a significantly increased adjusted RR for total mortality (1.57; 95% CI, 1.38 to 1.81; $P < .001$), death due to CVD (1.49; 95% CI, 1.27 to 1.74; $P < .001$), new MI (1.34; 95% CI, 1.14 to 1.57, $P < .001$), stroke (1.45; 95% CI, 1.09 to 1.92, $P = .009$), and new CHF

Figure 33-51 Marked increase in the risk of coronary artery disease in patients with type 2 diabetes mellitus (DM) compared with nondiabetic subjects, in a population-based study in Finland, over a 7-year follow-up period. Patients with diabetes who had no previous myocardial infarction (MI) had a risk of first MI approximately equal to that of nondiabetic subjects who had already sustained an MI. These data support recommendations from the American Diabetes Association to treat diabetic subjects as if they already have established coronary artery disease. (From Haffner SM, Lehto S, Ronnemaa T, et al. Mortality from coronary heart disease in subjects with type 2 diabetes and in nondiabetic subjects with and without prior myocardial infarction. *N Engl J Med*. 1998;339:229-234.)

(1.41; 95% CI, 1.24 to 1.60, $P < .001$). Diabetic patients without prior CVD had the same event rates for all outcomes as nondiabetic patients with previous vascular disease.

In another prospective cohort trial,⁷⁹⁷ the adjusted hazard ratio (HR) for overall mortality in diabetic patients ($n = 393$) after a first MI was 1.5 (95% CI, 1.1 to 2.0) compared with equivalent nondiabetic patients ($n = 1132$). The HR for cardiovascular mortality in diabetic patients was similar to that in nondiabetic patients who had experienced a previous MI. The risk of mortality from all causes was significantly higher in women than in men (adjusted HR, 2.7 versus 1.3, $P = .01$).

In contrast to these findings, two large observational trials failed to find that diabetes conferred equivalent or greater risk of mortality than previous MI.^{799,800} In the cross-sectional study, RR for all-cause mortality was 1.33 (95% CI, 1.14 to 1.55) for patients with MI compared to patients with T2DM. In the cohort study, patients with MI also had a significantly higher risk of all-cause death (adjusted RR, 1.35; 95% CI, 1.25 to 1.44), cardiovascular death (RR, 2.93; 95% CI, 2.54 to 3.41), and hospital admission for MI (RR, 3.1; 95% CI, 2.57 to 3.73). Based on these findings, the authors concluded that established CVD confers greater risk than diabetes.⁷⁹⁸

The risk of mortality conferred by diabetes was also assessed in the Atherosclerosis Risk in Communities (ARIC) study, a population-based cohort study that investigated the etiology of atherosclerosis in a biracial population in the United States.⁷⁹⁹ Patients with prior MI had an adjusted RR of 1.9 (95% CI, 1.35 to 2.56; $P < .001$) for fatal CHD or nonfatal MI and adjusted RR of 1.8 (95% CI, 1.22 to 2.72; $P = .003$) for fatal CHD or nonfatal MI, compared to the patients with diabetes and no previous MI. There was no significant difference in the risk of stroke in the two groups.

All of these studies demonstrated that diabetes alone results in a significantly increased risk of CVD. The strategy of considering diabetes as a CHD risk equivalent for purposes of assessing risk and defining a treatment regimen is appropriate.

The risk of CHD has also been evaluated in small subsets of patients with T1DM. In the Framingham Study, the cumulative CAD mortality in patients with T1DM was approximately four times that of nondiabetic patients by age 55 years.⁸⁰⁰ As in patients with T2DM, the first deaths related to CAD in patients with T1DM occurred by the fourth decade of life, and the cumulative mortality increased at a similar rate in both groups in the subsequent 20 years. The rise in CAD mortality with age in patients with T1DM is substantially higher in those patients with nephropathy. In these patients, the risk of CAD can be as much as 15 times higher than in patients without persistent proteinuria. Therefore, persistent proteinuria is a strong predictor of the development of CAD in this population. These findings suggest that proteinuria is a marker of generalized vascular damage that predisposes to CVD.

Two prospective epidemiologic studies, the Pittsburgh Epidemiology of Diabetes Complications study (EDC)⁸⁰¹ and Eurodiab,⁸⁰² a multicenter, clinic-based study in Europe, confirmed the Framingham findings and reported an incidence of total coronary events of 16% over 10 years and 9% over 7 years of follow-up in patients with T1DM. These incidence rates presumably reflect patients in their late 30s, 10 years beyond baseline age in the studies. In EDC, the total incidence of CAD (including angina and ischemic electrocardiographic changes) was more than 2% per year for those older than 35 years. A more recent report, using 12-year follow-up data,⁸⁰³ proposed that the annual rate of major CAD events (MI, fatal CAD, or revascularization) is 0.98% for those with diabetes duration of 20 to 30 years (average age, 28 to 38 years). The event rates are identical for both genders, consistent with a loss of the protection from CHD mortality in premenopausal women with diabetes.

The follow-up of the Diabetes UK cohort, a group of 23,751 subjects with insulin-treated diabetes diagnosed before the age of 30 years, also showed similar mortality rates for men and women, and the size of this cohort permitted robust gender-specific estimates of standardized mortality ratios (SMRs).⁸⁰⁴ Among those aged 20 to 29 years, the SMRs for ischemic heart disease mortality were 11.8 in men and 44.8 in women; for those aged 30 to 39 years, the SMRs were 8.0 and 41.6, respectively. Other forms of CVD, such as hypertension, valvular disease, cardiomyopathy, heart failure, and stroke, were also increased.

It is unclear whether there has been any recent decline in mortality or morbidity from CHD associated with T1DM. The Pittsburgh EDC reported no difference in the cumulative incidence of CAD with 20, 25, or 30 years' disease duration according to year of diagnosis (1950 through 1980).⁸⁰³ The benefits of improved diabetes care therefore do not appear to have reduced CAD mortality associated with T1DM.

Aggregation of Traditional Coronary Heart Disease Risk Factors in Diabetes

It is now well established that a number of traditional CHD risk factors (e.g., hypertension, dyslipidemia, obesity, insulin resistance) tend to occur together in patients with diabetes.⁸⁰⁵ Approximately 50% of patients with diabetes have hypertension, and more than 30% have hypercholesterolemia at the time of diagnosis. As in nondiabetic

Figure 33-52 Age-adjusted cardiovascular disease (CVD) death rates by number of risk factors for men with and without diabetes at baseline screened for the Multiple Risk Factor Intervention Trial. In the presence of diabetes, the cardiovascular death rate steeply rises at any level of concomitant risk factors. SBP, systolic blood pressure. (From Stamler J, Vaccaro O, Neaton JD, et al. Diabetes, other risk factors, and 12-year cardiovascular mortality for men screened in the Multiple Risk Factor Intervention Trial. *Diabetes Care*. 1993;16:434-444.)

patients, these risk factors independently predict the risk of CVD mortality.⁵¹ However, even in the presence of one or more concomitant risk factors, diabetes increases the CVD death rate (Fig. 33-52). It also appears that diabetes interacts synergistically with other risk factors to more sharply increase risk as the number of total risk factors increases.

There are data suggesting that the cardiovascular risk associated with T2DM is a consequence of insulin resistance during the prediabetic state.⁸⁰⁶ A population-based study of diabetes and CVD monitored Mexican American and non-Latin American white subjects for 7 years. Those subjects who converted to diabetes from a prediabetic state and who were insulin resistant had higher BP, higher triglyceride levels, and lower HDL-cholesterol levels. These CVD risk factors suggest that the atherogenic changes seen during the prediabetic state are primarily associated with increased insulin resistance and that treatment strategies that increase insulin secretion in these patients can reduce cardiovascular risk.

Other studies have also concluded that impaired insulin sensitivity during the prediabetic state contributes to atherogenic risk.⁸⁰⁷ Prediabetic subjects who were insulin resistant had higher levels of inflammatory markers (C-reactive protein, PAI-1, and fibrinogen) than converters with predominantly low insulin secretion or nonconverters. Therefore, a proinflammatory state can contribute to the atherogenic risk profile in prediabetic patients with increased insulin resistance. Evidence of inflammation is not seen in prediabetic patients with a primary defect in insulin secretion.

The UKPDS further confirmed the importance of risk factor aggregation in diabetic patients. In this large population of patients with newly diagnosed T2DM, the development of CAD during follow-up was significantly associated with increased concentrations of LDL-cholesterol, decreased concentrations of HDL-cholesterol, increased levels of HbA_{1c}, and systolic BP, and a history of smoking measured at baseline.⁸⁰⁸

Given the multifactorial nature of atherogenic risk in patients with T2DM, it is reasonable to conclude that an aggressive multifactorial intervention could significantly

reduce cardiovascular risk. The value of such a treatment regimen was tested in the Steno-2 study,⁵⁶¹ in which 160 patients with T2DM and microalbuminuria were randomized to receive either conventional treatment in accordance with national guidelines or intensive therapy that included behavior modification and targeted pharmacologic therapy for hyperglycemia, hypertension, dyslipidemia, and microalbuminuria along with secondary prevention of CVD with aspirin. Over a mean follow-up period of 7.8 years, patients who received intensive treatment had greater improvements in HbA_{1c}, BP, fasting serum cholesterol and triglyceride values, and urinary albumin excretion than patients receiving conventional therapy. The greater degree of improvement in risk factors with intensive therapy was also reflected in outcomes. Patients receiving intensive therapy had a significantly lower risk of CVD (HR 0.47; 95% CI, 0.24 to 0.73), nephropathy (HR 0.39; 95% CI, 0.17 to 0.87), retinopathy (HR 0.42; 95% CI, 0.21 to 0.86), and autonomic neuropathy (HR 0.37; 95% CI, 0.18 to 0.79). Overall, long-term intensive treatment of risk factors reduced the risk of CVD and microvascular events by about 50%.⁵⁶¹

Plasma Glucose and Insulin Resistance as Independent Risk Factors for Atherosclerosis

Hyperglycemia may be responsible for the high excess risk of CHD that cannot be accounted for by the interaction of multiple risk factors alone. This association appears to be graded and continuous, without a clear threshold below which the relationship ends. One study showed that mortality from all causes, CVD, and ischemic heart disease increased progressively across quintiles of fasting blood glucose levels in patients with T2DM (Fig. 33-53).⁸⁰⁹ Other data suggest a dose-response relationship between hyperglycemia and CVD mortality in diabetes, with patients with the highest levels of fasting blood glucose having a CVD mortality rate almost five times higher than patients with the two lowest levels combined.⁸¹⁰

Figure 33-53 All-cause mortality, cardiovascular mortality, and ischemic heart disease mortality in patients with type 2 diabetes mellitus by quintiles of average fasting blood glucose (FBG). Cardiovascular mortality and all-cause mortality increase throughout the range of fasting plasma glucose in a graded fashion. (From Andersson DK, Svardudd K. Long-term glycemic control relates to mortality in type II diabetes. *Diabetes Care*. 1995;18:1534-1543.)

In a more recent study of the relationship between blood glucose cardiovascular mortality, 17,869 male civil servants enrolled in the Whitehall Study from 1967 to 1969 were monitored, and outcomes were correlated with baseline measurements of the 2-hour postload blood glucose (2hBG) level after a 50-g oral glucose load.⁸¹¹ In these subjects, the HR for CHD mortality increased as a linear function of 2hBG for all values of 2hBG greater than 83 mg/dL. With 2hBG values between 83 and 200 mg/dL, the age-adjusted HR for CHD was 3.62 (95% CI, 2.3 to 5.6).

Tominaga and colleagues examined survival rates in a cohort of participants in a diabetes prevalence trial in Japan⁸¹² and concluded that the risk of cardiovascular mortality is based on impaired glucose tolerance rather than impaired fasting glucose.

Further substantiation of the role of impaired glucose tolerance in cardiovascular mortality risk was provided by an analysis of data from the Diabetes Epidemiology: Collaborative analysis of Diagnostic criteria in Europe (DECODE) study.⁸¹³ In this study, more than 25,000 men and women were monitored for a mean of 7.3 years, and outcomes were correlated with measurements of fasting glucose and 2hBG after a 75-mg glucose load at baseline. The results indicated that the oral glucose tolerance test provides the best index of risk of mortality associated with impaired glucose tolerance.

The Nurses' Health Study also implicated the prediabetic state as a risk factor for CVD.⁸¹⁴ In this large cohort of women, 5894 developed diabetes over a 20-year follow-up. In this group, the age-adjusted RR for MI was 3.75 (95% CI, 3.10 to 4.53) in the period before diagnosis of diabetes and 4.57 (95% CI, 3.87 to 5.39) after diagnosis, compared with women who did not develop diabetes, even after adjustment for other cardiovascular risk factors. The risk of stroke was also increased before onset of diabetes.

The continuum of CVD risk with rising glucose levels has also been identified in patients with T1DM⁸¹⁵ and in subjects without clinically overt diabetes but with varying levels of glucose intolerance.⁸¹⁶ Hyperglycemia also has adverse effects on the vessel wall as judged by objective assessment of CIMT.^{6,817-819}

The Metabolic Syndrome

Definitions and Diagnosis

Almost all patients with diabetes and the concomitant CVD risk factors of hypertension, obesity, and dyslipidemia also have insulin resistance.⁶¹ The clustering of these risk factors in a single patient has been termed the *metabolic syndrome*. Although there is general agreement on the components of the metabolic syndrome (i.e., obesity, hypertension, dyslipidemia, and dysfunctional glucose metabolism), the criteria for clinical diagnosis are still under discussion. Separate sets of diagnostic criteria for the metabolic syndrome have been published by the National Cholesterol Education Program (NCEP) Adult Treatment Panel III (ATP III),⁸²⁰ by the World Health Organization (WHO),⁸²¹ and by the International Diabetes Federation (IDF).⁸²²

According to the NCEP guidelines,⁸²⁰ the metabolic syndrome is based on the presence of three of the following five risk factors⁸²⁰:

- Abdominal obesity (waist circumference <40 inches in men, <35 inches in women)
- Plasma triglycerides 150 mg/dL or higher
- Plasma HDL-cholesterol <40 mg/dL in men, <50 mg/dL in women
- Blood pressure 130/85 mm Hg or higher
- Fasting plasma glucose 110 mg/dL or higher

The NCEP criteria give precedence to obesity as a contributor to the metabolic syndrome and apply cutpoints for triglycerides and HDL that are probably less stringent than would be used to identify a categorical risk factor, reflecting the fact that many marginal risk factors can result in a significant risk for CVD. The NCEP criteria do not require explicit demonstration of insulin resistance for diagnosis of the metabolic syndrome, and patients with diabetes are not excluded from the diagnosis.⁸²¹ There are modest differences between the NCEP criteria and those developed by the WHO⁸²¹ and the IDF.⁸²²

Epidemiology

The prevalence of the metabolic syndrome in the United States, as defined by the NCEP criteria, has been estimated from the National Health and Nutrition Examination Survey (NHANES) database.⁸²³ Based on data from the third NHANES (1988-1994) survey, the overall age-adjusted prevalence of the metabolic syndrome was 23.7%. The prevalence increased with age, ranging from 6.7% in subjects aged 20 to 29 years to 43.5% in subjects aged 60 to 69 years. There were also differences in prevalence based on ethnicity, with the highest overall prevalence among Mexican Americans (31.9%).

The Metabolic Syndrome and Cardiovascular Disease

The impact of metabolic syndrome on incidence and mortality of CVD has been examined in several studies.⁸²⁴⁻⁸²⁶ A Finnish prospective cohort study showed that the age-adjusted RR for CHD mortality was 2.96 (95% CI, 1.30 to 6.76), compared to patients without this condition. Similar increases in risk were also noted for CVD mortality (RR, 2.76; 95% CI, 1.45 to 5.24) and all-cause mortality (RR, 2.05; 95% CI, 1.31 to 3.21). Similar degrees of increase in risk with the metabolic syndrome were also seen when other diagnostic criteria were used.

In the United States, NHANES II studied the impact of the metabolic syndrome on CVD mortality.⁸²⁷ The HRs for CHD mortality and CVD mortality were 1.65 (95% CI, 1.10 to 2.47; $P = .02$) and 1.56 (95% CI, 1.15 to 2.12, $P = .005$), respectively, compared to subjects without the metabolic syndrome.

The West of Scotland Coronary Prevention Study⁸²⁶ also demonstrated increased risk of CHD in patients with the metabolic syndrome. In this study, elevated C-reactive protein was more common in subjects with the metabolic syndrome and added to the prognostic value for both CHD and diabetes.

A summary of all of the studies assessing the increased risk of mortality, CVD, and diabetes associated with the metabolic syndrome was published in 2005.⁸²⁷ Studies that used NCEP and WHO diagnostic criteria for defining the metabolic syndrome were analyzed separately. For three studies that used the exact NCEP definition of the metabolic syndrome, the increased risk of all-cause mortality was not significant. For seven studies that used the NCEP definition, the RR for CVD was 1.65 (95% CI, 1.38 to 1.99). Inclusion of four other studies that used a modified NCEP definition did not appreciably change the RR. In four studies that used the NCEP definition, the RR for diabetes was 2.99 (95% CI, 1.96 to 4.57). For studies that used the most exact WHO definition of the metabolic syndrome, the fixed-effects estimates of RR were 1.37 (95% CI, 1.09 to 1.74) for all-cause mortality, 1.93 (95% CI, 1.39 to 2.67) for CVD, and 6.08 (95% CI, 4.76 to 7.76) for diabetes.

Clinical guidelines for diagnosis and management of the metabolic syndrome were addressed in 2005 in a joint

TABLE 33-13

Treatment Goals for Prevention of Coronary Heart Disease in Patients with Diabetes

Glycosylated hemoglobin (HbA_{1c}) ≤6.2%
 Low-density lipoprotein cholesterol ≤100 mg/dL
 Blood pressure ≤130/85 mm Hg
 Aspirin 81-325 mg/day

statement by the American Heart Association and the National Heart, Lung, and Blood Institute summarizing available steps for managing the risk factors associated with the metabolic syndrome.⁸²⁸

It has been hypothesized that hyperinsulinemia is the underlying link between hyperglycemia and CVD in these patients.⁸²⁹ A number of studies have shown hyperinsulinemia to be an independent predictor of CVD risk. Furthermore, in patients spanning the spectrum of glucose tolerance, from normal to hyperglycemic to diabetic, insulin resistance positively correlates with atherosclerosis as assessed by CIMT.⁸³⁰

The San Antonio Heart Study, a population-based study of diabetes and CVD in Mexican Americans and non-Latin American whites, confirmed the relationship between insulin resistance or plasma insulin and CVD.⁶⁷

The Role of Glycemic Control

The UKPDS confirmed the positive association between plasma glucose levels and CHD risk for HbA_{1c} levels greater than 6.2% in patients with diabetes.⁸²⁹ CHD risk increased by 11% with each percentage point elevation in HbA_{1c} (Table 33-13). The question remains, however, whether intensive glycemic control can modify the cardiovascular risk profile of patients with diabetes.

Earlier studies, such as the DCCT and the smaller Veterans Affairs (VA) study, did not show a reduction in cardiovascular end points with intensive metabolic control. These studies had limitations, however. Although relatively large (N = 1441), the DCCT followed a relatively young (mean age, 27 years) population of patients with T1DM for more than 6 years. At the end of follow-up, few events had occurred.² Intensive therapy reduced the risk of CVD and peripheral vascular disease by 41% compared with conventional therapy, but the difference was not statistically significant. Similarly, in the VA study, intensive blood glucose control in patients with T2DM did not significantly reduce cardiovascular end points.⁸³¹ Both studies lacked adequate power to detect a difference in macrovascular events between treatment groups because of the small number of events in each group, small patient populations, and relatively short follow-up.

A 17-year follow-up of 1441 patients from the DCCT trial more unambiguously demonstrated the benefit of intensive glycemic control in T1DM.⁸³² This was part of the observational Epidemiology of Diabetes Interventions and Complications (EDIC) study. During follow-up, intensive treatment reduced the risk of CVD by 42% ($P = .02$) and the risk of nonfatal MI, stroke, or death from CVD by 57% ($P = .02$). After 11 years of follow-up, the treatment groups were virtually identical in terms of HbA_{1c}, BP, and lipid risk factors. Patients in the conventional treatment group had more albuminuria and microalbuminuria than intensively treated patients, but the differences in risk remained significant after adjustment for these factors. These findings indicate that intensive glycemic control reduced the long-term risk of CVD in patients with T1DM.

The UKPDS was larger and was adequately powered to detect a difference between groups in macrovascular events.³ Intensive glycemic control trended toward demonstrating a lower rate of MI than conventional treatment ($P = .052$).³ As in the DCCT, intensive therapy in the UKPDS significantly improved the rate of microvascular disease.

Despite the lack of overall efficacy of intensive treatment for management of macrovascular complications of diabetes in the UKPDS, there are indications that specific therapies may be effective.³ In a retrospective analysis of an overweight subset ($n = 342$) of the UKPDS cohort who were treated with metformin, there were significant reductions in the occurrence of any diabetes-related end point (32%), diabetes-related death (42%), and all-cause mortality (36%), compared with conventionally treated patients.

Two studies have suggested that thiazolidinediones can prevent macrovascular events associated with T2DM. Because these drugs work by increasing insulin sensitivity rather than by increasing insulin levels, this finding is consistent with data showing that insulin resistance is positively correlated with cardiovascular outcomes (described earlier). Sidhu and colleagues demonstrated that 8 weeks of treatment with rosiglitazone 4 mg daily significantly reduced progression of thickening of the common carotid intima-media, a surrogate index of atherosclerotic disease progression, compared with placebo treatment in nondiabetic patients who had established CAD.⁸³⁰ In the PROactive study (PROspective pioglitAzone Clinical Trial In macroVascular Events), 5238 patients with T2DM and evidence of macrovascular disease were randomized to receive or not receive pioglitazone in addition to glucose-lowering drugs and other medications.⁸³³ After a mean of 34.5 months, there was no significant difference in the two treatment groups in terms of the primary end point of the study, a composite of all-cause mortality, nonfatal MI, stroke, acute coronary syndrome, surgical intervention in the leg or coronary arteries, and amputation above the ankle. However, patients treated with pioglitazone had significantly lower risk for the secondary end point of composite all-cause mortality, nonfatal MI, and stroke, (HR 0.84; 95% CI, 0.80 to 1.02; $P = .027$). Compared with placebo, pioglitazone also significantly reduced the need to add insulin to glucose-lowering regimens.

Despite the effect of thiazolidinediones in these studies, the putative beneficial effect of rosiglitazone on CVD was challenged by a meta-analysis conducted by Nissen and coworkers that examined short-term trials designed to assess the effect of rosiglitazone on glycemic control and suggested that rosiglitazone was associated with a significant risk of excess MI. The studies in this meta-analysis did not examine cardiovascular events as primary end points and the cardiovascular events were not adjudicated. In contrast, another meta-analysis, conducted by Lago and associates, examined only randomized clinical trials in which cardiovascular end points were prespecified as events of interest or in which such events were adjudicated. This examination did not show that either rosiglitazone or pioglitazone conferred an excess risk of cardiovascular death.⁸³⁵

Three recent trials have examined whether lowering the target for glycemic control (to <7%) can reduce the risk for cardiovascular events. The ACCORD trial randomized patients with T2DM who had established CVD or multiple risk factors to a treatment-directed HbA_{1c} value lower than 7.0% or to standard therapy with an HbA_{1c} target value between 7.0% and 7.9%. Over 3.5 years of follow-up, total mortality was increased in the intensively treated group, and there was no significant reduction in cardiovascular events.⁸³⁶ The VADT randomized patients to either

intensive treatment (HbA_{1c} 6.9%) or standard therapy (HbA_{1c} 8.4%); it also did not demonstrate a reduction in cardiovascular events in the former group.⁸³⁷ The ADVANCE trial randomly assigned patients to an intensively treated group attaining an HbA_{1c} of 6.5% or a standard-control group attaining an HbA_{1c} of 7.3%; it demonstrated a relative reduction of 10% in the combined outcome of major macrovascular and microvascular events, primarily due to a 21% reduction in nephropathy.⁸³⁸ Taken together, these three studies do not support treatment to an HbA_{1c} value lower than the currently recommended 7.0% as a strategy to reduce cardiovascular events, despite the epidemiologic relationship between cardiovascular risk and HbA_{1c}.

The Bypass Angioplasty Revascularization Investigation 2 Diabetes (BARI 2D) trial randomized 2368 patients with T2DM and CAD to either prompt revascularization or intensive medical therapy alone, and to either insulin-sensitization or insulin-provision diabetes therapy. Randomization was stratified by the proposed revascularization method. The 5-year survival and major cardiovascular event rates were similar in all study subgroups except for those patients undergoing coronary artery bypass grafting (CABG), who had fewer major cardiovascular events after revascularization. There was less hypoglycemia and weight gain and greater apparent benefit from CABG in the insulin-sensitization group.

Dyslipidemia and Its Treatment in Patients with Diabetes Mellitus

Dyslipidemia is the best-characterized risk factor for increasing atherosclerosis in patients with T2DM. A number of features of dyslipidemia are uniquely associated with diabetes and appear to increase the predisposition to atherogenesis. Although patients with diabetes tend not to have marked elevations in plasma LDL-cholesterol levels, their LDL-cholesterol particles are generally smaller and more dense than typical LDL-cholesterol particles. These small, dense LDL-cholesterol particles are more susceptible to oxidation, particularly in the setting of poor glucose control. Other evidence suggests that glycation of LDL may be enhanced in diabetes, impairing recognition of the lipoprotein by its hepatoreceptor and extending its half-life. Conversely, levels of the cardioprotective lipid fraction, HDL-cholesterol, are decreased in patients with diabetes. The HDL-cholesterol of these patients may also be less effective at protecting LDL-cholesterol from oxidative stress, one of the proposed mechanisms for the cardioprotective effect of HDL-cholesterol.⁸³⁹

Undoubtedly, the key feature of diabetic dyslipidemia is an increase in the production of VLDL by the liver in response to elevations in FFAs. Although insulin mediates the uptake of FFAs by striated muscle, reducing the levels presented to the liver, insulin resistance results in the opposite effect, increasing the levels of FFAs available to the liver. The metabolic syndrome, with its characteristic abdominal obesity, also increases the delivery of FFAs to the liver. In addition, reduced lipoprotein lipase activity in T2DM leads to an accumulation of triglyceride-rich lipoproteins in the plasma of these patients. Triglyceride-rich lipoproteins also play a role in the reduced levels of HDL-cholesterol by increasing the transfer of cholesterol from these particles.

A number of landmark trials have proved that lowering lipid levels produces major clinical benefits in terms of reducing cardiovascular events in patients with and without a history of CHD at baseline. These findings have now been extended to the population of subjects with T2DM and

dyslipidemia. For example, even though LDL levels are often within the average range in these patients, treatment with 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitors (statins) has been shown to improve outcomes. In the Cholesterol and Recurrent Events (CARE) trial, diabetic patients treated with pravastatin had a significant 25% reduction in the incidence of CHD death, nonfatal MI, CABG, and revascularization procedures.⁷ In the Long-term Intervention with Pravastatin in Ischemic Disease (LIPID) study, patients with diabetes had a 19% reduction in major CHD (fatal CHD and nonfatal MI).⁸⁴⁰

In a post hoc subgroup analysis of secondary prevention in a large cohort of patients with diabetes, impaired glucose tolerance, or normal glucose tolerance, simvastatin normalized associated elevations in total cholesterol and triglycerides across the range of glucose values.⁸⁴¹ Treatment also significantly reduced major coronary events and revascularizations in patients with diabetes and reduced major coronary events, revascularizations, and total and coronary mortality in patients with impaired glucose tolerance.

Several studies have further verified the use of statins in patients with diabetes and related conditions.⁸⁴²⁻⁸⁴⁶ In the Heart Protection Study, a large ($N = 20,536$), randomized, placebo-controlled trial of the use of simvastatin 40 mg in high-risk patients, roughly 29% of the study participants had T2DM.⁸⁴⁷ Over the 5-year course of the study, treatment with simvastatin resulted in a significant reduction in the occurrence of major vascular events in patients with T2DM who had previous MI or other CHD (33.4% versus 37.8% in simvastatin- and placebo-treated patients, respectively), in diabetics with no prior CHD (13.8% versus 18.6%), and in both categories combined (20.2% versus 25.1%). Overall, the study also demonstrated a highly significant 12% RR reduction in all-cause mortality and an 18% RR reduction in coronary mortality among all subjects treated with simvastatin.

The Collaborative Atorvastatin Diabetes Study (CARDS) was a large ($N = 2838$), randomized, placebo-controlled trial that assessed the benefit of atorvastatin 10 mg/day for preventing acute CHD events, coronary revascularization, or stroke in patients with T2DM who had no documented history of CVD and plasma LDL levels lower than 160 mg/dL.⁸⁴⁸ The trial was terminated 2 years early because the prespecified efficacy criteria were met. After a median of 3.9 years follow-up, patients treated with atorvastatin had an RR reduction for first cardiovascular event of 37% (95% CI, 52% to 17% reduction; $P = .001$), compared with placebo-treated patients. Assessed separately, acute CHD, coronary revascularizations, and stroke were significantly reduced, by 36%, 31%, and 48%, respectively. Based on these results, the CARDS investigators concluded that in patients with T2DM, a threshold LDL-cholesterol level should not be the sole determinant of whether a statin is prescribed.

A post hoc study compared major coronary events, total mortality, and revascularization rates in two subsets of patients who received simvastatin 20 to 40 mg/day for a median of 5.4 years in the Scandinavian Simvastatin Survival Study (4S).⁸⁴² Treatment with simvastatin resulted in a 52% RR reduction of major coronary events, a greater treatment effect than was seen in the patients with isolated high LDL-cholesterol. Reanalysis of the data after exclusion of the patients with diabetes did not substantially alter the findings.

The Treating to New Targets (TNT) study compared the effects of atorvastatin 10 mg or 80 mg daily for a median follow-up period of 4.9 years in patients with clinically

evident CHD who also met the NCEP criteria for diagnosis of the metabolic syndrome.⁸⁴³ The study included 778 patients with T2DM, who constituted 22% of the study population. Treatment with atorvastatin 80 mg was significantly more effective for reducing major cardiovascular events than atorvastatin 10 mg (HR = 0.71; 95% CI, 0.61 to 0.84; $P < .0001$), presumably due to the significantly greater reduction in LDL-cholesterol seen with the higher dosing of atorvastatin.

The Arterial Biology for the Investigation of the Treatment Effects of Reducing Cholesterol (ARBITER)⁸⁴⁴ was a randomized, double-blind study in which patients were assigned to receive extended-release niacin 500 mg titrated to 1000 mg daily ($n = 87$) or placebo ($n = 80$) on a background statin therapy. The primary end point of the study was change in CIMT after 1 year of niacin treatment. Despite a significant 21% increase in HDL-cholesterol levels in the patients receiving niacin, the overall difference in CIMT progression between the niacin- and placebo-treated groups only tended toward significance ($P = .08$).

Fibric acid derivatives might also be beneficial in patients with diabetes, because these agents address the low HDL-cholesterol and high triglyceride levels typically associated with diabetes. In the VA High-Density Lipoprotein Cholesterol Intervention Trial (VA-HIT), men given gemfibrozil had lower rates of coronary events and strokes.⁸⁴⁵ A fibric acid derivative in combination with a statin may be the optimal approach in patients with diabetes and CHD who have hypercholesterolemia in association with elevated triglycerides and reduced HDL-cholesterol levels.

The Fenofibrate Intervention and Event Lowering in Diabetes (FIELD) study assessed the effect of long-term fenofibrate therapy on cardiovascular events in patients with T2DM.⁸⁴⁶ Patients were randomized to receive either micronized fenofibrate 200 mg/day ($n = 4895$) or placebo ($n = 4900$). During 5-year follow-up, 5.9% of the placebo-treated patients and 5.2% of the fenofibrate-treated patients had a coronary event, a difference that was not significantly different. Fenofibrate therapy significantly reduced total CVD events (HR, 0.89; 95% CI, 0.75 to 1.05; $P = .035$), progression of albuminuria, and the need for laser treatment of retinopathy. Statistical significance for the primary end point of the study might have been missed because a greater percentage of patients in the placebo group initiated lipid-lowering therapy during the study period, and this masked the treatment effect.

The ACCORD trial provided important information regarding the use of fibrates in patients with T2DM. This trial investigated whether combination therapy with simvastatin plus fenofibrate, compared with simvastatin alone, would reduce cardiovascular events in diabetic patients at high risk for CVD. In this randomized clinical trial comparing fenofibrate to placebo in statin-treated patients, combination therapy did not reduce the rate of cardiovascular mortality, nonfatal MI, or nonfatal stroke. In a prespecified subgroup with a high triglyceride ratio (triglycerides ≥ 204 mg/dL and HDL ≤ 34 mg/dL), fenofibrate was better than placebo in reducing the primary outcome. At this time, there is no recommendation that these patients receive combination statin-fibrate therapy as an ingredient in risk factor reduction on the basis of T2DM alone.⁸⁴⁹

The importance of dyslipidemia as a contributor to cardiovascular risk in patients with diabetes is reflected in the new guidelines of the NCEP ATP III.⁸²⁰ For the first time, diabetes is considered a CHD risk equivalent, meaning that patients with diabetes have a risk of CHD that is similar to that of patients with clinically manifest CHD ($>20\%$ risk of an event in the following 10 years). In addition, the

presence of multiple CHD risk factors, the metabolic syndrome, and mixed hyperlipidemia (high triglyceride and low HDL-cholesterol levels) should be taken into account when estimating a patient's global risk.

According to the NCEP ATP III guidelines, diabetic patients are candidates for cholesterol-lowering therapy if the LDL-cholesterol level is higher than 3.36 mmol/L (130 mg/dL), with the goal of reducing LDL-cholesterol to less than 2.57 mmol/L (100 mg/dL),⁸²² although many clinicians consider it prudent to approach therapy more aggressively by instituting drug treatment if the LDL-cholesterol level is higher than 2.57 mmol/L (100 mg/dL). Based on new trial information, these guidelines have been modified to state that, when risk is very high, a goal of less than 70 mg/dL LDL-cholesterol is a reasonable clinical strategy, even when the high-risk patient has a baseline LDL-cholesterol level lower than 100 mg/dL.⁸⁵⁰ Additionally, when a high-risk patient has low HDL-cholesterol or high triglyceride levels, the combination of niacin or a fibrate with an LDL-lowering drug should be considered. However, regardless of the drug regimen employed, patients with diabetes should maintain tight glycemic control, which in itself can help reverse the dyslipidemic profile that is prevalent in diabetes. As with all patients, lifestyle modification, including weight reduction and regular exercise, remains an important cornerstone of the treatment of dyslipidemia in patients with diabetes.

Signature Features and Treatment of Hypertension in Diabetic Patients

It has been estimated that up to 50% of patients with newly diagnosed diabetes also have high BP. As with dyslipidemia, hypertension interacts with diabetes to amplify the risk of cardiac mortality (see Fig. 33-52). Although the etiology of hypertension is multifactorial, the insulin-resistant state is one factor postulated to predispose patients to development of hypertension. In addition to its negative effects on the cardiovascular system, high BP is a key contributor to the development of microvascular disease in diabetes. Based on the guidelines of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC VII), BP should be reduced to less than 130/85 mm Hg in patients with diabetes.⁸⁵¹

Results of the most recent clinical trials underscore the benefits of aggressive treatment of hypertension in patients with diabetes, although none of these studies achieved mean BP reductions to currently recommended targets. Use of a long-acting dihydropyridine calcium channel blocker in the Systolic Hypertension in Europe (Syst-Eur) study resulted in substantial reductions in total mortality (55%), cardiovascular mortality (76%), and cardiovascular events (69%) in the diabetic subgroup, greater benefits than were seen in the subgroup without diabetes.

In the Heart Outcomes Prevention Evaluation (HOPE) study, in which almost 40% of patients had diabetes and one other cardiovascular risk factor, ramipril reduced the primary outcome by 24% and total mortality by 25%.⁸⁵³ Even in normotensive patients with diabetes, some benefit was seen, with a 2- to 4-mm Hg drop in BP with ACE inhibitor therapy.

Other rigorously designed studies, such as the UKPDS⁸⁵⁴ and the Hypertension Optimal Treatment (HOT) study,⁸⁵⁵ suggested even greater benefits from tight BP control in patients with diabetes.

In the Losartan Intervention For Endpoint Reduction in Hypertension (LIFE) study, patients with diabetes,

hypertension, and signs of left ventricular hypertrophy were randomly assigned to treatment with losartan-based ($n = 586$) or atenolol-based ($n = 609$) treatment for hypertension.⁸⁵⁶ Despite similar BP reductions, losartan was more effective than atenolol for reducing cardiovascular morbidity and mortality, mortality from CVD, and mortality from all causes. The ability of losartan to reduce events more effectively than atenolol may be related to the ability of ARBs to reverse left ventricular hypertrophy more effectively than β -blockers.

Although β -blockers are thought to worsen glycemic control in patients with diabetes, it is not clear whether this is a property of all members of this drug class or whether this property persists if β -blockers are given in combination with renin-angiotensin system inhibitors that are known to increase insulin sensitivity. In the Glycemic Effects in Diabetes Mellitus: Carvedilol-Metoprolol Comparison in Hypertensives (GENINI) trial, patients with documented T2DM and hypertension who were taking a stable dose of either an ARB or an ACE inhibitor were randomized to receive either carvedilol or metoprolol. Although the degree of BP control was similar with both β -blockers, HbA_{1c} and insulin sensitivity increased significantly with metoprolol but not with carvedilol. Therefore, carvedilol can prevent the adverse effects of metoprolol on glucose levels when used in combination with renin-angiotensin system inhibitors, although this conclusion needs to be tested in a longer-term outcome trial.

The investigators of the Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT) compared outcomes during first-step treatment of hypertension in 31,512 patients with T2DM, IFG, or normoglycemia with a calcium channel blocker (amlodipine 2.5 to 10 mg/day) or ACE inhibitor (lisinopril 10 to 40 mg/day) compared with a thiazide-type diuretic (chlorthalidone 12.5 to 25 mg/day).⁸⁵⁶ There was no significant difference in the occurrence of the primary outcome (fatal CHD or nonfatal MI) in patients with T2DM treated with a calcium channel blocker or an ACE inhibitor compared with chlorthalidone. Patients with IFG treated with a calcium channel blocker had a significantly higher RR for the primary outcome than patients receiving chlorthalidone.

A major unresolved question has been whether treatment of hypertension to lower targets than currently recommended would reduce cardiovascular risk in patients with T2DM. Most trials establishing the remarkable benefit of BP lowering, regardless of the medications used, have studied subjects whose BP was higher than 140 mm Hg. In the ACCORD trial, two strategies of BP management were examined as to their efficacy in lowering cardiovascular risk. One group was randomized to a systolic BP lower than 120 mm Hg (intensive therapy), and the other group was treated to a systolic pressure lower than 140 mm Hg (standard therapy). Targeting the lower BP level did not reduce the rate of fatal and nonfatal cardiovascular events. Based on this result, there is no recommendation to treat patients with T2DM and hypertension to a systolic BP lower than the currently recommended target of 130 mm Hg to decrease cardiovascular events. However, further reduction may reduce the incidence of diabetic nephropathy.^{526,857}

Acute Coronary Syndromes in Diabetes Mellitus

The case-fatality rate from MI is almost twice as high in patients with diabetes as in nondiabetic patients. This excess risk is seen both during the acute phase of MI and

in the early and late postinfarction period. A number of mechanisms have been deemed to be responsible for worse outcomes in patients with diabetes, including the following:

- Increased risk of CHF due to maladaptive remodeling of the left ventricle⁸⁵⁸⁻⁸⁶⁰
- Increased risk of sudden death due to sympathovagal imbalance as a consequence of autonomic neuropathy⁸⁶¹⁻⁸⁶³
- Increased likelihood of early reinfarction due to impaired fibrinolysis⁸⁶⁴⁻⁸⁶⁶
- Extensive underlying CAD^{867,868}
- Changes in myocardial cell metabolism, including a shift from glucose oxidation to FFA oxidation, with less generation of ATP at any level of oxygen consumption^{869,870}
- Associated cardiomyopathy.⁷⁶⁸

Collective data provide strong evidence that a variety of treatment modalities can improve outcomes from MI in patients with diabetes. In terms of interventions, patients with diabetes experiencing an acute MI respond as favorably to fibrinolytic therapy as do nondiabetic patients.^{42,867,868}

Excellent glycemic control is an essential component of overall management. Glucose levels at hospital admission have been independently correlated with early and late mortality after MI in patients with and without diabetes mellitus.⁸⁷¹⁻⁸⁷⁴

Studies such as the Diabetes and Insulin-Glucose Infusion in Acute Myocardial Infarction (DIGAMI) study have assessed the impact of intensive glycemic control in patients with diabetes during the acute phase of MI. Patients in this study were randomized to either intensive insulin therapy (insulin-glucose infusion for 24 hours, followed by subcutaneous insulin injection for 3 months) or standard glycemic control.⁸⁷⁵ The intensive insulin regimen lowered blood glucose level during the first hour after admission and at discharge compared with conventional therapy. One-year mortality was significantly reduced with the insulin infusion compared with control, a difference that was maintained after 3.4 years of follow-up.

DIGAMI 2, a prospective, randomized, open-label trial that followed up the DIGAMI trial, compared outcomes in patients with either T1DM or T2DM and failed to corroborate the earlier reported improvement in outcomes with intensive insulin treatment.⁸⁷⁶ The lack of effect of long-term insulin treatment on outcomes may be at least partially explained by the fact that 14% of the patients in the conventional treatment group received insulin-glucose infusions in violation of the protocol, and as many as 41% had extra glucose injections. As a result, the blood glucose levels in all three groups were not significantly different after treatment.

Although the mechanisms responsible for the potential benefit shown in the original DIGAMI study are not entirely clear, experimental data suggest that strict glycemic control can improve myocardial cell metabolism by increasing the availability of glucose as a substrate for ATP generation and reducing the formation of FFAs, thereby shifting cardiac metabolism from FFA oxidation to glycolysis and glucose oxidation. Intensive glycemic control can also reverse the impaired fibrinolysis that is typically seen in patients with diabetes.

The CREATE-ECLA (Clinical Trial of Reviparin and Metabolic Modulation in Acute Myocardial Infarction Treatment Evaluation-Estudios Cardiológicos Latin America) randomized, controlled trial assigned 20,201 patients who presented with ST-segment elevation MI within 12 hours after onset of symptoms to treatment with either high-dose

glucose-insulin-potassium (GIK) infusion (i.e., 25% glucose, 50 U/L regular insulin, and 80 mEq KCl) administered over 24 hours or to usual care.⁸⁷⁷ Roughly 18% of the patients in both treatment arms had T2DM. After 30 days, there were no differences in the rate of occurrence of mortality, cardiac arrest, cardiogenic shock, or reinfarction in the two treatment groups.

Sulfonylureas have been implicated in an increased cardiovascular mortality rate, particularly in patients undergoing revascularization for acute MI.⁸⁷⁸ The UKPDS did not show a deleterious effect of these agents on the incidence of sudden death or MI over 10 years of follow-up.³ The sulfonylureas act through the sulfonylurea receptor component of ATP-sensitive potassium channels in the pancreatic beta cell. In the heart, ATP-sensitive potassium channels are involved in ischemic preconditioning and coronary vasodilation.⁸⁷⁹⁻⁸⁸¹ It is not clear whether the sulfonylureas modulate these channels in the heart or vascular system or whether they significantly increase risk in diabetic patients with an acute MI.

ACE inhibitors dramatically reduce mortality after an MI in patients with diabetes, ostensibly through their effects to reduce infarct size and limit ventricular remodeling. In addition to these hemodynamic benefits, ACE inhibitors can also improve outcomes in diabetes by improving endothelial function,⁸⁸² improving fibrinolysis,⁸⁸³ and decreasing insulin resistance.⁸⁸⁴

In a retrospective analysis of the Gruppo Italiano per lo Studio della Sopravvivenza nell'Infarto Miocardico (GISSI-3) study,⁸⁸⁵ lisinopril administration within 24 hours after hospital admission substantially reduced both 6-week and 6-month mortality in patients with diabetes compared with the nondiabetic group. Similarly, a subgroup analysis from the Trandolapril Cardiac Evaluation Study (TRACE) showed that patients with diabetes suffering an anterior MII who were treated with trandolapril had greatly improved outcomes over 5 years compared with patients without diabetes, including an almost 50% reduction in the risk of sudden death, reinfarction, and progression of CHF.⁸⁸⁶

β -Blockers are now widely accepted for the treatment of acute coronary syndrome in patients with diabetes. Older, noncardioselective β -blockers might have adversely affected the lipid profile and inhibited the metabolic response to hypoglycemia, but more recent data with cardioselective β -blockers suggest that these agents have less negative effects on metabolic indices, perhaps because they increase peripheral blood flow and improve glucose delivery.^{887,888} Clinical trial data confirm that β -blockers reduce the rates of mortality and reinfarction in patients with MI in the presence of diabetes. In fact, their effects in patients with diabetes appear to exceed those seen in nondiabetic patients. A large review of data from more than 45,000 patients, 26% of whom had diabetes, showed that β -blocker therapy was associated with a lower 1-year mortality rate in patients with diabetes than in those without diabetes, with no evidence of an increase in diabetes-related complications.⁸⁸⁹

Postulated mechanisms for the benefit of β -blockers in patients with diabetes include dampening of the sympathetic nervous system overactivity that arises as a consequence of autonomic neuropathy. β -Blockers can also reduce FFA levels and thereby reduce myocardial oxygen requirements. Carvedilol, although not cardioselective, is a β -blocker that decreases insulin resistance and also has antioxidant effects, both of which may be of particular benefit in patients with T2DM.⁸⁹⁰

Aspirin is a cornerstone of therapy for the primary or secondary prevention of acute coronary syndrome in

patients with T1DM and T2DM who do not have contraindications to its use. Aspirin significantly lowers the risk of MI without increasing the risk of vitreous or retinal bleeding, even in patients with retinopathy.⁸⁹¹ Enteric-coated aspirin, 81 to 325 mg/day, is currently recommended by the ADA.⁸⁹² The benefits of this therapy are likely to result from effects on the enhanced platelet aggregation that is evident in patients with either T1DM or T2DM.⁸⁹³

Antiplatelet therapy with clopidogrel also benefits patients with diabetes. The CAPRIE trial compared outcomes in patients with non-ST-segment elevation MI treated with aspirin or with clopidogrel and included 3866 patients with diabetes.⁸⁹⁴ Although the event rate was higher among the diabetic patients than in the overall study population, the response to treatment was also better. The event rate for the primary end point (vascular death, ischemic stroke, MI, or rehospitalization for ischemia or bleeding) was 17.7% for diabetic patients treated with aspirin and 15.6% for those randomized to clopidogrel, a significant RR reduction of 12.5%.

Newer adjunct therapies, such as the platelet glycoprotein IIb/IIIa receptor antagonists that antagonize platelet action, have also been assessed in diabetic patients who present with unstable angina or non-Q-wave infarction. Overall, these agents appear to work equally well, or perhaps slightly better, in patients with diabetes compared with nondiabetic patients. In the Platelet Receptor Inhibition in Ischemic Syndrome Management in Patients Limited by Unstable Signs and Symptoms (PRISM-PLUS) study, the addition of tirofiban to heparin therapy reduced the 7-day composite end point, compared with heparin alone. This effect was greater in patients with diabetes than in patients without diabetes.⁸⁹⁵

In one study of patients undergoing percutaneous transluminal coronary angioplasty (PTCA), glycoprotein IIb/IIIa antagonist therapy was associated with fewer acute events but a higher rate of target-vessel revascularization in the long term in the diabetic cohort compared with the nondiabetic cohort.⁸⁹⁶ However, in another trial, in which stents were used, the rate of target vessel revascularization at 6 months was significantly decreased with the addition of a glycoprotein IIb/IIIa antagonist compared with placebo.⁸⁹⁷

Results of the Bypass Angioplasty Revascularization Investigation (BARI) showed that CABG provides better outcomes than PTCA in patients with diabetes, possibly because it addresses the extensive coronary vascular disease in these patients.⁸⁹⁸ This study did not employ stents or glycoprotein IIb/IIIa inhibitors, two modalities that, when used together, appear to improve outcomes after PTCA in patients with diabetes.

Cardiomyopathy in Patients with Diabetes Mellitus

Diabetes is associated with a fourfold increase in the risk of CHF, even after adjustment for other cardiovascular risk factors such as age, BP, cholesterol level, obesity, and history of CAD.⁸⁹⁹ Patients with diabetes experience higher rates of CHF than do nondiabetic patients after an acute MI, regardless of the size of the infarct zone.^{859,900} These findings suggest that diabetes itself causes deleterious effects on the myocardium, leading to poorer outcomes.

A number of key structural, functional, and metabolic factors in diabetes have been implicated in the increased risk of maladaptive remodeling that leads to CHF. For example, evidence of silent MI is found in up to 40% of patients with diabetes who present with a clinically

apparent MI and can lead to unrecognized regional and global ventricular dysfunction.^{885,901} As many as 50% of patients with diabetes and CAD have cardiac autonomic neuropathy, which is known to contribute to both systolic and diastolic dysfunction.⁷⁶⁸ Like hypertension, diabetes can cause fibrosis of the myocardium and increased collagen deposition.^{902,903} These effects are even more pronounced in patients with coexisting hypertension and diabetes. Enhanced endothelial dysfunction in diabetes has also been described as a pathophysiologic pathway to impaired microvascular perfusion and ischemia.^{904,905}

On a cellular level, both hyperglycemia and insulin resistance have direct negative effects on myocardial metabolism. Depression of myocardial GLUT4 levels in the setting of diabetes and ischemia inhibits glucose entry and glycolysis in the heart. As a result, intracellular metabolism shifts from glycolysis to FFA oxidation, thereby suppressing glycolytic ATP generation, a major source of energy under anaerobic (i.e., ischemic) conditions.⁸⁶⁹ The production of oxygen free radicals can also be enhanced in this situation, further depressing myocardial contractile function.⁹⁰⁵

Collectively, these various abnormalities potentiate the characteristic left ventricular remodeling of diabetes, which is clinically manifested as serial wall motion changes, reduced regional ejection fraction, and increased end-diastolic and end-systolic volumes.^{906,907}

THE DIABETIC FOOT

Of all the late complications of diabetes, foot problems are probably the most preventable. Joslin, who wrote in 1934 that “diabetic gangrene is not heaven-sent, but earth-born,” was correct: The development of foot ulceration mostly results from the way we care for our patients or the way patients care for themselves.

Increasing interest in the diabetic foot has resulted in a better understanding of the factors that interact to cause ulceration and amputation. The neuropathic foot does not spontaneously ulcerate; insensitivity in combination with other factors, such as deformity and unperceived trauma (e.g., inappropriate footwear), leads to skin breakdown. Increased knowledge of this pathogenesis should permit the design of appropriate screening programs for risk and preventive education. Much progress has been made, but it has not yet resulted in a universal decrease in amputation rates. In the VA system, for example, amputation rates in diabetic patients⁹⁰⁸ have not declined, although certain European countries have reported a significant reduction in amputation rates after implementation of foot screening and education programs.^{909,910} Much research is still needed to implement strategies to reduce ulceration and amputation, and this is particularly required in the fields of behavioral and psychosocial aspects of the diabetic foot.⁹¹¹

Two major texts on the diabetic foot were published in recent years.^{912,913} The reader is referred to these sources together with other major recent review articles^{914,915} for more detailed discussion of this topic.

Epidemiology and Pathogenesis of Diabetic Foot Ulceration

Foot ulceration is common and occurs in both T1DM and T2DM. Approximately 5% to 10% of diabetic patients have had past or present foot ulceration, and 1% have undergone amputation.⁹¹² Diabetes is the most common cause of nontraumatic lower limb amputation in the United States, and rates are 15 times greater than those in the

nondiabetic population. More than 80% of amputations are preceded by foot ulcers. A large community-based study in the United Kingdom showed an annual incidence of ulceration of approximately 2%; this rose to 7% with known diabetic neuropathy and to as high as 50% with a past history of ulceration.⁹¹⁶ The lifetime risk for development of a foot ulcer in a diabetic patient is estimated to be as high as 25%.⁹¹⁴

Pathway to Ulceration

Foot ulceration results from the interaction of a number of component causes, none of which alone is sufficient to cause ulceration but which, when combined, complete the causal pathway to skin breakdown. Knowledge of these component causes and their potential to interact facilitates the design of preventive foot care programs.

Diabetic Neuropathy

All three components of neuropathy—sensory, motor, and autonomic—can contribute to ulceration in the foot. Chronic sensorimotor neuropathy is common, affecting at least one third of older patients in Western countries. Its onset is gradual and insidious, and symptoms may be so minimal that they go unnoticed. Although uncomfortable, painful, and paresthetic symptoms predominate in many patients, some never experience symptoms. Clinical examination usually reveals a sensory deficit in a glove-and-stocking distribution, with signs of motor dysfunction, such as small muscle wasting in the feet and absent ankle reflexes. Although a history of typical symptoms strongly suggests a diagnosis of neuropathy, absence of symptoms does not exclude the diagnosis and must never be equated with a lack of foot ulcer risk. Therefore, assessment of foot ulcer risk must always include a careful foot examination, whatever the history.

Sympathetic autonomic neuropathy affecting the lower limbs results in reduced sweating, dry skin, and development of cracks and fissures. In the absence of large-vessel arterial disease, there may be increased blood flow to the foot, with arteriovenous shunting leading to the warm but at-risk foot.

The importance of neuropathy as a contributory cause to foot ulceration has been confirmed. The risk in patients with neuropathy is sevenfold higher than in those without this complication of diabetes.⁹¹⁶

Peripheral Vascular Disease

Peripheral vascular disease in isolation rarely causes ulceration. However, the common combination of vascular disease with minor trauma can lead to ulceration. Minor injury and subsequent infection increase the demand for blood supply beyond the circulatory capacity, and ischemic ulceration and risk of amputation develop. Early identification of those patients who are at risk for peripheral vascular disease is essential, and appropriate investigation involving noninvasive studies, together with arteriography, often leads to bypass surgery to improve blood flow to the extremities. Distal bypass surgery is often performed, with good short-term but mixed long-term results in terms of limb salvage.^{917,918} Doppler-derived ankle pressure can be misleadingly high in patients with long-standing diabetes. The presence or absence of a dorsalis pedis or posterior tibial pulse is the simplest and most reliable indicator of significant ischemia that can be elicited at the bedside.⁹¹⁷

Past Foot Ulceration or Foot Surgery

Foot ulceration is most common in patients with a history of similar problems. Even in experienced diabetic foot

Figure 33-54 The high-risk neuropathic foot. **A** and **B**, Two lateral views of a patient with typical signs of a high-risk neuropathic foot. Notice the small-muscle wasting, clawing of the toes, and marked prominence of the metatarsal heads. At presentation with type 2 diabetes mellitus, this patient had severe neuropathy with foot ulceration on both the right foot (shown here) and the left foot. (From Andersson DK, Svard-sudd K. Long-term glycemic control relates to mortality in type II diabetes. *Diabetes Care*. 1995;18:1534-1543.)

clinics, more than 50% of patients with new foot ulcers give a past ulcer history.

Other Diabetic Complications

Patients with retinopathy and renal dysfunction are at increased risk for foot ulceration. Among the diabetic patients at highest risk for ulceration are those on dialysis.⁹¹⁹

Callus, Deformity, and High Foot Pressures

Motor neuropathy, with imbalance of the flexor and extensor muscles in the foot, commonly results in foot deformity, with prominent metatarsal heads and clawing of the toes (Fig. 33-54). The combination of proprioceptive loss due to neuropathy and the prominence of metatarsal heads leads to increased pressures and loads under the diabetic foot. High pressures, together with dry skin, often result in the formation of callus under weight-bearing areas of the metatarsal heads. The presence of such plantar callus has been shown in cross-sectional and prospective studies to be a highly significant marker of foot ulcer risk. Conversely, removal of plantar callus is associated with a reduction in foot pressures and therefore a reduction in foot ulcer risk.⁹²⁰

It is the combination of two or more of the earlier described risk factors that ultimately results in diabetic foot ulceration. In 1999, a North American/United Kingdom collaborative study⁹²¹ assessed the risk factors that resulted in ulceration in more than 150 consecutive foot ulcer cases. From this study, a number of causal pathways were identified, but the most common triad of component causes—neuropathy, deformity, and trauma—was present in 63% of incident ulcers. Edema and ischemia were also common component causes.

Prevention of Foot Ulceration and Amputation

That diabetic foot ulceration is largely preventable is not disputed; small, mostly single-center studies have shown that relatively simple interventions can reduce amputations by up to 80%.^{909,910} Therefore, strategies for early identification of patients at potential risk for ulceration are required, and education programs that can be adapted for widespread application need to be developed. Because foot ulcers precede most amputations, are among the most common causes of hospital admission for patients with diabetes, and account for much morbidity and even mortality, the widespread application of preventive foot care strategies is urgently required.

Patients with any type of diabetes require regular review and screening of the feet for evidence of risk factors for foot ulceration, irrespective of disease duration. At a minimum, such screening should be carried out annually. Of all the long-term complications of diabetes, foot problems and their risk factors are probably the easiest to detect. No expensive equipment is required, and the feet can be examined for evidence of neuropathic and vascular deficits in the office setting using simple equipment. Neuropathy, vascular disease, and even foot ulceration may be the presenting feature of T2DM, so there can be no exception to the rule of screening (Fig. 33-55).

In 2008, a taskforce of the ADA published a report on the components that should comprise the annual Comprehensive Diabetic Foot Examination (CDFE), which is summarized in Table 33-14.⁹²² The most important message to practitioners is to have the patient remove shoes and socks and to look at the feet for risk factors such as presence of callus, deformity, muscle wasting, and dry skin, all of which are clearly visible on clinical inspection. A simple neurologic examination should include assessment of pressure perception using a 10-g monofilament; in a large U.K.

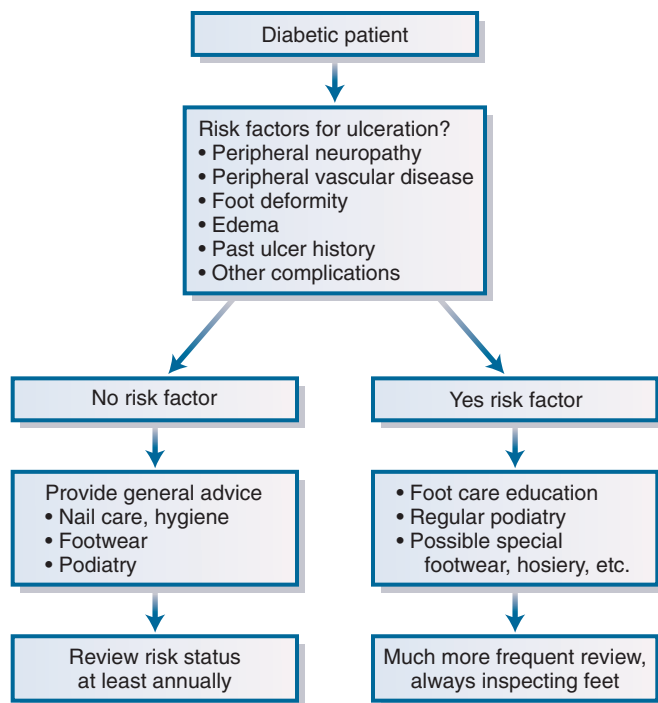

Figure 33-55 Simple algorithm for risk screening in the diabetic foot.

community study,⁹¹⁶ a simple clinical examination was the best predictor of foot ulcer risks. Absence of the ability to perceive pressure from a 10-g monofilament, inability to perceive a vibrating 128-Hz tuning fork over the hallux, and absent ankle reflexes all have been shown to be predictors of foot ulceration.^{916,920}

TABLE 33-14

Key Components of the Comprehensive Diabetic Foot Examination

Dermatologic

Skin status: color; thickness, dryness, cracking
Sweating
Infection: check between toes for fungal infection
Ulceration
Calluses/blistering: hemorrhage into callus?

Musculoskeletal

Deformity (e.g., claw toes, prominent metatarsal heads, Charcot joint)
Muscle wasting (guttering between metatarsals)
Assess whether shoes are appropriate for the feet (e.g., size, width)

Neurologic

Ability to perceive pressure from a 10-g monofilament plus one of the following:
Vibration using 128-Hz tuning fork
Pinprick sensation
Ankle reflexes
Vibratory perception threshold

Vascular

Foot pulses
Ankle-brachial index, if indicated

Adapted from Boulton AJM, Armstrong DG, Albert SG, et al. Comprehensive Foot Examination and Risk Assessment: a report of the Task Force of the Foot Care Interest Group of the American Diabetes Association, with endorsement by the American Association of Clinical Endocrinologists. *Diabetes Care*. 2008;31:1679-1686.

TABLE 33-15

Wagner Diabetic Foot Ulcer Classification System

Grade	Description
0	No ulcer, but high-risk foot (e.g., deformity, callus, insensitivity)
1	Superficial full-thickness ulcer
2	Deeper ulcer; penetrating tendons, no bone involvement
3	Deeper ulcer with bone involvement, osteitis
4	Partial gangrene (e.g., toes, forefoot)
5	Gangrene of whole foot

Modified from Oyibo S, Jude EB, Tarawneh I, et al. A comparison of two diabetic foot ulcer classification systems: the Wagner and the University of Texas wound classification systems. *Diabetes Care*. 2001;24:84-88.

The Diabetic Foot Care Team

Patients identified as being at high risk for foot ulceration should be managed by a team of specialists with interest and expertise in the diabetic foot. The podiatrist usually takes responsibility for follow-up and care of the skin and nails and, together with the specialist nurse or diabetes educator, provides foot care education. The orthotist, or shoe fitter, is invaluable for advising about and sometimes designing footwear to protect high-risk feet, and these members of the team should work closely with the diabetologist and the vascular and orthopedic surgeons. Patients with risk factors for ulceration require preventive foot care education and frequent review.^{910,920}

Classification of Foot Ulcers

Many different classification systems have been reported in the literature.^{914,920} The one developed by Wagner⁹²³ (Table 33-15) for grading diabetic foot ulcers has been widely used and accepted. More recently, the University of Texas (UT) group has developed an alternative classification system that, in addition to ulcer depth (as in the Wagner system), takes into account the presence or absence of infection and ischemia (Table 33-16).⁹²⁴ A prospective study from 2001 assessed and compared these two wound classification systems and concluded that the UT scheme is a better predictor of outcome than the older Wagner system.⁹²³

Management of Diabetic Foot Ulcers

Basic principles of wound healing apply equally to diabetic foot ulcers as to wounds in any other site or condition.

TABLE 33-16

University of Texas Wound Classification System

Stage	Grade 0	Grade 1	Grade 2	Grade 3
A	Preulcer or postulcer lesion; no skin break	Superficial ulcer	Deep ulcer to tendon or capsule	Wound penetrating bone or joint
B	+ Infection	+ Infection	+ Infection	+Infection
C	+ Ischemia	+ Ischemia	+ Ischemia	+Ischemia
D	+ Infection and ischemia	+ Infection and ischemia	+Infection and ischemia	+Infection and ischemia

Modified from Armstrong DG, Lavery LA, Harkless LB. Validation of a diabetic wound classification system. *Diabet Med*. 1998;14:855-859.

Basically, a diabetic foot ulcer will heal if the following three conditions are satisfied:

- Arterial inflow is adequate.
- Infection is treated appropriately.
- Pressure is removed from the wound and the immediate surrounding area.

Although this approach might seem simplistic, failure of diabetic foot ulcers to heal is usually a result of failure to pay sufficient attention to one or more contributing conditions, including pressure on the wound, infection, ischemia, and inadequate debridement.

The most common cause of nonhealing of neuropathic foot ulcers is the failure to remove pressure from the wound and immediate surrounding area. Patients who are advised not to put pressure over an ulcer find it difficult to adhere to such advice if peripheral sensation is lost or reduced. Pain results in protection of an injured area; the lack of pain permits pressure to be put directly onto the ulcer and results in nonhealing. A patient with normal sensation and a foot wound will limp to avoid putting pressure on the wound because doing so is painful; hence, the observation made initially in leprosy, and more recently in diabetic neuropathy, that a patient who walks on a plantar wound without limping must have neuropathy.

The effect of pressure relief on the histopathologic features of neuropathic ulcers was assessed in a randomized study.⁹²⁵ Patients with chronic neuropathic diabetic foot ulcers were randomly assigned to have a biopsy either at presentation or after 20 days of off-loading in a total-contact cast (TCC). Histologic features of chronic inflammation, with mononuclear infiltration, cellular debris, and scarce evidence of angiogenesis or granulation were seen in patients who underwent biopsy at presentation; granulation, neovascularization, and a predominance of fibroblasts were seen in patients treated with TCC before biopsy. These important observations strongly suggest that repetitive pressure on a neuropathic wound contributes to the chronicity of the wound, whereas pressure relief results in the wound's appearing, in several respects, more like an acute wound in the reparative phase.

The next most common error is inappropriate management of infection. Topical applications are usually unhelpful, and if clinical infection is present, it must be treated appropriately (see later discussion).

Another common error is the failure to appreciate ischemic symptoms that are atypical due to altered pain sensation as a result of neuropathy. The most difficult ulcer to heal is the neuroischemic ulcer, and symptoms and even signs of ischemia may be altered in the diabetic state. Therefore, appropriate noninvasive investigation and arteriography are indicated for patients with a nonhealing diabetic foot ulcer if there is any question about the vascular status.

Inappropriate wound debridement is another reason for slow healing or nonhealing of a diabetic foot ulcer. When patients with neuropathy put pressure on active ulcer areas, the pressure leads to an often extensive buildup of callus tissue. Appropriate debridement and removal of all dead and macerated tissue is essential in the local treatment of a diabetic foot ulcer and has been shown to result in more rapid healing of ulcers compared with wounds that are inadequately debrided.

The principles of management of neuropathic and neuroischemic foot ulcers are considered in the following sections. Because it is not possible to provide complete details on the individual stages and grades of ulcers, we refer to both the UT and the Wagner grading systems.

Neuropathic Foot Ulcer without Osteomyelitis (Wagner Grades 1, 2; University of Texas Grades 1a, 1b, 2a, 2b)

The most important feature in the management of neuropathic foot ulcers that typically occur under weight-bearing areas such as the metatarsal heads and great toe is the provision of adequate pressure relief. This is usually achieved by a cast such as a TCC or a removable Scotch cast boot.^{914,920}

The TCC has long been recognized as the gold standard for off-loading a foot wound and was confirmed as correct in a randomized, controlled trial in which Armstrong and colleagues compared three off-loading techniques and found that the TCC was associated with the shortest healing time.⁹²⁶ When any cast device is used, regular removal of the cast is essential, because regular debridement of the wound by a podiatrist is essential, and any casting device could injure insensitive skin, especially over bony prominences. For this reason, and because the TCC requires a specially trained casting technician to apply it, recent research has been directed toward alternative, removable devices that might be equally efficacious.

In the aforementioned trial by Armstrong's group,⁹²⁶ the removable cast walker (RCW) resulted in slower healing than the TCC, even though prior gait laboratory studies had suggested that they are equally efficacious at off-loading. The reason for this disparity was identified in an observational study of patients using RCWs in the treatment of their plantar neuropathic ulcers. Although patients were instructed to wear the RCW at all times, careful monitoring showed that RCWs were used for only 28% of all footsteps during a 24-hour period. It was therefore suggested that the RCW, which can be applied by any clinic personnel and does not require specialist training, might be rendered irremovable by wrapping it in casting material. A controlled trial showed that the irremovable RCW was as effective at healing neuropathic foot wounds as the TCC.⁹²⁷

Theoretically, complete healing of all superficial and neuropathic ulcers should be possible without the need for amputation. In the treatment of neuropathic ulcers with a good peripheral circulation, antibiotics are not indicated unless there are clear clinical signs of infection, including prominent discharge, local erythema, and cellulitis. The presence of any of these features in Wagner grade 1 or 2 ulcers would warrant reclassification in the UT system from 1a or 2a to 1b or 2b. In such cases, deep wound swabs should be taken and broad-spectrum oral antibiotic treatment should be started with either an amoxicillin-clavulanic acid combination (Augmentin) or clindamycin. The antibiotic may need to be altered after sensitivity results become available.⁹²⁸

Neuroischemic Ulcers (Wagner Grades 1, 2; University of Texas Grades 1c, 1d)

The principles of management of neuroischemic Wagner grade 1 and 2 ulcers are similar to those for neuropathic ulcers, with the following important exceptions. TCCs are not usually recommended for management of neuroischemic ulcers, although removable casts and pneumatic cast boots (Aircast) may be used in cases without infection. Antibiotic therapy is usually recommended for most neuroischemic ulcers. Investigation of the circulation is indicated, including noninvasive assessment and, if required, arteriography with appropriate subsequent surgical management or angioplasty.⁹¹⁷

Osteomyelitis (Wagner Grade 3; University of Texas Grades 3b, 3d)

Wagner or UT grade 3 ulcers are deeper and involve underlying bone, often with abscess formation. Osteomyelitis is a serious complication of foot ulceration and may be present in as many as 50% of diabetic patients with moderate to severe foot infections.⁹¹⁴ If the physician can probe down to bone in a deep ulcer, the presence of osteomyelitis is strongly suggested. Plain radiographs are indicated for any nonhealing foot ulcer and are useful in the diagnosis of osteomyelitis in more than two thirds of patients, although the radiologic changes may be delayed. In difficult cases, further investigation, such as MRI, bone scans, or an indium 111 (¹¹¹In) labeled white blood cell scan can be useful in diagnosing bone infection.⁹²⁹

Although the treatment of osteomyelitis is commonly surgical and involves resection of the infected bone, there have been reports of successful long-term treatment with antibiotics effective against the underlying bacterium, most commonly *Staphylococcus aureus*. Therefore, agents such as clindamycin (which penetrates bone well) or flucloxacillin are often used.

Gangrene (Wagner Grades 4, 5)

The presence of gangrene or areas of tissue death is always a serious sign in the diabetic foot. However, localized areas of gangrene, especially in the toes, that are without cellulitis, spreading infection, or discharge can occasionally be left to spontaneously autoamputate. The presence of more extensive gangrene requires urgent hospital admission; treatment of infection, often with multiple antibiotics; control of the diabetes, usually with intravenous insulin; and detailed vascular assessment. It is in this area that the team approach is most important, with close collaboration among the diabetes specialist, the vascular surgeon, and the radiologist.

Adjunct Treatments for Foot Ulcers

Platelet-Derived Growth Factors and Tissue-Engineered Skin

Genetically derived growth factors and novel bioengineered skin substitutes have been proposed as adjunctive treatments for diabetic foot ulcers. However, all of these new therapies are costly, as detailed in a recent systematic review and economic evaluation.⁹³⁰ This review covered treatments including Apligraf, a bilayered living human skin equivalent; Dermagraft, a human fibroblast-derived dermal substitute; and human PDGFs. Although the review did show some benefit for each of these agents, it is clear that they should be reserved only for those ulcers that fail to respond to the standard treatments noted earlier. Any new treatments should be seen not as a replacement but as an addition to good wound care, which must always include adequate off-loading and regular debridement.

Negative-Pressure Wound Therapy

Negative-pressure wound therapy, also known as vacuum-assisted closure, is increasingly used to treat large and complex diabetic foot wounds. The treatment appears to stimulate the development of granulation tissue in previously nonhealing wounds and can also be helpful in the postoperative management of diabetic foot wounds. Supportive data have been published from randomized, controlled trials in postoperative cases⁹³¹ and in complex nonhealing diabetic foot ulcers.⁹³²

Charcot's Neuroarthropathy

Charcot's neuroarthropathy is a rare and disabling condition that affects the joints and bones of the feet. Permissive features for the development of this condition include the presence of severe peripheral neuropathy and autonomic dysfunction with increased blood flow to the foot; the peripheral circulation is usually intact. In the Western world, diabetes is the most common cause of a Charcot foot, and increased awareness of this condition can enable earlier diagnosis and treatment to prevent severe deformity and disability.

The actual pathogenesis of the Charcot process is poorly understood; however, the patient with peripheral insensitivity and autonomic dysfunction with increased blood flow to the foot is vulnerable to trauma that the patient may not recall. Repetitive trauma results in increased blood flow through the bone, increased osteoclastic activity, and remodeling of bone. In certain cases, patients walk on a fracture, which leads to continuing destruction of bones and joints in that area. Recent evidence suggests that acute Charcot's neuropathy may be triggered in the susceptible (i.e., neuropathic) individual by any event that leads to localized inflammation in the affected foot. This may trigger a vicious cycle in which there is increasing inflammation, increasing expression of RANKL (a member of the tumor necrosis factor superfamily), and increasing bone breakdown. The likely involvement of the RANKL/OPG pathway might lead to new possibilities for future treatments.⁹³³

Charcot's neuropathy is sometimes difficult to distinguish from osteomyelitis or an inflammatory arthropathy.⁹²⁹ However, a unilateral swollen, hot foot in a patient with neuropathy must be considered to be a Charcot foot until proved otherwise.

Charcot's arthropathy can be diagnosed in most patients by plain radiography and a high index of suspicion. Radiographs may reveal bone and joint destruction, fragmentation, and remodeling, although in the early stages the radiographic finding may be normal. In such cases, the three-phase bisphosphonate bone scan shows increased bone uptake, although the ¹¹¹In-labeled bone scan will be negative in the absence of infection.

After diagnosis, management of the acute phase involves immobilization, usually in a TCC.⁹³⁴ Evidence suggests that treatment with bisphosphonates, which reduce osteoclastic activity, may reduce swelling, discomfort, and bone turnover markers, although larger trials are warranted in this area.^{920,933,934}

Although Charcot's neuroarthropathy is rare, it should be suspected in any patient with unexplained swelling and heat in a neuropathic foot. Early intervention with immobilization and possibly bisphosphonate treatment may halt progression that, in the untreated state, can lead to marked foot deformity and require local or major amputations.

Hypoglycemia

PHILIP E. CRYER

Glucose is an obligate metabolic fuel for the brain under physiologic conditions.¹⁻⁴ Because the brain cannot synthesize glucose, store more than a few minutes' supply as glycogen, or utilize physiologic concentrations of circulating nonglucose fuels effectively, survival of the brain, and therefore of the individual, requires a virtually continuous supply of glucose from the circulation.¹⁻⁴ Blood-to-brain glucose transport is a direct function of the arterial plasma glucose concentration and requires maintenance of the plasma glucose concentration within, or above, the physiologic range. Hypoglycemia causes functional brain failure, which is typically corrected after the plasma glucose concentration is raised.⁵ Rarely, it causes a fatal cardiac arrhythmia or, if it is profound and prolonged, brain death.⁵

Given the survival value of maintenance of the plasma glucose concentration, it is not surprising that physiologic and behavioral mechanisms that normally prevent or rapidly correct hypoglycemia⁴ have evolved. These mechanisms are so effective that hypoglycemia is an uncommon clinical event except in persons who use drugs that lower the plasma glucose concentration, such as insulin, sulfonylureas, or alcohol.^{2,3}

A clinical practice guideline for the evaluation and management of hypoglycemic disorders has been published,² and the topic of hypoglycemia in diabetes has been reviewed in detail.³

PHYSIOLOGY OF DEFENSE AGAINST HYPOGLYCEMIA

Glucose Metabolism

Glucose is derived from three sources: intestinal absorption that occurs after digestion of dietary carbohydrates; *glycogenolysis*, which is the breakdown of glycogen, the polymerized storage form of glucose; and *gluconeogenesis*, which is the formation of glucose from precursors including lactate (and pyruvate), amino acids (especially alanine and glutamine), and, to a lesser extent, glycerol. There are multiple fates of glucose transported into cells (external losses are normally negligible) (Fig. 34-1). Glucose may be stored as glycogen, or it may undergo glycolysis to pyruvate, which can be reduced to lactate, transaminated to form alanine, or converted to acetyl coenzyme A (CoA). Acetyl-CoA in turn may be oxidized to carbon dioxide and water through the tricarboxylic acid cycle, converted to fatty acids that can be incorporated into triglycerides, oxidized, or utilized for synthesis of ketone bodies (acetoacetate, β -hydroxybutyrate) or cholesterol. Finally, glucose may be released into the circulation. Only liver and kidneys express glucose-6-phosphatase, the enzyme necessary for the release of glucose into the circulation, at levels sufficient

Figure 34-1 Schematic representation of glucose metabolism. CoA, coenzyme A; P, phosphate; TCA, tricarboxylic acid.

to permit substantial contributions to the systemic glucose pool. Many tissues express the enzymes required to synthesize and hydrolyze glycogen (glycogen synthase and phosphorylase, respectively). The liver and kidneys also express the enzymes necessary for gluconeogenesis, including the critical gluconeogenic enzymes, pyruvate carboxylase, phosphoenolpyruvate carboxykinase, and fructose-1,6-bisphosphatase.

The liver is the major source of net endogenous glucose production (through glycogenolysis and gluconeogenesis).⁶ Conversely, the liver can be an organ of net glucose uptake. The kidneys also produce glucose (through gluconeogenesis) and utilize glucose.⁷

Muscle can take up and store glucose as glycogen, or it can metabolize glucose (through glycolysis) to pyruvate, which, among other fates, can be reduced to lactate or transaminated to form alanine. Lactate (and pyruvate) released from muscle can be transported to the liver and the kidneys, where it serves as a gluconeogenic precursor (the Cori or glucose-lactate cycle). Alanine, glutamine, and other amino acids can also flow from muscle to liver and kidneys, where they serve as gluconeogenic precursors. These constitute the glucose-alanine and glucose-glutamine cycles. Clearly, net new glucose formation is from precursors (e.g., amino acids) in which the carbons are not derived from glucose via these cycles. Although quantitatively less important than muscle, fat can also take up and metabolize glucose.

Glucose is essentially the sole metabolic fuel for the brain under physiologic conditions.¹ Glucose undergoes terminal oxidation in the brain. Although the adult human

brain constitutes only about 2.5% of body weight, its oxidative metabolism accounts for approximately 25% of the basal metabolic rate and more than 50% of whole-body glucose utilization. The brain can utilize alternative fuels if their circulating levels rise high enough for them to enter the brain in quantity. For example, during extended fasting, markedly elevated circulating ketone levels can support the majority of the energy needs of the brain and reduce its utilization of glucose. Nonetheless, that is not a physiologic condition. Furthermore, ketogenesis is suppressed during episodes of insulin-mediated hypoglycemia. Again, the brain is critically dependent on a virtually continuous supply of glucose from the circulation.¹⁻⁵

Systemic Glucose Balance

Normally, rates of endogenous glucose influx into the circulation and those of glucose efflux out of the circulation into tissues other than the brain are coordinately regulated—largely by the plasma glucose-lowering (regulatory) hormone insulin and the plasma glucose-raising (counterregulatory) hormones glucagon and epinephrine—such that systemic glucose balance is maintained, hypoglycemia (as well as hyperglycemia) is prevented, and a continuous supply of glucose to the brain is ensured (Table 34-1). This is accomplished despite wide variations in exogenous glucose influx (e.g., after meals versus during fasting) and in glucose efflux (e.g., during exercise versus rest). Hypoglycemia occurs when rates of glucose appearance in the circulation (the sum of endogenous glucose production and exogenous glucose delivery from ingested carbohydrates) fail to keep pace with rates of glucose disappearance from the circulation (the sum of ongoing glucose metabolism largely by the brain and of variable glucose utilization by tissues including muscle, fat, liver, and kidneys).

In healthy adults, the physiologic postabsorptive (fasting) plasma glucose concentration ranges from approximately 3.9 mmol/L (70 mg/dL) to 6.1 mmol/L (110 mg/dL), with a mean of about 5.0 mmol/L (90 mg/dL).⁴ In the postabsorptive steady state, rates of glucose production and utilization average approximately 12 μ mol/kg per minute (2.2 mg/kg per minute), with a range of 10 to 14 μ mol/kg per minute (1.8 to 2.6 mg/kg per minute). These rates are as much as threefold higher in infants, at least in part because of their greater brain mass relative to body weight.

TABLE 34-1

Systemic Glucose Balance* and Effects of Circulating Hormones on Endogenous Production and Use of Glucose

Source of Glucose Influx or Efflux	HORMONAL EFFECTS		
	Insulin	Glucagon	Epinephrine
Glucose Influx into the Circulation			
Exogenous glucose delivery			
Endogenous glucose delivery			
In liver: glycogenolysis and gluconeogenesis	↓	↑	↑
In kidneys: gluconeogenesis	↓		↑
Glucose Efflux out of the Circulation			
Ongoing brain glucose utilization			
Variable glucose utilization by other tissues (e.g., muscle fat, liver, kidneys)	↑		↓

*Total glucose influx = total glucose efflux.

The liver is the predominant source of endogenous glucose production in the postabsorptive state; the kidneys, which both utilize and produce glucose, contribute little to net glucose production. However, as in the liver, glucose production in the kidney is regulated; it is suppressed by insulin and stimulated by epinephrine but not by glucagon. As a result, net renal glucose production occurs under some conditions, including hypoglycemia.⁸ Therefore, endogenous glucose production cannot be equated with hepatic glucose production.

Gluconeogenesis and glycogenolysis are important for maintenance of the plasma glucose concentration.⁶ The glucose pool, namely free glucose in the extracellular fluids and in the cells of certain tissues (primarily the liver), is only about 83 to 111 mmol (15 to 20 g). Glycogen that can be mobilized to provide circulating glucose (e.g., hepatic glycogen) contains approximately 390 mmol (70 g) of glucose, with a range of about 135 to 722 mmol (25 to 130 g). Therefore, in an adult of average size, preformed glucose can provide less than an 8-hour supply, even at the diminished rate of glucose utilization that occurs in the postabsorptive state.

If fasting is prolonged to 24 to 48 hours, the plasma glucose concentration declines and then stabilizes; hepatic glycogen content falls to less than 55 mmol (10 g), and gluconeogenesis becomes the sole source of glucose production.⁶ Because amino acids are the main gluconeogenic precursors that result in net glucose formation, muscle protein is degraded. Glucose utilization by muscle and fat virtually ceases. As lipolysis and ketogenesis accelerate and circulating ketone levels rise, ketones become a major fuel for the brain. Glucose utilization by the brain declines by about half; this reduces the rate of gluconeogenesis required to maintain the plasma glucose concentration and hence decreases protein wasting.

After a meal, glucose absorption into the circulation increases to more than twice the rate of postabsorptive endogenous glucose production, depending on the carbohydrate content of the meal, the rate of gastric transit, and the rate of digestion and absorption. As glucose is absorbed, endogenous glucose production is suppressed, and glucose utilization by muscle, fat, and liver accelerates. The exogenous glucose is assimilated and, after a small rise, the plasma glucose concentration returns to the postabsorptive level.

Exercise increases glucose utilization (by muscle) to rates that can be several times greater than those of the postabsorptive state. Endogenous glucose production normally

accelerates to match use so that the plasma glucose concentration is maintained.

In summary, the plasma glucose concentration is normally maintained within a relatively narrow range despite wide variations in glucose flux and thus maintains the systemic glucose balance. This remarkable homeostatic feat is accomplished by an array of hormonal, neural, and substrate glucoregulatory factors.⁴ Glucoregulatory failure resulting in hyperglycemia (diabetes mellitus) is discussed in Chapters 31 and 32; that resulting in hypoglycemia is discussed in the paragraphs that follow.

Responses to Hypoglycemia

Falling plasma glucose concentrations cause a sequence of responses, with defined glycemic thresholds, in healthy individuals (Table 34-2).^{4,9-11} The first response is a decrease in insulin secretion. This occurs as glucose levels decline within the physiologic range. Increased secretion of glucose counterregulatory hormones, including glucagon and epinephrine, occurs as glucose levels fall just below the physiologic range. Lower plasma glucose concentrations cause a more intense sympathoadrenal (sympathetic neural as well as adrenomedullary) response and symptoms. Even lower glucose levels cause cognitive dysfunction and additional manifestations of functional brain failure⁵ including seizure or coma.

Clinical Manifestations of Hypoglycemia

The symptoms and signs of hypoglycemia^{12,13} are nonspecific. Clinical hypoglycemia—that sufficient to cause symptoms and/or signs²—is most convincingly documented by Whipple's triad: (1) symptoms, signs, or both consistent with hypoglycemia; (2) a low measured plasma glucose concentration; and (3) resolution of those symptoms and signs after the plasma glucose concentration is raised.

Neuroglycopenic symptoms are a direct result of brain glucose deprivation. They include cognitive impairments, behavioral changes, psychomotor abnormalities, and, at lower glucose levels, seizure and coma.^{2-5,12,13} Neurogenic (or autonomic) symptoms are largely the result of the perception of physiologic changes caused by sympathoadrenal (particularly the sympathetic neural¹³) discharge triggered by hypoglycemia. They include adrenergic (catecholamine-mediated) symptoms such as palpitations, tremor, and anxiety/arousal and cholinergic (acetylcholine-mediated) symptoms such as sweating, hunger, and paresthesias.

TABLE 34-2

Physiologic Responses to Decreasing Plasma Glucose Concentrations

Response	Glycemic Threshold* (mmol/L [mg/dL])	Physiologic Effects	Role in Prevention or Correction of Hypoglycemia (Glucose Counterregulation)
↓ Insulin	4.4-4.7 (80-85)	↑ R_a (↓ R_d)	Primary glucose regulatory factor; first defense against hypoglycemia
↑ Glucagon	3.6-3.9 (65-70)	↑ R_a	Primary glucose counterregulatory factor; second defense against hypoglycemia
↑ Epinephrine	3.6-3.9 (65-70)	↑ R_a , ↓ R_c	Involved, critical when glucagon is deficient, third defense against hypoglycemia
↑ Cortisol and growth hormone	3.6-3.9 (65-70)	↑ R_a , ↓ R_c	Involved, not critical
Symptoms	2.8-3.1 (50-55)	↑ Exogenous glucose	Prompt behavioral defense (food ingestion)
↓ Cognition	<2.8 (50)	—	(Compromises behavioral defense)

*Arterialized venous, not venous, plasma glucose concentrations.

R_a , rate of glucose appearance, glucose production by the liver and kidneys; R_c , rate of glucose clearance by insulin-sensitive tissues; R_d , rate of glucose disappearance, glucose utilization by insulin-sensitive tissues such as skeletal muscle (no direct effect on central nervous system glucose utilization).

Central mechanisms may also be involved in the generation of some of these symptoms (e.g., hunger).¹⁴ Subjective awareness of hypoglycemia is largely the result of the perception of neurogenic symptoms (Fig. 34-2).¹²

Signs of hypoglycemia include pallor and diaphoresis, which result from adrenergic cutaneous vasoconstriction and cholinergic activation of sweat glands, respectively.^{2,3} Heart rates and systolic blood pressures are raised, but often not greatly. Neuroglycopenic manifestations are often observable.

Maintenance of Systemic Glucose Balance

Although obligatory glucose utilization, largely by the brain, is continuous, the delivery of exogenous glucose from dietary carbohydrates is intermittent. Systemic glucose balance (see Table 34-1) is normally maintained, and hypoglycemia and hyperglycemia are prevented, by dynamic, minute-to-minute regulation of endogenous glucose production from the liver and kidneys and of glucose utilization by tissues outside the central nervous system (CNS), such as muscle.^{3,4} This regulation is exerted primarily by insulin, glucagon, and epinephrine^{3,4} (see Table 34-2 and Fig. 34-3), although an array of hormones, neurotransmitters, and substrates is involved.⁴

Neurogenic

Sweaty
Hungry
Tingling
Shaky/tremulous
Heart pounding
Nervous/anxious

Neuroglycopenic

Warm
Weak
Difficulty thinking/confused
Tired/drowsy
Faint
Dizzy
Difficulty speaking
Blurred vision

Figure 34-2 Neurogenic (autonomic) and neuroglycopenic symptoms of hypoglycemia in healthy humans. Among the neurogenic symptoms, “sweaty,” “hungry,” and “tingling” are cholinergic and “shaky/tremulous,” “heart pounding,” and “nervous/anxious” are adrenergic. See text for discussion. Mean subject scores (± standard error) for awareness of hypoglycemia (low blood sugar) are shown during clamped euglycemia (EU) and during three conditions of hypoglycemia (Hypo): alone; with combined α- and β-adrenergic blockade by infused phentolamine and propranolol (ADB); and with combined α- and β-adrenergic blockade plus muscarinic cholinergic blockade by atropine (panautonomic blockade, PAB). (From Towler DA, Havlin CE, Craft S, et al. Mechanism of awareness of hypoglycemia: perception of neurogenic [predominantly cholinergic] rather than neuroglycopenic symptoms. *Diabetes*. 1993;42:1791-1798, with permission of the American Diabetes Association.)

Figure 34-3 Physiologic and behavioral defenses against hypoglycemia in humans. α-cell, pancreatic islet alpha cells; β-cell, pancreatic islet beta cells; ACh, acetylcholine; NE, norepinephrine; PNS, parasympathetic nervous system; SNS, sympathetic nervous system; T1DM, type 1 diabetes. (From Cryer PE. Mechanisms of sympathoadrenal failure and hypoglycemia in diabetes. *J Clin Invest*. 2006;116:1470-1473, with permission of the American Society for Clinical Investigation.)

The key physiologic defenses against falling plasma glucose concentrations are (1) a decrease in insulin, (2) an increase in glucagon, and, in the absence of the latter, (3) an increase in epinephrine.^{3,4} The behavioral defense is carbohydrate ingestion prompted by symptoms that are largely sympathetic neural in origin (see Table 34-2 and Fig. 34-3).^{3,4,13}

The first physiologic defense against hypoglycemia is a decrease in insulin secretion by the pancreatic islet beta cells. Signaled primarily by declining glucose levels at the beta cells, this response occurs as plasma glucose concentrations decline within the physiologic range^{3,4} (see Table 34-2) and favors increased hepatic and renal glucose production with virtual cessation of glucose utilization by insulin-sensitive tissues such as muscle (see Fig. 34-3).^{3,4}

The second physiologic defense against hypoglycemia is an increase in glucagon secretion by pancreatic islet alpha cells. This occurs as plasma glucose concentrations fall just below the physiologic range^{3,4} (see Table 34-2) and stimulates hepatic glucose production, largely by stimulating glycogenolysis (see Fig. 34-3).^{3,4} This response is signaled primarily by a decrease in intra-islet insulin, perhaps among other beta-cell secretory products, in the setting of low alpha-cell glucose concentrations^{3,4,15} (see Fig. 34-3) and only secondarily by increased autonomic nervous system (sympathetic, parasympathetic, adrenomedullary) inputs.^{3,4,16}

The third physiologic defense against hypoglycemia, which becomes critical when glucagon is deficient, is an increase in adrenomedullary epinephrine secretion. Signaled via the CNS, it, too, occurs as plasma glucose concentrations fall just below the physiologic range^{3,4} (see Table 34-2) and raises plasma glucose concentrations largely by β_2 -adrenergic stimulation of hepatic and renal glucose production (see Fig. 34-3).^{3,4} However, the plasma glucose-raising actions of epinephrine also involve limitation of glucose clearance by insulin-sensitive tissues, mobilization of gluconeogenic precursors such as lactate and amino acids from muscle and glycerol from fat, and α_2 -adrenergic limitation of insulin secretion (Fig. 34-4).^{3,4,17}

Indeed, the adrenergic actions on beta-cell insulin secretion normally play an important role in the glycemic actions of epinephrine. α_2 -Adrenergic limitation of insulin secretion permits the glycemic response; β_2 -adrenergic stimulation alone has little effect because it also stimulates insulin secretion.⁴ On the other hand, some increase in insulin secretion—due to the rising glucose level, β_2 -adrenergic stimulation, or both—limits the magnitude of the glycemic response to epinephrine.¹⁷ These physiologic interactions explain why glycemic sensitivity to epinephrine is increased in patients who cannot increase insulin secretion (e.g., those with type 1 diabetes).¹⁷ Circulating epinephrine is derived almost exclusively from the adrenal medulla in adults.¹³ Whereas circulating norepinephrine is derived largely from sympathetic nerve terminals under resting conditions and in many stimulated states (e.g., exercise), the plasma norepinephrine response to hypoglycemia is derived largely from the adrenal medulla.¹³

These physiologic defenses against hypoglycemia typically abort episodes of declining plasma glucose concentration and prevent clinical (i.e., symptomatic) hypoglycemia. If they do not, the lower plasma glucose concentration causes a more intense sympathoadrenal response, resulting in symptoms (see Table 34-2).^{3,4} These symptoms, particularly the neurogenic symptoms, cause awareness of hypoglycemia that prompts the behavioral defense against hypoglycemia, ingestion of carbohydrates (see Fig. 34-3).^{3,4}

The integrated physiology of glucose counterregulation^{2,4} is further illustrated in Figure 34-5. Falling glucose levels within the pancreatic islets signal a decrease in insulin secretion and an increase in glucagon secretion. Falling glucose levels sensed in the periphery and in the CNS, acting through the hypothalamus, signal an increase in sympathoadrenal activity that results in an increase in adrenomedullary epinephrine secretion and in neurogenic symptoms, the latter largely resulting from increased sympathetic neural activity. The figure includes a putative cerebral network that may modulate the hypothalamic response.

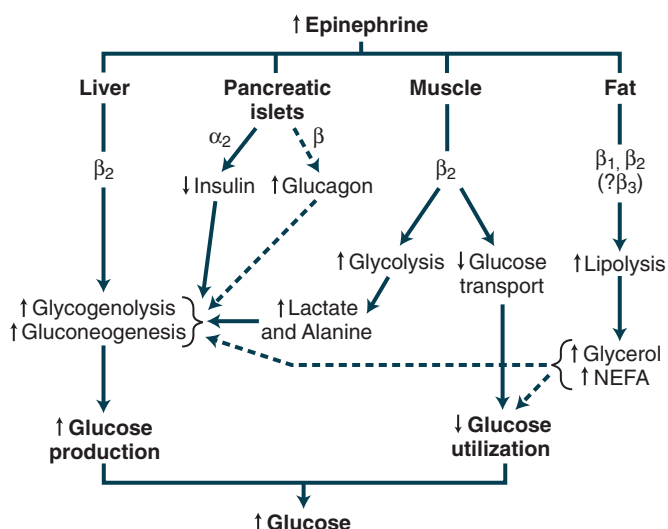

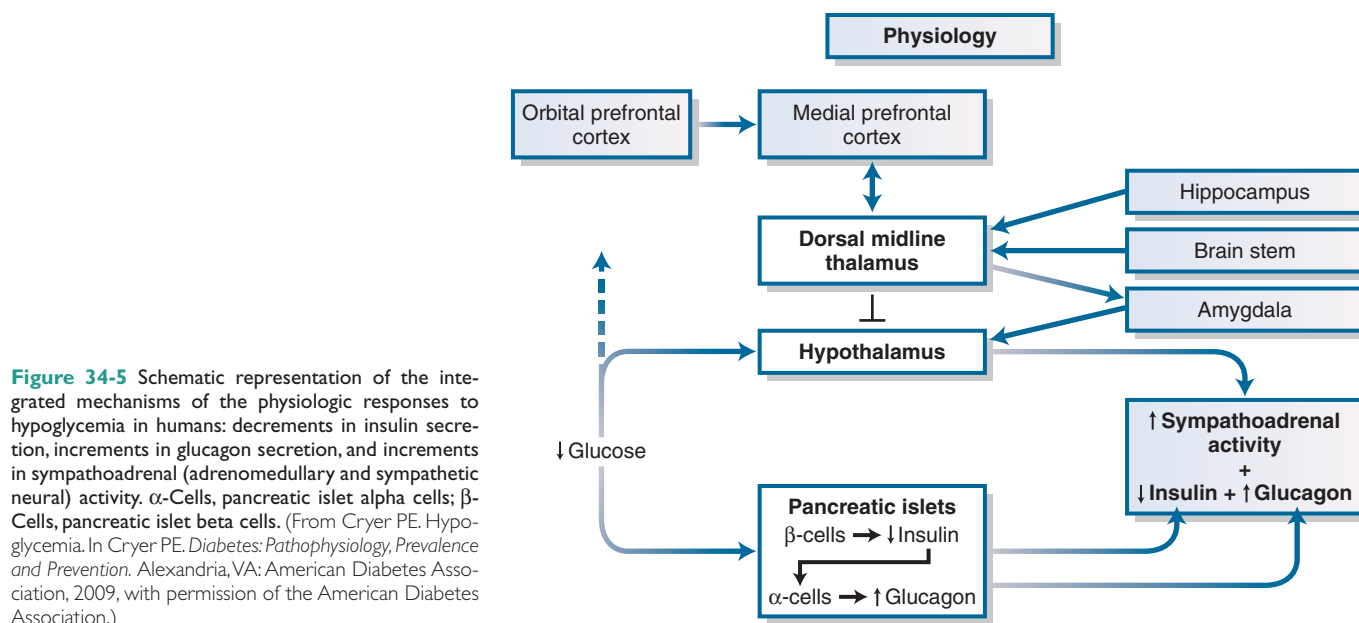

Figure 34-4 Schematic representation of the hyperglycemic effect of epinephrine, mediated by α - and β -adrenergic stimulation. NEFA, nonesterified fatty acids. (From Cryer PE. Catecholamines, pheochromocytoma and diabetes. *Diabetes Rev.* 1993;1:309-317, with permission of the American Diabetes Association.)

CLINICAL HYPOGLYCEMIA

Definition and Diagnosis

Clinical hypoglycemia is, by definition, a plasma glucose concentration low enough to cause symptoms or signs, including impairment of brain function.² The glycemic thresholds for symptoms and signs of hypoglycemia are dynamic; for example, they shift to lower plasma glucose concentrations in patients with recurrent hypoglycemia^{18,19} and to higher concentrations in those with poorly controlled diabetes.^{19,20} Therefore, it is not possible to state a single plasma glucose concentration that categorically defines hypoglycemia. Furthermore, the symptoms and signs of hypoglycemia are nonspecific,^{2,3} and a low measured plasma glucose concentration can be artifactual.² For all of these reasons, hypoglycemia is most convincingly documented by Whipple's triad: symptoms, signs, or both consistent with hypoglycemia; a low measured plasma glucose concentration; and resolution of those symptoms or signs after the plasma glucose concentration is raised.^{2,3}

Documentation of Whipple's triad is particularly important when hypoglycemia is suspected in a person who does not have diabetes mellitus, because hypoglycemic disorders are rare.² In the absence of diabetes, a thorough

diagnostic evaluation is recommended only for patients in whom Whipple's triad is documented.² Ideally, patients with diabetes being treated with an insulin secretagogue or insulin should monitor their plasma glucose concentration whenever they suspect hypoglycemia.^{2,3} However, that is sometimes not practical, and it often is not done. Nonetheless, the likelihood that a symptomatic episode is the result of hypoglycemia is high, because hypoglycemia is common in such patients.³ Given the potential detrimental effects of an untreated episode of hypoglycemia, documentation of Whipple's triad may be less critical to the diagnosis of an episode of hypoglycemia in patients with diabetes treated with these medications.

General Mechanisms of Hypoglycemia

Hypoglycemia develops when glucose efflux out of the circulation exceeds glucose influx into the circulation. Glucose efflux is the sum of ongoing obligatory glucose utilization, largely by the brain, and regulated glucose utilization by insulin-sensitive tissues, and glucose influx is the sum of endogenous glucose production and exogenous glucose delivery from ingested carbohydrates (see Table 34-1). Although hypoglycemia can result from excessive glucose efflux, it is typically the result of glucose influx that is too low—either absolutely low or low relative to high rates of glucose efflux.

Clinical Classification of Hypoglycemia

Causes of hypoglycemia² are outlined in Table 34-3. Drugs are, by far, the most common cause of hypoglycemia. Those include insulin secretagogues and insulin used to treat diabetes. Although persons with diabetes can suffer from the same hypoglycemic disorders as those without diabetes, their hypoglycemic episodes are usually the result of treatment of their diabetes.^{2,3} Furthermore, the pathophysiology of hypoglycemia in diabetes is unique, and the diagnostic and management approaches are different from those for individuals without diabetes.^{2,3} Therefore, hypoglycemia in persons with diabetes and hypoglycemia in those without diabetes are discussed separately in this chapter.

HYPOGLYCEMIA IN PERSONS WITH DIABETES

The Clinical Problem of Hypoglycemia in Diabetes

Iatrogenic hypoglycemia is the limiting factor in the glyceemic management of diabetes.³ It causes recurrent morbidity in most persons with type 1 diabetes mellitus (T1DM) and in many of those with advanced type 2 diabetes mellitus (T2DM), and it is sometimes fatal. The barrier of hypoglycemia precludes maintenance of euglycemia over a lifetime of diabetes and thus full realization of the vascular benefits of glyceemic control. Furthermore, hypoglycemia compromises physiologic and behavioral defenses against subsequent falling plasma glucose concentrations, resulting in a vicious cycle of recurrent hypoglycemia.

Hypoglycemia in diabetes is caused by pharmacokinetically imperfect treatment with an insulin secretagogue (such as a sulfonylurea or a glinide) or with insulin that results in episodes of therapeutic hyperinsulinemia. Thus, it is fundamentally iatrogenic. Episodes of substantial absolute therapeutic hyperinsulinemia can cause isolated episodes of hypoglycemia. However, as developed later in this chapter, recurrent hypoglycemia in diabetes is typically the result of the interplay of relative or mild to moderate absolute therapeutic hyperinsulinemia and compromised physiologic and behavioral defenses against falling plasma glucose concentrations.³

Frequency of Hypoglycemia in Diabetes

Hypoglycemia is a fact of life for people with T1DM (Table 34-4).^{3,21-25} The average patient suffers untold numbers of episodes of asymptomatic hypoglycemia (which are not benign because they impair defenses against subsequent hypoglycemia), approximately two episodes of symptomatic hypoglycemia per week (thousands of such episodes over a lifetime of diabetes), and roughly one episode per year of severe, at least temporarily disabling hypoglycemia, often with seizure or coma. This problem has not abated since it was highlighted by the report of the Diabetes Control and Complications Trial (DCCT)²¹ in 1993. In

From Cryer PE, Axelrod L, Grossman AB, et al. Evaluation and management of adult hypoglycemic disorders: an Endocrine Society clinical practice guideline. *J Clin Endocrinol Metab*. 2009;94:709-728, with permission of The Endocrine Society.

2007, the United Kingdom Hypoglycaemia Study Group (UKHSG) reported an incidence of severe hypoglycemia twice that reported in the DCCT among patients who had had T1DM for less than 5 years and five times the DCCT incidence among those with T1DM for more than 15 years (see Table 34-4).²⁴

The overall incidence of hypoglycemia during treatment of T2DM with an insulin secretagogue, or even with insulin, is lower than that in patients with T1DM (see Table 34-4).^{3,23,24,26-35} However, for pathophysiologic reasons discussed later, the incidence of hypoglycemia increases progressively over time as patients approach the end of the spectrum of T2DM (i.e., absolute endogenous insulin deficit).^{3,24,31,32} Indeed, the incidence of hypoglycemia has been reported to be similar in patients with T2DM and in those with T1DM matched for duration of insulin therapy.³² The UKHSG found a prevalence of severe hypoglycemia of 7% and an incidence of 10 episodes per 100 patient-years among patients with T2DM treated with insulin for less than 2 years; among those treated for longer than 5 years, these figures rose to 25% prevalence and 70 episodes per 100 patient-years (see Table 34-4).²⁴ The patterns for self-treated hypoglycemia were similar. Therefore, at least with current, less than euglycemic treatment goals, the frequency of iatrogenic hypoglycemia is relatively low during the first few years of treatment of T2DM with insulin but increases substantially in advanced T2DM, approaching the frequency among patients with T1DM.

Estimates of the incidence and prevalence of hypoglycemia in diabetes are generally underestimates because of the challenge of ascertainment.³ Asymptomatic episodes will be missed unless they are incidentally detected by self-monitoring of blood glucose or by continuous glucose sensing. Symptomatic episodes may not be recognized to be the result of hypoglycemia³⁶ because the symptoms of hypoglycemia are nonspecific. Even if they are recognized, they may not be remembered^{37,38} and reported at periodic patient contacts. Because they are dramatic events that are more likely to be reported (by the patient or an associate),^{37,38} estimates of the frequency of severe hypoglycemia (that requiring the assistance of another person) are more reliable, although they represent only a small fraction of the total hypoglycemic burden. Prospective, population-based studies with a focus on hypoglycemia should provide the most reliable data.

The prospective, population-based data of Donnelly and colleagues²³ indicate that the overall incidences of any hypoglycemia and of severe hypoglycemia in insulin-treated

T2DM are about one-third of those in T1DM (see Table 34-4). Two other population-based studies reported the incidence of severe hypoglycemia requiring emergency treatment in insulin-treated T2DM to be 40%³³ and 100%³⁴ of that in T1DM. Taken together, and considering that the prevalence of T2DM is approximately 20-fold greater than that of T1DM and that most patients with T2DM ultimately require treatment with insulin, these data suggest that most episodes of iatrogenic hypoglycemia, including severe hypoglycemia, occur in persons with T2DM.

Impact of Hypoglycemia in Diabetes

Iatrogenic hypoglycemia causes recurrent physical and psychosocial morbidity and impairs glycemic defenses against subsequent hypoglycemia in many patients with diabetes.³ The barrier of hypoglycemia precludes maintenance of euglycemia over a lifetime of diabetes.³ Hypoglycemia often causes functional brain failure that is typically reversed after the plasma glucose concentration is raised.⁵ Rarely, it causes sudden death, presumably the result of cardiac arrhythmia, or, if it is profound and prolonged, permanent brain dysfunction or death.⁵

At a minimum, an episode of symptomatic hypoglycemia is a nuisance and a distraction. It can impair judgment, behavior, and performance of physical tasks such as driving. It can cause a seizure or loss of consciousness. Transient neurologic deficits sometimes occur, but permanent neurologic damage is rare. Systematic long-term follow-up of the DCCT patients suggests that recurrent iatrogenic hypoglycemia does not cause chronic cognitive impairments,³⁹ but the possibility that it does so in young children^{40,41} remains, and there are no corresponding data in the elderly.³⁹ Among other psychological morbidities, fear of hypoglycemia can be a barrier to glycemic control.⁴²

Iatrogenic hypoglycemia can be fatal.³ Early reports indicated that 2% to 4% of persons with diabetes (mostly T1DM) died from hypoglycemia.⁴³⁻⁴⁵ More recent reports indicated that 6%,³⁹ 7%,⁴⁶ and 10%⁴⁷ of deaths of persons with T1DM were caused by hypoglycemia. Corresponding rates of hypoglycemia-associated mortality in T2DM are as yet unknown. Deaths of up to 10% of patients with severe sulfonylurea-induced hypoglycemia have been reported.^{48,49} The cause of excess mortality during intensive glycemic therapy of T2DM in the Action to Control Cardiovascular Risk in Diabetes (ACCORD) study⁵⁰ is not known. It could have been chance. It could have been the result of a non-glycemic effect of the intensive therapy regimen, such as an adverse effect of a drug, weight gain, or something else. Or, it could well have been the result of hypoglycemia. Hypoglycemia can be fatal in T2DM,^{3,48,49} and more patients died in the intensive glycemic therapy group⁵⁰ in ACCORD.

Although prolonged, profound hypoglycemia can cause brain death, most instances of sudden hypoglycemic death are thought to be the result of abnormal cardiac repolarization and ventricular arrhythmias triggered by an intense sympathoadrenal response to hypoglycemia.⁵ Experimental hypoglycemia prolongs the electrocardiographic corrected QT (QTc) interval, an effect that is prevented by β -adrenergic blockade, in nondiabetic individuals and in persons with T1DM.⁵¹⁻⁵³ QTc prolongation occurs during episodes of iatrogenic hypoglycemia in patients with T1DM.^{51,54,55} Sudden death has been associated with QT prolongation and reduced baroreflex sensitivity in patients with classic diabetic autonomic neuropathy.⁵⁶ Adler and colleagues⁵⁷ demonstrated, in studies of nondiabetic individuals, that hypoglycemia causes (1) reduced baroreflex sensitivity, (2) reduced muscle sympathetic nerve responses

to vasodilation, and (3) reduced plasma norepinephrine responses to lower-body negative pressure the following day. The induction of functional sympathetic failure by recent antecedent hypoglycemia as an additional, potentially fatal feature of the concept of hypoglycemia-associated autonomic failure (HAAF) in diabetes³ is discussed later in this chapter.

Clinical Definition and Classification of Hypoglycemia in Diabetes

The American Diabetes Association (ADA) Workgroup on Hypoglycemia⁵⁸ defined hypoglycemia in diabetes as “all episodes of abnormally low plasma glucose concentration that expose the individual to potential harm.” That is broader than the recommended definition of clinical hypoglycemia in persons without diabetes (i.e., a plasma glucose concentration low enough to cause symptoms or signs²) because it includes asymptomatic episodes. The latter are not benign in persons with diabetes; they compromise defenses against subsequent hypoglycemia,³ and they identify increased risk of imminent severe iatrogenic hypoglycemia.⁵⁹ Again, it is not possible to define a plasma glucose concentration that categorically defines hypoglycemia because the glycemic thresholds for responses to hypoglycemia are dynamic. They shift to lower plasma glucose concentrations in patients with recurrent hypoglycemia^{18,19} and to higher plasma glucose concentrations in those with poorly controlled diabetes.^{19,20}

The ADA Workgroup recommended that people with diabetes (implicitly those treated with an insulin secretagogue or insulin) become concerned about the possibility of developing hypoglycemia at a self-monitored plasma glucose concentration of 3.9 mmol/L (70 mg/dL) or less.⁵⁸ Within the error of self-monitoring (or continuous glucose sensing), that conservative alert value approximates the lower limit of the nondiabetic postabsorptive plasma glucose range⁴ and the normal glycemic thresholds for activation of physiologic glucose counterregulatory systems⁴ (see Table 34-2); it is low enough to reduce glycemic defenses against subsequent hypoglycemia⁶⁰ in nondiabetic persons. Therefore, the recommended glucose alert level of 3.9 mmol/L (70 mg/dL) or less is data driven; it usually gives the patient time to take action to prevent a clinical hypoglycemic episode, and it provides some margin for the limited accuracy of glucose monitoring devices at low plasma glucose concentrations. Although some have argued for a slightly lower glucose alert value, there is little disagreement on this ostensibly contentious issue.⁶¹

The recommended alert value does not, of course, mean that persons with diabetes should always self-treat for hypoglycemia at an estimated plasma glucose concentration of 3.9 mmol/L (70 mg/dL) or less. Rather, they should consider actions ranging from repeating the measurement in the near term, through behavioral actions such as avoiding exercise or driving until the glucose level is raised, to carbohydrate ingestion and subsequent adjustments of the therapeutic regimen.

The ADA Workgroup⁵⁸ also recommended a clinical classification of hypoglycemia in diabetes (Table 34-5).

Pathophysiology of Glucose Counterregulation in Diabetes

The pathophysiology of glucose counterregulation and its relationship to clinical hypoglycemia in diabetes have been reviewed in detail³ and are summarized in the paragraphs that follow (see earlier discussion and Figs. 34-3 and 34-5).

TABLE 34-5

Classification of Hypoglycemia in Diabetes

Clinical Classification	Definition
Severe hypoglycemia	An event requiring assistance of another person to actively administer carbohydrate, glucagon, or other resuscitative actions. Plasma glucose measurements may not be available during such an event, but neurologic recovery attributable to the restoration of plasma glucose to a normal level is considered sufficient evidence that the event was induced by a low plasma glucose concentration.
Documented symptomatic hypoglycemia	An event during which typical symptoms of hypoglycemia are accompanied by a measured plasma glucose concentration of ≤ 70 mg/dL (3.9 mmol/L).
Asymptomatic hypoglycemia	An event not accompanied by typical symptoms of hypoglycemia but with a measured plasma glucose concentration of ≤ 70 mg/dL (3.9 mmol/L).
Probable symptomatic hypoglycemia	An event during which symptoms typical of hypoglycemia are not accompanied by a plasma glucose determination but were presumably caused by a plasma glucose concentration of ≤ 70 mg/dL (3.9 mmol/L).
Relative hypoglycemia	An event during which the person with diabetes reports any of the typical symptoms of hypoglycemia and interprets those as indicative of hypoglycemia, with a measured plasma glucose concentration that is >70 mg/dL (3.9 mmol/L) but is approaching that level.

From American Diabetes Association Workgroup on Hypoglycemia. Defining and reporting hypoglycemia in diabetes. *Diabetes Care*. 2005;28:1245-1249, with permission of the American Diabetes Association.

Again, the key physiologic defenses against falling plasma glucose concentrations are a decrease in insulin, an increase in glucagon, and, in the absence of the latter, an increase in epinephrine.^{3,4} The behavioral defense is carbohydrate ingestion prompted by symptoms that are largely sympathetic neural in origin.^{3,4}

Insulin Excess

Episodes of therapeutic hyperinsulinemia, produced by treatment with an insulin secretagogue or with insulin, are a prerequisite for the development of iatrogenic hypoglycemia. Marked absolute insulin excess can cause isolated episodes of hypoglycemia. However, iatrogenic hypoglycemia is typically the result of the interplay of relative or mild to moderate absolute therapeutic hyperinsulinemia and compromised physiologic and behavioral defenses against falling plasma glucose concentrations (Fig. 34-6).^{3,62,63}

Defective Glucose Counterregulation and Hypoglycemia Unawareness

In established (C peptide–negative) T1DM, circulating (exogenous) insulin concentrations do not decrease as plasma glucose concentrations fall in response to therapeutic hyperinsulinemia.^{3,62} That is the result of absolute beta-cell failure with no regulated endogenous insulin secretion. Therefore, the first physiologic defense against hypoglycemia is lost. Furthermore, despite the presence of otherwise functional alpha cells, there is no increase in glucagon secretion (Fig. 34-7).^{3,62} That, too, is the result of beta-cell failure, which causes loss of the decrement in inrailelet

insulin, perhaps among other beta-cell secretory products, that normally signals an increase in alpha-cell glucagon secretion during hypoglycemia (see Figs. 34-3 and 34-5).^{3,15} Therefore, the second physiologic defense against hypoglycemia is also lost.

In addition, the increase in epinephrine secretion (see Fig. 34-7),^{3,62} the third physiologic defense against hypoglycemia, is typically attenuated (see Fig. 34-7).^{3,62} In the setting of absent insulin and glucagon responses, the attenuated epinephrine response causes the clinical syndrome of defective glucose counterregulation^{3,62,64,65} (see Fig. 34-6), which is associated with a 25-fold⁶⁴ or greater⁶⁵ increased risk of severe hypoglycemia in T1DM. The attenuated epinephrine response is a marker of attenuation of the sympathoadrenal response (including the sympathetic neural response) that normally causes neurogenic symptoms that largely prompt the behavioral response leading to carbohydrate ingestion (see Figs. 34-3 and 34-5). This attenuated response (largely the attenuated sympathetic neural response) causes the clinical syndrome of hypoglycemia unawareness³ (see Fig. 34-7), which is associated with a sixfold increased risk of severe hypoglycemia in T1DM.⁶⁶

Although the term *hypoglycemia unawareness* is used widely, “impaired awareness of hypoglycemia”⁶⁶ is more precise because there is a spectrum ranging from partial to complete loss of symptoms. Attenuated sympathoadrenal responses to falling plasma glucose concentrations can be caused by recent antecedent hypoglycemia^{3,62,63,67} (Figs. 34-8 and 34-9), prior exercise,^{3,68-70} or sleep^{3,71-73} (see later discussion of HAAF).

Hypoglycemia unawareness is largely the result of reduced release of the sympathetic neurotransmitters norepinephrine and acetylcholine.^{3,13} There is evidence of decreased β -adrenergic sensitivity, specifically reduced cardiac chronotropic sensitivity to isoproterenol, in affected patients.^{74,75} However, vascular sensitivity to a β -adrenergic agonist was not found to be reduced in unaware patients.⁷⁶ Reduced sensitivity to β -adrenergic signaling of neurogenic symptoms remains to be demonstrated in patients with unawareness, and it would be necessary to also postulate decreased cholinergic sensitivity to explain reduced cholinergic symptoms such as sweating.

In contrast to these compromised defenses in T1DM, defenses against hypoglycemia are intact early in the course of T2DM. However, they become compromised over time.^{3,63} In advanced T2DM (i.e., with absolutely deficient endogenous insulin), insulin and glucagon responses to falling plasma glucose concentrations are lost and sympathoadrenal responses to hypoglycemia are reduced by recent antecedent hypoglycemia, as is observed in T1DM.^{3,63}

In summary, the pathophysiology of glucose counterregulation is the same in T1DM and T2DM but with different time courses.^{3,62,63} The pathogenesis of an episode of iatrogenic hypoglycemia involves therapeutic hyperinsulinemia resulting in falling plasma glucose concentrations. With absence of appropriate decrements in insulin and increments in glucagon, hypoglycemia occurs. That, in turn, causes attenuated sympathoadrenal responses to subsequent falling glucose levels and recurrent episodes of hypoglycemia (see Fig. 34-6). Because beta-cell failure, which causes loss of both insulin and glucagon responses, occurs rapidly in T1DM but slowly in T2DM, the syndromes of defective glucose counterregulation and hypoglycemia unawareness develop early in T1DM but later in T2DM. That temporal pattern of compromised glycemic defenses explains why iatrogenic hypoglycemia becomes progressively more frequent as patients approach the insulin-deficient end of the spectrum of T2DM.

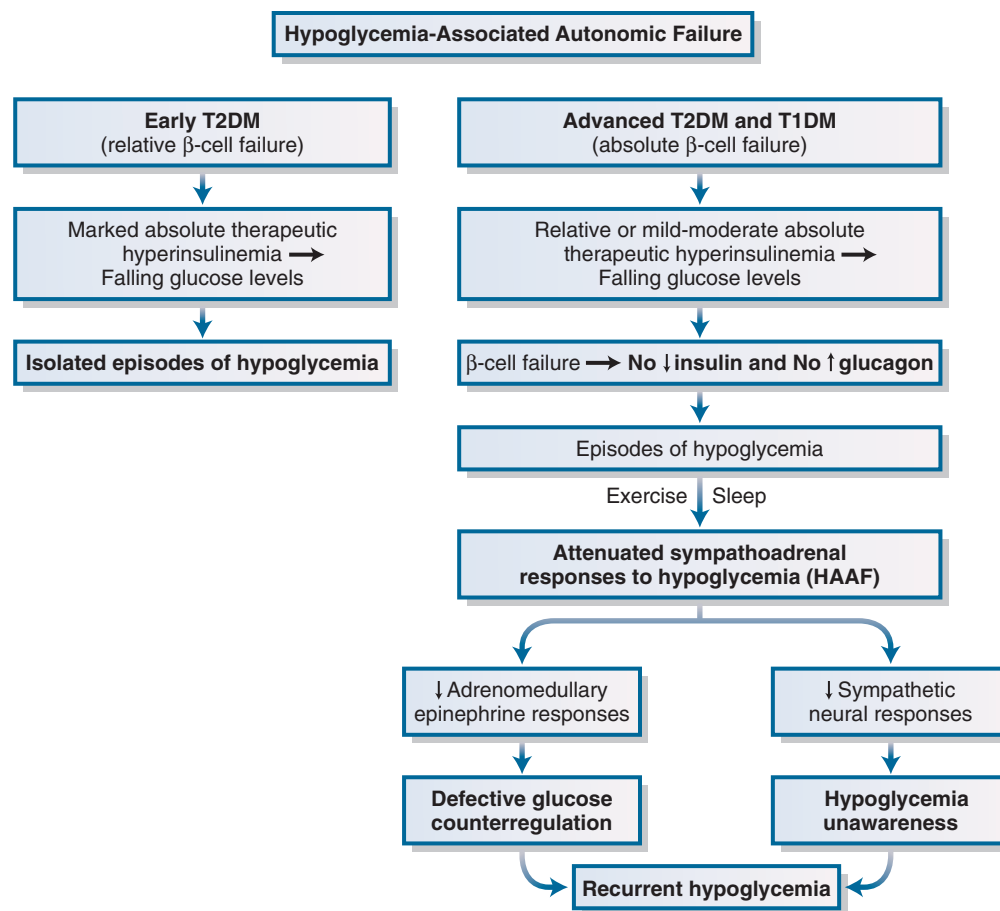

Figure 34-6 Schematic representation of the concept of hypoglycemia-associated autonomic failure (HAAF) in diabetes and the pathogenesis of iatrogenic hypoglycemia including the clinical syndromes of defective glucose counterregulation and hypoglycemia unawareness. β -Cell, pancreatic islet beta cells; T1DM, type 1 diabetes mellitus; T2DM, type 2 diabetes mellitus.

Hypoglycemia-Associated Autonomic Failure in Diabetes

The concept of HAAF in diabetes posits that recent antecedent hypoglycemia (see Figs. 34-8 and 34-9),^{3,62,63,67} prior exercise,^{3,68-70} or sleep^{3,71-73} can cause both defective glucose counterregulation and hypoglycemia unawareness during subsequent hypoglycemia. The mechanisms are, respectively, attenuation of the epinephrine response (in the setting of absent insulin and glucagon responses) and attenuation of the sympathoadrenal (including the sympathetic neural) response and the resulting neurogenic symptom responses. The development of these defects sets up a vicious cycle of recurrent hypoglycemia (see Fig. 34-6). HAAF is a functional form of autonomic failure, distinct from classic diabetic autonomic neuropathy. Nonetheless, an attenuated sympathoadrenal response to a given level of hypoglycemia, the key feature of HAAF, is more prominent in patients with autonomic neuropathy.^{77,78} In addition to its role in the pathogenesis of hypoglycemia, HAAF has cardiovascular implications because, like autonomic neuropathy, it reduces baroreflex sensitivity⁵⁷ and may predispose patients to ventricular arrhythmias.

Recent antecedent hypoglycemia, even asymptomatic nocturnal hypoglycemia, reduces epinephrine and symptomatic responses to a given level of subsequent hypoglycemia,⁷⁹ reduces detection of hypoglycemia in the clinical setting,⁸⁰ and reduces glycemic defense against hyperinsulinemia⁶² in T1DM. Perhaps the most compelling support for the clinical relevance of HAAF is the finding, originally from three independent laboratories,⁸¹⁻⁸⁴ that as little as 2 to 3 weeks of scrupulous avoidance of hypoglycemia reverses hypoglycemia unawareness (Fig. 34-10), and improves the attenuated epinephrine component of defective glucose counterregulation in most affected patients. HAAF also occurs in advanced T2DM.^{3,63}

There are three recognized causes of a reversibly attenuated sympathoadrenal response to hypoglycemia and, therefore, three forms of HAAF.³ Antecedent hypoglycemia-related HAAF led to the concept.^{3,62,63,67} Exercise-related HAAF^{3,68-70} is exemplified by late postexercise hypoglycemia, which typically occurs 6 to 15 hours after strenuous exercise and is often nocturnal.^{85,86} Sleep-related HAAF^{3,71-73} is the result of further attenuation of the sympathoadrenal response to hypoglycemia during sleep. Sleeping patients with T1DM are much less likely to be awakened by hypoglycemia than nondiabetic individuals,^{72,73} probably because of their attenuated sympathoadrenal responses. There may well be additional, unrecognized causes of HAAF, and there may also be a structural (neuropathic) component.³

The integrated pathophysiologic mechanisms of HAAF are illustrated in Fig. 34-11. Loss of insulin and glucagon responses to falling plasma glucose concentrations caused by therapeutic hyperinsulinemia is the result of beta-cell failure in T1DM and advanced T2DM. Neither can be attributed to loss of islet autonomic innervation, because low glucose concentrations decrease insulin secretion and increase glucagon secretion in patients with a transplanted (i.e., denervated) pancreas,⁸⁷ in dogs with a denervated pancreas,⁸⁸ and in isolated perfused pancreas and perfused islets. The mechanism of the attenuated sympathoadrenal response is not known, but it must involve the brain or the afferent or efferent components of the sympathoadrenal system.³ The proposed mechanisms include the systemic mediator, brain fuel transport, and brain metabolism hypotheses.^{3,89,90} There is considerable evidence against the first two of these proposed mechanisms.³

Figure 34-10 Mean (\pm standard error) neurogenic and neuroglycopenic symptom scores during hyperinsulinemic stepped hypoglycemic glucose clamps in nondiabetic subjects (rectangles) and in people with type 1 diabetes (IDDM) selected for clinical hypoglycemia unawareness studied at various time points during scrupulous avoidance of iatrogenic hypoglycemia: at baseline (0 days, open columns), after 3 days (first set of crosshatched columns), after 3 to 4 weeks (closed columns), and after 3 months (second set of crosshatched columns). IDDM, insulin-dependent diabetes mellitus. (From Dagogo-Jack S, Rattarasam C, Cryer PE. Reversal of hypoglycemia unawareness, but not defective glucose counterregulation, in IDDM. *Diabetes*. 1994;43:1426-1434, with permission of the American Diabetes Association.)

Much of the fundamental research into the mechanism of HAAF has focused on the hypothalamus, the central integrator of the sympathoadrenal response to hypoglycemia.⁹⁰ It is conceivable, however, that the changes in the hypothalamic/sympathoadrenal response reflect modulation by higher brain centers.³ For example, measurements of regional cerebral blood flow using oxygen 15-labeled water and positron emission tomography indicate that hypoglycemia increases synaptic activity in widespread but interconnected brain regions in humans⁹¹ and that recent antecedent hypoglycemia both reduces sympathoadrenal and symptomatic responses (a model of HAAF) and increases synaptic activation in the dorsal midline thalamus (and only in that brain region) during subsequent hypoglycemia.⁹² Therefore, it has been suggested that there may be a cerebral network that results in thalamic inhibition of hypothalamic activity in HAAF.⁹² Such a putative cerebral network is included in Figure 34-11 although it remains theoretical.

Risk Factors for Hypoglycemia in Diabetes

The risk factors for iatrogenic hypoglycemia^{3,93} (Table 34-6) follow directly from the pathophysiology of glucose counterregulation in diabetes and are based on the tenet that iatrogenic hypoglycemia is typically the result of the interplay of relative or absolute therapeutic insulin excess and compromised physiologic and behavioral defenses against falling plasma glucose concentrations (i.e., HAAF) in T1DM and advanced T2DM, as discussed earlier.

TABLE 34-7

Hypoglycemia Risk Factor Reduction

1. Acknowledge the problem.
2. Apply the principles of aggressive glycemic therapy.
 - Diabetes self-management (patient education and empowerment)
 - Frequent self-monitoring of blood glucose (and in some instances continuous glucose sensing)
 - Flexible and appropriate insulin (and other drug) regimens
 - Individualized glycemic goals
 - Ongoing professional guidance and support
3. Consider the conventional risk factors for hypoglycemia.*
4. Consider the risk factors for HAAF.*

HAAF, hypoglycemia-associated autonomic failure in diabetes.

*See Table 34-6.

allows the caregiver to move on, if hypoglycemia is not a problem, or to deal with it and keep it in perspective, if hypoglycemia is a problem. Some patients are reluctant to raise the issue, but their concerns about the reality, or even the possibility, of hypoglycemia can be a barrier to glycemic control.^{107,108} If possible, close associates of the patient should be asked whether they have observed clues to episodes not recognized by the patient. Even if no concerns are expressed, review of the record of self-monitoring of blood glucose (or continuous glucose sensing data) may disclose that hypoglycemia is a problem.

Apply the Principles of Aggressive Glycemic Therapy

These principles^{3,93,102-106} include diabetes self-management by a well-informed patient, frequent self-monitoring of blood glucose levels (and in some instances continuous glucose sensing), flexible and appropriate insulin and other drug regimens, individualized glycemic goals, and ongoing professional guidance and support (see Table 34-7).

As the therapeutic regimen becomes progressively more complex—early in T1DM and later in T2DM—successful glycemic management becomes progressively more dependent on the many decisions and the skills of a well-informed person with diabetes. Therefore, patient education and empowerment are fundamentally important. Patients treated with insulin secretagogues or insulin need to know the common symptoms of hypoglycemia, their individual most meaningful symptoms, and how to treat (and not overtreat) an episode. They need to know the relevant conventional risk factors for hypoglycemia, including the temporal patterns of the glucose-lowering actions of their individual secretagogue or insulin preparations and the effects of missed meals, the overnight fast, exercise, and alcohol ingestion. They also need to know that increasing episodes of hypoglycemia signal an increased likelihood of future, often more severe, hypoglycemia.^{26,35,96-98,109-112} Close associates also need to know how to recognize hypoglycemia, to understand why a neuroglycopenic patient may become uncooperative, and to know when and how to administer glucagon. Finally, patients need to learn to apply the data from their self-monitoring of blood glucose concentrations (or from continuous glucose sensing) toward the goal of minimizing hypoglycemia (as well as hyperglycemia).

Frequent self-monitoring also becomes more key to diabetes self-management as the therapeutic regimen becomes more complex, early in T1DM and later in T2DM. Ideally, patients should monitor their glucose level whenever they suspect hypoglycemia. That would confirm or refute an episode and help the patients learn their individual key

symptoms and might lead to regimen adjustments. It is important for patients with hypoglycemia unawareness to monitor glucose levels before performing critical tasks such as driving. Unfortunately, conventional blood glucose monitoring, in which a measurement is obtained at one point in time, does not indicate whether the glucose level is falling, stable, or rising. That shortcoming is being addressed by evolving technologies for continuous glucose sensing.¹¹³⁻¹¹⁷

Therapeutic hyperinsulinemia, a prerequisite for iatrogenic hypoglycemia, can occur during treatment with an insulin secretagogue (such as a sulfonylurea or a glinide) or with insulin. Early in its course, T2DM may respond to drugs that do not raise insulin levels at normal or low plasma glucose concentrations and therefore should not, and probably do not,¹¹⁸ cause hypoglycemia. Those include the biguanide metformin (which nonetheless has been reported to cause self-reported hypoglycemia^{30,119}), thiazolidinediones, α -glucosidase inhibitors, glucagon-like peptide 1 (GLP-1) receptor agonists, and dipeptidyl peptidase IV (DPP-IV) inhibitors. All of these drugs require endogenous insulin secretion to lower plasma glucose concentrations, and insulin secretion declines appropriately as glucose levels fall into the normal range. That is true even for the GLP-1 receptor agonists and DPP-IV inhibitors, which enhance glucose-stimulated insulin secretion (among other actions). However, that feature may be lost, and hypoglycemia can occur, if these drugs are used with an insulin secretagogue (e.g., a sulfonylurea) that raises insulin independent of glucose.¹²⁰ Indeed, all five categories of drugs increase the risk of hypoglycemia if used with such an insulin secretagogue or insulin.

Among the commonly prescribed sulfonylureas, hypoglycemia is more often associated with the longer-acting glyburide (glibenclamide) than with the shorter-acting glimepiride.^{121,122} In a therapeutic regimen involving multiple daily injections of insulin, the use of long-acting insulin analogues (e.g., glargine, detemir) rather than NPH insulin as the basal insulin preparation reduces at least the incidence of nocturnal hypoglycemia, and perhaps that of total and symptomatic hypoglycemia, in T1DM and T2DM.¹²³⁻¹²⁵ The use of a rapid-acting insulin analogue (e.g., lispro, aspart, glulisine) as the prandial insulin reduces the incidence of nocturnal hypoglycemia at least in T1DM.^{123,125} Albeit conceptually attractive, it has not been established convincingly that continuous subcutaneous insulin infusion is superior to multiple daily injections with insulin analogues in regard to hypoglycemia at comparable levels of glycemic control.^{126,127} Approaches to the prevention of nocturnal hypoglycemia, in addition to the use of insulin analogues, include attempts to produce sustained delivery of exogenous carbohydrate or sustained endogenous glucose production throughout the night.¹²⁸

A lifetime of euglycemia would be in the best interest of persons with diabetes if it could be accomplished safely. Partial glycemic control reduces, but does not eliminate, the microvascular complications of diabetes—retinopathy, nephropathy, and neuropathy—in T1DM^{21,22} and T2DM.^{129,130} Extrapolation of the DCCT retinopathy data suggests that long-term maintenance of euglycemia might eliminate those complications.¹³¹ Long-term follow-up of the DCCT patients seemingly indicates that an earlier period of partial glycemic control also reduces macrovascular complications in T1DM.¹³² With the exception of the metformin subset of the United Kingdom Prospective Diabetes Study Group (UKPDS),¹³⁰ randomized controlled trials have not documented a cardiovascular mortality benefit of partial glycemic control in T2DM.^{50,129} However,

those trials did not exclude a macrovascular benefit if glycemic control could have been maintained for a longer period of time. Long-term follow-up of the UKPDS patients also seemingly indicates a macrovascular benefit from an earlier period of partial glycemic control.¹³³ In any event, given its documented microvascular benefit, maintenance of euglycemia over a lifetime would be in the best interest of persons with diabetes if it could be accomplished safely.

A meaningful degree of glycemic control, theoretically even euglycemia, can be accomplished safely early in the course of T2DM with lifestyle changes, specifically weight loss, and with drugs that should not, and probably do not, cause hypoglycemia (discussed earlier). However, those measures become ineffective as beta-cell failure progresses over time in T2DM. Insulin secretagogues such as sulfonylureas and glinides are also effective early in T2DM but introduce the possibility of iatrogenic hypoglycemia. Because of the barrier of hypoglycemia, euglycemia is not an appropriate glycemic goal during treatment with an insulin secretagogue or with insulin. The generic glycemic goal is an HbA_{1c} level as close to the nondiabetic range as can be accomplished in a given patient^{134,135} at a given point in the evolution of his or her diabetes. Nonetheless, there is substantial long-term benefit from reduction of HbA_{1c}, even if it is still above recommended levels.^{21,22,129,130,136} Clearly, glycemic goals should be individualized. They may need to be reconsidered over time because of progression of endogenous insulin deficiency, or development of comorbid illness or functional impairment that negate the benefit of glycemic control,¹³⁷ or both.

Finally, because the glycemic management of diabetes is empiric, caregivers should work with each patient to find the most effective and safest regimen at a given point in the course of that patient's diabetes.

Consider the Conventional Risk Factors

The conventional risk factors are those that result in relative, as well as absolute, insulin excess (see Table 34-6). In addition to insulin secretagogue doses, timing, and type, they include conditions in which exogenous glucose delivery or endogenous glucose production is decreased, glucose utilization or sensitivity to insulin is increased, or insulin clearance is decreased.

Consider the Risk Factors for HAAF

The risk factors indicative of HAAF (see Table 34-6) include the degree of endogenous insulin deficiency; a history of severe hypoglycemia, hypoglycemia unawareness, or both and recent antecedent hypoglycemia, prior exercise, or sleep; and aggressive glycemic therapy per se. An episode of severe hypoglycemia is a clinical red flag. Unless the cause is easily remediable, it should prompt consideration of a fundamental change in the therapeutic regimen. Without such a change, the risk of a subsequent episode of severe hypoglycemia is high.^{3,26,96-98,109-112} In a patient with hypoglycemia unawareness, a 2- to 3-week period of scrupulous avoidance of hypoglycemia is advisable and can be expected to restore awareness.⁸¹⁻⁸⁴ This approach usually requires somewhat higher glycemic goals in the short term. A history of late postexercise hypoglycemia, nocturnal hypoglycemia, or both should prompt appropriately timed regimen adjustments to provide more carbohydrate intake, less insulin action, or both.

Treatment of Hypoglycemia in Diabetes

Most episodes of symptomatic hypoglycemia or of asymptomatic hypoglycemia detected by self-monitoring or

Figure 34-12 Mean (\pm standard error) plasma glucose concentrations during hypoglycemia produced by subcutaneous insulin injection in people with type 1 diabetes in response to 10 g (circles) or 20 g (squares) of oral (P.O.) glucose or 1.0 mg of subcutaneous (S.C.) glucagon (triangles), compared with placebo (shaded area). (From Wiethop BV, Cryer PE. Alanine and terbutaline in treatment of hypoglycemia in IDDM. *Diabetes Care*. 1993;16:1131-1136, with permission of the American Diabetes Association.)

continuous glucose sensing are effectively self-treated by ingestion of glucose tablets or carbohydrates.^{138,139} A reasonable dose is 20 g of glucose.¹³⁹ Clinical improvement should occur in 15 to 20 minutes. The temptation to over-treat is understandable but should be avoided. With ongoing hyperinsulinemia, the glycemic response to oral glucose is transient, typically lasting less than 2 hours (Fig. 34-12).¹³⁹ Therefore, ingestion of a snack or meal shortly after the glucose level is raised is usually advisable.

In a patient who is unable or unwilling (because of neuroglycopenia) to take carbohydrate orally, parenteral therapy is necessary. Glucagon, in a dose of 1.0 mg in adults, can be injected subcutaneously or intramuscularly by an associate of the patient. Administration of glucagon can be life-saving, but it often causes substantial, albeit transient, hyperglycemia (see Fig. 34-12), and it can cause nausea and even vomiting. Smaller doses of glucagon (e.g., 150 μ g), repeated if necessary, have been found to be effective without side effects.¹⁴⁰

Because it acts by stimulating glycogenolysis, glucagon is ineffective in glycogen-depleted individuals (e.g., after a binge of alcohol ingestion). Although it is not an issue in T1DM or advanced T2DM, glucagon stimulates insulin secretion. Indeed, glucagon has been reported to cause hypoglycemia in nondiabetic individuals (see later discussion). Glucagon can be administered intravenously by medical personnel, but in that setting intravenous glucose is the standard parenteral therapy. A common initial dose is 25 g.¹³⁸ The glycemic response to intravenous glucose is, of course, transient in the setting of ongoing hyperinsulinemia. Therefore, intravenous glucose administration often needs to be followed by glucose infusion and, once it is practical, by carbohydrate feeding.

The duration of an episode of severe hypoglycemia is a function of its cause. An episode caused by a rapid-acting insulin secretagogue or insulin analogue will be relatively brief. That caused by a long-acting insulin secretagogue or

insulin analogue can result in prolonged hypoglycemia requiring hospitalization.

HYPOGLYCEMIA IN PERSONS WITHOUT DIABETES

The Decision to Evaluate for Hypoglycemia

Although hypoglycemia is common in persons with diabetes,³ it is a distinctly uncommon clinical event in persons who do not have diabetes² because of the effectiveness of the normal physiologic and behavioral defenses against falling plasma glucose concentrations.⁴ Therefore, in the absence of diabetes, a thorough evaluation for hypoglycemia is recommended only for patients in whom Whipple's triad (see earlier discussion) is documented. In the absence of such documentation, evaluation for hypoglycemia may expose the patient to unnecessary evaluation, costs, and potential harm without expectation of benefit.²

Plasma glucose concentrations used to document Whipple's triad must be measured with a reliable laboratory method, not with a blood glucose self-monitor. A reliably measured low plasma glucose concentration obtained in the absence of recognized symptoms or signs should not be ignored. However, such a finding raises the possibility of "pseudohypoglycemia," an artifact of continued glucose metabolism by the formed elements of the blood after the blood sample is drawn.² This may occur if the sample is collected in a container that does not include an inhibitor of glycolysis and separation of the plasma or serum from the formed elements is delayed, particularly in the setting of erythrocytosis, leukocytosis, or thrombocytosis.

Venous sampling is standard in the clinical setting, but it is the arterial plasma glucose concentration that fuels the brain.⁴ Arteriovenous plasma glucose concentration differences are negligible in the postabsorptive state, but antecubital venous glucose levels are as much as one-third lower than arterial glucose levels when insulin secretion is increased (e.g., after an oral glucose load) stimulating glucose extraction across the forearm.¹⁴¹ Because of the provision of alternative fuels (specifically ketones) to the brain, plasma glucose concentrations lower than the overnight fasted physiologic range occur in healthy individuals, especially women and children, during extended fasting.⁴ Finally, the glycemic thresholds of responses to hypoglycemia shift to lower plasma glucose concentrations in patients with recurrent hypoglycemia.^{18,19} For all of these reasons, it is important to document Whipple's triad before concluding that a hypoglycemic disorder exists in a person without diabetes.² On the other hand, a reliably measured, unequivocally normal plasma glucose concentration (e.g., >3.9 mmol/L [70 mg/dL]) during a symptomatic episode in a nondiabetic person provides strong evidence that the symptoms were not the result of hypoglycemia.²

Clinical Classification of Hypoglycemic Disorders

The traditional classification of hypoglycemic disorders in nondiabetic persons, as either postabsorptive (fasting) or postprandial (reactive) hypoglycemias, has been supplanted by a clinical categorization. This distinguishes a patient who has a relevant disease or treatment from a patient who is otherwise seemingly well (see Table 34-3).^{2,142} The presence of postprandial symptoms without Whipple's triad, previously called "reactive hypoglycemia," is now considered a functional disorder in which symptoms are

not due to hypoglycemia and for which an oral glucose tolerance test is not indicated.²

Ill or Medicated Individual

Drugs are the most common cause of hypoglycemia.^{2,143-146} In addition to insulin secretagogues and insulin (discussed earlier), offending drugs include alcohol^{144,145} among many others (Table 34-8).¹⁴⁷ Drugs, often in the setting of critical illnesses including renal failure, are the most common cause of hypoglycemia in hospitals.¹⁴³ Again, insulin or insulin secretagogues are common offending drugs,^{143,148} particularly if they are administered when enteral or parenteral nutrition is interrupted.

Ethanol inhibits gluconeogenesis. Clinical alcohol-induced hypoglycemia typically follows a binge of alcohol consumption during which the person eats little food (i.e., in the setting of glycogen depletion).¹⁴⁵ Alcohol-induced hypoglycemia can be fatal, but with restoration of euglycemia and supportive care, recovery is the rule. Ethanol is usually measurable in blood at the time of presentation.

Hypoglycemia sometimes occurs in patients with critical illnesses (see Table 34-3).² Hepatogenous hypoglycemia occurs most commonly when destruction of the liver is rapid and massive (e.g., in toxic hepatitis). It is unusual in common forms of cirrhosis or hepatitis, although glucose metabolism is measurably altered in uncomplicated viral hepatitis.¹⁴⁹ Hypoglycemia is also unusual in metastatic liver disease despite extensive hepatic replacement.¹⁵⁰ The pathogenesis of hypoglycemia in some patients with renal

failure is unknown and likely multifactorial; it has been attributed to drugs, sepsis, or inanition.^{143,151-153} Reduced renal clearance of insulin and reduced renal glucose production might be relevant factors. However, renal transplantation did not correct hypoglycemia in patients with glucose-6-phosphatase deficiency.¹⁵⁴

The pathogenesis of the hypoglycemia occasionally seen in patients with severe cardiac failure is also not understood. The finding of elevated blood lactate levels associated with hypoglycemia¹⁵⁵ raises the possibility of inhibited gluconeogenesis. Sepsis is a relatively common cause of hypoglycemia.^{143,144,156} Increased glucose utilization (by skeletal muscle and by macrophage-rich tissues such as liver, spleen, and lung), which is thought to be cytokine-mediated and is matched initially by increased glucose production, characterizes experimental sepsis.¹⁵⁷⁻¹⁵⁹ The later decline in glucose production, which in the setting of persistently high glucose utilization results in hypoglycemia, is not the result of glucose counterregulatory failure; rather, it is caused by decreased responsiveness to appropriate glucoregulatory signals (i.e., low insulin and high glucagon and epinephrine levels).¹⁶⁰ Finally, hypoglycemia can be caused by inanition.¹⁶¹ A plausible suggestion is that glucose becomes the sole oxidative fuel in the setting of total body fat depletion, and the resulting high rates of glucose utilization exceed the capacity to produce glucose because of a limited supply of gluconeogenic precursors (e.g., amino acids). Postabsorptive hypoglycemia (with low circulating alanine concentrations) has been reported in patients with profound muscle atrophy;^{162,163} hypoglycemia is presumably the result of substrate limitation of gluconeogenesis in such patients.

With the notable exception of hypoglycemia-associated autonomic failure in patients with T1DM and advanced T2DM³ (discussed earlier), hormone deficiencies resulting in hypoglycemia are not common. Postabsorptive hypoglycemia, typically after a period of caloric deprivation caused by an intercurrent illness, can occur in patients with deficient secretion of cortisol, growth hormone, or both, particularly infants and young children.¹⁶⁴⁻¹⁶⁶ That glycemic intolerance of fasting is largely corrected by glucocorticoid replacement; growth hormone replacement has a lesser effect.^{165,166} Because cortisol normally supports gluconeogenesis by increasing gluconeogenic enzyme activities and mobilizing gluconeogenic precursors,^{165,167} the hypoglycemic mechanism is thought to be reduced glucose production in the setting of glycogen deficiency. Nonetheless, most adults with deficiencies of these hormones do not experience hypoglycemia. Indeed, plasma glucose concentrations and rates of endogenous glucose production after overnight fasting have been reported to be indistinguishable from normal values in short-term glucocorticoid-withdrawn patients with hypopituitarism never treated with growth hormone.¹⁶⁸ Hypoglycemia has been reported in adrenocorticotrophic hormone (ACTH)-deficient adults when glucose utilization or loss was increased (as during exercise or pregnancy, respectively)¹⁶⁹ or when glucose production is impaired (as after alcohol ingestion).¹⁷⁰

Non-islet cell tumor hypoglycemia (NICTH) is rare. The tumors are usually, but not invariably, large, clinically apparent, and mesenchymal in origin. NICTH is often the result of overproduction of incompletely processed pro-insulin-like growth factor 2 (pro-IGF2),¹⁷¹ but hypoglycemia attributed to overproduction of insulin-like growth factor 1 (IGF1) has also been reported.¹⁷² The pro-IGF2 binds poorly to its binding proteins and therefore more freely enters tissue spaces, where its insulin-like actions cause hypoglycemia. Concentrations of plasma free IGF2

(or IGF1¹⁷²) are elevated,¹⁷³ but these measurements are not widely available. Because of suppression of growth hormone secretion and the resulting low IGF1 levels, the ratio of plasma IGF2 to IGF1 is elevated in pro-IGF2-mediated hypoglycemia. Plasma total IGF2 levels may be within the normal range, but the ratio of pro-IGF2 to IGF2 may be elevated.¹⁷⁴ Endogenous insulin secretion is suppressed appropriately during hypoglycemia in NICTH. Treatment of the tumor is seldom curative but may alleviate hypoglycemia. Treatment with a glucocorticoid, growth hormone, or both is sometimes effective.

Seemingly Well Individual

In seemingly well individuals with no evidence of drug, critical illness, hormone deficiency, or non-islet cell tumor as a cause of their hypoglycemia, the differential diagnosis narrows to two categories: accidental, surreptitious, or even malicious hypoglycemia and endogenous hyperinsulinism (see Table 34-3).^{2,175,176} Consideration of the former possibility should precede a systematic assessment of the latter. Medical, pharmacy, and hospital errors can result in hypoglycemia and do occur. Surreptitious hypoglycemia¹⁷⁵⁻¹⁷⁹ is more common in people with knowledge of, and access to, glucose-lowering medications. Malicious hypoglycemia^{175,176} can be accomplished by administration of an insulin secretagogue or insulin.

Insulinomas (insulin-secreting pancreatic beta-cell tumors) are the prototypical, but not the only, cause of endogenous hyperinsulinemic hypoglycemia.^{2,142,175,180} Patients with an insulinoma typically present with a history of episodes of neuroglycopenia occurring in the postabsorptive (fasting) state. However, an appreciable subset of patients (6% in one series¹⁸⁰) report symptoms exclusively in the postprandial state. Insulinomas are rare; an incidence of 1 in 250,000 patient-years has been reported.¹⁸¹ Fewer than 10% of the patients have malignant insulinomas, multiple insulinomas, or the multiple endocrine neoplasia type 1 (MEN1) syndrome.¹⁸¹ Long-term survival is the rule after successful surgical removal of an insulinoma.¹⁸¹

Some patients (4% of one series¹⁸²) with fasting endogenous hyperinsulinemic hypoglycemia do not have an insulinoma but have diffuse islet involvement with islet hypertrophy, sometimes with hyperplasia, and enlarged and hyperchromatic beta-cell nuclei.¹⁸²⁻¹⁹² This condition is often termed *nesidioblastosis*, although the histologic finding of islets budding from pancreatic ducts is not invariably present.^{182,183} Such patients are clinically indistinguishable from those with an insulinoma.¹⁸²⁻¹⁸⁵ Other patients have the noninsulinoma pancreatogenous hypoglycemia syndrome (NIPHS)¹⁸⁶⁻¹⁸⁹ or post-gastric bypass hypoglycemia.¹⁹⁰⁻¹⁹⁶

NIPHS¹⁸⁶⁻¹⁸⁹ is characterized by spells of neuroglycopenia caused by endogenous hyperinsulinemic hypoglycemia occurring typically, but not invariably, after a meal.² Most patients are men. NIPHS is less common than insulinoma.² Because the pathology is diffuse, anatomic imaging studies are uniformly negative. Given documented postprandial hyperinsulinemic hypoglycemia, documentation of diffuse beta-cell hyperfunction depends on a positive selective arterial calcium stimulation test. The findings from that test can be used to guide partial pancreatectomy if empiric medical therapy (e.g., diet, an α -glucosidase inhibitor, diazoxide, octreotide) fails.

Some patients who have undergone Roux-en-Y gastric bypass develop postprandial endogenous hyperinsulinemic hypoglycemia several months after the surgery.¹⁹⁰⁻¹⁹² The pathophysiologic mechanism is unknown.¹⁹³⁻¹⁹⁶ The

incidence of post-gastric bypass hypoglycemia is unknown but is seemingly higher than that of insulinoma.² Partial pancreatectomy may be required if empiric medical therapy fails.

Autoimmune hypoglycemia caused by an antibody to insulin is rare.^{197,198} Affected individuals often have a history of other autoimmune disorders. Hypoglycemia occurs in the late postprandial period as insulin, secreted in response to the meal and then bound to the circulating antibody, dissociates from the antibody in an unregulated fashion. A clue to the diagnosis is the finding of very high measured plasma insulin levels during hypoglycemia. The diagnosis is made by the finding of high-titer serum insulin antibodies. There is no consistently effective therapy. A similar disorder has been reported in patients with a high-capacity insulin-binding monoclonal paraprotein.¹⁹⁹

Accidental or surreptitious ingestion of an insulin secretagogue causes endogenous hyperinsulinemic hypoglycemia indistinguishable from that caused by an insulinoma aside from the presence of a measurable oral hypoglycemic agent in the circulation at the time of hypoglycemia.²

Very rare causes of insulin-related hypoglycemia have been linked to a mutation of the insulin receptor,²⁰⁰ to exercise-induced hyperinsulinemia,²⁰¹ or to an agonist antibody to the insulin receptor.²⁰² In the last case, endogenous insulin secretion is suppressed appropriately, and inappropriately high insulin levels are thought to result from blockade of receptor-mediated insulin clearance by the antibody. Finally, although seemingly convincing cases of ectopic insulin secretion have been reported (e.g., by Seckl et al.²⁰³), the condition must be extraordinarily rare.

Diagnostic Approach

Patients with a hypoglycemic disorder present with a history of symptomatic episodes compatible with hypoglycemia, a serendipitously measured low plasma glucose concentration, or a familial syndrome that includes a hypoglycemic disorder (e.g., MEN1).^{2,142,175} A careful history of any spells—including the specific symptoms, their timing in relation to meals, their duration, and any factors that aggravate or alleviate them—is important for the formulation of a diagnostic plan. A history that includes neuroglycopenia is particularly compelling.² Again, documentation of Whipple's triad establishes that a hypoglycemic disorder exists.² The diagnostic strategy recommended in the Endocrine Society clinical practice guideline² is described here.

First, review the history, physical findings, and all available laboratory data seeking clues to specific disorders such as drugs, critical illnesses, hormone deficiencies, non-islet cell tumors (see Table 34-3), and pursue those.² This approach will identify the cause of hypoglycemia in most instances. Again, drugs^{2,143-148} are, by far, the most common cause of hypoglycemia (see Table 34-8).

If the cause of a hypoglycemic disorder is not evident (i.e., in a seemingly well individual), measure plasma glucose, insulin, C-peptide, proinsulin, and β -hydroxybutyrate concentrations, screen for oral hypoglycemic agents during an episode of spontaneous hypoglycemia, and observe the plasma glucose response to intravenous injection of 1.0 mg of glucagon.² Also, measure insulin antibodies.²

Failure of insulin secretion to fall to very low rates as plasma glucose concentrations fall to hypoglycemic levels is the key pathophysiologic feature of endogenous hyperinsulinism. Hypoglycemia is the result of low rates of glucose production rather than high rates of glucose utilization.²⁰⁴ Plasma insulin, C-peptide, and proinsulin

concentrations may not always be high relative to normal values obtained under euglycemic conditions, but they are almost always inappropriately high in the setting of low plasma glucose concentrations.^{2,142,175} The critical diagnostic criteria (assuming Whipple's triad is documented) are plasma insulin concentrations equal to or greater than 18 pmol/L (≥ 3 μ U/mL), plasma C-peptide concentrations of 0.2 nmol/L (0.6 ng/mL) or higher, and plasma proinsulin concentrations of 5.0 pmol/L or higher when plasma glucose concentrations are less than 3.0 mmol/L (<55 mg/dL).^{2,142,180} Plasma β -hydroxybutyrate concentrations equal to or lower than 2.7 mmol/L and an increase in the plasma glucose concentration of more than 1.4 mmol/L (>25 mg/dL) over 30 minutes after glucagon injection provide evidence of biologic actions of inappropriately high insulin (or IGF) levels, with suppression of lipolysis and ketogenesis and preservation of hepatic glycogen stores, respectively. In the aggregate, these criteria provide greater than 90% sensitivity and greater than 70% specificity in patients with insulinomas.¹⁸⁰ The patterns of findings in patients with a hypoglycemic disorder and in those with hyperinsulinemic (or IGF-mediated) hypoglycemia are summarized in Table 34-9. Occasionally, a patient with an insulinoma may not fulfill these criteria even during a 72-hour fast,²⁰⁵ and a few have plasma insulin levels lower than 18 pmol/L (<3 μ U/mL) during hypoglycemia, but plasma C-peptide levels are usually 0.2 nmol/L (0.6 ng/mL) or higher, and plasma proinsulin levels are usually 5.0 pmol/L or higher in such patients (e.g., see Vezzosi et al.²⁰⁶).

If Whipple's triad has not been documented and the measurements described have not been obtained during an episode of spontaneous hypoglycemia, an attempt should be made to recreate the circumstances in which symptomatic hypoglycemia is likely to occur.² This can be accomplished by withholding food in a patient with a history suggestive of fasting hypoglycemia or by providing a mixed meal likely to cause a symptomatic episode in a patient with a history suggestive of postprandial hypoglycemia. Failing these relatively informal procedures, a patient with a history suggestive of fasting hypoglycemia should undergo a prolonged supervised fast.² The fast should be continued until Whipple's triad is documented (or until a plasma glucose concentration of <3.0 mmol/L [<55 mg/dL] if reached if Whipple's triad was unequivocally documented previously²⁰⁵) unless a progressive increase in plasma β -hydroxybutyrate levels signals a negative fast. Serial plasma glucose concentrations should be measured with a precise method, not with a point-of-care glucose monitor. About two thirds of patients with an insulinoma meet the diagnostic criteria during a fast of less than 24 hours; most, but not all, do so in less than 48 hours.²⁰⁵ Therefore, the diagnostic fast can be initiated, and often completed,¹⁸⁰ in the outpatient setting and continued in the inpatient setting if necessary. On the other hand, a patient with a history suggestive of postprandial hypoglycemia should undergo a mixed meal test conducted over 5 hours. Standards for interpretation of the findings of the mixed meal test have not been established; current usage² is to apply the criteria developed under fasting conditions.¹⁴² Detailed suggestions for performance of a prolonged supervised fast and of a mixed meal test have been published.²

A patient with documented Whipple's triad; inappropriately high levels of insulin, C-peptide, and proinsulin and no detectable circulating oral hypoglycemic agent; suppressed β -hydroxybutyrate levels; a brisk glycemic response to intravenous glucagon during fasting (or even postprandial¹⁸⁰) hypoglycemia; and no circulating insulin antibody

TABLE 34-9

may well have an insulinoma. However, as noted earlier, there are other causes of hyperinsulinemic hypoglycemia (see Tables 34-3 and 34-9). Therefore, the next step is to attempt to localize an insulinoma.²

Computed tomography (CT), magnetic resonance imaging (MRI), and transabdominal ultrasonography detect approximately 75% of insulinomas.^{180,207,208} They also detect metastases in the minority of patients who have a malignant insulinoma. Somatostatin receptor scintigraphy is somewhat less sensitive.²⁰⁹ Endoscopic pancreatic ultrasonography (EUS), with the option of fine-needle aspiration of a detected tumor, has a sensitivity of greater than 90%.^{210,211} With the combination of noninvasive imaging and, if necessary, EUS, preoperative localization of insulinomas has become the rule.¹⁸⁰ Given the promise of positron emission tomography with radiotracers such as fluorine 18-labeled dihydroxyphenylalanine,²¹² noninvasive localization of insulinomas may become the rule. If anatomic localization of insulinoma is negative or equivocal, selective pancreatic arterial calcium injections, with an end point of at least a twofold^{213,214} increase (or perhaps a greater than fivefold increase with contemporary assays²¹⁵) in hepatic venous insulin levels over baseline regionalizes insulinomas with high sensitivity.^{215,216} Although this invasive procedure is seldom necessary in patients with an insulinoma, it is the procedure of choice for confirming NIPHS¹⁸⁶⁻¹⁸⁹ and hypoglycemia occurring after Roux-en-Y gastric bypass (see Table 34-9).¹⁹⁰⁻¹⁹² Finally, intraoperative pancreatic ultrasonography almost invariably localizes tumors that are not apparent even to the experienced pancreatic surgeon.

Treatment of Hypoglycemia Disorders

Prevention of ongoing or recurrent hypoglycemia requires treatment that corrects or circumvents the hypoglycemic mechanism.² Obviously, treatment should be tailored to

the specific hypoglycemic disorder identified. Offending drugs can be discontinued or their dosage reduced. Critical illnesses can often be treated. Deficient hormones, such as cortisol, can be replaced. Reduction of non-islet cell tumor mass with surgery, irradiation, or chemotherapy may alleviate hypoglycemia even if the tumor cannot be cured. Treatment with a glucocorticoid, growth hormone, or even octreotide may alleviate hypoglycemia in such patients. Surgical resection of a benign insulinoma is typically curative. Medical treatment with diazoxide, octreotide, or both can be used if resection of an insulinoma is not feasible. Diet, including frequent feedings, an α -glucosidase inhibitor, diazoxide, or octreotide, can be tried in patients with NIPHS or post-gastric bypass hypoglycemia, but partial pancreatectomy may be required. Treatment of autoimmune hypoglycemia (with a glucocorticoid or another immunosuppressive medication) is problematic, but the disorder is sometimes self-limited. Failing these treatments, frequent feedings during the day and bedtime administration of large doses of uncooked cornstarch or even overnight intragastric glucose infusion may be necessary.

HYPOGLYCEMIA IN INFANCY AND CHILDHOOD

The fetus receives a continuous supply of glucose from the maternal circulation. Plasma glucose concentrations decline after birth as the neonate makes the transition to endogenous glucose production. Because mobilizable glycogen stores are limited and feeding is intermittent, the newborn is largely dependent on gluconeogenesis initially. In the setting of relatively low plasma glucose concentrations, the normal combination of hypoinsulinemia and activated glucose counterregulatory systems favors not only gluconeogenesis but also lipolysis and eventually

TABLE 34-10

Causes of Hypoglycemia Unique to, or Typically with Onset in, Infancy and Childhood**Intolerance of Fasting**

Preterm or small-for-gestational-age infants
 Hypopituitarism, adrenal hypoplasia, congenital adrenal hyperplasia
 Ketotic hypoglycemia of childhood

Hyperinsulinism

Infant of a diabetic mother
 Maternal drugs (sulfonylurea, β_2 -adrenergic agonist)
 Congenital hyperinsulinism, insulinoma
 Others: Rh incompatibility, Beckwith-Wiedemann syndrome, exchange transfusions, perinatal stress

Enzyme Defects

Carbohydrate metabolism: glycogen storage disease types I, III, and VI; glycogen synthase deficiency; fructose-1,6-bisphosphatase deficiency; fructose-1-phosphate aldolase deficiency; galactose-1-phosphate uridylyltransferase deficiency
Protein metabolism: branched chain α -keto acid dehydrogenase complex deficiency
Fat metabolism: fatty acid oxidation defects including deficiencies in the carnitine cycle, the β -oxidation spiral, the electron transport system, and the ketogenesis sequence

ketogenesis. Impairment of these glucoregulatory mechanisms can cause transient or persistent neonatal hypoglycemia. Enzymatic defects can cause hypoglycemia in infants that persists into childhood.^{217,218}

As in adults,² a diagnosis of clinical hypoglycemia should include symptoms and signs, but those are quite nonspecific in a neonate, and it is not possible to state a single low plasma glucose concentration that categorically defines neonatal hypoglycemia.²¹⁷⁻²¹⁹ A statistical lower limit of the plasma glucose concentration at 12 hours of postnatal life is 2.0 to 2.5 mmol/L (36 to 45 mg/dL).²¹⁹ A cutoff value of 2.5 mmol/L (45 mg/dL)²¹⁹ seems reasonable, but higher values have been advocated.

Hypoglycemia in children can be caused by the same mechanisms as in adults² (see Table 34-3), including drugs and critical illnesses. For example, 18% of children receiving resuscitative care were found to be hypoglycemic.²²⁰ Of the 10 who died, 5 were hypoglycemic. Nonetheless, several hypoglycemic disorders are unique to, or have their onset in, infancy and childhood.^{217,218} In general, those hypoglycemic disorders can be classified as intolerance of fasting, hyperinsulinism, and enzyme defects (Table 34-10).

Intolerance of Fasting

At least in the absence of seizure or coma, neonatal hypoglycemia is usually transient. It is particularly common in preterm or small-for-gestational-age infants and is thought to result from incomplete development of gluconeogenic mechanisms.^{217,221} Deficiency of cortisol can be congenital and can cause hypoglycemia through mechanisms discussed earlier.

The syndrome of ketotic hypoglycemia of childhood, which typically has its onset between ages 2 and 5 years and remits spontaneously before age 10 years, may represent those children who are least tolerant of fasting, because hypoglycemia occurs when feeding is interrupted, usually during an intercurrent illness.²¹⁷ It appears to involve diminished mobilization of gluconeogenic precursors.²²²

Hyperinsulinism

Maternal diabetes is a common cause of transient neonatal hypoglycemia.²¹⁷ Infants of diabetic mothers have been hyperglycemic in utero in proportion to the mother's hyperglycemia. Presumably because of chronic stimulation of fetal insulin secretion in utero and the failure of insulin to fall normally as glucose levels decline shortly after birth, transient neonatal hypoglycemia develops. Affected infants are typically macrosomic. Transient hyperinsulinemia also causes transient neonatal hypoglycemia under other conditions listed in Table 34-10. As in adults, hyperinsulinemic hypoglycemia can be accidental, surreptitious, or even malicious, and postprandial hypoglycemia analogous to that occurring after gastric bypass can follow Nissen fundoplication.

Congenital hyperinsulinism^{217,223,224} is the most common cause of nontransient neonatal hypoglycemia, although it occurs in only 1 of every 30,000 to 50,000 live births. Hypoglycemia may persist from the neonatal period or become apparent during the first year of life. (Patients in that age range rarely harbor an insulinoma; however, an insulinoma is occasionally found in children who develop endogenous hyperinsulinemic hypoglycemia after the first year of life.) The need for very high glucose infusion rates is a diagnostic clue.

Glucose-stimulated insulin secretion normally involves increased glucose transport into beta cells, glucokinase-mediated phosphorylation of glucose, glucose metabolism resulting in an increase in the ratio of adenosine triphosphate (ATP) to the diphosphate (ADP), closure of membrane ATP-gated potassium (K_{ATP}) channels and their SUR1 and Kir6.2 subunits, membrane depolarization, calcium influx, and exocytosis of insulin. Several inherited abnormalities of these cellular mechanisms are now known to cause congenital hyperinsulinism and hypoglycemia in neonates and infants.²²²

Congenital hyperinsulinism has been associated with mutations of six genes: the sulfonylurea receptor-1 (SUR1, encoded by *ABCC8*), the potassium inward rectifying channel (Kir6.2, encoded by *KCNJ11*), glucokinase (GK, encoded by *GCK*), glutamate dehydrogenase (GDH, encoded by *GLUD1*), short-chain 3-hydroxyacyl-CoA dehydrogenase (SCHAD encoded by *HADH*), and ectopic expression on beta-cell plasma membranes of *SLD16A1*, which encodes monocarboxylate transporter 1 (MCT1).²²²

Inactivating SUR1 or Kir6.2 mutations, typically recessively inherited, are the most common and most severe causes of congenital hyperinsulinism. They result in reduced K_{ATP} channel activity and, consequently, increased constitutive insulin secretion. Therefore, affected patients do not respond to treatment with the K_{ATP} channel agonist (opener), diazoxide, which normally suppresses insulin secretion. (Patients with dominantly inherited mutations²²³ do retain responsiveness to diazoxide.) Approximately half of patients with these mutations have diffuse islet involvement; for those who do not have a sustained response to medical therapy (e.g., frequent feedings and octreotide), near-total pancreatectomy is required. Other affected patients have focal lesions that are the result of loss of heterozygosity involving a paternally derived mutation of the *ABCC8* or *KCNJ11* gene and a specific loss of maternal alleles of the imprinted chromosome region 11p15. The focal lesion is potentially curable by surgical resection. It can often be detected noninvasively with [¹⁸F]-dihydroxyphenylalanine positron emission tomography.²²⁵⁻²²⁷

Activating, dominantly inherited mutations of the glutamate dehydrogenase gene cause the hyperinsulinemia

and hyperammonemia syndrome, the second most common form of congenital hyperinsulinism. Hypoglycemia typically develops after several months of life and is responsive to diazoxide. Activating, dominantly inherited mutations of the glucokinase gene cause varying degrees of hypoglycemia that may respond to diazoxide but may require pancreatectomy. Recessively inherited mutations of the SCHAD gene result in hypoglycemia that is generally responsive to diazoxide. In addition to hyperinsulinemic hypoglycemia, biochemical markers include increased levels of plasma 3-hydroxybutyrylcarnitine and increased urinary 3-hydroxy-glutarate. Dominantly inherited mutations of the monocarboxylate transporter-1 gene (*SLC16A1*), resulting in increased pyruvate transport into beta cells and hyperinsulinism, have been associated with exercise-induced hypoglycemia.

Clinical manifestations, including low plasma glucose concentrations and inappropriately high levels of plasma insulin and C-peptide coupled with low plasma β -hydroxybutyrate levels and a brisk glycemic response to administered glucagon—all analogous to hyperinsulinemic hypoglycemia in adults²—characterize congenital hyperinsulinism in neonates and infants.²²² As in adults with endogenous hyperinsulinism,² plasma insulin concentrations are not invariably 18 pmol/L or higher (≥ 3 μ U/mL) during hypoglycemia in patients with congenital hyperinsulinism,²²² although hyperinsulinism is often documented by serial insulin measurements and by inclusion of C-peptide measurements during hypoglycemia. Therefore, the pattern of clinical hypoglycemia with low β -hydroxybutyrate levels and a brisk glycemic response to glucagon needs to be considered. Genetic testing for *ABCC8*, *KCNJ11*, *GCK*, and *GLUD1* mutations is available commercially.

Given the array of potential causes of hypoglycemia in neonates and infants, the differential diagnosis is facilitated by an array of measurements during hypoglycemia when the precise hypoglycemic mechanism is obscure.^{217,218,222} In addition to glucose, insulin, C-peptide, and β -hydroxybutyrate levels (and the glycemic response to glucagon), such measurements should include plasma bicarbonate, ammonia, lactate, nonesterified fatty acid (NEFA), growth hormone, and cortisol levels. A plasma acylcarnitine profile and measurement of urine organic acids are also needed but do not have to be obtained during hypoglycemia.

Enzyme Defects

Hypoglycemia that develops in infancy and persists into adult life with effective therapy can be caused by enzymatic defects in carbohydrate, protein, or fat metabolism (see Table 34-10).²¹⁸ Hypoglycemia usually becomes apparent later in infancy as the intervals between feedings become longer.

Glycogen storage disease (GSD) type Ia (von Gierke's disease) is caused by mutations in *G6PC*, the gene that encodes glucose-6-phosphatase. It occurs in approximately 1 of every 100,000 live births.^{228,229} The absence of glucose-6-phosphatase activity results in low rates of endogenous glucose production and severe fasting hypoglycemia²²⁹ with no glycemic response to administered glucagon. Clinical findings include failure to thrive, hepatomegaly (due to both glycogen and fat accumulation), hypertriglyceridemia, accelerated lipolysis and ketogenesis, and lactic acidosis with hyperuricemia. With the exception of hepatomegaly, these abnormalities can be reversed by effective prevention

of hypoglycemia with frequent feedings during waking hours and continuous intragastric glucose infusion during sleep or bedtime administration of large doses of uncooked cornstarch. (Liver transplantation corrects hypoglycemia and the associated metabolic abnormalities.²³⁰) Late complications include progressive renal disease and hepatic adenomas. GSD type Ib is caused by mutations in *G6PT1*, the glucose-6-phosphate transporter. The diagnosis of GSD type Ia and type Ib is confirmed by mutation analysis of *G6PC* and *G6PT1*. Hypoglycemia is less prominent in GSD type III (amylo-1,6-glucosidase deficiency due to mutations in *AGL*), GSD type VI (glycogen phosphorylase deficiency due to mutations in *PYGL*), and GSD type IX (phosphorylase kinase deficiency due to mutations in *PHKA2*). Hypoglycemia can also be caused by glycogen synthase deficiency (GSD type 0), which results from mutations in *GYS2* and does not cause hepatomegaly.

Hypoglycemia can also be caused by enzymatic defects in gluconeogenesis, including fructose-1,6-bisphosphatase, phosphoenolpyruvate carboxykinase, and pyruvate carboxylase deficiencies.²¹⁸ In patients with a mutation in the glucose transporter 1 (*GLUT1*) gene, plasma glucose concentrations are normal but brain glucose levels are low, causing neuroglycopenia.²³¹ Hypoglycemia has been attributed to *GLUT2* deficiency in the Fanconi-Bickel syndrome.²³¹ Postprandial, rather than postabsorptive, hypoglycemia occurs in galactosemia and in hereditary fructose intolerance (fructose-1-phosphate aldolase deficiency).²¹⁷

Deficiencies of enzymes involved in protein metabolism (see Table 34-10) that can cause fasting hypoglycemia include branched-chain ketoaciduria (maple syrup urine disease). The pathogenesis of hypoglycemia is unclear but includes defective gluconeogenesis.

Several defects that ultimately impair fatty acid oxidation result in hypoglycemia with hypoketonemia during extended fasting.^{218,232,233} Mitochondrial fatty acid oxidation and ketogenesis require transport of fatty acids across the plasma membrane, formation of fatty acyl-CoA derivatives, and transport of those derivatives into mitochondria. Because the inner mitochondrial membranes are not permeable to long-chain (as opposed to medium-chain and short-chain) fatty acyl-CoA esters, the long-chain fatty acyl-CoA esters are transesterified to fatty acylcarnitines at the outer surface of the membranes (by carnitine palmitoyltransferase 1, CPT1), transported across the membranes (by a translocase), and reconverted to the fatty acyl-CoA esters (by carnitine palmitoyltransferase 2, CPT2) at the inner surface of the membranes. Then, they can be oxidized or converted to ketones. Insulin decreases fat oxidation and ketogenesis by decreasing lipolysis and by increasing lipogenesis and the formation of malonyl-CoA, which inhibits CPT1. Conversely, low insulin levels favor fatty acid oxidation and ketogenesis. High glucagon levels do so by decreasing malonyl-CoA; catecholamines do so largely by stimulating lipolysis. Any defect in this complex sequence (see Table 34-10) decreases fatty acid oxidation (and ketogenesis) and reciprocally increases glucose oxidation, resulting in hypoketonemic postabsorptive hypoglycemia. Reduced plasma carnitine levels (20% to 50% of normal) are the rule in these disorders, but extremely low carnitine levels characterize the carnitine transport defect, a true carnitine deficiency state that is responsive to carnitine supplementation.²³⁴ The diagnosis of specific fatty acid oxidation defects is typically accomplished by blood acylcarnitine profiling,²³⁵ although molecular diagnosis is increasingly possible.

There are many fatty acid oxidation disorders that result in hypoketonemic hypoglycemia.²¹⁸ The most common is

medium-chain acyl-CoA dehydrogenase (MCAD) deficiency. Because affected patients can become symptomatic—fatigue, vomiting, seizure, coma—before becoming hypoglycemic, a normal acylcarnitine profile should be documented before a diagnostic fast is performed in such infants. Other fatty oxidation disorders include very long-, long- and short-chain acyl-CoA dehydrogenase defects as well as defects in electron transfer (glutaric acidemia type 2), 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) synthase deficiency, and HMG-CoA lyase deficiency. Defects in carnitine transport and in the carnitine cycle that cause hypoketonemic hypoglycemia include primary carnitine deficiency due to autosomal recessive mutations in the carnitine transporter (*OCTN2*). Others are CPT1 deficiency, carnitine acylcarnitine translocase (*CACT*) deficiency, and CPT2 deficiency. Treatment includes frequent feedings and a low-fat diet rich in medium-chain triglycerides in CPT1 deficiency²³⁶ and carnitine supplementation in primary carnitine deficiency.

In summary, neonatal hypoglycemia with suppressed levels of (NEFA) and β -hydroxybutyrate suggest hyperinsulinism, and that with high NEFA but low β -hydroxybutyrate suggests a defect in fatty acid oxidation or ketogenesis. Hypoglycemia with high lactate levels suggests a defect in gluconeogenesis or glucose release. High concentrations of both NEFA and β -hydroxybutyrate suggest a defect in glucose production or release including deficiency of cortisol, although NEFA and ketone levels need not be elevated in patients with hypopituitarism.

ACKNOWLEDGMENTS

The author's original work cited in this chapter has been supported, in part, by U.S. Public Health Service, National Institutes of Health grants R37 DK27085, M01 RR00036 (now UL1 RR24992), P60 DK20579, and T32 DK07120 and a fellowship award from the American Diabetes Association. The author is grateful for the contributions of postdoctoral fellows and the skilled nursing, technical, dietary, and data management statistical assistance of the staff of the Washington University General Clinical Research Center. Ms. Janet Dedek prepared this manuscript.

This chapter was written shortly after the author chaired a panel that developed *Evaluation and Management of Adult Hypoglycemic Disorders* (an Endocrine Society clinical practice guideline² and publication of the author's book, *Hypoglycemia in Diabetes: Pathophysiology, Prevalence and Prevention*.³ Therefore, much of the factual and interpretive content here is the same, as is no small part of the phraseology.

DISCLOSURES

The author has served as a consultant to several pharmaceutical or device firms including Amgen Inc., Johnson & Johnson, MannKind Corp., Marcadia Biotech, Medtronic MiniMed Inc., Merck and Co., Novo Nordisk A/S, Takeda Pharmaceuticals North America, and TolerRx Inc. in recent years. He does not receive research funding from, hold stock in, or speak for any of these firms.

CHAPTER

35

Neuroendocrine Control of Energy Stores

ROGER D. CONE • JOEL K. ELMQUIST

HISTORICAL PERSPECTIVE

The increasing incidence of obesity and diabetes is a major health issue facing society. In the past decade, several key molecules, including hormones and receptors controlling energy homeostasis, have been identified. We now have a rough central nervous system (CNS) road map of the pathways through which key metabolic signals exert their effects. For example, it is established that key components of the central control of energy balance are located in the hypothalamus. In the 21st century, it is taken for granted that the hypothalamus is required for coordinated control of food intake and energy homeostasis. The intimate interaction of the hypothalamus and the pituitary gland has been appreciated for some time. However, understanding of the primary role of the hypothalamus in controlling long-term energy stores and, consequently, adipose mass is relatively recent.

For example, at the end of the 19th century, clinicians including Alfred Fröhlich described an adiposogenital dystrophic condition in patients with pituitary tumors. This

condition became known as Fröhlich's syndrome and was characterized by pituitary tumors associated with excessive subcutaneous fat and hypogonadism.^{1,2} However, whether this syndrome was caused by injury to the pituitary gland or damage to the overlying hypothalamus was extremely controversial. Several groups, including Cushing and his colleagues, argued that the syndrome was caused by disruption of the pituitary gland.³⁻⁵ However, Aschner demonstrated in dogs that mere removal of the pituitary gland without damage to the overlying hypothalamus did not result in obesity.⁶ The most definitive evidence of the vital role of the hypothalamus was provided by Hetherington and Ranson when they demonstrated that destruction of the medial basal hypothalamus without damage to the pituitary gland could result in morbid obesity and neuroendocrine derangements in a very similar fashion to the syndrome reported by Fröhlich.⁷ These and subsequent studies firmly established that an intact hypothalamus is required for normal energy and glucose homeostasis.

After the discoveries that hypothalamic lesions could cause obesity, it also became apparent that lesions in other

regions, such as the lateral hypothalamus, could cause leanness. Based on these results, it was suggested that a feeding center was located in the lateral hypothalamus and a satiety center in the ventromedial hypothalamus (VMH).⁸ As a result of these and other studies, the importance of the hypothalamus as an integrator and effector of energy balance and neuroendocrine function was generally accepted.

Humans and other mammals have a remarkable ability to match caloric intake and expenditure, leading to relative stability of body weight and adipose mass over long periods. Based on this observation, Kennedy⁹ proposed a mechanism of body weight regulation in which a signal related to energy stores elicited compensatory changes in food intake and energy expenditure, with the result being maintenance of adipose mass at a presumed set point. This view was supported by studies in rodents showing that weight gain from forced overfeeding resulted in a compensatory decrease in voluntary food intake, increased energy expenditure, and eventual restoration of body weight to the previous level, whereas starvation or lipectomy stimulated feeding and decreased energy expenditure, restoring body weight and adipose mass to a previous set point.¹⁰⁻¹²

The signals mediating the potential interaction between adipose tissue and the brain were not known for many years. Studies by Hervey¹³⁻¹⁵ offered important insights into potential signals linking energy stores with energy homeostatic mechanisms. He showed that parabiosis between obese rats with VMH lesions and normal (nonlesioned) rats led to starvation and weight loss in the latter. In contrast, the VMH-lesioned rats gained weight when parabiosed with lean rats or other VMH-lesioned rats. Results of these studies were thought to indicate that obese VMH-lesioned rats produced a circulating "satiety factor" leading to inhibition of feeding in nonlesioned parabiotic rats. The lack of response in VMH-lesioned rats was consistent with the existence of a satiety center proposed in earlier studies.⁸

This concept received further support from discovery of the *ob* and *db* recessive mutations, both of which led to hyperphagia, decreased energy expenditure, and morbid obesity.¹⁶ Parabiosis of lean (wild-type) and *ob/ob* mice suppressed weight gain in the *ob/ob* mice, whereas parabiosis of wild-type and *db/db* mice caused profound hypophagia and weight loss in the wild-type mice.¹⁷⁻¹⁹ These results were interpreted as meaning that the *ob* locus was necessary for or involved in the production of a circulating satiety factor, whereas the *db* locus encoded a component required for the response mechanism to the satiety factor. Predictions based on parabiosis studies were confirmed by the cloning of *ob* and *db* genes in the mid-1990s.²⁰⁻²² The hormone product of the *ob* gene was named "leptin" (from the Greek root *leptos*, meaning "thin") because it potentially inhibited feeding, body weight, and adipose mass when injected into leptin-deficient or normal mice.²³⁻²⁶

In addition to the obese and diabetic mouse strains, the lethal yellow agouti (AY) mouse had long been known to express an obesity syndrome. Just as molecular cloning of the *ob* and *db* loci led to the discovery of the primary adipostatic factor and its receptor, cloning and characterization of the agouti gene²⁷⁻²⁹ has led to characterization of one of the important CNS circuits involved in regulation of energy homeostasis, the central melanocortin system.^{30,31} These and related discoveries over the past decade have taken the understanding of energy homeostasis from the level of gross anatomy to the beginnings of a cellular and molecular basis for the neuroendocrine control of energy stores, the topic of this chapter (Fig. 35-1).

FEEDING AND SATIETY CIRCUITS

As noted, key circuits regulating energy homeostasis and food intake originate in the hypothalamus and brainstem (Fig. 35-2). The hypothalamus is an essential and evolutionarily highly conserved region of the mammalian brain, and it is the ultimate brain structure that allows mammals to maintain homeostasis. Destruction of the hypothalamus is not compatible with life.³² Hypothalamic control of homeostasis stems from the ability of hypothalamic neurons to orchestrate behavioral, autonomic, and behavioral responses. This control is derived from the anatomic connections (both inputs and outputs) of the hypothalamus.

The hypothalamus receives sensory inputs from the external environment (e.g., light) and information regarding the internal environment (e.g., blood glucose levels). In addition, several hormones known to be key in regulating food intake and metabolism (e.g., glucocorticoids, estrogen, leptin, ghrelin) directly act on neurons in the hypothalamus. The hypothalamus integrates all of this information and provides motor outputs to key regulatory sites including the anterior pituitary gland, the posterior pituitary gland, the cerebral cortex, premotor and motor neurons in the brainstem and spinal cord, and autonomic (parasympathetic and sympathetic) preganglionic neurons. The patterned hypothalamic outputs to these effector sites ultimately result in coordinated endocrine, behavioral, and autonomic responses that maintain homeostasis in several physiologic systems, including energy balance.

Within the hypothalamus, several hypothalamic sites are thought to be key in regulating energy homeostasis (see Fig. 35-1). A group of sites located in the medial hypothalamus includes the arcuate nucleus, the ventral medial nucleus, the dorsal medial nucleus, and the paraventricular nucleus. In addition, the lateral hypothalamus (lateral hypothalamic area and perifornical hypothalamus) is key in regulating food intake and energy homeostasis.

In addition to the hypothalamus, it is now clear that circuits in the brainstem are involved in the coordinated control of food intake.³³ The brain receives a wide variety of signals from visceral organs including the gastrointestinal tract. These include visceral sensory afferents that converge on the dorsal vagal complex. The dorsal vagal complex comprises the nucleus of the solitary tract (nucleus tractus solitarius; NTS), the vagal motor neurons (dorsal motor nucleus of the vagus; DMV), and the area postrema. Sensory afferent signals carried by the glossopharyngeal and vagus nerves include indications of taste, gastric stretch, and levels of glucose and lipids in the liver and portal vein. Nerve terminals carrying this information innervate the NTS. This information is relayed to the DMV. The vagal motor neurons in turn innervate the entire gastrointestinal tract including the pancreas.

In addition, key sensory inputs to the NTS from the gastrointestinal tract and taste information are directly relayed to the paraventricular, dorsomedial, and arcuate nuclei of the hypothalamus and the lateral hypothalamic area; the central nucleus of the amygdala and bed nucleus of the stria terminalis; and the parabrachial nucleus.^{32,34} The parabrachial nucleus then projects to the thalamus, the cerebral cortex, the amygdala, and several hypothalamic sites.³²

The area postrema is a circumventricular organ (CVO) that lies directly above the NTS. Unlike the NTS, which lies inside the blood-brain barrier (BBB) and therefore is not in direct contact with circulating factors and hormones,

Figure 35-1 Regulation of energy homeostasis by the brain-gut-adipose axis. CCK, cholecystokinin; GLP-1, glucagon-like peptide 1; PYY, peptide YY.

neurons in the area postrema sit outside the BBB.³⁵ Neurons in the area postrema may respond to circulating gut hormones such as cholecystokinin (CCK) and glucagon-like peptide 1 (GLP1) and relay those signals to the NTS and the parabrachial nucleus.³⁶⁻⁴⁰

The Arcuate Nucleus Is a Key Node of Hypothalamic Control of Energy Balance

The arcuate nucleus is perhaps the best characterized hypothalamic nucleus involved in the control of energy balance. It is thought to be critical in mediating the actions of metabolic signals such as leptin, insulin, and ghrelin.

Specifically, pro-opiomelanocortin (POMC) and neuropeptide Y (NPY)/agouti-related peptide (AgRP) neurons within the arcuate nucleus are required for regulating energy homeostasis, food intake, and glucose homeostasis. POMC is a multifunctional pro-peptide that is differentially processed into key peptides in different tissues (Fig. 35-3).⁴¹ In the brain, melanocortin peptides such as α -melanocyte stimulating hormone (α -MSH) are key products that regulate food intake and energy homeostasis. α -MSH is the agonist for the melanocortin-4 receptor (MC4R), which is clearly established as key in regulating food intake, energy homeostasis, and glucose homeostasis in mice and humans.^{41,42} Uniquely, an endogenous MC4R antagonist (AgRP) exists

Figure 35-2 Brain structures involved in energy homeostasis. Receipt of long-term adipostatic signals and acute satiety signals by neurons in arcuate nucleus and brainstem, respectively. Light blue boxes indicate nuclei containing pro-opiomelanocortin (POMC) neurons; yellow boxes indicate nuclei containing melanocortin-4 receptor (MC4R) neurons that may serve to integrate adipostatic and satiety signals; and dark blue boxes show some circumventricular organs involved in energy homeostasis. Red arrows designate projections of POMC neurons; blue arrows show projections of agouti-related protein (AGRP) neurons). AP, area postrema; ARC, arcuate nucleus; BST, bed nucleus of the stria terminalis; CCK, cholecystokinin; CEA, central nucleus of the amygdala; CNS, central nervous system; DMV, dorsal motor nucleus of the vagus; LH, lateral hypothalamic area; LPB, lateral parabrachial nucleus; ME, median eminence; NTS, nucleus tractus solitarius; PVN, paraventricular nucleus of the hypothalamus; RET, reticular formation. (Adapted from Fan W, Ellacott KL, Halatchev IG, et al. Cholecystokinin-mediated suppression of feeding involves the brainstem melanocortin system. *Nat Neurosci.* 2004;7:335-336.)

and is coexpressed with neuropeptide Y (NPY) in other neurons in the arcuate nucleus of the hypothalamus.

Supportive of a key role of the arcuate nucleus in regulating food intake and energy homeostasis is the observation that leptin deficiency (*ob/ob* mice) and fasting (which lowers leptin levels) result in decreased POMC expression and increased AgRP and NPY expression.^{43,44} POMC and NPY/AgRP neurons are located in the arcuate nucleus (Figs. 35-4 and 35-5) and are directly regulated by leptin, ghrelin, glucose, and other metabolic signals. Leptin directly depolarizes (activates) POMC neurons and hyperpolarizes (inhibits) AgRP/NPY neurons,^{45,46} and deletion of leptin receptors selectively in POMC neurons produces mild

obesity.⁴⁷ However, leptin also has physiologically relevant actions outside the arcuate nucleus. For example, deletion of leptin receptors from neurons in the ventral medial nucleus produces obesity equal in magnitude to deletion from POMC neurons.^{48,49}

In addition to leptin, other key metabolic signals act directly on POMC and AgRP neurons in the arcuate nucleus. For example, ghrelin directly depolarizes AgRP/NPY neurons,⁵⁰ and serotonin directly activates POMC neurons⁵¹ and inhibits NPY/AgRP neurons.⁵² Moreover, the anorexic properties of fenfluramine depend in part on MC4Rs.⁵² Fenfluramine was used in combination with phentermine (Fen/Phen) to successfully reduce food intake and body

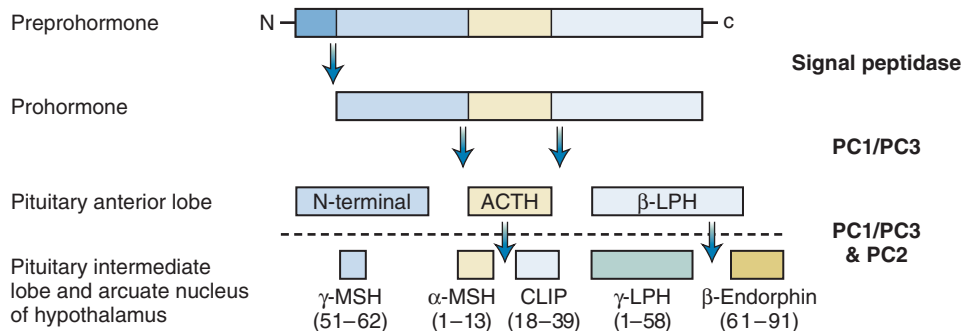

Figure 35-3 Organization of pro-opiomelanocortin (POMC), the precursor hormone of corticotropin (ACTH), β -lipoprotein (β -LPH), and related peptides. The precursor protein contains a leader sequence (signal peptide), followed by a long fragment that includes sequence 51-62, corresponding to γ -melanocyte-stimulating hormone (γ -MSH). This fragment is cleaved at Lys-Arg bonds to form corticotropin 1-39, which in turn includes the sequences for α -MSH (corticotropin 1-13) and corticotropin-like intermediate lobe peptide (CLIP; corticotropin 18-39) and a sequence corresponding to β -LPH (1-91) that includes γ -LPH (1-58) and β -endorphin (61-91). The β -endorphin sequence also includes a sequence corresponding to met-enkephalin. The precursor molecule in the anterior lobe of the pituitary is processed predominantly to corticotropin and β -LPH. In the intermediate pituitary lobe (in the rat), corticotropin and β -LPH are further processed to α -MSH and a β -endorphin-like material. In all extrapituitary tissues, post-translational processing of the pro-hormone resembles that in the intermediate lobe. Hypothalamic processing is similar but not identical to that in the intermediate lobe. In the latter, β -endorphin and α -MSH are present predominantly in their acetylated forms. PC, prohormone-converting enzyme. (Figure provided by Dr. Malcolm Low, University of Michigan, Ann Arbor, Mich.)

Figure 35-4 **A** and **B**, Photomicrographs demonstrate that α -melanocyte stimulating hormone-immunoreactive (α -MSH-IR) neurons are present in the human hypothalamus. The neurons are found in the arcuate nucleus of the hypothalamus (Arc; infundibular nucleus). 3v, third ventricle. (Modified from Elias CF, Saper CB, Maratos-Flier E, et al. Chemically defined projections linking the mediobasal hypothalamus and the lateral hypothalamic area. *J Comp Neurol*. 1998;402:442-459.)

weight in humans, before the formulation was removed from the market due to associated heart valve disorders and pulmonary hypertension. Importantly, the NPY/AgRP neurons send dense projections to POMC neurons, so the orexigenic NPY/AgRP and anorexigenic POMC neurons of the arcuate are coordinately regulated by a wide variety of hormones, drugs, and perhaps nutrients (Fig. 35-6).

Melanocortin-4 Receptors Regulate Energy and Glucose Homeostasis

Several pieces of evidence definitively demonstrate the role of MC4Rs in the regulation of energy homeostasis. For example, ectopic expression of MC4R antagonists in the brain induces obesity and diabetes.^{42,53} MC4R deletion in mice produces obesity,³¹ and humans with MC4R mutations display obesity.⁵⁴⁻⁵⁷ Estimates suggest that 5% of cases of severe early-onset obesity are the result of heterozygous MC4R mutations.

MC4Rs are widely expressed in the brain, and many of them could play a role in regulating energy balance.⁵⁸⁻⁶⁰ The sites in the brain that mediate the varied effects of MC4R agonists are beginning to emerge. Evidence suggests that MC4Rs expressed by hypothalamic neurons contribute to the effects of MC4R agonists to regulate energy

Figure 35-5 Photomicrographs demonstrate that agouti-related peptide-immunoreactive (AgRP-IR) neurons are present in the human hypothalamus. **A** and **B**, Two rostral to caudal low-power photomicrographs demonstrate that AgRP-IR neurons localize to the arcuate nucleus of the hypothalamus (Arc; infundibular nucleus). In **B**, Immunoreactive fibers are also observed streaming dorsally out of the arcuate nucleus. **C** and **D**, AgRP-IR neurons are observed in the arcuate nucleus. **D** is a higher magnification of boxed area in **C**. 3v, third ventricle; fx, fornix; ot, olfactory tubercle. (Modified from Elias CF, Saper CB, Maratos-Flier E, et al. Chemically defined projections linking the mediobasal hypothalamus and the lateral hypothalamic area. *J Comp Neurol*. 1998;402:442-459.)

Figure 35-6 Regulation of the arcuate nucleus of the hypothalamus by various hormones and neuropeptides. NPY/AgRP and POMC neurons within the arcuate nucleus form a coordinately regulated network due to dense NPY/AgRP fibers that project to POMC cell bodies. Some receptors for the large numbers of hormones and neuropeptides known to regulate the network are indicated. AgRP, agouti-related peptide; GABA, γ -aminobutyric acid; GHS, growth-hormone secretagogue receptor; Lep, leptin; MC3, melanocortin 3; NPY, neuropeptide Y; μ -OR, μ -opioid receptor; R, receptor. (Modified from Cowley MA, Smart JL, Rubinstein M, et al. Leptin activates anorexigenic POMC neurons through a neural network in the arcuate nucleus. *Nature*. 2001;411:480-484.)

homeostasis.^{61,62} For example, selective restoration of MC4Rs in the paraventricular nucleus of the hypothalamus (PVH) in mice lacking MC4Rs everywhere else normalizes food intake and greatly reduces body weight.⁶² Extrahypothalamic MC4Rs contribute to melanocortin action to decrease adipose mass and food intake and increase energy expenditure. For example, MC4R messenger RNA (mRNA) is densely expressed in the DMV⁶³ including the cholinergic parasympathetic preganglionic neurons.^{59,60} In addition, injections of the MC4R agonists into the fourth ventricle decreases food intake, and similar injections of MC4R antagonists dose-dependently increase food intake.^{64,65} Injections of both MC4R agonists and antagonists into the region of the DMV alter food intake. This effect is likely mediated by MC4Rs in the brainstem, because it occurs at doses that are ineffective when injected into the fourth ventricle. These findings suggest that extrahypothalamic MC4Rs contribute to the effects of the MC4R agonists to regulate food intake, insulin secretion, and energy expenditure. This includes the amplification of satiety signals emanating from the gut such as that mediated by the gut peptide, CCK.⁶⁶

The Lateral Hypothalamus Links Coordinated Food Intake Control and Arousal

The lateral hypothalamus includes the lateral hypothalamic area (LHA) and the perifornical hypothalamus. This region of the brain has long been suggested to play a key role in the regulation of ingestive behavior, since the early lesion studies of Anand and Brobeck.⁶⁷ In the past decade, two neuropeptides were discovered that are expressed by neurons in the lateral hypothalamus. These metabolically regulated peptides are melanin-concentrating hormone (MCH) and the orexins (also known as hypocretins).⁶⁸⁻⁷¹ MCH and orexin are expressed by distinct subsets of intermingled neurons in the LHA.^{72,73} However, both populations broadly innervate the entire neuraxis including monosynaptic projections to other hypothalamic sites, the cerebral cortex, the amygdala, the brainstem, and the spinal cord.^{68,74} The expression patterns of the receptors for both peptides are also widespread.⁷⁵⁻⁷⁷

Current data support the view that these LHA neuropeptides play a key role in regulating food intake, adipose mass, and glucose homeostasis. For example, injection of MCH into the brain increases food intake.⁶⁹ Mice lacking MCH (knockouts) are hypophagic and lean, and mice that overexpress MCH are obese and hyperleptinemic.^{78,79} Mice lacking MCH and leptin are leaner than mice that lack leptin but express MCH.⁸⁰ The role of orexins in regulating food intake is complex, but it is clear that orexins are required for normal energy balance.^{81,82} For example, central injections of orexin peptides increase feeding behavior.^{70,83} However, the best characterized role for orexins is in the regulation of state control and the maintenance of wakefulness,^{84,85} because it has been demonstrated that defective orexin signaling causes narcolepsy in mice, dogs, and humans. Other studies have demonstrated the ability of orexin neurons to sense changing levels of glucose (see later discussion).

The exact sites targeted by MCH and orexin neurons to induce feeding remain to be determined and represent an area of active investigation. MCH and orexin neurons have very similar and widespread projection patterns that include the hypothalamus, the brainstem, the cerebral cortex, and the spinal cord. Targets in the brainstem

include motor systems and cranial nerve motor nuclei that underlie behaviors such as chewing, licking, and swallowing.^{33,40} The MCH and orexin neurons also innervate the sympathetic and parasympathetic preganglionic nuclei in the medulla and the spinal cord, suggesting that both may be key in regulating the autonomic nervous system.

A key target for MCH and orexin neurons in coordinating feeding behavior may be their reciprocal connections with the nucleus accumbens. The nucleus accumbens is known to be critical in mediating rewarding components of several stimuli (e.g., drugs of abuse) and, potentially, the rewarding aspects of feeding. Although the subject is still being investigated, it is likely that MCH and orexin neurons may be able to enhance the hedonic value of food.⁴⁰ Regardless of the specific sites that mediate these effects, it is clear that MCH and orexin neurons are ideally positioned to regulate complex behavior, endocrine function, and autonomic outflow, all of which are key for coordinated control of energy balance.

CENTRAL NERVOUS SYSTEM CONTROL OF THERMOGENESIS

Coordinated energy homeostasis necessarily includes a balance between energy intake and energy expenditure. Energy expenditure is often considered in three categories: energy required for basal metabolism, energy required for voluntary and involuntary physical activity, and the thermic effect of food.

The last category, often referred to as diet-induced thermogenesis (DIT) is estimated to account for 8% to 10% of total expenditure and is defined as the increased energy expenditure in response to energy intake.⁸⁶ This process is under the control of the sympathetic nervous system, and thyroid-axis energy expenditure is increased by stimulation of β -adrenergic receptors or elevation of thyroid hormone. In rodents, one tissue mediating this response is brown adipose tissue (BAT), which contains adipocytes with dense collections of mitochondria.⁸⁷ In addition, the brown adipocytes express uncoupling protein 1 (UCP1), which uncouples mitochondrial respiration and thereby induces energy expenditure and heat. In humans, the key tissue mediating energy expenditure in response to changing energy intake remains to be determined but likely includes skeletal muscle.⁸⁷ In any case, it is clear that the sympathetic nervous system is required for coordinated control of energy expenditure and resistance to diet-induced obesity. For example, mice lacking β -adrenergic receptors (triple knockouts) develop severe obesity when placed on a high-fat diet.⁸⁸ Therefore, coordinated control of the sympathetic nervous system is required for control of diet-induced thermogenesis.

The CNS integrates metabolic information into a coordinated set of endocrine, autonomic, and behavioral responses to maintain homeostasis.^{32,89,90} Key mediators of these responses are parasympathetic and sympathetic preganglionic neurons in the brainstem and spinal cord.^{32,91} Sympathetic preganglionic neurons (SPNs) extend from the upper thoracic to the upper lumbar segments of the spinal cord and are found within the intermediolateral cell column (IML). Different rostral-caudal levels of the IML provide innervation to different target organs and thus mediate distinct autonomic responses. For example, SPNs in the upper thoracic levels of the IML are thought to be important for control of the heart and cardiovascular system. SPNs in the T6-T12 level of the IML provide

innervation of the adrenal gland and the endocrine pancreas.^{89,92-96}

In addition to the autonomic preganglionic neurons themselves, a key component of the central autonomic control system is direct (monosynaptic) descending innervation from key regulatory groups in the hypothalamus and brainstem.^{32,97,98} The projection to the SPNs in the spinal cord is composed of inputs from the arcuate nucleus/retrochiasmatic area, the PVH, and the lateral hypothalamus.^{89,98-104} Major projections also arise from the brainstem and include inputs from the raphe pallidus, catecholaminergic cells in the A5 group of the pons, and C1 cells in the rostral ventral lateral medulla that are critical in maintaining sympathetic tone in the cardiovascular system.¹⁰⁵⁻¹⁰⁸ Therefore, there is a relatively circumscribed distribution of neurons providing descending input to SPNs that regulate the cardiovascular system, energy expenditure, adrenal catecholamine secretion, and the endocrine pancreas.

As noted earlier, in rodents central melanocortins are known to regulate energy expenditure in addition to food intake. MC4R blockade in mice prevents diet-induced thermogenesis¹⁰⁹ and blocks the upregulation of BAT activity¹¹⁰; this prevents upregulation of the expression of uncoupling proteins normally seen when mice are placed on a high-fat diet.¹¹¹ The sites mediating the effects of MC4R agonists on energy expenditure are still not definitively identified. However, a site of MC4R action relevant to the control of energy expenditure may be the SPNs themselves, which express MC4Rs.⁵⁹ Notably, these neurons receive direct inputs from leptin-responsive POMC neurons.¹¹² Therefore, MC4Rs expressed by SPNs in the spinal cord may contribute to melanocortin's effects on energy expenditure.

Evidence suggests that the effects of MC4R agonists on energy expenditure are mediated by MC4R-bearing neurons in the raphe pallidus in the brainstem.^{113,114} Neurons in the raphe pallidus innervate SPNs in the IML.^{115,116} In addition, raphe pallidus neurons are activated by "thermogenic" stimuli and have been shown to control BAT thermogenesis.^{117,118} Injections of MC4R agonists into the raphe pallidus increases sympathetic nerve activity to BAT.¹¹⁴ Therefore, MC4R-expressing neurons in the raphe nucleus may be key to the ability of melanocortin receptor agonists to increase energy expenditure.

HORMONAL REGULATORS OF THE BRAIN-GUT-ADIPOSE AXIS

Adipostatic Factors

Leptin Is the Prototypical Regulator of Energy Homeostasis

Discovery of the molecular bases for several obesity syndromes, prominent among them the hormone leptin¹¹⁹ and its receptor,²¹ has rapidly and dramatically increased understanding of the pathophysiology of obesity and related disorders. Leptin, the product of the *ob* gene,¹¹⁹ is produced by white adipose tissue and affects feeding behavior, thermogenesis, and neuroendocrine status. Leptin protein is highly conserved throughout evolution; mouse and human leptin are 84% homologous, and leptin has been found in birds and tentatively identified in fish. This protein comprises 167 amino acids and 16 kD and circulates in the blood at concentrations proportional to the amount of fat depots. Leptin circulates in the bloodstream as a free

protein and also bound to a soluble isoform of its receptor (Ob-Re). Leptin is secreted primarily from the adipocyte, but minor levels of regulated leptin expression also occur in other sites, such as skeletal muscle, placenta, and stomach.^{120,121}

Total lack of leptin or leptin signaling in rodents and humans causes morbid obesity that is accompanied by a wide array of neuroendocrine abnormalities. Replacement with exogenous leptin normalizes these abnormalities.¹²²⁻¹²⁵ Starvation, a time of low energy stores, leads to a fall in serum leptin levels and has profound effects on several neuroendocrine systems, including activation of the hypothalamic-pituitary-adrenal (HPA) axis, inhibition of the growth hormone and thyroid axes, and inhibition of reproductive function.¹²⁶⁻¹²⁸ Lack of leptin results in many physiologic responses that are also found in a state of starvation. Many of these starvation-induced endocrine and autonomic changes are blocked or blunted by pretreatment with systemic leptin.¹²⁶ The dose needed to reverse these abnormalities is lower than that needed to induce weight loss in normal rodents. These observations have led to the suggestions that circulating leptin may have evolved to signal the brain that energy stores are sufficient and that a lack of leptin may be responsible for multiple neuroendocrine abnormalities caused by starvation.^{129,130}

Soon after the discovery of leptin, it became clear that most of the varied effects of leptin are mediated by the brain. More recent studies have begun to unravel some of the complex circuitry involved in leptin signaling.⁴⁹

Distribution of Leptin Receptors

After its transport through the BBB, leptin binds to specific receptors in the hypothalamus and brainstem. The "long-form" leptin receptor (OB-Rb) is a member of the cytokine-receptor superfamily.^{20,21,131} The leptin receptor binds janus kinases (JAK), tyrosine kinases involved in intracellular cytokine signaling. Activation of JAK leads to phosphorylation of members of the signal transduction and transcription (STAT) family of proteins. In turn, STAT proteins activate transcription of leptin target genes.

The long-form leptin receptor is required for normal energy homeostasis; mutations of this gene result in the obese phenotype of the *db/db* mouse and the Zucker rat.^{20,132,133} Leptin receptors are highly expressed by several hypothalamic nuclei within the medial basal hypothalamus,¹³⁴⁻¹³⁹ including the arcuate, dorsomedial, ventromedial, and ventral premammillary nuclei. They are also expressed in several extrahypothalamic sites, including the NTS (where vagal afferents terminate), the substantia nigra, and the ventral tegmental area.

Understanding of the role of extrahypothalamic leptin receptors is evolving, but evidence is accumulating that leptin has important sites of action within the brainstem. For example, leptin administration increased STAT3 phosphorylation in several extrahypothalamic sites, including the parabrachial nucleus, dorsal raphe, and NTS.¹⁴⁰ Moreover, administration of leptin into the fourth ventricle and into the dorsal vagal complex significantly reduced food intake.^{33,141-144}

The Role of Insulin and Glucose in Regulating Energy Homeostasis

The concept that the CNS plays a primary role in the control of insulin action and glucose homeostasis is an old one. In 1849, Claude Bernard suggested that the CNS regulates blood glucose levels after his famous experiments demonstrating that "pique" of the floor of the fourth

ventricle of rabbits produced increases in blood glucose that were measured by glucose levels in the urine.^{4,145} Remarkably, he concluded that the effect was mediated by stimulation of the autonomic input to the liver. Later lesion studies of the hypothalamus also teased out actions of insulin that are independent of food intake.⁴ These early observations fit remarkably well with findings predicting that diabetes, similar to obesity, may be viewed as a disorder with underlying defects in the CNS.¹⁴⁶⁻¹⁵⁰

Insulin Action in the Brain. In addition to its well-known role in increasing glucose uptake in tissues such as muscle and fat, insulin has actions on the brain to regulate energy balance.¹⁵¹ Insulin receptors are expressed in the brain, and injections of insulin into the brain reduce food intake.^{151,152} Furthermore, deletion of insulin receptors specifically from neurons results in mild obesity.¹⁵³

The role of insulin action in the CNS has been investigated in the context of regulation of glucose homeostasis. Downregulation of insulin receptors affects glucose homeostasis, including glucose production by the liver.¹⁴⁹ Therefore, insulin action in the brain may be key in the coordinated physiologic responses to changing levels of metabolic fuels. However, the physiologic significance and relative contributions of central versus peripheral actions of insulin in regulating glucose homeostasis, especially glucose production by the liver, are still unclear¹⁵⁴⁻¹⁵⁶ and represent a key area of diabetes and obesity research.

Glucose Levels Are Sensed by Neurons in the Brain. Changing levels of blood glucose are sensed by several distinct populations of neurons in the brain. This was first suggested by classic experiments¹⁵⁷ demonstrating that some classes of neurons are activated by rising concentrations of glucose and others are inhibited by rising glucose. Several contemporary models predict that neurons that are activated by rising glucose respond and behave very similarly to beta cells of the endocrine pancreas.¹⁵⁸⁻¹⁶⁰ The chemical identity and location of these glucose-sensing neurons are still to be determined. Several populations of glucose-sensitive neurons have been described in the hypothalamus, but neurons in the brainstem also sense glucose and are capable of inducing coordinated responses to falling levels of glucose.¹⁶¹⁻¹⁶³

The cellular mechanisms underlying glucose-mediated neuronal excitation likely involve a rise in adenosine triphosphate (ATP), resulting from an increase in glucose metabolism, that promotes the closure of K_{ATP} potassium channels.¹⁶⁰ The mechanisms underlying the ability of neurons to be inhibited by rising glucose levels (or to be activated by falling glucose) are not as clearly defined but may involve the TASK subfamily of two-pore domain potassium channels as mediators of the glucose-activated inhibitory current in orexin neurons.¹⁶⁴ Collectively, these observations have led to predictions that changes in glucose levels alter the electrical activity of specific neurons, leading to changes in feeding behavior and glucose production. These models also predict that dysregulation of nutrient sensing in the CNS may contribute to the metabolic alterations that are characteristic of diabetes and obesity.

POMC Neurons Sense Changes in Glucose Concentration

Consistent with the demonstration that metabolic cues such as leptin directly act on POMC neurons, a key role of the central melanocortin system in regulating glucose homeostasis has emerged. POMC neurons increase their

activity in response to rising glucose.¹⁶⁰ Mice lacking MC4Rs are hyperinsulinemic before the onset of obesity.^{31,147} Experimental data have reinforced the concept that vagal input to the liver is a key regulator of hepatic glucose production, potentially including that mediated by melanocortin agonists.¹⁶⁵ The parasympathetic (cholinergic) innervation to the pancreas and liver is provided by the DMV.^{96,166,167} The sympathetic innervation of the pancreas is from postganglionic neurons in the celiac ganglia^{95,168} that are innervated by preganglionic neurons from mid-thoracic levels of the spinal cord.

Central administration of MC4R agonists decreased plasma insulin levels in lean and obese mice.¹⁴⁷ This effect was blocked by blockade of α -adrenergic receptors, suggesting that central MC4R agonists inhibit insulin secretion by activating the sympathetic nervous system. Administration of MC4R agonists increases glucose tolerance, and lean MC4R knockout mice are insulin resistant before the onset of obesity.¹⁴⁷ Moreover, MC4R-deficient humans are hyperinsulinemic, more so than would be expected from their degree of obesity alone, including subjects as young as 12 months old.^{54,55} The sites in the CNS that mediate these effects are still to be determined, but MC4Rs are expressed by both parasympathetic preganglionic neurons and SPNs.^{59,60} Therefore, it is likely that MC4R agonists exert a tonic inhibitory influence on insulin secretion by increasing the sympathetic input to the pancreas while simultaneously diminishing the parasympathetic input.¹⁴⁷

As noted earlier, the activity of orexin neurons of the lateral hypothalamus is altered by changing levels of blood glucose. Specifically, orexin neurons are activated by physiologically relevant decreases in glucose concentrations.^{164,169-172} Orexin neurons may be key in coordinating endocrine and autonomic responses to falling glucose levels. It is also likely that orexin neurons may represent one of the populations of “glucose-inhibited” neurons in the lateral hypothalamus that respond to physiologic falls in glucose levels with an increase in activity.^{159,173} Because of its unique anatomic and physiologic properties, the central orexin system may be required to link glucose sensing with wakefulness (i.e., hypoglycemic unawareness) and coordinated autonomic responses.

Satiety and Hunger Factors

Role of the Brainstem in Satiety and Hunger

The brainstem is classically understood as the center for detection and response to hunger and satiety signals. The NTS is the primary site for innervation by vagal afferents from the gut (see review by Schwartz¹⁷⁴ and Fig. 35-2). The afferent branches deriving from different aspects of the gastrointestinal tract map viscerotopically along the NTS from its rostral to its caudal aspect.¹⁷⁵ Rostrally, the NTS is a bilaterally symmetric nucleus that merges into a single medial body at its caudal extent, called the *commissural NTS*.³²

Vagal afferents deriving input from the upper gastrointestinal tract are responsive to three basic stimuli: gastric and duodenal distention or contraction, chemical contents of the lumen, and gut peptides and neurotransmitters released from the stomach and duodenum in response to nutrients.¹⁷⁴ In the rat, vagal afferents responding to gastric and duodenal distention tend to map to the medial and commissural divisions of the NTS.^{176,177} Vagal afferents responsive to the gut peptide CCK also map to the caudal NTS.¹⁷⁸

The DMV, located just ventral to the NTS, is the primary site of motor efferents to the gut and is densely innervated by NTS fibers. Together, these cell groups, with the area postrema, a CVO, form the dorsal vagal complex (DVC) and serve as the neuroanatomic substrate for the vagovagal reflex.

Gut Peptides Involved in Satiety and Hunger

In addition to signals from gut distention, gut peptides stimulated by meal intake mediate satiety through centers in the brainstem. Signals received by the brainstem are thought to interact primarily with long-term weight regulation centers, via neural connections to the hypothalamus, to regulate total daily intake by adjusting meal size, the number of meals, or both.

With the discovery of ghrelin, gut factors that stimulate food intake must also be considered. Chapter 39 examines gastrointestinal hormones in detail, focusing on their peripheral actions. Here we consider their central actions. As discussed later, newer data suggest that a subset of these gastrointestinal hormones may also act directly on hypothalamic control centers.

Cholecystokinin. CCK is produced by the gastrointestinal tract in response to meal ingestion, and its diverse actions include stimulation of pancreatic enzyme secretion and intestinal motility, inhibition of gastric motility, and acute inhibition of feeding. Early experiments with peripheral administration of CCK supported a role for increased CCK levels in the early termination of a meal.^{179,180} The finding that repeated injections of CCK lead to reduced meal size without a change in body weight, owing to a compensatory increase in meal frequency, argued against CCK action as a signal regulating long-term energy stores.^{181,182}

Two subtypes of the CCK receptor belonging to the G protein-coupled family of receptors have been described: CCKA and CCKB. Studies using CCK receptor-specific antagonists and surgical or chemical vagotomy have demonstrated that the satiety effects of CCK are specifically

mediated via CCKA receptors on afferent vagal nerves.¹⁸³⁻¹⁸⁹ This interaction between acute vagal input from CCKA receptors and meal termination involves activation of cells in the NTS and area postrema, modulated by neural connections from the hypothalamus receiving inputs from insulin and leptin.

Peripheral administration of CCK potently activates large numbers of neurons in both the NTS and the area postrema (Fig. 35-7). Furthermore, central administration of insulin and leptin potentiates the satiety-inducing effects of peripherally administered CCK¹⁸⁸⁻¹⁹⁴ and leads, with repeated injections, to sustained weight loss that is greater than injection of the agents separately.¹⁹⁵ However, more remains to be learned regarding the neuroanatomic substrate underlying this convergence of long-term and short-term information. Whereas basomedial hypothalamic cell groups involved in leptin signaling are densely innervated by catecholaminergic neurons from the brainstem, it has been demonstrated that norepinephrine is not required for CCK-induced reduction of feeding, in that the dopamine β -hydroxylase knockout mouse is still responsive to CCK-induced satiety.¹⁹⁶ The central melanocortin system may be one element of this integration of satiety with long-term energy homeostasis, because MC4R blockade in the brainstem appears to inhibit the satiating activity of peripherally administered CCK.⁶⁶

In addition to its function in the induction of satiety through vagally mediated signaling, a small body of literature supports a central role for CCK action in regulation of feeding. Immunohistochemistry of the brain and spinal cord shows that the CCKA and CCKB receptors are widely distributed in the CNS, including in the arcuate nucleus¹⁹⁷ and other hypothalamic regions.^{197,198} Intracerebroventricular (ICV) administration of CCK to mice¹⁹⁹ inhibits food intake; this effect is reversible by prior administration of a CCKA receptor antagonist. The significance of these hypothalamic-arcuate CCK receptors to weight regulation in the free feeding state is not known.

Figure 35-7 Brainstem neurons activated by satiety. **A**, Neurons activated by intraperitoneal administration of 10 µg/kg cholecystokinin (CCK) in the nucleus tractus solitarius (NTS) of the mouse. Neurons visualized by immunohistochemical reaction against Fos, a marker of neuronal activation. **B**, Neurons in the NTS activated by CCK encompass a variety of different neurochemical subtypes, such as glucagon-like peptide I (GLP1)-positive neurons, and the pro-opiomelanocortin (POMC)-positive neurons. POMC neurons are visualized through immunohistochemical detection of green fluorescent protein in tissue from a transgenic mouse in which green fluorescent protein (GFP) is expressed under the control of the POMC promoter. (Reproduced from Cowley MA, Smart JL, Rubinstein M, et al. Leptin activates anorexigenic POMC neurons through a neural network in the arcuate nucleus. *Nature*. 2001;411:480-484. Photographs provided by Dr. Kate L.J. Ellacott, Vanderbilt University School of Medicine, Nashville, Tenn)

Peptide YY. Peptide YY (PYY), a peptide related to NPY and pancreatic peptide (PP), is postprandially released by endocrine cells in the ileum and colon.²⁰⁰ PYY is found in vivo in both a full-length, 36-amino-acid form and a 34-amino-acid form (PYY₃₋₃₆) in approximately a 2:1 to 1:1 molar ratio.²⁰¹ PYY is a potent agonist of both Y1 and Y2 receptors, whereas PYY₃₋₃₆ is a Y2-specific agonist with approximately a 1000 times greater affinity for the Y2 than for the Y1 receptor.²⁰² Y1- and Y2-preferring binding sites are located in the area postrema and in the dorsal vagal complex (NTS and DMV). Peripheral administration of PYY (300 mg/kg) in the rat induces c-fos (Fos) in the area postrema and in the medial and commissural NTS, the latter being the same region of the NTS that is known to express POMC.²⁰³ Infusion of PYY within the physiologic range has numerous effects, including inhibition of gastric emptying,²⁰⁴ gastric acid secretion,²⁰⁵ and pancreatic exocrine secretion.²⁰⁵ These actions of PYY appear to be mediated by direct action of PYY on the dorsal vagal complex and on gastric mucosal enterochromaffin-like cells (see review by Yang²⁰⁶). Both Y1 and Y2 receptors are found within the DVC.²⁰⁷ PYY appears to inhibit gastric acid secretion primarily through vagal innervation of the gastric fundus.²⁰⁸ The ability of low-dose PYY and PYY₃₋₃₆ to inhibit the activity of DMN efferents appears to be Y2 mediated, and Y1 agonists appear to stimulate these cells.²⁰⁶

Peripheral administration of PYY₃₋₃₆ in pharmacologic doses appears to have an anorexigenic effect in rodents and in humans,²⁰⁹⁻²¹⁵ suggesting that the peptide also functions as a satiety factor. The mechanisms underlying the action of PYY₃₋₃₆ in reducing food intake have not been fully elucidated. Intraperitoneal administration of PYY₃₋₃₆ was found to activate 12% to 13% of arcuate POMC neurons, as assayed by increased expression of Fos.^{209,216} However, vagotomy also blocks PYY₃₋₃₆-induced inhibition of feeding.²¹⁷ The existence of a direct hypothalamic site of action has been challenged by several studies. Inhibition of feeding by PYY₃₋₃₆ persists in the MC4R knockout mouse,²¹⁶ the POMC knockout mouse,²¹¹ and the obese agouti mouse.²¹⁸ Therefore, release of melanocortin peptides derived from POMC and subsequent activation of the MC4R, a well-characterized anorexigenic pathway, does not appear to be required for the inhibition of feeding by PYY₃₋₃₆. Furthermore, PYY induced conditioned taste aversion in rodents and nausea in some human studies, suggesting an aversive effect of the peptide that is likely to involve brainstem sites such as the area postrema.

Despite the short-acting anorexic effects of the PYY in most experimental models, suggesting that it may be a satiety factor like CCK, two knockout studies demonstrated that removal of the gene encoding the peptide produces obese hyperinsulinemic mice.^{219,220} These data suggest that the peptide may also play an important role in the regulation of long-term energy stores. One study suggested that the peptide may be specifically involved in the satiating effects of protein in the diet.²¹⁹

Ghrelin. Identified as an endogenous ligand for the growth-hormone secretagogue receptor (GHSR),^{221,222} ghrelin is an acylated, 28-amino-acid peptide that is predominantly secreted by the stomach, is regulated by ingestion of nutrients,²²³⁻²²⁶ and has potent effects on appetite.^{225,226} In rodents and humans, ghrelin levels are markedly reduced with meal ingestion but rebound to baseline before the next meal or increase after an overnight fast (Fig. 35-8).²²⁴⁻²²⁶ In rodents, this was demonstrated to be a nutrient-specific effect in that a similar volume of

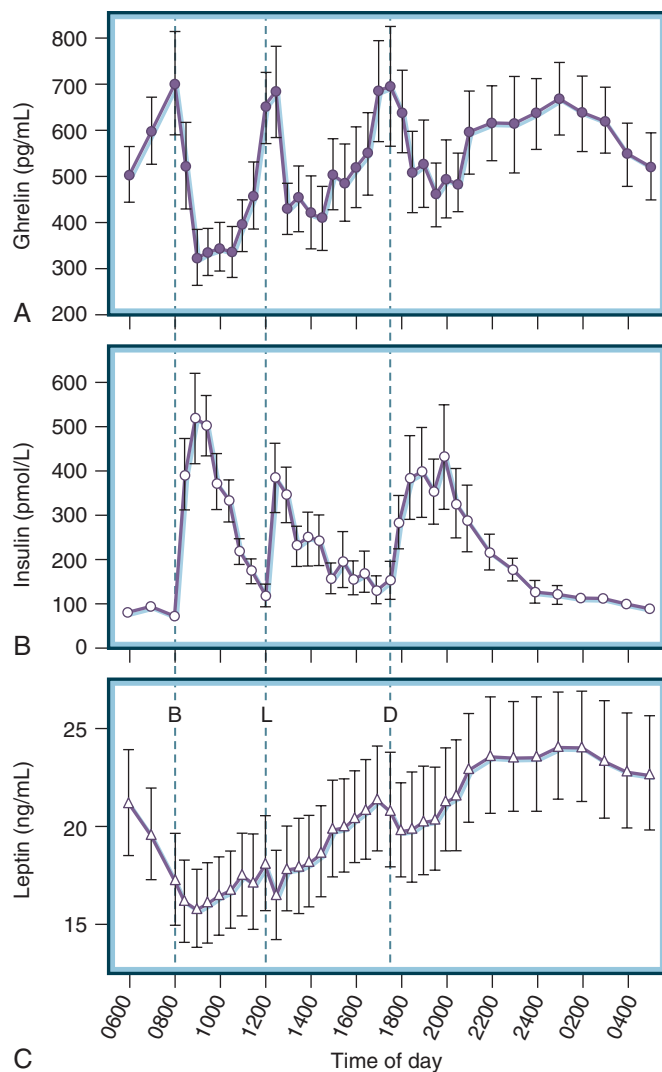

Figure 35-8 Average plasma ghrelin, insulin, and leptin concentrations during a 24-hour period in 10 human subjects consuming breakfast (B), lunch (L), and dinner (D) at the times indicated (0800, 1200, and 1800 hours, respectively). (Reprinted from Cummings DE, Purnell JQ, Frayo RS, et al. A preprandial rise in plasma ghrelin levels suggests a role in meal initiation in humans. *Diabetes*. 2001;50:1714-1719.)

saline infused into the stomach did not affect ghrelin levels.²²⁵ GHSR have been demonstrated on arcuate NPY-containing neurons.²²⁷ Pharmacologic doses of ghrelin injected peripherally or into the hypothalamus activate Fos and Egr1 solely in arcuate NPY neurons in rats²²⁸ and stimulate food intake and obesity, in part by stimulating NPY and AgRP expression,²²⁸⁻²³⁴ which antagonize leptin's anorexic effect.²³³

This orexigenic action occurs in rodents even with peripheral administration of ghrelin that matches fasting levels.²³⁵ Stimulation of appetite and food intake during an infusion of ghrelin over 4.5 hours in humans has also been demonstrated,²³⁶ and ghrelin may also effect gastric emptying. This study established that, similar to its action in rodents, ghrelin can stimulate appetite and food intake in humans when given in a supraphysiologic dose, but a role for physiologic changes in ghrelin levels or signaling in human energy homeostasis remains unknown.

Ghrelin's characteristics make it unique among the gut-derived signals. Unlike other enteropancreatic signals involved with energy homeostasis, ghrelin secretion is inhibited in response to meals; and instead of acting as a satiety signal (like CCK or PYY₃₋₃₆), ghrelin stimulates appetite, potentially through arcuate signaling. These properties strongly suggest that ghrelin is a candidate "meal-initiating" signal, as proposed by Cummings and colleagues.²²⁶ In addition, fasting ghrelin levels have been shown to be inversely proportional to body weight²³⁷ and to be higher in underweight subjects with anorexia nervosa and cardiac cachexia compared with controls.^{223,238} Downregulation of ghrelin in obese subjects suggests an adaptive response to the obese state, whereas a rise in levels in weight-reduced subjects is compatible with a counterregulatory role to restore fat depots. These properties inversely parallel those of insulin, which is stimulated by meals, inhibits food intake when injected ICV, circulates in the fasting state in direct proportion to body weight, and is secreted in decreased amounts after weight loss.

Much work remains to establish the physiologic role of ghrelin in meal initiation and energy homeostasis and its mechanisms of action. Evidence indicates that the melanocortin system is central to ghrelin's effects on food intake. Stimulation of food intake by ghrelin administration is blocked by administration of NPY/Y1 and Y5 antagonists²³³ and is reduced in the NPY^{-/-} mouse, and administration of the melanocortin agonist Melanotan II (MTII) blocks further stimulation of weight gain by growth hormone-releasing peptide 2 (GHRP-2) in the NPY^{-/-} mouse.²³⁹

Peripheral administration of ghrelin activates Fos expression only in arcuate NPY/AgRP neurons, not in other hypothalamic or brainstem sites,²⁴⁰ and ablation of the arcuate nucleus blocks the actions of ghrelin administration on feeding but not on elevation of growth hormone.²⁴¹ Despite activating Fos only in arcuate NPY neurons, peripheral ghrelin may access the arcuate via vagal afferents: GHSR is expressed on vagal afferents, ghrelin suppresses firing of vagal nerves, and surgical or chemical vagotomy blocks stimulation of feeding as well as Fos activation in the arcuate by peripheral but not central ghrelin administration.²⁴² Peripheral ghrelin may largely suppress brainstem satiety centers, which would explain the lack of Fos activation at these sites. The NTS sends dense catecholaminergic projections to the arcuate; therefore, although a convergence of ascending vagal afferent information arrives at the arcuate from both brainstem and intermediate hypothalamic sites, it is possible that NTS neurons inhibited by ghrelin synapse directly with NPY arcuate neurons. This would explain the absence of other hypothalamic neurons activated by peripheral ghrelin.

Administration of another peptide hormone derived from proghrelin, termed *obestatin*, was demonstrated to inhibit food intake and was proposed to be the ligand for an orphan GPCR known as GPR39.²⁴³ However, most groups have been unable to repeat this finding, and even the identity of obestatin as a GPR39 ligand has been called into question.²⁴⁴⁻²⁴⁶

Preproglucagon-Derived Peptides. Current strategies for the treatment of type 2 diabetes mellitus are not optimally effective, and even multiple drug combinations fail to normalize glycemia in a sustained manner in many subjects. Hence, there remains intense interest in new therapies that safely and effectively lower blood glucose in diabetic subjects. Strategies that mimic the actions of the incretin class of hormones are being used to treat type 2 diabetes and

obesity.^{247,248} Incretins are hormones that are released by oral ingestion of nutrients and increase insulin secretion. The prototypical incretin hormone is GLP1, which is derived from the proglucagon gene. The proglucagon-derived peptides are generated in the A cells of the pancreas (principally glucagon), in the L cells of the intestine (GLP1, GLP2, and glicentin), and in the brain (glucagon, GLP1, GLP2).^{247,248}

As outlined in detail in Chapter 31, GLP1 receptor agonists induce multiple desirable antidiabetic and antiobesity actions, and protease-resistant long-acting GLP1 analogues are currently available for the treatment of type 2 diabetes.^{247,248} The first of these drugs, Byetta (exenatide), is a potent GLP1 receptor agonist that mimics the GLP1 enhancement of glucose-dependent insulin secretion, slowing gastric emptying, inhibiting gastric acid secretion, and reducing food intake. The last effect may be due to action on circuits in the brain involved in the control of energy homeostasis (see later discussion).

GLP1 and GLP1R Neurons in the Central Nervous System. Despite intense interest in GLP1 and related peptides, it is little appreciated that GLP1 is an endogenous neuropeptide expressed by neurons in the CNS, and the CNS actions of GLP1 are less well understood. With the development of GLP1 analogues to treat diabetes, understanding of the central actions of GLP1 is relevant for predicting the biologic consequences of sustained GLP1 administration.

Initial interest in the CNS actions of GLP1 stemmed from the observation that GLP1 inhibits food intake.²⁴⁹⁻²⁵³ In humans, peripheral GLP1 administration to normal and diabetic subjects induced satiety and reduces food intake in short-term studies.²⁵⁴⁻²⁵⁷ Chronic continuous GLP1 administration to human diabetic subjects was associated with modest weight loss.²⁵⁸ The effects of GLP1 on appetite may be mediated in part by inhibition of gastric emptying and may also reflect direct effects of GLP1 on satiety and induction of taste aversion.^{38,259-263}

The CNS expression of GLP1 is very restricted and includes a population of neurons within the caudal NTS. Caudal NTS neurons receive and process viscerosensory information from thoracic and abdominal viscera. The NTS is reciprocally connected with various brain areas, including hypothalamic areas thought to regulate feeding.^{32,264} Additionally, the NTS is located adjacent to a CVO, the area postrema, and the NTS contains fenestrated capillaries, potentially allowing circulating peptides access to the nucleus. Therefore, neurons in the NTS (including GLP1 cells) process information arising from a variety of neural and humoral sources. GLP1 neurons are in a prime position to rapidly modify ingestive behavior in direct response to transiently altered levels of metabolic cues (e.g., leptin, glucose) or to neural modulators from other brain sites, including POMC neurons in the arcuate nucleus. For example, the adipocyte-derived hormone leptin communicates the status of energy stores to the brain. Most investigations of the neural circuits that mediate leptin action have focused on the hypothalamus. However, increasing evidence implicates a significant role for extrahypothalamic sites of leptin action.^{33,141} Intravenous leptin increases neuronal activation (induces Fos-IR) in regions of the hind-brain, including GLP1 neurons in the NTS²⁶⁵ as well as POMC neurons in some cases.²⁶⁶

In addition to the varied inputs, GLP1 neurons in the NTS also have a widespread projection pattern in the brain.²⁶⁷ There are direct innervations of several hypothalamic nuclei, including the PVH, LHA, and arcuate nucleus,

and GLP1 receptor mRNA has been found within those areas.²⁶⁸ The location of GLP1 neurons in the NTS and their diffuse projection pattern suggest that GLP1 neurons are ideally situated to integrate key signals and regulate complex physiologic processes.

Amylin. Amylin, or islet amyloid polypeptide (IAPP), is a 37-amino-acid polypeptide that colocalizes with insulin in beta cells in the pancreas. In humans, IAPP in the pancreas can form amyloid fibrils and is thought to play a role in the decline in islet cell function that accompanies type 2 diabetes.^{269,270} In addition, IAPP has been shown to impair gastric motility and to have effects independent of insulin on energy homeostasis mediated through hypothalamic signaling.

IAPP is cosecreted with insulin in response to nutrient intake and insulin secretagogues.^{271,272} IAPP readily enters the brain, and high-affinity IAPP-binding sites have been found in several brain regions, including the hypothalamus and arcuate nucleus.^{273,274} Both peripheral and ICV infusions of IAPP inhibit food intake acutely, and chronic infusion leads to a sustained reduction in body weight.²⁷³⁻²⁷⁸ This anorectic effect was shown by Rushing and colleagues to be blocked by coadministration of the IAPP antagonist AC187 centrally, and AC187 resulted in a significant increase in body adiposity when infused ICV over 14 days, compared with control animals.²⁷⁸ Studies of coadministration of IAPP with other gastrointestinal hormones have shown that the acute satiety effects of IAPP are equipotent to those of CCK²⁷⁹ and are additive when IAPP is peripherally coinjected with either CCK²⁸⁰ or insulin.²⁸¹ The precise central neuroendocrine mechanisms mediating IAPP's anorectic effects have yet to be elucidated. The diverse CNS binding of IAPP suggests that multiple sites may have roles in the anorectic effects of IAPP; however, the inhibition of appetite with ICV administration and demonstrated binding in the arcuate suggests that the hypothalamus may be an important site of IAPP action.

Bariatric Surgery and the Role of the Gastrointestinal System in the Control of Energy Homeostasis

No pharmacologic treatment has yet been devised that is capable of resetting the adipostat—that is, allowing significant long-term weight loss to be maintained. In contrast, certain types of bariatric surgery, such as the Roux-en-Y gastric bypass (described in Chapter 36 and reviewed by Cummings²⁸² and Sjostrom²⁸³), appear to cause not only significant weight loss but also maintenance of this weight loss for many years (Fig. 35-9). Furthermore, improvement in diabetes after these procedures is often seen before significant weight loss occurs, and this can now be modeled in rodents as well.²⁸⁴ Both of these findings imply that the procedures have a profound impact on the central control of long-term energy stores, satiety, and glucose homeostasis. Conventional models have argued that gastrointestinal hormones regulate satiety, but individually they do not have significant impact on the control of long-term energy stores. For example, deletion or blockade of CCK increases meal size but not 24-hour food intake or body weight. The facts that bariatric surgery appears capable of creating a new, stable weight set point and that PYY deletion causes obesity suggest that hormonal and vagal and nutritional signals from the gut may have a more profound impact on long-term energy homeostasis than was previously thought.

Figure 35-9 Apparent alteration of the adipostatic set point after bariatric surgery. (Modified from Sjostrom L, Lindroos AK, Peltonen M, et al.; Swedish Obese Subjects Study Scientific Group. Lifestyle, diabetes, and cardiovascular risk factors 10 years after bariatric surgery. *N Engl J Med*. 2004;351:2683-2693.)

GLUCOCORTICOIDS AND GONADAL STEROIDS

Both glucocorticoids and gonadal steroids are known to act centrally on circuits involved in energy homeostasis. Orchiectomy decreases food intake in rodents, whereas ovariectomy has the opposite result.²⁸⁵ Hormone replacement therapy with drugs such as tamoxifen has been demonstrated to reduce the weight gain seen with menopause.²⁸⁶ Estrogen receptors appear to be expressed at significant levels in the arcuate nucleus of the hypothalamus. Data suggest that estrogen may act at both POMC and NPY/AgRP neurons, perhaps explaining, in part, the cellular mechanism of the hormone's action in the CNS.^{287,288} Mice lacking estrogen receptor α (ER α) develop increased visceral adiposity, elevated insulin levels, and reduced glucose tolerance.²⁸⁹ However, obesity in this knockout model does not appear to be caused by hyperphagia. Deletion of ER α exclusively in neurons of the VMH leads to a similar syndrome of obesity and metabolic syndrome, suggesting an important role for estrogen in the control of energy expenditure and implicating the VMH in estrogen action.²⁹⁰ The vagal nerve is also a site of estrogen action where the hormone has been demonstrated to alter responsiveness to satiety factors, such as CCK.²⁸⁵

In contrast to estrogen, glucocorticoids stimulate food intake and weight gain. Excessive glucocorticoids are associated with the unusual deposition of excess adipose tissue, for example in Cushing's disease (see Chapter 7). However, glucocorticoids have an enormous diversity of effects in the periphery and in the CNS, and the glucocorticoid receptor is extremely widely expressed throughout the CNS.²⁹¹ Glucocorticoids have anti-inflammatory effects in the CNS and provide feedback inhibition to the HPA axis (see Chapter 7), both actions having secondary effects on energy homeostasis. Glucocorticoids also appear to be critical in determining the tone of adipostatic circuits.²⁸⁵ For example, the ability of centrally administered NPY to produce obesity and the obesity resulting from leptin deficiency are both dramatically reduced by adrenalectomy. ICV administration of dexamethasone to adrenalectomized rats also dose-dependently reduces leptin potency.

The complexity of glucocorticoid action in energy homeostasis results from the broad number of tissues affected, the multiple physiologic systems involved, and action in a variety of time scales. Rapid actions of glucocorticoids in the hypothalamus, not mediated by the conventional glucocorticoid receptor, have also been linked in sites like the PVN to rapid synthesis and retrograde release of endocannabinoids, which suppress synaptic excitation through presynaptic CB1 receptors. In support of this newly identified pathway, leptin appears to block glucocorticoid-mediated endocannabinoid release.²⁹²

CYTOKINES AND ENERGY BALANCE

The profound effect of cytokines, largely derived from the immune system, on energy balance is most clearly evident in the case of disease wasting or cachexia. The term *cachexia* describes a constellation of symptoms that occurs in multiple independent infectious and chronic diseases including some forms of cancer, heart failure, renal failure, and acquired immunodeficiency syndrome. These symptoms include anorexia, increased energy expenditure, and a loss of lean mass. The normal response to anorexia and the initial loss of adipose mass—a decrease in energy expenditure and neuroendocrine changes designed to save energy (e.g., hypothyroidism)—occur in anorexia nervosa but not in cachexia. Research in rodents and humans demonstrates that cachexia results from the action of a variety of cytokines in the CNS and, in particular, the dysfunctional response of circuits involved in the central control of energy homeostasis.

Neuroendocrine-Immune Interactions

Stimulation of the immune system by foreign pathogens leads to a stereotypical set of responses orchestrated by the CNS. These responses are the result of the complex interaction of the immune system and the CNS and are often referred to as the cerebral component of the acute phase reaction.²⁹³ This constellation of responses is adaptive and is mediated in large part by the hypothalamus and, just as in the normal control of energy homeostasis, comprises coordinated autonomic, endocrine, and behavioral components. These responses include fever, alterations in the activity of almost every neuroendocrine axis, changes in the sleep-wake cycle, anorexia, and inactivity.

It is now clear that cytokines produced by white blood cells of the immune system mediate the CNS responses. Early evidence supporting this hypothesis was provided by the seminal observations that cytokines such as interleukin-1 β (IL-1 β) can activate the HPA axis.²⁹⁴⁻²⁹⁶ Although it is established that cytokines modulate hypothalamic activity, it is also important to note that the immune system is modulated by the nervous system. This occurs largely by two routes: endocrine mechanisms and direct innervation. This innervation includes lymphoid organs such as the thymus and spleen, which receive direct inputs from the autonomic nervous system.^{297,298} As noted in Chapter 7, the hallmark of cytokine action on the hypothalamus is the activation of the HPA axis. The resultant glucocorticoid secretion acts as a classic negative feedback to the immune system to dampen the immune response (Fig. 35-10). In general, glucocorticoids inhibit most limbs of the immune response, including lymphocyte proliferation, production of immunoglobulins, cytokines, and cytotoxicity. These inhibitory reactions form the basis of the anti-inflammatory actions of glucocorticoids.

This section addresses several of the hypothesized mechanisms by which cytokines engage neural pathways to mediate neuroendocrine and autonomic effects. Many nonlymphocyte cells, including endocrine cells, adipose cells, and neurons, also synthesize cytokines that exert effects independent of immunomodulation. Examples of cytokines secreted by adipocytes include leptin and tumor necrosis factor- α (TNF- α), which have profound effects on metabolism.²⁹⁹

Mechanisms of Cytokine Signaling in the Central Nervous System

Cytokines made outside the CNS can alter the activity and function of populations of hypothalamic neurons. Administration of lipopolysaccharide (LPS) is widely used as an experimental model and induces the secretion of several pyrogenic cytokines, including IL-1 β , TNF- α , and IL-6, that mimic the patterns of cytokine production seen in natural infections.³⁰⁰⁻³⁰³ Many other studies have used systemic injections of cytokines such as IL-1 β and TNF- α to stimulate the CNS. Three models based on methodologies such as these are discussed here to explain how immune system signals might act on the CNS (Fig. 35-11).

Interaction of Cytokines with the Circumventricular Organs

The CVOs (described earlier) are specialized regions along the margins of the ventricular system that have fenestrated capillaries and therefore no BBB.³⁵ Many circulating hormones, such as angiotensin II, act on neurons in the CVOs, converting bloodborne signals into CNS responses.²⁹³

Several models of fever production have hypothesized that cytokines may enter the CNS via the CVOs, particularly at the organum vasculosum of the lamina terminalis (OVLT; see Fig. 35-10).³⁰⁴⁻³⁰⁷ However, definitive evidence establishing this model as a predominant mechanism is still lacking. Large lesions of the preoptic area of the hypothalamus including the OVLT block fever, but they inevitably damage nearby regions that are critical for thermoregulation.³⁰⁵ Small lesions of the OVLT do not block fever or corticotropin responses.³⁰⁸ However, an inherent limitation of this type of study is that the lesion itself breaches the BBB, allowing entry of cytokines. Moreover, knife cuts just caudal to the OVLT that interrupt connections from the OVLT to the PVH do not block activation of the HPA axis by IL-1.^{309,310}

Other studies have focused on the area postrema, a CVO located in the medulla oblongata lying along the surface of the NTS at the caudal end of the fourth ventricle (see Fig. 35-10). Lesions of the area postrema can block the IL-1-induced activation of the HPA axis and the induction of Fos mRNA in the PVH.³¹¹ However, others have found that more circumscribed lesions, which do not injure the NTS, do not prevent CNS responses to intravenous IL-1.³¹²

Interactions of Cytokines at the Barriers of the Brain: The Requirement of Prostaglandins

One of the hallmarks of CNS response to inflammation is that many of its components, including fever and activation of the HPA axis, can be prevented by blocking the production of prostaglandins. This is typically done by administration of nonsteroidal anti-inflammatory drugs (NSAIDs) such as aspirin or indomethacin.³¹³⁻³¹⁵ Decades ago, the work of Milton and Wendlandt demonstrated

Figure 35-10 A model of the central nervous system circuitry activated by cytokines. CVOs (organs devoid of blood-brain barrier) and the blood vessels (bv) are crucial target sites of cytokines of systemic origin that are produced during the acute phase response. Among these integrative structures, the PVN is critical in coordinating autonomic and endocrine responses, including the activity of the hypothalamic-pituitary-adrenal (HPA) axis. For example, corticotropin-releasing factor neurons of the parvocellular PVN confer HPA-axis activation in endotoxin-treated animals. ACTH, adrenocorticotropic hormone; AP, area postrema; ARC, arcuate nucleus; BnST, bed nucleus of the stria terminalis; bv, blood vessels; chp, choroid plexus; CeA, central nucleus of the amygdala; chp, choroid plexus; COX-2, cyclooxygenase 2; CVOs, circumventricular organs; DMH, dorsomedial nucleus of the hypothalamus; EP, prostaglandin E receptor; IL, interleukin; IL-1R1, IL-1 type 1 receptor; IκBα, inhibitor of NF-κB; LC, locus ceruleus; LDT, laterodorsal tegmental nucleus; LPS, lipopolysaccharide; ME, median eminence; MPOA, medial preoptic area; NF-κB, nuclear factor-κB; NTS, nucleus of the solitary tract; OVLT, organum vasculosum of the lamina terminalis; PGE₂, prostaglandin E₂; PB, parabrachial nucleus; PP, posterior pituitary; PVN, paraventricular nucleus of the hypothalamus (parvocellular [pc] and magnocellular [mc] divisions); SFO, subfornical organ; SO, supraoptic nucleus; TLR, toll-like receptor; TNFα, tumor necrosis factor α; TNFR, tumor necrosis factor receptor; VLM, ventrolateral medulla; VmPO, ventral medial preoptic area. (Modified from Rivest S, Lacroix S, Vallières L, et al. How the blood talks to the brain parenchyma and the paraventricular nucleus of the hypothalamus during systemic inflammatory and infectious stimuli. *Proc Soc Exp Biol Med*. 2000;223:22-38.)

that central injections of prostaglandins increase body temperature.^{316,317}

Two isoforms of cyclooxygenase (COX) exist. COX1 is the constitutive form of the enzyme and is not thought to be regulated by inflammatory stimuli. COX2 is an inducible isoform and is increased in several cell types in response to immunologic stimuli.^{318,319} In the normal brain, COX2 mRNA and the COX2 protein are found exclusively in neurons.^{302,320-322} In contrast, immune stimulation by LPS or cytokines induces the COX2 mRNA and protein throughout the brain in non-neuronal cells associated with blood vessels, the meninges, and the choroid plexus. In addition, systemic administration of IL-1β induces the expression of prostaglandin E (PGE) synthase mRNA.³²³ This likely includes endothelial cells and perivascular microglial cells as well as meningeal macrophages.³²⁴⁻³²⁶ Regardless of the cell type, it seems clear that circulating LPS or cytokines induce COX2 in cells in the perivascular space, which in turn may produce prostaglandins to stimulate nearby brain regions inside the BBB.

PGE₂, the predominant endogenous isoform of PGE in the brain, is thought to be an essential mediator of cytokine modulation of hypothalamic function.³²⁷ Evidence supporting this claim includes the fact that microinjections

of PGE receptor agonists into the brain of rats^{306,328,329} and other species^{330,331} produces fever. The preoptic area of the hypothalamus surrounding the OVLT is thought to be critical in the response to PGE. For example, microinjections of as little of 1 ng of PGE₂ into the anteroventral preoptic area of rats reliably produces fevers.³²⁸ Conversely, a COX2 inhibitor, ketorolac, attenuates LPS-induced fever with injections placed in the same region.³³² This PGE-sensitive zone is the same as the region containing the highest concentrations of PGE₂ binding sites.^{333,334} The cloning of the PGE (EP) receptors will ultimately allow a more definitive analysis of the receptors in the hypothalamus that mediate the effects of PGEs on both fever and anorexia (see Fig. 35-11).

Four EP receptors have been identified: EP₁, EP₂, EP₃, and EP₄.^{301,335,336} All four subtypes are expressed in the preoptic area of the hypothalamus.^{301,337-341} Pharmacologic evidence suggests that EP₁ and EP₃ receptor agonist administration mimics PGE₂-induced fever.^{342,343} Moreover, an EP₁ receptor antagonist blocks PGE₂ fever.³⁴³ In contrast, targeted deletion of the EP₃ gene results in mice that do not show an early phase of fever after injection of LPS or PGE₂ (ICV).³³⁶ EP₁ and EP₃ receptors do not individually appear to be essential for cancer-mediated anorexia in rodent models.³⁴⁴

Figure 35-11 Immune stimulation activates key brain regions involved in energy homeostasis. A series of photomicrographs demonstrating the distribution of Fos-like immunoreactivity (Fos-IR) in the rat brain 2 hours after intravenous injection of 125 $\mu\text{g/kg}$ lipopolysaccharide (LPS). LPS administration is a commonly used model of immune stimulation, and Fos-IR is a widely used marker of neuronal activation. LPS activates immune functions (induces Fos-IR) in the ventral medial preoptic (VMPO) area and in the organum vasculosum of the lamina terminalis (OVLt), shown in **A**; in the subfornical organ (SFO) (**B**); in the paraventricular nucleus of the hypothalamus (PVH) (**C**); and in the area postrema (AP) and nucleus of the solitary tract (NTS) in the brainstem (**D**). Prominent Fos-IR is seen throughout the subdivisions of the PVH, including the dorsal (dp), ventral (vp), and medial (mp) parvocellular and posterior magnocellular (pm) divisions. Notice that LPS also activates neurons in the circumventricular organs (OVLt, SFO, and AP). 3v, third ventricle.

There is upregulation of EP₄ receptor expression in several areas of the brain, including the corticotropin-releasing hormone (CRH) neurons of the PVH, after immune challenge.^{337,340} In addition, paraventricular neurons that express Fos after ICV PGE₂ also express EP₄ receptors.³⁴⁰

Therefore, production of PGE₂ is certainly an obligate step in the pathogenesis of the febrile response. Furthermore, knockout of the gene for enzyme microsomal prostaglandin E synthase-1 (mPGES-1), essential for PGE₂ synthesis, blocks IL-1 β -induced anorexia.³⁴⁵ However, LPS-induced anorexia remains intact in these animals, suggesting both PGE₂-dependent and PGE₂-independent pathways are involved in the anorexic component of cachexia.³⁴⁵

Entry of Cytokines into the Brain

Circulating cytokines are proteins that cannot easily penetrate the BBB. The kinetics of entry of cytokines into the brain have been examined, and evidence suggests that saturable transport of IL-1 α , IL-1 β , IL-6, and TNF- α into the brain occurs.³⁴⁶⁻³⁴⁸ However, it is not clear whether sufficient levels of cytokines are detectable in brain after acute intravenous administration to account for CNS responses to acute infection. Therefore, the physiologic setting and the significance of this mechanism remain to be established. Moreover, levels of circulating IL-1 β do not rise significantly during immune challenges.^{349,350}

In contrast to IL-1 β , large increases in levels of circulating and brain IL-6 are found during fever. Although the mechanism is not completely understood, it appears that synthesis of IL-6 within the BBB, and not crossing of peripheral IL-6 through the BBB, is critical in the production of fever.³⁵¹ Several studies have demonstrated

that cells located at the BBB and cells within the meninges respond to LPS stimulation with induction of IL-1 β and TNF- α , the NF- κ B inhibitor (I κ B α), and the LPS receptor (CD14).^{301,352-354} Cells with a similar morphology lining the blood vessels that penetrate the CNS and the meninges that cover it also have IL-1 receptors, suggesting that they may also respond to cytokines.³⁵⁵ Hence, endothelial and perivascular cells at the blood-brain interface may have the ability to elaborate cytokines after an LPS or cytokine signal. The physiologic role of centrally produced cytokines in the response to peripheral immune cues has been reviewed in detail elsewhere.^{301,350}

Brain Regions Involved in the Cytokine Response

Many studies have used the immediate expression of early genes such as *FOS* or its protein product (Fos)³⁵⁶ as a marker of neuronal activity. This has allowed investigators to assess the involvement of extended neuronal systems during the complex physiologic responses that occur after immune challenge. Mapping of the patterns of activation in the CNS after administration of either IL-1 β or LPS has allowed new insights into the functional neuroanatomy underlying the coordinated autonomic, endocrine, and behavioral responses during the febrile response.^{310,313,357-359} Immune activation using moderate to high doses of LPS and IL-1 β activates central autonomic and endocrine structures at almost every level of the neuraxis, including several neuroendocrine regulator sites, such as central nucleus of the amygdala, paraventricular hypothalamic nucleus, arcuate nucleus of the hypothalamus, subfornical organ, OVLt, and ventral medial preoptic area. Engaged brainstem sites include the parabrachial nucleus, NTS, area postrema, and rostral and caudal levels of the ventrolateral medulla.^{310,313,357-368} In the PVH, LPS and cytokines activate parvocellular CRH neurons.

Although it is established that the hypothalamus is responsible for inducing a febrile response and anorexia, hypothalamic systems also exist that attenuate rises in body temperature. These include arcuate POMC neurons (see Figs. 35-2 and 35-10) and arginine vasopressin neurons, both of which are thought to be endogenous antipyretic neuromodulators.³⁶⁹⁻³⁷²

Neuronal activation patterns elicited by LPS or cytokines likely include neurons engaged to limit rises in body temperature. Tatro and colleagues found that exogenous α -MSH administration can block LPS-induced fever.³⁷³ The discovery that central melanocortin agonists can both inhibit food intake³⁰ and increase energy expenditure³⁷⁴ suggested that stimulation of the central melanocortin system might be involved in mediating a component of cachexia. Direct experimental testing of this hypothesis demonstrated that the central melanocortin system does contribute to anorexia during systemic illness.^{373,375,376} In rodents, MC4R blockade prevents illness-induced anorexia and cachexia associated with cancer and kidney failure.^{377,378}

Researchers have coupled neuroanatomic tract tracing with methods assessing immediate-early gene expression to investigate the circuitry that is activated by peripheral immune signals. For example, intravenous administration of IL-1 β induced Fos in C1 adrenergic neurons in the ventrolateral medulla that project to the PVH. The C1 adrenergic cell group targets the medial parvocellular subdivision of the PVH, the site of the CRH neurons 7-26.³¹⁰ Lesions interrupting the input from the C1 cells to the PVH prevent the HPA response to IL-1 β . These studies suggest that the activation of C1 cells by locally produced prostaglandins³¹²

may play a critical role in activating the HPA axis in response to IL-1 β .

SPNs in the IML, extending from the first thoracic through the upper lumbar segments of the spinal cord, also show Fos expression in response to LPS.³⁶⁷ Preganglionic neurons in the upper thoracic (T1-4) levels mediate thermogenesis by BAT,^{379,380} and this is a key mechanism used by rats to control heat production and body temperature.³⁸¹ SPNs in the T2-5 levels are important for control of the heart,^{89,382} which is significant because there are changes in cardiac output in the febrile state. SPNs receive direct, monosynaptic input from a series of well-defined nuclei in the brainstem and the hypothalamus (see Fig. 35-2) and provide another way in which the hypothalamus can contribute to the coordinated autonomic response to inflammatory signals. The major input to the sympathetic preganglionic column arises from neurons in the hypothalamus.³⁸³ This innervation includes the PVH (dorsal, ventral, and lateral parvocellular subnuclei), the LHA, and the arcuate nucleus and retrochiasmatic area.^{99,176} Direct projections to the IML also arise in the brainstem from the A5 noradrenergic cell group in the ventral pons, the caudal part of the NTS, the ventromedial medulla including the medullary raphe nuclei, and the rostral ventrolateral medulla, including the C1 adrenergic cell group.^{89,176,384}

Fos expression in hypothalamic and brainstem neurons projecting to the IML after LPS administration has been examined.³⁸⁴ LPS-activated cells that innervate the IML are found in the rostral ventrolateral medulla (C1 adrenergic cell group) and in the A5 noradrenergic cell group in the brainstem. A prominent population of cells was found in the dorsal parvocellular division of the PVH. These results suggest that neurons in the parvocellular PVH specifically innervate SPNs in the spinal cord that regulate LPS-induced fever. Furthermore, as noted earlier, activation of CRH neurons in the PVH is a signature of the CNS response to immune stimulation. Therefore, the paraventricular hypothalamic nucleus is a key site for mediating both neuroendocrine and autonomic responses to immune stimulation.

INTERSECTION OF ENERGY BALANCE AND REWARD CIRCUITS

If rational strategies to combat obesity are to be developed, an increased understanding of the molecular mechanisms of the rewarding aspects of feeding behavior is required.⁴⁰ A relatively recent and novel concept is that food and drug rewards share some common neural substrates.^{40,385} Motivation and reward have been studied in the context of drug addiction.³⁸⁶⁻³⁸⁸ The nucleus accumbens and its dopamine inputs have been strongly implicated in mediating several rewarding stimuli.^{386,389}

Although it is widely accepted that dopamine is involved in reward processes, the relationship between dopamine and reward is complex.⁴⁰ Lesions of the nucleus accumbens reduce food intake³⁹⁰ or the ability to display operant conditioning in response to food,³⁹¹ but there is also a dopamine component of food reward. For example, mice lacking the ability to produce dopamine would normally die of starvation, but they resumed feeding after reintroduction of the dopamine into the striatum.^{392,393}

Key metabolic cues act directly on dopamine neurons in the midbrain. For example, midbrain dopamine neurons express leptin and ghrelin receptors.³⁹⁴⁻³⁹⁶ Fulton and

colleagues demonstrated that leptin also affects brain self-stimulation,³⁹⁷ suggesting that leptin has the ability to affect CNS circuits classically involved in reward. Taken together, these findings suggest that alterations of cues such as leptin and ghrelin may not only affect hypothalamic pathways but also act directly on midbrain dopamine neurons. Although this field of study is still evolving, models based on these findings could have broad implications. Such models could provide a mechanism for signals regulating food intake to intersect with brain circuitry that is critical in the regulation of motivated behaviors. Moreover, dysregulation of these pathways may be relevant to the pathophysiology of obesity and eating disorders such as anorexia nervosa.³⁹⁸

NEUROENDOCRINE DISORDERS OF ENERGY HOMEOSTASIS

A wide variety of disorders of hypothalamic and neuroendocrine function are known to produce obesity. Insults to the function of the basal hypothalamus, including Fröhlich's syndrome and craniopharyngioma, are known to cause obesity (see earlier discussion). In the past 15 years there have been a number of important discoveries related to genetic syndromes underlying certain human obesity disorders (see Chapter 36). Two of the most informative monogenic disorders are discussed here in the context of their effects on the neuroendocrine control of energy stores.

Leptin and Leptin Receptor Deficiencies in Humans

Despite being extremely rare, leptin deficiency³⁹⁹ and leptin receptor defects⁴⁰⁰ in humans are illustrative of the physiologic importance of this hormone. Serum leptin levels in humans are generally proportional to adipose mass.^{128,401} Therefore, most obese humans may be considered to be leptin-resistant rather than deficient in leptin.^{42,127,402} Despite rapid increases in understanding of obesity and leptin action, the molecular basis of leptin resistance remains poorly understood.

Clinical studies have demonstrated that leptin treatment is safe and well tolerated and clearly effective in individuals with congenital leptin deficiency¹²⁵ and in patients who are very low in adipose tissue.^{403,404} For example, doses of methionyl-leptin were given to subjects with congenital deficiency and resulted in leptin levels 10% of those predicted based on body fat. Leptin in this study was well tolerated and resulted in dramatic declines in appetite, body weight, and food intake.¹²⁵ In addition, administration of recombinant leptin to women with hypothalamic amenorrhea due to strenuous exercise training and very low body fat normalized several endocrine indices of reproductive function and bone density.⁴⁰⁴ In individuals with common obesity, however, leptin had only very modest effects on appetite and body weight.⁴⁰⁵

A newer concept is that leptin has potent effects on whole-body glucose and lipid homeostasis independent of its effects on body weight.^{49,146} Studies of leptin action may be relevant to models linking diabetes and hypothalamic resistance to metabolic cues. Leptin deficiency, as seen in lipodystrophic mice and humans, induces severe insulin resistance that is corrected by leptin replacement.⁴⁰⁶⁻⁴⁰⁸ This can be explained by actions of leptin in the arcuate nucleus

of the hypothalamus. Restoration of leptin receptors only in the arcuate nucleus of mice lacking leptin receptors everywhere remarkably improved glucose homeostasis.^{409,410} Therefore, leptin action in the arcuate nucleus is sufficient to mediate the antidiabetic actions of leptin.

Obesity Resulting from Defective Melanocortin Signaling

Evidence that the melanocortin obesity syndrome can occur in humans resulted from the astute recognition in two families of an agouti-mouse-like syndrome resulting from null mutations in the *POMC* gene (Fig. 35-12).⁴¹¹ These patients had a rare syndrome that includes ACTH insufficiency, red hair, and obesity resulting from the lack of ACTH peptide in the serum, together with a lack of melanocortin peptides in skin and brain. These data demonstrated, for the first time, that the central melanocortin circuitry subserves energy homeostasis in humans, as it does in the mouse. Shortly thereafter, heterozygous frameshift mutations in the human *MC4R* were reported and were associated with nonsyndromic obesity in two separate families.^{412,413} Additional reports⁴¹⁴⁻⁴¹⁶ provided a clearer picture of the frequency and diversity of *MC4R* mutations and showed that haploinsufficiency of *MC4R* in humans is the most common monogenic cause of severe obesity, accounting for up to 5% of cases. Two more recent reports provided a detailed clinical picture of the syndrome.^{417,418} Remarkably, the syndrome is virtually identical to that reported for the mouse,^{31,109,373} with increased adipose mass, increased linear growth and lean mass, hyperinsulinemia greater than that seen in matched obese controls, and severe hyperphagia.

Obesity

SAMUEL KLEIN • ELISA FABBRINI • JOHANNES A. ROMIJN

Obesity is a chronic disease that is causally related to serious medical illnesses. In the United States alone, the consequences of obesity account for an estimated 300,000 deaths per year.¹ The medical expenses and cost of lost productivity due to obesity are greater than \$100 billion per year.² This review addresses the important clinical and pathophysiologic issues in obesity.

DEFINITION OF OBESITY

Body Mass Index

Body mass index (BMI) is calculated by dividing a person's weight (in kilograms) by height (in meters squared); alternatively, the weight (in pounds) multiplied by 704 and divided by height (in inches squared) may be used. There is a curvilinear relation between BMI and percent body fat mass.³ However, the current practical definition of obesity is based on the relationship between BMI and health outcome rather than BMI and body composition.

Table 36-1 summarizes the guidelines for classifying weight status by BMI proposed by the major national and

international health organizations.⁴⁻⁷ Many large epidemiologic studies^{8,9} have established an inverse relationship between BMI and mortality for BMI values of 25.0 kg/m² or higher. Men and women with a BMI between 25.0 and 29.9 kg/m² are considered to be overweight, and those with a BMI greater than 30.0 kg/m² are considered to be obese. Obese persons are at higher risk for adverse health consequences than those who are overweight (Fig. 36-1). These criteria for overweight and obesity represent imposed cutoff values along a continuum on the curve of mortality rate versus BMI.

The prevalence of obesity-related diseases, such as type 2 diabetes (T2DM), begins to increase at BMI values lower than 25.0 kg/m² (Fig. 36-2). Therefore, if the risk for T2DM were used to define overweight and obesity, the relationship curve would be shifted to the left, and the cutoff BMI values would be lower.

Data from the National Health and Nutrition Examination Surveys (NHANES) collected between 1971 and 2000 question the relationship between overweight status and increased mortality risk.⁹ These data found that persons who were overweight or even had class I obesity (BMI 30.0-34.9 kg/m²) did not have a significant increase in mortality risk.

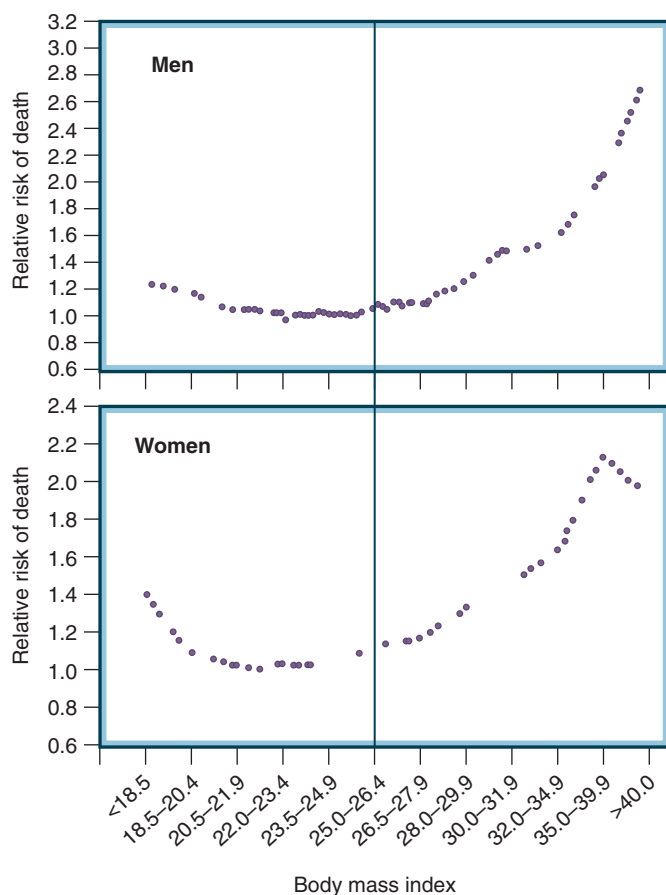

Figure 36-1 Relationship between body mass index and cardiovascular mortality in men and women in the United States who never smoked and had no preexisting illness. The vertical line separates underweight and lean subjects (left side) from overweight and obese subjects (right side). (Adapted from Calle EE, Thun MJ, Petrelli JM, et al. Body-mass index and mortality in a prospective cohort of U.S. adults. *N Engl J Med*. 1999;341:1097-1105.)

Factors Affecting Body Mass Index–Related Risk

Several factors influence BMI-related health risk (see Table 36-1). They include body fat distribution, age, concomitant medical illness, weight gain, aerobic fitness, and ethnicity.

TABLE 36-1

Weight Classification by Body Mass Index (BMI)

Weight Classification	Obesity Class	BMI (kg/m ²)	Risk of Disease
Underweight		<18.5	Increased
Normal		18.5-24.9	Normal
Overweight		25.0-29.9	Increased
Obesity	I	30.0-34.9	High
	II	35.0-39.9	Very high
Extreme Obesity	III	≥40.0	Extremely high

Adapted from the National Institutes of Health, National Heart, Lung, and Blood Institute. Clinical guidelines on the identification, evaluation, and treatment of overweight and obesity in adults: the evidence report. *Obes Res*. 1998;6(suppl 2):51S-209S.

Figure 36-2 Relationship between body mass index and type 2 diabetes in men and women in the United States. The vertical line separates underweight and lean subjects (left side) from overweight and obese subjects (right side). The data demonstrate that the risk of diabetes begins to increase at the upper end of the lean body mass index category. (Adapted from Colditz GA, Willett WC, Rotnitzky A, et al. Weight gain as a risk factor for clinical diabetes mellitus in women. *Ann Intern Med*. 1995;122:481-486; and Chan JM, Rimm EB, Colditz GA, et al. Obesity, fat distribution, and weight gain as risk factors for clinical diabetes in men. *Diabetes Care*. 1994;17:961-969.)

Body Fat Distribution. Obese persons with excess abdominal fat are at higher risk for diabetes, hypertension, dyslipidemia, and ischemic heart disease than obese persons whose fat is located predominantly in the lower body.¹⁰ Those with increased lower body fat mass are protected from metabolic complications.¹¹⁻¹³ Waist circumference is highly correlated with abdominal fat mass and is often used as a surrogate marker for abdominal (upper body) obesity.

Waist circumference is an important predictor of health outcomes in adult men and women of all age groups and ethnicities, including Caucasians, African Americans, Asians, and Hispanics. The relationship between waist circumference and clinical outcome is strongest for diabetes risk, and waist circumference is an independent and better predictor of diabetes than BMI.¹⁴ The recommended waist circumference thresholds for increased cardiometabolic risk is 40 inches (102 cm) in men and 35 inches (88 cm)¹⁵ in women; these cutoff values were derived from waist circumference values that correlated with a BMI of 30 kg/m² or greater.¹⁶ However, they are based on populations of European origin and might not be appropriate for non-Europeans.

Asian populations tend to have a higher percentage of body fat for the same BMI value and an increased prevalence of cardiovascular risk factors at lower BMI values compared with Caucasians.¹⁷⁻¹⁹ Moreover, at any given waist circumference, the relative risk of mortality is higher in Asians than in African Americans or Europeans.²⁰ The World Health Organization (WHO) has indicated that waist circumference thresholds denoting increased risk in the Asian population should be 90 cm for men and 80 cm for women.²¹ Different levels have been suggested in Japan and China, with cutoff values of 85 cm for men and 80 cm for women, and slightly lower values have been suggested in India.²²

Age. The BMI value associated with the lowest relative risk of mortality increases with increasing age.^{9,23}

Concomitant Medical Illness. In patients with certain medical conditions, being overweight or obese is associated with lower mortality rates than for similar patients with normal BMI values. This BMI paradox is associated with (1) cardiovascular disease (myocardial infarction,²⁴ congestive heart failure,²⁵ hypertension and coronary heart disease (CHD),²⁶ coronary artery bypass graft surgery,²⁷ heart transplant²⁸); (2) renal disease (end-stage renal disease)²⁹; (3) hip fractures³⁰; (4) rheumatoid arthritis³¹; and (5) tuberculosis.³²

Weight Gain. Another factor that modifies the risk of obesity-related complications is weight gain during adulthood. In both men and women, weight gain of 5 kg or more since the ages of 18 to 20 years increases the risk of developing diabetes, hypertension, and CHD, and the risk of disease increases with the amount of weight gained.³³⁻³⁸

Aerobic Fitness. The risk of developing obesity-associated diabetes or cardiovascular disease can be modified by aerobic fitness. In a cohort of more than 8000 men who were monitored for an average of 6 years, the incidences of diabetes³⁹ and cardiovascular mortality⁴⁰ were lower in those who were fit, as defined by maximal ability to consume oxygen during exercise, compared with those who were unfit across a range of body adiposity.

Ethnicity. BMI-associated health risk is also influenced by ethnicity.⁴¹ For example, when matched on BMI, the risk of diabetes is higher in Southeast Asian populations than in whites.⁴²

PHYSIOLOGY OF ENERGY HOMEOSTASIS

Energy homeostasis, which includes all processes that aim to maintain energy balance, requires complex molecular and physiologic processes and constant communication within and among adipose tissue, skeletal muscle, liver, pancreas, and the central nervous system. The homeostatic control of energy homeostasis relies on physiologic integration of biologic signals from these different organs as well as nutrient-related signals, postprandial neural and hormonal influences, and stimuli related to hedonic, situational, or stress-related circumstances. A complex physiologic system regulates energy homeostasis by integrating signals from peripheral organs with central coordination in the brain.⁴³ The hypothalamus functions as the main cerebral center in which these signals converge.⁴⁴

A balanced interaction between two sets of neurons occurs within the arcuate nucleus of the hypothalamus. Activation of neurons secreting neuropeptide Y (NPY) and agouti-related protein (AgRP) promotes food intake, whereas that of neurons secreting pro-opiomelanocortin (POMC) and cocaine- and amphetamine-regulated transcript (CART) has an anorexigenic effect. The NPY/AgRP neurons also inhibit POMC/CART neurons through γ -aminobutyric acid (GABA). The orexigenic and anorexigenic signals from the NPY/AgRP and POMC/CART neurons are sent to other brain nuclei, ultimately resulting in alterations in food intake and energy expenditure. The system is very complex and involves interactions among various areas of the brain.

The endocannabinoid system is also involved in the regulation of food intake, particularly the cannabinoid 1 (CB₁) receptors (encoded by *CNRI*) and their endogenous ligands, anandamide (*N*-arachidonoyl-ethanolamine) and 2-arachidonoylglycerol. Absence of CB₁ receptors in mice with a disrupted CB₁ gene causes hypophagia and leanness.⁴⁵ Administration of cannabinoids increases food intake and promotes body-weight gain, and treatment with selective CB₁ receptor antagonists decreases food intake and body weight in obese mice.⁴⁶ Randomized, controlled trials (RCTs) in obese human patients have shown that treatment with rimonabant, a CB₁ receptor antagonist, decreases body weight.^{47,48} These studies demonstrated that the cannabinoid system has an important role in the regulation of ingestive behavior in animals and humans.⁴⁹ In 2008, the clinical development program of rimonabant was discontinued because of the risk of serious psychiatric disorders.

The major peripheral organs participating in the regulation of food intake are the stomach, gut, pancreas, and adipose tissue.⁴⁴ The stomach and the duodenum secrete the orexigenic peptide ghrelin, which increases before eating and decreases after feeding. Many so-called satiety signals are transmitted to the brain via vagal afferent fibers from the gut that synapse in the nucleus tractus solitarius (NTS) in the hindbrain, which participates in gustatory, satiety, and visceral sensation. For instance, oral taste receptor cells generate information that is transmitted to the NTS by afferent sensory fibers. Insulin, secreted by the pancreas, has an anorexigenic effect through the arcuate nucleus. The PYY(3-36) form of peptide YY is secreted by the gastrointestinal tract after food ingestion and might have an anorexigenic effect.⁵⁰ Glucagon-like peptide 1 (GLP1) is derived from pre-proglucagon and secreted in response to food ingestion by the proximal gastrointestinal tract. It exerts pleiotropic effects, including slight anorexic effects.⁵¹ Satiety is also mediated by other gut proteins, such as cholecystokinin (CCK). Leptin, secreted by the adipose tissue, also serves as an anorexigenic signal.

PATHOGENESIS

Energy Balance

Obesity is caused by an excessive intake of calories in relation to energy expenditure over a long period of time. The gastrointestinal tract has the capacity to absorb large amounts of nutrients. Large increases in body fat can result from even minor, but chronic, differences between energy intake and energy expenditure. In 1 year, the ingestion of only 5% more calories than expended can promote the gain of approximately 5 kg in adipose tissue. Over 30 years, the daily ingestion of only 8 kcal more than expended can increase body weight by 10 kg. This represents the average amount of weight gained by Americans during the 30-year period between 25 and 55 years of age.⁵²

Genes and Environment

Body size depends on the complex interaction between genetic background and environmental factors. In humans, genetic background explains only an estimated 40% of the variance in body mass.⁵³ The marked increase in the prevalence of obesity since the 1980s must have resulted largely from alterations in environmental factors that increase energy intake and reduce physical activity. For example, more meals are now eaten outside the home, there is

greater availability of convenience and snack foods, serving sizes are larger, and daily physical activity has decreased because of sedentary lifestyle and work activities.

Environmental Effects in High-Risk Populations

Dramatic examples of the influence of environment on body weight have been reported globally. These examples illustrate that persons of certain genetic backgrounds are especially prone to gain weight and develop obesity-related diseases when exposed to a "modern" lifestyle.

Since the 1950s, striking changes in the lifestyle of Pima Indians living in Arizona have led to an epidemic of obesity and diabetes in this population.⁵⁴ The diet of these urbanized Pimas is much higher in fat (50% of energy as fat) than the traditional Pima diet (15% of energy as fat). In addition, urbanized Pimas are much more sedentary than the Pimas who remained in the Sierra Madre Mountains of Northern Mexico and are isolated from Western influences. These rural Pimas eat a traditional diet and are physically active as farmers and sawmill workers; they have much lower incidences of obesity and diabetes than their Arizona kindred.

The Aborigines of northern Australia are another high-risk population whose weight and health status have been compromised by exposure to a modern environment. Urbanized Aborigines are heavier than hunter-gatherer kindred, who are usually very lean (BMI <20.0 kg/m²), and they have high prevalences of T2DM and hypertriglyceridemia.⁵⁵ The traditional hunter-gatherer lifestyle of the Aborigines involves a low-fat, low-calorie diet of wild game, fish, and plants and a high level of physical activity. In one study, short-term (7 weeks) re-exposure to the traditional lifestyle resulted in weight loss and significant improvements or normalization of glucose tolerance and fasting blood glucose, insulin, and triglyceride concentrations in urbanized Aborigines with T2DM and hypertriglyceridemia.⁵⁶

Influences of Childhood and Parental Obesity

The risk of becoming an obese adult is influenced both by having been obese as a child and by having had at least one obese parent. The risk of adult obesity increases with increasing age and with the severity of obesity in childhood. For example, the risk of being obese at 21 to 29 years of age ranged from 8% for persons who were obese at 1 to 2 years of age and had nonobese parents to 79% for persons who were obese at 10 to 14 years of age and had at least one obese parent.⁵⁷ Although persons who were obese at 1 to 2 years of age and had lean parents did not have an increased risk of obesity in adulthood, persons who became obese after 6 years of age had a greater than 50% chance of becoming obese adults.

Monogenic Causes of Obesity

Since the discovery of the adipose tissue protein leptin, much progress has been made in understanding the molecular basis of body-fat regulation. It has nonetheless been disappointing that a genetic cause of obesity has been identified in only a very few persons. Several rare, monogenic causes of obesity have been described in recent years.

Leptin Gene Mutation

The pathophysiologic relevance of leptin was established in two extremely obese cousins with hyperphagia who belonged to a consanguineous family of Pakistani origin.⁵⁸ These cousins were homozygous for a single nucleotide deletion at position 398 of the leptin gene. This mutation

resulted in a frameshift of the leptin-coding region and premature termination of leptin synthesis. The parents of the cousins were heterozygous for this mutation.

Another mutation, this time involving a homozygous single-nucleotide transversion in the leptin gene that resulted in a substitution of Trp for Arg in the mature peptide and low serum leptin levels, was discovered in three extremely obese persons, including one adult man and one adult woman, both of whom were hyperinsulinemic.⁵⁹ The man exhibited hypothalamic hypogonadism and dysfunction of the sympathetic nervous system, and the woman had primary amenorrhea.

Leptin treatment has successfully reversed the obesity of leptin-deficient patients. Treatment with recombinant human leptin resulted in a weight loss of 1 to 2 kg/month over a 12-month period. Loss of fat mass accounted for 95% of this weight loss.⁶⁰

The possibility that leptin levels are reduced in obesity has been investigated in large groups of subjects. However, serum leptin levels increase exponentially with fat mass, suggesting that most obese persons are resistant or insensitive to body weight regulation by endogenous leptin.⁶¹

Leptin Receptor Mutation

Three extremely obese sisters from a consanguineous family were found to have markedly high serum leptin levels and to be homozygous for a single-nucleotide substitution at the splice site of exon 16 of the leptin receptor gene.⁶² This mutation resulted in a truncated protein that lacked both the transmembrane and the intracellular domains of the receptor. The sisters displayed hypogonadotropic hypogonadism, failure of pubertal development, growth delay, and secondary hypothyroidism. This finding confirms the endocrine abnormalities in leptin-deficient subjects and implies a role for leptin and its receptor in the central regulation of energy balance and hypothalamic endocrine functions in humans.

Prohormone Convertase 1 Gene Mutation

A mutation in the gene encoding prohormone convertase 1 (PC1), now called *PCSK1*, was identified in a 43-year-old obese woman with a history of severe childhood obesity.⁶³ This woman had impaired glucose tolerance, postprandial hypoglycemia, low plasma cortisol levels, and hypogonadotropic hypogonadism. In addition, she had increased plasma concentrations of proinsulin and POMC but very low plasma insulin concentrations. She was a compound heterozygote for two mutations in the *PCSK1* gene, which resulted in loss of the autocatalytic cleavage ability of PC1. A second patient has also been described.⁶⁴ Melanocortins, including α -melanocortin-stimulating hormone (MSH), are formed through the processing of POMC by PC1. Therefore, reduced production of melanocortin might have been responsible for obesity in these patients.

Pro-Opiomelanocortin Gene Mutation

A mutation in the POMC gene was described in two obese children with hyperphagia.⁶⁵ The children also had red hair pigmentation and were deficient in adrenocorticotrophic hormone (ACTH). The mutations resulted in complete loss of the ability to synthesize α -MSH and ACTH. The red hair pigmentation and obesity are believed to be due to deficiency of α -MSH.

Melanocortin 4 Receptor Mutation

Although they are rare, mutations in the melanocortin 4 receptor (MC4R) are the most common monogenic cause of obesity.⁶⁶ Moreover, MC4R mutations are characterized

by both dominant and recessive modes of inheritance, in contrast to the other monogenic forms of obesity, which have recessive modes of inheritance. In children with MC4R mutations, the degree of obesity and hyperphagia correlates with the extent of impairment of MC4R signaling. However, adult carriers of the mutations cannot be phenotypically distinguished from other obese subjects.⁶⁷

Mutation of the Neurotrophin Receptor TrkB

The survival and differentiation of neurons in the peripheral nervous system are dependent on neurotrophic factors, which are secreted by the target tissues. Neurotrophin signaling occurs through the specific activation of receptor tyrosine kinases of the Trk family. An 8-year-old boy with a complex developmental syndrome and severe obesity was found to be heterozygous for a de novo missense mutation resulting in a Tyr722Cys substitution in the neurotrophin receptor TrkB. This mutation markedly impaired receptor autophosphorylation and signaling to mitogen-activated protein kinase. Mutation of *NTRK2*, the gene encoding for TrkB, seems to result in a unique human syndrome of hyperphagic obesity.⁶⁸

Obesity in Pleiotropic Syndromes

About 30 mendelian disorders have been described in which obesity is a clinical feature; often, this obesity is associated with mental retardation, dysmorphic features, and organ-specific developmental abnormalities—the pleiotropic syndromes. Positional genetic techniques have led to the identification of different mutations underlying these syndromes. However, in most cases these genes encode for proteins whose function is unresolved.⁶⁹

Obesity Syndromes due to Chromosomal Rearrangements

Prader-Willi Syndrome

The Prader-Willi syndrome is characterized by obesity, mental retardation, short stature, and secondary hypogonadism. It is the most common syndromic cause of obesity, occurring in 1 of every 25,000 births.⁷⁰ In these patients, the paternal segment 15q11.2-q12 is absent. The omission can result from deletion of the paternal segment (75%) or from loss of the entire paternal chromosome 15, with the presence of two maternal homologs (uniparental maternal disomy). The role of the genes encoded by the paternal segment and the mechanisms by which they cause the obesity syndrome have not been resolved.⁷⁰

SIMI Gene Mutation

A de novo balanced translocation between chromosomes 1 and 6 was found in a severely obese girl who weighed 47 kg at 67 months of age.⁷¹ The mutation caused a disruption in *SIMI*, the human homolog of the *Drosophila* single-minded (*sim*) gene that regulates neurogenesis. *SIMI* encodes a transcription factor involved in the formation of the paraventricular and supraoptic nuclei. It is likely that this abnormality altered energy balance in this patient by stimulating food intake, because measured resting energy expenditure was normal.

Polygenic Causes of Obesity

Obesity is likely to result from the interaction of many different gene-gene and gene-environment interactions. In contrast to the small number of single-gene mutations that clearly cause obesity in rare patients, a large number of

human genes have been identified that show variations in DNA sequences that might contribute to obesity.⁷²

The use of the genome-wide association approach has identified many genes with robust associations but usually with only modest contributions to overall genetic susceptibility to common obesity or high BMI. It is a challenge to determine how these results fit into current models of the genetic architecture and physiology of obesity, because no existing hypothesis explains all the data. Some of these associations will undoubtedly prove to be more important than others. The first major breakthrough provided by genome-wide association studies was the discovery of the fat mass and obesity-associated gene (*FTO*) as a potential obesity gene.

Data from several studies have documented a strong association between fat mass (or BMI) and a single-nucleotide polymorphism (SNP) in *FTO* in both childhood and adult obesity. Frayling and colleagues⁷³ found that SNP rs9939609 in the *FTO* gene was strongly associated with T2DM, but this allele was also strongly associated with an increased BMI. The association between this *FTO* SNP and T2DM was abolished by adjustment for the BMI, suggesting that the risk of diabetes was due to the increase in BMI. The association of this variant with BMI was replicated in 13 cohorts containing more than 38,000 subjects. Sixteen percent of the adults were homozygous for this particular SNP; they weighed about 3 kg more than the subjects without this SNP and had a 1.67-fold increased risk of obesity.⁷³

Independently, Dina and colleagues⁷⁴ found another SNP, rs1121980, in the first intron of the *FTO* gene that was strongly associated with severe adult obesity (odds ratio, 1.55) in French individuals of European ancestry. This finding was replicated by a similarly strong association of several *FTO* SNPs in a study of approximately 900 severely obese adults and 2700 nonobese French controls. Three of the four most significantly associated SNPs (rs17817449, rs3751812, and rs1421085) are putatively functional. The same report also showed associations of SNPs in the *FTO* gene with obesity in three additional cohorts including children or adults.⁷⁴

In another independent study of over 4000 Sardinians, Scuteri and colleagues⁷⁵ showed that another SNP in *FTO*, rs9930506, and other nearby variants are associated with BMI, hip circumference, and total body weight. Additional associations of BMI with SNPs in the *FTO* gene were shown in both European-American and Hispanic-American cohorts in the same report.
